Dedication

This work is dedicated to Drs. R.D. Schoenwald, J. Keith Guillory, L.E. Matheson, the late D.J.W. Grant, G. Amidon, V. Stella, E.L. Parrott, D.R. Flanagan, D.E. Wurster, and P. Veng-Pedersen.

By generously sharing their experience, time, and wisdom, they have taught us well beyond what we learned in school.

We are also forever indebted to our families for their love, understanding, and sacrifice.

1.1 INTRODUCTION

1.1.1 Implication of solubility in dosage form development

The solubility of a drug is one of its most important physicochemical properties. The determination of drug solubility and ways to alter it, if necessary, are essential components of pharmaceutical development programs. The bioavailability of an orally administered drug depends primarily on its solubility in the gastrointestinal tract and its permeability across cell membranes. This forms the basis for the biopharmaceutical classification system (BCS).[1] Drug molecules are required to be present in a dissolved form in order for them to be transported across biological membranes. Therefore, low aqueous solubility can either delay or limit drug absorption. Knowledge of the solubility of a drug is also important when direct administration into the bloodstream is desired. Injectable formulations usually require a drug to be in solution for administration. In addition, a drug solution is preferred for conducting pharmacological, toxicological, and pharmacokinetic studies during the drug development stage. Thus, poor aqueous solubility not only limits a drug's biological application, but also challenges its pharmaceutical development. As a result, investigation into approaches for solubility enhancement has been a regular element of pharmaceutical research for several decades. The need for such approaches has been rising following the introduction of combinatorial chemistry and high-throughput screening techniques to the drug discovery arena. The advent of these techniques, resulting in a rapid development of libraries of pharmaceutically active compounds, has led to a greater number of highly active compounds. At the same time, it has resulted in the generation of a far higher percentage of extremely lipophilic and poorly water-soluble compounds, adding more challenges to formulation development. It has been reported[2] that more than a third of the compounds registered by Pfizer in the late 1990s had solubilities that were less than 5 μg/mL.

While solubility enhancement remains one of the primary areas of focus during the drug development phase, there are several situations that may require solubility reduction. Sustained release products, taste masking, and enhancement of chemical stability are examples of such situations.

Knowledge of solubility is also useful when developing analytical methods for drugs. Reverse-phase liquid chromatography is one of the most widely used techniques for pharmaceutical separation and analysis. Separation is based on the differential affinity of the solute toward the mobile phase and the stationary phase, which is a direct outcome of its solubility in these phases. The analysis of concentration using ultraviolet (UV) spectroscopy is also performed on drug solutions.

Based on this discussion, it should be clear that solubility plays an important role in several avenues of pharmaceutical research. As a consequence, the determination of solubility remains one of the most commonly conducted experiments for any new compounds. While solubility experiments are sometimes perceived as trivial, accurate determination of solubility is a challenging exercise. A number of experimental variables may affect the solubility results, inducing high degrees of scatter in the data.[3] This builds a strong case for the applicability of tools for the estimation of solubility based on theoretical calculations. While most of these calculation approaches are useful with respect to providing reasonable estimation and saving time, they can never completely replace the experimentally determined values.

Developing Solid Oral Dosage Forms
DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00001-7

This chapter is written with the intent of developing a thorough understanding of the concepts of solubility. The various physicochemical forces and factors that determine the solubility of a solute in a solvent will be discussed in detail. The thermodynamics of solubilization and various theoretical models for its estimation have also been included. Considerable emphasis has been placed on the techniques used for solubility enhancement, along with practically relevant examples. In addition, the various aspects of solubility determination experiments including challenges and strategies to overcome them are discussed.

1.1.2 Basic concepts of solubility and dissolution

A true solution is a homogenous mixture of two or more components on a molecular level. Any sample collected from such a mixture will be representative of the entire bulk. In a two-component system, the component present in the larger proportion is generally referred to as the *solvent*, and the other as the *solute*.

When a solute is placed in contact with a solvent, mixing occurs due to the propensity of all molecules toward randomization, resulting in an increase in overall entropy of the system. The solute molecules start to break away from the surface and pass into the solvent system. The detached solute molecules are free to move randomly throughout the solvent bulk to form a uniform solution. Some of these solute molecules strike the bulk solute surface and are redeposited onto it. Initially, when the concentration of solute molecules is low in the solution, the number of molecules leaving the bulk solute surface is much higher. As the solvent bulk starts becoming saturated with the solute molecules, the redeposition process starts to accelerate. Once sufficient solute molecules have populated the solvent bulk, the rate of molecules leaving becomes equal to the rate of redeposition (dynamic equilibrium). The concentration of the solute in the solvent at which this equilibrium is reached is defined as the *thermodynamic solubility*, and the rate at which the equilibrium is achieved is the *dissolution rate.* Thus, solubility is an equilibrium concept, while dissolution is a kinetic phenomenon. Both are dependent on the experimental conditions, including temperature. The dissolution rate of a solute in a solvent is directly proportional to its solubility, as described by the Noyes-Whitney equation[4,5]:

$$\text{Dissolution Rate} = \frac{dM}{dt} = \frac{DA}{h}(C_s - C_t) \qquad (1.1)$$

where:

dM/dt is the rate of mass transfer.
D is the diffusion coefficient (cm^2/s).
A is the surface area of the drug (cm^2).
h is the static boundary layer (cm).
C_s is the saturation solubility of the drug.
C_t is the concentration of the drug at time (t).

Solubility is expressed in units of concentration, including percentage on a weight or volume basis, mole fraction, molarity, molality, and parts. The U.S. Pharmacopeia and National Formulary defines the term *solubility* as the number of milliliters of solvent required to dissolve 1 g of the solute.

It follows from the previous discussion that the equilibrium solubility of a solute will depend on its relative affinity toward solvent molecules and fellow solute molecules. Thus, the strength of molecular interactions, both inter and intra, affect solubility. While a detailed description of these interactions can be found in any physical chemistry book, they are discussed here briefly.

1.1.2.1 Ionic interactions

Pure ionic interactions occur between two oppositely charged ions. Such interactions are relevant to pharmaceutical salts and ion pairs. An ion can also interact with a polar molecule (ion-dipole) or induce a dipolar character to a nonpolar molecule (ion-induced dipole). When sodium chloride is dissolved in water, the free sodium and chloride ions interact with polar water molecules such that the positive heads of water molecules interact with the chloride ions, while the negative heads of water molecules interact with the sodium ions. By virtue of these interactions, pharmaceutical salts generally have a higher solubility than their free form. The strength of ionic interactions depends on the electrostatic charge density of the interacting ions, as well as the media properties, including dielectric constant and temperature.

1.1.2.2 van der Waals interactions

Two molecules with permanent dipole moments can interact when placed in sufficiently close proximity (dipole-dipole or Keesom interactions). The molecules will try to arrange themselves in a manner that minimizes the energy associated with them. Thus, the positive head of one molecule will position close to the negative head of the other molecule. The positioning, however, may not be ideal due to geometric constraints and random thermal motion of the participating molecules (entropic influence). As a consequence, a situation arises where the participating molecules, on average, spend more time in an aligned position. Strongly polar molecules can induce polar attributes to nonpolar molecules, resulting in dipole-induced dipole (Debye) interactions. The strength of van der Waals interactions is a direct outcome of the dipole moment and polarizability of the participating

molecules, and it is also affected by the media properties, such as temperature.

1.1.2.3 Dispersion interactions

Also known as *London forces*, dispersion interactions occur between any adjacent pair of atoms or molecules when they are present in sufficiently close proximity. These interactions account for the attractive forces between nonionic and nonpolar organic molecules, such as paraffin and many pharmaceutical drugs. The origin of these forces remains unclear, but it is believed that at any given instance, molecules are present in a variety of distinct positions due to thermal oscillations. These positions give rise to a temporary molecular dissymmetry, resulting in a dipole-type characteristic. This instantaneous dipole then induces a polar character to the neighboring molecules and starts interacting with them.

1.1.2.4 Hydrogen bonding

These interactions occur between hydrogen bond–donating groups and strong electronegative atoms such as halogens, oxygen, and nitrogen. Hydrogen atoms become associated with electronegative atoms by virtue of electrostatics and result in the formation of hydrogen bridges. These interactions are prevalent in aqueous and alcoholic systems. A large number of drugs are involved in either intermolecular or intramolecular hydrogen bonding. The aqueous solubility of a drug is directly related to its hydrogen-bonding capability. The higher water solubility of phenol, as compared to benzene and toluene, can be attributed to the former's hydrogen-bonding nature. The evolving field of cocrystals is based on the hydrogen bond interactions between molecules of the drug and the cocrystal. The strength of hydrogen bond interactions depends upon the electronegativity of the participating atoms, as well as the temperature of the media. Since the requirement of ideal positioning is highest for hydrogen-bonding interactions, they are more sensitive to temperature than other interactions.

1.2 THERMODYNAMICS OF SOLUTIONS

In order to grasp the concepts of solubility, it is essential to understand the basic thermodynamics of mixing. This section covers the various thermodynamic aspects that dictate the process of mixing.

1.2.1 Volume of mixing

The volume of mixing, ΔV_{mix}, is the difference between the physical volume occupied by the mixture (V_{uv}) and the sum of physical volumes occupied by the solute (V_u) and solvent (V_v):

$$\Delta V_{mix} = V_{uv} - (V_u + V_v) \tag{1.2}$$

A negative volume of mixing is indicative of strong intermolecular interactions between the solute and solvent molecules. Aqueous solutions of strong electrolytes have significantly large negative volumes of mixing due to the strong hydration of ions in the solution.[3] In the case of most pharmaceutically active compounds, the volume of mixing is small and can be ignored.

1.2.2 Enthalpy of mixing

The enthalpy of mixing, (ΔH_{mix}), is the difference between the sum of enthalpies of the solute (H_u), the solvent (H_v), and of the mixture (H_{uv}):

$$\Delta H_{mix} = H_{uv} - (H_u + H_v) \tag{1.3}$$

From a strictly enthalpic standpoint, mixing is favored if ΔH_{mix} is negative. The excess enthalpy is liberated in the form of heat (ie, an exothermic process).

The energy of mixing (ΔE_{mix}) is related to the enthalpy of mixing as

$$\Delta E_{mix} = \Delta H_{mix} - P \bullet \Delta V_{mix} \tag{1.4}$$

As previously mentioned, ΔV_{mix} is small, so the values of ΔE_{mix} and ΔH_{mix} are close to one another.

1.2.3 Entropy of mixing

The entropy of a pure system is a measure of the randomness of its molecules. Mathematically:

$$S = R \ln \Omega \tag{1.5}$$

where:

Ω is the number of ways that molecules can be present in the system.

Since Ω is always equal to or greater than unity, entropy is either zero or positive. The entropy of a mixture (ΔS_{mix}) is related to the number of ways that the solute and solvent molecules can exist in pure form and in mixtures:

$$\Delta S_{mix} = R \ln \left(\frac{\Omega_{mix}}{\Omega_u + \Omega_v} \right) \tag{1.6}$$

Generally, the molecules have more freedom to move around in a mixture; that is, Ω_{mix} is greater than $\Omega_u + \Omega_v$. As a consequence, ΔS_{mix} is usually positive. However, in rare situations where the molecules have less freedom in the mixture (solute molecules undergoing complexation-like

interactions with solvent molecules),[6,7] ΔS_{mix} can be negative.

The entropy of mixing is related to the composition of the solution as

$$\Delta S_{mix} = -R(X_u \ln X_u + X_v \ln X_v) \quad (1.7)$$

where:

X_u and X_v are the mole fractions of the solute and solvent in the mixture, respectively.

In a two-component system $X_v = 1 - X_u$, ΔS_{mix} can be written as

$$\Delta S_{mix} = -R(X_u \ln X_u + [1 - X_u]\ln[1 - X_u]) \quad (1.8)$$

$$\Delta S_{mix} = -R(X_v \ln X_v + [1 - X_v]\ln[1 - X_v]) \quad (1.9)$$

It follows from Eq. (1.7) that ΔS_{mix} will be highest for solutions containing equimolar amounts of solute and solvent molecules.

The slope of entropy of mixing as a function of solution composition is given by

$$\frac{\partial \Delta S_{mix}}{\partial X_u} = -R \ln X_u + R \ln(1 - X_u) = -R \ln X_v + R \ln(1 - X_v) \quad (1.10)$$

It follows from Eq. (1.10) that the slope will be highest in dilute solutions (when either X_u or X_v is small). Thus, the manifestation of entropy is highest in dilute solution, which explains why thermodynamically, there is some miscibility between all systems.

1.2.4 Free energy of mixing

The free energy of mixing, ΔG_{mix}, determines the possibility and extent of two compounds mixing to form a solution. It combines the effects of enthalpy and entropy on mixing and is mathematically described as

$$\Delta G_{mix} = \Delta H_{mix} - T \bullet \Delta S_{mix} \quad (1.11)$$

where:

T is the temperature in Kelvin.

Like any thermodynamic process, mixing will occur if the free energy of mixing is negative. On the other hand, if the free energy of mixing is greater than zero, there will be phase separation. As mentioned in the previous section, solubility depends on the temperature of the system. It follows from Eq. (1.11) that an increase in temperature will increase the effect of entropy, thus making mixing more favorable. In addition, temperature may affect ΔH_{mix}, particularly for hydrogen-bonded solvents such as water. It is well known that the strength of hydrogen-bonding interactions is very sensitive to temperature. An increase in temperature makes the self-associated structure of water weaker. Since the self-associated structure of water is primarily responsible for the poor aqueous solubility of nonpolar solutes, including drugs, increasing the temperature thereby facilitates their solubility.

1.3 THEORETICAL ESTIMATION OF SOLUBILITY

While solutions of all states of matter (gas, liquid, and solid) exist in practice, the focus of this chapter will be on solutions comprising of liquid solvent since these systems are most commonly encountered and have the highest relevance in the pharmaceutical field. The backbone of the concepts discussed here may be applied to other systems, with some modifications.

1.3.1 Ideal solutions

In an ideal solution, the strength and density of interactions between the solute molecules and the solvent molecules are equal to that in the solution. In other words, the solute-solvent interactions are equal in magnitude to the solute-solute interactions and solvent-solvent interactions. Thus, the solute and solvent molecules have no preference in terms of interacting with other molecules present in the solutions. This results in the enthalpy (ΔH_{mix}^{ideal}) and volume of mixing (ΔV_{mix}^{ideal}) being 0. Such solutions rarely exist in practicality, but understanding the concept of ideal mixing provides a good platform to understand more complex systems. A solution comprising of solute and solvent bearing very close structural resemblance (in terms of functionality and size) may make nearly ideal solutions. A solution of water in heavy water nearly fits the description of an ideal solution.

The entropy of mixing of an ideal solution (ΔS_{mix}^{ideal}) is given by Eq. (1.7). The partial molar entropy of mixing of the solute in a dilute solution is given by

$$\Delta S_{mix}^{ideal}(u) = -R \ln X_u \quad (1.12)$$

Since X_u is always less than 1, ΔS_{mix}^{ideal} is positive. The free energy of mixing for an ideal solution (ΔG_{mix}^{ideal}), which is the difference between the enthalpy and entropy of mixing, will therefore always be negative. Thus, in ideal solutions, a liquid solute will be miscible with the solvent in all proportions:

$$\Delta G_{mix}^{ideal}(u) = TR \ln X_u \quad (1.13)$$

1.3.2 Effect of crystallinity

In the case of an ideal solution of a crystalline solute, more considerations are required. As discussed

previously, the solute molecules have no preference in terms of interacting with other molecules in the solution. However, if the solute exists as a crystalline solid, the enthalpic component related to the crystallinity of the solute also warrants consideration. In other words, the liquid solute molecules are free to move around in the solution, while the crystalline solute molecules have to be removed from the crystal lattice before they can start moving around. Mathematically, this can be stated as

$$X_{\text{solid}}^{\text{ideal}}(u) = X_{\text{liquid}}^{\text{ideal}}(u) - \text{Effect of Crystallinity} \qquad (1.14)$$

The process is conceptually similar to melting of a solid, which is followed by dissolution of the liquid solute molecules, and is governed by the same interactions as melting.

The effect of crystallinity of a solid on its solubility is described by the Clausius-Clapyron equation:

$$R \ln X_{\text{u}}^{\text{ideal}} = \int_{T_{\text{m}}}^{T} \frac{-\Delta H_{\text{m}}^{(at\ T)}}{T^2} dT \qquad (1.15)$$

$X_{\text{u}}^{\text{ideal}}$ represents the ideal solubility of the crystal and the effect of crystallinity on the solubility.

According to Kirchoff's law, the energy of an irreversible process is equal to the energy of a series of reversible processes between the same end points. Therefore, the irreversible enthalpy of melting at any temperature $T(\Delta H_{\text{m}}^{\text{T}})$ can be described as the sum of the enthalpies for the following three reversible processes: heating the solid to its melting point, T_{m} (quantified by the heat capacity of the solid); melting the solid at its melting point (enthalpy of fusion); and cooling the liquid back down to T (quantified by the heat capacity of the liquid). The heat of melting at T can thus be related to its value at the melting point as

$$\Delta H_{\text{m}}^{\text{T}} = \Delta H_{\text{m}}^{\text{Tm}} + C_{\text{p}}^{\text{C}}(T_{\text{m}} - T) - C_{\text{p}}^{\text{L}}(T_{\text{m}} - T) \qquad (1.16)$$

C_{p}^{C} and C_{p}^{L} are the heat capacities of the crystal and liquid form, respectively.

Combining Eqs. (1.15 and 1.16), the effect of crystallinity can be calculated to be

$$R \ln X_{\text{u}}^{\text{ideal}} = -\Delta H_{\text{m}} \frac{(T_{\text{m}} - T)}{T_{\text{m}} T} + \Delta C p_{\text{m}} \left[\frac{T_{\text{m}} - T}{T} - \ln \frac{T_{\text{m}}}{T} \right] \qquad (1.17)$$

where:

$\Delta C p_{\text{m}}$ is the heat capacity of melting.

According to the van't Hoff expression, the heat capacity of melting is close to zero. The Hildebrand[8] expression states that the heat capacity of melting is equal to the entropy of melting $(\Delta H_{\text{m}}/T_{\text{m}})$. This expression has been used by several researchers, including Prausnitz et al.,[9] Grant et al.,[10] and Mishra.[11] Later, Mishra and Yalkowsky[12] compared the mathematical significance of the two expressions and concluded that the results using either expression are close for solids melting below 600 K. Thus, Eq. (1.17) can be simplified to the following form:

$$\log X_{\text{u}}^{\text{ideal}} = -\Delta H_{\text{m}} \frac{(T_{\text{m}} - T)}{2.303 R T_{\text{m}} T} \qquad (1.18)$$

Eq. (1.18) may be further simplified by applying Walden's rule for entropy of melting. Walden[13] showed that the entropy of melting of coal tar derivatives, which can be assumed to represent organic solids like drugs, is constant, at approximately $6.9R$. Martin et al.,[14] Dannenfelser and Yalkowsky,[15] and Jain et al.[16] have successfully verified and extended the applicability of Walden's rule to several organic nonelectrolytes. Applying this approximation, the effect of crystallinity on the solubility of crystalline solute at 25°C can be calculated by

$$\log X_{\text{u}}^{\text{crystalline}} \approx -0.01(MP - 25) \qquad (1.19)$$

where:

MP is the melting point of the solute expressed in °C.

The obvious interpretation of Eq. (1.19) is that the effect of crystallinity will be greater for high-melting solutes. It is intuitive that a high-melting crystalline solid will offer greater resistance toward solubilization. It also follows that an increase in temperature will diminish the effect of crystallinity and therefore result in increased solubility.

For liquid solutes, where there is a complete absence of crystallinity, Eq. (1.19) should be omitted while calculating the solubility. The effect of crystallinity on solubility is demonstrated in Fig. 1.1.

1.3.3 Nonideal solutions

Nearly all solutions encountered in the pharmaceutical arena are not ideal. Nonideal solutions or real solutions are formed when the affinity of solute molecules for each other is different than that toward the solvent molecules, or vice versa. In either case, the enthalpy of mixing is not ideal. This results in a deviation from ideality that is related to the activity coefficient of the solute. The activity of a solute in a solution is equal to the product of its concentration and activity coefficient as

$$\alpha_{\text{u}} = X_{\text{u}} \bullet \gamma_{\text{u}} \qquad (1.20)$$

where:

γ_{u} is the activity coefficient of the solute.

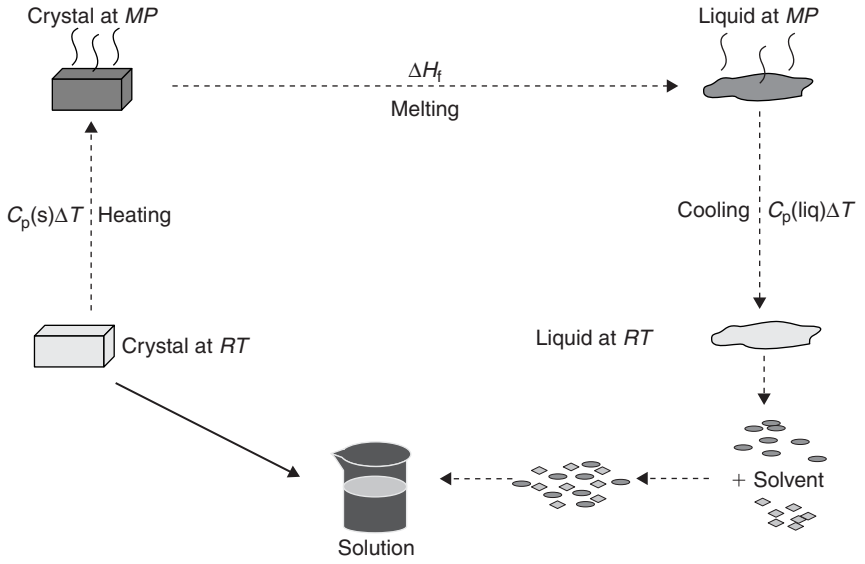

FIGURE 1.1 Role of crystallinity in the solubility of solids. *Source: Modified from a presentation by Dr Kenneth Morris (Short Course on Solubility and Solubilization of Drugs, 2007).*

The mole fraction solubility of a crystalline solute in a nonideal solution can be calculated by combining Eqs. (1.19 and 1.20):

$$\log X_u^{real} = -0.01(MP-25) - \log \gamma_u \qquad (1.21)$$

In the case of ideal solutions, γ_u is 1 and the solubility is ideal.

The mathematical meaning of γ_u is derived using various theories depending upon the type of solute and solvent molecules. Two of the most commonly accepted theories are regular solution theory and aqueous solution theory, discussed next.

1.3.4 Regular solution theory

The regular solution theory is applicable largely to nonhydrogen bonding systems. According to the theory, γ_u is a function of the following three steps, in which mixing occurs:

1. *Removal of a solute molecule from the solute surface.* This involves the breaking of solute-solute bonds, and the work required to accomplish this is given by W_{uu}.
2. *Removal of a solvent molecule from bulk to create a cavity in which the solute molecule can fit.* This involves breaking of solvent-solvent bonds, and the work required for this is given by W_{vv}.
3. *Insertion of the free solute molecule in the created cavity.* This results in gain of work, which is given by W_{uv}. The cavity filling involves the surfaces of both solute and solvent molecules, and that is why the total work gained is $2W_{uv}$.

The total work is therefore equal to $(W_{uu}+W_{vv}-2W_{uv})$. The activity coefficient of a solute is related to this work by the following relationship:

$$\log \gamma_u = (W_{uu}+W_{vv}-2W_{uv}) \bullet \frac{V_u \Phi_v^2}{2.303RT} \qquad (1.22)$$

where:

V_u is the molar volume of the solute.
Φ_v is the volume fraction of the solvent.

It is assumed that W_{uv} is the geometric mean of W_{uu} and W_{vv}. Upon applying this assumption, Eq. (1.22) transforms to

$$\log \gamma_u = (W_{uu}+W_{vv}-2\sqrt{W_{uu}\cdot W_{vv}}) \bullet \frac{V_u \Phi_v^2}{2.303RT} \qquad (1.23)$$

Eq. (1.23) may be rewritten in the following form:

$$\log \gamma_u = (\sqrt{W_{uu}}-\sqrt{W_{vv}})^2 \bullet \frac{V_u \Phi_v^2}{2.303RT} \qquad (1.24)$$

The terms $\sqrt{W_{uu}}$ and $\sqrt{W_{vv}}$ are the solubility parameters of the solute (δ_u) and solvent (δ_v), respectively. Thus, Eq. (1.24) becomes

$$\log \gamma_u = (\delta_u-\delta_v)^2 \bullet \frac{V_u \Phi_v^2}{2.303RT} \qquad (1.25)$$

The solubility parameter is a measure of the cohesive energy density (also referred to as the internal pressure) of a compound:

$$\delta = \sqrt{\frac{\Delta E_v}{V_m}} \qquad (1.26)$$

ΔE_v and V_m are the enthalpy of vaporization and molar volume, respectively.

The solubility parameter is a measure of intermolecular interactions of a compound and can be used as a measure of polarity. Hildebrand and Scott[17] compiled solubility parameters for a number of compounds, and so did Hansen and Beerbower.[18] Hansen and Beerbower further extended the concept by ascribing contributions of the nonpolar, polar, and hydrogen-bonding components of a molecule to the total solubility parameter.

Fedor[19] proposed a scheme to estimate the solubility parameters of liquid organic compounds based on a group contribution approach. Similarly, Sanghvi and Yalkowsky[20] proposed a group contribution scheme to estimate the enthalpy of vaporization of organic compounds.

Eq. (1.21) can be combined with the following equation to calculate the solubility of a crystalline solute according to the regular solution theory:

$$\log X_u^{regular} = -0.01(MP-25)-(\delta_u-\delta_v)^2 \bullet \frac{V_u \Phi_v^2}{2.303RT} \quad (1.27)$$

It follows from Eq. (1.27) that the solubility of a solute is a function of the difference in the cohesive energy densities of the solute and solvent. Thus, a liquid solute (with no crystal term) with a molar volume of 100 mL will be completely miscible in a solvent if their solubility parameter difference is less than 7 $(J/cm^3)^{0.5}$.

The regular solution theory has been applied by several groups to successfully estimate the solubility of organic compounds in nonpolar solvents. It appears that the geometric mean assumption does not seem to hold well for strongly hydrogen-bonded systems, limiting the applicability of the regular solution theory mainly to organic media. Martin et al.[21] proposed a correction factor to cater to the hydrogen-bonding interactions of the solvent. Similarly, the extended Hildebrand solubility approach[8] utilized an extra activity coefficient term to account for strong forces, including hydrogen bonding.

1.3.5 Aqueous solution theory

As discussed in the previous section, the regular solution theory is not applicable to hydrogen-bonding systems like water, since the geometric mean assumption is not valid in such systems. Yalkowsky et al.,[22–24] and later Amidon et al.,[25] proposed that instead of using pressure-volume work to account for enthalpy of mixing, surface tension–area work should be considered. This theory is based on the concept that only the surface of the solute molecule is capable of interacting with solvent molecules. Thus, using surface area instead of volume work is more meaningful. The following equation was proposed to calculate the energy requirement for solubilization in an aqueous system:

$$\Delta E_u^{aqueous} = \Delta H_u^{aqueous} = (\gamma_w + \gamma_u - \gamma_{uw})A_u = \Sigma \gamma_{uw} A_u \quad (1.28)$$

where:

γ_u and γ_w are the surface tensions of the pure solute and water, respectively.
γ_{uw} is the solute-solvent interfacial tension.
A_u is the surface area of the solute.

The entropy of mixing of aqueous systems is also nonideal. The water molecules cluster around an organic solute to form a so-called iceberglike structure. The aqueous solution theory accounts for this deviation by introducing a correction factor in the entropy term:

$$\Delta S_u^{aqueous} = \Delta S_u^{ideal} + \Sigma h_i A_u \quad (1.29)$$

where:

h_i is the contribution of the entropy of mixing per unit area due to the iceberg formation at the molecular surface.

The free energy of mixing the aqueous solution is calculated using Eqs. (1.28 and 1.29):

$$\Delta G_u^{aqueous} = \Sigma \gamma_{uw} A_u - T(\Sigma h_i A_u + \Delta S_u^{ideal}) \quad (1.30)$$

This can be written as

$$\Delta G_u^{aqueous} = \Sigma \gamma_{uw} A_u - T\Sigma h_i A_u + T(RX_u \ln X_u + X_v \ln X_v) \quad (1.31)$$

or

$$\Delta G_u^{aqueous} = \Sigma g_u A_u + T(RX_u \ln X_u + X_v \ln X_v) \quad (1.32)$$

where: $g_u = -\Upsilon_{iw} A_i - T\ (h_i A_i)$ is the group contribution to the activity coefficient, which caters to both the enthalpic and the entropic deviations to ideality.

The solubility of a crystalline solute in a hydrogen-bonding solvent can be calculated by combining Eqs. (1.21 and 1.32):

$$\log X_u^{aqueous} = -0.01(MP-25) - \Sigma g_u A_u \quad (1.33)$$

In a number of studies, Myrdal et al.[26–29] developed a robust group contribution scheme, called the *AQUAFAC approach*, for estimation of the aqueous activity coefficient of organic compounds. Their work successfully demonstrates the applicability of aqueous solution theory.

1.3.6 General solubility equation

The general solubility equation (GSE) utilizes the relation between the octanol-water partition coefficient of a solute and its water solubility, first proposed by Hansch et al.[30]

$$\log S_w = -A \log K_{ow} + B \tag{1.34}$$

where:

K_{ow} is the octanol-water partition coefficient of a liquid solute, while A and B are solute-specific constants.

The octanol-water partition coefficient is the ratio of the activities of the solute in octanol (a_o) and that in water (a_w). For dilute solutions where the activity coefficient is close to unity, K_{ow} can be approximated as

$$K_{ow} = \frac{S_o}{S_w} \tag{1.35}$$

where:

S_o and S_w are the solubilities of the liquid solute in octanol and water, respectively.

Eq. (1.35) can be transformed as follows:

$$\log S_w = \log S_o - \log K_{ow} \tag{1.36}$$

Jain and Yalkowsky[31] proposed that $\log_{10} S_o$ can be replaced by 0.5 for solutes that are completely miscible with octanol. The explanation they provided is as follows.

The concentration of pure octanol is 6.3 M. The saturated solution of a completely miscible solute of a similar molar volume as octanol will contain 3.15 moles of the solute. Since the logarithm of 3.15 is about 0.5, Eq. (1.36) can be modified in the following form to give the molar aqueous solubility of a liquid solute:

$$\log S_w = 0.5 - \log K_{ow} \tag{1.37}$$

It has been discussed previously that, according to the regular solution theory, the miscibility of a solute with a solvent depends on the difference in their solubility parameters and molar volumes. Sepassi and Yalkowsky[32] showed that in the case of octanol (solubility parameter of 21.1 $(J/cm^3)^{0.5}$ and molar volume of 158 cm^3), a liquid solute of molar volume 200 cm^3 will be completely miscible if its solubility parameter is between 15.2 and 27 $(J/cm^3)^{0.5}$. Since the solubility parameters of most drugs are in this range, their liquid forms are expected to be completely miscible in octanol.

Consistent with previous discussions, solute crystallinity should be taken into consideration while calculating the solubility of a crystalline solute. Thus, the solubility of a crystalline solute can be estimated using the GSE by combining Eqs. (1.19 and 1.37):

$$\log S_w = 0.5 - \log K_{ow} - 0.01(MP - 0.5) \tag{1.38}$$

The GSE provides a very simple means of estimating aqueous solubility. Unlike the regular solution theory and aqueous solution theories, which require a number of empirically generated coefficients, the GSE requires only two input parameters (melting point and octanol-water partition coefficient). The measurement of both parameters is a routine part of the active pharmaceutical ingredient (API) characterization process. The value of $\log_{10} K_{ow}$ can also be estimated from the chemical structure by using one of several commercially available software packages (eg, ClogP, ACDlogPdB, and KowWin). Machatha and Yalkowsky[33] compared these estimation schemes and concluded that ClogP was the most accurate predictor of $\log_{10} K_{ow}$.

A variety of schemes for the prediction of melting points of organic compounds have been proposed. These have been reviewed by Katritzky et al.,[34] Dearden,[35] and Bergstrom et al.,[36] among others. Jain and Yalkowsky[37] proposed a reasonably accurate group contribution scheme for melting point estimation using experimental data for over 2200 organic compounds, including a number of drugs.

The accuracy of the GSE has been sufficiently demonstrated for several hundred nonionizable organic compounds.[38–41] Recently,[42] the application of the GSE has been extended to weak ionizable compounds by combining it with the Henderson-Hasselbalch equation.

Notice that in Eqs. (1.37 and 1.38), the solubility is expressed in moles per liter. The constant (0.5) will change to 2.7 ($\log_{10}$500) if the solubility is expressed in grams per liter.

Besides the regular solution theory and aqueous solution theory, several other schemes have been proposed for the estimation of solubility. These were reviewed extensively by Dearden[43] and Jorgensen and Duffy.[44] Abraham and Li[45] developed a model for estimating solubility based on specific solute-solvent interactions. The parameters used in the model include excess molar refraction, dipolarity, polarizability, hydrogen-bond acidity and basicity, and molecular volume of the solute. In addition, hydrogen-bonding terms are included to make the model more sophisticated. This model is very intuitive and simple to follow. However, the coefficients involved with each parameter have to be determined experimentally, and therefore using the model for drug molecules can be very cumbersome. Taskinen and Yliruusi[46] compiled the various prediction schemes based on a neural network approach.

1.4 SOLUBILIZATION OF DRUG CANDIDATES

The solubility of drug candidates can be altered by modifying the crystal form or by changing solvent properties and conditions. As discussed in the previous sections, the equilibrium solubility is dependent

on the properties and nature of interactions in solid state, as well as in solution state. Modifications in the solid state can be accomplished by the use of prodrugs, use of metastable crystal forms, or amorphous state of the drug, salt formation, or co-crystal formation. In solution state, the solubility can be influenced by altering solution pH (for ionizable drugs) or use of additives such as complexing agents, surfactants, or cosolvents. Orally administered drugs must undergo dissolution in the gastrointestinal tract (GI) prior to absorption across the intestinal epithelium. The dissolution rate is not only dependent on the physicochemical properties of the drug, but also the physiological conditions in the GI tract. The in vivo physiological conditions that influence the oral dissolution and solubilization include intestinal pH, GI transit time, bile salts, and lipid content. In the following sections, the impact of solvent pH (ie, drug ionization and salt formation), complexation, micellar solubilization by surfactants, cosolvency, and the combined effects of these factors on drug solubility will be discussed.

1.4.1 Solubility enhancement by pH control and salt formation

A significant portion of drug candidates are weak acids, bases, and their salts.[47,48] As will be shown in the following sections, solubility of these compounds is dependent on the pH of the aqueous medium and the electrolytes in solution. The ionization equilibria and the intrinsic solubility of various unionized (free form) and ionized (salt form) species determine the nature of dependency of drug solubility on pH.

1.4.1.1 Theoretical expressions to describe pH–solubility profiles

The pH-solubility profile of a monoprotic acid (HA) is obtained by the superposition of the two distinct pH-solubility curves for the free form and the salt form, with the constraint that the solubility of either species cannot be exceeded at a given pH (Fig. 1.2). This profile is obtained by following the solubility of free acid (HA) in solutions containing different amounts of a base (eg, MOH).

The profile can be divided into two regions,[48] In Region I, the free acid is present as the excess solid in equilibrium with the solution. The total solubility is the sum of concentrations of unionized (free acid) and the dissociated form:

$$S_T = C_{HA} + C_{A^-} \tag{1.39}$$

At equilibrium (saturation), the concentration of the free acid, C_{HA}, is equal to its intrinsic solubility (S_{HA}).

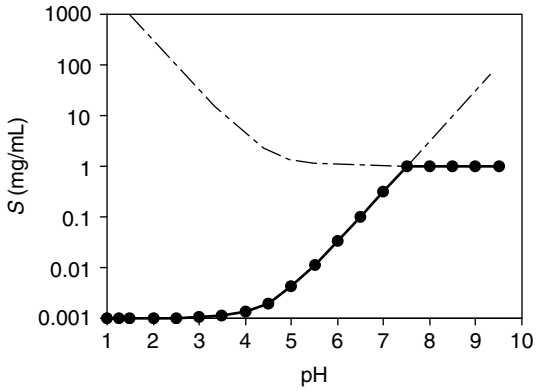

FIGURE 1.2 pH solubility of free acid or its salt.

The concentration of the dissociated form, C_{A^-}, is dependent on the free acid concentration, acid ionization constant, and pH:

$$C_{A^-} = C_{HA}\frac{K_a}{[H^+]} \tag{1.40}$$

Thus, the total solubility of the free acid as a function of pH is given by the following equations:

$$S_T = C_{HA} + C_{A^-} = S_{HA} \bullet \left(1 + \frac{K_a}{[H^+]}\right) \tag{1.41}$$

$$S_T = S_{HA} \bullet (1 + 10^{(pH - pKa)}) \tag{1.42}$$

In Region I, as the pH increases beyond the pK_a of the solute, the concentration of the ionized form increases, leading to an increase in the total solubility in an exponential fashion. This exponential increase in solubility occurs until a point (pH_{max}) where the maximum salt solubility is reached and Region II of the pH-solubility profile begins. In Region II, the salt form is the excess solid in equilibrium with the solution. At equilibrium (saturation), the concentration of the dissociated form (salt), C_{A^-}, is equal to its intrinsic solubility (S_{A^-}). The concentration of the unionized form, C_{HA}, is defined by the ionization equilibrium and is dependent on the ionized form concentration (S_{A^-}) and the acid ionization constant, K_a:

$$S_T = C_{HA} + C_{A^-} = S_{A^-} \bullet \left(1 + \frac{[H^+]}{K_a}\right) \tag{1.43}$$

The solubility of the salt, S_{A^-}, is dependent on the solubility product of the salt, K_{sp}, and the counterion concentration, M^+:

$$K_{sp} = S_{A^-} \bullet [M^+] \tag{1.44}$$

In Region II of Fig. 1.2, the solubility is constant, but this may not be the case when excess counterions (more than stoichiometric amounts) are present in solution, as this will lead to suppression of the salt

solubility (Eq. 1.44). If the counterion M^+ is generated by a weak base, additional ionization equilibria between the charged and uncharged counterion need to be included in Eq. (1.44). The ability of in situ salt formation thus would depend on the pK_a of the acid and pK_a of the conjugate acid of the base.

These equations are expressed in terms of concentration, with the assumption that the activity coefficient for all the species is 1.0. This assumption may be reasonable for neutral species, but for charged species in solutions at high ionic strength, the activity coefficients are less than 1.0. Therefore, the assumption that activity coefficients are unity should be verified.[49] The expressions generated here are valid regardless of whether the excess solid that is added at the beginning of the experiment is in free acid or salt form. The solubility at any given pH, therefore, is governed by pH, the intrinsic solubility of the free acid, the solubility product of the salt, and the concentration of the common ions. The various ionization and solid/liquid equilibria during solubilization of weak acid are shown in Scheme 1.1. It is imperative that the solid phase be analyzed after equilibration during solubility experiments, as the solid phase exists either as the free acid (AH) or its salt (A^-M^+), except at pH_{max}.

By analogy, the pH-solubility profile of a monobasic compound and its salt can be described by the following three equations.

In Region I, when $pH > pH_{max}$:

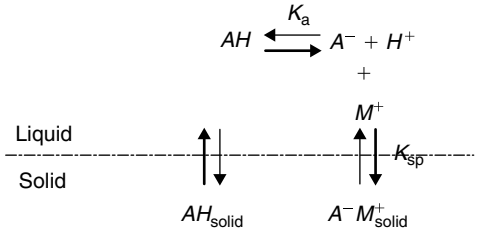
$$S_T = S_B \bullet (1 + 10^{(pKa - pH)}) \tag{1.45}$$

In Region II, when $pH < pH_{max}$:

$$S_T = S_{BH^+} \bullet (1 + 10^{(pH - pKa)}) \tag{1.46}$$

$$K_{sp} = S_{BH^+} \bullet [X^-] \tag{1.47}$$

Fig. 1.3 shows the pH-solubility profile of a free base obtained by titrating with two different acids, *HY* and *HX*. The solubility curves generated in the two experiments (with different acids) show a similar exponential increase in solubility with pH in Region I (freebase is the solid phase). The solubility increases as the pH is lowered until pH_{max}, where the solubility product of the individual salt is limiting.



SCHEME 1.1 Ionization and solid–liquid equilibria. *Source: Drawn based on Serajuddin ATM and Pudipeddi M.* Handbook of pharmaceutical salts. *Wiley-VCH; 2002. p. 135–160 and Chowhan ZT.* J Pharm Sci; *1978;67:1257–60.*

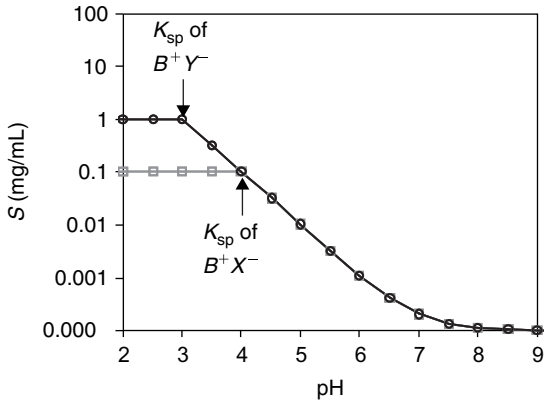


FIGURE 1.3 pH-solubility profile of a free base in the presence of acids *HX* and *HY*.

At equilibrium, at all the pH values (except at pH_{max}), only one solid phase (free base or salt) exists, regardless of the nature of the starting solid material.[51] Therefore, it is important to confirm the identity of the form of the solid phase during solubility experiments. The ratio of the salt solubility and free form solubility drives the location of pH_{max}, which in turn defines the form of the solid phase at equilibrium. The location of pH_{max} is important, as it provides an indication of the relative physical stability of the free form versus salt form in aqueous media and formulations. For example, it may be possible to make a salt of a very weak base (eg, pK_a is approximately 2–3), but when exposed to aqueous conditions in the pH range 1.0–9.0 that are relevant to physiology or formulations, the salt will likely be disproportionate to the free base. A thorough understanding of the pH-solubility profile of ionizable drugs is important for successful development of an ionizable drug candidate.

The discussion in this section has focused on the monoprotic acids and monobasic compounds. However, pH dependency for other weak electrolytes such as zwitterions,[52] dibasic,[48] and diprotic drug candidates can easily be extended by using the same principles of mass balance, ionic equilibria, and the constraint that the solubility of any one of the species cannot be exceeded at a given pH.

1.4.2 Solubilization using complexation

For pharmaceutical systems, *complexation* may be defined as a reversible noncovalent interaction between *m* molecules of drug with *n* molecules of a ligand species[53]:

$$m \cdot D + n \cdot L \overset{K_{m:1}}{\rightleftharpoons} D_m L_n$$

The equilibrium constant $K_{m:n}$ is sometimes known as the complexation or binding or stability constant:

$$K_{m:n} = \frac{[D_m{:}n]}{[D]^m \bullet [L]^n} \tag{1.48}$$

It is possible for a drug to interact with the ligand to form more than one complex, each having a different stoichiometry, and each of these complexation reactions can be defined by the stoichiometry (m:n) and the equilibrium constant ($K_{m:n}$).

In the context of solubility and solubilization, complexation can best be studied using the phase solubility methods described by Higuchi and Connors[54] and Repta.[53] Based on the phase solubility diagram (ie, dependence of solubility on ligand concentration), Higuchi and Connors suggested classifying the complexation phenomena/complexes into the following two categories:

1. Type A phase diagrams, wherein the complex is soluble and does not precipitate regardless of the ligand concentration
2. Type B phase diagrams, wherein the complex precipitates when the ligand concentration reaches a critical value

The type A phase diagrams are further classified into A_L, A_P, and A_N, whereas type B phase diagrams are classified into B_I and B_S phase diagrams. The A_N and B_I types of phase diagrams are neither common nor particularly useful from a solubilization perspective.

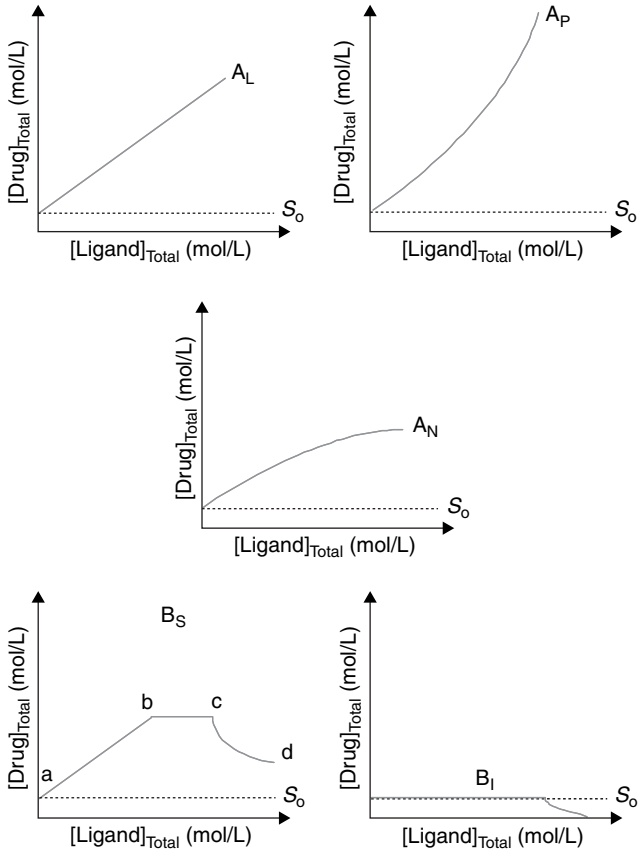

FIGURE 1.4 Drug-ligand phase solubility diagrams. *Source: Classified based on Higuchi T, Connors KA.* Adv Anal Chem; *1965:117.*

1.4.2.1 A_L-type phase diagrams

As shown in Fig. 1.4, A_L-type systems show a linear increase in the drug solubility, S_T, as a function of the ligand concentration, L_T. Such an increase is seen when a soluble drug-ligand complex with a stoichiometry of m:1 is formed. The total drug solubility, S_T is given by

$$S_T = D + m \bullet [D_m L] = S_0 + m \bullet [D_m L] \tag{1.49}$$

By applying mass balance on the ligand concentration and using the definition of equilibrium constant, $K_{m:1}$, the following relationship between total drug solubility and total ligand concentration can be obtained:

$$S_T = S_0 + m \bullet \left(\frac{K_{m:1} \bullet [S_0]^m}{1 + K_{m:1} \bullet [S_0]^m} \right) \bullet [L_T] \tag{1.50}$$

It is noteworthy that an A_L-type phase diagram alone is not sufficient to define the stoichiometry of the soluble drug-ligand complex to be 1:1. As has been demonstrated, total drug solubility linearly increases with total ligand concentration for m:1 drug-ligand complexes.

In recent years, cyclodextrins have received considerable attention as ligands to solubilize hydrophobic drugs by forming inclusion complexes. For an inclusion complex with a stoichiometry of 1:1, the slope of the line from the A_L-type phase diagram can be used to estimate the equilibrium (binding) constant:

$$S_T = S_0 + \left(\frac{K_{1:1} \bullet S_0}{1 + K_{1:1} \bullet S_0} \right) \bullet [CD_T] \tag{1.51}$$

$$K_{1:1} = \left(\frac{\text{Slope}}{(1 - \text{Slope}) \bullet S_0} \right) \tag{1.52}$$

1.4.2.2 A_P-type phase diagrams

The formation of soluble complexes containing more than one molecule of ligand leads to positive deviation from linearity, and such phase diagrams are classified as A_P-type. Let us consider a drug-ligand system forming 1:1 and 1:2 complexes. The complexation equilibria can be written as follows:

$$D + L \overset{K_{1:1}}{\rightleftharpoons} DL$$

$$DL + L \overset{K_{1:2}}{\rightleftharpoons} DL$$

$$S_T = S_0 + K_{1:1} \bullet S_0 \bullet [L] + K_{1:2} \bullet K_{1:1} \bullet S_0 \bullet [L]^2 \tag{1.53}$$

The free ligand concentration, [L], can be related to the total ligand concentration, [L_T], using a mass balance equation for the ligand. Clearly, the total drug solubility will show positive deviation from linearity because, as the concentration of the ligand increases, the contribution of 1:2 complex formation increases. Dilution of drug-ligand systems forming higher-order complexes (A_P-type) may lead to precipitation of the drug, as the concentration of the drug after dilution may be higher than the solubility in the diluted solution.

1.4.2.3 B_S-type phase diagrams

A B_s-type phase diagram can be divided into three regions. In Region I (a–b), the drug solubility initially increases (linearly or nonlinearly, depending on the complex stoichiometry) with an increase in ligand concentration. Region II (b–c), representing the plateau portion, has both the complex and drug in the solid phase, and the total solubility is the sum of intrinsic solubility of the drug and that of the complex. Region III (c–d) begins when the ligand concentration becomes large enough to deplete the free drug concentration, thus decreasing the total drug solubility. At high ligand concentrations, complete removal of the free drug (leading to a solid phase containing pure complex and the total drug concentration) will be equal to the solubility of the complex.

Although drug-ligand solid complexes were reported on in the 1950s,[55,56] they have received considerable attention recently, but by a different name—*cocrystals*.[57–59] Recently, Nehl et al.[60] developed a theoretical framework for cocrystal (drug-ligand complex) phase solubility for cases where the drug and ligand form 1:1 complexes, 1:2 complexes, or both.

The cocrystal solubility (drug concentration in solution with a cocrystal as the solid phase) can be described by the solubility product alone when the two components of the cocrystal do not interact in solution:

$$DL_{solid} \overset{K_{sp}}{\rightleftharpoons} D_{soln} + L_{soln}$$

$$K_{sp} = [D]\bullet[L] \tag{1.54}$$

When the two components in solution also interact to form a 1:1 complex in solution, the total cocrystal solubility is dependent on the solubility product and the equilibrium (binding or complexation) constant:

$$D_{soln} + L_{soln} \overset{K_{1:1}}{\rightleftharpoons} DL_{soln}$$

$$K_{11} = \frac{[DL]}{[D]\bullet[L]} = \frac{[DL]}{K_{sp}} \tag{1.55}$$

The total solubility of the drug is given by

$$S_T = [D]_T = [D]_{free} + [DL] = \frac{K_{sp}}{[L]} + K_{11}\bullet K_{sp} \tag{1.56}$$

The total drug solubility as a function of L_T can be modified to

$$S_T = \frac{K_{sp}}{[L]_T - K_{11}\bullet K_{sp}} + K_{11}\bullet K_{sp} \tag{1.57}$$

This equation describes the total drug solubility as a function of ligand concentration for a phase solubility system that contains a pure, 1:1 drug-ligand cocrystal in the solid phase, and a solution where a 1:1 complex is formed. As predicted by Eq. (1.57), the total solubility decreases as the ligand concentration increases. For the case of the carbamazepine/nicotinamide 1:1 cocrystal, Nehl et al.[60] showed that the total carbamazepine solubility decreased with an increase in nicotinamide concentration, according to Eq. (1.57). In the case where there is no interaction of the drug and ligand in solution (ie, $K_{11} = 0$), the drug solubility is simply defined by the solubility product and ligand concentration in solution.

When studying the phase solubility of complexing agents, it is important to determine the nature of the solid phase along with the drug concentration in the solution phase. Based on the experimentally determined solubility data, a phase diagram illustrating where the drug, ligand, and cocrystal can exist or coexist in the solid phase must be constructed. Understanding the thermodynamic domains of the different forms (drug, ligand, and cocrystal) is essential in the crystallization of the desired cocrystal, preventing undesirable phase transformations during the crystallization and formulation of cocrystals.

1.4.3 Solubilization by cosolvents

The use of cosolvents is well recognized in altering the solubility of organic compounds. Yalkowsky[61] presented some general features of cosolvents and solubilization by cosolvents. Cosolvents are partly polar, due to the presence of hydrogen bond donors, acceptors, or both, thus ensuring miscibility with water. Cosolvents improve the solubility of drugs (nonpolar) because the small hydrocarbon regions of cosolvents reduce the ability of the water to squeeze out nonpolar solutes. The presence of cosolvents in aqueous medium leads to decreased solvent-solvent interactions, leading to a reduction in properties (surface tension, dielectric constant, and solubility parameter) that are reflective of solvent polarity.

The solubility enhancement by a cosolvent is a function of both drug and cosolvent properties.

The greatest enhancement in drug solubility is achieved by cosolvents or cosolvent-water mixtures with similar polarity to the drug. The addition of cosolvent can lead to increase or decrease in solubility, depending on the polarity of the drug candidate. Gould et al.[62] observed that the solubility of oxfenicine is decreased in the presence of ethanol. In some cases, a maximum solubility is observed for an intermediate composition of cosolvent and water, rather than in pure solvents.

Yalkowsky et al.[22,24,63–66] presented a log-linear model to explain the solubility of nonpolar solutes in cosolvent systems. The mixed solvent is assumed to behave similarly to the weighted linear combination of the individual solvents. The general equation describing the solubilization by a cosolvent is defined by

$$\log S_{mix} = \log S_w + \sigma \bullet f_c \tag{1.58}$$

where:

S_{mix} is the solubility in the mixed solvent with f_c as the fractional cosolvent volume, S_w is the solubility in water, and σ is defined as the solubilizing power of the cosolvent.

This equation indicates that the solubility changes exponentially with the cosolvent volume fraction. The logarithm of solubility increases linearly with the volume fraction of the cosolvent, and the slope of this line, σ, is dependent on the properties of both solute and cosolvent:

$$\sigma = S \log K_{ow} + T \tag{1.59}$$

where:

K_{ow} is the octanol-water partition coefficient and is related to the polarity of the drug molecule, whereas S and T are empirically derived cosolvent-dependent constants. The S and T values have been estimated by Millard et al.[66] for a number of cosolvents. The log-linear model is very useful, as it allows the estimation of solubilization of drugs in cosolvent systems, based on the partition coefficient and the known values of S and T, for various pharmaceutically acceptable cosolvents.

Although the cosolvents enhance the solubility of drug candidates by several orders of magnitude, their use is limited due to toxicity, especially at high concentrations. Due to the exponential dependence of drug solubility on volume fraction, dilution may lead to precipitation of the drug, as the drug concentration after dilution may be higher than the solubility in the diluted solution.

1.4.4 Solubilization by surfactants (micellar solubilization)

Surfactants are amphiphilic molecules that self-associate in solution and form aggregated structures known as *micelles*. The two most common models of micellization are the two-phase model and mass action model. From a solubilization perspective, drug molecules interact with micelles to form soluble drug entities. In the two-phase model, the drug is assumed to be incorporated into the micelle, whereas in the mass action model, the drug is assumed to reversibly bind to self-associated surfactant aggregates (micelles).

The two-phase model, also known as the *phase-separation model*, assumes that above a critical concentration of surfactant molecules in aqueous solution, micelles form. The micelles are considered to be a separate phase from the aqueous phase. It is assumed that micellization occurs only above the critical micellar concentration (CMC). Below the CMC, the total surfactant concentration is assumed to be the same as the monomer (aqueous phase) surfactant concentration. Above the CMC, the free monomer (aqueous phase) surfactant concentration is assumed to be constant (equal to the CMC), and the micelle concentration can be obtained by subtracting the CMC from the total surfactant concentration.

Hydrophobic, nonpolar drugs are thought be squeezed out of water into the hydrophobic regions of the micelles.[61] Since the interaction of drug molecules with surfactant monomers is assumed to be negligible, the solubility of the drug in aqueous solution at concentrations below the CMC is assumed to be the same as its intrinsic solubility, S_0. At surfactant concentrations above the CMC the total solubility of the drug, S_T, is given by the following equation:

$$S_T = S_0 + k(P_T - \mathrm{CMC}) \tag{1.60}$$

where:

P_T is the total surfactant concentration drug, and k is a proportionality constant, known as the solubilizing capacity of the surfactant.

The total solubility varies linearly with an increase in total surfactant concentration (ie, micelle concentration). The nonlinearity in solubility enhancement means that the solubilization capacity assumed to be a constant is, in reality, dependent on the surfactant concentration. This can be due to changes in micelle shape or aggregation numbers of the micelle.

Based on the mass action law model, self-association equilibrium between n surfactant monomers and the micelle is expressed as follows:

$$n \cdot P_1 \overset{\beta_n}{\rightleftharpoons} P_n$$

The total surfactant concentration, P_T, can be defined by the following expression:

$$P_T = [P_1] + n \times [P_n] = [P_1] + n \times \beta_n \times [P_1]^n \tag{1.61}$$

Drug solubilization in the surfactant solution can be depicted by multiple equilibria between the self-associated surfactant, P_n, and the drug:

$$i \cdot D + P_n \overset{k_i}{\rightleftharpoons} D_i P_n$$

The saturation solubility of a drug in a surfactant solution is given as

$$S_T = S_0 + [P_n] \sum_{i=1}^{M} i \times k_i \times [S_0]^{in} \tag{1.62}$$

It is difficult to estimate the individual equilibrium constants for the various species, so the two-phase model is a more convenient and often sufficient way to describe the solubility of drugs in surfactant solutions.

1.4.5 Solubilization by combination of approaches

In the previous sections, the most popular techniques to improve solubility by pH control or by use of complexing agents, cosolvents, and surfactants have been discussed. However, it is common to find that a single approach of solubilization is not adequate to improve the aqueous solubility to the desirable extent. Generally, the combination of ionization with cosolvency, complexation, or micellar solubilization leads to synergistic improvement in the solubility of weak electrolytes. The combined effect of complexation and cosolvency, or complexation and micellar solubilization, on drug solubility can be variable. In the following sections, the theoretical framework describing drug solubilization by a combination of approaches is discussed.

1.4.5.1 Combined effect of ionization and cosolvency

The total solubility of an ionizable drug in a mixed solvent can be derived by writing the log-linear model for various drug species in solution. When considering a monoprotic weak acid or monobasic compound, the solubilization by cosolvency for the ionized and unionized drug moieties can be expressed using the log-linear model equations[61]:

$$\log S_u^f = \log S_u + \sigma_u \bullet f_c \tag{1.63}$$

$$\log S_i^f = \log S_i + \sigma_i \bullet f_c \tag{1.64}$$

where:

S_u^f and S_i^f are the solubility of the unionized and ionized species, respectively, in the mixed solvent; S_u and S_i are solubility of the unionized and ionized species, respectively, in water; and σ_u and σ_i are the solubilization power of the cosolvent for the unionized and ionized species. The total drug solubility is obtained by the sum of S_u^f and S_i^f and is provided by the following equation:

$$S_T = S_u \bullet 10^{\sigma_u f_c} + S_i \bullet 10^{\sigma_i f_c} \tag{1.65}$$

For a monoprotic weak acid:

$$S_T = S_0 \bullet 10^{\sigma_u f_c} + S_0 \bullet 10^{(pH - pKa)} \bullet 10^{\sigma_i f_c} \tag{1.66}$$

For a monobasic compound:

$$S_T = S_0 \bullet 10^{\sigma_u f_c} + S_0 \bullet 10^{(pKa - pH)} \bullet 10^{\sigma_i f_c} \tag{1.67}$$

The solubilization capacity of the unionized species, σ_u, is typically found to be greater than that for the ionized species, σ_i, because the cosolvent can solubilize the unionized species (more polar) with greater efficiency than the ionized species (less polar). However, the decrease in solubilization capacity is more than compensated for by the increase in solubility of the ionized species (ie, $S_i >> S_u$). Therefore, it is possible that the combined effect of ionization and cosolvency is better than any single technique. The solubility of 2,2-diphenyl-4-piperidyl dioxolane hydrochloride salt in propylene glycol–water mixtures was better than the solubility of the free base in the mixed solvent or the hydrochloride salt in water.[67]

1.4.5.2 Combined effect of ionization and micellization

The total solubility of a weak electrolyte undergoing ionization and micellization can be described by accounting for the free unionized drug, free ionized drug, micellized unionized drug, and micellized ionized drug:

$$S_T = S_u + S_i + k_u[P_T - CMC] + k_i[P_T - CMC] \tag{1.68}$$

This equation is valid for surfactants that are either neutral or completely ionized in the pH range of interest. Li et al.[68] demonstrated that the falvopiridol (a free base with pK_a of 5.68) showed synergistic improvement in solubility due to the combined effect of lowering pH and using polysorbate 20.

1.4.5.3 Combined effect of ionization and complexation

The combined effect of ionization and complexation on drug solubility has been derived similarly to this scenario of solubilization by ionization and micellization. The total drug solubility has been derived by different researchers[69–71] by considering the various species in solutions (ie, free unionized drug, ionized drug, unionized drug-ligand complex, and ionized drug-ligand complex). Rao and Stella[72] derived an equivalent expression for the total solubility of a weak electrolyte undergoing 1:1 complexes with a ligand, based on the

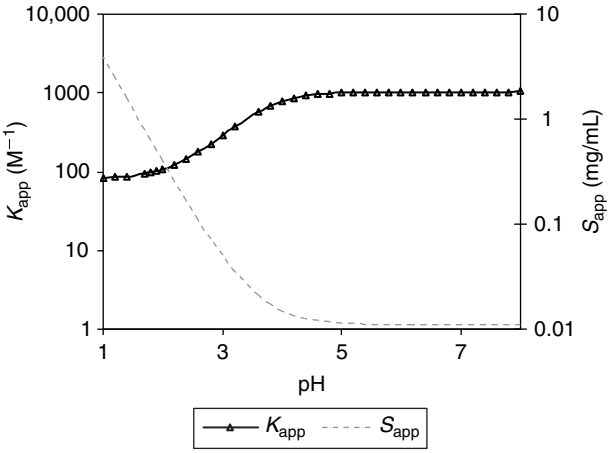

FIGURE 1.5 Variation of S_{app} and K_{app} as a function of pH for thiazolobenzimidazole. *Source: The curves are reproduced based on equations in Yang G, Jain N, Yalkowsky SH.* Int J Pharm*; 2004;269:141–48. and data from Johnson MD, Hoesterey BL, Anderson BD.* J Pharm Sci*; 1994;83:1142–46.*

apparent solubility and apparent binding constant at any given pH, as

$$S_T = S_{app} + \frac{K_{app} S_{app}}{1 + K_{app} S_{app}} [L_T] \tag{1.69}$$

For monoprotic weak acids, K_{app} and S_{app} are defined as follows (Fig. 1.5):

$$K_{app} = K^o \frac{[H^+]}{K_a + [H^+]} + K^- \frac{K_a}{K_a + [H^+]} \tag{1.70}$$

$$S_{app} = S_o \frac{K_a + [H^+]}{[H^+]} \tag{1.71}$$

K_a is the ionization constant; K^o and K^- are the binding constants for the neutral drug-ligand complex and anionic drug-ligand complex, respectively. Similarly, for monobasic compounds,

$$K_{app} = K^o \frac{K_a}{K_a + [H^+]} + K^+ \frac{[H^+]}{K_a + [H^+]} \tag{1.72}$$

$$S_{app} = S_o \frac{K_a + [H^+]}{K_a} \tag{1.73}$$

where:

K_a is the ionization constant; and K^o and K^+ are the binding constants for the neutral drug-ligand complex and cationic drug-ligand complex, respectively.

Rao and Stella[72] presented an interesting analysis of binding constant values for neutral versus ionized species (both acids and bases) with HP- and SBE-β-CD. They reported the ratio of $K^{charged}$ (K^+ or K^-) to K° falls within two orders of magnitude, regardless of the type of cyclodextrins or drugs. However, S_{app} can vary over several orders of magnitude depending on the ionization type (acid or base), its pK_a, and the pH value. Although the variation of K_{app} and S_{app} with pH is in the opposite direction, the magnitude of increase in S_{app} far outweighs the decrease in K_{app} due to ionization, leading to a synergistic increase in total drug solubility, due to ionization and complexation.

1.4.5.4 *Combined effect of cosolvency and complexation*

The combined effects of complexation and cosolvents on drug solubilization can be of a synergistic or antagonistic nature. Some of the factors that need to be considered when using combinations of cosolvent and complexing agents are:

- Due to solubilization by cosolvency, the free drug concentration available for complexation may be higher, leading to a synergistic improvement in solubility.
- Formation of soluble drug-ligand-cosolvent ternary complexes leads to synergistic improvement in solubility.
- Competition between the drug and cosolvent molecules for complexation with the ligand leads to a decrease in drug solubility.
- Decrease in apparent binding constant for drug-ligand in cosolvent can occur.

Thus, the impact of the combination of cosolvency and complexation on drug solubility needs to be evaluated on a case-by-case basis. Li et al.[68] provided a mathematical model for the total solubility by considering the free drug, drug-ligand complex, and drug-solvent complex. The authors assumed that the solubilizing power of the cosolvent remains unchanged even in the presence of a complexing agent; the decrease in binding constant can be empirically related to cosolvent concentration in an exponential fashion. They also assumed negligible complexation between cosolvent molecules and the complexing agent. Fluasterone solubility increased linearly with HP-β-CD in all ethanol-water mixtures. In the absence of HP-β-CD, an exponential increase in solubility with percentage w/w of ethanol in line with the log-linear model discussed previously was observed. In the presence of HP-β-CD, the drug solubility first decreased and then increased with an increase in percentage w/w of ethanol. Using the mathematical models developed for this system, the authors were able to explain the experimental data.

1.4.5.5 *Combined effect of complexation and micellar solubilization*

Several interactions (equilibria) can coexist in solubility experiments in aqueous solutions containing a

complexing agent, surfactant, and drug. They include competitive complexation of the drug and surfactant monomer with the complexing agent, equilibria between monomer and micelle, and solubilization of drug in the micelle. Yang et al.[73] presented experimental data and a semiquantitative analysis of solubilization of NSC-639829 in aqueous solutions of SLS and (SBE)7M-β-CD. Rao et al.[74] presented a mathematical model to study the combined effect of micellar solubilization and complexation. This model assumes that ligand molecules or drug-ligand complexes do not interact with micelles, and higher order drug-ligand or surfactant monomer:ligand complexes are not formed. The phase-solubility profile in the presence of both complexing agent and surfactant are dependent on a number of factors. However, it is possible for one to predict this behavior, provided that the binary interaction parameters among the drug, complexing agent, and surfactant are known.

The first step in understanding the various equilibria is to determine P_f, the surfactant concentration that is unbound to the complexing agent. This requires solving the following quadratic equation:

$$K_P \times [P_f]^2 + (1 + K_P \times L_T + K_D \times S_0 - K_P \times P_T) \times [P_f] - (P_T + P_T \times K_D \times S_0) = 0 \quad (1.74)$$

K_P and K_D are 1:1 binding constants for surfactant monomer-ligand and drug-ligand, respectively.

If P_f is found to be less than the known CMC value for the surfactant, the total drug solubility can be described as follows:

$$S_T = [D_f] + [D - CD] = S_o + \frac{K_D \times S_0 \times [L_T]}{1 + K_P \times [P_f] + K_D \times S_0} \quad (1.75)$$

According to this equation, the total solubility will be lower in the presence of surfactant, due to competition between the drug and surfactant monomer for the complexing agent (Scheme 1.2a).

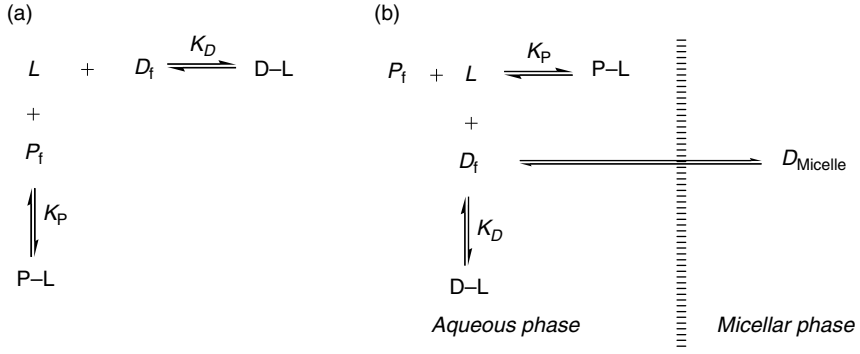
If P_f is greater than the known CMC value of the surfactant, the total solubility is defined as

$$S_T = S_o + K_M\left(P_T - \mathrm{CMC} - \frac{K_P \times \mathrm{CMC} \times [L_T]}{1 + K_P \times \mathrm{CMC} + K_D \times S_0}\right) + \frac{K_D \times S_0 \times [L_T]}{1 + K_P \times \mathrm{CMC} + K_D \times S_0} \quad (1.76)$$

According to this equation, the combined solubility is less than the sum of the solubility values in the presence of individual additives; that is, the complexing agent or surfactant (Scheme 1.2b). It is also possible that the combined solubility is less than individual solubility values. Yang et al.[73] showed that for NSC-639829, the combined solubility in aqueous solutions containing both SLS and (SBE)7M-β-CD is less than the sum of the solubility values in aqueous solutions containing SLS or (SBE)7M-β-CD.

1.5 EXPERIMENTAL DETERMINATION OF SOLUBILITY

The importance of knowing the solubility of a drug was discussed earlier in this chapter. As a consequence, the determination of solubility remains one of the most routinely conducted experiments during the drug development stage. Although these experiments are commonly perceived as simple, accurate solubility determination may be far more challenging. Pontolillo and Eganhouse[75] have noted a scatter of five log units in the experimentally determined solubility of dichlorodiphenyltrichloroethane (DDT). The AQUASOL database records a scatter of 10−30 times in the solubility of anthracene and fluoranthrene reported in the literature. These observations showcase the fact that getting an accurate determination of solubility is not a trivial task. Various aspects related to the solute and solvent of interest, experimental conditions, and the analytical



SCHEME 1.2 (a) Competitive complexation of drug and surfactant monomer to ligand ($P_f < \mathrm{CMC}$). (b) Competitive complexation and drug solubilization into micellar phase ($P_f > \mathrm{CMC}$). *Source: Redrawn based on Pontolillo J, Eganhouse E.* US geological survey, report 4201.

techniques employed, play important roles in the determination of actual solubility. This section covers the various methods that have been conventionally employed for solubility determination. In addition, several factors that may affect the solubility and its measurement will be discussed.

All methods used for solubility determination primarily consist of two parts: saturating the solvent with the solute and measuring the amount of solute present per unit of the solvent at that saturation state. In simple terms, the first part involves providing ample exposure of the solute to the solvent such that the dissolved solute molecules are in dynamic equilibrium with the undissolved molecules. A variety of analytical methods can then be used to measure the concentration of dissolved solute.

Before designing any solubility experiments, it is essential to identify whether the requirement is to determine thermodynamic equilibrium solubility or a kinetic dissolution rate. These concepts were discussed in the previous section. The need to determine one over the other depends upon the application of the results obtained. If the goal is to prepare a liquid formulation, the equilibrium solubility information is more meaningful. However, dissolution rates are needed to access the release of drug from the formulation and its subsequent absorption in the gastrointestinal tract.

The conventional approaches for measuring equilibrium solubility are based on the phase-solubility technique proposed by Higuchi and Connors.[54] An excess amount of the solute is placed with the solvent in a closed container and shaken for a sufficient length of time. Immersing sealed containers in a constant temperature bath may be used to control the temperature of the system. Once equilibrated, the sample is phase-separated to remove undissolved solute, and then analyzed quantitatively for dissolved solute content using nephlometry, UV absorbance, or potentiometric measurements.[76,77] It is necessary to maintain the same temperature used for equilibration during the phase-separation process. The main disadvantage of this method is that it can be time consuming, especially when there is a desire to run solubility experiments on a large number of compounds during the early discovery phase. Therefore, many variants of kinetic solubility experiments have been developed to rapidly screen a large number of compounds by either dissolving them in a solvent such as dimethyl sulfoxide (DMSO) or using an unidentified crystalline or amorphous phase. Various considerations are required while determining the solubility using this approach. Although the specific requirements can (and will) vary case by case, some general points are discussed next.

1.5.1 Stability of solute and solvent

It is essential that both the solute and solvent remain chemically and physically stable during the equilibration. The solute undergoing chemical degradation can result in more or less soluble products and provide misleading results. If the solvent is aqueous, hydrolysis of the solute may occur, generally resulting in the formation of more soluble degradation products. If the analytical method is not highly specific, such as UV-spectrophotometry, the measured solubility will be artificially higher than the actual solubility. The physical stability of both the solute and solvent must also be adequately considered. A hygroscopic solvent, like polyols, may pick up moisture during equilibration, which will result in a compositional change. For such solvents, care must be taken to protect against exposure to moisture. Similarly, while dealing with volatile solvents like low-molecular-weight alcohols, the container must be tightly closed to avoid solvent loss.

The physical form of the solute is an important determinant of its solubility. Polymorphic transitions, including conversion to or from hydrates/solvates, may occur during the equilibration process. Thus, it is essential to determine the form of the undissolved solute after equilibrium is achieved using a solid-state characterization technique like powder X-ray diffractometry. Determination of equilibrium solubility of a metastable form is difficult due to the conversion to the more stable form,[78] and this is particularly the case for compounds that are anhydrates or lower-order hydrates that convert to the hydrate formed upon equilibration. The best that one can do is to determine apparent solubility, often assumed to be the highest concentration observed during a solubility experiment.[79] Alternatively, the ratio of intrinsic dissolution rates for the two forms at identical hydrodynamic conditions, along with the solubility of the stable form, can be used to determine the solubility of the metastable form.[80]

On similar grounds, for ionizable solutes, it must be determined whether the solute exists in the free form or as a salt. If the solubility is to be determined at a specific pH, adequate measures must be taken to maintain the pH in the desired range using buffers. The choice of buffer should be based on the pH range desired and the selected buffer should have adequate buffer strength in that range. Monitoring and adjusting the pH of the system are essential, and the frequency of doing so strictly depends on the strength of the buffer used, ionic strength of the solute, and its dissolution rate. In addition to the pH, the ionic strength of the media affects the equilibrium solubility and must be maintained during the equilibration using common salts such as sodium or potassium chloride. The salt

selected must not contain the same ion present in the solute to avoid the common-ion effect.[81,82] Buffer components and salts used to adjust ionic strength may themselves form salts with ionizable drugs that have limited solubility. Thus, the identity of all insoluble residues must be confirmed, and the absence of buffer components or counterions of salts used to adjust ionic strength must be demonstrated.

1.5.2 Shakers and containers

Proper wetting of the solute has to be ensured by choosing an appropriate shaker. The use of several types of shakers has been reported in the literature, including end-over-end shakers, wrist action shakers, magnetic stirrers, vortexers, etc. The selection of a shaker depends on the volume and viscosity of the solvent used. Generally, end-over-end shakers provide good solute-solvent exposure for small volumes (>20 mL) of solvents that have viscosity similar to that of water. Industrial-size shakers are available for the manufacture of solution formulations. The compatibility of the solute and the solvent with the container is essential. Glass is generally the material of choice, at least for small-scale experiments, as it is relatively chemically inert. Protection from light exposure for photo-labile systems can be achieved by either using amber vials or covering the container with an opaque material such as aluminum foil.

1.5.3 Presence of excess undissolved solute

The presence of some undissolved solute during the entire length of equilibration is essential. However, a lot of undissolved solute must be avoided, as there have been several reports claiming the dependence of the equilibrium solubility on the amount of excess solute present during equilibration. Wang et al.[82] noticed that the solubility of a diprotic weak base depended on the amount of hydrochloride salt added. More recently, Kawakami et al.[83] reported that when 40 μg of indomethacin was added to 1 mL pH 5 or 6 citrate buffer, a much higher solubility was obtained compared to 5 mg added to the same solution, while a reverse trend was noticed in pH 6.5 and 7.0 phosphate buffer.

Supersaturation is another cause of imprecise solubility data. Ledwidge and Corrigan[84] reported that the self-association near pH_{max} reduces the rate of nucleation of the final salt, and that when the free drug is used as the starting material, higher levels of supersaturation are achieved.

Caution must be taken if the solute contains soluble impurities. These impurities can influence the property of the media and, consequently, the solubility of the solute. They may also interfere with the technique used for solubility analysis. This is of particular concern if the analytical technique used is nonselective. The presence of impurities has been shown to affect the solubility of 7-(2-hydroxypropyltheophylline).[85]

1.5.4 Determination of equilibrium

Information from prior experiments can be useful for gauging the time to achieve equilibrium. If no prior information is available, several samplings may be required to establish the time it takes to reach equilibrium. The periodicity of withdrawing sample depends on the dissolution rate of the solute. In order to minimize sampling, the interval can progressively be doubled. In other words, if the first sampling is performed 2 h following the start of the experiment, the second sampling can be done after 4 h, the third after 8 h, and so on. The sampling should be continued until the solubility for the last two sampling points is equal, indicating the attainment of equilibrium. The last sampling point can be conservatively treated as the time required for the equilibration. While conducting this exercise, it is important not to replace the solvent removed during sampling, as it will push the system out of equilibrium.

1.5.5 Phase separation

Once the equilibrium between the dissolved and undissolved solute is achieved, the dissolved phase has to be separated and analyzed for solute concentration. Several methods can be used to phase-separate the system. Filtration provides a convenient way to separate the dissolved phase and the undissolved solute. Appropriate filters can be chosen from a variety of configurations available to suit the need of the experiment. Commercial filters are available in a variety of sizes, pore dimensions, and membrane materials. The compatibility of the filter with both the solute and solvent must be determined. Strongly organic solvent systems can leach out components from the filter membrane or its housing. On the other hand, some solutes can adsorb on the filter assembly, which can result in solubility artifacts. An example is amiodarone, which adsorbs onto some polyvinyl-based filters. As a general practice, the filter system must be "rinsed" by passing through the solution two to three times before collection. This ensures that the system is saturated with the solute and solvent prior to sampling and will reduce artifacts.

Phase separation can also be achieved by centrifugation. This technique is particularly useful if both the

solute and the solvent are liquids. Following phase separation, the clear supernatant is collected, leaving behind the undissolved solute. Considerations must be made for possible compatibility issues of the solute or solvent with centrifuge tubes. Glass tubes are preferred whenever possible to minimize adsorption issues. Other factors include the speed and length of centrifugation, which depend on the properties of the solute and solvent.

Other methods for phase separation include the evaporative collection of solvent and selective adsorption of dissolved phase. These methods, although they can be useful in some situations, are less practical to carry out. Whichever method of phase separation is used, control over temperature during the separation process is essential. Prolonged contact of undissolved solids with the supernatant-saturated solution during the separation process at a temperature other than that at which equilibration was performed will likely result in underestimation or overestimation of solubility, depending on the temperature difference between the equilibration process and the phase-separation process.

1.5.6 Determination of solute content in the dissolved phase

Once the dissolved phase is separated, the solute concentration is determined analytically. Several techniques can be used, including spectrophotometry, gravimetry, and pH measurement. Spectrophotometry is the most commonly employed technique based on its simplicity, accuracy, and chemical specificity. This technique is based on the well-known Beer's law, according to which the absorbance of a chemical species is directly proportional to its concentration. A simple analysis can be performed by plotting a standard curve using known concentrations of the solute, followed by quantification of the unknown solute concentration in the solution. The solution may be diluted if needed, to fit into the concentration range of the standard curve.

In order to use this technique, it is essential that the analyte molecules contain a chromophore; that is, it is spectrally active in the UV or visible light region. If that is not the case, it can be chemically derivatized to make it spectrally active. The complexity of derivatization reactions depends upon the chemical structure of the solute, and in some cases, it may be a limiting factor.

It is a common practice to couple spectrophotometry with separation techniques, such as chromatography, to improve the specificity of the experiment. This approach is very useful in cases where either solvent or impurity/degradation products interfere with direct solute determination. It is particularly important at the early stages of development, where solute purity may not be known.

Gravimetric analysis involves the determination of the weight of dissolved solute in solution. This is primarily achieved either by solvent evaporation or solute precipitation using physical or chemical means. This approach is relatively simple, inexpensive, and does not require lengthy method-development steps. However, its broader application is marred by lack of sensitivity, selectivity, and practicality. Measurements of indirect properties, such as the pH of the system or colligative properties that can yield information on the concentration of solute in a given solution, also have been proposed.

1.5.7 Experimental conditions

The external conditions in which the experiment is carried out can have a huge impact on the solubility results. The effect of temperature on solubility has been detailed in the discussion following Eq. (1.11). Temperature may have a positive or a negative influence on the solubility, depending upon the solute and solvent properties. Pressure significantly affects the solubility of gases but generally has little influence on the solubility of liquids and solids. The presence of light may affect the chemical stability of photolabile solutes and may artificially affect their solubility.

Besides the thermodynamically correct phase-solubility method, the solubility can be ball-parked by using the synthetic method. According to this method, a known amount of solute is added to a known amount of solvent, followed by a mixing step. If the solute dissolves completely, more is added and the process continues until a stage is reached after which the added solute does not dissolve. Alternatively, if the solute does not dissolve completely after the first round, more solvent is added, and the process continues until the solute dissolves completely. The approximate solubility can be calculated by the knowledge of the amount of solvent required to completely dissolve a known quantity of the solute. This method provides a simple means for approximate solubility determination. It is particularly useful for solutes available in limited amounts, as the development of involved analytical method is not required. However, the approach lacks the sensitivity and selectivity of the phase-solubility approach.

CHAPTER

2

Crystalline and Amorphous Solids

G.G.Z. Zhang and D. Zhou

AbbVie Inc., North Chicago, IL, United States

2.1 INTRODUCTION

Of the several states of matter in which a substance can reside, the solid state is most commonly encountered; therefore, it is the most important and relevant state for pharmaceutical development. Most of the pharmaceutical products on the market or formulations presently being developed are in the solid dosage form. Even when a product is marketed or developed as a solution or a semisolid formulation, a solid is usually selected and manufactured as an active pharmaceutical ingredient (API) for such reasons as the ability to crystallize (and therefore to be purified), ease of handling, and better chemical stability in comparison with liquids. Therefore, an understanding of the various solid forms that may occur, as well as the rational selection of solid forms for development, are critical to the facile development of a particular chemical entity. Many books[1–7] and special journal issues[8–12] are devoted to this topic. This chapter, due to space limitations, provides only a brief introduction to the fundamental principles and practical aspects of pharmaceutical solids. Interested readers are encouraged to read the books and reviews cited here.

2.2 DEFINITIONS AND CATEGORIZATION OF SOLIDS

The various types of pharmaceutical solids are shown in Fig. 2.1. Solids can show differences either externally or internally. External differences are considered as the shape, habit, or morphology of the particles, where the internal structures that make up the solid particles remain the same. Although important for pharmaceutical development, these elements are not discussed in this chapter. The focus of this chapter is on solids with distinct differences in their internal structures.

Based on the degree of long-range order/periodicity, solids are categorized into three groups. Amorphous phases are those solids that do not exhibit long-range order in any of the three physical dimensions. However, short-range order could exist for amorphous solids. Because of the importance of this class of solids to pharmaceutical development, it is discussed in detail in Section 2.7 of this chapter. If materials have long-range order in only one or two dimensions, they are liquid crystalline in nature. Liquid crystalline materials can be further categorized based on the number of components contained therein, as is the case for crystalline solids. Since liquid crystals, with properties intermediate to conventional liquids and three-dimensional solids, are not frequently encountered, they will not be discussed in detail. The vast majority of pharmaceutical solids fall into the category of crystalline solids because they exhibit long-range order in all three dimensions.

Crystalline solids can be further categorized into various subtypes based on the number of components that make up the solid internally, in a homogeneous fashion. The solid could be composed of the drug alone, or as adducts with one (binary), two (ternary), three (quaternary), other chemical species. Although the number of other chemical species, apart from the drug itself, can increase without limit, it usually is a relatively low integer.

When the overall chemical composition of solids is the same, they can be different in internal structures. The ability of a substance to exist as two or more crystalline phases that have different arrangements or conformations of the molecules in a crystalline lattice is called *polymorphism*, and these different solids are termed *polymorphs*. One point to emphasize is that, according to

Developing Solid Oral Dosage Forms
DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00002-9

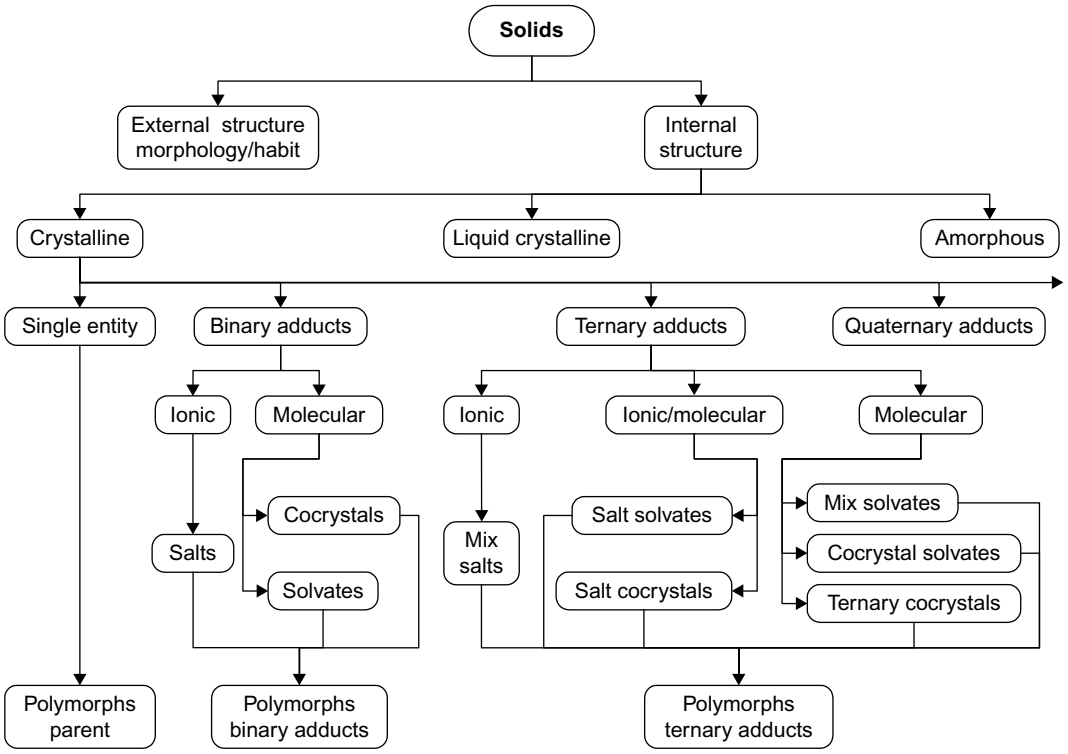

FIGURE 2.1 Categorization of pharmaceutical solids.

the strict definition of this term, different polymorphs are only different physically, not chemically. When these solids are melted or dissolved in solutions, they are exactly the same, both physically and chemically. However, in some special cases, the definition of polymorphism is extended slightly for convenience. There are many possible reasons for a substance to exhibit polymorphism, and sometimes it may be difficult to pinpoint a single one. These reasons include packing; conformation (which usually will exhibit different packing as well); hydrogen bonding pattern/motif; chirality (ie, racemic compound versus racemic conglomerate; the definition is extended here because the racemic conglomerate is an equal molar physical mixture of the enantiomerically pure crystals, and therefore is not a single phase); and tautomerism (again, the definition is extended because different tautomers are chemically not equivalent). Polymorphism is relevant not only to solids composed of single components, but also to adducts of multiple components (binary, ternary, quaternary, etc.). However, different polymorphs should have the same chemical composition, qualitatively and quantitatively, apart from the extensions of the definition mentioned here.

Adducts are formed where multiple chemical species are present in the crystalline lattices, again in a homogeneous fashion. Adducts can be categorized further based on the ionization states of these species: ionic, molecular, or ionic/molecular. The same subcategorization described in this chapter applies to quaternary and higher adducts.

An ionic adduct is one that is made of ions only—cations and anions. For binary adducts, these are called *salts.* Various acids and bases can pair up to form different salts. The same acid/base pair can form salts of different stoichiometries. For ternary adducts, these are called *mixed salts,* where one additional acid or base is involved in salt formation.

A molecular adduct is one that is made of neutral molecules. Depending on the physical states of the additional components, it can be a solvate or a cocrystal. When this additional component is a liquid in ambient conditions in its pure form, the molecular adduct is called a *solvate.* If the solvent is water, it is called a *hydrate.* However, when the additional component is a solid in ambient conditions, the molecular adduct is called a *cocrystal.* The boundary separating these two types of solids is somewhat arbitrary. Therefore, many published articles include solvates as cocrystals. However, there are distinct differences between the two types of solid adducts. In some situations, it may be helpful to distinguish them.

An ionic/molecular adduct is one that is made of both ionic and neutral molecules. This type of solid only exists for adducts with three or more

components. One important thing to clarify here is that an acid or a base is not considered the same component as its ion. Thus, a ternary ionic/molecular adduct is composed of one salt molecule (two components) and one neutral molecule. Again, based on the physical state of the neutral component, it could be a salt solvate or a salt cocrystal. Unlike the previous categorization of solids,[13] this categorization system does not consider the structural details within the solids; therefore, it is widely applicable and easier to use.

Cocrystals, although they have physically existed for some time and were formerly termed *molecular complexes*, are a relatively new concept. The definition of the term has been a topic of discussion in recent years.[14–19] Based on these discussions, and the authors' personal viewpoints, the term *cocrystal* is here defined as "structurally homogeneous crystalline molecular adducts, made from components that are apparently neutral, that are by themselves solids at ambient conditions. The components are held together by interactions other than covalent or ionic bonds (hydrogen bonding, $\pi-\pi$, van der Waals, charge-transfer, halogen–halogen, etc.)."

Most adducts are stoichiometric in nature; that is, there is a defined ratio between the components. However, some are nonstoichiometric,[20–25] such as cromolyn sodium and cefazolin sodium hydrates.[22,23]

In view of the importance of salts to pharmaceutical development, they will be discussed separately in chapter "API Solid-Form Screening and Selection." This chapter will include discussions on the other crystalline solids (ie, polymorphs, solvates/hydrates, cocrystals, and amorphous solids).

2.3 THERMODYNAMICS AND PHASE DIAGRAMS

Thermodynamics is one of the most important aspects of understanding pharmaceutical solids. Phase diagrams are usually constructed to express the thermodynamic relationships among various solid phases, qualitatively or quantitatively. Depending on the types of solids, phase diagrams are constructed with respect to variables of different physical significance.

2.3.1 Polymorphs

2.3.1.1 Enantiotropy and monotropy

When examining a pair of polymorphs, Polymorph I and Polymorph II, the stability relationship between the two polymorphs is determined *exclusively* by their free energy differences at different temperatures. The free energy of a particular solid is expressed in Eq. (2.1):

$$G = H - TS \tag{2.1}$$

where:

G is the Gibbs free energy,
H is the enthalpy,
T is the temperature,
S is the entropy.

Thus, the free energy for the transition from Polymorph I to Polymorph II is expressed as

$$\begin{aligned}\Delta G_{\mathrm{I}\to\mathrm{II}} &= G_{\mathrm{II}} - G_{\mathrm{I}} = (H_{\mathrm{II}} - TS_{\mathrm{II}}) - (H_{\mathrm{I}} - TS_{\mathrm{I}}) \\ &= \Delta H_{\mathrm{I}\to\mathrm{II}} - T\Delta S_{\mathrm{I}\to\mathrm{II}}\end{aligned} \tag{2.2}$$

$$\Delta H_{\mathrm{I}\to\mathrm{II}} = H_{\mathrm{II}} - H_{\mathrm{I}} \quad \text{and} \quad \Delta S_{\mathrm{I}\to\mathrm{II}} = S_{\mathrm{II}} - S_{\mathrm{I}}$$

At any particular temperature, three different situations exist:

1. $\Delta G_{\mathrm{I}\to\mathrm{II}} < 0$: Polymorph II has lower free energy and is therefore more stable than Polymorph I. The transition from Polymorph I to Polymorph II is a spontaneous process.
2. $\Delta G_{\mathrm{I}\to\mathrm{II}} > 0$: Polymorph II has higher free energy and is therefore less stable than Polymorph I. The transition from Polymorph I to Polymorph II is not a spontaneous process, but the transition from Polymorph II to Polymorph I is.
3. $\Delta G_{\mathrm{I}\to\mathrm{II}} = 0$: Polymorph I and Polymorph II have the same free energy. Therefore, both polymorphs have equal stability. There will be no transition between the two polymorphs.

As shown in Eq. (2.2), the free energy difference between the two polymorphs changes with temperature. The temperature at which the two polymorphs have equal stability is defined as the transition temperature (T_t).

If T_t is located below the melting points of both polymorphs, the two polymorphs are said to be *enantiotropes*, and the polymorphic system is said to exhibit enantiotropy or to be enantiotropic in nature. A representative phase diagram for an enantiotropic polymorphic system is shown in Fig. 2.2a. Below T_t, Polymorph I is more stable. Above T_t, Polymorph II is more stable. In this type of system, the melting point of Polymorph I is lower than that of Polymorph II, although the melting point of Polymorph I may not be experimentally accessible because of facile solid-solid transitions at lower temperatures.

If T_t is located above the melting points of both polymorphs, the two polymorphs are said to be *monotropes*, and the polymorphic system is said to exhibit monotropy or to be monotropic in nature. A representative

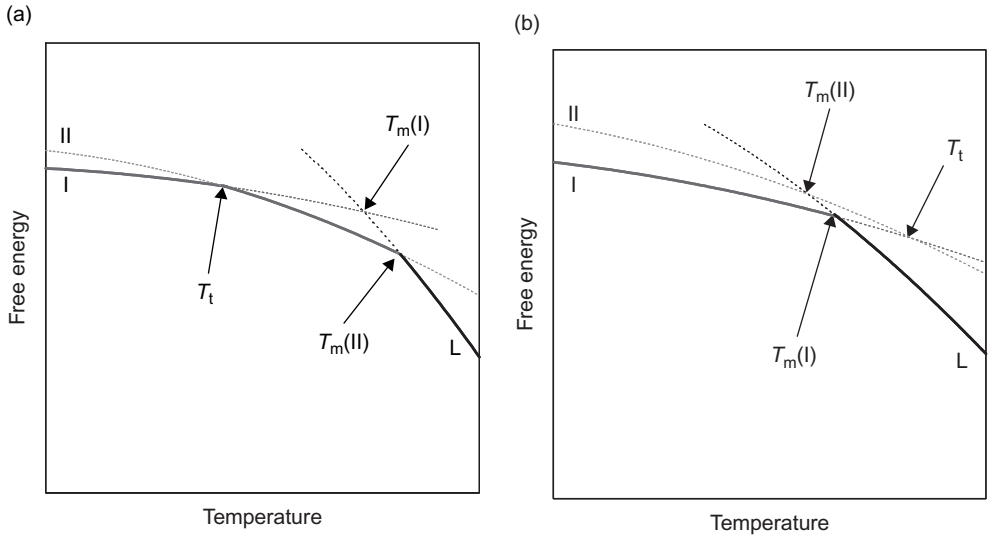

FIGURE 2.2 Thermodynamic phase diagrams of polymorphs. (a) Enantiotropy and (b) Monotropy.

phase diagram for a monotropic polymorphic system is shown in Fig. 2.2b. Throughout the temperature range, Polymorph I is more stable. Here, T_t is a hypothetical temperature, which is experimentally not accessible. In this type of system, the melting point of Polymorph I is higher than that of Polymorph II, although that of Polymorph II may not be experimentally accessible because of facile solid-solid transitions at lower temperatures.

In constructing phase diagrams, the convention is to plot data for the stable phase using a solid line and to use dotted lines to represent metastable phases, as shown in Fig. 2.2.

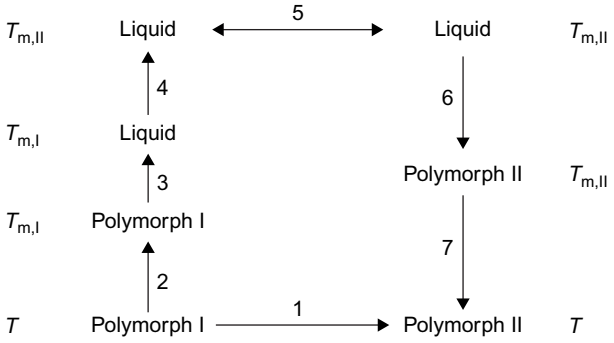

FIGURE 2.3 Hess cycle for polymorphic transition.

2.3.1.2 *Methods of determining stability relationships between polymorphs*

Many methods are available for determining stability relationships between polymorphs. Qualitative methods only determine the relationship with no precise knowledge of T_t. Quantitative methods, on the other hand, determine T_t first. The T_t is then compared to the melting points of each polymorphic form, and the stability relationship is thus defined. The relevant temperatures in which the stability relationship is of interest usually ranges from ambient temperatures to the melting point. However, in certain cases, the pertinent lower end of this range can extend below ambient temperatures—for instance, down to −50°C, which is relevant to freeze-drying processes.

2.3.1.2.1 Quantitative methods

2.3.1.2.1.1 Using heat of fusion data[26] When heats of fusion can be experimentally determined, the stability relationship of the two polymorphs can be determined by calculating T_t and comparing the result to the melting points. If T_t is less than the lower melting point of the two polymorphs, the system is enantiotropic. If the calculated T_t is more than the higher melting point of the two polymorphs, the system is monotropic.

Calculation of T_t begins with the design of a Hess cycle for the polymorphic transition, as shown in Fig. 2.3, assuming that Polymorph II has a higher melting point. Process 1 represents the polymorphic

transition I→II at the temperature of interest. Alternatively, the same transition can be achieved by the series of Processes 2−7. The thermodynamic quantities, ΔH and ΔS, for each process are listed in Table 2.1.

Since Process 1 is equivalent to the sum of Processes 2−7, the enthalpy and entropy of Process 1 are the sums of the enthalpies and entropies of Processes 2−7 (Eq. 2.3):

$$\begin{aligned}
\Delta H_{\mathrm{I}\to\mathrm{II}} &= \int_{T}^{T_{\mathrm{m,I}}} C_{\mathrm{p,I}}dT + \Delta H_{\mathrm{m,I}} + \int_{T_{\mathrm{m,I}}}^{T_{\mathrm{m,II}}} C_{\mathrm{p,L}}dT + 0 \\
&\quad - \Delta H_{\mathrm{m,II}} - \int_{T}^{T_{\mathrm{m,II}}} C_{\mathrm{p,II}}dT \\
&= (\Delta H_{\mathrm{m,I}} - \Delta H_{\mathrm{m,II}}) - \int_{T}^{T_{\mathrm{m,I}}} \Delta C_{\mathrm{p}}dT \\
&\quad - \int_{T_{\mathrm{m,I}}}^{T_{\mathrm{m,II}}} (C_{\mathrm{p,II}} - C_{\mathrm{p,L}})dT \\
&\approx (\Delta H_{\mathrm{m,I}} - \Delta H_{\mathrm{m,II}}) - \int_{T}^{T_{\mathrm{m,I}}} \Delta C_{\mathrm{p}}dT \\
&\approx \Delta H_{\mathrm{m,I}} - \Delta H_{\mathrm{m,II}} \\
\Delta S_{\mathrm{I}\to\mathrm{II}} &= \int_{T}^{T_{\mathrm{m,I}}} \frac{C_{\mathrm{p,I}}}{T}dT + \Delta S_{\mathrm{m,I}} + \int_{T_{\mathrm{m,I}}}^{T_{\mathrm{m,II}}} \frac{C_{\mathrm{p,L}}}{T}dT + 0 \\
&\quad - \Delta S_{\mathrm{m,II}} - \int_{T}^{T_{\mathrm{m,II}}} \frac{C_{\mathrm{p,II}}}{T}dT \\
&= \left(\frac{\Delta H_{\mathrm{m,I}}}{T_{\mathrm{m,I}}} - \frac{\Delta H_{\mathrm{m,II}}}{T_{\mathrm{m,II}}}\right) - \int_{T}^{T_{\mathrm{m,I}}} \frac{\Delta C_{\mathrm{p}}}{T}dT \\
&\quad - \int_{T_{\mathrm{m,I}}}^{T_{\mathrm{m,II}}} \left(\frac{C_{\mathrm{p,II}}}{T} - \frac{C_{\mathrm{p,L}}}{T}\right)dT \\
&\approx \left(\frac{\Delta H_{\mathrm{m,I}}}{T_{\mathrm{m,I}}} - \frac{\Delta H_{\mathrm{m,II}}}{T_{\mathrm{m,II}}}\right) - \int_{T}^{T_{\mathrm{m,I}}} \frac{\Delta C_{\mathrm{p}}}{T}dT \\
&\approx \frac{\Delta H_{\mathrm{m,I}}}{T_{\mathrm{m,I}}} - \frac{\Delta H_{\mathrm{m,II}}}{T_{\mathrm{m,II}}}
\end{aligned} \tag{2.3}$$

The free energy of Process 1 can then be calculated from its enthalpy and entropy (Eq. 2.4):

$$\begin{aligned}
\Delta G_{\mathrm{I}\to\mathrm{II}} &= \Delta H_{\mathrm{I}\to\mathrm{II}} - T\Delta S_{\mathrm{I}\to\mathrm{II}} \\
&= (\Delta H_{\mathrm{m,I}} - \Delta H_{\mathrm{m,II}}) - \int_{T}^{T_{\mathrm{m,I}}} \Delta C_{\mathrm{p}}dT \\
&\quad - \int_{T_{\mathrm{m,I}}}^{T_{\mathrm{m,II}}} (C_{\mathrm{p,II}} - C_{\mathrm{p,L}})dT \\
&\quad - T\left(\frac{\Delta H_{\mathrm{m,I}}}{T_{\mathrm{m,I}}} - \frac{\Delta H_{\mathrm{m,II}}}{T_{\mathrm{m,II}}}\right) + T\int_{T}^{T_{\mathrm{m,I}}} \frac{\Delta C_{\mathrm{p}}}{T}dT \\
&\quad + T\int_{T_{\mathrm{m,I}}}^{T_{\mathrm{m,II}}} \left(\frac{C_{\mathrm{p,II}}}{T} - \frac{C_{\mathrm{p,L}}}{T}\right)dT \\
&= \left[\Delta H_{\mathrm{m,I}}\left(1 - \frac{T}{T_{\mathrm{m,I}}}\right) - \Delta H_{\mathrm{m,II}}\left(1 - \frac{T}{T_{\mathrm{m,I}}}\right)\right] \\
&\quad - \left(\int_{T}^{T_{\mathrm{m,I}}} \Delta C_{\mathrm{p}}dT - T\int_{T}^{T_{\mathrm{m,I}}} \frac{\Delta C_{\mathrm{p}}}{T}dT\right) \\
&\quad - \left[\int_{T_{\mathrm{m,I}}}^{T_{\mathrm{m,II}}} (C_{\mathrm{p,II}} - C_{\mathrm{p,L}})dT - T\int_{T_{\mathrm{m,I}}}^{T_{\mathrm{m,II}}} \left(\frac{C_{\mathrm{p,II}}}{T} - \frac{C_{\mathrm{p,L}}}{T}\right)dT\right] \\
&\approx \left[\Delta H_{\mathrm{m,I}}\left(1 - \frac{T}{T_{\mathrm{m,I}}}\right) - \Delta H_{\mathrm{m,II}}\left(1 - \frac{T}{T_{\mathrm{m,II}}}\right)\right] \\
&\quad - \left(\int_{T}^{T_{\mathrm{m,I}}} \Delta C_{\mathrm{p}}dT - T\int_{T}^{T_{\mathrm{m,I}}} \frac{\Delta C_{\mathrm{p}}}{T}dT\right) \\
&\approx \Delta H_{\mathrm{m,I}}\left(1 - \frac{T}{T_{\mathrm{m,I}}}\right) - \Delta H_{\mathrm{m,II}}\left(1 - \frac{T}{T_{\mathrm{m,II}}}\right)
\end{aligned} \tag{2.4}$$

In Eqs. (2.2)−(2.4), the first approximation results from ignoring the heat capacity difference between Polymorph II and liquid, while the second approximation results from ignoring the heat capacity difference between Polymorph I and II.

Set $\Delta G_{\mathrm{I}\to\mathrm{II}}$ to zero, and the solution is the transition temperature. The caution to be exercised in this approach is that the solids of both polymorphs need to be highly crystalline; consequently, the melting points and heats of fusion can be accurately determined.

TABLE 2.1 Thermodynamic Quantities of Individual Processes in the Hess Cycle of a Polymorphic Transition

Process	Nature of the process	ΔH	ΔS
1	Polymorph transition from I to II	$\Delta H_{\mathrm{I}\rightarrow\mathrm{II}}$	$\Delta S_{\mathrm{I}\rightarrow\mathrm{II}}$
2	Raise temperature of Polymorph I from T to its melting point	$\int_{T}^{T_{\mathrm{m,I}}} C_{\mathrm{p,I}}\,dT$	$\int_{T}^{T_{\mathrm{m,I}}} \frac{C_{\mathrm{p,I}}}{T}\,dT$
3	Melt Polymorph I to liquid at its melting point	$\Delta H_{\mathrm{m,I}}$	$\Delta S_{\mathrm{m,I}} = \frac{\Delta H_{\mathrm{m,I}}}{T_{\mathrm{m,I}}}$
4	Raise the temperature of the liquid from melting point of Polymorph I to that of Polymorph II	$\int_{T_{\mathrm{m,I}}}^{T_{\mathrm{m,II}}} C_{\mathrm{p,L}}\,dT$	$\int_{T_{\mathrm{m,I}}}^{T_{\mathrm{m,II}}} \frac{C_{\mathrm{p,L}}}{T}\,dT$
5	Maintain the liquid at the melting point of Polymorph II	0	0
6	Crystallize Polymorph II from liquid at its melting point	$-\Delta H_{\mathrm{m,II}}$	$-\Delta S_{\mathrm{m,II}} = -\frac{\Delta H_{\mathrm{m,II}}}{T_{\mathrm{m,II}}}$
7	Lower temperature of Polymorph II to T from its melting point	$-\int_{T}^{T_{\mathrm{m,II}}} C_{\mathrm{p,II}}\,dT$	$-\int_{T}^{T_{\mathrm{m,II}}} \frac{C_{\mathrm{p,II}}}{T}\,dT$

2.3.1.2.1.2 Using eutectic fusion data Calculation of T_t using heat of fusion data requires experimentally accessible data. Very often, compounds chemically decompose upon melting or physically transform before melting. In these cases, reliable heat of fusion data is not available. However, eutectic melting can be employed and eutectic melting data can be used to calculate the free energy difference between the polymorphs.[27] This method has been successfully applied to complicated polymorphic systems such as ROY,[28,29] chiral drugs such as tazofelone,[27,30] amino acids such as glycine,[27] and sugars such as D-mannitol.[27] Due to limitations of space and the complexity of derivation, interested readers are encouraged to study the original articles referenced here for derivations and applications.

2.3.1.2.1.3 Using solubility/intrinsic dissolution rate data The solubility of a solid is directly related to its free energy. If we define the standard state in solution as having an activity of 1, which corresponds to the free energy of zero, then the free energy of transfer from the standard state to Polymorph I is

$$\begin{aligned} G_{\mathrm{I}} - G_{\mathrm{s}} = G_{\mathrm{I}} &= RT\ln a_{\mathrm{I}} - RT\ln 1 = RT\ln a_{\mathrm{I}} \\ &= (H_{\mathrm{I}} - H_{\mathrm{s}}) - T(S_{\mathrm{I}} - S_{\mathrm{s}}) \end{aligned} \tag{2.5}$$

The free energy of transfer from the standard state to Polymorph II is

$$\begin{aligned} G_{\mathrm{II}} - G_{\mathrm{s}} = G_{\mathrm{II}} &= RT\ln a_{\mathrm{II}} - RT\ln 1 = RT\ln a_{\mathrm{II}} \\ &= (H_{\mathrm{II}} - H_{\mathrm{s}}) - T(S_{\mathrm{II}} - S_{\mathrm{s}}) \end{aligned} \tag{2.6}$$

Therefore, the free energy of transfer from Polymorph I to II is

$$\begin{aligned} \Delta G_{\mathrm{I}\rightarrow\mathrm{II}} &= G_{\mathrm{II}} - G_{\mathrm{I}} = (H_{\mathrm{II}} - H_{\mathrm{I}}) - T(S_{\mathrm{II}} - S_{\mathrm{I}}) \\ &= \Delta H_{\mathrm{I}\rightarrow\mathrm{II}} - T\Delta S_{\mathrm{I}\rightarrow\mathrm{II}} \\ &= RT\ln\left(\frac{a_{\mathrm{II}}}{a_{\mathrm{I}}}\right) = RT\ln\left(\frac{f_{\mathrm{II}}}{f_{\mathrm{I}}}\right) \\ &= RT\ln\left(\frac{p_{\mathrm{II}}}{p_{\mathrm{I}}}\right) \approx RT\ln\left(\frac{m_{\mathrm{II}}}{m_{\mathrm{I}}}\right) \end{aligned} \tag{2.7}$$

where:

a is activity,
f is fugacity,
p is vapor pressure,
m is molal concentration.

The approximation is valid if Henry's law is obeyed. Application of the van't Hoff isochore gives

$$\begin{aligned} \frac{d\ln a_{\mathrm{I}}}{d(1/T)} &= \frac{-(H_{\mathrm{I}} - H_{\mathrm{s}})}{R} \approx \frac{d\ln m_{\mathrm{I}}}{d(1/T)} \quad \text{and} \\ \frac{d\ln a_{\mathrm{II}}}{d(1/T)} &= \frac{-(H_{\mathrm{II}} - H_{\mathrm{s}})}{R} \approx \frac{d\ln m_{\mathrm{II}}}{d(1/T)} \end{aligned} \tag{2.8}$$

From which it follows that

$$\begin{aligned} \frac{d\ln\left(\frac{a_{\mathrm{II}}}{a_{\mathrm{I}}}\right)}{d(1/T)} &= \frac{-(H_{\mathrm{II}} - H_{\mathrm{I}})}{R} = \frac{-\Delta H_{\mathrm{I}\rightarrow\mathrm{II}}}{R} \\ &= \frac{d\ln\left(\frac{f_{\mathrm{II}}}{f_{\mathrm{I}}}\right)}{d(1/T)} = \frac{d\ln\left(\frac{p_{\mathrm{II}}}{p_{\mathrm{I}}}\right)}{d(1/T)} \approx \frac{d\ln\left(\frac{m_{\mathrm{II}}}{m_{\mathrm{I}}}\right)}{d(1/T)} \end{aligned} \tag{2.9}$$

When plotting the logarithms of the solubility values against reciprocal absolute temperature, a straight line should result if the solutions behave ideally. The temperature at which the two straight lines for the two polymorphs intersect corresponds to T_t. Alternatively, one could plot the logarithm of the solubility ratios against reciprocal absolute temperature. Again, a straight line should result. Extrapolation of this line to zero indicates the solubility ratio of the two polymorphs is 1, and the temperature corresponds to T_t.

When plotting solubility values against reciprocal temperature, weight-based concentration units (ie, molal

concentrations) are preferred over volume-based (molar) concentration units. This practice will eliminate errors due to thermal expansion of the solutions. However, there is minimum of concern if the solubility ratios are being plotted because the changes in volume cancel each other out.

If dissolution from the solid is solely diffusion controlled, there exists proportionality between the solubility and intrinsic dissolution rate (IDR) by the Noyes–Whitney equation.[31] One could measure the IDR at various temperatures for both polymorphs, analyze the data in the same way as that for solubility, and obtain T_t. This method is particularly helpful when phase transitions occur readily, yet not instantaneously. However, one should exercise caution when comparing dissolution rates of ionic or ionizable compounds in protic solvents because many such dissolution rates have significant contributions from reactive dissolution.

2.3.1.2.1.4 Using solubility/intrinsic dissolution rate and heat of solution data The temperature dependence of solubility is related to the heat of solution, and again for ideal solutions, as shown in Eq. (2.8). If the solubility and the heat of solution are measured at one temperature, the entire solubility-temperature curve can be constructed. Comparing the curves for both polymorphs yields T_t.

Alternatively, one can measure the solubility-IDR ratio at one temperature, which yields the free energy difference at that temperature. The enthalpy difference between the two polymorphs is the difference in the heats of solution (which could also be measured by other means). A simple calculation will yield the T_t.

2.3.1.2.2 Qualitative methods

2.3.1.2.2.1 Using the definition The stability relationship between the two polymorphs at one particular temperature can be determined by one of the following techniques:

1. The higher melting polymorph is more stable at higher temperatures.
2. When spontaneous transition is observed, the resulting polymorph is the more stable phase at the temperature where the transition is observed. The transition could be solid-solid transition isothermally or during heating, or solution-mediated in a nonsolvate-forming solvent.
3. The polymorph with lower solubility in a nonsolvate-forming solvent is more stable.

If the relationships that are determined at two different temperatures are the same, the polymorphic system is monotropic within this temperature range. On the other hand, if the determined relationships are different, then the system is enantiotropic within this temperature range. When an enantiotropic relationship is affirmed, the transition temperature is usually bracketed to a narrower range by determining the stability order at a series of temperatures.

2.3.1.2.2.2 Using the heat of fusion rule To help decide the relationship between two polymorphs, Burger and Ramberger[32,33] developed four thermodynamic rules. One of the two most useful, and reliable, rules is the heat of fusion rule:

> If the higher melting form has the lower heat of fusion, the two forms are usually enantiotropic, otherwise they are monotropic.

Fig. 2.4 illustrates the heat of fusion rule from a thermodynamic point of view. Several precautions should be taken in applying this rule:

1. Be aware of the normal experimental errors in melting points and heats of fusion, especially when they are close for the two polymorphs.
2. Use materials of high crystallinity and high purity. Solids of lower crystallinity usually have lower melting points and heats of fusion than those having high crystallinity. Melting-point depression by impurities is a well-known phenomenon.

2.3.1.2.2.3 Using the heat of transition rule Another useful and reliable rule, developed by Burger and Ramberger,[32,33] is the heat of transition rule for solid-state transitions, which states:

> If an endothermic transition is observed at some temperature, it may be assumed that there is a transition point below it; i.e., the two forms are related enantiotropically. If an exothermic transition is observed at some temperature, it may be assumed that there is no transition point below it; i.e., the two forms are either related monotropically or the transition temperature is higher.

Again, Fig. 2.4 illustrates the thermodynamic point of view. Several precautions should be taken in applying this rule:

1. Be aware that a crystallization exotherm from amorphous phase could be confused with a polymorphic transition. Therefore, materials of high crystallinity should be used in the study. It is a good practice to examine the solid phase after heating beyond the transition to ensure that the exotherm corresponds to a polymorphic transition.
2. One can use the overall heat of transition when the polymorphic transition goes through melting and recrystallization. However, the heat of fusion of the recrystallized polymorph should be comparable to

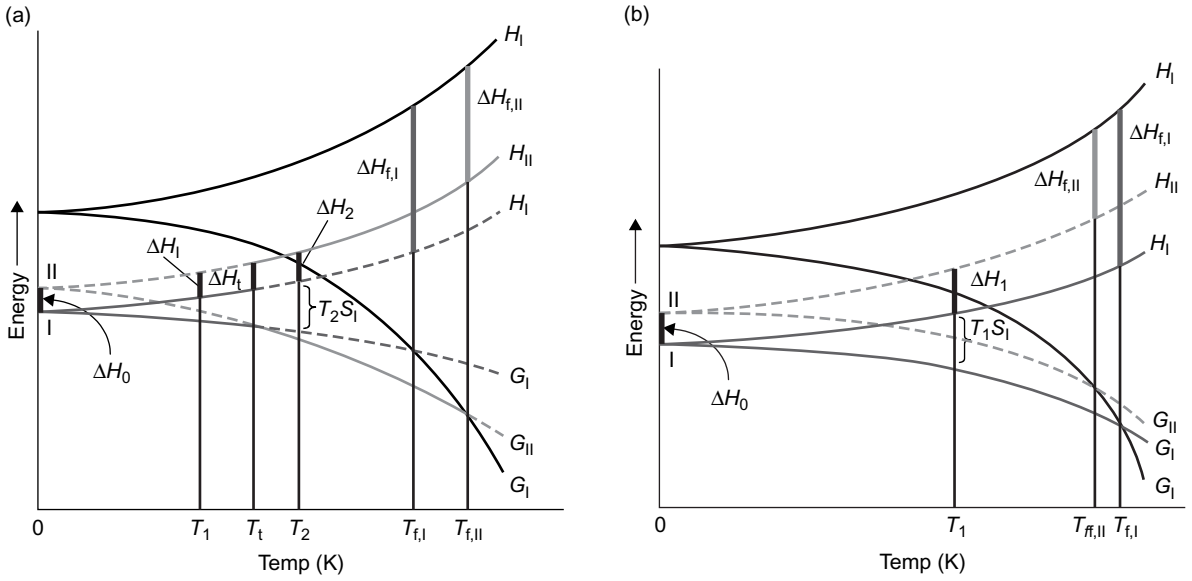

FIGURE 2.4 Schematic illustration of Burger and Ramberger thermodynamic rules. (a) Enantiotropy and (b) Monotropy. *Replotted according to Burger A, Ramberger R. On the polymorphism of pharmaceuticals and other molecular crystals. II. Applicability of thermodynamic rules. Mikrochimi Acta [Wien] 1979;**II**:273–316.*

the reference material to ensure complete crystallization and thus the accuracy of the overall heat of transition.

2.3.2 Solvates/Hydrates

Of the many solvents that are incorporated into the crystal lattice, water is by far the most important for pharmaceutical development. Therefore, all discussions and derivations in this section will use hydrates as examples. However, the principles described are the same and the equations derived can be easily converted and applied to solvates.

2.3.2.1 Anhydrate/Hydrate equilibrium at constant temperature

The equilibrium between the anhydrate and hydrate of a drug (D) at a constant temperature and total pressure can be achieved by equilibrating through the vapor phase. The equilibrium is represented by Eq. (2.10):

$$\mathrm{D}\cdot n\mathrm{H_2O_{(solid)}} \xleftrightarrow{K_d} \mathrm{D_{(solid)}} + n\mathrm{H_2O_{(vapor)}} \quad (2.10)$$

where:

$\mathrm{D_{(solid)}}$ is the anhydrate solid,
$\mathrm{D}\cdot n\mathrm{H_2O_{(solid)}}$ is the hydrate solid,
n is the stoichiometry of the hydrate,
K_d is the hydration/dehydration equilibrium constant between the two solids.

The equilibrium constant can be described by Eq. (2.11) and then simplified based on the assumption that water vapor acts as an ideal gas, and the activities of the solids are taken to be unity:

$$K_d^{\text{vapor}} = \frac{\left[a_{\mathrm{D_{(solid)}}}\right]\left[a^c_{\mathrm{H_2O_{(vapor)}}}\right]^n}{\left[a_{\mathrm{D}\cdot n\mathrm{H_2O_{(solid)}}}\right]} = \left[a^c_{\mathrm{H_2O_{(vapor)}}}\right]^n = [RH^c]^n = \left[\frac{p^c}{p^s}\right]^n \quad (2.11)$$

In this equation, a is the activity, superscript c represents critical values, RH represents relative humidity, p^c represents the critical water vapor pressure, and p^s represents the saturated water vapor pressure at this temperature.

Three situations exist:

1. $p > p^c$; $RH > RH^c$; $a_{\mathrm{H_2O_{(vapor)}}} > a^c_{\mathrm{H_2O_{(vapor)}}}$: The hydrate is more stable than the anhydrate; therefore, the anhydrate will spontaneously convert to the hydrate thermodynamically.
2. $p < p^c$; $RH < RH^c$; $a_{\mathrm{H_2O_{(vapor)}}} < a^c_{\mathrm{H_2O_{(vapor)}}}$: The anhydrate is more stable than the hydrate; therefore, the hydrate will spontaneously convert to the anhydrate thermodynamically.
3. $p = p^c$; $RH = RH^c$; $a_{\mathrm{H_2O_{(vapor)}}} = a^c_{\mathrm{H_2O_{(vapor)}}}$: The hydrate and the anhydrate have equal stability, and they will coexist thermodynamically. There will be no transformation in either direction.

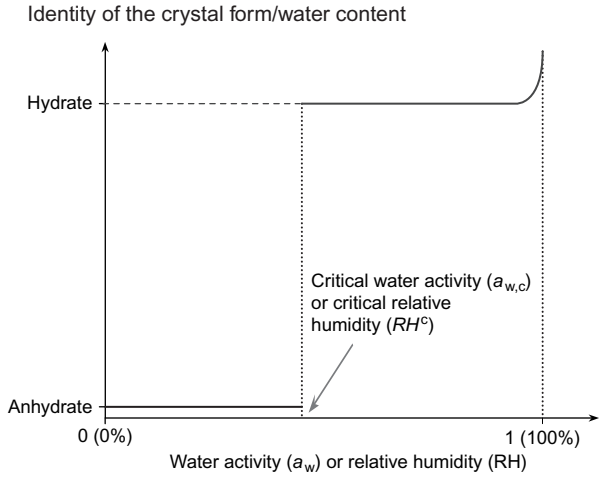

FIGURE 2.5 Thermodynamic phase diagram of an anhydrate/hydrate pair.

A typical phase diagram for anhydrate/hydrate is shown in Fig. 2.5. The curved portion, at high RH, represents deliquescence and further dilution of the solution. Anhydrate/hydrate equilibration through the vapor phase is a slow process, and it can take weeks to months to achieve equilibrium. Therefore, studies are usually conducted to take advantage of the higher mobility in the solution state to attain equilibrium within a short period of time.[34,35] In these studies, water-miscible organic solvents were employed to systematically modify the water activities in these solutions. Solids of anhydrate or hydrate, or mixtures of the two, were suspended in a series of these solutions and equilibrated at a defined temperature with agitation. The solids were recovered after certain periods of time, which were much shorter than the time required for equilibration through the vapor phase, and examined by appropriate analytical techniques. The stability order at each individual water activity value was determined by the nature of the solid recovered. The critical water activity was then bracketed to a narrow range. Once developed, this method has been applied successfully to many other anhydrate/hydrate systems.[36–41]

When an organic/water solution is in equilibrium with its vapor phase, the water activities in the solution and the vapor phases are the same. Therefore, it is common to further equate the water activity in solution to the RH in the vapor phase. For example, 0.35 water activity is equivalent to 35% RH. The critical water activity values obtained from solution equilibration for anhydrate/hydrate systems are also equated to the critical RH values obtained from the vapor phase equilibration (RH^c). The reason why this can be done is demonstrated next.

In the case of solution phase equilibration, water molecules released via dehydration are not present as water vapor; instead, they simply become part of the solution. Therefore, the equilibrium of interest and the corresponding equilibrium constant are shown in Eqs. (2.12) and (2.13), respectively:

$$\mathrm{D}\cdot n\mathrm{H_2O_{(solid)}} \xleftrightarrow{K_d} \mathrm{D_{(solid)}} + n\mathrm{H_2O_{(solution)}} \tag{2.12}$$

$$K_d^{\text{solution}} = \frac{\left[a_{\mathrm{D_{(solid)}}}\right]\left[a^c_{\mathrm{H_2O_{(solution)}}}\right]^n}{\left[a_{\mathrm{D}\cdot n\mathrm{H_2O_{(solid)}}}\right]} = \left[a^c_{\mathrm{H_2O_{(solution)}}}\right]^n \tag{2.13}$$

This equilibrium can be converted to the Eq. (2.10) type of equilibrium (ie, water as vapor) through a further equilibrium of solution-vapor under constant water activity (Eq. 2.14). However, the process of vaporization under constant water activity is at equilibrium, having ΔG of zero and K_{vap} of unity:

$$n\mathrm{H_2O_{(solution)}} \xleftrightarrow{K_{vap}} n\mathrm{H_2O_{(vapor)}} \tag{2.14}$$

The addition of Eqs. (2.12) and (2.14) affords Eq. (2.10). Therefore, the equilibrium constant in Eq. (2.10) is the product of those in Eqs. (2.12) and (2.14) (Eq. 2.15):

$$K_d^{\text{vapor}} = K_{vap}\cdot K_d^{\text{solution}} = K_d^{\text{solution}} \tag{2.15}$$

Thus, the equilibrium constant obtained by equilibrating through the vapor phase is equal to that obtained through equilibrating through the solution phase. In the following section, superscripts and subscripts will not be used to differentiate the different routes of determination.

2.3.2.2 *Temperature dependence of anhydrate/hydrate equilibrium*[42]

When temperature varies, the van't Hoff equation (also known as the *van't Hoff isochore*), which describes the temperature dependence of any equilibrium constant, can be applied. This affords the determination of the temperature dependence of the critical water activity or RH ($a^c_{H_2O}$ or RH^c), and the critical water vapor pressure (p^c), thus establishing the complete phase diagram with regard to both RH (or water vapor pressure) and temperature. Applying the van't Hoff equation to the anhydrate/hydrate equilibrium, the following equation is obtained:

$$\frac{d\ln K_d}{dT} = \frac{nd\ln(a^c_{H_2O})}{dT} = \frac{nd\ln(RH^c)}{dT} = \frac{nd\ln\left(\frac{p^c}{p^s}\right)}{dT} = \frac{\Delta H_d}{RT^2} \tag{2.16}$$

where ΔH_d is the dehydration enthalpy and R is the gas constant. Rearranging Eq. (2.16) affords the following equation:

$$d\ln K_d = d\ln(a^c_{H_2O}) = d\ln(RH^c) = d\ln\left(\frac{p^c}{p^s}\right) = -\frac{\Delta H_d}{nR} d\ln\left(\frac{1}{T}\right) \quad (2.17)$$

Assuming a constant dehydration enthalpy within the temperature range studied, the definite integral of this differential equation (Eq. 2.17) between temperatures T_1 and T_2 is given by the following equation:

$$\frac{\Delta H_d}{nR}\left(\frac{1}{T_1}-\frac{1}{T_2}\right) = \ln K_d^2 - \ln K_d^1 = \ln(a^c_{H_2O})_2 - \ln(a^c_{H_2O})_1 = \ln(RH^c)_2 - \ln(RH^c)_1 = \ln\left(\frac{p^c}{p^s}\right)_2 - \ln\left(\frac{p^c}{p^s}\right)_1 \quad (2.18)$$

Since $\Delta G_d = \Delta H_d - T\Delta S_d$ and $\Delta G_d = -RT\ln K_d$, it follows that

$$\ln K_d = \ln(a^c_{H_2O}) = \ln(RH^c) = \ln\left(\frac{p^c}{p^s}\right) = -\frac{\Delta H_d}{nRT} + \frac{\Delta S_d}{nR} \quad (2.19)$$

Here ΔS_d is the dehydration entropy. Therefore, a plot of the natural logarithm of K_d or $a^c_{H_2O}$, or RH^c, or p^c/p^s, versus the reciprocal temperature gives a straight line. The slope of the line is equal to $-\Delta H_d/nR$ and the intercept is equal to $\Delta S_d/nR$. Based on this set of equations, and on the fact that dehydration is endothermic, it is apparent that the critical water activity or critical RH increases upon raising the temperature. Therefore, it is desirable to keep hydrates in a cool, humid environment to avoid dehydration.

Another important parameter of the anhydrate/hydrate system is the critical temperature, T_c, which is defined as the temperature at which the critical water activity is unity or critical RH is 100%. In other words, it is the higher limit of the temperature range where a hydrate is thermodynamically stable at some water activity or RH. At temperatures higher than T_c, hydrate cannot be the stable phase. Applying this to Eq. (2.18) affords this equation:

$$\ln K_d = \ln(a^c_{H_2O}) = \ln(RH^c) = \ln\left(\frac{p^c}{p^s}\right) = \frac{\Delta H_d}{nRT_c} - \frac{\Delta H_d}{nRT} \quad (2.20)$$

Comparing Eqs. (2.19) and (2.20), it is apparent that $T_c = \Delta H_d/\Delta S_d$. Thus, T_c is characteristic of the anhydrate/hydrate system of interest.

In studying the physical stability of hydrates, p^c is frequently used. Therefore, it is useful to extend this analysis beyond $K_d, a^c_{H_2O}, RH^c$, and p^c/p^s. Rearranging Eq. (2.18) affords the following:

$$\ln\frac{(p^c)_2}{(p^c)_1} - \ln\frac{(p^s)_2}{(p^s)_1} = \frac{\Delta H_d}{nR}\left(\frac{1}{T_1}-\frac{1}{T_2}\right) \quad (2.21)$$

The temperature dependence of saturated water vapor pressure can be described by the well-known Clausius–Clapeyron equation:

$$\ln\frac{(p^s)_2}{(p^s)_1} = \frac{\Delta H_{vap}}{R}\left(\frac{1}{T_1}-\frac{1}{T_2}\right) \quad (2.22)$$

Here, ΔH_{vap} is the enthalpy of vaporization of water at the temperature of interest. Coupling Eqs. (2.21) and (2.22) yields

$$\ln\frac{(p^c)_2}{(p^c)_1} = \left(\frac{\Delta H_d}{nR} + \frac{\Delta H_{vap}}{R}\right)\left(\frac{1}{T_1}-\frac{1}{T_2}\right) \quad (2.23)$$

Eq. (2.23) dictates that the plot of $\ln p^c$ against the reciprocal temperature will exhibit a greater slope than that of $\ln K_d (\Delta H_d/nR + \Delta H_{vap}/R$ versus $\Delta H_d/nR)$. This phenomenon was previously observed, but it has not been explained.[43]

2.3.3 Cocrystals

Since cocrystals differ from solvates only by the physical state of the pure components, the stability treatment is expected to be analogous to that used for solvates. Indeed, an extension of the stability treatment was recently applied to cocrystals[44] and is discussed in the following sections. The equilibrium among the drug (D), the cocrystal former (CCF), and the corresponding cocrystal (CC; ie, D·nCCF) are shown in Eq. (2.24). In this case, the CCF is assumed to come into intimate contact with the drug through a solution; however, the treatment is valid if the contact is achieved by other routes:

$$D_{solid} + nCCF_{solution} \xleftrightarrow{K_c} CC_{solid} \quad (2.24)$$

Here, n is the stoichiometry of the cocrystal and K_c is the cocrystal formation equilibrium constant. Analogous to the anhydrate/hydrate or nonsolvate/solvate system, K_c can be expressed by the activities of the species involved in the equilibrium (Eq. 2.25) and simplified based on the assumption that CCF

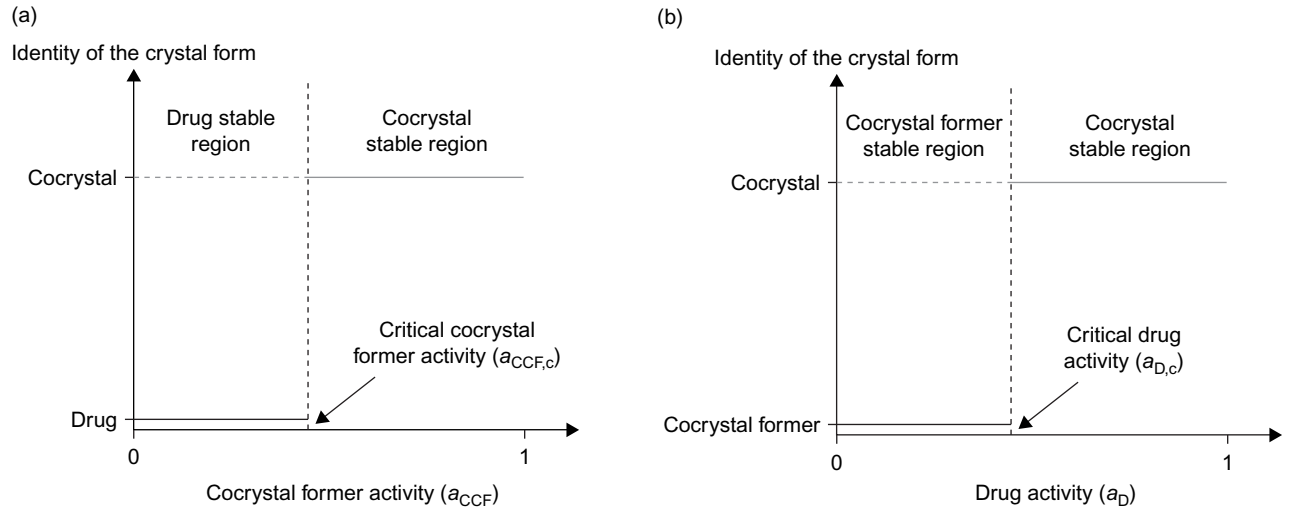

FIGURE 2.6 Thermodynamic phase diagrams of cocrystals. (a) With respect to the activity of the cocrystal former and (b) With respect to the activity of the drug.

molecules behave ideally in the solution, and the activities of the solids are taken to be unity:

$$K_c = \frac{\left[a_{CC_{(solid)}}\right]}{\left[a_{D_{(solid)}}\right]\left[a^c_{CCF_{(solution)}}\right]^n} = \left[a^c_{CCF_{(solution)}}\right]^{-n} \qquad (2.25)$$

Here, $a^c_{CCF_{(solution)}}$ is the critical CCF activity in solution (and can be expressed as $a_{CCF,c}$). As a first approximation, the activity of CCF in the solution equals the ratio of the concentration of the free CCF (uncomplexed with D) in solution, and the solubility of CCF in the absence of D in the same solvent. Again, three situations exist:

1. $\left[a_{CCF_{(solution)}}\right] < \left[a^c_{CCF_{(solution)}}\right]$: D is favored over CC; therefore, CC will spontaneously decompose to D thermodynamically.
2. $\left[a_{CCF_{(solution)}}\right] > \left[a^c_{CCF_{(solution)}}\right]$: CC is favored over D; therefore, CC will spontaneously form from D and CCF thermodynamically.
3. $\left[a_{CCF_{(solution)}}\right] = \left[a^c_{CCF_{(solution)}}\right]$: D and CC have equal stability, and they will coexist in a suspension of the CCF solution.

The same equations can be written if the drug is in solution and CCF and CC are in the solid state. This thermodynamic treatment can be easily extended to cocrystal systems with multiple stoichiometries. The phase diagrams are shown in Fig. 2.6.

2.3.4 Amorphous solids

If a crystalline solid is heated beyond its melting temperature and cooled back to its original temperature, and if sufficient time is not allowed for nucleation to occur, the liquid will become amorphous at temperatures below its melting point. That is, it will lose all long-range order. Initially, the supercooled liquid was able to adjust itself to the changing environment (temperature), giving off excess enthalpy, entropy, and volume, following the equilibrium line extended from the liquid state (Fig. 2.7). The amorphous material in this temperature range is called a *rubber* or a *supercooled liquid*. However, at a certain lower temperature, due to the increased viscosity and decreased molecular mobility, the amorphous material will not be able to continue to follow the equilibrium line extended from the liquid state. Instead, it will deviate from the line, quenching the excess thermal motions that accommodate excess quantities such as free energy, enthalpy, entropy, and volume. The amorphous phase in this temperature range is called a *glass*. This transition of states is called a *glass transition*, and the temperature at which this transition occurs is called the *glass transition temperature* (T_g). The glassy state is a kinetically frozen state and is not thermodynamically stable. Therefore, a glass will relax gradually over time, releasing excess enthalpy, entropy, and volume to the environment to achieve a more stable state. This process is termed *physical aging* or *annealing* (discussed further in Section 2.7.1).

Theoretically, one could continue to extrapolate the liquid line beyond T_g. In doing so, it will eventually intersect the crystalline line and pass beyond it. This presents a conceptual contradiction, called the *Kauzmann paradox*,[45] which dictates that the disordered supercooled liquid has less entropy than the ordered crystal. The temperature at which this occurs is called the *Kauzmann temperature* (T_K). In reality, this entropy

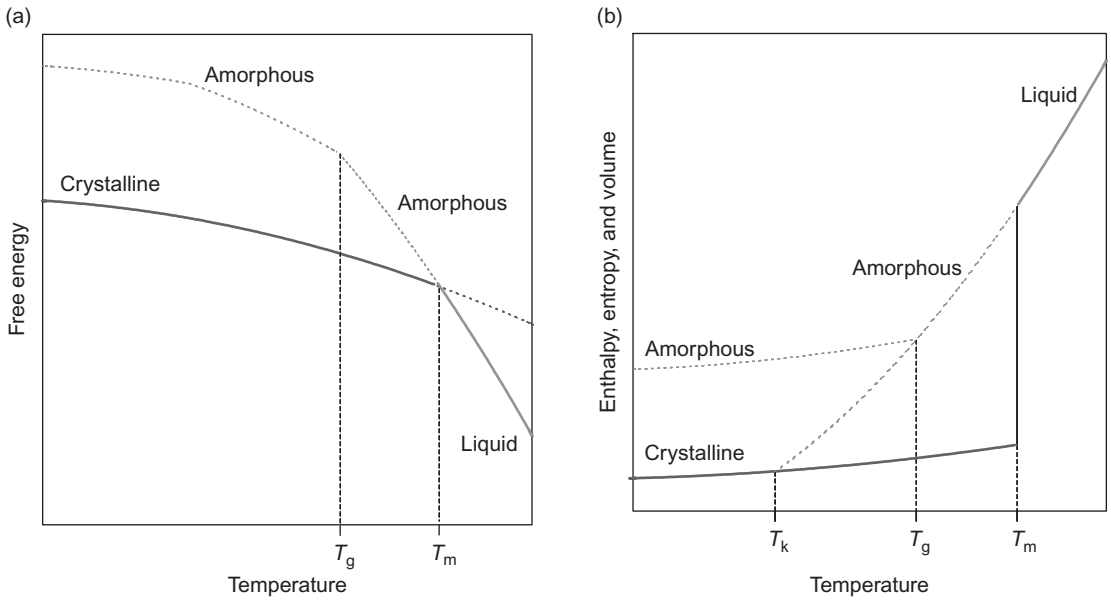

FIGURE 2.7 Phase diagrams of amorphous solids. (a) Free energy and (b) Enthalpy, entropy, and volume.

crisis is avoided through the intervening glass transition. Compared to its crystalline counterpart, the amorphous solid possesses excess thermodynamic quantities, including free energy, enthalpy, entropy, and volume (Fig. 2.7). These excess quantities are termed *configurational* quantities. From the phase diagram (Fig. 2.7), it is clear that, unlike polymorphs, solvates, and cocrystals, amorphous phases are always metastable with respect to the crystalline phases, regardless of the environment (temperature, pressure, etc.). Unlike the first-order phase transitions, such as melting or vaporization, no discontinuity exists at the glass transition for thermodynamic properties, such as volume, enthalpy, and entropy. However, the isobaric expansivity, α, isothermal compressibility, κ, and isobaric heat capacity, C_p, all show a step change around T_g, indicating a second-order phase transition according to the definition by Ehrenfest.[46]

The amorphous phase presents unique characteristics and challenges to pharmaceutical development, and this topic is discussed in detail in Section 2.7.

2.4 PHARMACEUTICAL RELEVANCE AND IMPLICATIONS

As mentioned at the beginning of this chapter, crystalline solids are especially relevant to pharmaceutical development. Regardless of the types of formulations, APIs are mostly crystalline. The majority of APIs are polymorphs of the parents and salts.[47] A significant proportion of APIs are hydrates.[47] Solvates with various organic solvents are not usually used as APIs. However, they are frequently encountered in crystallization and characterization of pharmaceutical solids. Cocrystals, a reemerging class of solids, have yet to be used intentionally in pharmaceutical products. However, they offer the potential to engineer properties of solids that are critical to pharmaceutical development. Although crystalline APIs are usually preferred during pharmaceutical development, varying degrees of amorphous content can be generated inadvertently during pharmaceutical processing, such as milling, wet granulation, drying, and compaction (see chapter: Drug Stability and Degradation Studies). Many pharmaceutical excipients, such as naturally existing polymers (eg, cellulose and starch), synthetic polymers (eg, poly(methyl methacrylate), poly(acrylic acid), and poly(glycolic acid)), and other chemically modified natural or synthetic polymers, are either amorphous or partially amorphous. Small amounts of amorphous content exist in almost every crystalline API. The presence of amorphous content in the API itself or other components of a drug product may have confounding impacts on the physicochemical properties and ultimate performance of the drug product.

Owing to the differences in the internal structure (composition, dimensions, shape, symmetry, capacity (number of molecules), and void volumes of their unit cells for crystalline phases, and the lack of periodicity for the amorphous phases), various solids exhibit a variety of properties. Over the years, these properties have been summarized for polymorphs,[48–51] but they are properly applicable to all solids. These properties are listed in Table 2.2.

TABLE 2.2 Physical Properties That Differ Among Various Solids[51]

1. Packing properties
   - a. Molar volume and density
   - b. Refractive index
   - c. Conductivity, electrical, and thermal
   - d. Hygroscopicity
2. Thermodynamic properties
   - a. Melting and sublimation temperatures
   - b. Internal energy (ie, structural energy)
   - c. Enthalpy (ie, heat content)
   - d. Heat capacity
   - e. Entropy
   - f. Free energy and chemical potential
   - g. Thermodynamic activity
   - h. Vapor pressure
   - i. Solubility
3. Spectroscopic properties
   - a. Electronic transitions (ie, ultraviolet—visible absorption spectra)
   - b. Vibrational transitions (ie, infrared absorption spectra and Raman spectra)
   - c. Rotational transitions (ie, far infrared or microwave absorption spectra)
   - d. Nuclear spin transitions (ie, nuclear resonance spectra)
4. Kinetic properties
   - a. Dissolution rate
   - b. Rates of solid-state reactions
   - c. Stability
5. Surface properties
   - a. Surface free energy
   - b. Interfacial tensions
   - c. Habit (ie, shape)
6. Mechanical properties
   - a. Hardness
   - b. Tensile strength
   - c. Compactibility, tableting
   - d. Handling, flow, and blending

Many properties that differ among crystal forms provide the means to detect them, such as melting points and spectroscopic properties. Some properties are particularly important for pharmaceutical development, having a significant impact on the performance and quality of drug products. They will be discussed in more detail in the following sections.

2.4.1 Solubility

As shown in Section 2.3.1, the solubility values of different polymorphs are directly related to their free energy. Therefore, different polymorphs will have different solubilities in the same solvent, and the difference in solubility will be a function of temperature (Fig. 2.8). At one temperature (except for T_t), the metastable polymorph will be more soluble than the stable polymorph. It is this difference in solubility that is causing the difference in dissolution rates and driving the solution-mediated phase transformation (SMPT) (Section 2.5.3) for polymorphs. A survey of the solubility differences between polymorphic pairs has been conducted ($n = 81$).[52] The general trend reveals that the ratio of polymorph solubility is typically less than 2, although occasionally higher ratios can be observed.[52] Based on thermodynamics, the solubility ratio of the polymorphs is independent of the nature of the solvents, provided that Henry's law is obeyed (Section 2.3.1). In most dilute solutions, this is a valid statement.

Adducts (solvates, hydrates, and cocrystals), on the other hand, exhibit different solubility behaviors. The solubility ratio, even the rank order, changes in solvents with different activity values. As in the case of polymorphs, this is also driven by thermodynamics. In pure organic solvents, where the activity of the solvent is nearly 1, the solvate with the specific solvent will be the most stable phase and have the lowest solubility. Other solid phases, such as polymorphs, hydrates, amorphous phases, and solvates with other organic solvents, will be metastable and have higher solubility values. Hydrates, as a special case of solvates, will have the same characteristics. In the same survey ($n = 24$),[52] a similar trend is observed for anhydrate/hydrate solubility ratios, although anhydrate/hydrate solubility ratios appear to be more spread out and higher than the typical ratio for polymorphs. The solubility of cocrystals is a function of the concentration of the cocrystal former.[53,54] The dependence is very much analogous to the solubility product (K_{sp}) for insoluble salts.

Thermodynamic analysis of amorphous phases indicates that it possesses higher free energy than its crystalline counterpart at all temperatures below the melting point. Therefore, amorphous materials will have a higher solubility than crystalline solids at all temperatures (below the melting point) in any solvent.[55–59] This is of special interest to the delivery of poorly soluble drug molecules and oral bioavailability enhancement.

2.4.2 Dissolution rate and bioavailability

As mentioned earlier, if dissolution from the solid is solely diffusion-controlled, proportionality exists between the solubility and dissolution rate as determined by the Noyes–Whitney equation.[31] Thus, the differences in solubility translate directly to the differences in IDR among various solids. When particle size and distribution are similar, they also translate to the powder dissolution rates. Some of the classic examples include dissolution of the solid

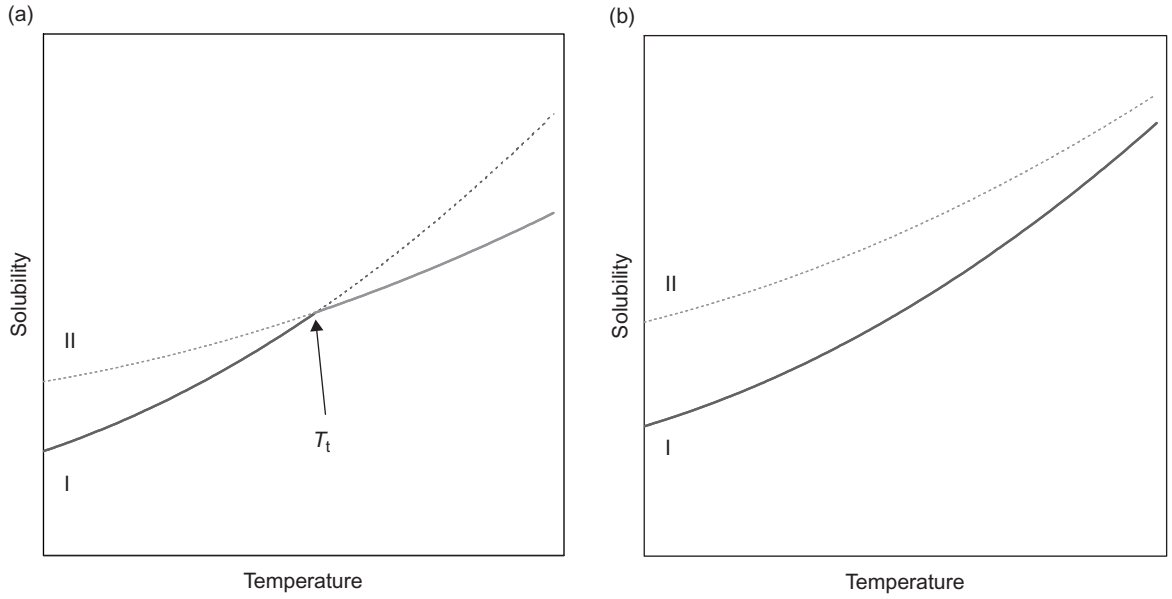

FIGURE 2.8 Solubility values of polymorphs as a function of temperature. (a) Enantiotropy, (b) Monotropy.

forms of succinylsulfathiazole[60] and iopanoic acid.[61] As generally understood, oral absorption is determined by the rate of dissolution of a dosage form in the gastrointestinal (GI) tract and the rate of drug molecule permeation through the GI membrane. Drug absorption can be improved by rendering the drug amorphous for biopharmaceutical classification system (BCS) class II and IV compounds, where low solubility presents a significant barrier for oral absorption. Therefore, utilizing metastable solid forms, such as amorphous phases, and amorphous solid dispersions[62–69] is a powerful tool in combating the poor absorption profiles of many modern drug candidates. Selecting the appropriate solid forms for development is thus critical to the facile development of high quality products.

One important consideration in this approach is that this solubility and dissolution enhancement is a transient effect. The higher concentrations achieved in the in vitro or in vivo dissolution media, beyond the equilibrium solubility, create driving forces for the nucleation and crystallization of the stable phases. Eventually, the stable phases will nucleate, and crystallize. However, a certain amount of time is required before the depletion of concentrations in solution. During this lag time, significant absorption could be accomplished. For some compounds, extremely high permeability leads to the effective transport of the molecules through the GI membrane. In these cases, the concentration buildup in the GI fluid will not occur.

2.4.3 Hygroscopicity

Moisture interacts with solids via four primary modes: adsorption, absorption, deliquescence, and lattice incorporation.[70,71] Water molecules can be adsorbed onto a solid surface by interacting with the molecules on the surface. Since water is a polar molecule capable of forming hydrogen bonding, polar moieties on the solid surface are important factors governing the affinity toward water adsorption. Particle size plays a role in moisture uptake by affecting the available surface area. Under normal conditions, water adsorption leads to monolayer formation, as well as a few additional molecular layers at higher RH values. The solid-water interactions are the strongest between the surface and water molecules in the monolayer, and they become weaker as the distance from the surface increases. Therefore, water molecules in the adsorbed layers beyond the monolayer better resemble bulk water, which may bear some importance to chemical instability.

A more significant mode of water–solid interactions is perhaps the absorption or sorption, which refers to the water molecules' penetration into the bulk solid, incorporation into the defects or amorphous regions, and formation of a solution. Due to the high free energy nature of the amorphous form, its affinity toward water molecules is much greater, resulting in much elevated moisture sorption. It has been shown that moisture adsorption can account for only a very insignificant portion of moisture content typically encountered in

pharmaceutical solids (eg, a few percent), for which the sorption mechanism is primarily responsible.[72] *Deliquescence* refers to the formation of a saturated solution around the solids when exceeding its critical RH. This mode of water–solid interaction is only important for relatively water-soluble compounds at high RH. Hydrates form when water molecules are incorporated into the crystal lattice. In this case, a critical water activity or RH exists that governs the physical stability of the respective hydrate form (Section 2.3.2).

Moisture uptake can be greatly affected by solid forms. Adsorption is a surface property; therefore, the surface of a solid form is a determining factor. In that sense, a more stable polymorph may not necessarily adsorb the least amount of moisture; rather, what matters are the moieties that are exposed on the surface. However, the amorphous content or defects are the primary cause of the moisture uptake normally seen with pharmaceuticals, as discussed previously, due to its high energetic nature and a different mode of interaction. A small amount of amorphous content virtually exists for every crystalline API and is likely exacerbated by API treatments such as milling and by formulation processing such as wet granulation and drying. Therefore, its influence on moisture uptake and distribution, as well as subsequent product attributes, could be enormous.

2.4.4 Reactivity and chemical stability

Solid forms can affect the reactivity and chemical stability of both API and drug in the finished product. The way in which solid forms influence their chemical stability is more apparent by examining the mechanisms of "solid-state" reactions.

2.4.4.1 Topochemical reactions

The reactivity of a solid in a topochemical (or true solid-state) reaction is completely determined by its crystal lattice. This type of reaction is facilitated by the proper positioning and orientation of the reacting moieties in the crystal lattices, so it requires minimum movement of the reacting molecules. Molecular packing in the crystal lattice is the primary factor dictating the rate of a topochemical reaction.

Solid forms are the best manifestation of topochemical reactions based on their very nature. Solid forms can determine the end-reaction product. For example, 2-ethoxycinnamic acid showed polymorph-dependent photodimerization products.[73] The α polymorph formed a cis-dimer, the β polymorph formed a trans-dimer, while dimerization was not observed in solution. Solid forms can also determine whether a reaction can occur. For example, *p*-methylcinnamic acid undergoes photodimerization only with the β polymorph.[74] Its α polymorph is not reactive because the distance separating the neighboring cinnamic acid double bonds is too long to allow a (2 + 2) cyclization. For prednisolone and hydrocortisones, the reactivity toward O_2 was observed only in the hexagonal solvates, where solvent channels were speculated to allow oxygen to access host molecules.[75,76] Increasing molecular mobility by destroying a crystalline order can actually slow down a topochemical reaction. For example, the rearrangement of methyl *p*-dimethylaminobezenesulfonate proceeded 25 times faster in solid state than in the melt.[77,78]

2.4.4.2 Nontopochemical reactions

The degradation of most pharmaceuticals is not topochemical in nature. These reactions require significant movement of the reacting molecules and are not true solid-state reactions. Nevertheless, these reactions are modulated by the physicochemical and particle characteristics of the solids, such as crystallinity, moisture content, solubility, pH of the aqueous surface layer, particle size, and melting temperature, although it may be difficult to deconvolute the respective contributions.

Chemical stability of most pharmaceuticals is modulated by moisture. The earlier model proposed by Leeson and Mattocks[79] sheds some light on drug degradation, where a film of saturated solution was assumed to form around solid particles, although deliquescence is not generally expected below critical RH. The concepts of tightly bound (eg, monolayer) and loosely bound (eg, those beyond monolayer) moisture may also shed some light, despite their oversimplified nature. Probably the most significant is the moisture sorption into amorphous regions or defects, leading to significant increase in moisture uptake, as discussed previously.

Besides the topochemical reactions where crystal lattice dictates reactivity, solid forms can affect chemical stability by modifying the particular characteristics. First, the moieties exposed on crystal surfaces could vary significantly among different solid forms (or morphologies), which could either accelerate or inhibit a particular reaction. For example, the reactivity of flufenamic acid polymorphs with ammonia was related to accessibility of ammonium to host molecules on major faces, but not to the relative energetics of the polymorphs.[80] Second, the solid forms can differ in their aqueous solubility, as mentioned previously, which is certainly important for degradation through the Leeson–Mattocks model. Third, moisture sorption could be drastically more significant for certain solid forms. Amorphous content has a higher affinity to water molecules and forms solutions with the latter.

Since water is a great plasticizer, the water molecules absorbed into the amorphous regions can cause a significant increase in molecular mobility and are potentially harmful to chemical stability.[72,81] Certain higher energetic solid forms that may be used in pharmaceutical development, such as "desolvated solvate," tend to absorb more moisture and cause greater chemical degradation. Complete or partial phase transformations can occur inadvertently during manufacturing, which can profoundly change chemical degradation in drug products.[82]

2.4.5 Mechanical properties

In different solids, the molecules are arranged differently. The nature and extent of interactions among the molecules also varies among different solids. Intuitively, one would anticipate that these solids would respond differently under mechanical stresses. Under compression, plastic flow along slip planes has been well documented as a mechanism for consolidation.[83] In the case of acetaminophen polymorphs, the stable polymorph (Form I, monoclinic) was found to be poorly compressible, requiring a significant amount of excipients to form tablets.[84–86] On the other hand, metastable polymorphs (Form II, orthorhombic) have been reported to have a higher cohesion index[87] and thus improved tableting properties. Careful analysis of crystal structure and face indexing[88] revealed that these crystals cleaved parallel to the {001} plane. This cleavage occurred due to a well-developed slip system, which is attributed to the presence of two-dimensional molecular sheets in Form II solids. These improved tableting properties of Form II were also confirmed by Heckel analysis, compressibility, and compactibility assessments.[89] Similarly, sulfamerazine metastable polymorph I has well-defined slip planes in its crystal lattice, thus exhibiting superior plasticity and therefore greater compressibility and tabletability than the stable Polymorph II.[90] Water produced by the crystallization in *p*-hydroxybenzoic acid monohydrate facilitates plastic deformation of the crystals, thereby enhancing their bonding strength and forming stronger tablets than the anhydrate.[91]

2.5 TRANSFORMATIONS AMONG SOLIDS

As discussed in Section 2.3.1, polymorphic transformation is widely used in understanding polymorphic relationships. This section focuses on the various pathways for transformation between crystalline solid forms. Crystallization from amorphous materials, owing to its importance to pharmaceutical development, will be discussed separately in Section 2.7. In general, thermodynamics dictates the possibility of transformation between the various phases. Therefore, the discussion in Section 2.3 and an understanding of the particular system should be kept in mind.

Most of the transitions described here are second-order transitions; that is, they are kinetic in nature (except for melting). Therefore, the timescale of experiments can drastically change the pathways that a solid will take in transforming into the other forms. Sometimes the resulting solid phase can also be different.

2.5.1 Induced by heat

Molecular motions and mobility in solids generally increase when the temperature of the solid is raised. In addition, the free energy of the various phases changes with respect to temperature, as determined by thermodynamics. Therefore, heating is particularly effective in inducing phase transformations.

2.5.1.1 Polymorphic transitions

As shown in Section 2.3.1 earlier in this chapter, a pair of polymorphs can be related to each other, either monotropically or enantiotropically. When heated, they exhibit different behaviors upon undergoing transformations. Fig. 2.9 illustrates all potential polymorphic transitions that can be observed when a polymorphic solid is heated in differential scanning calorimetry (DSC). The descriptions of the phase transitions are placed next to the thermal events in DSC traces and are explained in detail in Table 2.3. This table is arranged according to the polymorphic system, then the starting polymorph, and then the different possibilities of the transitions. Not all situations constitute polymorphic transition. When examining the thermal traces for polymorphic transitions, it is helpful to have the phase diagrams on hand (Fig. 2.2).

Most of the transitions listed in Table 2.3 have been observed in real life, except for E II-3. In this case, Polymorph II converts via a solid-solid route to Polymorph I at a temperature below T_t. Unlike in E II-2, where the resulting Polymorph I converts back to Polymorph II when heated past T_t, Polymorph I melts without converting to Polymorph II. The reason that E II-3 is not observed is that the mobility of the solid is higher at higher temperatures; therefore, the kinetic resistance to polymorphic transitions is also likely to be less at higher temperatures.[50] For one pair of enantiotropic polymorphs, if the conversion in one direction is observed at lower temperatures, the likelihood of not

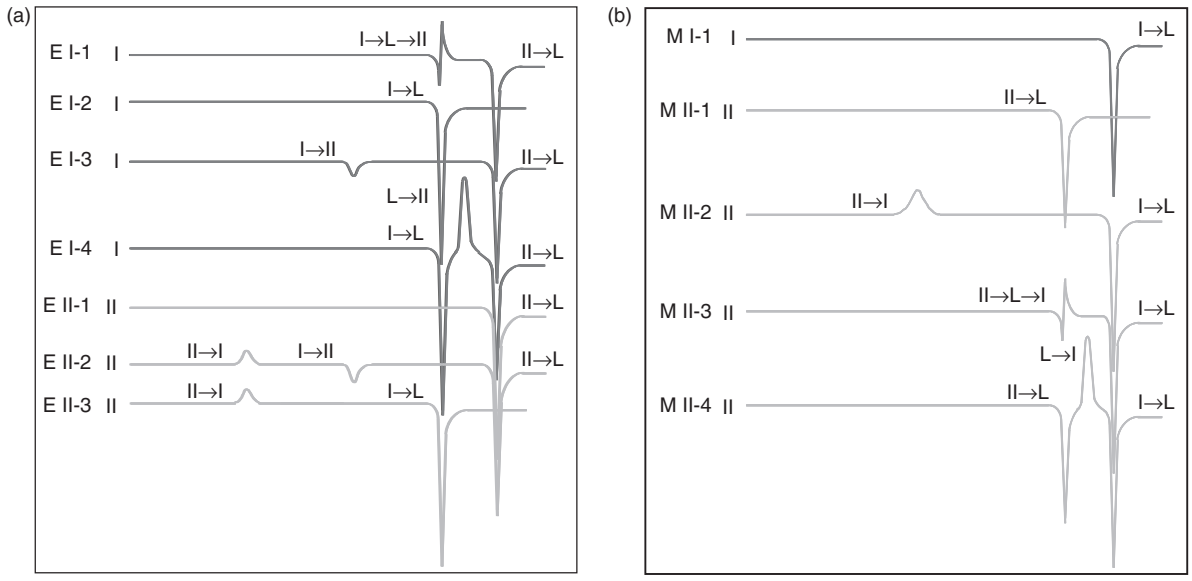

FIGURE 2.9 Potential polymorphic transitions induced by heat. (a) Enantiotropy and (b) Monotropy.

observing the conversion in the other direction at higher temperatures is very low.

Experimentally, one could heat the solids to a temperature slightly above the transition, cool the solid back to ambient, reheat, and observe the reversibility of the transitions. Techniques like this have been used extensively to demonstrate the enantiotropic relationship between two polymorphs.[92–94] Due to differences in the mobility of solids at different temperatures, one can only draw positive conclusions, not negative ones. In other words, if reversibility of the transition is observed, it is conclusive for an enantiotropic relationship. However, when reversibility is experimentally not observed, one cannot conclude that the polymorphs are monotropically related.

For purposes of illustration, only dimorphic systems are described here. In reality, many polymorphic systems have three or more polymorphs. Therefore, the transformations upon heating could be much more complex than those demonstrated here. In complex cases, several complementary analytical methods should be used together in order to understand the system.

2.5.1.2 *Dehydration/Desolvation*

The thermodynamic of solvates and hydrates (Section 2.3.2) dictates that they will be less stable at higher temperatures. Indeed, heating has been routinely applied to remove crystallization solvents that are incorporated into the lattice (ie, desolvation). Thermogravimetric analysis (TGA) is one of the main characterization methods for solvates/hydrates. In principle, TGA monitors the weight change as a function of temperature. The total weight loss corresponds to the stoichiometry of the solvate/hydrate, while the temperature at which the weight loss begins is indicative of the physical stability of the solvate/hydrate.

The resulting solvent-free solids could be different when desolvating different solvates, desolvating the same solvate under different conditions, or desolvating the same solvate under the same conditions but different batches, and with different amounts of residue solvent.[95] Therefore, desolvation is one of the major approaches in polymorph screening to search for polymorphs.

2.5.1.3 *Cocrystal formation*

Before the term *cocrystal* was invented, this type of adducts was called *solid-state molecular complexes*. Many of them have been reported in the pharmaceutical literature. Very often, the discoveries resulted from experiments to construct binary melting-point phase diagrams. In the early days, thermomicroscopy was used. One would watch the solids as they were heated. Very often, after eutectic melting, the liquid would crystallize into a new solid, which might correspond to a solid-state complex. Later, the construction of phase diagrams shifted to DTA/DSC when they became widely available. The common practice was to melt the mixtures of solids first, cool them, and let them crystallize to ensure perfect thermal contact between the sample and the pans and intimate mixing of the two components, and then collect melting points during the second heating. This practice led to an even higher probability of the crystallization of complexes because the liquid spent more time at higher temperatures and had more opportunity for crystallization.

TABLE 2.3 Potential Thermal Events Observed When Heating a Polymorphic Solid

Thermal trace ID	Polymorphic system	Starting polymorph	Transitions (In order of increasing temperature)
E I-1	Enantiotropic	I	Melting of I with concurrent recrystallization of II
			Melting of II
E I-2	Enantiotropic	I	Melting of I
E I-3	Enantiotropic	I	Solid-state conversion from I to II
			Melting of II
E I-4	Enantiotropic	I	Melting of I
			Recrystallization of II from liquid
			Melting of II
E II-1	Enantiotropic	II	Melting of II
E II-2	Enantiotropic	II	Solid-state conversion from II to I below T_t
			Solid-state conversion from I to II above T_t
			Melting of II
E II-3	Enantiotropic	II	Solid-state conversion from II to I below T_t
			Melting of I
M I-1	Monotropic	I	Melting of I
M II-1	Monotropic	II	Melting of II
M II-2	Monotropic	II	Solid-state conversion from II to I
			Melting of I
M II-3	Monotropic	II	Melting of II with concurrent recrystallization of I
			Melting of I
M II-4	Monotropic	II	Melting of II
			Recrystallization of I from liquid
			Melting of I

2.5.2 Induced by vapor

Since the vapor pressures of solids are usually very low, this section is more applicable to solvates and hydrates and less relevant to cocrystals. The thermodynamics of solvates clearly demonstrates that they are stable under a subset of conditions where the vapor pressure of the solvent in the environment is higher than some critical values. Under these conditions, the nonsolvated crystal forms are metastable, and driving forces exist for converting them to the solvate forms. On the other hand, under the conditions where the vapor pressure is below this critical value, solvates are metastable, and driving forces exist for converting the solvates to the nonsolvated forms.

Also demonstrated by thermodynamics, activities of the solvents are related to temperature. The same vapor pressure results in lower activities at higher temperatures. Thus, the desolvation phenomenon discussed in Section 2.5.1 is applicable here. However, what is different is the solvation/hydration phenomenon when nonsolvated forms are exposed to a high-solvent vapor pressure. Since exposure only to the organic solvent vapor is quite rare in pharmaceutical development, the discussions here will focus on the role of water vapor and hydrate formation.

RH can vary significantly from location to location and from season to season. Therefore, the phase transition behavior of anhydrates and hydrates has been of particular interest in pharmaceutical development. The kinetic aspect of dehydration has also been studied extensively. From the thermodynamic point of view, when the RH of the environment is closer to RH^c, the driving force for dehydration is lower. Therefore, the dehydration rate should decrease. This is, in fact, observed experimentally for the dehydration of amoxicillin trihydrate.[96] Isothermal dehydration rates were measured at a range of water vapor pressures at 68°C. Dehydration resulted in a poorly crystalline phase, and the phase boundary–controlled kinetic model, under all conditions studied, best described the rates. When the rate constants are plotted against water vapor pressure, regardless of the size of the samples employed, straight lines result, and both extrapolate to a common intercept (within experimental error) on the *x*-axis (Fig. 2.10). This intercept corresponds to the RH^c.

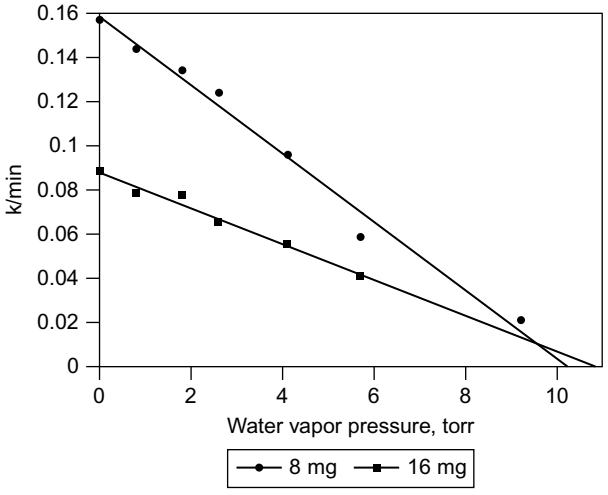

FIGURE 2.10 Plot of the dehydration rate constant of amoxicillin trihydrate as a function of water vapor pressure.[96]

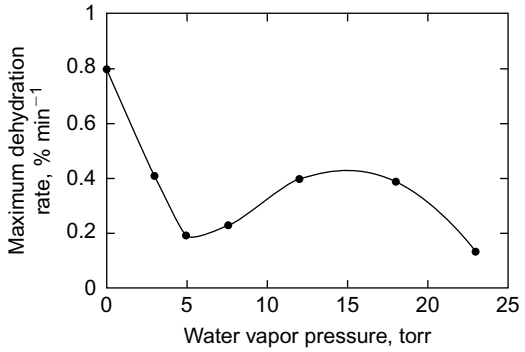

FIGURE 2.11 Maximum dehydration rate of carbamazepine dihydrate as a function of water vapor pressure at 44°C.

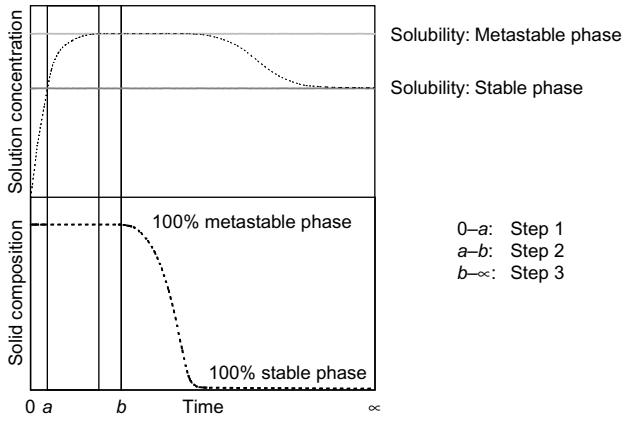

FIGURE 2.12 Concentrations in the solution and the solid compositions as a function of time during the solution-mediated phase transformation.

In the case of carbamazepine dihydrate, however, the rate constant did not follow the same trend (Fig. 2.11).[97] When dehydrating the hydrate at progressively higher water vapor pressure, the rates decrease at first, pass through a minimum, increase and pass through a maximum, and finally decrease again. This phenomenon is known as the *Smith-Topley effect*.[98–100] It has been observed in the dehydration of many other hydrates.[101–107] The cause of this "unusual" behavior is the existence of different dehydration products at low and high water vapor pressures. At extremely low water vapor pressure, the dehydrated phase is amorphous. The water of dehydration will have to diffuse through the amorphous matrix outside each hydrate particle. However, slight increases in water vapor pressure result in the amorphous dehydrated phase undergoing transition to a crystalline phase, therefore creating channels for water to escape and facilitating dehydration. At even higher water vapor pressure, the driving force for dehydration starts to diminish, as in the case of amoxicillin trihydrate.

Exposing anhydrous solids to moisture to form hydrates usually requires excessively higher RH than the RH^c. The probable explanation is that the mechanism of transformation here is not solid-solid, but is instead a solution-mediated transformation. Therefore, bulk solution needs to be present for this mechanism to operate, which is only possible at very high RH.

2.5.3 Induced by solvents

When metastable solids are exposed to solvent (ie, forming a suspension), conversion to the stable phase is facilitated due to a phenomenon called *SMPT*. The presence of the solvent does not change the thermodynamics and stability relationship unless a solvate/hydrate forms with the solvent. However, owing to the much higher mobility in the solution state than in the solid, transformation to the stable phase occurs much faster. This process is analogous to the effect of catalysts for chemical reactions. Mechanistically, SMPT consists of three consecutive steps:[108–110]

1. Initial dissolution of the metastable phase into the solution to reach and exceed the solubility of the stable phase
2. Nucleation of the stable phase
3. Crystal growth of the stable phase coupled with the continuous dissolution of the metastable phase

The schematic representation of concentrations in the solution, as well as the solid compositions as a function of time, are shown in Fig. 2.12 for a typical SMPT process. Kinetically, each step is influenced by a number of factors. Some of the important ones are summarized in Table 2.4. In the overall SMPT process, Step 2 is usually the slowest, and therefore it is the rate-determining step because it involves nucleation. For some fast-nucleating systems, the overall process could be dominated by Step 3. In this case, further differentiation can be made as to whether the process is dissolution or growth controlled.[108] However, differentiation was made based only on rates. Therefore, for the same system (the same solid plus solvent), the controlling step could change by varying some of the experimental conditions (such as temperature, solid/solvent ratio, agitation, particle size, and distribution) and at different extents of transformation.

Many types of phase transitions have been observed for SMPT, including the following:

1. Amorphous to crystalline transition
2. Polymorphic transition
3. Interconversions among the parent and the adducts (ionic, molecular, ionic/molecular)
4. Interconversions between the adducts.

TABLE 2.4 Factors Influencing the Kinetics of the Elementary Steps of SMPT

SMPT step	Factors
1	Temperature (which in turn affects the solubility, diffusion coefficient, and viscosity of the medium)
	Agitation (which in turn affects the thickness of the diffusion layer)
	Initial solution concentration
	Initial particle size and distribution (which in turn affects the initial surface area)
	Solid to solvent ratio
	Solvent medium (which in turn affects the solubility and diffusion coefficient)
	Impurities or additives in the solution (eg, polymers, which in turn affects the diffusion coefficient).
2	Temperature
	Solubility ratio between the two phases
	Solubility
	Nature of the solvent
	Agitation
	Impurities or additives
	Nature and quantity of the contact surfaces (for heterogeneous nucleation)
3	Dissolution component:
	Same as in Step 1, except that the concentration in the solution is higher than the solubility of the table phase
	Crystal growth component
	Temperature
	Solubility ratio between the two phases
	Solubility
	Nature of the solvent
	Agitation
	Available sites for growth
	Number of nuclei
	Presence of secondary nucleation
	Surface roughness
	Impurities or additives in the solution

The occurrences and utility of SMPT span a wide range of pharmaceutically relevant processes including solubility experiments, dissolution (in vitro and in vivo), API crystallization, polymorph/cocrystal screening and characterization, and pharmaceutical processing (such as wet granulation).

2.5.4 Induced by mechanical stresses

When mechanical stresses are applied to solids, they generate many defects. These imperfections create the necessary space and energy to initiate solid-state transitions, such as polymorphic conversion[110–112] and cocrystal formation from a mixture of the corresponding solids.[113,114] Extensive milling, however, often results in a loss of crystallinity and conversion to amorphous material.

2.6 METHODS OF GENERATING SOLIDS

This section briefly summarizes the various methods to generate solids. All crystalline phases are generated by crystallization, where crystallization can occur from gas, liquid (neat or solution), and solid states. Amorphous solids, on the other hand, are generated by the lack of crystallization processes. Hydrates and solvates are generated when crystallized from an environment with high and appropriate water/solvent activities. Ultimately, the driving force for crystallization is the difference in activity (chemical potential), which can be represented differently in gas (vapor pressure), liquid (concentration), and solid states (free energy). Various methods are discussed in some detail next, and they are arranged according to the states of the media through which crystallization occurs: gas, liquid, or solid state.

2.6.1 Through gas

All liquids and solids have vapor pressures at a given temperature. The vapor pressure is a function of temperature, as described by the Clapeyron–Clausius equation. At higher temperatures, the vapor pressure is higher as well. Therefore, by heating a liquid or solid, one can achieve a certain vapor pressure (provided that the substance does not decompose). When this vapor is in contact with a cooler surface, the material in the vapor phase will condense onto the cooler surface, thus generating crystalline polymorphs if nucleation occurs. If nucleation does not occur, the material will condense as an amorphous phase (this is usually termed *vapor deposition*).

Heating is not the only method to generate supersaturation through vapor. It has been demonstrated that reactions in the vapor phase could effectively generate supersaturation and crystallize adducts. One example is the formation of an ephedrine free-base

racemic compound from two opposite enantiomers that are physically separated.[115]

This mode of crystallization is not usually used for hydrates and solvates.

2.6.2 Through liquid

2.6.2.1 Through neat liquid

As shown in Section 2.5.1 earlier in this chapter, polymorphs can be generated via crystallization from the neat liquid at high temperatures. They can also be generated at lower temperatures via crystallization from amorphous phases. The resulting polymorph is a result of the dynamic interplay between the nucleation and growth kinetics of the different polymorphs.

When exposed to moisture or organic solvent vapor, an amorphous phase will absorb solvent molecules from the vapor phase, leading to a reduced glass transition temperature, increased molecular mobility, and ultimately crystallization. This is further discussed in Section 2.7. Potentially hydrates and solvates can crystallize by this method.

2.6.2.2 Through solution

2.6.2.2.1 Solvent evaporation

When evaporating solvent from a solution, the capacity that the solution can accommodate solute is reduced, so supersaturation is eventually created. Upon nucleation, crystalline phases are generated. This evaporative crystallization can also be performed in a solution containing a mixture of solvents. The more volatile solvents, ideally, are good solvents for the solute in this case. When activities of solvent or water are high during the crystallization process, the respective solvates or hydrates may be prepared. On the other hand, amorphous phases are generated if nucleation is sluggish or impaired.

Spray drying is on the extreme side of the rate of solvent removal. Usually, this process generates amorphous material because no time is given for nucleation to occur. However, crystalline phases have been generated via spray drying for some fast-nucleating systems.

2.6.2.2.2 Antisolvent addition

When an antisolvent (which does not provide solvency for the solute) is added to a solution, the composition of the solvent system changes. As a result, the solubility of the solute consequently changes. The supersaturation necessary for nucleation can be generated in this fashion. Again, nucleation leads to crystalline solids, and the lack of nucleation leads to the precipitation of amorphous materials.

The vapor diffusion method involves placing a solution over the vapor of a volatile antisolvent. This method is, in fact, a combination of solvent evaporation and antisolvent addition methods. During the course of the process, the good solvent will evaporate from the solution. Meanwhile, the volatile antisolvent migrates to the solution via the vapor phase.

2.6.2.2.3 Reactive solvent addition

For ionizable compounds, pH adjustment in aqueous media is especially effective at creating supersaturation because of the drastic differences in the solubility. The net effect is to increase the concentration of the less soluble unionized form. Again, nucleation leads to crystalline solids, and the lack of nucleation leads to the precipitation of amorphous materials.

2.6.2.2.4 Temperature gradient

Most organic compounds have temperature-dependent solubility; that is, solubility is usually higher at higher temperatures. Therefore, cooling a saturated solution from higher temperatures will create supersaturation, generating crystalline phases upon nucleation.

Lyophilization is a common method of generating amorphous phases. It is a combination of temperature gradient and solvent evaporation methods. It usually begins with fast cooling of the solution to avoid nucleation. Crystallization of the solvents and subsequent sublimation of solvent crystals effectively remove the solvent from the system, leaving behind an amorphous solid.

2.6.2.2.5 Suspension method

As discussed in Section 2.5.3, the suspension method is particularly effective in generating more stable phases, polymorphs, solvates, or hydrates. Recently, this method has also been extended to screen for cocrystals[44,53,54] and has proven to be successful in screening for novel cocrystals.[116,117]

2.6.3 Through solid

As shown in Section 2.4, solid-state phase transitions are one of the main methods used to generate various solid forms. Heating and cooling, varying RH, and mechanical treatments often result in a change of solid form, thus making solid-state phase transition an attractive means of generating new solids.

2.7 AMORPHOUS DRUGS AND SOLID DISPERSIONS

As mentioned in Sections 2.3 and 2.4 earlier in this chapter, an amorphous phase has higher free energy,

enthalpy, and entropy than the crystalline counterpart, and thus finds application in improving oral bioavailability for BCS class II or IV compounds. However, its unique properties and metastable nature present significant challenges in commercial applications of this concept. In reality, there are only a handful of pharmaceutical products containing amorphous APIs that have been successfully marketed, despite several decades of efforts in research and development. As pointed out by Serajuddin,[118] the limited commercial success reflected challenges from manufacturing difficulties to stability problems. This section aims to briefly survey the fundamental properties of amorphous pharmaceuticals and their solid dispersions.

2.7.1 Characteristics of amorphous phases

2.7.1.1 *Origin of the glass transition*

A number of theories have been proposed to explain the origin of the glass transition and various properties of amorphous materials. The free volume theory and thermodynamic theory are among the most widely accepted.

Free volume theory[119–124] assumes that the volume of a liquid consists of the volume occupied by the constituent molecules and the free volume in which molecules are free to move. The latter exists as voids between molecules and provides room for molecular diffusion. A void can open up due to thermal fluctuations, thus allowing a molecule to move through. The glass transition occurs when the free volume of the system falls below a critical value, and molecular motion by diffusion ceases compared to the experimental timescale.

Dolittle[125] proposed the following relationship between viscosity and free volume:

$$\eta = A\exp(bv_0/v_f) \tag{2.26}$$

Here, v_0 is the molecular volume at 0 K, v_f is the free volume, and A and b are constants. Cohen and Turnbull[122] further related the molecular transport in glasses based on the free volume concept:

$$D = (1/3)(3k_BT/m)^{\frac{1}{2}}\exp(-\gamma v^*/v_f) \tag{2.27}$$

where:

D is the diffusivity,
k_B is the Boltzmann constant,
m is the molecular mass,
v^* is the critical free volume for molecular diffusion.

The free volume theory provides a simple and plausible explanation and is consistent with many experimental observations.

As mentioned previously, the glass transition exhibits the features of a second-order phase transition. Although the glass transition temperature does show kinetic characteristics, it has been suggested that a true second-order transition is masked. The Adam-Gibbs (AG)[126,127] model appears to be able to put together a rigorous explanation of the nature of glass transitions and identify the true second-order transition temperature with the Kauzmann temperature, thus avoiding the entropy crisis. It further relates the molecular relaxation time to the excess entropy of the amorphous phase or the configurational entropy, S_c:

$$\tau = \tau_0\exp\left(\frac{C}{TS_c}\right) \tag{2.28}$$

Here, τ_0 is the relaxation time of molecules at an infinitely high temperature, which conceptually is the relaxation time of the unrestricted molecular relaxation.[128] The overall constant, C, is considered to be a material-dependent parameter that determines the magnitude of the temperature dependence of the relaxation time.

AG theory has been used extensively to explain the properties of the glassy state, and it is more successful than the free volume theory in accounting for the pressure dependence of the glass transition temperature.[129] However, it is not without criticism.[130,131]

2.7.1.2 *Configurational thermodynamic quantities*

The higher heat capacity, entropy, enthalpy, free energy, and other thermodynamic quantities of the amorphous state are due to additional modes of molecular motion in this state, including rotation and translation, which are collectively called *configurations*. Therefore, the excess thermodynamic functions are often called *configurational quantities*. It should be noted that anharmonic vibration might make a significant contribution to those quantities, as noted by Goldstein.[132]

The configurational heat capacity, ΔC_p, entropy, ΔS, enthalpy, ΔH, and free energy, ΔG, can be calculated based on standard thermodynamic treatments:

$$\Delta C_p(T) = C_p^a(T) - C_p^x(T) \tag{2.29}$$

$$\Delta H(T) = H^a(T) - H^x(T) = \Delta H_m + \int_{T_m}^{T}\Delta C_p\,dT \tag{2.30}$$

$$\Delta S(T) = S^a(T) - S^x(T) = \Delta S_m + \int_{T_m}^{T}\frac{\Delta C_p}{T}dT \tag{2.31}$$

$$\Delta G(T) = G^a(T) - G^x(T) = \Delta H(T) - T\Delta S(T) \tag{2.32}$$

Here, the superscripts a, x, and m denote amorphous, crystalline, and melting, respectively.

2.7.1.3 Molecular relaxation in the amorphous state

A glass transition occurs when the timescale of molecular relaxation in the system crosses over the timescale of the observer. Therefore, the glass transition can be studied by changing the timescale of the system under study or the experimental probe. In that sense, the glass transition is purely a kinetic phenomenon, and the molecular relaxation time at the glass transition will apparently depend on the experimental conditions. For example, a fast heating or cooling rate corresponds to a shorter timescale of the probe, which causes the glass transition temperature to shift to a higher temperature (shorter timescale). Periodic perturbations can also be applied, such as in the case of dynamic mechanical analysis, temperature-modulated DSC, dielectric analysis, and rheometric analysis, where the frequency can be changed. Sometimes the comparison among different techniques is not straightforward. However, the average molecular relaxation time at T_g (onset) is approximately 100 seconds for typical DSC scans at 10°C/min.[133]

The temperature dependence of the molecular mobility in the metastable equilibrium supercooled liquid state is usually described by the Vogel-Tammann-Fulcher (VTF) equation,[134–136] as shown here, which also can be approximated by the AG treatment:

$$\tau = \tau_0 \exp\left(\frac{DT_0}{T - T_0}\right) \tag{2.33}$$

where T_0 is the temperature where molecular motion ceases (T_K), while D is a parameter signifying the temperature dependence of the relaxation time constant, or strength of the glass-former. Angell classified glass-formers as either "strong" or "fragile."[137,138] A strong glass has less (lower activation energy) temperature dependence on molecular mobility near T_g than a fragile glass. Molecular mobility in strong glasses typically exhibits Arrhenius-like temperature dependence, while the Arrhenius plot for a fragile glass is significantly nonlinear. A stronger glass is also indicated by smaller change in heat capacity at T_g than a fragile glass. The strength parameter D is higher for strong glasses (such as >100 for SiO_2). Most organic glass-formers are fragile, generally with $D < 15$. Another useful parameter is the fragility parameter, m, which is related to D as follows[139]:

$$m = \frac{\Delta H}{2.303RT_g} = \frac{DT_0}{2.303T_g(1 - T_0/T_g)^2} \tag{2.34}$$

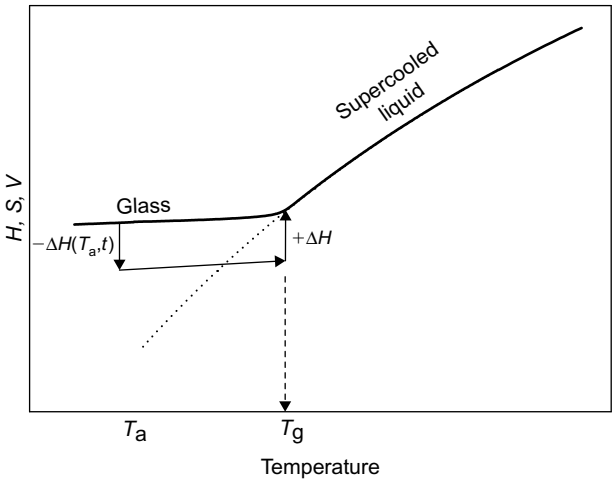

FIGURE 2.13 Schematic representation of the structural relaxation when a glass is annealed at temperature T_a for duration t.

ΔH is the apparent activation energy near T_g, which can be obtained through the heating rate dependence of the glass transition temperature[140,141]:

$$\Delta H = -R\frac{d\ln q}{d(1/T_g)} \tag{2.35}$$

To an experimental observer, molecular motion appears to stop at $T < T_g$ because it takes longer than the timescale of the probe. However, molecular motion can be revealed at a longer timescale. An experimental glass is in a nonequilibrium state. When a glass is stored at temperatures below its T_g, this nonequilibrium state, coupled with mobility over a longer timescale, leads to the so-called physical aging or annealing phenomena. This is due to structural relaxation of the nonequilibrium glass toward the metastable equilibrium or supercooled liquid state (ie, the ideal glass). A schematic representation of this structural relaxation is shown in Fig. 2.13.

According to the AG theory on molecular relaxation in glass-forming liquids, these thermodynamic and dynamic properties are coupled. Therefore, as the excess enthalpy and entropy of the nonequilibrium glass decrease during annealing, the molecular mobility should also decrease. The rate and extent of this decrease in molecular mobility may be important to the physical stability of pharmaceutical glasses.[142]

Molecular relaxation time constant in the annealed glasses can be calculated using the AGV equation[133,143] via the concept of fictive temperature,[133,143–148] T_f:

$$\tau(T, T_f) = \tau_0 \exp\left(\frac{DT_0}{T - (T/T_f)T_0}\right) \tag{2.36}$$

One feature of the structural relaxations in glasses is their nonlinearity or nonexponentiality. Briefly, this

refers to the nonconstant relaxation time constant, which is due to the coupling between the relaxation time and configurational entropy or other quantities. Molecular mobility continuously decreases during the storage of pharmaceutical glasses.[142]

The nonlinearity produces so-called memory effects; therefore, history is an important factor in studying the structural relaxation in glasses. Nonlinearity has been described using the stretched exponential KWW equation:

$$\phi(t) = \exp\left[-\left(\int_0^t \frac{dt'}{\tau(t')}\right)^{\beta}\right] \tag{2.37}$$

Here, $\phi(t)$ is the fraction remaining at time t and β is an empirical parameter indicating the distribution of relaxation time constants ($0 \leq \beta \leq 1$).

2.7.2 Characteristics of amorphous solid dispersions

The term *amorphous solid dispersion* refers to an amorphous drug dispersed in a carrier or matrix in the solid state. Strictly speaking, the term *dispersion* itself implies phase immiscibility. However, in pharmaceutical literature, amorphous solid dispersions are loosely defined, and they also include systems where the drug is dispersed in the matrix at the molecular level (ie, solid solutions). The carriers usually consist of polymers and other "inert" excipients such as surfactants. These carriers could be either amorphous or crystalline. However, amorphous carriers with complete phase miscibility in amorphous drugs offer the most advantages for pharmaceutical applications.

The presence of other components (eg, polymeric carriers) will certainly modify the characteristics of the amorphous drug. Conceptually, two different scenarios could arise: amorphous drug-crystalline polymers, and amorphous drug−amorphous polymers. In the amorphous drug-crystalline polymer system, due to complete phase separation, most likely the properties of the system will be dominated by individual components, except that the interfacial interactions may change certain characteristics of the system (eg, dissolution, aggregation, crystallization, etc.). The following discussion focuses on the other, more common, scenario: amorphous drug−amorphous carrier solid dispersions.

2.7.2.1 Thermodynamic analyses and phase miscibility

Phase miscibility in amorphous solid dispersions is dictated by the thermodynamics of mixing. A decrease in free energy is a necessary condition to initiate mixing. However, it alone does not guarantee phase miscibility.

2.7.2.1.1 Entropy of mixing

Similar to the mixing of small molecules, the mixing of a polymer with a small molecule leads to an increase in entropy, and therefore mixing is favored. However, unlike small molecular mixing, the position availability is limited for polymers due to restraint by the polymer chain, resulting in a smaller ΔS_{mix}. The entropy of mixing for a drug-polymer system can be treated by the Flory−Huggins lattice model:

$$\Delta S_{mix} = R(N_d \ln\phi_d + N_p \ln\phi_p) \tag{2.38}$$

The subscripts d and p designate drug and polymer, respectively; N is the number of sites occupied by the drug or polymer; and ϕ is the volume fraction of drug or polymer in the mixture. In the lattice model treatment, the lattice site is usually defined by the volume of the small molecule. Each polymer molecule then occupies m such sites, where m is the ratio of the molecular volume of the polymer to that of the drug.

2.7.2.1.2 Enthalpy of mixing

Similar to the treatment of regular solution theory, molecular interactions can be built into the lattice model. However, the original regular solution theory merely treated van der Waals interactions, which only accounted for positive deviations from Raoult's law. In the lattice model, specific interactions such as hydrogen bonding were also considered, which play an important role in dictating phase miscibility, and possibly physical stability, in amorphous solid dispersions. The enthalpy of mixing is often expressed as

$$\Delta H_{mix} = RT(N_0 + mN_p)\chi\Phi_0\Phi_p \tag{2.39}$$

where χ is called the Flory−Huggins parameter and χkT represents the enthalpy change of introducing one solvent molecule to the polymer. Depending on the nature of polymer-drug interaction, the enthalpy of mixing can be positive (eg, in the case of only van der Waals interactions) or negative (eg, in the case of hydrogen bonding). Obviously, positive χ causes an increase in enthalpy and free energy, which disfavors mixing.

2.7.2.1.3 Free energy of mixing

Based on the Flory−Huggins model, the total free energy of mixing can be expressed as

$$\begin{aligned}\Delta G_{mix} = RT\,[&N_0 \ln\Phi_0 + N_p \ln\Phi_p \\ &+ (N_0 + mN_p)\chi\,\Phi_0\Phi_p]\end{aligned} \tag{2.40}$$

The entropy of mixing is the only term that always favors mixing. However, this term is much smaller

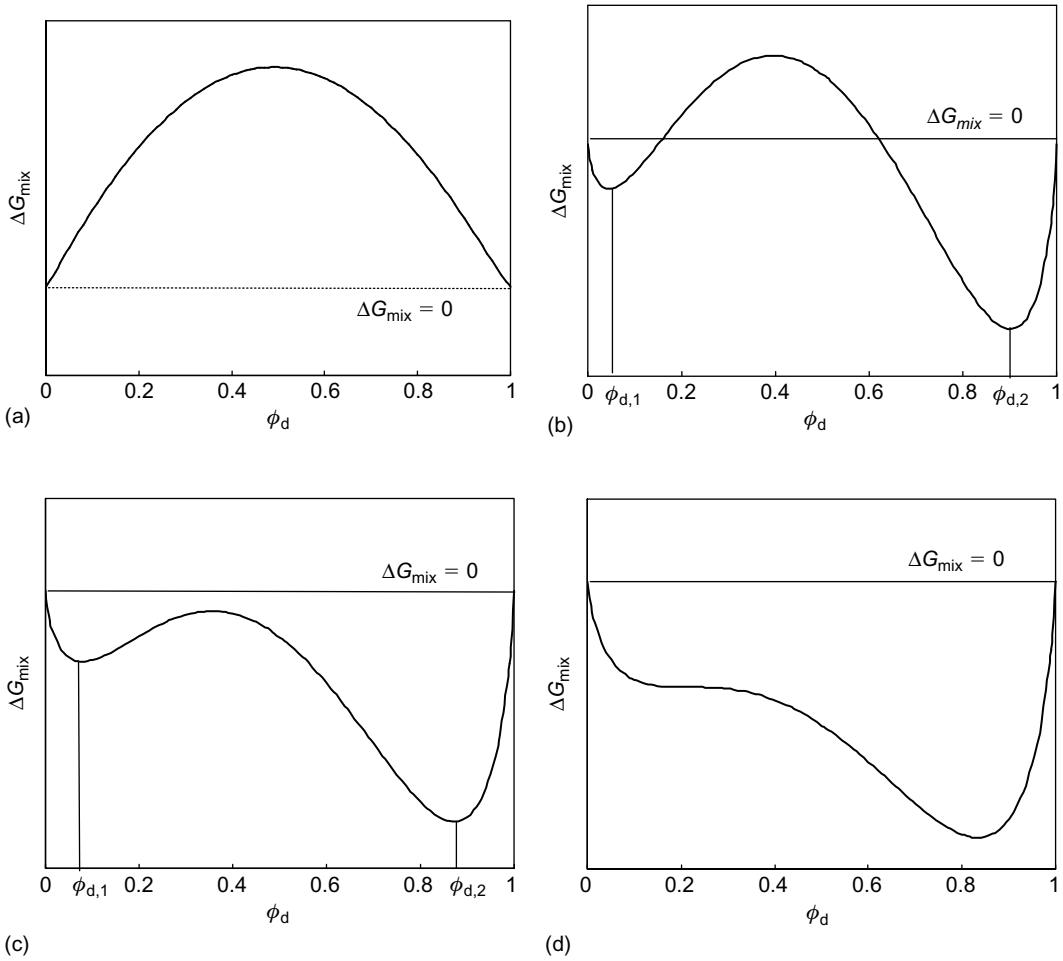

FIGURE 2.14 Schematic free energy of mixing (a) no mixing; (b) partial miscibility; (c) mixing but with phase separation at some compositions; and (d) complete miscibility.

than observed in the mixing of small molecules, and it cannot offset a large positive enthalpy of mixing. Therefore, the free energy of mixing could be negative or positive depending on the sign and magnitude of the Flory–Huggins parameter. If the Flory–Huggins parameter is too large ($\chi > \chi_{crit}$), the free energy of mixing will be positive and no mixing is expected. Specific interactions such as hydrogen bonding make χ negative, so phase miscibility may be favored.

By itself, $\Delta G_{mix} < 0$ does not necessarily imply a single phase. Fig. 2.14 illustrates typical scenarios when mixing small drug molecules with amorphous polymeric carriers. In Fig. 2.14a, $\Delta G_{mix} > 0$ for virtually all compositions; therefore, mixing will not occur and the amorphous drug and polymer will stay in their own pure phases. (Strictly speaking, there will always be a certain extent of mixing. However, in reality, the equilibrium phases can be considered the same as each individual component.) Fig. 2.14b represents partial miscibility. Phase miscibility occurs when $\phi_d < \phi_{d,1}$ or $\phi_d > \phi_{d,2}$. When $\phi_{d,1} < \phi_d < \phi_{d,2}$, the solid dispersion will be phase separated, but not in their individual components, but in a drug-rich phase ($\phi_{d,2}$) and a polymer-rich phase ($\phi_{d,1}$). In Fig. 2.14c, $\Delta G_{mix} < 0$ for all compositions. However, any composition in the range $\phi_{d,1} < \phi_d < \phi_{d,2}$ will still decompose to two local minima represented by $\phi_{d,1}$ and $\phi_{d,2}$, similar to Fig. 2.14b. Therefore, $\Delta G_{mix} < 0$ is only a necessary condition for complete phase miscibility. Fig. 2.14d represents the complete phase miscibility.

2.7.2.2 Molecular mobility in amorphous solid dispersions

When a drug is molecularly dispersed in a polymer, its molecules experience an environment with both other drug molecules and the polymer molecules. The same is true for the polymer. Molecular relaxation in such a dispersed matrix, therefore, is expected to reflect such an environment. The average mobility is usually intermediate between those of the pure components. Assuming additivity of free volumes of each component (ideal mixing), the T_g of an ideal binary

mixture can be estimated using the Gordon–Taylor equation:[149,150]

$$T_{g,mix} = \frac{w_1 T_{g1} + K w_2 T_{g2}}{w_1 + K w_2} \tag{2.41}$$

where w_1 and w_2 are the weight fractions of the components, and K is a constant that can be approximated by the ratio between the respective changes in heat capacity at T_g:

$$K = \Delta C_{p_2} / \Delta C_{p_1} \tag{2.42}$$

To the drug, the presence of the polymer usually causes an increase in T_g, which is often termed an *antiplasticization effect*. In addition, the presence of specific drug-polymer interactions can lead to an increase in T_g above that predicted. However, if the drug-polymer (adhesion) interaction is less than those in drug-drug or polymer-polymer (cohesion) pairs, then T_g is expected to be lower than predicted.

The change in molecular mobility in the amorphous phase by incorporating a second component is of practical relevance to pharmaceuticals other than amorphous solid dispersions. Moisture sorption is vastly increased in an amorphous phase compared to the corresponding crystalline phase. This can be explained by two reasons. The first is that an amorphous phase is more energetic, thus increasing affinity between water and the drug molecules. The second reason is that by removing the crystal lattice, the previous barrier preventing water molecules from entering the crystal lattice vanishes, and water molecules are now able to access almost every host molecule. The latter reason is probably more important. Instead of moisture adsorption on the crystal surface, water molecules form a molecular dispersion with the drug, and the phenomenon is more appropriately called *sorption*. As predicted by the Gordon–Taylor equation, the consequence of moisture sorption into an amorphous phase is a drastically reduced T_g, and increased molecular mobility even for a small amount of moisture sorbed, due to the great plasticization effect of water, which has a T_g of −137°C.

2.7.2.3 Solubility in polymeric matrix

It is apparent that a solid dispersion is metastable only when the drug loading exceeds the solubility limit. Therefore, the solubility of a crystalline drug in a polymeric matrix is of both theoretical and practical importance.

It has been challenging to determine drug solubility in amorphous solid dispersions experimentally, due to the highly viscous nature and slow kinetics of such systems. Theoretically, the solubility could be estimated once the Flory–Huggins interaction parameter becomes known. Methods to derive this parameter in polymer solutions include vapor pressure reduction, osmotic pressure, and other solution techniques, as well as melting-point depression. Most of these solution techniques are difficult to apply to drug-polymer systems. However, the melting-point depression[151,152] can be well adapted to amorphous solid dispersions.[153] This approach is briefly described next.

When a crystalline drug is in equilibrium with a polymer, the chemical potential of the crystalline drug equals that of the dissolved drug in the drug-polymer system. The chemical potential of the drug in solution can be derived based on the free energy of mixing:

$$\begin{aligned}\Delta\mu_d = \mu_d - \mu_d^0 &= \left(\frac{\partial \Delta G_{mix}}{\partial N_d}\right)_{N_p,T,P} \\ &= RT\left[\ln \Phi_d + \Phi_p\left(1 - \frac{1}{m}\right) + \chi \Phi_p^2\right]\end{aligned} \tag{2.43}$$

Here, μ_d^0 is the chemical potential of the pure amorphous drug, which is the same as the molar free energy of the pure amorphous drug at the temperature of the reduced melting point, T_m.

The molar free energy of pure amorphous drug can be related to that of the crystalline drug:

$$\begin{aligned}\mu_d^0(T_m) = G^a(T_m) = G^x(T_m) + \Delta H_m(1 - T_m/T_m^0) \\ + \int_{T_m^0}^{T_m} \Delta C_p\, dT - T\int_{T_m^0}^{T_m} \frac{\Delta C_p}{T}\, dT\end{aligned} \tag{2.44}$$

Here, T_m^0 is the melting temperature of the pure crystalline drug, and $G^x(T_m)$ is the molar free energy of the crystalline drug at T_m, which is identical to its chemical potential, $\mu^x(T_m)$. The following relationship can then be obtained by equating the chemical potential of the drug in polymer and that of the crystalline drug:

$$\begin{aligned}-\frac{\Delta H_m}{R}\left(\frac{1}{T_m} - \frac{1}{T_m^0}\right) - \frac{1}{RT}\int_{T_m}^{T} \Delta C_p\, dT + \frac{1}{R} \\ \times \int_{T_m}^{T} \frac{\Delta C_p}{T}\, dT + = \ln \Phi_0 + \left(1 - \frac{1}{m}\right)\Phi_p + \chi \Phi_p^2\end{aligned} \tag{2.45}$$

The χ-parameter can then be estimated, based on Eq. (2.45) using melting-point depression data. A simplified equation has been used in the literature by ignoring the contribution from excess heat capacity:

$$-\frac{\Delta H_m}{R}\left(\frac{1}{T_m} - \frac{1}{T_m^0}\right) = \ln \Phi_0 + \left(1 - \frac{1}{m}\right)\Phi_p + \chi \Phi_p^2 \tag{2.46}$$

Once the χ parameter becomes known, one can estimate the solubility at lower temperatures.

However, two points need to be made. First, Eq. (2.46) only applies to systems where the amorphous drug and amorphous polymer are in a single phase. As discussed in the previous section, the free energy of mixing will be further reduced if phase separation exists while $\Delta G_{mix}<0$. Second, the solubility obtained from melting-point depression corresponds to that in the rubbery state. However, amorphous solid dispersions are intended to be stored in the glassy state. Therefore, a large discrepancy might indeed be expected.

Solubilization certainly further reduces the driving force for crystallization of the amorphous drug. However, drug solubility in polymers at room temperature is generally quite small; therefore, the tangible impact at normal storage temperatures is possibly limited.

2.7.3 Crystallization of amorphous drugs and dispersions

Crystallization or physical instability is probably one of the greatest challenges for developing amorphous solid dispersions. Although there has been extensive research in this area, consensus has not been reached. A brief summary on the current thinking on this subject follows.

2.7.3.1 Molecular mobility

Molecular mobility plays a key role in physical and chemical stability in amorphous phases, and its importance can be readily understood. For any physical or chemical process, the molecules involved must take appropriate positions and orientations, so that it can proceed.[154] Therefore, molecular motions, such as translation and rotation, are essential in any physical or chemical change of the system. In solution or in the melt, molecular translation and rotation are usually faster than the physical or chemical change itself, so that the overall rate is independent of diffusion of the reactant or product. However, in the solid state, molecular diffusion is orders of magnitudes slower than in solution and, in most cases, can be comparable to, or even slower than, the rate of reaction. It is likely that molecular motion becomes partially or completely rate-limiting in solid-state reactions.

The partial correlation between molecular mobility and physical/chemical stability has been demonstrated for a number of pharmaceutical systems.[155–159] The crystallization rates of amorphous nifedipine in the presence of different excipients were correlated to the spin-lattice relaxation time of D_2O in these matrices.[155] Differences in crystallization rates of amorphous nifedipine, phenobarbital, and flopropione were attributed to their differences in molecular mobility.[156] In a follow-up study, the temperature dependence of physical stability of amorphous nifedipine and phenobarbital were correlated to a large extent to the temperature dependence of molecular relaxation time constant.[157] Physical stability of a lyophilized monoclonal antibody in sucrose and trehalose was correlated to molecular mobility measured by enthalpy relaxation, but not the glass transition temperature.[158] It was also shown that the fragility of the formulations played a role. Chemical degradation of amorphous quinapril hydrochloride demonstrated significant correlation with molecular relaxation time constant at temperatures below T_g.[159] Bimolecular reaction rates of acetyl transfer, as well as the Maillard reaction in lyophilized aspirin-sulfadiazine formulations, were concluded to be predictable based on molecular mobility.[160] While the chemical stability of lyophilized insulin showed correlation with the molecular mobility in trehalose formulation, the contribution of molecular mobility was found to be negligible in a PVP formulation.[161,162]

To maintain adequate physical stability, storage below T_g is apparently needed. However, unlike the metastable equilibrium supercooled state, molecular mobility in the glassy state is much higher and is less dependent on temperature. Therefore, the advantage achieved by just storing an amorphous formulation at temperatures far below T_g is not as great as expected, based on that predicted using the VTF equation. Along the same lines, the suggestion of storage at the Kauzmann temperature (typically $T_g=-50°C$, but varying depending on the fragility) will likely not provide the intended consequences because realistic glasses possess much higher mobility than ideal glasses, and molecular mobility at T_K is still significant. Nevertheless, raising the T_g of amorphous dispersions by incorporating a high T_g excipient is still a sound tactic, as implied by the Gordon–Taylor equation. However, the limitations of this approach need to be kept in mind. T_g is not necessarily a predictor of physical stability.[158] In addition, compromises may be necessary because a higher process temperature will usually be required for higher T_g formulations if the melt method is employed in manufacturing.

The rate of crystallization may also decouple from the viscosity of glasses. Hikima et al.[163] studied the *o*-terphenyl system and observed that crystal growth increased abruptly near T_g and below, orders of magnitude faster than expected from diffusion-controlled growth. Most recently, Yu and coworkers identified a few pharmaceutical systems exhibiting similar behavior, including indomethacin,[164] nifedipine,[165] and the ROY system.[166,167] Many questions remain to be answered; however, this glass–crystal mode of crystal growth appeared to be related to the precursors present in liquid and crystal structure (polymorph).[166,167]

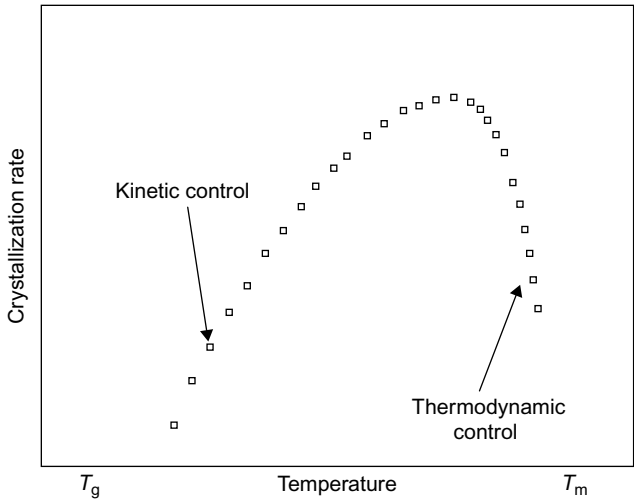

FIGURE 2.15 Schematic representation of crystallization rate from supercooled liquids.

2.7.3.2 *Free energy driving force*

In addition to the molecular mobility, the role of the free energy driving force has been historically discussed when dealing with crystallization from supercooled melts.[168] Mobility determines how fast a molecule can impinge on the surface of a growing crystal. However, not every impingement leads to successful incorporation of the molecule. The probability of the molecule not coming back to the liquid phase is related to the free energy driving force: the higher the free energy difference, the more likely the molecule will stay in the crystal lattice. The relationship can be described as follows:[164]

$$u = (k/\eta)[1-\exp(-\Delta G/RT)] \tag{2.47}$$

where:

η is the viscosity (proportional to molecular relaxation time constant),

ΔG is the free energy driving force,

R is a gas constant,

k is a constant.

While the viscosity of a supercooled liquid can be described by an empirical equation such as VTF, ΔG is approximately proportional to the degree of supercooling, $\Delta T = T_m - T$. Based on this relationship, the temperature for the maximum crystallization rate falls between the glass transition temperature and the melting temperature, as depicted in Fig. 2.15.

2.7.3.3 *Configurational entropy*

Considering the metastable nature of an amorphous phase (ie, $\Delta G = G^a - G^x > 0$), it is interesting that the amorphous phase has both higher enthalpy and higher entropy. From the thermodynamic relationship $\Delta G = \Delta H - T\Delta S$, it can be concluded that the higher free energy of amorphous phase is due to the enthalpy factor, while the entropy term partially offsets the enthalpy term, which actually reduces the overall free energy. It is apparent that the free energy and the enthalpy of amorphous state facilitate reversion to the crystalline form. The entropy term appears to behave somewhat differently.

As discussed previously, crystallization from supercooled melts are generally discussed in the context of molecular mobility and free energy driving force. For crystallization near and below T_g, which is generally the case where physical stability of amorphous pharmaceuticals is concerned, crystallization is mainly dictated by molecular mobility. Indeed, molecular mobility is generally accepted as a principal factor governing the physical stability of amorphous phases.[62,169,170] One simple fact is that crystallization of amorphous phases proceeds much faster in the rubbery state compared to the glassy state. As briefly noted, molecular mobility has been correlated partially or fully to physical/chemical stability in a number of pharmaceutical systems.

Nevertheless, significant differences in crystallization behavior are observed across compounds, and these cannot be explained by mobility alone. For example, some amorphous phases crystallize almost immediately at the glass temperature (eg, acetaminophen[171]), some crystallize below T_g in a relatively short time (eg, griseofulvin[172] and nifedipine[156,157]), while others are quite stable. For some of the more stable amorphous phases, such as ritonavir,[171] crystallization in the glassy state is not observed, and it does not proceed at a significant rate above T_g without seeding. Because T_g corresponds to the temperature where the molecular relaxation time of the amorphous phase is equivalent to the experimental timescale, it is clear that the same molecular mobility results in different crystallization tendencies.

The authors have explored the physical stability of a diverse group of pharmaceutically relevant compounds, attempting to identify thermodynamic quantities contributing to crystallization tendency. Through this analysis, it was concluded that the calorimetric configurational entropy also played an important role.[142,171]

In simple terms, configurational entropy is a measure of the difference in the number of configurations between the amorphous and crystalline phases. For molecules in the amorphous state to crystallize, the molecule has to pack into a defined crystal lattice with a defined configuration or orientation. Therefore, the higher the configurational entropy, the lower the probability that the molecules will assume the desirable orientation for packing into the crystal lattice. Hence, a metastable amorphous compound with large

configurational entropy tends to show greater physical stability. This is analogous to the common experience of chemists and biochemists that large molecules with numerous rotatable bonds are generally difficult to crystallize from solution. It has been hypothesized that configurational entropy serves as a thermodynamic measurement of the probability of nucleation, while the molecular mobility dictates the rate at which a molecule can change its configurations and serves as a kinetic measurement of nucleation. When these two quantities were evaluated with respect to molecular structure, it was possible to provide an assessment of physical stability. Therefore, in relative terms, small, rigid molecules will tend to crystallize more easily than large, flexible compounds.

Recently, Ediger et al.[173] surveyed the crystallization rates of a number of inorganic and organic systems and identified a correlation between rate of crystallization and entropy difference. In light of this new development, it seems appropriate that roles of mobility, entropy, and free energy during crystallization can be discussed in the context of three consecutive events during crystallization: mobility determines the rate of molecule approaching a crystal surface; entropy relates to the probability of that approaching molecule having the desirable configurations; and the free energy dictates the probability of that molecule not returning to the liquid phase. A more or less quantitative relationship may be represented as

$$u = (k/\eta^{\xi}) \exp(-\Delta S/R)[1-\exp(-\Delta G/RT)] \qquad (2.48)$$

Here, ξ is a constant describing the extent of correlation between crystallization rate and diffusivity.

2.7.3.4 *Crystallization inhibition*

Historically, polymers have been found to inhibit crystallization from solution. Among those pharmaceutically relevant ones, PVP has been extensively studied.[174–178] Other crystallization inhibitors include Pluronic F68,[179] cellulose derivatives,[180] and cyclodextrins.[181]

Polymeric carriers or other additives have also been shown to inhibit crystallization from amorphous solid dispersions. Thermodynamics dictates that amorphous drug would crystallize if given sufficient time. However, from the perspective of a formulation scientist, it is of great benefit if one can delay this crystallization process to obtain adequate shelf life. There are many examples of crystallization inhibition in amorphous solid dispersions;[182–188] however the mechanisms of such effects remain to be determined.

When dealing with solid dispersions, a key parameter is the molecular mobility or, approximately, T_g. The antiplasticization effect of polymeric carriers is considered important and could conceptually lead to a more stable amorphous phase than the drug itself. However, this factor alone is not entirely responsible for some experimental observations. For example, amorphous solid dispersions of felodipine with PVP, hydroxypropyl methylcellulose acetate succinate (HPMCAS), and hydroxypropyl methyl cellulose (HPMC)[188] showed similar stability profiles, while only its dispersion with PVP showed a significant increase in T_g for polymer loading up to 25%.

Specific interactions between drug and polymers were also considered to be important. For example, the inhibition of crystallization of amorphous indomethacin by PVP and PVP-*co*-PVA was ascribed to the hydrogen bonding interaction between the polymers and drug molecules.[183] PVP was found to inhibit the crystallization of indomethacin more with larger particles than smaller ones,[184] and was consistent with the observation of predominantly surface nucleation. An ion-dipole interaction was proposed to be partially responsible for the crystallization inhibition in solid dispersions of PVP[185] and a developmental drug, which could not be attributed to mobility alone. The increase in physical stability of amorphous nifedipine in ethylcellulose and Eudragit RL dispersions were also explained by the hydrogen-bonding interaction between drugs and polymers.[186] Strong interactions were observed in acetaminophen/aminoacetanilide and PVP/polyacryric acid polymers, which led to improved physical stability[187] and correlated with the strength of the specific interaction.[189] However, the felodipine dispersions with PVP, HPMC, and HPMCAS showed similar inhibitory effects, although the hydrogen-bonding strengths followed PVP > HPMC > HPMCAS.[188] These findings may not appear to be consistent. The situation is quite complex with the presence of specific interactions. On the one hand, strong drug-polymer interactions lead to greater reductions in molecular mobility than predicted by free volume additivity alone. On the other hand, the presence of certain intermolecular structures between drug and polymer molecules due to specific interactions may create a kinetic barrier for the amorphous drug to crystallize. Additionally, specific interactions decrease the free energy of the system. All these factors appear to work toward stabilization, albeit maybe to different extents. However, it is difficult to delineate the individual contributions.

While it is important to maintain the physical stability of amorphous dispersions during storage, it is also useful to utilize similar concepts for solid dispersions during in vivo dissolution. The higher dissolution rate and apparent solubility of an amorphous drug usually causes supersaturation during in vivo dissolution, and therefore may lead to precipitation in the GI tract and compromise oral

bioavailability. If such a crystallization-inhibitory polymer is incorporated into the amorphous solid dispersion, then the in vivo precipitation may be delayed or completely eliminated, resulting in much improved oral absorption. It is ideal if the polymeric carrier can function as a crystallization inhibitor, both during storage and during in vivo dissolution. However, the mechanisms may not be the same, and different inhibitors may indeed be necessary. A few examples have been reported. Various itraconazole solid dispersions were prepared by hot-melt extrusion and compared with the commercial drug Sporanox in a clinical study.[66] The bioavailability relative to Sporanox was 102.9%, 77.0%, and 68% for the HPMC, Eudragit E 100, and Eudragit E 100-poly(vinylpyrollidone-*co*-vinylacetate) solid dispersions, respectively, in opposite rank order of their in vitro dissolution data. The reason was speculated to be due to the crystallization-inhibitory role of HPMC during dissolution. Similarly, an in vitro dissolution study indicated that supersaturation was maintained for an amorphous solid dispersion of albendazole in hydroxypropyl methylcellulose phthalate (HP-55), but not with HPMC,[190] which lead to its higher in vivo performance in rabbits.[190]

2.8 SPECIAL TOPICS

2.8.1 Polymorph screening and stable form screening

Polymorph screening is a practice focusing on the discovery of crystalline solids, mostly polymorphs. However, it includes the search for hydrates and solvates as well. Historically, polymorph screening usually included the following approaches:

1. Recrystallization under various conditions: the crystallinity of the original solid is removed by dissolving in solutions or melting. Crystallinity is then regenerated under a variety of conditions (such as temperature, solvent, supersaturation, additives, etc.) to see whether it results in other crystal forms.
2. Examining the solid-solid transitions induced by heat, humidity, mechanical stresses, etc.

Although it is valuable to screen and discover all crystal forms for a particular compound, finding the most stable polymorph is practically the most important aspect in polymorph screening. A polymorph-screening procedure that provides a greater probability of finding the stable polymorph was formulated.[191] The use of a suspension/slurry and the principle of SMPT to facilitate this process was described in detail as follows:

1. Recrystallization:
   a. Use the available polymorph.
   b. Ensure complete dissolution of the solid, to eliminate any seeds of the original polymorph.
   c. Recrystallize at a low rate, either at a low cooling rate or at a low rate of solvent evaporation.
   d. Use a wide range of final temperatures. If cooling crystallization is employed, the induction time and the rate of transformation of the metastable phase to the stable phase may vary with temperature.
2. After recrystallization, add a small amount of the original polymorph to the suspension and stir for various times, and examine the solid phase regularly. The length of time depends on the compound of interest, and the longer the better, provided that it has satisfactory chemical stability in the solution. The minimum time recommended is 7 days.
3. A range of solvents, with a variety of different characteristics such as hydrogen bonding, dielectric constant, solvency for the compound, should be employed.

This procedure improves the chance of finding the stable polymorph when a new pharmaceutical candidate is under investigation. Although slightly more time and effort are required, this procedure is technically easy, and the outcome may easily outweigh the effort.

Recently, one variation of this procedure, where initial crystallization was not performed, was reported being used in the routine early screening for stable phases.[192] Encouraging statistical data were reported by the authors:

> Based on limited statistics ($n = 43$), approximately 26% of early discovery compounds (received as crystalline phases) converted to more stable polymorphs during the stable polymorph screen. To date, more stable polymorphs have not been observed for any of those 43 candidates that have advanced into development.

2.8.2 High-Throughput crystallization

Automation in crystallization has been on the rise in recent years and has shown great promise in the areas of polymorph screening and crystal engineering; that is, searching for cocrystals of better physicochemical properties.[193–196] There are several advantages of robotic crystallization over conventional manual crystallization. First, the robot is designed to perform tasks in a parallel fashion; therefore, it is able to

examine the various parameters quickly. Second, because of the rapidity, robotic crystallization is able to explore parameters influencing crystallization more thoroughly, leading to a better understanding. Third, robotic crystallization requires less material. Fourth, because of the thoroughness, robotic crystallization may produce crystal forms that are otherwise not accessible by conventional crystallization.

2.8.3 Miniaturization in crystallization

Another trend in the crystallization of pharmaceutical materials is miniaturization. Reducing the material needed is essential for studies during early development, where the cost of API is extremely high and availability is scarce. Several studies were conducted using capillary tubes.[197–199] In addition to the benefit of reduced material consumption (5–50 μL of solution), the authors reported the discovery of previous unknown polymorphs owing to crystallization in a confined space in some cases.

Most recently, microfluidics technology that is capable of scaling down further by 10- to 100-fold has been applied to crystallization. Although most of the current applications are toward the crystallization of proteins,[200–203] the extension to pharmaceutically relevant small molecules has already begun.[204–206]

CHAPTER

3

Solid-State Characterization and Techniques

D. Law and D. Zhou

AbbVie Inc., North Chicago, IL, United States

3.1 INTRODUCTION

Understanding characterization of pharmaceutical solids encompasses three areas: (1) single-component characterization such as raw material, active pharmaceutical ingredient (API), excipient; (2) formulation or multicomponent characterization; and (3) understanding the pros and cons of the analytical techniques used in the characterization. All or most analytical techniques usually rely on measuring response to a perturbation. Therefore, analytical measurements of a solid pose a particular challenge because it is in a condensed state and thus has slower molecular mobility. Consequently for solids, be it crystalline or amorphous, the response is weaker than in a solution, and any additional heterogeneity contributes to variability in the signal. Heterogeneity arises from differences in particle size, morphology, trace impurities, and crystal defects that are inherent to all pharmaceutical solids. In addition, for formulations, the presence of excipients further complicates the analysis. Therefore, multiple methods are utilized before conclusions can be drawn. It is analogous to solving a jigsaw puzzle where each technique provides a piece of the answer, and at the end, each piece is required to sum up to provide a consistent picture. Consequently there exists a plethora of techniques that are utilized by pharmaceutical scientists, and these range from evaluating macroscopic properties such as surface area and particle size to molecular properties such as crystal packing, molecular mobility, and solid-state interaction. Additionally some of these techniques glean information about the powder bed, for example, flow or compressibility, while others provide information regarding intrinsic properties such as crystal packing. Furthermore, combination techniques, which are also called hyphenated techniques, for example, variable temperature-powder X-ray diffraction (PXRD), are becoming more and more popular in recent times because they allow multifaceted evaluation and increased sensitivity.

It is not possible to describe every technique a pharmaceutical scientist utilizes in the development of solid dosage form. Therefore, it is acknowledged that there are numerous commonly used techniques both macroscopic, such as specific surface area measurement, flow property evaluation, and compressibility, as well as molecular-level evaluations such as pycnometry, dielectric spectroscopy, and terahertz pulsed spectroscopy, that are not discussed in this chapter, nor is it possible to provide an in-depth description of each technique with respect to theory and fundamentals as well as applications. There are several excellent books available that describe the instrumental fundaments. The focus of the chapter will be to provide an understanding of some commonly used techniques with a few examples on the application of the techniques for pharmaceutical scientists.

The chapter will cover some of the more commonly used techniques that are used for solid-state characterization of both APIs as well as formulations. For each technique, the section provides an introduction to the technique including a brief summary of the fundamentals followed by examples/citations of the use of the technique for characterization for a single component (eg, API ingredient) as well as multicomponent (eg, formulation) system. The conclusion of each section will outline some pros and cons associated with each technique. The goal for each section will be to highlight the technique with respect to its application as well as to provide the reader with citations that are valuable for further research.

3.2 MICROSCOPY

Microscopy as a tool for analyzing pharmaceuticals is common because it forms a very powerful basis for characterization of pharmaceutical solids. Fundamentals of this technique can be found in several books.[1] There are several types of microscopes that are used for solid-state characterization, and a few have been discussed in this section. The method selected here considers the basis of interaction with the sample: (1) light or photon interaction is the basis for optical microscopy, (2) electrons instead of light constitute electron microscopy, and (3) a probe may be used to generate the image in the case of probe microscopy. The first two of the three techniques are most common; therefore, emphasis will be placed on optical and electron microscopy.

3.2.1 Optical microscopy

An optical microscope or light microscope uses visible light and a system of lenses to magnify a small sample. A basic optical microscope can be as simple as a magnifying glass (single lens microscope). For pharmaceutical applications, compound microscopes generally are used because they provide better resolution. Often these compound microscopes are connected to a charge-coupled device camera so that images can be directly viewed on a computer screen.

A cartoon of a compound optical microscope is presented in Fig. 3.1a. The ocular lens or the eyepiece provides 10× to 15× magnification and is connected via a barrel to the objective lenses. The objective lenses can be raised or lowered via the arm, and they revolve around the nosepiece. These lenses come in various magnifications, for example, 4×, 10×, 40×, and 100×, and are distinctly marked. Usually there are four lenses. Below the lens is the stage where the sample slide is placed. There are clips on this stage to hold the sample slide in place. The adjustment knobs on the side of the microscope involve both coarse and fine adjustments and are used to bring the sample into focus. Located below the stage is the lamp or the light source, and its brightness can be adjusted using the dimmer. The diaphragm is a circular disc between the lamp and the stage that varies the light intensity going through the sample.

A special case of compound microscope is the polarizing microscope, where a polarizer is placed after the light source. The sample is placed on a rotating stage, and an analyzer is placed before the eyepiece. Polarizing light microscopy exploits electromagnetic properties of light and anisotropy of crystalline solids to generate pleochroism.

If we follow Fig. 3.1b, light is an electromagnetic wave, or it is constructed of a longitudinal wave or the electric spectra, and at 90° to it is the lateral wave or the magnetic spectra. Focusing only on the electric wave vector, ordinary light or nonpolarized light has vectors at all different directions. When nonpolarized light is passed through an element called the polarizer, linear polarized light can be produced. This element has a slit that allows light to pass through in only in one direction. Crystals are usually anisotropic with intrinsic properties related to crystal packing, for example, refractive indices are different in different directions. There are, however, crystalline materials such as sodium chloride that are isotropic, but most pharmaceutical crystals are anisotropic. If an anisotropic material is placed in the path of the polarized light, it will split the beam into two perpendicular components: magnetic and electric. This ability to split the light is called birefringence. The velocities of the components will be dependent on the sample's intrinsic properties. When this light passes through the analyzer, which is simply another polarizer but placed perpendicular to the previous polarizer, the analyzer

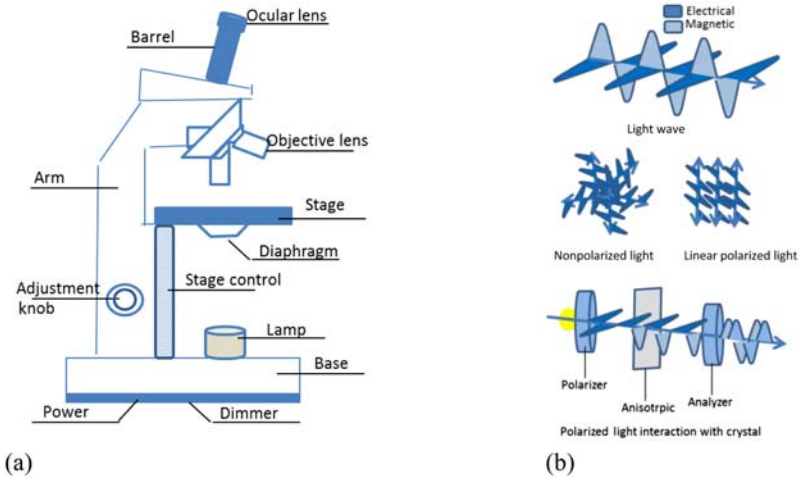

FIGURE 3.1 (a) Light microscope. (b) Polarized and unpolarized light and interaction of polarized light anisotropic sample.

combines the light. The difference in velocity will lead to constructive and destructive interference.

If the birefringent specimen is rotated, it produces brilliant colors as well as extinctions depending on the angle of the rotating stage. On the other hand, if the specimen is isotropic (ie, intrinsic properties are the same in all directions viewed with a set of polarizers), then either all light will pass through it and it looks bright, or no light will pass through, and it looks dark. Polarized light microscopy is a simple but a powerful tool to the pharmaceutical scientist and often is the first technique used to identify if the sample is amorphous or crystalline. In addition to optical microscopy and polarized light microscopy, there are other techniques such as fluorescent microscopy and phase contrast microscopy that are used to limited extent by pharmaceutical scientists.

Most pharmaceutical active ingredients are crystalline, and the molecules are packed to produce a 3-D periodicity over a long range. This 3-D periodicity influences a variety of properties, and one such influence is the way the material interacts with light. The spacing of molecules along the crystallographic axis determines the crystal system, most notably the optical properties. Extreme cases are diamond and graphite. In the case of diamond, the C-atoms atoms have a tetrahedral arrangement, creating planes that synergistically refract the light producing its brilliance, while the same C-atom assumes a planar structure with hexagonal packing that synergistically absorbs light, and it looks black. Likewise, pharmaceuticals do exhibit marketedly different optical properties and, therefore, can be easily identified using optical microscope. For example, ROY or 5-methyl-2-[(2-nitrophenyl)amino]-3-thiophenecarbonitrile, is known for its red, orange, and yellow crystals and has seven polymorphs with solved structures, which is the largest number in the Cambridge Structural Database (Fig. 3.2).[2]

Polarized light microscopes have frequently been used for monitoring, understanding, and observing phase changes. For example, the amorphous-to-crystalline transition[3] was monitored during the dissolution of indomethacin (Fig. 3.3a), while the degradation studies[4] of different crystal forms of indomethacin were monitored as seen in Fig. 3.3b.

As noted by the authors[2] themselves, it is rare in the pharmaceutical field to have polymorphs of different colors. Most active pharmaceuticals (both API and excipients) are white to off-white powders. However, when viewed under a polarized light microscope, they can exhibit birefringence that is inherent to the crystal form. Depending on pleochroism of the different polymorphs, it might be possible to use a polarized light microscope to identify different polymorphs. This method was particularly useful for studying phase transition of the low-dose pharmaceutical (Fig. 3.4).[5]

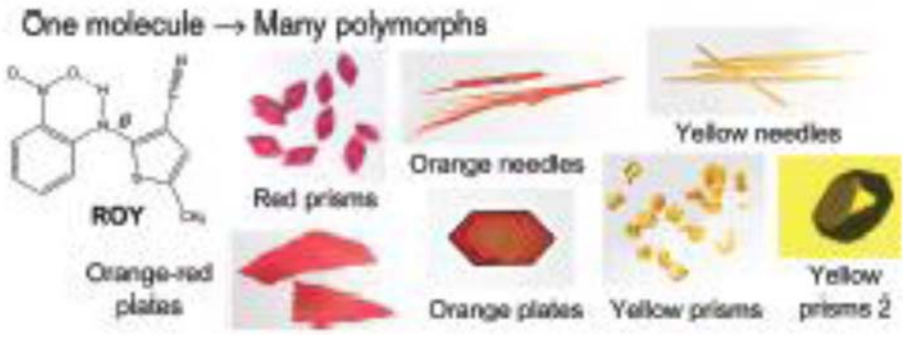

FIGURE 3.2 Crystalline polymorphs of ROY: different polymorphs viewed using optical microscope.

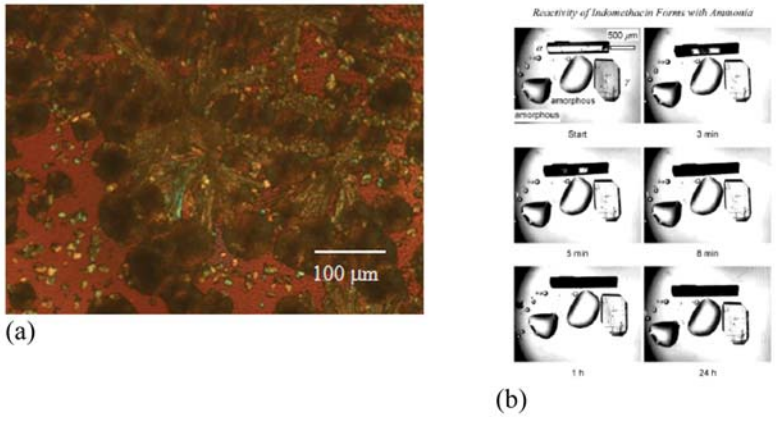

FIGURE 3.3 (a) Solvent-mediated crystallization from amorphous. (b) Decomposition of different forms of indomethacin.

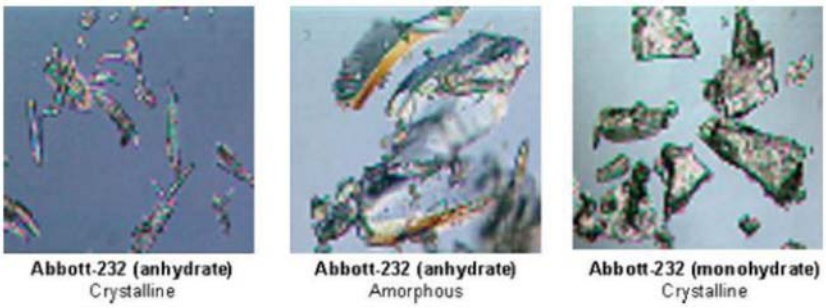

FIGURE 3.4 Different crystal forms exhibit different birefringence.

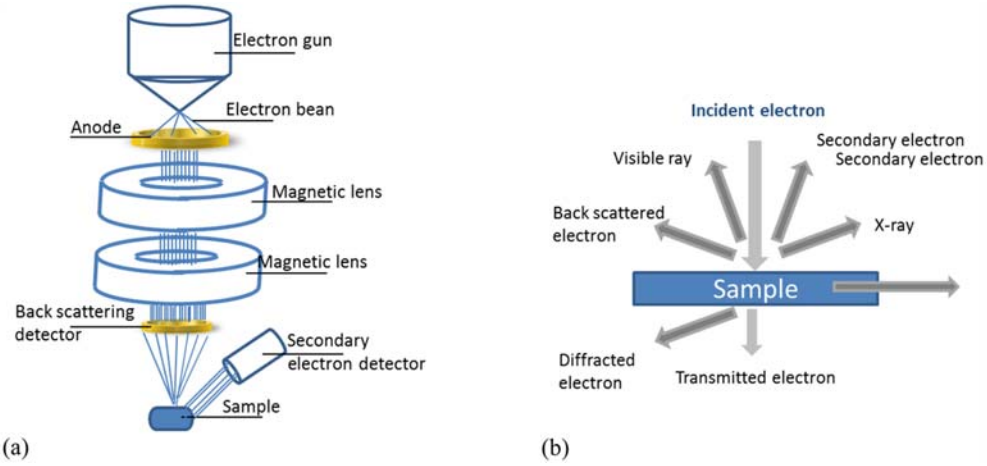

FIGURE 3.5 (a) Schematic principle of electron microscope. (b) Electrons scattering by the sample.

In this case, the authors found that when the crystals were oriented in a certain direction, one crystal form was pleochroic, while the other was not; thus they could identify the presence of the correct form in the tablet using a polarized light microscope. These are only a few applications of optical microscopy, illustrating that although it is a qualitative technique, it is also a useful tool for analyzing both API and formulations.

3.2.2 Electron microscopy

Unlike light microscopy, in the case of electron microscopy, electrons are used instead of light. There are two main types of electron microscopes: scanning electron microscopes (SEM) and transmission electron microscopes (TEM). As the name suggests, in SEM, the electron beam scans the surface, while in TEM the beam is transmitted through a thin specimen. For pharmaceutical solids, SEM is more widely used than TEM because the latter does require the production of thin films. Therefore, this section will focus on fundamentals and the use of SEM for pharmaceutical applications.

Fig. 3.5a provides a schematic for the operation of a SEM. It consists of an electron gun that releases electrons. This gun is usually a tungsten filament heated to 2400°C when it starts emitting electrons. These electrons go through an anode, which being positively charged accelerates and collimates the electrons. The accelerating potential can be varied by the operator from 1 to 30 kV. In the case of an optical microscope, glass lenses are used, while an electron microscope uses magnetic lens. The magnetic lens focuses the electrons into a narrow electron beam as well as controls the amount of electrons hitting the surface of the sample. Then there are detectors that collect the signal and are connected to computers that construct the image. Before discussing the detectors, it is important to take a minute to discuss what happens when the electron beam encounters the sample.

When electron beams encounter the sample, electrons can be absorbed, reflected, excite the surface releasing secondary electrons, or emit specific radiation (Fig. 3.5b). The reflected electron is the backscattered electrons, so there is always a backscattering detector. The most important signal comes from the secondary electrons. This signal is used to construct the surface structure of the sample. Since there is no light that is used for this technique, one cannot see the sample or colors; it is the distance these secondary electrons travel that allows for the construction of the image. There may be some sample-specific X-ray radiation generated by the absorbed electrons, so

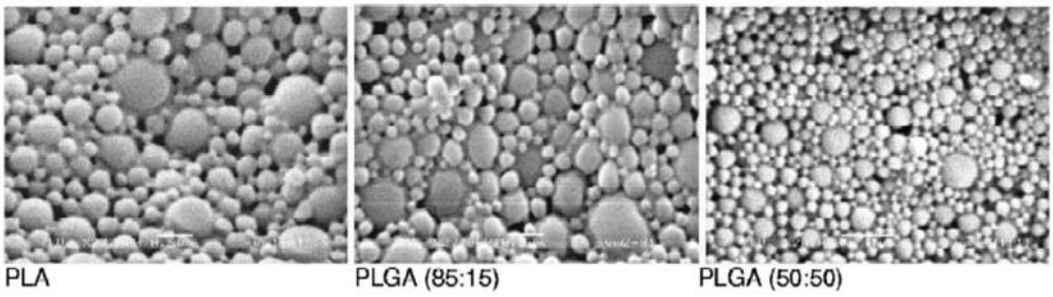

FIGURE 3.6 SEM image of TPGS impact on PLGA nanoparticles.

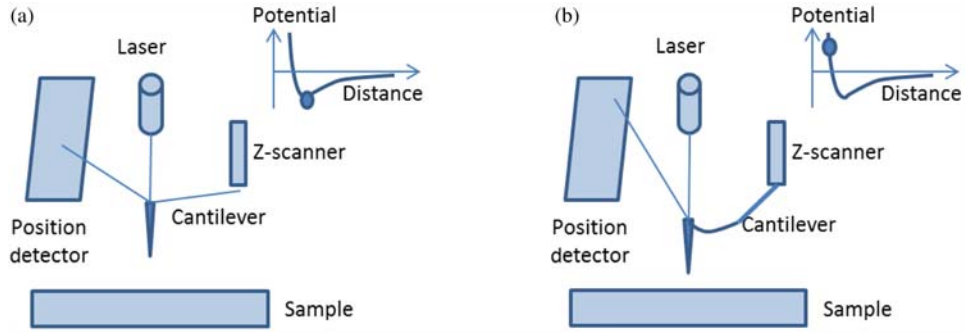

FIGURE 3.7 Schematic principle of an atomic force microscope with cantilever at a reference position (a) and with cantilever scanning down to sample surface (b).

sometimes SEMs have X-ray detectors in addition to backscattering and secondary electron detectors. These X-ray detectors, if present, can provide some information regarding the surface composition.

The most popular application of SEM in the field of pharmaceuticals is in the evaluation and understanding of the morphology of APIs, excipients, and granulations. Here is one application[6]: paclitaxel is an anticancer agent that has exhibited solubility-related drug delivery challenges. Although formulations with cremophor have proven to be successful in paclitaxel delivery, this surfactant has toxic side effects; therefore, TPGS-PLGA nanoparticles were explored to minimize toxicity. As seen in Fig. 3.6, SEM provided valuable information regarding the impact of nanoparticle morphology as a function of TPGS concentration as well as the mechanism in which the TPGS was incorporated.

3.2.3 Probe microscopy

Probe microscopy is the next step or an extension of electron microscopy. These methods allow still higher resolution than SEM or TEM. In this case, the sample surface at an atomic or molecular scale or nanoscale dimensions can be evaluated using a sharp cantilever tip. There are two types of microscopes in this field: (1) a scanning tunneling microscope (STM) and (2) an atomic force microscope (AFM). Since the AFM is more widely used in the pharmaceutical field, this section will focus only on AFM techniques and applications. The basic principle of AFM is outlined in Fig. 3.7. In AFM, a cantilever with a very sharp tip is used to scan the sample surface. As the cantilever approaches the surface, the attractive forces cause the cantilever to bend, but as the cantilever gets close to the surface such that it makes contact, repulsive forces takeover, causing the cantilever to deflect away from the surface. A laser coupled with a photo-diode is used to monitor the deflection of the cantilever. This deflection as a function of surface topography is then used to generate the sample image. This is the description when the instrument is operated in contact mode. AFM is currently available in contact mode, tapping mode, and peak force tapping mode, and the different modes are used to obtain the desired resolution.

Some of the early pioneering work using molecular crystals in the field of AFM evaluated crystallization from a solution phase. Fig. 3.8a shows the crystallization of calcite in the absence and presence of aspartic acid.[7] The addition of aspartic acid to growth solutions has a dramatic effect on the spiral morphology, with the crystal growth hillocks becoming asymmetric and rounded. The authors evaluated growth mechanisms in both organic solution as well as biomaterials, which led to greater understanding of the molecular

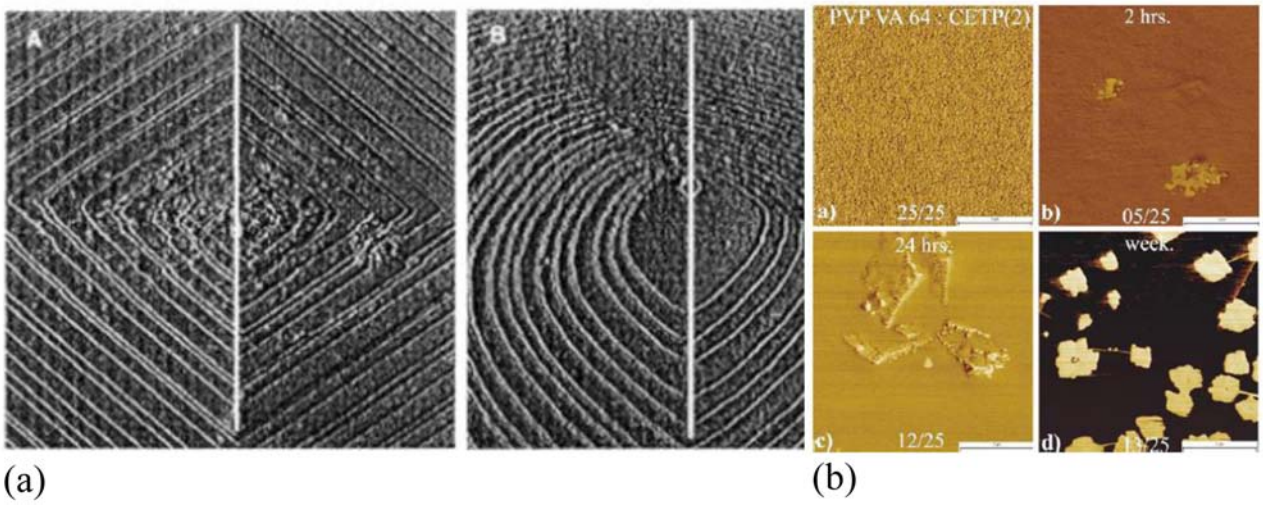

FIGURE 3.8 (a) Crystallization of pure calcite in the presence of aspartic acid. (b) Crystallization of amorphous formulation when exposed to high relative humidity.

organization in the crystal lattice. More recently, AFM was used to evaluate formulation stability. Again, an example has been provided[8]: In Fig. 3.8b, amorphous formulations (of CETP inhibitor) in a polymer (PVP VA 64) were exposed to 75% RH, and crystal growth was monitored as a function of time. The authors evaluated a list of polymers for developing amorphous formulation (Eudragit L100, HPMCAS, PVP, etc.), and these studies allowed them to choose the polymer that provided the best stability when exposed to humidity. These microscopic techniques, although not quantitative, are powerful in detecting small changes in samples with the best precision.

The microscopes described in this section vary from those that are simple and provide information regarding morphology to highly sophisticated ones that allow visualization of crystal growth steps. The key advantages of microscopy are that one can see the sample, small changes can be detected, and a very small amount of sample is required, but the technique is qualitative and visual, not quantitative.

3.3 POWDER X-RAY DIFFRACTION

X-ray diffraction techniques have been used for determining crystal structure, but in the pharmaceutical industry, by far the most common use of X-ray diffraction is associated with analyzing powder samples. This technique is nondestructive and is typically used for evaluating the degree of crystallinity, characterizing polymorphs and solvates, and the study of phase transitions.

Crystalline solids have long-range 3-D periodicity. The unit cell as shown in Fig. 3.9a is the basic repeating unit or symmetry that defines the crystal lattice structure. This unit repeats in all three dimensions over a long range to produce the crystal structure (Fig. 3.9b). It can be envisioned that the molecules in the unit cell can pack in different ways, producing different crystal structures. When a pharmaceutical solid can exist in different molecular packing, it is said to exhibit polymorphism. Since this crystal structure influences the intrinsic properties of a solid, understanding it is an integral aspect of drug development. A dramatic impact of packing can be demonstrated with diamond (Fig. 3.9c) and graphite (Fig. 3.9d). In diamond the tetrahedral packing of carbon results in planes that reflect light synergistically, producing its luster. In graphite the same carbon packs in laminar layers, allowing synergistic light absorption causing a black appearance. Diamond is one of the hardest known crystals, whereas in the case of graphite, the planar layers can slide under stress, making graphite a relatively soft crystal that can readily deform. This example demonstrates the consequence of packing the results in dramatically different responses to light or mechanical stress perturbation. In fact, crystal packing can influence thermodynamic properties such as melting and solubility, kinetic properties such as stability and dissolution, and surface properties such as morphology and spectroscopic properties.[9]

Therefore, in order to have consistent bioavailability, stability, or manufacturability, it is essential to maintain the desired crystal form for the API or excipient, thus making utilization of powder diffraction technique essential for drug development as well as on-market support. A brief description of the concept and experimental technique is discussed, but the reader should refer to specialized textbooks for details.[10,11]

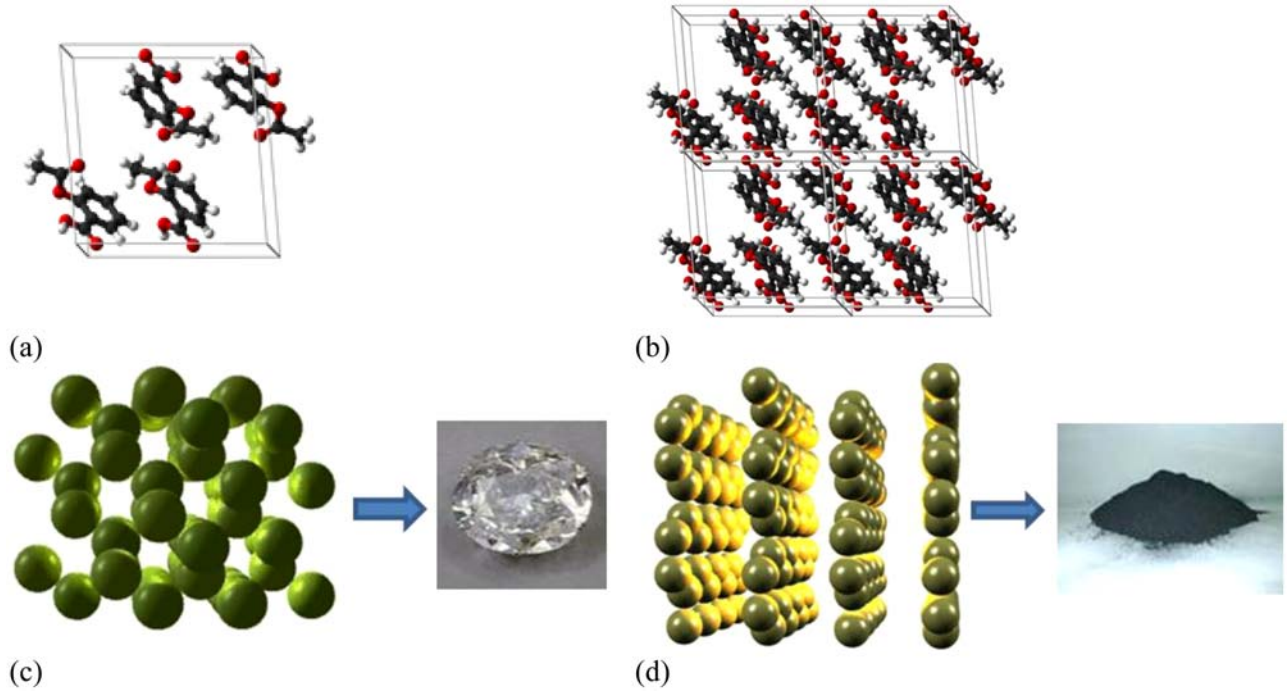

FIGURE 3.9 (a) Unit cell. (b) 3-D repeat of unit cell leads to the long-range periodicity. (c) Tetrahedral packing of C in diamond. (d) Planar packing of C in graphite.

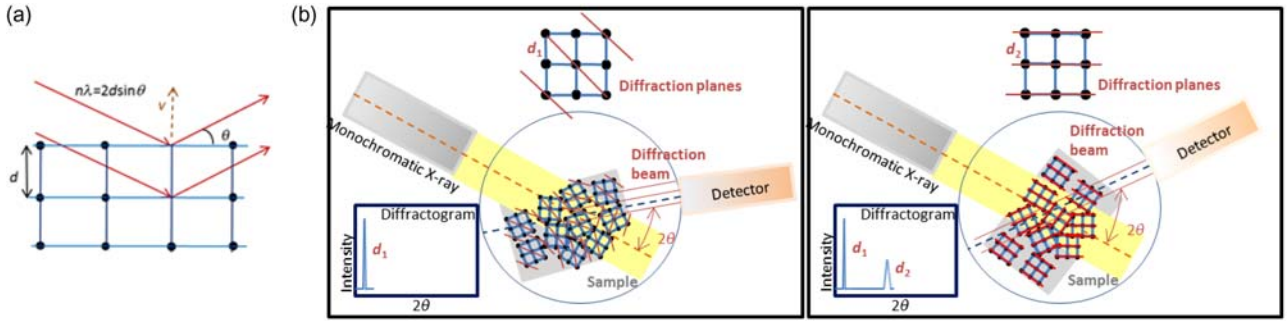

FIGURE 3.10 (a) Bragg diffraction condition for coherent scattering. (b) A θ:2θ arrangement for generating diffraction patterns.

The diffraction patterns depend on a series of planes in a crystal lattice. The orientation of these planes is a function of the molecular packing and is defined by Miller indices by considering how the planes intersect the main crystallographic axes of the solid. A set of rules leads to the assignment of the Miller indices (*hkl*), which is a group of numbers that represent the reciprocal axial intercepts and uniquely identify the planes of a crystal. Although Miller notations are used to define direction as well as planes, for the purpose of this discussion, only planes (*hkl*) and family of planes {*hkl*} will be considered.

Diffraction is a *scattering* phenomenon. X-rays are electromagnetic radiation that lie between ultraviolet (UV) and gamma radiation in the electromagnetic spectrum, and when X-rays are incidental to crystalline solids, they are scattered in all directions. Bragg's law (Fig. 3.10a) describes the conditions under which these scattered beams are completely in phase and reinforce one another to form diffracted beams. Thus, per Bragg's law, diffraction will occur if a perfectly parallel and monochromatic X-ray beam of wavelength λ is incident on a crystalline sample at an angle θ:

$$n\lambda = 2d_{hkl}\sin\theta$$

where d_{hkl} is the vector extending from the origin to the plane (*hkl*). The magnitude of this vector is the distance between parallel planes in the {*hkl*}. In most diffractometers, X-ray wavelength is fixed so the family planes produce peaks as a function θ (Fig. 3.10b).

The essential parts of an X-ray diffractometer are: (1) X-ray tube or the source; (2) incident-beam optics, which consists of the slits and monochromators that remove unwanted radiation, reduce divergence, and refocus the beam to parallel path; (3) the goniometer consisting of the platform that holds and moves the sample, optics, detector, and/or tube; (4) the sample and the sample holder; (5) the receiving-side optics that conditions the diffracted beam; and (6) the detector that counts the number of X-rays scattered by the sample.

Typically the source where X-rays are produced is an evacuated tube similar to cathode ray tubes. An applied current heats up a cathode filament (eg, tungsten), which liberates electrons. The liberated electrons are accelerated by a high-voltage potential toward a target, which is a metal anode. The bombarding electrons generate X-rays from the anode. Most instruments today use copper (Cu) as the anode. The bombarding electrons eject electrons from the inner shells of the atoms of the target metal (Cu) producing vacancies. Those vacancies are quickly filled by electrons dropping down from higher levels, emitting X-rays with sharply defined frequencies. The X-rays pass through a slit, which determines the angular width of the beams. Wider slits give more energy but also give wider diffraction lines and, therefore, lesser resolution. The beam then passes through a filter that removes undesired radiation. Note in the case of the Cu anode there are three types of radiation: CuKα1, CuKα2, and CuKβ. The lines for CuKα1 and CuKα2 are overlapping; these are used for most X-ray diffraction techniques. The low-energy CuKβ is filtered out by a nickel filter. Some very expensive instruments can also remove the CuKα2, providing extremely high resolution. The beams are incident to a sample at an angle θ, and the diffraction vector v bisects the incident and diffracted beam. X-rays at an angle θ are reflected by internal crystal planes separated by distance d. Bragg diffraction results from constructive interference when the quantity $2d\sin\theta$ is an integral number of wavelengths. Before discussing the sample or the detector, it is important discuss the goniometer.

The goniometers satisfy the Bragg–Brentano geometries where the diffraction vector v is normal to the sample. There are two different setups that are common. The setup shown in Fig. 3.10b is a θ:2θ arrangement where the source is fixed. The sample moves at θ°/minutes, while the detector rotates at $2\theta^\circ$/minutes. This setup allows for precision movement of the goniometer but has the disadvantage that the sample is vertical and often falls off the holder. In θ:θ arrangement, the sample is always vertical, while both the source and the detector move at θ°/minutes.

In Fig. 3.10b, the polycrystalline powder packed in a sample holder contains thousands of crystallites, allowing for the observance of all possible diffraction peaks. The basic assumption is that for every set of planes there is an equal number of crystallites that will diffract, and there is a statistically relevant number of crystallites. In reality only a small fraction of crystallites in the sample contribute to the diffraction pattern; therefore, unusably, the sensitivity is increased by spinning the sample. The diffraction patterns are collected as 2θ versus intensity, and for pharmaceuticals, this is how the data are represented. The more accurate representation would be to transform the data such that the representation eliminates instrumental parameters. This transformation involves normalizing the peak intensities to the area of the largest peak and using Bragg's relationship to convert the 2θ values to d_{hkl}, an intrinsic property since it corresponds to a family of planes in the sample.

Finally a few words regarding the detector: the two common types of detectors are a point detector and a position sensitive detector. One type of detector from each of these two categories will be briefly mentioned. The scintillation counter is a point detector that converts X-ray photons to an electrical signal in a two-stage process. The photons collide with a scintillator producing photons in the blue region of the visible spectrum. These photons are then converted to a signal or voltage pulse by means of a photomultiplier. The scintillation counters have high efficiency in response time, making them ideal for point intensity measurements, but the energy resolution is poor. Although gas-filled point detectors are available, these are less common than gas-filled position sensitive detectors. The gas-filled detectors work on the principle that X-ray photons can ionize inert gas. Since the ionization energy is low, an X-ray photon can produce several hundred ion pairs. These ion pairs are accelerated toward a wire causing further ionization. The burst of electrons is then converted to a voltage pulse, which is shaped and counted by the electronics. The use of special types of wires and a multichannel analyzer enables this type of detector to record data over a large range of scattering angles, improving the speed of acquisition.

PXRD is the gold standard for solid form identification. Today every drug development program starts by identifying the most developable crystal form and uses X-ray diffraction as a tool for characterizing API or the drug product. Therefore, there are various review articles written on this technique[12–14] as well as books.[15] Not only is the technique used for the identification of the solid phase, it has been used for studying the kinetics of phase transformation examples during processing,[16,17] quantitative determination of polymorphic phases in a mixture or quantitative determination of degree of crystallinity,[18] stability studies for amorphous formulations,[19] and the analysis of counterfeit product.[20]

This gold standard technique for phase identification is largely a qualitative technique. Through careful experimental design, quantitative information has been extracted, but it is not possible to obtain thermodynamic quantities or even information regarding functional groups in the molecules using this method.

3.4 THERMAL ANALYSIS

Thermal properties (eg, heat, heat capacity, mechanical, and gravimetric) accompanying physical and/or chemical changes may be revealed when a sample is subjected to a temperature program (heating, cooling, or isothermal). The methods for characterizing these changes are called thermal analysis, and they provide information on the underlying physical or chemical processes such as phase transition, chemical reaction, and decomposition. Since 1887 when Le Chatelier conducted the first thermal analysis experiment, the techniques have matured in theory, instrumentation, and automation, and they have become the standard tools used in many fields. Thermal analysis is widely used in characterizing pharmaceutical solids. A number of reviews are available on the applications of thermal analysis to pharmaceuticals.[21–24]

3.4.1 Differential scanning calorimetry

3.4.1.1 Instrumentation

Differential scanning calorimetry (DSC) is a further development of the earlier technique called differential thermal analysis (DTA). In both DSC and DTA, a sample is measured against an inert reference. In DTA, the sample and the reference are heated simultaneously in a single furnace with a symmetrical design. The temperatures of both parts are expected to be the same after a short equilibration time, but that of the sample may change at a different rate from the reference during a thermal event, such as freezing, melting, evaporation, dehydration/desolvation, or glass transition. The temperature difference (ΔT) between the sample and the reference is recorded during a controlled temperature program (heating/cooling). However, the classical DTA instrumentation design where thermocouple junction is inserted into the sample prevents a true quantitative analysis. Significant temperature inhomogeneity or temperature gradient may exist in the sample for classical DTA, which renders the quantitative results of a thermal event dependent on its apparent thermal resistance, which is a function of the nature of the material, morphology, and sample preparation such as packing density.

The Boersma design[25] introduced a controlled heat leak by inserting a low-resistance heat flow path between the sample and the reference by placing the thermocouple junction outside (just below the sample platform) the sample to reduce the impact of thermal resistance on ΔT. The Boersma design results in a much smaller ΔT because of the good thermal contact, which diminishes the impact on the measured heat flow by the apparent sample thermal resistance and makes the technique quantitative for calorimetric information. So the Boersma DTA becomes a calorimetry and bears the name of heat-flux DSC, or hf-DSC. The hf-DSC measures heat flow indirectly as a result of the ΔT, and the calorimetric information is obtained through calibration using a known standard.

Another design is called power compensation DSC (pc-DSC). In pc-DSC the sample and references are enclosed into separate furnaces that are controlled independently. The temperatures of the sample and the reference are made identical by varying the power input into the two furnaces. The difference in power measures the changes in enthalpy or heat capacity of the sample relative to the reference. Pc-DSC directly measures the enthalpy changes against a reference and has improved sensitivity.

Fig. 3.11 illustrates the key design differences between heat flux and power compensation DSCs.

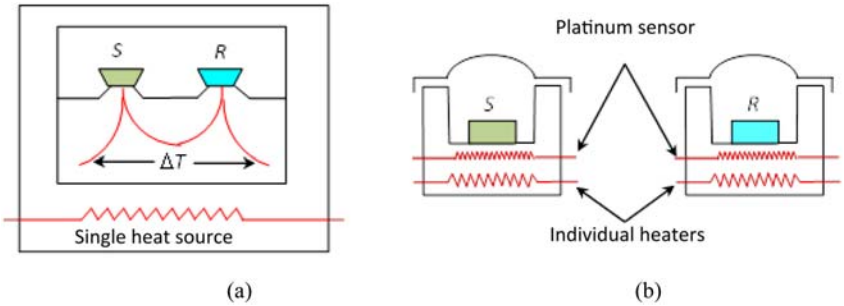

FIGURE 3.11 Schematic representation of hf-DSC (a) and pc-DSC (b) (*S* = sample, *R* = reference).

Conventional DSC employs a linear heating or linear cooling method, so the reference temperature profile may be represented as:

$$T = T_0 + ßt$$

where T_0 is the initial temperature, $ß$ is the linear heating rate (°C/minutes or K/minutes), and t is the heating time (minutes). The heat flow, dQ/dt, at constant pressure may be represented as:

$$\left(\frac{dQ}{dt}\right)_p = mC_p ß + f(T,t)$$

where m is the mass of the sample, C_p is the specific thermodynamic heat capacity ($J.K^{-1}.mol^{-1}$), and $f(T,t)$ represents heat flow due to a kinetic process (physical or chemical). The total heat flow is composed of two parts. One part is a function of the sample's true heat capacity, and the other, $f(T,t)$, is a function of temperature and time. However, these two components are not separated by the conventional DSC.

In temperature-modulated DSC (TMDSC), a periodic temperature modulation is added to a linear heating/cooling or isothermal temperature program. Temperature modulations such as sinusoids (sine or cosine) are the most convenient forms, but other forms such as sawtooth have also been used. The temperature program for a sinusoidal modulation may be represented as:

$$T = T_0 + ßt + A\sin(\omega t + \varphi)$$

where A is the amplitude, ω is the modulation frequency, and φ is phase angle.

Fourier transformation is applied in TMDSC to deconvolute the apparent heat flow signal into a reversible and a nonreversible component. The separation of heat flow facilitates the study and interpretation of many complex thermal events encountered for various materials. It also allows the thermodynamic heat capacity of a material to be measured more accurately. Fig. 3.12 provides an example of temperature modulation.

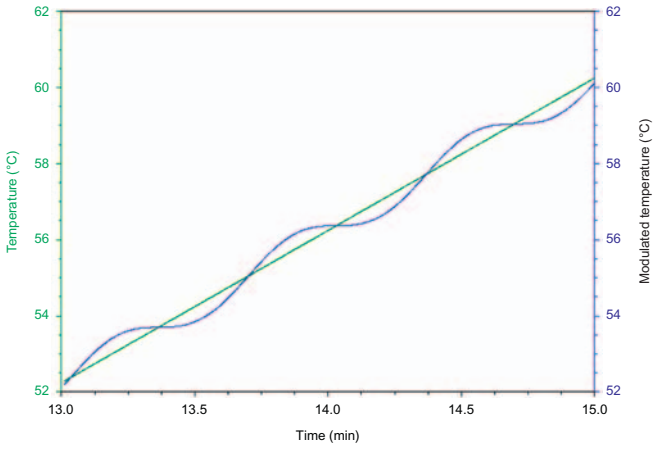

FIGURE 3.12 A representative temperature profile for TMDSC.

3.4.1.2 Applications

The following four applications are worth mentioning:

1. Melting and phase diagram.
2. Characterization of polymorphs.
3. Characterization of solvates/hydrates.
4. Characterization of amorphous phases.

3.4.1.2.1 Melting and phase diagram

DSC is widely used in the characterization of pharmaceutical solids commonly used in formulation/dosage form development. The melting temperature (T_m), enthalpy of melting (ΔH_m), and entropy of melting (ΔS_m) of a crystalline or partially crystalline material can be obtained readily from a simple DSC scan. As for any other first-order phase transitions, the change in free energy is zero during melting, therefore, $\Delta S_m = \Delta H_m/T_m$, where T_m is expressed on absolute scale (K). This relationship does not hold when melting is accompanied by other thermal events, such as decomposition, when there is no clean separation between those events.

Melting temperature depression occurs in the presence of impurities that are dissolvable and miscible in the liquid state. The formation of a liquid mixture lowers the free energy of the system; therefore, the system will melt at a lower temperature. The relationship can be derived based on ideal solution as follows:

$$\left(\frac{\partial \ln x_2}{\partial(1/T)}\right)_p = -\frac{\Delta H_m}{R}$$

$$\ln x = \frac{\Delta H_m}{R}\left(\frac{1}{T_{m,0}} - \frac{1}{T_m}\right)$$

where x is the concentration (molar fraction) of the substance of interest in the testing specimen, R is the universal gas constant, and $T_{m,0}$ is the melting temperature of the pure phase or a purity reference. This equation forms the basis of purity test by DSC.

DSC is a convenient tool to construct such phase diagrams of solids that are miscible in molten state. Mixtures of a binary system with varying compositions are scanned by DSC. The onset melting temperature of each component is recorded and then is plotted against the composition.

In a binary system consisting of two crystalline materials, the melting temperature of both will be lowered provided that the two materials are miscible in the liquid state, as dictated by the free energy decrease.

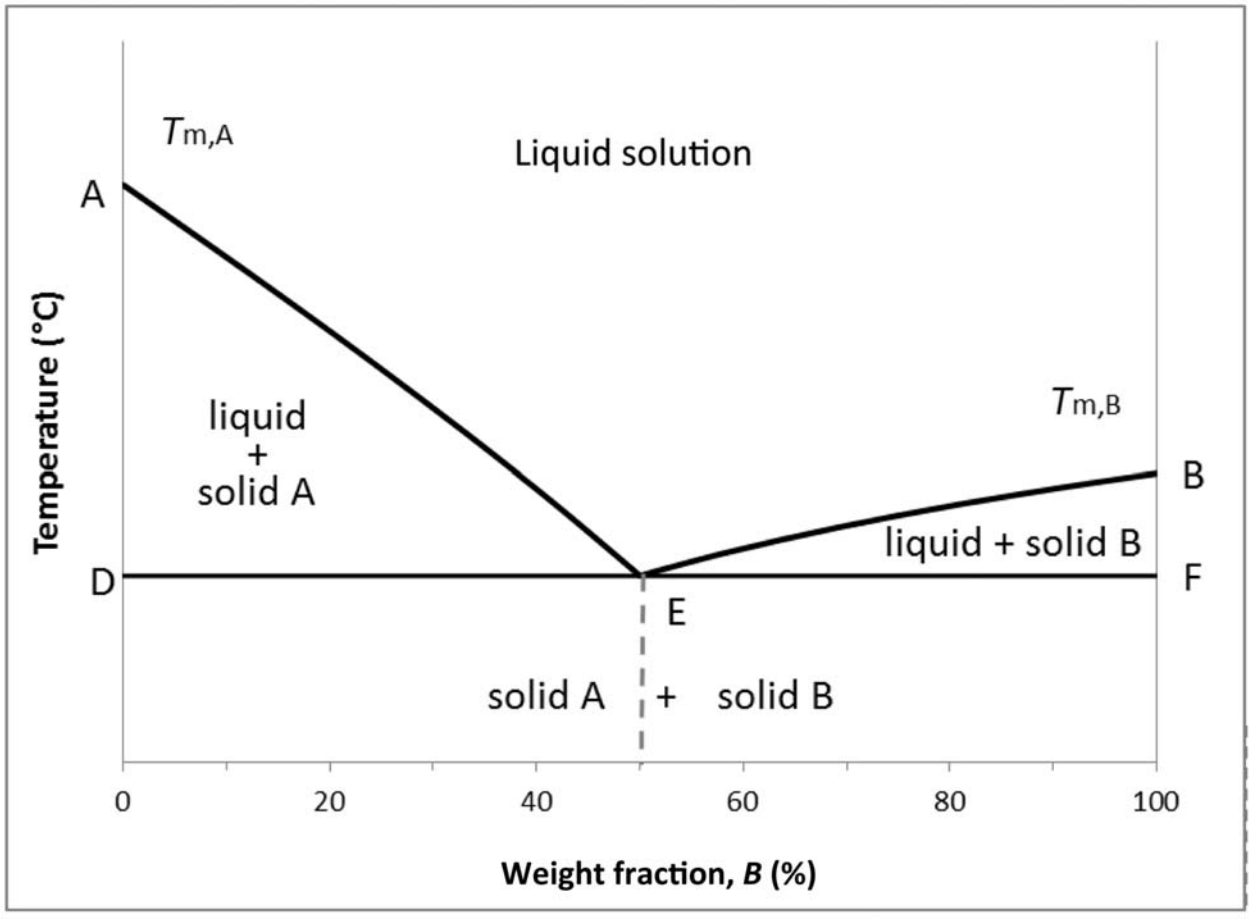

FIGURE 3.13 A basic phase diagram with eutectic melting.

Fig. 3.13 is a basic temperature-composition phase diagram of such a system. The melting temperature of component A follows the curve AE, which may be described by the above equation for melting depression of component A. Similarly, the melting point of component B follows the curve BE. At point E, both components reach equilibrium and melt at the same temperature. This temperature is called the eutectic temperature, and the corresponding composition is said to be a eutectic mixture.

3.4.1.2.2 Characterization of polymorphs

In the previous section on PXRD, it was discussed that polymorphism is the existence of more than one crystal packaging by the same molecule entity. Organic molecules including drugs are notorious for their formation of multiple crystalline forms.[26,27] Polymorphs can have a significant difference in solubility, stability, mechanical properties, and thermal properties and thus may impact formulation, manufacture, and performance of pharmaceutical products. Hence, agencies generally require that crystal forms of a drug substance be examined carefully against the properties that may be relevant to the dosage form design, process development, manufacturing, and in vivo performance of the product and implement appropriate controls to safeguard the identity, strength, quality, purity, and potency of the drug product.

Polymorphs represent the local minimums in the free energy landscape of the crystalline molecule. An important topic in polymorph characterization is to delineate the thermodynamic relationship among the different crystal forms. A thermodynamically more stable form is often preferred due to the less likelihood of phase transformation in general. Metastable forms could be used, and in some cases, they may be beneficial to the manufacturing process or in vivo performance. However, the incorporation of a metastable form may have significant implications to the dosage form design, manufacturing, storage, and regulatory compliance.

Two polymorphs may be thermodynamically related as enantiotropes or monotropes. In the temperature domain, an enantiotropic relationship exists if one form is more stable under one temperature range and the other more stable under another, that is, their conversion is thermodynamically reversible. On the

contrary, if one polymorph is always more stable at all temperatures (below the melting temperature), they are said to be related monotropically. The relationship could also be explained in terms of the transition temperature, T_t, which is the temperature where the two forms are in thermodynamic equilibrium (or change in free energy, $\Delta G = 0$). Two polymorphs are related enantiotropically if T_t lies below the melting temperatures of both forms; otherwise, they are monotropically related. The free energy landscape between any two polymorphs is represented as in Fig. 2.2.

The free energy relationship between two polymorphs may be determined by DSC. Polymorphic transformation is generally a solid-state phase transition and is often accompanied by a small change in enthalpy. If the interconversion is observed between two forms reversibly (ie, during heating and reversely during cooling), then the relationship is the enantiotropic. However, a transformation may not be observed in some cases due to insufficient kinetic rate, even if the transformation is thermodynamically favorable. In other words, a thermodynamically favorable polymorphic transformation may not happen during a DSC experiment. If a polymorphic transformation does occur at temperature T_{obs} during heating, the true transition temperature is somewhat below T_{obs} due to the kinetic lag. The same is true during a cooling cycle.

Burger and Ramburger[28,29] formulated several rules of polymorphic relationships based on DSC data. The heat of transition rule states that two forms are related enantiotropically if an endothermic transition is observed at some temperature, and they are related monotropically if an exothermic transition is observed at some temperature. The heat of fusion rule states that if the higher melting form has the lower heat of fusion, the two forms are usually enantiotropic. Otherwise they are monotropic. The form that melts at a higher temperature is always more stable at a high temperature. These two rules are well illustrated in Fig. 2.4.

Similarly to other rules of thumb, exceptions to the Burger and Ramburger rules do occur. A more comprehensive thermodynamic treatment of the polymorphic relationships was later introduced.[30] Yu's treatment considers both the fusion data and the temperature dependence of the extrapolated free energy differences and, therefore, can resolve the misclassifications by the Burger and Ramburger rules in some exceptions.

3.4.1.2.3 Characterization of hydrates

Many drug molecules form hydrates. A hydrate is a crystal packing fulfilled by the drug (host) molecules and water (guest) molecules via various intermolecular interactions, with hydrogen bonding (H-bond) interaction being particularly important. Nonspecific van der Waals interaction may also play important role in nonstoichiometric hydrates where the water molecules are simply occupying the void space in a crystal. Incorporation of water molecules in a crystal lattice changes many pharmaceutical properties.[31] A hydrate usually has lower aqueous solubility than its anhydrate, and a similar relationship exists between higher hydrates and lower hydrates. Other properties such as density, mechanical properties, physical and chemical stability could also be impacted.

Similarly to polymorphs (to that end a hydrate is also called a pseudopolymorph), physical stability of pharmaceutical hydrates is important to drug product development. Whether an anhydrate or a hydrate is selected for development, the risks of hydration/dehydration during manufacturing and storage should be understood because humidity, or the lack of, is ubiquitous in our environment. Appropriate measures should be implemented to prevent the inadvertent form conversion.

DSC is routinely used to characterize hydrates. As indicated in Chapter 2 "Crystalline and Amorphous Solids," a critical relative humidity, RH_C, exists for each hydrate. A hydrate is more stable at $RH > RH_C$ than the anhydrate or the lower hydrate, if it exists, and vice versa. While a conventional DSC is not capable of determining the critical RH for a hydrate, it is used extensively to identify and characterize a hydrate, and it provides useful information when combined with other complementary tools such as gravimetric analysis, Karl Fischer titrimetry, mass spectroscopy, and Fourier-transformed infrared (FTIR). Dehydration is often revealed as endothermic peaks during a DSC scan. Dehydration often occurs at lower temperatures (eg, $<100^\circ C$), reflecting the relatively weak host-guest interactions. A relatively weak hydrate may start to lose water immediately after being introduced in the DSC cell when purged with an inert gas. Some strong hydrates may hold from losing water until reaching a high temperature (eg, $>100^\circ C$). As a general observation, the dehydrate temperature may serve as a useful indication on the physical stability of the hydrate.

A hydrate may undergo stepwise dehydration, forming a lower hydrate first, followed by losing additional water at a higher temperate. This behavior reflects the different groups of water molecules in the crystal lattice, and the group of water molecules with weaker interactions is lost first. This is the case for eprosartan mesylate dehydrate.[32]

A hydrate may dehydrate and form a crystalline anhydrate directly, which melts at the anhydrate melting point. However, it has also been frequently observed that dehydration leads to the formation of an amorphous/disordered phase, which crystallizes and then melts at a higher temperature. The crystallization and dehydration events may overlap, and the peaks

may not be well developed. In some cases, the first crystallized phase is a metastable form, which converts to a more stable form and melts.

It should be noted that the humidity in the purging gas in the furnace is essential zero so that dehydration in DSC is irreversible in nature. Therefore, it is not surprising that dehydration behavior may change with the sample pan configuration. For example, dehydration is generally delayed to a higher temperature when a sample is prepared in hermetically sealed pans. The dehydration temperature may slightly increase when samples are packed in sealed pans with pinholes than in an open pan where the water vapor may escape freely.

If the RH in the dehydration environment can be controlled, then the critical RH information may be obtained.[33] The idea is to study the dehydration temperature at different relative humidity levels, which allows the critical RH to be extrapolated to the temperature of interest (usually ambient) based on the Van't Hoff equation where the effect of temperature on chemical equilibrium is delineated.

3.4.1.2.4 Characterization of amorphous phases

An amorphous phase has higher apparent solubility, and it has been exploited to improve the bioavailability of many water-insoluble drugs. However, it is thermodynamically unstable and always bears the risk of recrystallization during manufacturing, storage, or during in vivo dissolution. When recrystallization occurs, the product performance may be sacrificed. Therefore, the physical stability of amorphous pharmaceuticals has been a significant focus over the last 20–30 years.[34]

DSC has been used extensively to study the glass transition, molecular mobility, thermodynamics, enthalpy relaxation, and recrystallization of amorphous pharmaceuticals.[35–44]

Glass transition is a second-order phase transition, where the heat capacity shows a step change. Glass transition is also a kinetic phenomenon, reflecting the molecular mobility of the amorphous phase. Therefore, the value of the glass transition temperature, T_g, is dependent on the heat/cooling rate because it reflects the temperate time it takes the molecules to move approximately the same as the experimental time scale. A higher heating/cooling rate results in a higher T_g value.

The difference in the thermodynamic quantities between the amorphous phase and the crystalline counterpart is called the configurational thermodynamic quantity (see Section 2.7). These configurational parameters can be readily derived based on data on heat capacity and melting, and DSC is the instrument of choice for these measurements. TMDSC is particularly useful and convenient for measuring the thermodynamic heat capacity of both amorphous and crystalline materials.[41,42]

Extrapolation of the configurational thermodynamic quantities from supercooled liquid states to lower temperatures results in a negative configurational quantity at temperature (T_K) above the absolute zero. This is the Kauzmann paradox where the metastable amorphous phase is more stable than the crystalline phase. Of course, this would never happen in reality. However, the Kauzmann temperature T_K represents the zero mobility temperature of an ideal glass.

As indicated in chapter "Crystalline and Amorphous Solids," molecular mobility in the supercooled liquid phase generally follows the Vogel–Tammann–Fulcher (VTF) equation:

$$\tau = \tau_0 \exp\left(\frac{DT_K}{T - T_K}\right)$$

where τ is the relaxation time (reciprocal of mobility), and D is a parameter signifying the temperature dependence of the relaxation time or strength of the glass-former (classified as strong or fragile). Molecular mobility in strong glasses typically exhibits Arrhenius-like temperature dependence, while the Arrhenius plot for a fragile glass is significantly nonlinear. The strength parameter may be derived from the apparent activation energy of the glass transition, ΔH, which again is conveniently determined by measuring the temperature dependence of the glass transition temperature using a DSC:

$$\Delta H = -R\frac{d\ln \beta}{d(1/T_g)}$$

$$D = \frac{\Delta H(1 - T_K/T_g)^2}{RT_K}$$

The fragility parameter, m, is related to D and can be determined similarly:

$$m = \frac{\Delta H}{2.303RT_g}$$

The determining of the configurational heat capacity and configurational entropy allows the molecular mobility of amorphous phase[41,42] to be calculated using the Adam–Gibbs model:

$$\tau = \tau_0 \exp\left(\frac{C}{TS_C}\right)$$

where S_c is the configurational entropy, and C is a material-dependent constant. Findings from thermodynamic and crystallization studies have revealed that configurational entropy plays an important role in determining the crystallization tendency of an amorphous phase.[42]

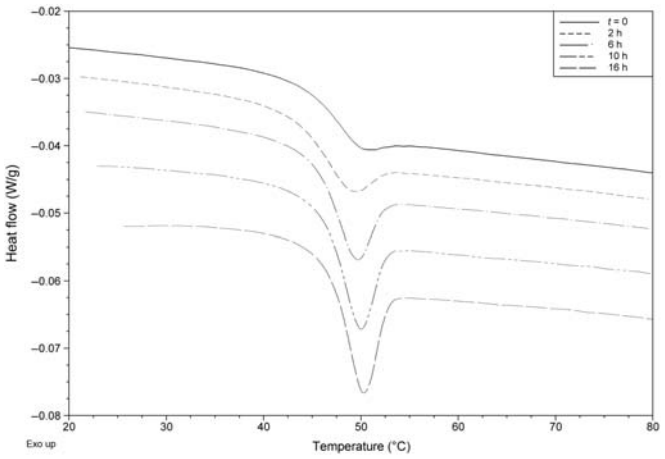

FIGURE 3.14 Enthalpy relaxation of ritonavir glass annealed at 35°C.

Molecular motion at temperatures below T_g, takes longer time, and the resulted enthalpy loss along the process is recovered during reheating in the DSC (Fig. 3.14 as an example). Enthalpy relaxation data has been used to derive the molecular mobility based on the KWW model.[35] We have used enthalpy relaxation to characterize the molecular mobility using the Adam–Gibbs model and the configurational thermodynamic quantities in fresh and annealed glasses. The importance of configurational entropy in glass stability was also confirmed.[44] The configurational entropy has been used to classify the physical stability of amorphous phases in conjunction with the molecular mobility.

Crystallization may be observed above T_g when molecular mobility is large enough. The relative position of the crystallization peak between T_g and T_m can be related to the ease of crystallization tendency.[41] DSC can be used to follow the recrystallization events and extract the kinetic information of the process.[37,43]

3.4.2 Thermogravimetric analysis

As the name suggests, thermogravimetric analysis (TGA) monitors the weight of a sample along with a temperature program. Similarly to DSC, the furnace is generally heated under the purge of an inert gas. TGA is primarily used to monitor thermal decomposition of compounds and is frequently combined with DSC to provide information about the nature of a thermal event, such as dehydration/desolvation, desorption, or melt decomposition.

3.4.3 Microcalorimetry

Isothermal microcalorimetry (IMC) is a highly sensitive calorimetry that is used to study thermal processes at a set temperature in the range of 5–95°C. IMC instrumentation can detect signals in the order of 10^{-6}°C in ΔT, far exceeding the sensitivity in conventional DSC (on the order of 10^4 times increased sensitivity). Thermal reactions that lead to physical and/or chemical stability may be studied at higher temperatures where the processes proceed at significant kinetic rates. However, pharmaceutical products are in general concerned about the stability during normal and accelerated storage conditions (eg, 5–40°C). Extrapolation of kinetic information to temperature and other conditions that are of interest to pharmaceuticals may be challenging and not reliable due to potential changes in reaction pathways or their relative contributions. The introduction of IMC in the 1980s (eg, thermal activity monitor, TAM) has made it possible to monitor heat processes and deduce stability information of pharmaceuticals at temperatures of interest directly.

The heat flow from an IMC experiment can be represented as:

$$\frac{dQ}{dt} = \Delta H \cdot C_0 \cdot \frac{d\alpha}{dt}$$

where ΔH is the enthalpy of the process under investigation, C_0 is the initial reactant concentration, α is the extent of conversion, ranging from 0 to 1, and $d\alpha/dt$ is the rate of the reaction.

IMC has been used to study most typical physical chemical processes of pharmaceuticals, including crystallization, polymorphic transformation, dehydration/hydration, and chemical reaction such as drug decomposition and excipient compatibility in formulation design.[22,45–48] The volume of the IMC cells allows the humidity of the headspace to be controlled through a humidity-stat such as a salt solution. Therefore, it can be useful to study the hygroscopicity, dehydration/hydration of drugs, and other pharmaceutical components.

One drawback of IMC is that it is incapable of temperature scanning. To that end, micro DSC is capable of performing both isothermal and nonisothermal calorimetric studies. Because of the increased sample size and the sensitivity requirements, the scanning rate is generally small (up to about 1°C/minutes), and the temperature ranges are generally limited (from about −40°C to anywhere between 100°C and 200°C). However, to the plus, the instrument allows for a very slow scanning rate such as 0.001°C/minutes to be controlled. Micro DSC has been used to study the phase transition of biological samples, hydration/dehydration of hydrates, and crystallization of amorphous materials under controlled RH, as well as drug degradations.

3.5 VIBRATIONAL SPECTROSCOPY

Spectroscopy is a way to figure out molecular structure, and it primarily uses electromagnetic

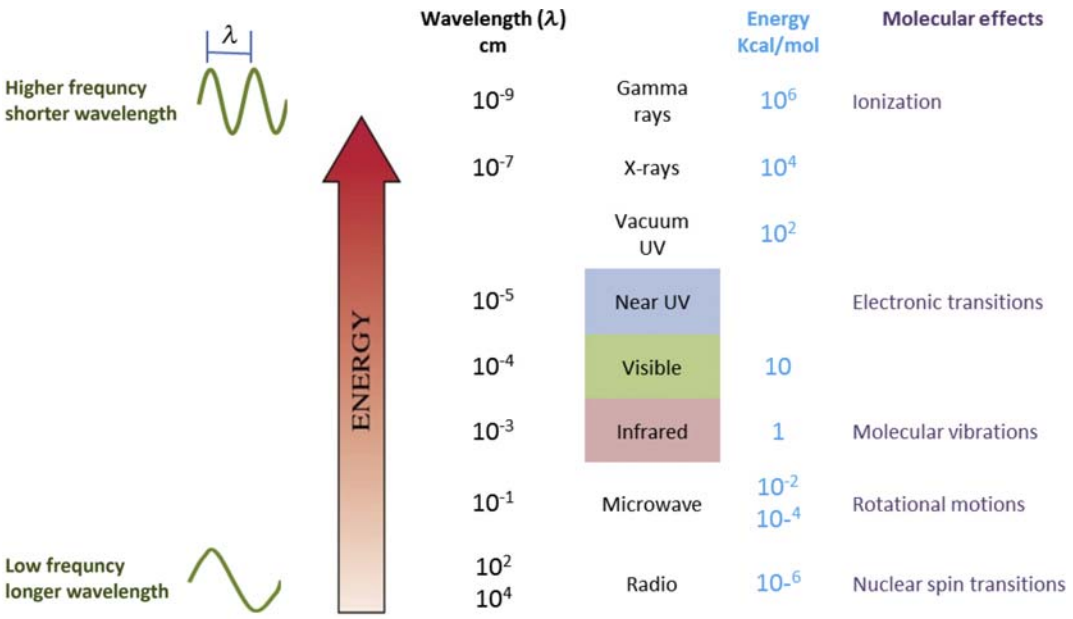

FIGURE 3.15 Regions of electromagnetic spectrum.

radiation. Fig. 3.15 highlights the major regions of the electromagnetic spectrum. Note the larger the wave number, the higher the energy. It is important to note the relationship between wave numbers and wavelength (λ):

$$\text{Wavenumbers} = \frac{1}{\text{Wave length } (\lambda)}$$

Visible light is used for determining the atomic structures of H and He, and both visible and UV light is used to study the electronic structure of atoms and molecules. Infrared light is in the region of energy where there is bond vibration, and thus it can provide information regarding functional groups and some knowledge of the structure of the molecule. The radio spectrum region provides information regarding quantum transitions; thus it provides the most definitive structural information.

Spectroscopic techniques primarily used for solid-state characterization in pharmaceutics are: infrared, Raman, and solid-state nuclear magnetic resonance (SSNMR). Therefore, each of the techniques will be discussed in some detail, including instrumental fundamentals, and then some applications will be used to illustrate the value of the method for solid-state characterization.

3.5.1 IR and Raman spectroscopy

3.5.1.1 IR spectroscopy

When exposed to IR radiation, *absorption* of electromagnetic radiation by molecules occurs depending on the functional groups leading to bond vibration (stretching, contracting, bending, wiggling, and twisting). It is possible to measure how much energy is absorbed at each particular wavelength and make inferences about the types of bonds that are present in the molecule. IR spectrum identifies functional groups by looking at the transitions between quantized vibration states, and it involves the change in dipole moment of the molecule.

TABLE 3.1 Regions of IR Spectrum

Region	Wavenumber (cm^{-1})
Near IR	4000–14,000
Mid IR	500–4000
Far IR	5–500

Infrared region of the electromagnetic spectra can be divided into three main regions, and the mid-IR region is the most useful (Table 3.1).

As already alluded to, there are several types of molecular vibrations. For a molecule to be IR active, it must possess a dipole moment (a permanent dipole). Dipole moment is a vector that is equal in magnitude to the charge multiplied by the distance between the changes and direction toward the net positive charge. Homonuclear diatomic molecules such hydrogen, oxygen, and nitrogen undergo symmetrical stretching and are not IR active, since there is no resultant dipole moment. As an example, Fig. 3.16 depicts stretching vibrations of an oxygen molecule, and it is evident that none of the three

FIGURE 3.16 Symmetrical stretching of oxygen where bonds are represented as springs.

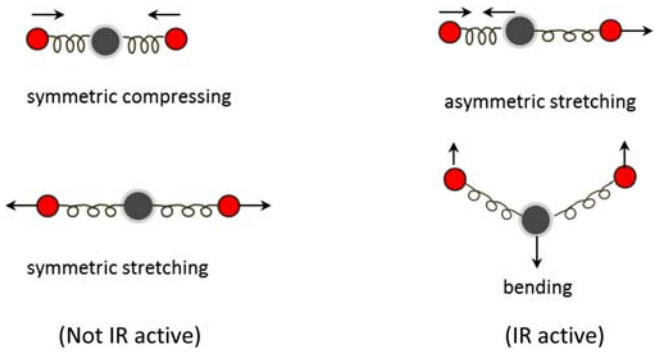

FIGURE 3.17 Carbon dioxide has some vibrations that have a resultant dipole.

configurations would result in a change in dipole; therefore, oxygen is inactive to IR.

On the other hand, molecular vibrations that lead to a resultant dipole are IR active, as illustrated in Fig. 3.17 using carbon dioxide. For the linear geometry with symmetric stretching, the dipole moment is zero, making these configurations IR inactive. However, a carbon dioxide molecule can assume additional configurations: asymmetric stretching and bending that result in positive dipole, and these configurations are IR active.

Other modes of vibration that molecules may exhibit include rocking, wagging, and twisting. The energy difference between the ground state and the higher energy is utilized in generating the IR spectrum. The lower energy state absorbs a photon of energy, that is, a specific wavelength of the electromagnetic band, to go to the higher energy state, but it can give up a photon of energy to return to the ground state. This absorption of energy creates the peak in the IR spectrum. In the case of organic molecules, there are many bonds that have vibrations where photons fall within the IR band of the electromagnetic spectrum. When monochromatic electromagnetic radiation (radiation of a specific wavelength) is passed through a sample, if the wavelength of light matches the energy of bond vibration, then energy will be absorbed, leading to more of that specific vibration that leads to resonance. As the sample is scanned across the IR band, the energy will come into resonance with specific vibrations, and absorption will occur. This absorbed energy produces the peak. The intensity of the peak depends on both the change in dipole moment and the number of specific bonds that are involved.

The simplest form of an IR spectrophotometer involves a source of IR radiation, a sample holder, grating, and a detector. However, there are instrument-related noises that need to be minimized to improve signal; therefore, the double-beam setup described in Fig. 3.18 is common.

In Fig. 3.18, the IR beam is split, with half going through the sample and other half going through the reference. A set of mirrors direct the beam coming from the sample/reference to a rotating chopper. The chopper consists of a transparent end and a mirrored end. The transparent end allows the light from the sample to go through the slit, and the mirrored end reflects the reference light toward the slit. In other words, the alternating light (once sample, then reference) goes through the slit to the grating. The grating then selects the monochromatic light that passes on to the mirror, alternating between the sample and the reference. This light finally reaches the detector, and the difference between the reference and sample light arising from absorption of light by the sample is translated to the IR spectra. It is worth noting that Fig. 3.18 depicts a dispersive IR spectrophotometer, which is rarely or never used. Today the spectrophotometers are FTIR spectroscopy because they offer better signal-to-noise ratio, better frequency accuracy, and faster acquisition and analysis time.

The key to FTIR spectroscopy is the interferometer, and a schematic is provided in Fig. 3.19, which will be used to discuss the functioning of the equipment.

Let's start by just looking at the sample. The light (assume monochromatic for now) from the source goes

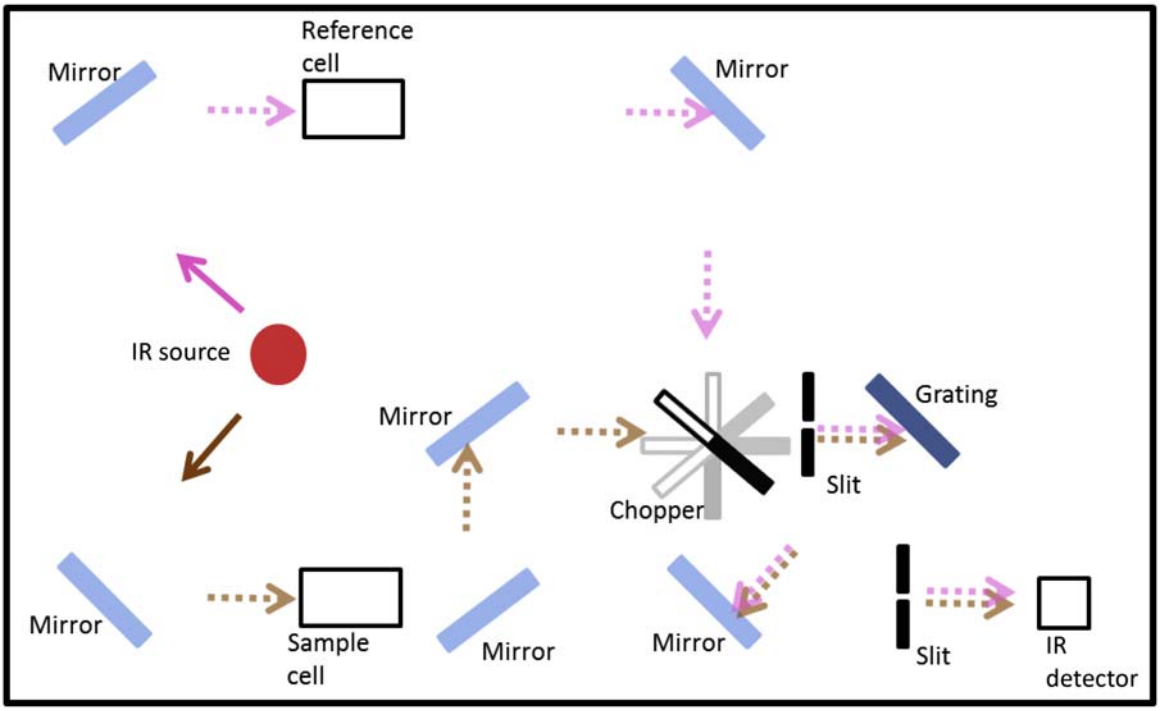

FIGURE 3.18 Double-beam dispersive IR spectrophometry.

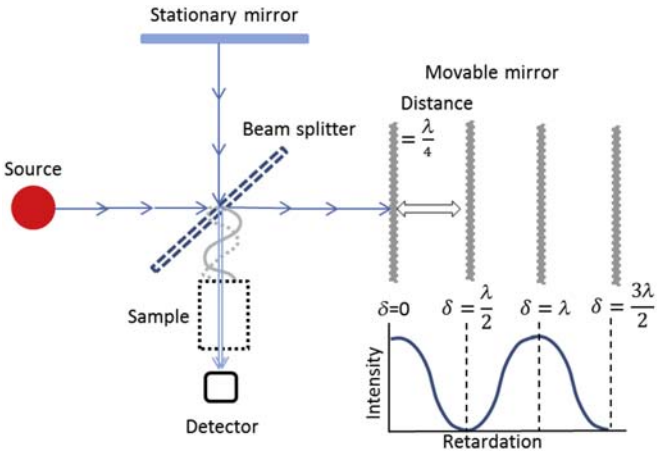

FIGURE 3.19 Schematic of an interferometer.

to a beam splitter, which reflects some of the light to the stationary mirror and transmits the rest (say 50/50 for now) to the movable mirror. The rays are then reflected back to the beam splitter where again half of each ray is reflected and other half transmitted. In other words, the ray that came back from the stationary mirror will be split, with half going back to the source and half going through the sample to the detector. The same happens to the ray returning from the movable mirror. The two optical paths, beam splitter to stationary mirror and beam splitter to movable mirror, are not usually equal; therefore, the light going to the samples will not always be in phase. This means there will be interference.

Two times the difference in the path between the stationary and movable mirror is called retardation (δ). If δ is an integer value of wavelength λ, then the interference is constructive, and if δ is an integer value of $\lambda/2$, then the interference is destructive interference. In between those two values, the interference is variable. The output graph, intensity versus retardation, is the interferogram. The interferogram from the reference and the sample are Fourier transformed to produce the spectrum. Note in reality the light from the source is a broad-spectrum IR source, and the beam splitter has an efficiency associated with its ability to split the beam, and this efficiency is an instrument constant.

3.5.1.2 *Raman spectroscopy*

Complementary to infrared spectroscopy is Raman spectroscopy. Raman is a *scattering* phenomenon that occurs when molecules interact with an electromagnetic field. Light that is scattered from a molecule is primarily elastically scattered; that is the incident and the scattered photons have the same energy, and this is called Rayleigh scatter. Rayleigh scattering is not useful for analysis, and most instruments filter out this elastic scattering. However, an exceedingly small fraction of photons maybe scattered inelastically, resulting in either a net gain or loss of energy of the scattered photon.

TABLE 3.2 IR versus Raman Spectroscopy

IR	Raman
Results from absorption of light by vibrating molecule	Results from scattering of light by vibrating molecule
Vibration is IR active if there is a change in dipole moment during vibration	The vibration is Raman active if it causes a change in polarizability
Molecule possess a permanent dipole	Molecule does not need to possess a permanent dipole
Water cannot be used as solvent	Water can be used as solvent
Sample preparation requires care. Gaseous samples can rarely be used	Sample preparation is simple

The Raman process can be described as a molecule in an initial vibrational state that is excited to a higher energy state and then returns to a vibrational state (higher or lower than initial) with simultaneous scattering of a new photon from this state. The difference in energy between the incident and scattered photon is equal to the energy difference between the initial and final vibrational states of the molecule. A loss in photon energy (ie, when it returns to a lower energy state) is termed Stokes–Raman scattering, and a gain in photon energy or when it returns to a higher energy state is termed anti-Stokes–Raman scattering. Not all vibrational transitions can be accessed by Raman scattering. Raman-active transitions are those that are associated with a change in polarizability of the molecule. Polarizability is the ease with which the electron cloud can be distorted by an applied field. In other words, Raman activity is associated with induced dipole. A Raman spectrum is a plot of scattered light intensity versus Raman shift reported in wavenumbers (cm^{-1}).

As stated before, IR and Raman are complementary techniques, with some similarities and differences. Table 3.2 summarizes the differences, and Fig. 3.20 illustrates the advantages of using these two techniques in conjunction in order get information regarding the functional groups.

The use of these two techniques is illustrated using carbon tetrachloride. CCl4 has a tetrahedral configuration with the chlorine atoms being more electronegative than the carbon atom. The scissoring, rocking, and symmetric stretching vibrations do not result in molecular dipole moment, and, therefore, they are IR inactive, but polarizability of the electron cloud results in a Raman shift. Only the asymmetric stretching vibration produces an induced dipole; therefore, this vibration is IR active.

In the field of solid-state pharmaceutics, these techniques are used not only for elucidating functional groups but to find far greater use in a variety of applications that span research that focuses on elucidating molecular packing associated with various crystal forms[49–52]; uses that lead to material identification[53]; formulation performance, which may be solid properties,[54–57] release, or stability[58]; manufacturing tool for endpoint determination[59,60] or for looking at phase transformations[61,62]; and monitoring counterfeit products,[63–65] to name a few. Since these techniques are so widely used in pharmaceutical manufacturing, there are many reviews that discuss pharmaceutical applications of IR and Raman spectroscopy.[66,67] It is evident that that method is a valuable tool for pharmaceutical analysis, and if one were to mention any disadvantage, it is less sensitive compared to PXRD in distinguishing between crystal forms or between crystalline and amorphous.

3.5.2 SSNMR spectroscopy

Nuclear magnetic resonance (NMR) spectroscopy is a technique that exploits the magnetic properties of certain nuclei to study physical, chemical, and biological properties. It involves the absorption of electromagnetic radiation in the radiofrequency (rf) region. The basic principles covered utilize minimum mathematics and no quantum mechanics; therefore, the reader should refer to specialized textbooks for details.[68–70] Briefly, atoms that have an odd number of protons, neutrons, or both can behave like magnets (Fig. 3.21a), for example, ^{1}H, ^{13}C, ^{15}N, ^{17}O, and ^{19}F. The strength of their magnetic field is measured by a vector called magnetic moment, which is related to a fundamental nuclear property called the nuclear spin (I). The rules for determining the net spin of a nucleus are as follows:

1. If the number of neutrons and the number of protons are both even, then there is no spin, and it is not NMR active.
2. If the number of neutrons plus protons is odd, then the spin is half-integer (ie, 1/2, 3/2, 5/2).
3. If the number of neutrons and protons are both odd, then the spin is an integer (ie, 1, 2, 3).

A nucleus of spin I has $2I+1$ orientations. Therefore, ^{1}H atom with $I=1/2$ has two possible orientations ($I=1/2$, $I=-1/2$). In the absence of an external magnetic field, the magnetic moments of the

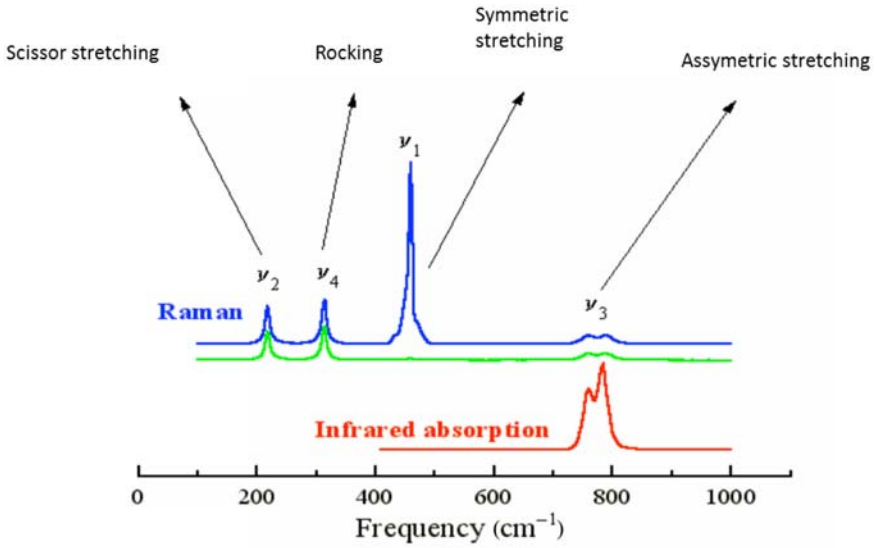

FIGURE 3.20 Raman and IR spectrum for carbon tetrachloride. Taken from http://www.ccmr.cornell.edu/igert/modular/docs/Raman_Scattering.pdf

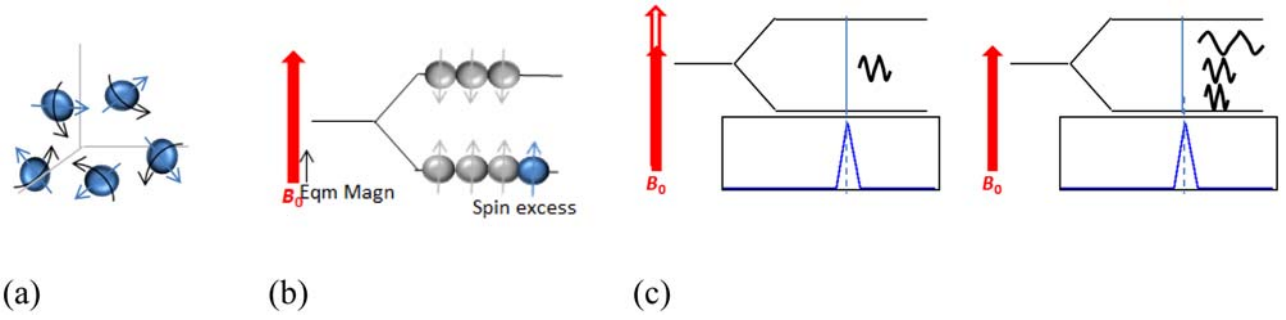

FIGURE 3.21 (a) Nucleus (ex. ^1H, $I = 1/2$) with an angular momentum randomly oriented. (b) Splitting of nuclear spin under applied magnetic field B_0, producing a small magnetization. (c) Two techniques for continuous wave NMR: The first increases the magnetic field while a constant frequency is on, while the second does a frequency sweep at constant B_0. Absorption occurs at Larmor frequency.

nuclei are random, or there is isoenergic distribution of nuclear spin. The distribution is described as a Boltzmann distribution.

When a magnetic field (B_0) is applied (Fig. 3.21b), the energy levels split (Zeeman splitting), and the nucleus (the "magnets") will line up with the external magnetic field. There is usually a slight preponderance of excess spin at the lower energy state that results in equilibrium magnetization (Fig. 3.21b), which aligns with the external magnetic field. This excess is detected as a signal, but it is a weak signal. If, on the other hand, the sample size is large, there could be an abundance of this spin excess nucleus. When an oscillating energy with a frequency equal to the difference in energy states is applied while B_0 is increased, absorption occurs. Alternatively B_0 can be held constant, and a frequency sweep can be applied, and when there is a match in frequency (or resonance occurs), there is absorption. This absorption results in NMR signal (Fig. 3.21c). However, these types of experiments, even with a large sample size, give weak signals.

Two important concepts, relaxation time and precession, need to be discussed. At equilibrium, the net magnetization vector lies along the direction of the applied magnetic field B_0 and is called the equilibrium magnetization (Figs. 3.21b or 3.22a). It is possible to change the net magnetization by exposing the nuclear spin system to the energy of a frequency equal to the energy difference between the spin states. If enough energy is put into the system, it is possible to saturate the spin system and make this magnetization zero. Then when the energy source is removed, the magnetization vector will return to the original equilibrium state, and the time constant of this transition is called the spin lattice relaxation time, T_1.

Since the particles are spinning in the presence of this applied magnetic field (B_0), the net magnetization vector will not only be in the z-direction, but it will rotate about the z-axis, a phenomenon called precession. This precession is evident only when the axis of the nucleus is not exactly aligned with the magnetic field. The precision frequency (ω) or Larmor frequency

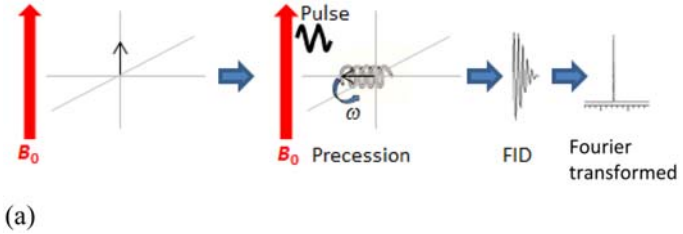

FIGURE 3.22 (a) NMR spectroscopic configuration. (b) Shielding due to secondary field generated by electron cloud.

is independent of the orientation of the nucleus to the magnetic field but dependent on B_0 and the gyromagnetic ratio (γ) of the nucleus. The γ is a characteristic of the nucleus. Note:

$$\omega = \gamma B_0$$

This equation relates precession frequency (ω) or Larmor frequency to the applied magnetic field and the gyromagnetic ratio of the nucleus and is the most important equation for NMR spectroscopy. When the oscillating energy orthogonal to B_0 is introduced, it tips the nuclei out of its equilibrium position, causing a transition between the two energy levels of the spin. When the energy source is removed, the spin relaxes to the equilibrium state with a spin−spin time constant T_2. As spin relaxation occurs, the net magnetization reaches equilibrium. It should be noted that Fig. 3.22a depicts a 90° pulse technique, which has the problem that the rf field must be turned off before signal can be collected. There are other techniques used to overcome this problem that are beyond the present scope.

In NMR, the energy source is a probe coil that produces the rf signal (transmitter), and as the nucleus returns to the equilibrium state, the signal that decays with time is in the form of an oscillating voltage and is picked up by the same coil, which then acts as a receiver. In the most commonly used NMR spectroscopic configuration, the signal is in time domain and is called the free induction decay. It is Fourier transformed into frequency domain to provide the NMR signal.

Once the spectrum is obtained in the frequency domain, there are two types of information that can be gleaned from it: the amount of nuclei generating the spin, which can be achieved by integrating the peak, and the chemical environment of the nucleus generating the signal, which determines the position of the peak in the NMR spectrum. The chemical environment where there are other electrons are present can lead to shielding of the nuclei, which requires less energy to bring it into resonance, and conversely deshielded nuclei require more energy, and the peaks appear downstream. It is worth noting that since the shielding tensor is dependent on the applied magnetic field, a chemical shift needs to be calibrated with a reference.

In solid-state NMR spectroscopy, molecular motions are restricted to local vibrations and rotations; therefore, dipolar interactions are the primary interactions. In the absence of rapid molecular tumbling that leads to average conformation in a solution, in powder samples, the NMR spectrum consists of a superposition of numerous lines that originate from a given nucleus. This leads to excessive peak broadening. Such broad peaks are not useful. Therefore, ^{1}H NMR is not used for obtaining chemical shift information when the sample is a powder. Since the chemical shift anisotropy leads to broad peaks from overlapping patterns and interplay between different broadening mechanisms, the elimination of anisotropic interactions in high-resolution SSNMR is achieved by spinning the sample around an axis inclined at 54.74°, known as magic angle. Since dipolar interactions are weakened by fast rotation, rotor spin rates are selected such that they are larger than the anisotropic interactions. Magic angle spinning (MAS) is combined with decoupling to improve spectral resolution. Decoupling consists of an application of short pulses that prevent line splitting of the less abandoned nuclei. SSNMR sensitivity for a low-sensitive nucleus (eg, ^{13}C) can additionally be increased by using a cross-polarization (CP) technique. It is based on excitation of the sparse spin system through the abundant one. In the case of ^{1}H-^{13}C CP, if the Larmor frequencies ω_H and ω_C are made equal by adjusting the oscillating field amplitude (satisfying the Hartmann−Hahn condition $\gamma_H B_H = \gamma_C B_C$), then resonance exchange of energy between the two types of nuclei can easily take place. In fact, this condition can be considered as thermal exchange, and the time taken to cool down ^{13}C is associated with the warming of ^{1}H and is called contact time (CT). A 90° pulse is applied, and then the two spin systems are put in thermal contact through a pulse train having CT duration that allows Hartmann−Hahn matching. Finally the ^{1}H nucleus is decoupled, and acquisition of ^{13}C signal is performed. SSNMR of adamantine in Fig. 3.23 demonstrates the advantages of CP MAS NMR.

High-resolution SSNMR can be used to extract both structural and dynamic information, but such experimentation requires significant expertise, expensive instrumentation, large sample size, and is time consuming. However, this powerful, nondestructive

but theoretically complex tool has been used for qualitatively and quantitatively analyzing crystalline and amorphous pharmaceutical samples and for characterizing both active ingredients as well as formulations. SSNMR is widely used in pharmaceutical applications, and there are several reviews that go into further depth with regard to theory and application.[72–74] A few applications are highlighted here. In conjunction with single crystal structural information, SSNMR of erythromycin and clarithromycin was analyzed to gain understanding for the propensity of these molecules to form hydrates and solvates.[75] The stability of an amorphous statin was investigated by solid SSNMR, and a strong dynamic heterogeneity was attributed to the stability of simvastatin.[76] Investigations that involved formulations have used SSNMR for studying polymorphism in dosage forms when the active ingredient is present in low doses.[77] In the development of amorphous solid dispersion, the solubility of nifedipine in PVP was investigated by SSNMR.[78]

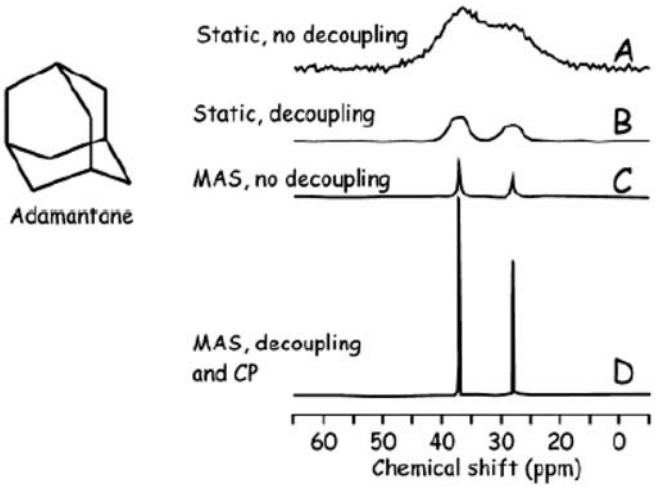

FIGURE 3.23 SSNMR spectrum of adamantine.[71]

3.6 MOISTURE SORPTION

Vapor sorption is a sensitive technique that is extensively used for characterizing API's, excipients and formulations. It can be destructive if there is extensive loss or gain of weight during testing. However, the method is simple, requires a tenth of a sample as compared to PXRD, and is almost 10-fold more sensitive in detecting the presence of a mixture of phases, making it an attractive tool for routine utilization, but it has applications other than phase purity evaluation.

The concept and the equipment design are amazingly simple. The method relies on the concept that water sorption is a function of water activity (a_w). Water activity (a_w) is defined by the ratio of vapor pressure of water (p_w) divided by vapor pressure of pure water (p_o) at a given temperature, and 100 times that ratio is relative humidity (%*RH*):

$$a_w * 100 = \frac{p_w}{p_o} * 100 = \%RH$$

Instrumentation involves a temperature-controlled chamber, a few flow meters, and a microbalance to which are attached a reference and a sample pan (Fig. 3.24). In Fig. 3.24a, the chamber is kept at constant temperature. Dried nitrogen (N_2) flows into the chamber and is split into two streams. One stream passes over a solvent, which is usually water, producing a stream of wet N_2 at 100% RH. Then the wet and dry N_2 are mixed at a given ratio controlled by the

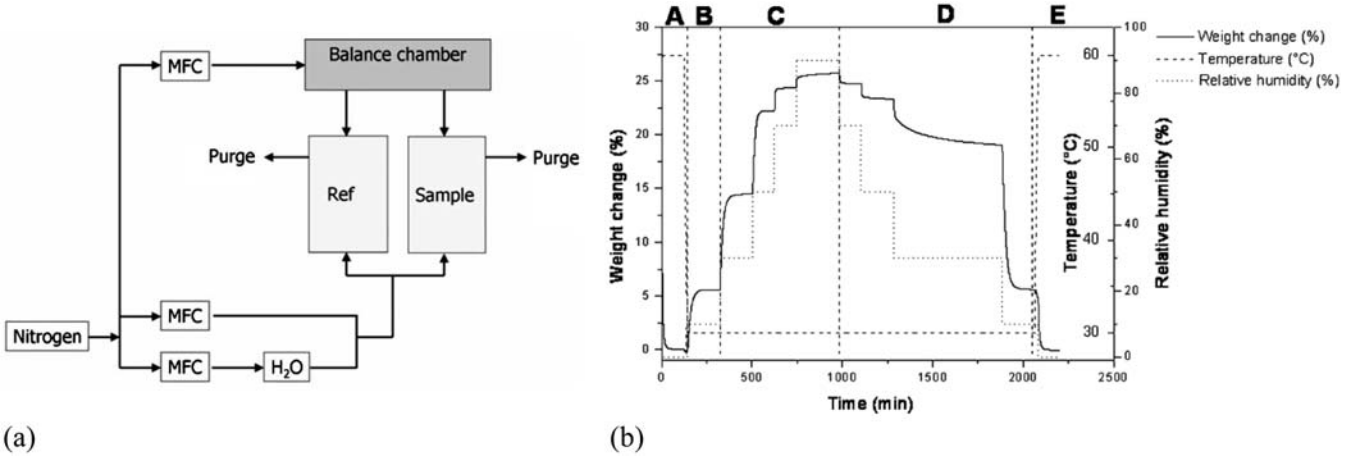

FIGURE 3.24 (a) Experimental setup for dynamic vapor sorption gravimetric analysis. (b) An example: isothermal measurement of silica.[79]

respective mass flow controllers to obtain a N_2 of a given relative humidity. This N_2 of a defined humidity flows through the reference and sample chambers.

The sample is first dried and then exposed to changing humidity values, and the weight change is recorded as a function of humidity. Usually the humidity is increased from 0% to 90% RH in steps of 10% or 20% RH between equilibration times. Finally the humidity is decreased in steps of 10% or 20% RH. Following Fig. 3.24b, the sample is first dried at 0% RH when there is weight loss, as depicted by the solid line in segment A. In segment B, the dotted line indicates that the RH was ramped up by 20%, and the solid line indicates that the initial sample rapidly gains weight, and then there is no appreciable weight change (ie, the sample reaches an equilibrium at 20% RH). Between segments B and C, there are four more steps of humidity increase (dotted line), and at each step, the sample, after initially gaining weight, stabilizes to the humidity conditions. In segment D, the humdity is decreased in steps, and at each step, the sample loses weight. The sample equilibrates at each step before the RH is changed.

The abscissa in Fig. 3.24b is in time, and it is evident that the stabilization at a given RH is dependent on whether appreciable weight gain or loss occurs at that RH. The goal is to ensure equilibrium weight at each RH; thus the greater the weight change, the longer the time for the step. It is common to plot this weight change data as a function of %RH. These plots provide valuable information, and some examples have been provided in Fig. 3.25, mainly to demonstrate that it is both the extent of moisture uptake/loss and the nature of the plots that provide valuable information. It is also common to present this data without including segment A (ie, the weight change of the sample is normalized to dry basis). Finally only two examples will be used to demonstrate the types of information that can be obtained from moisture uptake profiles.

Fig. 3.25a is an example that depicts the moisture uptake profile of amorphous and crystalline solids. At any given RH, the moisture uptake by the amorphous is greater than the crystalline counterpart. The adsorption (upward solid arrow) and desorption (downward solid arrow) curves exhibit a hysteresis or a shift to higher water content at a given %RH during desorption. There are a few theories associated with the existence of this hysteresis for adsorption-desorption curves, and they are beyond the scope of this present text. However, it is important to note that most materials that undergo adsorption-desorption without any phase change may exhibit such hysteresis.

When phase change occurs, the moisture uptake profiles become complicated. In the example in Fig. 3.25b, the amorphous rapidly takes up 10% (w/w) water up to 80% RH. At 80% RH, there is 5% (w/w) weight loss, and even when the humidity is increased to 90% RH, the weight gain of the sample remains at ~5% (w/w). During desorption the sample remains almost unchanged from 90% to 30% RH. Between 30% and 10% RH, the sample has ~3% (w/w) water content. This type of sample behavior is typical for amorphous samples that undergo crystallization. Initially, the amorphous rapidly absorbs water, similar to what was seen in Fig. 3.25a, but since water is a potent plasticizer, in this case it promotes crystallization. Whether crystallization occurs or not is a material property. The crystallizing solid loses water, leading to the observed

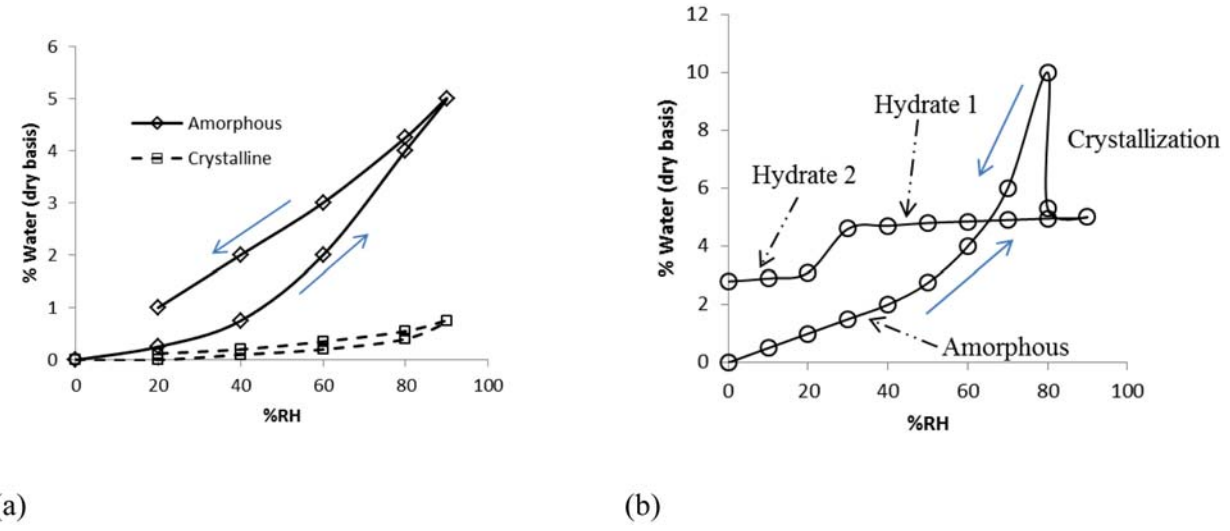

FIGURE 3.25 Examples of dynamic vapor sorption gravimetric analysis of (a) amorphous and crystalline solids with no phase change and (b) amorphous undergoing moisture mediated crystallization.

weight loss. In this example, the solid after weight loss at 80% RH contains 5% (w/w) water; therefore, it can be assumed that a hydrate was formed. In other words, the water in the sample at this stage is no longer sorbed water but has become a part of the lattice. If it were an anhydrous phase, it would have lost almost all of the water it had originally gained. Finally, there is another step change that occurs at 30% RH, indicating the formation of a lower hydrate containing ~3% (w/w) water. These moisture sorption profiles give an indication of changes as a function of water uptake/loss, but these changes need to be confirmed by orthogonal techniques such as PXRD. Fig. 3.25 not only provides information regarding the existence of different solid phases (amorphous, hydrate 1, hydrate 2), it also provides information regarding the hygroscopicity of each solid phase. Again it is evident that the moisture uptake rate by the amorphous is greater than either of the crystalline solids.

The moisture uptake technique described above is very widely used in the pharmaceutical industry, and some examples have been cited, but there are a few other techniques that are widely used in drug development that are worth mentioning. Since electrolytes depress the vapor pressure of water at a given temperature, a saturated salt solution will have a defined RH. Therefore, a cheap gravimetric method capitalizing on the above concept (ie, water uptake by a solid) is a function of a_w of the environment, which utilizes desiccators and salt solutions for exposing the sample to various humidity conditions.

The other two techniques that are commonly used when the total water content of a sample needs to be determined are: loss on drying (LOD) and Karl Fischer titration. Both these are common compendial methods. In the case of LOD determination, a given weight of the sample is heated to a defined temperature, and the weight loss is recorded. Therefore, this LOD method is also a gravimetric technique, but it cannot provide indication of the presence or absence of hydrates or solvates. Sometime orthogonal techniques such as PXRD before and after LOD determination are used to investigate phase change. It is worth noting that this LOD method does not provide information on whether the weight loss is associated with water, solvent, or decomposition.

In Karl Fischer titration, water in a sample can be determined by either volumetric or coulometric titration. Volumetric titration is used when the sample contains a relatively large amount of water (1−100 mg being titrated), while the coulometric method is used for titrating microgram quantities of water. Briefly, the titration is performed in an alcoholic solution (methanol) in the presence of a base, sulfur dioxide, and a known quantity of iodine. One mole of iodine consumes a mole of water. As is evident, Karl Fischer titration is more specific to water determination than the LOD method, but it also suffers from the disadvantage that it cannot differentiate between surface water and water present as a part of the crystal structure.

In the pharmaceutical industry, information regarding moisture content and moisture uptake is used for several applications, and here are a few examples: solid form selection (ie, polymorph and salts[80–83]), characterizing amorphous formulations,[84,85] detecting process-induced phase transformations,[86] and evaluating packaging configurations.[87]

3.7 HYPHENATED TECHNIQUES

The above techniques are often used in combination, and when they are combined, they provide a multifaceted analytical tool for solid-state characterization. For example, thermal analysis using DSC affords information regarding change; for example, an endotherm occurs for loss of residual solvent, melting, polymorphic transition, desolvation, or decomposition. Although it affords quantitative information regarding heat consumed during the change, it affords no information regarding the type of transition. Hot-stage microscopy involves a heating stage combined with microscopy such that the sample is heated at a given rate on a microscope stage allowing one to observe melting, polymorphic transition, or decomposition. If the experiments are performed with the sample suspended in oil, it is also possible to observe dehydration and even differentiate between residual solvent loss and desolvation. Although hot-stage microscopy does not provide any quantitative data, it allows for precise identification of the type of transition. Another common technique is variable-temperature PXRD, which has been commonly used to study transformation of one crystal form to another as the sample is heated and repeatedly scanned at a predefined rate to generate PXRD pattern. In other cases, a controlled humidity purge has been used in conjunction with PXRD to study the kinetics of moisture-mediated transformation or the kinetics of hydrate formation. Likewise it is possible to combine other techniques such as SSNMR with variable temperature to gain insight. Combined thermal methods such as DSC/TGA have also been commercialized so that both calorimetric and gravimetric information may be obtained in a single scan. When combined with a mass spectrometer (MS) or an FTIR spectrometer, the technique allows the nature of the gaseous reaction products formed in the TGA to be investigated directly and identified directly, even in the presence of multiple volatile degradants. Thus

TGA-MS and TGA-FTIR can be useful in the identification of the starting material and degradation, including kinetics and pathways. Raman microscopy has been used for evaluating uniformity of API in pharmaceutical formulation and especially in the case of amorphous solid dispersion formulations where it is imperative that the API is homogeneously dispersed in the polymer matrix. This technique has also been used to monitor the crystallization or physical stability of amorphous solid dispersions as a function of heat and humidity. These are only a few examples of hyphenated techniques. Advanced instrumentation is available that combines several tools together in order to obtain as much information as possible from a single experiment.

3.8 CONCLUSION

Solid dosage form development often involves the characterization of raw materials going into the manufacturing of the API so that the correct form for development can be selected, characterization of the excipient, intermediates in dosage form manufacturing, and the finished product during release, stability and on-market. Since every imaginable step in development relies on testing such that the material is well understood, there is a plethora of techniques that pharmaceutical scientists utilize. This chapter provides a flavor of some of the common techniques used in support of pharmaceutical development and research. As stated in the introduction, there are a number of other techniques that have been left out. However, the goal is to provide an understanding of some of the common and somewhat complex tools with respect to instrumentation and application.

API Solid-Form Screening and Selection

M.Y. Gokhale and R.V. Mantri

Drug Product Science & Technology, Bristol-Myers Squibb, New Brunswick, NJ, United States

4.1 INTRODUCTION

Most active pharmaceutical ingredients (APIs) are solid in nature and could exist in many forms that vary significantly in their properties leading to different physical, chemical, mechanical, and biopharmaceutical properties.[1–6] The ideal API solid form is one that, not only can be manufactured reproducibly, characterized in detail with respect to identity and stability, but also be formulated as a drug product (DP) that meets the intended target product profile. Therefore, screening and selection of the API solid form are critical components in drug development that influence the quality, performance, and manufacturing of a drug substance and DP. Additionally, in today's competitive pharmaceutical landscape, since development timelines are getting much shorter, the need to select the right candidate the first time is becoming more important.

Solid forms of APIs can exist as crystalline forms including polymorphs, hydrates, solvates, cocrystals, and salts as well as amorphous forms. The aim of solid form screening and selection is to identify and characterize as many forms as possible and select a form with optimal physical, chemical, and biopharmaceutical properties.[7] Crystalline forms are generally preferred over amorphous forms because they can be reproducibly manufactured, often with greater purity and stability. Therefore, the solid form screening is primarily focused on the identification and characterization of crystalline forms prior to selection. The amorphous forms are selected either because a crystalline form is not identified or the known crystalline forms have inadequate solubility, dissolution rate, and bioavailability.

Typically API solid form selection strategy is executed by implementing a tiered or integrated approach that involves multiple steps.[7–9] It is desirable to identify a wide range of crystalline polymorphs, hydrates, and the relevant solvates during the form screening stage. Initial assessments that influence the selection strategy include considerations such as ionization of the molecule, solubility, and stability along with formulation considerations and route of administration.[10–16] For ionizable drugs (anionic, cationic, and zwitterionic), salt formation is the most common strategy to enhance solubility and bioavailability.[16,17] Salts can also provide improved solid-state properties, stability, crystallinity, hygroscopicity, melting point and bulk physical properties. For nonionizable drugs, weak bases, or acid molecules where salt formation is limited, cocrystals are an attractive option.[15,18] Screening of solid forms may be achieved by high-throughput and/or manual crystallization approaches with the goal of identifying crystalline forms using various cosolvents to assess solvates, hydrates, and potential counter ion screens for salts or cocrystals followed by scaling up of the crystalline leads. The lead candidates are characterized using solid-state analytical techniques such as thermal analysis, crystallography, X-ray diffraction (XRD), and spectroscopy.[19–23] An additional goal of form characterization is also to determine the thermodynamic relationship between known polymorphs (monotropic vs enantiotropic), pseudopolymorphs (eg, hydrate/anhydrate), salts (eg, pHmax for salt vs free form), or cocrystals (eg, K_{sp} and Keu). Assessment of hygroscopicity, solubility, and chemical and physical stability is also routinely conducted. Additional factors that influence the form selection include considerations for API isolation (crystallization, filtration, and drying) process as well as the formulation strategy to meet the target product profile. Thus, the selection of the form is done after careful review of results from characterization studies including physical, chemical stability, and solubility/dissolution behavior as well as in vivo

Developing Solid Oral Dosage Forms
DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00004-2

performance and manufacturing considerations. It is known that mechanical and physical property differences between forms can affect manufacturability and physical attributes of the solid oral dosage forms as has been reported for theophylline,[6] sulfamerazine,[24] polymorphs of metoprolol tartrate,[25] paracetamol,[26] or carbamazepine.[27] The mechanical properties are also influenced by particle size and shape/morphology in addition to the solid form. Generally, these properties are often optimized by particle engineering approaches on the selected form at a later stage in development and are outside the scope of this chapter.

4.2 SOLID-FORM SELECTION CONSIDERATIONS

Ideally, the selected form is a single-phase, nonhygroscopic, highly crystalline form. It also possesses excellent thermal, physical, and chemical stability to ensure good quality during manufacturing and storage of API and dosage form. The selected form does not have complexities of polymorphism and pseudopolymorphism and can be manufactured in large scale with good yield and purity in a consistent fashion. Although mechanical properties of the solid form are not thoroughly evaluated during the solid-form selection stage, the selected form should be amenable to shape/morphology and size as required by the selected formulation and process. Finally, the solid form should have the solubility and dissolution rate characteristics to provide pharmacokinetics and bioavailability as dictated by the target product profile of the dosage form.

4.2.1 Key physicochemical property considerations

4.2.1.1 Solid-form stability

Stability testing of drug substance and DP are conducted during development with a goal of establishing and assuring that quality is maintained during the recommended storage conditions and time (shelf-life). It is critical to select a solid form that is stable as a function of time and environmental factors such as temperature, humidity, and light. For APIs that exist in multiple solid-state forms, it is important to understand the relative thermodynamic stability of the various forms and its relevance not only to manufacturing but also to storage conditions and shelf-life.

Physical stability of solid forms is related to phase transformations and interconversion between different crystalline polymorphic or pseudopolymorphic forms or conversion of thermodynamically unstable amorphous to crystalline form or salt form to free form. As part of the form selection process, understanding these transformations in relevance to thermodynamic or kinetic factors during API processing or DP processing and on shelf-life is an important element of the selection process. Solid forms can display a wide variety of physicochemical properties, including solubility, melting points, density, and morphology, and transformation of one solid form to another form can lead to formation of undesirable forms and pose risks to quality and in-vivo performance. For example, for amorphous API or dispersions, maintaining the glassy state and keeping the material amorphous are critical to ensure higher solubility and improved bioavailability as intended with these systems. On the other hand, for crystalline forms, even small amounts of amorphous can result in undesired effects such as increased water uptake and reduced chemical stability. Similarly for salts or cocrystals, dissociation to the free form during storage or in the presence of certain formulation excipients can lead to poor performance. Various processing conditions during DP manufacture, including wet granulation, milling, drying, and compaction, can cause phase transformations from anhydrate to hydrate, crystalline to amorphous, desolvation of a solvate, or conversion to different polymorphs, and can all lead to lower solubility, slower dissolution rates, and potentially lower in vivo exposures.[28–31] It is, therefore, important to first understand the thermodynamic stability of known polymorphs, hydrates, and relevant solvates. The relative stability of polymorphs (ie, enantiotropic vs monotropic systems) needs to be assessed to ensure that the chosen form is thermodynamically stable. For salts, it is important to determine the relative stability of salt versus free forms as a function of pH to assess the potential risk(s) of dissociation in solid dosage form. As with salts, similar dissociation of cocrystals to individual components can lead to physical instability. Phase diagrams for cocrystals are useful in demonstrating conditions where a cocrystal component is supersaturated, and selection of these conditions should avoid dissociation of the cocrystal.[32] In case of hydrates and anhydrates, at a constant temperature over a range of given relative humidity (RH) or water activity, one crystal form is stable, and at a critical water activity, both forms can exist simultaneously. However, based on the kinetics and conditions of conversion, transient metastable forms may exist during the hydration or dehydration process. In aqueous systems, conversion to the more stable hydrate form is a key concern from a bioavailability standpoint, since hydrates are known to have lower solubility typically in the order of two- to threefold.[33] Additionally, conversion to hydrate on storage during shelf life can also impact the chemical stability of the DP. The anhydrate-to-hydrate conversion is an important consideration in designing

solution dosage forms to ensure that the hydrate solubility is not exceeded, and in the case of suspensions, no conversion is seen during the shelf life that can lead to increased particle size and caking of the suspension leading to instability. The extent and time taken for conversion to the more stable form can be controlled by modifying the kinetics, and it depends on various factors such as the solubility of a drug, energy input during mechanical processes, temperature, and the presence of certain excipients.[33]

While selection of the most stable form is important to ensure adequate physical stability, when the desired physicochemical properties are not achieved, the use of metastable forms with higher solubility such as amorphous solid dispersions are widely used as a strategy for improved in-vivo performance.[34] In such cases where the metastable forms are chosen for development, understanding the kinetic stability of these systems is extremely critical. Molecular mobility is an important consideration in understanding the amorphous-to-crystalline phase transitions, and this has been discussed later.

Another important stability consideration is the chemical stability that involves the degradation of an API or a reaction with excipients to form new degradants.[13] During form selection, evaluating the chemical stability of a selected form is an integral part of the form screening process. In some cases, polymorphs (or psuedopolymorphs) of some drugs can exhibit different chemical stability, as in the case of carbamazepine,[35] indomethacin,[36] or furosemide,[37] to name a few. Generally speaking, the thermodynamically stable form is the most chemically stable. However, in case of indomethacin, the metastable α-form has a higher density than the more stable γ-form, but it is still more reactive. This is due to differences in hydrogen bonding and crystal packing that expose the reactive carboxylic acid group on the crystal surface for the α-form.[36]

Chemical instability can also be seen as an outcome of physical changes in the form. For example, in the case of either amorphous forms or crystalline API where amorphous regions are introduced during the various processing operations such as grinding, milling, compaction, or lyophilization, molecular mobility plays an important role in chemical reactivity in the solid state. Increased molecular mobility is shown to result in increased rates of chemical degradation in a wide variety of reactions, including hydrolysis, cyclization, and even oxidation.[38,39] In such cases, water acts as a plasticizer and is important when considering such drugs or excipients. Amorphous material can sorb large amounts of water, which will be more localized in the amorphous regions,[40,41] leading to varying chemical reactivity depending on the extent of such disordered regions in the DP. Similarly for drug excipient interactions, water can play a significant role by increased water content brought in by the excipient that is adsorbed into the drug or increases the amount of water in the sorbed layer at the drug excipient point of contact, thus increasing or facilitating the rate of chemical degradation with that excipient.

Typical solid-state reactions include hydrolysis, oxidation, cyclization, and racemization. Excipients used in DPs are typically related to chemical instability by virtue of the reactive impurities found in these systems and the choice of form influences the potential chemical reactivity.[42] Similarly polymorphs can also have varying stability as seen in the case of chloroquine diphosphate,[43] where the stability under light varies, or for the various polymorphs of prednisolone *t*-butyl acetate, where only one form was found to be susceptible to oxidation and had a tunnel parallel to the hexagonal axis of the crystal that allowed oxygen to penetrate, while the other forms had closely tight packing.[44]

4.2.1.2 Hygroscopicity

Hygroscopicity refers to the ability of a solid to take up and retain water at various RH and temperatures. Both the equilibrium moisture and the rate of uptake are important to understand to assess the hygroscopicity of various forms and potential impact. Various forms, morphology, crystallinity, and the state of hydration affect the water uptake under different experimental conditions. Low hygroscopicity is always preferred for the selected API form. Based on the extent of water uptake, pharmaceutical solids can be classified into nonhygroscopic, slightly hygroscopic, and hygroscopic solids.[45] Moisture adsorption isotherms, plots of equilibrium water content of a solid as a function of RH at a constant temperature, are commonly used to assess the hygroscopicity of pharmaceutical solids.

Hygroscopicity can be determined by storing solids at various controlled RH and temperature over long periods of time to equilibrate and measure weight gain or more typically in recent times by the automated sorption microbalance technique or dynamic vapor sorption instruments. In this, small quantities of drug (about 5 mg) are purged with humid nitrogen and equilibrated at controlled humidity and temperature, and the weight change is recorded. Highly crystalline solids typically have negligible surface adsorption of water, whereas high amounts of water uptake are seen typically for amorphous or deliquescent materials. Stepwise increase in water uptake is typically seen for stoichiometric hydrates, while nonstoichiometric or channel hydrates show a more gradual increase in water uptake as a function of RH.[46–48] Typically, percent weight change associated with the solid can be

used to determine the stoichiometry of the hydrate based on the molecular weight of the compound. Measurements of hygroscopicity using the dynamic sorption technique typically include an initial drying phase, which should be avoided for forms that may be solvates or hydrates. Differences in kinetics of adsorption and desorption are sometimes observed, leading to the two isotherms not coinciding and resulting in a hysteresis. The most common reason for hysteresis is the slower sorption kinetics, but a few other likely reasons are deliquescence at high humidity followed by no recrystallization during the desorption phase or amorphous material undergoing conformational changes due to water uptake or formation of a new form (hydrates) that show varying kinetic stabilities.[49,50] Typically adsorption-desorption studies are coupled with analysis of the solids such as powder X-ray diffraction (PXRD) to confirm the API form identity at various parts of the adsorption-desorption cycle. Sometimes crystalline material due to surface amorphous regions show larger amounts of water uptake and can cause issues with processing and handling of pharmaceutical API during manufacture and storage. Measurement of hygroscopicity of early lots of API showing differences in moisture uptake profiles can be an indication of amorphous regions, phase impurities, and crystal defects and provides information on early lot-to-lot variability. These studies can provide important insight into phase transformations and critical water activity ranges between hydrates and anhydrate forms as long as the isotherms are completely reversible; however, when hysteresis is observed, the kinetics are critical in correlating relevance on long-term moisture uptake.[51]

Increased hygroscopicity can lead to an increase in molecular mobility and solid-state reactivity. Deliquescence, conversion of forms (formation of hydrates), and potential chemical instability due to higher degradation are all possible due to increased water absorption by surfaces of solids.[13] Additionally, physical instability due to changes in moisture content leading to dissociation of salts, conversion of hydrates to anhydrates or vice versa during DP processing or storage can result in dissolution slow down.[52,53] Given the impact of changes in moisture content of the API form to alter physicochemical properties and altered product performance, low hygrosopicity is a desirable property during form screening. Understanding the critical water activity ranges for various hydrates/anhydrates is also important. Considerations of the potential impact of unit operations such as drying, milling on API form, and the potential generation of crystal defects, amorphous regions, and altered moisture uptake profiles are important considerations during form evaluation.

The hygroscopicity behavior can vary significantly across various forms, polymorphs, or hydrates of a given molecule. For example, in the case of carbamazepine, which is hygroscopic at high RH and converts to the dihydrate, formation of cocrystals with nicotinamide coformer have shown to prevent dihydrate formation up to 1 month at 40°C/94% RH.[54]

4.2.1.3 Solubility, dissolution rate, and bioavailability

Differences in crystal packing result in wide range of physicochemical properties, including melting point differences, differences in internal energy, enthalpy, free energy, chemical potential, and solubility. In case of polymorphs or pseudopolymorphs, the thermodynamic stability also dictates the solubility. Pudipeddi et al.[55] surveyed over 55 compounds and their polymorphs/pseudopolymorphs and found that the average solubility ratio of the individual polymorphs to the most stable (least soluble) one was 1.7.

Polymorphs with two-fold or larger difference in solubility may have improved in-vivo performance, as seen in the case of chloramphenicol palmitate, where a fourfold solubility difference showed a sixfold difference in C_{max} in humans, whereas mefenamic acid with a 1.3-fold solubility difference showed no significant improvement in vivo.[1] Another classic case of the impact of polymorphs on solubility and dissolution rate is for ritonavir. A new thermodynamically stable form II was discovered a couple of years after form I was launched in the market. The two forms had a greater than fivefold solubility difference, and hence form II supersaturated and was much less soluble in the semisolid formulation, forcing the manufacturer to recall the original formulation.[56,57] However, the impact on bioavailability between various polymorphs also depends on additional factors such as solubility difference, dose, permeability, and formulation factors. Biopharmaceutics Classification System (BCS) analysis or computational simulations using physiologically based pharmokinetic (PBPK) modeling with software programs such as GastroPlus can be used to assess the interplay between solubility, dose, and permeability to predict overall impact on bioavailability.

The lower aqueous solubility typically imparted by hydrates is an important consideration when evaluating neat and hydrate forms for a given drug and its potential risk to in vivo exposure. The kinetic advantage of the higher aqueous solubility of the anhydrate form is important in the consideration of various forms or designing dosage forms that may impart longer supersaturation states with respect to the lower solubility hydrate forms.

Typical solubility measurements include the equilibrium solubility, which is the solubility at equilibrium. These measurements are usually run over 24 hours or longer, and the results can be impacted by changes in temperature during the study or phase changes such as the formation of hydrates, solvates, and disproportionation of salt forms. Evaluating solution-mediated phase transformation during these dissolution or solubility studies is an important consideration. Even though phase conversion is expected to occur based on thermodynamics driving force, the kinetics will govern whether it will occur during the relevant conditions and time. Assessing the kinetic dissolution as a function of time provides information not only on the equilibrium solubility but also the metastable forms and their dissolution rates. Two commonly used methods for assessing form solubility is powder dissolution and intrinsic dissolution.[58] In cases of polymorphs, salts, or cocrystals, if the form is physically unstable under biorelevant aqueous condition, equilibrium solubility may not be relevant to correlate to oral absorption, and kinetic solubility or intrinsic dissolution rates (IDRs) over a few hours are more relevant.

The intrinsic rate is a dissolution rate measured by an intrinsic apparatus and is independent of surface area. The rotating-disk system is used most commonly used, and a good correlation of results is observed compared with the fixed-disk system[59]. The IDR can serve as a surrogate to the equilibrium solubility studies. These measurements provide information on any phase transformations during the solubility study and are able to capture transient supersaturation concentrations. The IDR study results can vary based on internal and external factors (properties of solid state, surface area, hydrodynamic condition, composition of dissolution media, vibration, rotation speed, presence of dissolved gases in dissolution media, and sample sites), and hence when comparing results, the methods should be standardized. Any change in phase transition during the experiment such as the conversion of amorphous atorvastatin into crystalline,[60] conversion of diclofenac salt to free acid form,[2] or conversion of polymorphs can be picked up easily by nonlinear dissolution curves for the amount dissolved versus time due precipitation of the more stable form. However, intrinsic rates can still be obtained from the linear portion of the curves. The ratio of IDR of two solid forms of the same drug (eg, polymorphs, hydrates) corresponds to the solubility ratio between the same forms. Therefore, the IDR experiments are advantageous over solubility experiments when studying the relative stability of solid forms, especially when there is phase transformation during solubility studies.

Drug dissolution is the first step in the absorption process, and both solubility and the rate of dissolution play an important role in the in vivo absorption. The drug dissolution rate can be described by[61]:

$$DR = \frac{dX_d}{dt} = \frac{A \times D}{\delta} \times \left[\frac{C_s - X_d}{V}\right]$$

where A is effective surface area, D is the diffusion coefficient, δ is the diffusion layer thickness, C_s is saturation solubility, X_d is amount of drug in solution, and V is volume of dissolution media. In-vivo gastrointestinal conditions such as bile salt concentration and the pH level of the stomach can both impact the solubility or dissolution rate of the drug and affect in-vivo absorption.

When evaluating in-vitro dissolution or solubility measurements, it is important to have media that are close in composition to in-vivo conditions to have predictive ability. Typical aqueous buffers used as dissolution media can simulate the pH appropriately but cannot simulate the ionic strength, bile salt composition, surface tension, or viscosity. In order to simulate the in-vivo conditions adequately, assessing dissolution and solubility in more physiologically relevant in-vitro methods is important for poorly water-soluble drugs. The common biorelevant dissolution media are simulated gastric fluid and simulated intestinal fluid under fasted (FaSSIF) or fed (FeSSIF) conditions. Composition of the media greatly influences the predictability, and many studies have been conducted over the years to establish the compositions. For example, for FaSSIF and FeSSIF media, sodium taurocholate is used as representative bile salt since it closely represents cholic acid, which is found in human bile.[62] Additionally, the buffer capacity of FaSSIF is much lower than FeSSIF to represent in-vivo conditions. In the case of fed-state conditions, to represent the post-meal conditions, taurocholate and lecithin are included at much higher concentrations. A detailed review by Klein describes the various biorelevant media, compositions, and examples on the application of biorelevant dissolution and correlation to in-vivo studies for various drugs including danazol, itraconazole, or phenytoin.[61] As part of solid-form screening, especially for BCS Class II molecules where solubility is rate limiting, solubility measurements should be conducted in biorelevant media with dose/solubility ratios calculated, and dissolution tests in these media can potentially provide a tool for more meaningful in-vitro to in-vivo correlation.

Typically forms are designed to provide higher solubility and dissolution, which translate to higher bioavailability in vivo. Given the wide range of solubility and dissolution rates between forms, the choice of form can dictate bioavailability and can also impact

PK parameters such as C_{max} and T_{max}.[63] In vitro data generated in biorelevant media for various forms can serve as a selection criteria to pick lead candidates in preclinical animal studies to assess the impact on bioavailability. Assessing in-vivo performance of various forms in preclinical animal models such as dogs, monkeys, or rats under fed, fasted, or famotidine-treated conditions is an important aspect during selection. Data from in-vitro biorelevant solubility studies and preclinical animal PK data can then be used into computational simulations using physiology-based pharmacokinetic modeling softwares (eg, GastroPlus, Simulations Plus, Inc.) that are now routinely used to assess the impact of rate-limiting factors affecting the overall absorption. This approach can be very effective during form selection to identify limits on potential physicochemical properties such as solubility to maximize bioavailability. Chiang et al. demonstrated the use of PBPK modeling during the salt selection process of phenytoin to determine the solubility requirement for the salts at the relevant dose, which was used to guide the salt selection process.[64]

4.2.2 Considerations for various forms

As detailed in the previous section, the ideal solid form possesses desirable physical, chemical, and biopharmaceutical properties to enable both API and DP. The solid-form selection is conducted with this end goal in mind and involves identifying and characterizing multiple forms ranging from the crystalline solids (polymorphs, cocrystals, solvates/hydrates) to amorphous solids. The following section provides guidance on theoretical and practical considerations for salt and cocrystal formation, polymorphs/ hydrates, solvates, and amorphous solids.

4.2.2.1 Salts

A large fraction of drug molecules are ionizable and amenable for salt formation. Some of the key reasons to select salts over their free forms include increased solubility, dissolution rate, and/or bioavailability,[65] enhancement in physical and chemical stability, reduced hygroscopicity and improvement in purity, and handling and processability of API.[3,15–17,65–67] Salts may also afford improved powder properties such a compactibility leading to advantages in the DP manufacturing processes. One clear disadvantage of salt over the free form is the increase in the weight of a drug substance for the same amount of active moiety due to the inclusion of the counterion. In some cases, salt formation may be an additional step in the API manufacturing process. It is also possible that, for some cases, the salts may have inferior properties compared to the free forms.[68] Some of the key considerations in salt selection are detailed below.

4.2.2.1.1 pH-solubility profile and salt solubility

The aqueous solubility of weakly acidic and basic drugs is a function of pH and is governed by the ionization or dissociation constant.[17] The intrinsic solubility is defined as the solubility of the unionized form of the molecule. The relationship of pH and solubility of an ionizable molecule is described by the Henderson–Hasselbalch equation. The pH–solubility profile of a weak base can be described by two independent curves, one where the base is the equilibrium species, and the other where the salt is the equilibrium species. Fig. 4.1 shows the pH solubility of a weak base where it can be divided into Region 1 and 2. At equilibrium, at all pH values other than at the pH_{max} (pH of maximum solubility), only one solid phase (free form or salt) exists whatever is the starting material.

The total solubility for a base is a sum of its unionized (free base) and ionized form:

$$S = \left[BH^+\right] + [B]$$

where S is total solubility, $[BH^+]$ is the ionized base (salt), and [B] represents the unionized base.

As shown in Fig. 4.1, for a monobasic compound when dissolved in water, the following equilibrium exists:

$$BH^+ + H_2O \underset{K_a}{\Leftrightarrow} B + H_3O^+$$

or

$$K_a = \frac{[B][H_3O^+]}{[BH^+]}$$

where K_a is the ionization constant.

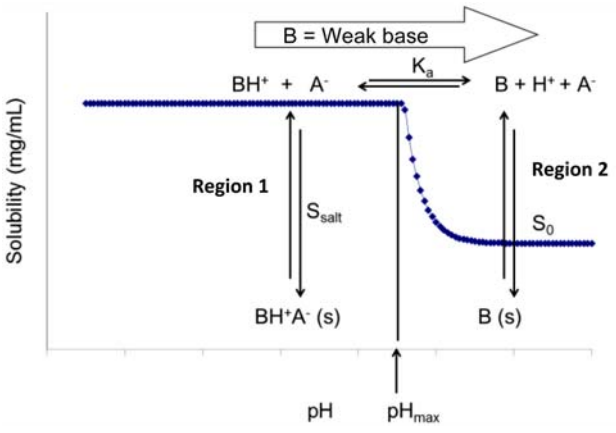

FIGURE 4.1 pH–solubility curve for a weak base.

In Region 2, where pH > $pH_{max,}$ the excess solid is the free base, and the solubility curve is described by the free base solubility and can be defined as

$$S = S_0\left(1 + \frac{[H_3O^+]}{\lfloor K_a \rfloor}\right)$$

where S is total solubility, S_0 is intrinsic solubility, and K_a is the ionization constant.

In Region 1 of Fig. 4.1 for a weak base, where pH < pH_{max}, the excess solid in equilibrium with the saturated solution is the salt. The solubility in this region is defined as:

$$S = \sqrt{K_{sp}}\left(1 + \frac{K_a}{[H_3O^+]}\right)$$

$$K_{sp} = [BH^+][A^-]$$

where K_{sp} is solubility product of the salt.

The pH value where Region 1 and 2 curves intersect is called the pH_{max} or the pH of maximum solubility.[69]

For a weak base, as the pH increases up to the $pH_{max,}$ the solubility is that of the salt. Even though the Figure 4.1 shows a pH independent region, there is a weak dependence on pH due to ionization of the salt. At pH values beyond the pH_{max}, the solubility decreases drastically due to decreased dissociation of salt to free base. At pH ≫ pK_a, the solubility again represents the intrinsic free base solubility and is independent of pH.

At the pH_{max}, in the presence of excess solid, the solution is saturated with respect to both the salt and the free form. Equating equations 2 and 3 above, the pH_{max} for bases can be defined as:

$$pH_{max} = pK_a + \log\frac{S_0}{\sqrt{K_{sp}}}$$

Similarly, the pH_{max} for weak acids is defined as:

$$pH_{max} = pK_a - \log\frac{S_0}{\sqrt{K_{sp}}}$$

The location of pH_{max} provides an indication of relative stability of salt versus free base as a function of pH in aqueous solutions or in the diffusion layer of solid particles, which provides the microenvironmental pH. The equation above shows the impact of the pK_a, $S_{0,}$ and K_{sp} on the pH_{max} and thus provides a measure of the stability of a salt as a function of aqueous pH.[70] For example, for a weak base, as the strength of the weak base increases (pK_a increases by one unit), the pH_{max} increases by one unit. Similarly, an order of magnitude increase in solubility of salt ($\sqrt{K_{sp}}$) decreases the pH_{max} by one unit. Given this, it can be perceived that the pH_{max} can shift over several orders of magnitude depending on the choice of counterions, which in turn relates to differences in the solubility or K_{sp} for the various salts and can be correlated to the melting point (crystal lattice forces).[71] In the case of weak acids above the pH_{max} and in the case of weak bases below the $pH_{max,}$ the solubility profiles are those of the respective acid or base salts. Ideally, the pH-solubility profiles generated using the free form or its salt should be superimposable when the same acid or base is used for pH adjustment in both cases. However, it is not uncommon to observe deviations from the ideality, as reported by Ledwidge and Corrigan.[72]

4.2.2.1.2 Selection of counterions and salt formation

Commonly used anions and cations typically considered for salt formation are listed in Table 4.1. Based on experience, for weakly basic acids and bases, a difference of two pK_a units (ie, the acid pK_a should be at least two units lower than the base) is ideal for obtaining a stable salt. This rule of thumb has not been formally proven but is often used in the salt selection.[14,73–75] Cruz-Cabeza[76] reviewed the relative occurrences of 6465 neutral and ionized acid-base crystal structures in the Cambridge Structural Database. Salts or ionized acid-base complexes were exclusively observed when the pK_a difference was 4 or greater, and nonionized acid-base complexes (cocrystals) were exclusively observed when the pK_a differences were −1 or lower. Both salts and cocrystals occurred when the pK_a difference was in the range of −1 and 4, although the probability of salt formation increased with an increase in pK_a difference in a linear fashion. Given this rule of thumb, very weak bases (pK_a 1−2) are limited to strong acids, whereas bases such as imidazole (pK_a 6−7) can form salts with a wider range of acids.[16] Paulekuhn et al.[77] surveyed the Orange Book database published by the Food and Drug Administration (FDA) in 2007 for the frequency of occurrence of different counterions in pharmaceutical salts. Chloride and sodium counterions were the most frequent for anionic and cationic choices respectively, but there was an increasing number of other counterions also being used.

A major factor in salt selection is enhancement of solubility and dissolution of oral solids, especially for immediate-release products. A priori prediction of salt solubility (K_{sp}) based on salt former properties such as hydrophilicity, pK_a is difficult. For example, as shown by Hsieh et al. in Table 4.2 for miconazole salts, despite of having a similar pK_a value to methanesulfonic acid (pK_a −1.89), the nitrate salt of miconazole (pK_a of nitric acid = −1.3) exhibits almost a threefold lower solubility.[78]

The salt solubility will not only depend on the structure and properties of the drug and salt former but also on the solid-state properties of the resulting

salt. The salt-forming counterions could impact salt solubility by changing both the crystal lattice and solvation energies[79,80]; therefore, salt solubility is often determined experimentally. Sometimes the experimental determination of aqueous solubility of salts may be challenging due to disproportionation (eg, for low pHmax), self-association, supersaturation, or other experimental factors.[70,79] An additional factor that can contribute to changes in salt solubility is the presence of common ions in solution. For example, the presence of sodium chloride led to a decrease in hydrochloride salt solubility compared to the theoretical curve due to the common ion (chloride) effect.[81]

Tong and Whitesell[75] developed an in situ salt-formation methodology that also provides a rapid assessment of solubility values of possible salts. A negative result of not observing a crystalline salt from an in situ salt-screening approach may not necessarily mean that a salt can't be crystallized. A more detailed approach to solid-form screening is discussed in a later section of this chapter. In the event that a crystalline salt is observed during the in situ screening approach, it allows for an estimation of salt solubility by combining mass balance and ionic equilibria equations. For determining solubility of the salt of a freebase, the approach involves measurement of solubility of weak bases in the presence of excess amounts of acids that generate salt-forming counterion and tracking the amount of base, the concentration of the acid, volume, and final pH. The solubility product for a 1:1 salt precipitated during the experiment is given by the following equation:

$$K_{sp} = \frac{S}{MW}\left[\frac{[A] - \frac{(X - S \times V)}{V \times MW}}{1 + [H^+]/K_a}\right]$$

where X (mg) is the amount of solid base added, S (mg/mL) is the solubility in the acid solution, MW is the molecular weight of the base, V (mL) is the volume of the solution, [A] is the molar concentration of the acid, pK_a' is the ionization constant of the acid used, and pH is the final pH at the end of the experiment. This is especially important for hydrochloride salts in vivo where the chloride ion common effect can result in further suppressing the hydrochloride salt solubility.

4.2.2.1.3 Dissolution and oral absorption of salts

Dissolution of ionizable drugs and salts in unbuffered and buffered systems has been explained by applying the diffusion boundary layer theory, taking into account the ionic equilibria.[82] The pH of the diffusion layer (sometimes referred to as the microenvironmental pH) is a key factor in controlling the dissolution rate of the solid. The diffusion layer pH for the free form of an ionizable drug could be very different from the bulk pH due to the self-buffering action of the free form and dependent on the pK_a and solubility of the free form.[82] Salts also have the self-buffering capability and thus influence the diffusion layer pH. A number of reports on the relative dissolution rates of salts and free forms in reactive media have been reported.[17,83]

TABLE 4.2 Physicochemical Properties of Miconazole Free Base and Salts

Salt	pK_a	pH_{max}	pH at saturation	Salt solubility (M)	Free base solubility (M)

Li et al.[84] reported that the dissolution rate dependence on dissolution medium pH for free base, chloride, and mesylate salts could be explained by the diffusion layer pH. A summary of the results are provided in Table 4.3. It is clear that at very low pH conditions, the free base and mesylate salt showed similar dissolution rates as they all converted to chloride salt. As the pH increased, the salts outperformed the free base; the mesylate salt showed significantly higher solubility relative to the chloride salt owing to its higher K_{sp} that is expected to lower the diffusion layer pH.

In this example, the diffusion layer pH for both the salts was lower than the $pH_{max,}$ and there was no conversion of the salt to free base. For many salts, that may not be the case when the diffusion layer pH favors the free form. Understanding the kinetics of supersaturation, dissolution, and precipitation during the dissolution process becomes very important. In solution, salts can form supersaturated solutions, which is a metastable kinetically favored process near the pH_{max} where solubility values greater than saturation or theoretical solubility of the salt are observed.[65,67,68,85,86] The ability to kinetically maintain supersaturation is an important factor in providing the dissolution rate advantage for salts. Hawley et al. outlined[87] two mechanisms of precipitation: bulk precipitation, where the free form precipitates in solution; and surface precipitation, where the free form precipitates on the surface of the dissolving salt. In bulk precipitation, the solution concentration exceeds a certain critical concentration only after which precipitation starts occurring and continues until the solubility reaches that of the free form. In surface precipitation, the free form starts precipitating on the surface of the salt, and since the free form has lower solubility, the dissolution curve immediately slows down. The surface precipitation mechanism impacts dissolution of solubility the most by forming a coating of the free form on the surface, decreasing its dissolution. For salts, the supersaturation is the highest at the surface or in the diffusion layer surrounding the particles, and this leads to faster rates of free form precipitation at the surface, causing a layer of free base and slowing down overall dissolution. Diffusion layer-based dissolution models have been described in literature to predict the surface pH in dissolution media.[82] Understanding these dissolution and precipitation mechanisms can enable formulation design by altering the diffusion layer by inclusion of excipients to modify the pH of the diffusion layer and thus increase dissolution and absorption.[88]

It is important to consider the pH changes as the drug transits through the gastrointestinal tract. Following dissolution of the salt, precipitation and redissolution may occur, depending on the properties of the drug including pH-solubility profile, absorption rate, dose, and particle size. These factors play a role in the choice of salts versus their free forms. Ku[89] proposed that for highly soluble drugs (ie, BCS Class I and III), salts may not be beneficial compared to the free forms from a purely oral absorption perspective. The importance of salts in overcoming dissolution and absorption problems for poorly soluble drugs can't be overstated. When salts of free bases are administered, dissolution readily takes place in acidic conditions in the stomach. The chloride common-ion effect may sometimes be observed with hydrochloride salts, or the drug may convert to hydrochloride salt in the solid phase. Upon transiting into the intestine, the portion of the drug that is dissolved may remain in solution prior to absorption, or it may precipitate as free base. The undissolved portion of the salt is likely to convert to the free base or dissolve. The salt forms are generally beneficial for oral absorption of weak bases. Salts of weak acids are expected to undergo rapid dissolution and potentially precipitate as free acid in the stomach. The dissolved drug is absorbed in the intestine, and the undissolved drug undergoes dissolution prior to absorption. Although the case for salts of weak acids may not appear to be strong from an oral dissolution-absorption perspective, the kinetics of supersaturation, dissolution, and precipitation needs must be considered for the individual salt and free acid forms.

4.2.2.1.4 Toxicity of counterions

When a drug is administered in a solid dosage form, depending on the salt form dosed, the in-vivo solubility can be varied, thus influencing the pharmacokinetic and toxicological profile.[90] The choice of counterion can impact absorption through modification of the dissolution rate. The potential toxicity of a counterion is related to key factors such as dose, route of administration, pharmacokinetics, and the therapeutic indication.

Some counterions may lead to the formation of toxic impurities that may need to be controlled. For example, sulfonic acid salts such as mesylate, tosylates, and even sulfate salts can potentially lead to the formation of alkyl esters, which are known to be genotoxic in the presence of alcoholic solvents during processing. The toxicity concern can be addressed by implementing a good control strategy to monitor their levels in API and DPs.[91]

Pfannkuch et al.[10] has classified salt formers into three categories based on their toxicity profiles. Class 1 includes counterions such as chloride and sodium that are physiologically ubiquitous. Class 2 includes counterions that have been widely used and have relatively low toxicity and good tolerability, and Class 3 includes those that may be used for special considerations, for example, to provide some pharmacological effects.

In the case of cations, metal ions specifically such as sodium, potassium, calcium, and magnesium, since naturally abundant under physiological conditions, do not pose toxicity concerns and are considered inert at typical physiological levels. Similarly, nitrogen bases that are essential amino acids are of no concern. However, other cations such as lithium are used as therapeutic materials and are not inert. Also, long-term dosing of lithium in humans can cause irreversible damage to the kidneys,[92] while maleate salts have been reported to cause renal damage in dogs even after a single dose at 9 mg/kg.[93] Anions such as chlorides and phosphates are physiologically abundant and well tolerated, while other anions such as bromide, iodide, and nitrate need to be considered based on the amounts used. Certain salts may cause local irritation such as alprenolol HCl, which has an irritant effect on the esophagus, but benzoate salt has no such effect.[94] A more detailed review of toxicology considerations of various counterions and the effect of dose and route of administration for nonclinical and clinical use have been reported by Thackaberry[95] and Saal and Becker.[90] Tables 4.4 and 4.5, adapted from Saal and Becker, categorize the commonly available and maximum doses for various counterions for oral use. However, other considerations such as special populations (pediatric/geriatric/nursing women) should be considered if relevant during salt selection. Additional details on toxicology studies conducted for each pharmaceutical salt can be found on the FDA websites.

While the choice of a counterion during salt selection is mainly driven to enhance bioavailability or stability, safety of these salts is a key criteria of selection. Given this, while counterions are typically considered inert, along with factors such as ionization constants, solubility, and product stability, toxicity considerations are a key element in counterion selection. Other factors such as thermodynamic stability, disproportionation risk to free form, and supersaturation phenomenon shown by salts all go into the selection process and are discussed later.

4.2.2.1.5 Chemical stability considerations

The form of the API plays a significant role in influencing the chemical stability of a drug. Salt formation can lead to enhancement of the chemical stability of drugs. The microenvironmental pH also plays a significant role in determining the chemical reactivity of the DP. For example, for molecules that are acid labile, the selection of an acidic salt will increase the propensity

TABLE 4.4 Identified Maximum Daily Dose of Anionic Salt Formers Used in Oral Products

Salt former	Maximum daily dose (counterion)	Salt
Acetate	50 mg	Flecainide acetate
Benzoate	14 mg	Rizatriptan benzoate
Besylate	160 mg	Mesoridazine besylate
Bromide	300 mg	Pyridostigmine bromide
Carbonate	1500 mg	Lithium carbonate
Citrate	5250 mg	Piperazine citrate
Edisylate	20 mg	Prochlorperazine edisylate
Estolate	1450 mg	Erythromycin estolate
Fumarate	120 mg	Quetiapine fumarate
Gluconate	730 mg	Quinidine gluconate
Hippurate	1120 mg	Methenamine hippurate
Iodide	99 mg	Potassium iodide
Malate	60 mg	Diltiazem malate
Maleate	250 mg	Acetophenazine hydrogenmaleate
Mesylate	420 mg	Nelfinavir mesylate
Methylsulfate	200 mg	Diphemanil methylsulfate
Napsylate	170 mg	Propoxyphene napsylate
Oxalate	5 mg	Escitalopram oxalate
Pamoate	325 mg	Hydroxyzine pamoate
Phosphate	380 mg	Chloroquine dihydrogenphosphate
Stearate	1500 mg	Erythromycin stearate
Succinate	90 mg	Loxapine hemisuccinate
Sulfate	380 mg	Indinavir sulfate
Tartrate	3900 mg	Cysteamine hydrogentartrate
Tosylate	890 mg	Lapatinib ditosylate

Chloride is not included in this table since it is an endogenous physiologically ubiquitous ion.

TABLE 4.5 Identified Maximum Daily Dose of Cationic Salt Formers Used in Oral Products

Salt former	Maximum daily dose (counterion)	Salt
Calcium	672 mg	Edetate calcium
Lithium	338 mg	Lithium carbonate
Lysine	860 mg	Ibuprofen lysine
Magnesium	4.9 mg	Omeprazole hemi-magnesium
Meglumine	8220 mg	Diatrizoate meglumine
Olamine	21 mg	Eltrombopag diolamine
Potassium	3575 mg	Aminosalicylate potassium
Tromethamine	2650 mg	Fosfomycin tromethamine

Sodium ion not listed since it's an endogenous and physiologically ubiquitous ion.
Adapted with permission from Saal, C.; Becker, A. Pharmaceutical salts: A summary on doses of salt formers from the Orange Book, European Journal of Pharmaceutical Sciences 49 (2013) 614–623.

of a hydrolysis reaction. Among the strategies to influence the chemical reactivity of a drug is through the modification of the microenvironmental pH. Badawy et al. showed that by choice of the mesylate salt form of the API or addition of acidic pH modifiers, which lower the microenvironmental pH, the ester hydrolysis reaction was successfully mitigated to enable a stable DP.[3,96] Similar to a stabilization effect, the use of excipients that can destabilize a salt form, as in the case of sertraline salts, was shown to induce conversion to free base in the DP leading to oxidative instability.[66] It is also possible that degradation may be exacerbated by salt formation either due to unfavorable microenvironmental pH conditions or direct interaction between the drug and counterion (eg, Michael addition between primary amine and fumaric acid).

4.2.2.1.6 Disproportionation of salts

In the case of salts, the physical stability related to the risk of disproportionation both in the solid state in DP and in vivo are key considerations, and kinetics of supersaturation and conversion to free form need to be assessed during salt selection. Disproportionation of salts is dissociation of the ionic species into its neutral and acidic or basic counterion, and this typically leads to the loss of the improved solubility due to formation of lower solubility free acid or base or alternately poor physicochemical properties, including lower stability. In case of cocrystals, dissociation involves the separation of the API molecules and the coformer.

The general rule of thumb to form stable salts is for the counterion and the active molecule pK_as to differ by a unit of 2. However, this is not the only criteria governing the disproportionation potential. Some critical factors include the microenvironmental pH (in solid state) and the pH_{max}. The microenvironmental pH is the pH of the microscopic layer that surrounds the solid particles of API, where a saturated solution of the solid exists due to adsorbed moisture. In oral solid dosage forms, the pH of the excipients that are mixed with the API dictate the microenvironmental pH.

Hence, modification of the microenvironmental pH of salts of drugs in solid dosage forms has been a successful strategy to mitigate the risk of disproportionation.[96,97] Similarly for acidic salts, the addition of basic excipients can increase the microenvironmental pH, thus resulting in conversion to free base, and depending on the reactivity of the various forms, the free base could be more reactive, leading to increased chemical degradation. The choice of excipients used in the DP will influence the microenvironmental pH, which then dictates the extent of disproportionation depending on the pH when compared against the pH_{max}.[66,98] If the microenvironmental pH is greater than the pH max, then the difference in solubility in the saturated layer between the free form and salt will govern the stability.

As described above, the pH solubility profile of a weak acid or base is a function of the K_{sp}, pK_a, and intrinsic solubility. For a weak base molecule, in the region above the $pH_{max,}$ the free base solubility is limiting, whereas in the region below the $pH_{max,}$ the salt solubility is limiting. At the $pH_{max,}$ the salt and acid are in equilibrium, and it represents the pH of maximum solubility, as described in the earlier section.

The microenvironmental pH will dictate whether thermodynamically disproportionation will be favored. Based on the equation for the pH_{max}:

$$pH_{max} = pK_a + \log \frac{S_0}{\sqrt{K_{sp}}}$$

where S_0 is solubility of the base, and $\sqrt{K_{sp}}$ is the intrinsic solubility of salt. Consistent with this equation, it can be seen that the more soluble a salt, the lower the $pH_{max,}$ resulting in a narrower practical operating pH range where the salt will be stable based on the microenvironmental pH. Thus, it's not only the pK_a that governs the disproportionation potential but also the pH_{max}. This is demonstrated in Fig. 4.2 by Hsieh et al., where a strong correlation is seen between the extent of disproportionation and the pH_{max} for a series of miconazole and sertraline salts.[78] Additionally, the buffering capacity of the salt may also play a role in dictating the disproportionation potential.[78,99]

Stephenson et al.[100] conducted a survey of around 203 active molecules and their counterions, which shows that no salts were reported for weak bases with pK_as of less than 4.6.

Along with these concepts, another important factor is the buffering capacity of the salt. As expected, salts with a lower buffering capacity tend to disproportionate more. The choice of excipients, for example magnesium stearate or croscarmellose sodium, and their buffering capacity influences the microenvironmental pH and are also important in the disporportionation potential.[99,101]

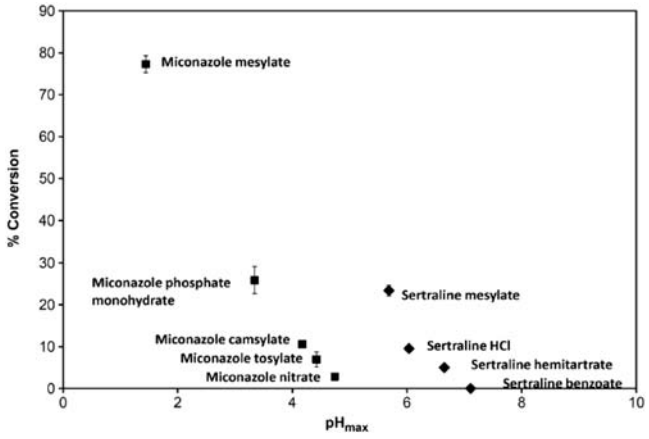

FIGURE 4.2 Relationship between pH_{max} and the extent of disproportionation for a series of miconazole and sertraline salts. *Reproduced from Hsieh YL et al. Salt stability—the effect of pH_{max} on salt to free base conversion. Pharm Res 2015;32(9):3110–8 with permission.*

This dependency on pH_{max} has led to building a theoretical model to predict the salt disproportionation[78,102] in the solid state and correlates to experimental data showing reasonable success. The key assumption for this model was a solution-mediated conversion, and the accuracy of predictions was found to be related to water content for the various salts and the buffering capacity provided by the API itself. This figure shows how the moisture content influences the equilibria for salt disproportionation:

$$[BH^+A^-]_s \xrightleftharpoons{\text{Sorbed } H_2O} [BH^+]_{aq}$$

$$+ [A^-]_{aq} \xrightleftharpoons[\text{Salt formation } pH < pH_{max}]{\text{Disproportionation } pH > pH_{max}} [B]_{aq}$$

$$+ [H^+]_{aq} + [A^-]_{aq} \rightleftharpoons [B]_s$$

This relationship to pH_{max} also highlights that while having a salt with high solubility is typically desirable, the salt with highest solubility may not be the best form,[103] but rather the optimal salt balancing the solubility with the disproportionation risk should go into selection of a salt form.

Additional factors such as temperature, particle size, RH, and drug-to-excipient ratios can also influence the extent of disproportionation. Studies by Hsieh at al. demonstrate that for three mesylate salts studied, disproportionation kinetics in the presence of a base at high humidity (57%) showed the disproportionation curve to overlap with the weight gain curve, which was indicative of the moisture uptake by the salts during the study course.[78,101] Similarly, an increase in surface area and a lower drug-to-excipient ratio also results in higher disproportionation, which is likely related to

an increased surface area per unit mass that results in increased water uptake or higher excipient contact, resulting in conversion to free form. The effect of temperature is opposite to that of moisture uptake, that is, an increase in temperature causes reduced moisture uptake but results in increased disproportionation.[101] The increased propensity of disproportionation with temperature is related to an increase in solubility of a given salt, which results in a subsequent decrease in the pH_{max}. This discussion highlights the importance of formulation composition as well as process and storage conditions considerations in the successful development of salts of weak acids and bases.

4.2.2.1.7 Dosage form consideration

The selection of any API solid form, including salt selection, needs to be done with the DP in mind. The considerations of dose and dosage form are critical in salt-form selection. Dose is an important consideration in the development of drug candidates and is exemplified in the BCS. It is possible that for some poorly soluble ionizable drugs salt form is not advantageous over the free form at low doses but could become beneficial at higher doses. Such an example is presented as Case Study 1 in this chapter. The solid form requirements for a controlled-release formulation is different from the immediate-release dosage form. Low solubility may be advantageous for controlled or extended-release formulations, and, therefore, poorly soluble salts may be advantageous. As described in the above sections, the choice of salt form of weakly ionizable drugs will likely influence the selection of excipients and formulation composition as well as the DP process.

4.2.2.2 *Cocrystals*

In recent years, similar to salts, another class of molecules called cocrystals has advanced significantly due to its ability to enhance solubility and dissolution or to crystallize otherwise difficult-to-crystallize drugs (eg, amorphous drugs with pK_as not favorable for salt formation). Fig. 4.3 depicts potential configurations and molecular differences between cocrystals and salts. A cocrystal is a molecular multicomponent complex that contains two or more different molecules in the same crystal lattice.[104] Cocrystals differ from solvates in that all components are solids at room temperature and from salts based on the extent of proton transfer. Cocrystals depend on noncovalent, nonionic interactions, which include hydrogen bonding, $\pi-\pi$, and van der Waals interactions. The properties of cocrystals can be varied significantly by the choice of coformer and component stoichiometry. Similar to salts, the physicochemical properties for cocrystals including

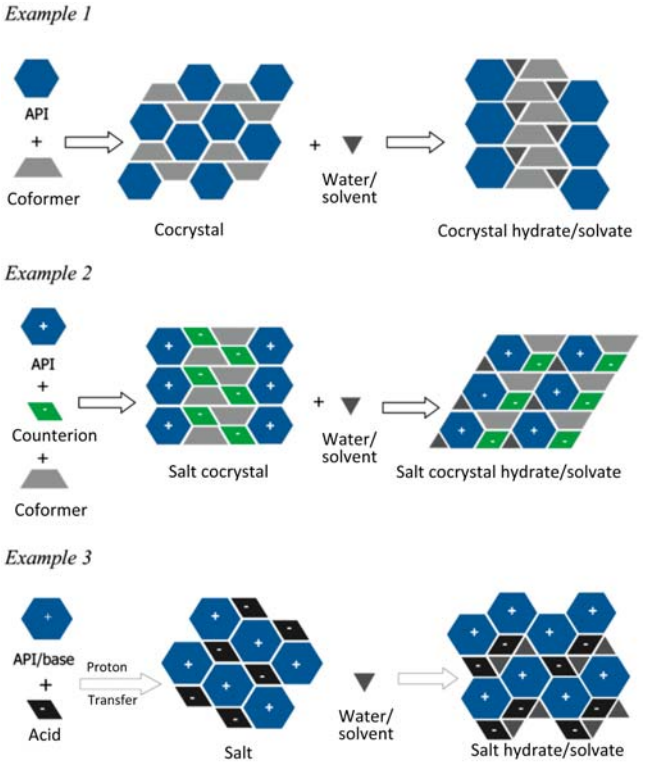

FIGURE 4.3 Possible multicomponent systems: cocrystals, salt cocrystals, and salts along with their respective solvate/hydrate forms. *Reproduced from Schulthesiss N, Newman A. Pharmaceutical cocrystals and their physicochemical properties. Crystal Growth Design 2009;9(6):2950–67 with permission.*

solubility, stability, dissolution rate, and melting point are important to assess during form screen.

Enhancement of solubility is the one of the primary drivers for cocrystal formation. As with salts, solubility is defined based on the solubility product, K_{sp}. For a cocrystal where A is a drug and B is a ligand, the solubility is described by the chemical equilibrium of solid cocrystal with solution and the corresponding equilibrium constant given by[105,106]:

$$A_\alpha B_{\beta(s)} \rightleftharpoons \alpha A_{(soln)} + \beta B_{(soln)}$$

Subscripts refer to the stoichiometric number of molecules of A or B in the complex. The equilibrium constant is given by

$$K \rightleftharpoons \frac{a_A^\alpha a_B^\beta}{a_{AB}}$$

If the activity of the solids is equal to 1, and assuming the activity coefficients (γ) of A and B equal unity for low-solute levels, cocrystal solubility can be described by solubility product K_{sp}:

$$K_{sp} = a_A^\alpha a_B^\beta \approx [A]^\alpha [B]^\beta$$

where [A] and [B] are the concentrations of components.

Two key factors influence the solubility behavior of cocrystals. One is the crystal lattice energy and solvation of the cocrystal components. Decreasing the crystal lattice energy or increasing the solvent affinity both lead to increased solubility of the cocrystal. In the case of cocrystals, a poor correlation is seen of solubility to melting point, but a reasonable correlation is seen with coformer solubility, indicating that solvation is often a greater parameter compared to lattice energy.[105,107]

4.2.2.2.1 Selection of coformer

The science of crystal engineering to form cocrystals is growing, and a number of API characteristics including hydrogen donor acceptor ability, pK_a, conformational flexibility, and solubility are important factors. An extensive review of cocrystals and coformers that existed prior to 2000 is compiled in the article by Stahly.[108]

The solubility values of 25 cocrystals from combinations of three drugs (carbamazepine, theophylline, and caffeine) and seven coformers (malonic acid, nicotinamide, salicylic acid, saccharin, succinic acid, glutaric acid, and oxalic acid) in four solvents (water, isopropyl alcohol, methanol, and ethyl acetate) were studied and ranked based on their solubility advantage over the drug.[26] The measured cocrystal solubility value ranged from 0.1 to over 100-fold of their respective drug solubility, and the coformer solubility spanned several orders of magnitude. A plot of cocrystal-to-drug solubility ratio against coformer-to-drug solubility ratio for each cocrystal showed a linear dependence. The larger coformer-to-drug solubility ratios showed a higher cocrystal solubility relative to the drug. The work demonstrated that cocrystal solubility enhancement could be rationally selected based on knowledge of the coformer solubility.

Since cocrystal solubility is dependent to a large extent on the concentration of cocrystal components in the solution phase, especially for highly soluble cocrystals (relative to the drug), assessing the solubility product K_{sp} is more reliable for cocrystal solubility estimation. High-solubility cocrystals compared to the parent drug can significantly impact equilibrium concentrations and may undergo solution (aqueous) mediated transformation to the less soluble drug, making solubility measurement a challenge.[109] The true cocrystal solubility is underestimated when transformation occurs during a solubility measurement in which the cocrystal is suspended in an aqueous solution. The drug concentrations observed during these kinetic measurements is highly dependent on the solution conditions and cannot be extrapolated to other solution conditions. Good et al.[110] developed a method for the determination of cocrystal solubility under equilibrium conditions. This is based on developing phase solubility diagrams and measuring the solution composition at the cocrystal transition or eutectic point. Shown in Fig. 4.4 is a plot of a drug against the coformer concentration. The cocrystal concentration decreases as a function of coformer concentration and intersects the drug concentration solubility curve at a point called the eutectic point, where the two solid phases (cocrystal and drug or coformer and the solution phase) are all in equilibrium at a constant temperature and pH. The eutectic point can be experimentally determined and is a key parameter that establishes the regions of

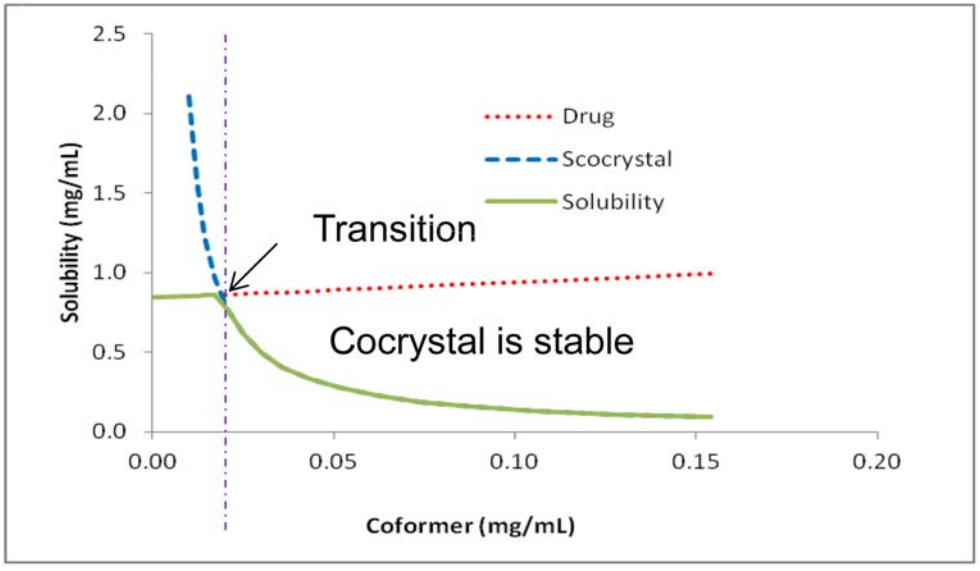

FIGURE 4.4 Phase solubility curve as a function of coformer concentration for the formation of cocrystals showing the transition or eutectic point.

thermodynamic stability of a cocrystal relative to its components. Similar to the pH_{max} in the case of salts, the eutectic point for cocrystals is a point where all phases, the solution, the solid cocrystal, and a solid component (drug or coformer), exist in equilibrium. This cocrystal eutectic point is an isothermal invariant point base on the Gibbs phase rule.

Multiple eutectic points can exist depending on what solid phases coexist at equilibrium. From the concentrations of drug and coformer at the eutectic point, the cocrystal solubility product K_{sp} can be calculated.

Cocrystal eutectic constant (K_{eu}), is the ratio of solution concentrations of cocrystal components at the eutectic point and is shown to be a function of the solubility ratio of cocrystal and drug in pure solvent. Similar to cocrystal solubility, it is shown to depend on solution chemistry including solvent, complexation, and ionization.[110] For a 1:1 cocrystal:

$$K_{eu} = \frac{[B]_{eu}}{[A]_{eu}}$$

Typically cocrystals are formed with acidic, basic, amphoteric, or zwitterionic coformers. Examples of coformers include but are not limited to benzoic, salicylic, maleic, glutaric, oxalic, fumaric, malic, and caprylic acids, to name a few.[111–113] Given the wide range of coformers similar to salts, cocrystal solubility can vary significantly based on ionization properties of coformers.

Cocrystals are typically made using solvent-based crystallization, mechanical grinding, or melt crystallization techniques. In solvent-based crystallization methods, it is predominantly recommended to utilize nonstoichiometric ratios of the components to create a large thermodynamic driving force for cocrystal formation. This use of nonstoichiometric composition has been termed a reaction crystallization method. Alternatively, stoichiometric ratios of reactants could be dissolved in a solvent of choice to achieve supersaturation either through a temperature difference or through evaporation of the solvent (solvothermal or evaporative methods). Further detail on screening strategies and cocrystal engineering is not covered here but can be found in a number of references.[8,32,111–115] Pharmaceutical cocrystals are becoming increasingly important as an alternate way to improve bioavailability and/or potential stability, mainly for weakly ionizable or nonionizable molecules with multiple ongoing efforts in supramolecular or crystal engineering to explore this.

4.2.2.3 *Polymorphs, solvates, and hydrates*

All crystalline forms such as neutral molecules, salts, or cocrystals can exist as polymorphs,[116] having the same chemical composition but different internal structures (lattice structures and conformations).[46] Polymorphs have been characterized based on structural differences in the crystal lattice as packing polymorphism or conformational polymorphism.[47] In the case of packing polymorphism, rigid molecules assemble into three-dimensional structures through different intermolecular mechanisms,[117] while in the other, flexible molecules are packed in different arrangements and are packed differently into the crystal structure.[118] When temperature is introduced as criteria, polymorphs can be classified as monotropic where the same polymorph is stable regardless of temperature, whereas for enantiotropic systems, there exists a transition temperature where the stability relationship inverts.

Solvates and hydrates are referred to as pseudopolymorphs where the crystalline form includes a solvent molecule such as water (hydrate) or any other solvent (solvate) in the crystal lattice. From a US regulatory perspective, solvates, hydrates, and polymorphs belong to the class of polymorphs.[119] Based on the structure crystalline hydrates can be categorized as channel hydrates, isolated-site hydrates or ion-associated hydrates.[47] Channel hydrates can be nonstoichiometric where additional water molecules can enter the channels when exposed to high humidity and dehydrate under low humidity, expanding or contracting the crystal lattice. Nonstoichiometric hydrates are of specific concern, if chosen for development, due to changes in water content in the crystals.[120]

For polymorphs, the free energy temperature diagrams and the Burger–Ramberger thermodynamic rules[121] are common to assess stability relationships. The relative thermodynamic stability of the forms at a constant temperature and pressure is defined based on the difference in the Gibbs free energy given as

$$\Delta G = \Delta H - T\Delta S$$

where ΔH is the enthalpy difference between forms as it relates to the lattice energy difference and ΔS relates to entropy difference or crystal disorder. A negative free energy or decrease in the free energy indicates a spontaneous process and is thermodynamically favored, while a positive value indicates a thermodynamically unfavored process. When $\Delta G = 0$, the system is at equilibrium, and the free energy of the two phases is the same.

Fig. 4.5 shows a relationship of the Gibbs free energy versus temperature for a solid that can exist in multiple crystalline and amorphous states, showing the relative thermodynamic stability of one related to the other.[116] The intersection points represent crystalline solids in equilibrium, with liquid denoted by T_m or transition temperatures of crystalline-to-crystalline or crystalline-to-amorphous transitions.[116]

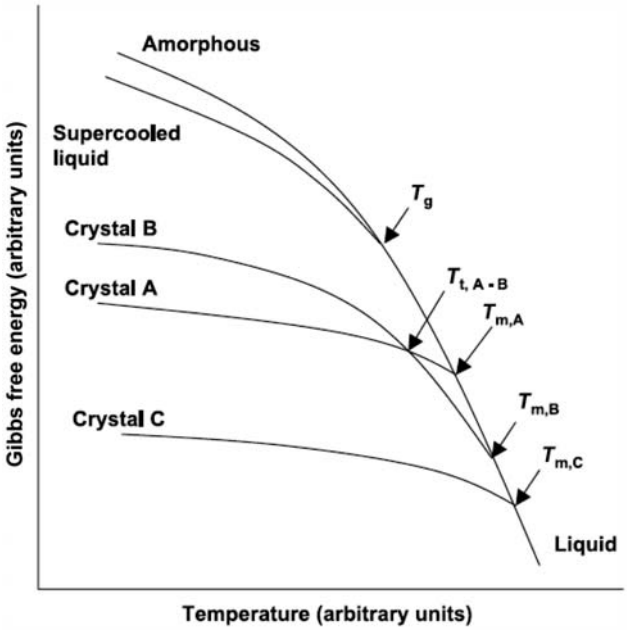

FIGURE 4.5 Schematic of Gibbs free energy curves for a hypothetical single-component system that exhibits crystalline and amorphous phase transitions. Monotropic systems (A and C, A and B), enantiotropic system (A and B) with transition temperature T_t, and an amorphous and supercooled liquid with a glass transition temperature T_g. Melting points, T_m, for the crystalline phases are shown by the intersection of the curves from the crystalline and liquid states. *Reprinted with permission Rodriguez-Spong B, et al. General principles of pharmaceutical solid polymorphism: a supramolecular perspective. Adv Drug Deliv Rev 2004;56:241–74.*

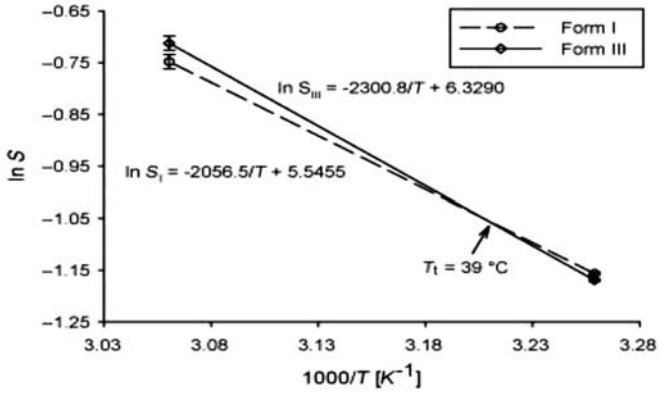

FIGURE 4.6 Van't Hoff plot showing monotropic and enantiotropic systems for form 1 and form II of flufenamic acid.[123] Reprinted with permission. *from Hu Y, et al. Estimation of the transition temperature for an enantiotropic polymorphic system from the transformation kinetics monitored using Raman spectroscopy. J Pharm Biomed Anal 2007;45(4):54651.*

For polymorphs, the thermodynamics of conversion or the stability of the various polymorphs is governed by ΔG, the Gibbs free energy. For crystalline solids that exist as multiple polymorphs, the polymorph with the lowest Gibbs frees energy will be the stable one under a specific set of conditions. The most stable polymorph will have the highest crystal lattice energy and the lowest solubility. All other intermediate solubility forms will be metastable and may be kinetically favored, but the thermodynamic stable form is still the one with the least solubility.

Depending on the relative dependence of each polymorph on temperature, it could be enantiotropic or monotropic. For a G versus T plot for two polymorphs, the monotropic forms always exist with one having a lower free energy than the other until the melting point, while for the enantiotropic forms, at some temperature on the G versus T curve, the stability relationship switches. At the point of intersection, the two forms are equally stable, and the $\Delta G = 0$. Van't Hoff plots[122] constructed using solubility or melting point data provide information on the stability of polymorphs, distinguishing between monotropic versus ennatiotropic systems. Fig. 4.6 shows the Van't Hoff plot for forms I and II for flufenamic acid with the transition temperature at 39°C.[123] From a practical consideration, during assessment of Van't Hoff plots using solubility measurements at various temperatures (log solubility vs $1/T$), care must be taken in the choice of solvents and the potential formation of solvates during solubility assessments. Also the phase purity of two polymorphs being evaluated needs to be known as well as any changes in the excess solid in the solubility measurements to ensure meaningful relationships.

Another method reported by Gu et al. is based on measuring the heat of a solution and solubility or dissolution rates at any one temperature[124] to estimate the transition temperature and stability between polymorphs. They demonstrated good agreement for the transition temperature of sulfamerazine polymorphs I and II to be between 51°C and 54°C determined by this method and confirmed experimentally. The choice of the method depends on the applicability to the system; for example, for thermally labile molecules and solvates, the melting point method is not suitable. Similarly, the method using solubility at various temperatures is unsuitable for polymorphs that undergo rapid transition in solution. All these methods are based on the assumption that the heat capacity difference between these is negligible.[122,124]

Solvates and hydrates can also have significantly different solubility and dissolution rates compared to each other and other neat forms. Incorporation of water or solvent molecules into the crystal lattice results in additional bonding with API molecules, altering crystal lattice density, internal energy and enthalpy, changing free energy, and the chemical potential of the solid. This may result in changes in physicochemical properties. Hydrate formation mainly depends on temperature and water activity. In

mixed-solvent systems, the activity of water is the key contributor for determining the phase transformation between hydrates and anhydrates. At a given temperature, at a given activity of water, solubility curves of the hydrate and anhydrates cross, and this is referred to as the critical water activity. For hydrates and anhydrates, to evaluate the risk of conversion, it is important to assess the critical water activity, which is the range of water activity where an anhydrate form switches to the hydrate form or vice versa. For a given drug at a given temperature, above the critical water activity (RH), a hydrate form will be more stable thermodynamically. The critical water activity can be determined by measuring the solubility of the anhydrate and the hydrate in a mixed-solvent system where accurate water activity measurements can be obtained and the solid phase monitored. Care needs to be taken that the mixed-solvent system selected does not have a propensity to form solvates. These studies may be long and time-consuming, and care must be taken to ensure that undesirable solvates are not formed during these experiments.

An alternative method by Li et al. proposed the use of this equation to estimate the critical water activity that requires determination of solubility ratios of hydrate and anhydrate[125]:

$$a_T[H_2O] = \sqrt[m]{\frac{x[A]}{x'[A]}}a[H_2O]$$

where, x[A] and x'[A] are the solubility of hydrate and anhydrate, m is the number of moles of water, $a_T[H_2O]$ is the activity of water at the transition point, and a [H_2O] is the activity of water at a given composition. Above the critical water activity for hydrate formation, hydrates typically are thermodynamically more stable and have lower solubility.[126,127] In an aqueous system, typically the solubility decreases as the order of hydrates increase, that is, an anhydrate form will have higher solubility than the monohydrate followed by its dihydrate. However, in a few cases, the hydrate may be intrinsically more soluble[128,129] than the anhydrate.

Estimates of the critical activity for systems that form hydrates and neat phases are important in the process design/control and in form selection.

4.2.2.4 *Amorphous forms*

During the form selection process, though crystalline forms are typically desired, some API solids may not crystallize under multiple conditions evaluated and only form amorphous solids. In other cases, none of the crystalline forms identified provide the necessary physicochemical properties such as solubility that are adequate to provide the desired in vivo exposures. In such cases where crystalline solid forms are not achievable or where they do not provide desired properties, an amorphous state may be considered.

Amorphous solids are defined as those that lack any crystalline structure and are composed of only disordered regions. They are known to have short-range molecular arrangements but lack long-range order. Amorphous forms possess excess thermodynamic properties such as enthalpy, entropy, and Gibbs free energy compared to the crystalline forms. In addition to the excess thermodynamic properties, amorphous forms also have greater mobility. Due to their high-energy state, amorphous forms could lead to increased apparent solubility, dissolution, and absorption. However, the physical stability of amorphous solids is a risk that requires characterization and mitigation. One common way to improve the physical stability is to make a solid dispersion with a polymer where the drug is dispersed in the polymer matrix.

An important parameter to assess the stability of amorphous systems is the glass transition temperature or T_g, which is the temperature below which the material is glassy or does not have molecular mobility and above which the amorphous solid is said to be in a rubbery state. Given that amorphous systems are high-energy systems, they possess higher solubility and dissolution rates compared to their crystalline forms and can provide a kinetic advantage when considering improved physicochemical properties of low-solubility drugs, thus providing higher in-vivo exposures. However, their physical stability needs to be considered, and maintaining the systems below their T_g ensures the material will be amorphous throughout the shelf life of the DP. Conversion of amorphous to crystalline is often known to be promoted by the presence of water, which can act as a plasticizer, lowering the T_g. This is another important consideration when evaluating the solid-state stability of amorphous systems when exposed to high humidity, since amorphous systems can adsorb a large amount of water, which can change the bulk properties. Since amorphous systems can adsorb large amounts of water, the chemical stability of these also needs evaluation, since larger amounts of water can be available for chemical reactions that are mediated with water.

Various processes are used to make amorphous material, including quenching of melts, rapid precipitation by antisolvent addition, freeze-drying, spray-drying, introduction of impurities, and solid dispersions. Mechanical or chemical process stresses such as grinding, milling, drying of crystalline hydrates, or wet granulation can also lead to amorphous formation.[130] Typical analytical methods used to assess amorphous systems are XRD, differential scanning calorimetry (DSC), solid state NMR, and modulated DSC, to name a few.[130]

It is well known in literature that polymers can potentially inhibit crystallization of the amorphous systems by either increasing T_g or by improved ionic or hydrogen bonding as well as potentially impacting the kinetics of crystallization.[131] Typically, it is assumed that for polymeric amorphous dispersions the ratio of T_g/T_m is around 0.75 or 0.8, and the dispersions are considered to be potentially stable against crystallization. T_g is a kinetic parameter. However, another important criteria to consider for stability of polymeric dispersions containing an amorphous drug is the thermodynamic driving force for crystallization and the activation energy for nucleation, which relates to the tendency of crystallization of the pure drugs themselves.[41,131,132] Sometimes it is difficult to crystallize, and an amorphous solid may be chosen as a form in this case. A detailed discussion on the selection, risks, and mitigation are outside the scope of this chapter.

4.3 SCREENING SOLID-FORMS OF API

Screening includes a wide range of API forms (polymorphs, hydrates, solvates, cocrystals, and salts) to ensure a reproducible, stable form with the desired physicochemical, biopharmaceutical, and powder properties can be obtained as part of this process. Typically, a thermodynamically stable form is the preferred choice, though in occasional cases, one may select a metastable form for improved pharmaceutical properties.

Balancing various properties such as crystallinity, hygroscopicity, stability and dissolution rate/solubility is needed to find an optimal form. Either a tiered or integrated approach is used toward screening. An integrated approach looks at a comparison of all key attributes across multiple forms, including crystallinity, polyphorphism, chemical and physical stability, hygroscopicity, and manufacturability and selecting an optimal form based on all these properties across multiple forms. While this approach is robust with polymorphism built into the early screen, it is extremely resource and material intensive. Fig. 4.7 shows an integrated approach to form selection.

In contrast to this, a tiered approach includes screening and eliminating various forms based on first assessment of crystallinity and solubility, followed by other properties such as thermal properties, hygroscopicity, stability scale-up feasibility, and bioavailability and finally leading to polymorph screening only on the lead candidates from the earlier tiered screens. This approach, while resource and material sparing, can result in eliminating some potentially useful forms early without complete characterization. Striking a balance between these approaches depending on the intrinsic properties of the molecule, key challenges, material availability, phase of development, and any

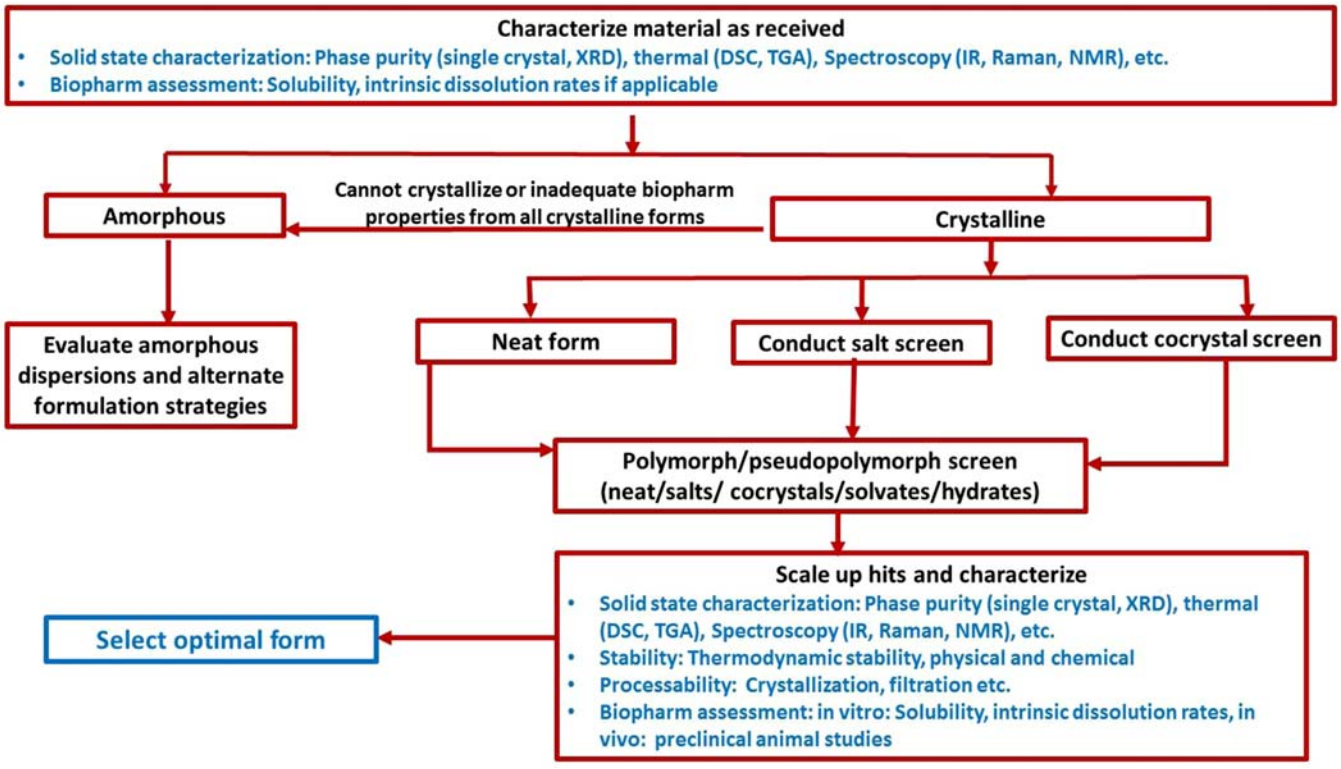

FIGURE 4.7 Integrated strategy for form screening and selection.

therapeutic area constraints as well as any formulation considerations is important during form screening.

4.3.1 Screening techniques

Crystallization is the common technique used to screen forms and is typically described by a nucleation step followed by crystal growth. For a polymorphic system, the polymorph that nucleates first has the fastest nucleation rate and the lowest free energy barrier to nucleation. However, the polymorph that actually crystallizes out depends on the combination of relative rates of nucleation and crystal growth. Hence, at a given time, multiple nuclei can exist, and if kinetic factors prevent equilibrium, a mixture of forms may be obtained. Various factors such as the degree of supersaturation during the process, temperature and cooling curves during the process, seeding, agitation, solvent composition, pH, polarity, and the presence of certain impurities or other additives that inhibit nucleation process have all shown to influence crystallization process and can be tailored to favor one form over another. The more stable form is obtained under thermodynamic conditions, while a metastable form is obtained under kinetic conditions. Typically, crystallization from solution (cooling or evaporative, slurry conversion) and recrystallization from neat compound (sublimation, thermal treatment, crystallization from melt, grinding, thermal, and desolvation) are common methods. The outcome of form from a crystallization experiment is influenced by both composition and process parameters, as shown in Table 4.6,[8] and can be tailored to obtain the thermodynamically stable or metastable forms. Supersaturation and temperature are the key driving forces that govern the kinetics of nucleation and crystal growth, thus influencing the form that crystallizes. Temperature, as discussed above, can generate different types of polymorphs for enantiotropic versus monotropic systems. The selection of the right solvent is also important and should cover a wide range of properties, considerations of solvents used in synthesis or formulation, and solvent water mixtures for assessment of potential hydrates. Another important factor that can play a role in solvent-based methods is the solubility of the API, and for highly soluble materials, an antisolvent addition may be a preferred way to crystallize. For salts and cocrystals, the solubility of the API and the counterion in the solvent both need to be considered while designing crystallization studies. To ensure better control on the crystallization process, understanding both thermodynamics and kinetics is important, and the conditions and parameters that control the crystallization process need to determined. Seeding with the desired form is often used to drive the process quickly toward the more stable polymorph.

Early screens are more qualitative in nature and may not translate into scalable processes, but they serve as a guide for future robust screens to pursue focused forms. These early experiments can also generate material for seeds for future manual assessments. Typical screens include high-throughput crystallizations, manual screens, or alternate screens.

4.3.2 High-throughput screening

Given the number of experimental parameters for form screening coupled with limited predictive capabilities, high-throughput crystallizations using an automated robotic setup offer an attractive option for a large array of forms and conditions to be explored in

TABLE 4.6 Crystallization Composition and Processing Variables[46,133]

parallel. These experiments can cover a wide range of screens with limited material consumption given the small scale. Typically, high-throughput screening (HTS) screens are the first line of screens, and hits obtained from these studies can then be used to inform subsequent focused manual screens where material is further scaled up. Typical HTS include a polymorph screen, screening for acidic and basic counterions for salts (if applicable), cocrystal screen, and potentially even an amorphous dispersion screen if relevant. Screening is done in a 96-well plate in which solid (up to 10 mg) is dissolved in a suitable solvent, dispensed using the automated liquid handling systems. Supersaturation is varied by heating/cooling evaporation and slurry evaluations. Common methods such as thermal cooling crystallization, antisolvent, and evaporative crystallization are used. Thermal cooling crystallization includes the initial dissolution of API in the solvent followed by temperature ramps and controlled cooling to induce supersaturation and then crystallization. Antisolvent addition relies on the fact that an API is soluble to varying degrees in the crystallization medium but is largely insoluble in a particular solvent or solvents (eg, the antisolvent). Evaporative crystallization can be carried out by slowly increasing the concentration of API to achieve supersaturation and increase the degree of supersaturation (by preferential evaporation) in order to induce crystallization. In this method, differential rates of solvent loss from mixtures result in the unknown composition of the crystallization medium during nucleation, and the degree of supersaturation changes over the course of experiment, resulting in appearance of multiple crystal forms.[8] HTS is then coupled with optical image analysis and spectroscopic techniques such as Raman or XRPD that can read the high-throughput wells directly.[8] The initial characterization is followed by grouping of samples based on similar patterns for the wide number of crystallizations and provides a roadmap for further developing the desired form.

The advantage of these screens lies in the high throughput and wide range of the conditions analyzed. However, since these screens are typically meant to be fast screens and not always set under thermodynamic conditions, they can lead to metastable forms or cases with no crystalline hits. Considerations of form reproducibility, poor signal-to-noise ratio, and preferred orientation impact in spectra also need to be considered and sometimes limit the predictive capability on scale-up. There is literature supporting the use of proper design of experiments, and appropriate analysis for compounds with high-polymorphic states that HTS methods can demonstrate comparable results compared to the traditional intensive manual screens.[134]

4.3.3 Manual screens

Unlike the high-throughput automated screens, the manual screens are prepared as individual samples. They are conducted at a relatively larger scale than the HT screens and further identify the most stable or desirable form. A number of methods can be utilized such as solvent-based methods (most common) or solid-based methods such as subjecting the solid to various temperature or RH equilibration, grinding, compression or sublimation of solids, and also cooling from melt to assess the form that crystallizes out. Manual screening involves samples set up in individual vials or containers under a variety of conditions, including both solvent and solid.

Solvent-based methods are most widely used due to the large range of solvents and conditions that can be utilized. Solvent-based methods include cooling a solution, evaporation, antisolvent addition, vapor diffusion, and suspensions (slurries). Variations on these methods can include changes in solvent, solvent mixtures, antisolvent, temperature, cooling rate, concentration, rate of addition, and order of mixing, to name a few possibilities.[9] Nonsolvent methods consist of crystallization from melt, heat-induced transformations, sublimation, desolvation of solvates, salting out, and pH changes.

The goal of manual screens typically is to find the most stable form, and these studies include running under thermodynamic conditions such as slurrying for a few days, slow evaporation, slow cooling, slow antisolvent addition, or a combination of these methods. One of the common ways of ensuring the reaction reaches equilibrium with respect to the most stable form is seeding. Seeding is the addition of solids of the desired form into the crystallization to promote nucleation. For slurry conversion methods, solids are slurried and kept stirring in a wide range of solvents and aged for up to a few weeks, and the solid phase is assessed over time. A few limitations of the slurry method include the limitation of finding a stable form only at the experimental temperature, the presence of impurities that could prevent the stable form to crystallize, or very low solubility of API in solvents that could prevent transformations. Monitoring both the wet and dry cakes from slurry experiments ensures no transient solvates are missed, which dehydrate upon drying.

In the case of hydrates, exposure to RH, water slurry, temperature cycling of aqueous suspensions, mixed-solvent systems, and vapor diffusion by exposure of solid API to RH values ranging from 5% to 95% are commonly used to probe hydrate formation. For mixed-water-solvent systems, understanding the water activity is critical, since different solvent aqueous mixtures at a given mole fraction of water will have varying water

activity. (A 0.2 mol fraction of water in methanol gives 0.25 water activity, while in isopropanol, it will give 0.45.) This can lead to the formation of different stoichiometric hydrates or anhydrates at the same water content in various solvents.[9,135,136]

4.3.4 Alternate screens

Recently, several alternate techniques such as capillary crystallization, laser-induced crystallization, and sonocrystallization that promote nucleation have been explored to generate newer forms. More detailed discussion on these screens can be found in the references listed here.[9,116]

4.4 IDENTIFICATION AND ANALYSIS OF FORMS

Various analytical techniques used for assessing solid forms include a variety of physical, thermal, spectroscopic, and diffractometric methods. Typically, multiple techniques are used for complete characterization of the solid covering both molecular level (spectroscopic or single-crystal XRD) and particulate level (XRD, thermal methods, or microscopy). Thermal (DSC/TGA/modulated DSC), spectroscopic (NIR, IR, Raman, NMR), XRD, and microscopy-based techniques are the most common used. In addition, DVS to assess hygroscopicity is also an important characterization tool. Sometimes specialized techniques such as terahertz pulsed spectroscopy (TPS) or terahertz time-domain spectroscopy (THz-TDS), which is a vibrational spectroscopic technique, can be used to assess particulate-level, small structural changes. Techniques typically used for solid-state characterization are listed in Table 4.7.

Solubility/dissolution, stability, and hygroscopicity are key characterization elements that have already been described in detail in earlier sections. The next sections briefly describe commonly used analytical techniques during form selection process.

4.4.1 Single-crystal and PXRD

A single crystal is defined as a crystal consisting of a noninterrupted repetition of the unit cell in three dimensions. The single-crystal XRD method provides information on the structure of the unit cell, bond lengths and angles, molecular conformation, molecular packing, hydrogen bonding pattern, density, and crystal disorder. To acquire data from a single crystal, the sample is mounted, and a narrow beam of X-rays is passed through it and diffracts against the sample, and this diffracted beam is collected on the detector. Calculated powder-diffraction patterns from single-crystal data provide information on preferred

TABLE 4.7 Solid-State Characterization Methods

Method	Data measured	Measurement use
X-ray diffraction (single-crystal and PXRD)	Diffractogram	Crystallographic properties
Infrared (IR) spectroscopy	IR spectrum	Chemical information
Raman spectroscopy	Raman spectrum	Chemical information
Terahertz pulsed spectroscopy	Terahertz pulsed spectrum	Chemical information, lattice photon modes
Near-infrared (NIR) spectroscopy	NIR spectrum	Chemical information (overtones and combinations of IR vibrations)
Solid-state NMR	Magnetic resonance	Chemical information
Differential scanning calorimetry	Heat flow vs temperature	Thermal events
Thermogravimetry (TG)	Change of mass vs temperature	Solvate/hydrate studies
Microscopy, polarized light microscopy (PLM), scanning electron microscopy (SEM)	Microscopy under the influence of light or electron radiation	Morphology, surface examination, dehydration, polymorphism (PLM)
Microcalorimetry	Heat flow vs time	Quantification of amorphous form
Solution calorimetry	Heat flow during dissolution	Quantification of polymorphs and amorphous form
Moisture sorption/desorption isotherms	Change of mass vs RH%	Hygroscopicity, hydrate formation, dehydration, amorphous crystallization
Solubility/dissolution	Amount dissolved in different solvents or temperatures/time	Solubility or dissolution rate measurement

orientation and phase purity. *Phase purity* refers to the presence of a single dominant crystalline phase, which is a desirable attribute for an API. Phase impurities are typically low levels of other forms that can be present along with the desired form and impact the stability and potentially the performance of the DP. Single-crystal X-ray determination offers a powerful tool to assess the phase purity.

Determining the crystal structure using this approach is the most common and accurate way of understanding the three-dimensional structure, and it is important to understand the physical properties of one crystalline form versus another. It also shows the intermolecular interactions of the atoms within the crystal. The XRD pattern obtained using the single-structure analysis serves as a reference diffractogram The technique does rely on obtaining high-quality crystals of adequate size and hence needs crystals grown to be able to get crystal structure.

PXRD is one of the most common bulk techniques used for the analysis of powders and is similar in concept to the single-crystal analysis, except the data is generated on the bulk powder instead of a single crystal. The diffractogram obtained for a given form contains information about the unit cell and is extremely sensitive to changes in the cell parameters, which makes it a gold standard for screening polymorphs during form selection and the drug development process. Crystalline material shows sharp, intense peaks, while amorphous material shows a broad peak or peaks, called an amorphous halo. This also makes PXRD a technique of choice to understanding the crystallinity of a given sample.

4.4.2 Thermal techniques

The most common and routinely used thermal techniques are DSC and thermogravimetric analysis (TGA). The techniques are based on heating the solids and monitoring changes in the physical properties. In DSC the difference in temperature between the sample and the reference as the temperature is changed is monitored to provide information on enthalpy change. TGA provides information on the change in mass of a solid as a function of temperature.

The DSC technique measures heat absorbed or released on heating, cooling, or maintaining a sample at a constant temperature. Thermodynamic parameters such as melting point, heat capacity, and heat of fusion can be obtained by this technique in addition to transition events that occur due to phase transitions. The endotherm represents a process where heat is absorbed such as melting, solvent loss, or phase transitions, while exotherm represents a process where heat is liberated such as recrystallization or chemical reactions where heat is involved. The area under the peak is proportional to heat change and gives enthalpies of transition. In the case of amorphous solids, the glass transition temperature is seen on the DSC curve by a change in heat capacity.

The method can be used for accurate melting point and purity assessment where phase impurities can be determined by additional shifts in endothermic peaks. Additional experimental variables such as pan configuration (open or closed), heating rates, and sample and particle size can also affect the shape of DSC curves. For materials that are partially amorphous or mixtures of crystalline and amorphous, glass transition events could coincide with other endothermic or exothermic events, and modulated DSC which separates the thermodynamic and kinetic components, can be used. In recent years, hyper-DSC or high-speed DSC has become popular given its ability to scan at extremely fast rates of 100−500°C/min range, which have enabled more sensitivity to some transitions.[20,137] DSC is a powerful tool to assess the relationship between polymorphs (enantiotropic vs monotropic), evaluate mixtures of polymorphs, physical stability of amorphous dispersions, and quantify amorphous content.[138,139] In some cases, traditional DSC scan rates are too slow and may cause some materials to recrystallize during the melting process or decompose immediately after melting. In such cases, the HyperDSC (fast-scan DSC) technique, which uses scanning rates as fast as 100−500°C/min in heating as well as cooling over a broad temperature range, has been used.[20,137,140,141] These fast scanning rates inhibit kinetically controlled processes such as recrystallization during melting and decomposition after melting, which are either completely eliminated or significantly reduced by this method. Thus, HyperDSC has been successfully used to detect small amorphous contents in crystalline material,[137] study thermal properties between polymorphs as in the case of carbamazepine,[140] or understand polymorphic phase impurities in crystalline material.[141]

Another most commonly used technique is the thermogravimetric analysis. TGA analysis that monitors change in mass with temperature can be run in the isothermal mode where the temperature is kept constant or nonisothermal (dynamic) mode where the temperature is raised, typically linearly at a fixed rate. Similar to the DSC, the TGA setup including heating pan configuration, sample and particle size, and heating rate can all affect the TGA curves. Typically a dry nitrogen purge is used during the study to minimize the impact of RH, atmospheric oxygen, or liberated gases to further impact the sample. TGA curves run in isothermal mode coupled with DSC curves can be used to provide additional information on

endothermic events such as melt versus decomposition or desolvation. Additionally, isothermal curves of weight loss as a function of time can be used to determine reaction rates.

Another thermal technique is microcalorimetry, which measures heat liberated or taken up during various physical or chemical processes. For example, heats of solution estimation to determine the thermodynamic stability between polymorphs, amorphous-to-crystalline transitions, or quantification of amorphous in crystalline material can all be detected by this technique since it is very sensitive in small changes in the heat taken up or liberated.[142] In isothermal microcalorimetry, the sample and the reference are both maintained at a constant temperature, and the heat released or absorbed by the progression of the reaction is quantitatively measured via thermocouples as a function of time.[21]

4.4.3 Spectroscopic techniques

Various spectroscopic techniques are routinely used to probe the solid state forms and short-range structure in molecular solids. Raman and IR spectroscopy probe the solid state predominantly on the intramolecular level. XRD and the various thermal analytical techniques predominantly probe the intermolecular level.[23]

Raman and IR spectroscopy are the most common vibration spectroscopic techniques, and they provide information on the structure and the molecular conformation in the solid state. In case of polymorphs, these techniques are useful in distinguishing the differences in hydrogen bonding or crystal lattice energies based on the differences in packing between various polymorphs. Near infrared (NIR) is one of the most advanced spectroscopic techniques used as a PAT tool. Raman spectroscopy can be used to monitor crystallization process. Solid-state nuclear magnetic resonance (SSNMR) is another powerful technique that provides short-range information about the solid-state structure primarily. Various nuclear isotopes are used such as ^{13}C, ^{1}H, ^{15}N, ^{19}F, ^{23}Na, and ^{31}P. SSNMR spectroscopy has been applied in a number of pharmaceutical applications including studies of polymorphism, understanding phase purity, amorphous content, solvation, salts, cocrystals, and various types of formulations.[143]

Initial assessments include single-crystal analysis to determine crystalline structure, obtain phase purity information, and understand polymorphism for a given API solid. Once this has been determined, additional spectroscopic techniques such as Fourier transform infrared spectroscopy (FTIR), Raman, and SSNMR can be employed to further characterize the various solids. Alongside thermal methods such as DSC and TGA, ITC can provide insights into assessing physical stability as in case of salts and cocrystals determine transitions between metastable and stable forms, and assess thermodynamic stability including enantiotropic/monotropic relationships between polymorphs. As described above, a combination of these analytical techniques are used during the form selection process to completely characterize these forms.

4.5 CONCLUSIONS

Drug substance solid forms should be selected not only to enable drug substance quality and manufacturability but also DP considerations. Ideally, the selected form possesses optimal physical, chemical, mechanical, and biopharmaceutical properties. The formation of salts, cocrystals, solvates, and hydrates as well as existence of polymorphs is rarely predictable. Therefore, the selection process typically involves broad screening for solid forms and characterization including thermodynamics and kinetics as well performance assessment with a view toward selecting a solid form that is not only suitable as a drug substance but also an optimal DP dosage form. Screening may be manual or automated in a high-throughput fashion and utilize a variety of techniques such as crystallization, precipitation, and thermal techniques. The screening may be broad; however, the experimental design is based on some physical-chemical properties in choosing solvents and concentrations as well as counterions and coformers. Several solid-state techniques and solid/solution experimental approaches are used to assess thermodynamics and kinetic stability. Developing an understanding of thermodynamics of polymorphs, hydrates, and solvates (in process-relevant solvents) is important to completely avoid or minimize risks. In addition to these characterization studies, the quality and performance of a solid form is assessed by conducting accelerated stability testing, solubility/dissolution testing, and, if necessary, in-silico and in vivo studies for pharmacokinetics evaluation. A thorough solid-form screening, characterization, and selection are essential to maximize the potential of enabling a drug candidate from patient, quality, and manufacturing perspectives.

4.6 CASE STUDIES

4.6.1 Case study 1: RPR111423[144]

RPR 111423 is a very weak base with a pK_a of 4.25. The strategy was to first carry out a comprehensive screening of various counterions and solvent matrix to

identify two crystalline salts: monohydrochloride and a mesylate. The properties of these salts and the free base were then studied and compared.

The results showed that both salts significantly enhance solubility but exist in four to six different polymorphs. They both readily convert to free base in water and intestinal fluids. The corresponding results for the free base indicated that it appeared to be the better candidate. It showed no evidence of polymorphism, and it was not hygroscopic. A subsequent study performed on samples of the drug substance and on simple capsule formulations demonstrated that the dissolution rates of the micronized free base were equivalent or superior to those of the salts under the same conditions. Thus, the free base was selected for further development.

A few key observations can be drawn from this case study. First of all, identifying what properties to modify by forming a salt prior to any salt screening can save time and resources; a salt may not always be needed. In-vitro dissolution experiments and in-silico simulation can be very useful tools to evaluate the need for a salt from a PK point of view. Additionally, a pharmacokinetic study in animals comparing a solution formulation to a suspension of the micronized free base at the projected clinical dose can provide further indication of whether a salt is needed. However, if the projected dose gets much higher for this compound, a salt would provide advantages. Sensitivity analysis using GastroPlus software or the estimation of the maximum absorbable dose can be good tools in understanding at what doses solubility and dissolution may become rate-limiting to absorption.

4.6.2 Case study 2: LY333531[145]

The following case study is extracted from an excellent article by Engel et al., which reported an integrated, tiered-approach to select a salt form of a drug candidate.

LY333531 is a weakly basic drug with low solubility of the free base ($<1\ \mu g/mL$). Although the pK_a of the drug is not reported by the authors, it is estimated to be 9−11, based on the presence of a tertiary amine. Based on the need for oral dosage form of this BCS class II drug, the authors evaluated salt forms. They crystallized small lots (<1 g) of hydrochloride, sulfate, mesylate, succinate, tartrate, acetate, and phosphate salts. Preliminary characterization using polarizing microscopy, thermal analysis, PXRD and solubility was conducted on all seven salts. Based on the poor crystallinity, low solubility, and difficulty in chemical purification, only two salts (namely, hydrochloride and mesylate) were chosen for further consideration. The two salts, hydrochloride and mesylate, were subjected to further characterization including polymorphism, hydrate formation and hygroscopicity, stability, purification, filterability, and pharmacokinetics in dogs. Although methanol/water was initially used to prepare the mesylate salt, an alternate-solvent system using acetone/water (9:1 v/v) was chosen to avoid generation of methyl methanesulfonate, a mutagen. Three forms of hydrochloride forms with varying degrees of hydration were identified: an anhydrate form and two hydrates. The two interconverting hydrates were tentatively assigned to be monohydrate and tetrahydrate based on the vapor pressure isotherm data, although the exact structures of these hydrates were not determined. The anhydrate form did not show significant hygroscopicity (water uptake) during the vapor isotherm experiments and was considered for further stability and bioavailability assessments. Only a monohydrate form of mesylate salt was reported, and it showed no significant water uptake up to 90% RH. No change in PXRD pattern was seen at the end of the vapor isotherm experiments, although a small amount of hysteresis was seen during the desorption phase. The aqueous solubility of mesylate (0.5 mg/mL) was 5X higher than the hydrochloride salt (0.1 mg/mL). The chemical stability of the two salts as well as blends with three excipients was found to be acceptable after 1 month of storage at 40°C/75% RH and 50°C. Preliminary crystallization and filtration studies on both salts indicated that while there was no filtration advantage of one salt over the other, the purification was a lot better with the mesylate salt than the hydrochloride salt. The mesylate salt was found to be 2.6X more bioavailable compared to the hydrochloride salt when dosed as an oral suspension at 20 mg/kg in dogs. The mesylate salt monohydrate form was chosen as the API for further development.

4.6.3 Case study 3[146]

The following case study is summarized based on the work of McNamara et al. The authors demonstrated the screening, characterization, and evaluation of glutaric acid cocrystal to improve oral bioavailability of a low solubility API.

Compound 1 is a poorly soluble drug with $<0.1\ \mu g/mL$ in aqueous media. Salt formation was not possible even with strong acids such as hydrochloric, sulfuric, or phosphoric acids because of the low pK_a (estimated to be -0.7). The authors made some attempts to make amorphous forms but decided to look at cocrystals because of the risk of crystallization of the amorphous solid (low T_g). The authors screened for cocrystals with 26 different carboxylic acid-based coformers using the binary melt method on a hot-stage microscope. Five different new solid phases

(cocrystals) were obtained and analyzed by spectroscopy. The authors selected the glutaric acid cocrystal[2] for further evaluation because of the relatively high melting point of the cocrystal and the expected high water solubility of the cocrystal because of the high water solubility of the coformer. A solvent-based crystallization was developed to scale-up the process to make gram quantities of cocrystal.

Single-crystal X-ray data showed that one carboxylic group of the coformer hydrogen bonds to the amide functionality in an eight-membered ring motif, and the second acid group forms an interaction with a pyrimidine acceptor site. DSC thermal scans revealed that the cocrystal[2] melts at 142°C, whereas compound 1 melts at 206°C. The cocrystal[2] showed a significantly higher dissolution rate in water compared to compound 1. The intrinsic dissolution of the cocrystal was 18 times greater than compound 1.

The cocrystal[2] was found to be nonhygroscopic as it sorbed less than 0.08% even at 95% RH. Both chemical and physical stability was good after 2 months of storage at 40°C/75% RH and 60°C. Though the cocrystal[2] did convert to compound 1 in 37°C liquid water after 24 hours, the cocrystal[2] did not convert to compound 1 during the 90 minutes required for the dissolution test or after 6 hours of exposure to 100% water vapor at RT. A dog PK study showed a significant increase in plasma concentration values after oral dosing of 2 relative to 1 at doses of 5 and 50 mg/kg. In summary, the authors reported the viability of the cocrystal as a crystalline solid form of a poorly soluble drug that was not amenable to salt formation.

CHAPTER

5

Drug Stability and Degradation Studies

D. Zhou[1], *W.R. Porter*[2] *and G.G.Z. Zhang*[1]

[1]AbbVie Inc., North Chicago, IL, United States [2]Abbott Laboratories, Abbott Park, IL, United States

5.1 INTRODUCTION

Degradation studies are an important aspect of preformulation evaluation of the stability of drug candidates. These experiments aim to aid further formulation development by evaluating the intrinsic stability properties of a drug candidate in a timely manner by deliberately applying stress to cause degradation. To fulfill this purpose, preformulation scientists induce degradation of test materials by raising temperature, by increasing humidity when relevant (eg, solid-state chemical and physical stability), by subjecting materials to sheer or compressive forces (eg, solid-state physical stability), by exposing the test materials to various pH conditions or intensive ultraviolet (UV)–visible light (eg, photostability) or by adding other reactants (eg, acids, bases, and peroxides). Forced degradation studies are sometimes described as stress testing, and they are also performed to support analytical method development.

Preformulation degradation studies and forced degradation studies used to support analytical method development share many common features. Analytical chemists employ forced degradation studies as part of their program to develop stability-indicating analytical methods. Early drug degradation studies also serve to identify and prepare degradants that are likely to appear in the final drug product and limit its shelf life. In addition, these studies aid in the elucidation of degradation pathways, as well as the qualification of materials used in toxicology experiments. Forced degradation studies conducted to support analytical method development often put more emphasis on identifying the degradants. Preformulation degradation studies, on the other hand, aim to predict the intrinsic stability of a drug candidate in order to anticipate problems that may arise down the development path. Cost savings can be realized if these activities can be coordinated.

Degradation studies can provide predictive information. Under certain circumstances, such as hydrolysis in solution, prediction of shelf life may be achieved with reasonable accuracy. However, in other cases, extrapolation of stability under stressed conditions (eg, oxidative testing) to normal storage conditions is challenging. Stress testing is, therefore, a more qualitative than quantitative predictive tool; nevertheless, rank-order comparisons are often not only possible, but also useful for designing subsequent formulations. Early signs of instability of a drug candidate help to identify potential development issues, to foster development of potential stabilization strategies, and to suggest ways to optimize manufacturing processes.

This chapter will discuss the basic treatments of drug degradation studies, including kinetics, pathways, important factors, and typical practices for assessing both the chemical and physical stability of pharmaceutical compounds.

5.2 CHEMICAL STABILITY

Chemical degradation probably represents the most important stability aspect of pharmaceuticals. Pharmaceutical scientists are responsible for examining the chemical stability of new drug candidates, for assessing the impact of stability issues on pharmaceutical development and processing, and for designing strategies to stabilize an unstable compound if necessary. They must understand the kinetics of chemical degradation, both in solution and in the solid state. They must also understand the commonly encountered

Developing Solid Oral Dosage Forms
DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00005-4

degradation pathways of active pharmaceutical ingredients (APIs), as well as practical approaches for performing degradation studies.

5.2.1 Solution kinetics

Chemical degradation reactions of pharmaceuticals follow the well-established treatments of chemical kinetics. A brief overview of chemical kinetics is presented next, followed by a discussion of catalysis and rate-pH profiles that are most relevant to the degradation of pharmaceuticals.

5.2.2 Rate equations

When a chemical reaction starts, the concentrations of reactants and products change with time until the reaction reaches completion or equilibrium. The concentrations of the reactants decrease, while those of the products increase over time. Therefore, the rate of a reaction can be represented either by the decreasing change in the concentration of a reactant or the increasing change in the concentration of a product with respect to time.

An arbitrary chemical reaction can be represented as

$$aA + bB \rightarrow cC + dD \tag{5.1}$$

Here, a, b, c, and d are the stoichiometric coefficients indicating the molar ratio of the reactants and products of the reaction. The rate of change of concentration of each species can differ, depending on the stoichiometric coefficients. Hence, a unified expression of the rate is preferred, which can be obtained via normalization:

$$\text{rate} = -\frac{1}{a}\frac{d[A]}{dt} = -\frac{1}{b}\frac{d[B]}{dt} = \frac{1}{c}\frac{d[C]}{dt} = \frac{1}{d}\frac{d[D]}{dt} \tag{5.2}$$

A negative sign is used for reactants so that the rate of a reaction is positive if it moves toward equilibrium or completion.

The rate of a reaction often depends on the concentrations of the reactants/products when other conditions are kept identical. Consider the hydrolytic reaction of ethyl acetate under alkaline conditions:

$$CH_3COOC_2H_5 + OH^- \rightarrow CH_3COO^- + C_2H_5OH \tag{5.3}$$

The rate of this reaction is proportional to the concentrations of each reactant species:

$$\begin{aligned}\text{rate} &= -\frac{d[CH_3COOC_2H_5]}{dt} = \frac{d[C_2H_5OH]}{dt} \\ &= k[CH_3COOC_2H_5][OH^-]\end{aligned} \tag{5.4}$$

Here, k, the proportional constant, is called the *specific rate constant*, or just the *rate constant*. This hydrolytic reaction is first order with respect to either ethyl acetate or hydroxide, and is an overall second-order reaction. The terms *first order* and *second order* will be defined later in this chapter.

In general, the rate of the arbitrary reaction (Eq. 5.1), may be written as

$$\text{rate} = k[A]^{\alpha}[B]^{\beta} \tag{5.5}$$

Here, α and β are the reaction order with respect to A and B, respectively. The order of the overall reaction is $n = \alpha + \beta$. This rate equation can be expanded to include more reactant/product species.

5.2.3 Elemental reactions and reaction mechanism

The way a reaction equation is written merely represents the overall outcome of the reaction and does not usually indicate how the actual reaction proceeds at a molecular level. For example, the reaction of hydrogen with bromine in the gas phase is usually written as

$$H_2 + Br_2 = 2HBr \tag{5.6}$$

As written, it appears as if one H_2 molecule collides with one Br_2 molecule and generates two HBr molecules in one step. However, the reaction actually proceeds with a free radical chain mechanism, which consists of the following steps:

$$Br_2 \rightarrow 2Br\bullet \tag{5.7}$$

$$H_2 + Br\bullet \rightarrow HBr + H\bullet \tag{5.8}$$

$$H\bullet + Br_2 \rightarrow HBr + Br\bullet \tag{5.9}$$

As shown previously, each step in a reaction scheme representing how the reactant molecules collide to form products is called an *elementary reaction*. The reaction equation representing the overall outcomes is called the *overall reaction*. The number of molecules reacting in an elementary reaction is called the *molecularity* of that elementary reaction, and this is a different concept from reaction order. An elementary reaction involving a single molecule is called *unimolecular*, one that involves two molecules is called *bimolecular*, and so on. Processes involving three (*termolecular*) or more molecules in one step are rare.

An overall reaction may contain a number of elementary reactions. A complete scheme of these elementary reactions represents the actual path of a reaction, and this is called the *mechanism* of the reaction. The beauty of the elementary reaction concept is that its rate follows the law of mass action. In simple words, the rate of an elementary reaction is directly proportional to the concentration of each reactant species involved in the elementary reaction, which is an outcome that depends upon the statistical aspects of

the reaction. Therefore, the rate equation of an elementary reaction can be readily derived.

Among the elementary reactions comprising an overall reaction, one of these steps usually proceeds with the slowest rate. This slowest step is called the *rate-determining* step of a reaction and determines the rate of the overall reaction. Once the reaction mechanism is known and the rate-determining step is identified, the expression of the overall rate of the reaction may also be readily derived.

5.2.4 Typical simple order kinetics

Simple order reactions described in the following sections refer to reactions that are zero-, first-, and second-order. These reaction orders are commonly encountered in studies of the stability of pharmaceuticals. Their mathematical treatments are also relatively simple.

5.2.4.1 Zero-order reactions

In zero-order reactions, the rate of the reaction does not depend on the concentration of the reactant; thus, the rate is a constant:

$$\text{rate} = -\frac{d[\text{A}]}{dt} = k[\text{A}]^0 = k \tag{5.10}$$

Here, A is the reactant and k is the zero-order rate constant. In this case, the decrease in concentration of A is linear with time:

$$[\text{A}]_t = [\text{A}]_0 - kt \tag{5.11}$$

Here, $[\text{A}]_t$ is the concentration of A at time t, while $[\text{A}]_0$ is that at time zero, or the initial concentration.

5.2.4.2 First-order reactions

First-order reactions appear to be the most commonly encountered in pharmaceutical stability studies. The rate of a first-order reaction is proportional to the concentration of the reactant:

$$\text{rate} = -\frac{d[\text{A}]}{dt} = k[\text{A}] \tag{5.12}$$

The concentration-time profile of the reactant for a first-order reaction follows an exponential decay to a limiting value, while that of the product follows an exponential increase to a different limiting value:

$$\text{A} \rightarrow C \tag{5.13}$$

$$[\text{A}]_t = [\text{A}]_0 \exp(-kt) \tag{5.14}$$

$$[\text{C}]_t = [\text{A}]_0[1 - \exp(-kt)] \tag{5.15}$$

The half-life, $t_{1/2}$, of the reaction is the time required for the reactant concentration to decrease to 50% of its original value; similarly, the times for the reactant concentration to decrease to 95% and 90% of its original values are designated as t_{95}, and t_{90}, respectively. These quantities can be obtained readily for a first-order reaction if the rate constant is known:

$$t_{1/2} = \frac{\ln 2}{k}; \quad t_{95} = \frac{\ln 0.95}{k}; \quad t_{90} = \frac{\ln 0.9}{k} \tag{5.16}$$

A characteristic feature of first-order reactions is that the time required to lose the first 50% of the material ($t_{1/2}$) is the same as the time required to drop from 50% remaining to 25% remaining, from 25% remaining to 12.5% remaining, and so on.

5.2.4.3 Second-order reactions

Many apparently first-order reactions observed for pharmaceuticals are actually second order. Usually, two reactant molecules must collide in order to react. However, in practice, one reactant (eg, water, hydrogen ion, hydroxyl ion, buffer species, etc.) may be in great excess so that its change in concentration is negligible, and an apparent first-order reaction is therefore observed.

For a second-order reaction where two reactants are involved,

$$\text{A} + \text{B} \rightarrow \text{C} \tag{5.17}$$

The rate equation can be written as

$$\text{rate} = -\frac{d[\text{A}]}{dt} = -\frac{d[\text{B}]}{dt} = k[\text{A}][\text{B}] \tag{5.18}$$

The rate is first-order with respect to each reactant, but the overall reaction is second order. The concentration-time profile of a second-order reaction can be represented as

$$\frac{1}{[\text{A}]_0 - [\text{B}]_0}\left(\ln\frac{[\text{A}]_t}{[\text{B}]_t} - \ln\frac{[\text{A}]_0}{[\text{B}]_0}\right) = kt \tag{5.19}$$

When the initial concentrations of A and B are identical, the concentration-time profile can be simplified as

$$\frac{1}{[\text{A}]_t} - \frac{1}{[\text{A}]_0} = kt \tag{5.20}$$

The $t_{1/2}$, t_{95}, and t_{90} values for a second-order reaction all depend upon the initial concentration of each species.

Fig. 5.1 plots the reactant concentration-time profiles for theoretical zero-, first-, and second-order kinetics. Table 5.1 summarizes the rate equations, the formula for calculating reactant concentration-time profiles, and half-lives for these simple order kinetics. The rate constants used to generate Fig. 5.1 were assumed to be numerically identical in all cases. Identical initial reactant concentrations were assumed for the second-order reaction in both Fig. 5.1 and Table 5.1.

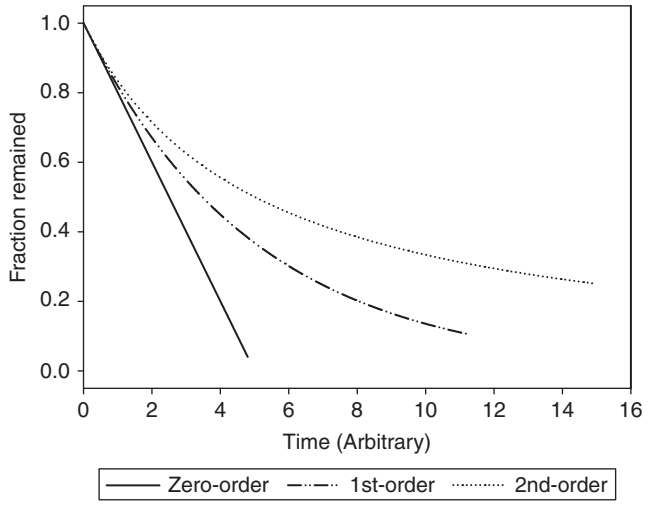

FIGURE 5.1 Reactant concentration-time profiles for theoretical zero-, first-, and second-order reactions.

TABLE 5.1 Rate Equations, Reactant Concentration-Time Profiles, and Half-Lives for Zero-, First-, and Second-Order Reactions

Reaction order	Rate equation	Concentration-time profile	Half-life
Zero	$-\frac{d[A]}{dt} = k$	$[A]_t = [A]_0 - kt$	$t_{1/2} = \frac{[A]_0}{2k}$
First	$-\frac{d[A]}{dt} = k[A]$	$[A]_t = [A]_0 \exp(-kt)$	$t_{1/2} = \frac{\ln 2}{k}$
Second	$-\frac{d[A]}{dt} = k[A]^2$	$\frac{1}{[A]_t} - \frac{1}{[A]_0} = kt$	$t_{1/2} = \frac{1}{k[A]_0}$

5.2.4.4 *Apparent pseudokinetic orders*

Zero-, first-, and second-order kinetics have been briefly discussed already in this chapter; these models are likely to be the most frequently encountered in drug stability studies. In practice, only the concentration of the API is usually monitored over time, while other reactants such as hydrogen ion, hydroxyl ion, and other buffer components are in great excess and are usually kept constant by methods such as pH-stating. Hence, a second-order overall reaction could appear to be a first-order reaction (with respect to drug concentration). The reaction is now said to be apparently first-order or pseudo-first-order. This is the case for most pharmaceutical hydrolytic reactions that are catalyzed by various species of buffers.

Apparent zero-order kinetics arise in situations when a source of the reactant exists that maintains the concentration of the reactant during the reaction. For example, the concentration of a drug in the solution phase of a suspended formulation is kept constant (at its solubility limit) if the dissolution rate of the drug from the solid phase is faster than the rate of degradation. Supposing that only the drug molecules in solution degrade significantly, the overall degradation kinetics would be apparently zero-order or pseudo-zero-order, although the actual kinetics may be first-order or apparently first-order in solution. Apparent zero-order kinetics may also arise in other situations, such as degradation in a surfactant solution where the overall concentration of the surfactant is much higher than the critical micelle concentration, and degradation in the micellar phase is negligible. Finally, apparent zero-order kinetics occur when the extent of degradation is so small that the dependence of the reaction rate on the concentration of a reactant cannot be demonstrated because of experimental errors in measurement. Fig. 5.1 shows that, assuming a reaction to proceed by a zero-order mechanism always predicts the greatest degree of decomposition as a function of time, other factors being equal. Thus, when the order of a reaction is in doubt, the conservative choice is to assume a zero-order kinetic model for the purpose of predicting the maximum amount of degradation that could be expected at some future time.

A distinction between true and apparent kinetic orders can be made by changing concentrations of other species (eg, buffer concentration, pH, or even different buffer components) or by changing the system so that the solubility of a drug can be altered without changing the reaction mechanism.

5.2.5 Complex reactions

Many reactions involve more than a single step and are known as *complex reactions*. Depending on the reaction schemes and the magnitude of respective rate constants, the overall kinetics may be approximated by zero-, first-, or second-order rate equations. However, more often than not, the kinetic expressions are more complicated. Some commonly encountered complex reaction schemes are described next.

5.2.5.1 *Reversible reactions*

Essentially, all reactions are reversible to some extent. However, the equilibrium constant may be so huge that the overall reaction can be treated as virtually one-directional. For the following simplest reversible reaction:

$$A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} B \tag{5.21}$$

Here, k_1 and k_{-1} are the first-order rate constants for the forwarding and reversing reactions, respectively. The rate equation can be written as

$$\text{rate} = -\frac{d[A]}{dt} = \frac{d[B]}{dt} = k_1[A] - k_{-1}[B] \tag{5.22}$$

At equilibrium, the concentrations of species A and species B do not change any further because the

rate of the forward reaction equals that of the reverse reaction:

$$\text{rate} = -\frac{d[\text{A}]}{dt} = \frac{d[\text{B}]}{dt} = k_1[\text{A}]_{\text{eq}} - k_{-1}[\text{B}]_{\text{eq}} = 0 \qquad (5.23)$$

The subscript "eq" designates quantities at equilibrium. Therefore:

$$K = \frac{[\text{B}]_{\text{eq}}}{[\text{A}]_{\text{eq}}} = \frac{k_1}{k_{-1}} \qquad (5.24)$$

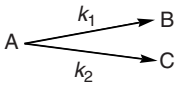
K is the equilibrium constant and is equal to the ratio between the rate constant of the forward reaction to that of the reverse reaction. Thus, Eq. (5.24) provides a connection between the thermodynamic chemical equilibrium and the kinetics of a reversible reaction. The concentration-time profile of a reversible first-order reaction can then be obtained:

$$\ln\left(\frac{[\text{A}]_0 - [\text{A}]_{\text{eq}}}{[\text{A}] - [\text{A}]_{\text{eq}}}\right) = (k_1 + k_{-1})t \qquad (5.25)$$

Fig. 5.2 shows the time-concentration profiles for a theoretical reversible reaction, assuming $K = 3$, $k_1 = 0.3$, and $k_{-1} = 0.1$.

5.2.5.2 Parallel reactions

Sometimes more than one reaction pathway exists for degradation of a drug candidate. These pathways might lead to identical degradants or, more commonly, different degradants. Take for an example the following simplest parallel reaction:



(5.26)

Here k_1 and k_2 are the first-order rate constants for reaction A→B and A→C, respectively. The corresponding rate equation is:

$$\text{rate} = -\frac{d[\text{A}]}{dt} = k_1[\text{A}] + k_2[\text{A}] = (k_1 + k_2)[\text{A}] = k_{\text{obs}}[\text{A}] \qquad (5.27)$$

Here, $k_{\text{obs}} = k_1 + k_2$ is the observed apparent first-order rate constant. Mathematically, the concentration-time profiles can be obtained as follows:

$$[\text{A}]_t = [\text{A}]_0 \exp(-k_{\text{obs}}t) \qquad (5.28)$$

$$[\text{B}]_t = [\text{B}]_0 + \frac{k_1}{k_{\text{obs}}}[\text{A}]_0\left[1 - \exp(-k_{\text{obs}}t)\right] \qquad (5.29)$$

$$[\text{C}]_t = [\text{C}]_0 + \frac{k_2}{k_{\text{obs}}}[\text{A}]_0\left[1 - \exp(-k_{\text{obs}}t)\right] \qquad (5.30)$$

Fig. 5.3 shows the concentration-time profile for a parallel reaction with $k_1 = 0.2$ and $k_2 = 0.1$.

5.2.5.3 Consecutive reactions

Consecutive reactions involve an intermediate formed from the initial reactant that in turn is converted to the final product. For a simple first-order consecutive reaction from reactant A to product C via intermediate B:

$$A \xrightarrow{k_1} B \xrightarrow{k_2} C \qquad (5.31)$$

The rate equations may be obtained as

$$-\frac{d[\text{A}]}{dt} = k_1[\text{A}] \qquad (5.32)$$

$$\frac{d[\text{B}]}{dt} = k_1[\text{A}] - k_2[\text{B}] \qquad (5.33)$$

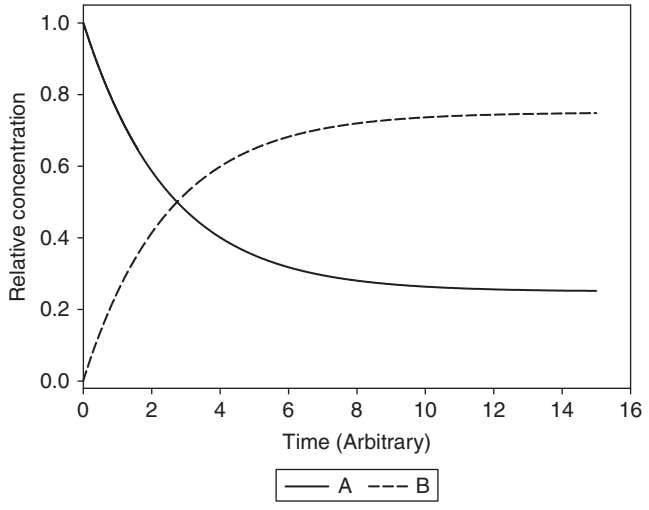


FIGURE 5.2 Concentration-time profiles for a theoretical reversible reaction.

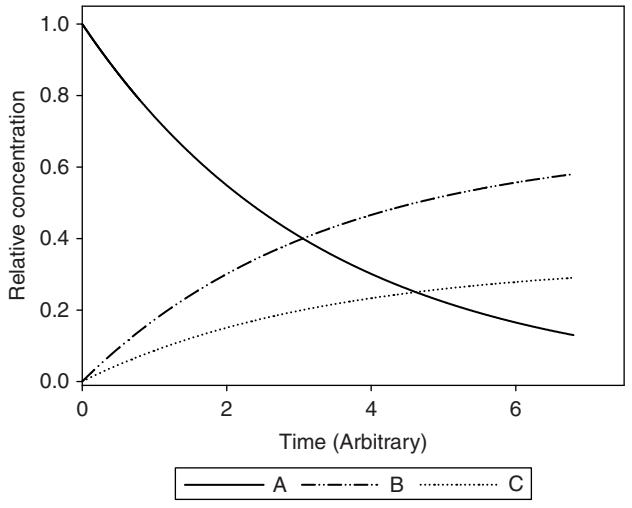

FIGURE 5.3 Concentration-time profiles for a theoretical parallel reaction.

$$\frac{d[\mathrm{C}]}{dt} = k_2[\mathrm{B}] \tag{5.34}$$

The concentration-time profiles can be obtained by simultaneously solving the differential equations (Eqs. 5.32–5.34), getting the following results:

$$[\mathrm{A}] = [\mathrm{A}]_0 \exp(-k_1 t) \tag{5.35}$$

$$[\mathrm{B}] = \frac{k_1}{k_2 - k_1}[\mathrm{A}]_0\{\exp(-k_1 t) - \exp(-k_2 t)\} \tag{5.36}$$

$$[\mathrm{C}] = [\mathrm{A}]_0 + \frac{1}{k_1 - k_2}[\mathrm{A}]_0\{k_2 \exp(-k_1 t) - k_1 \exp(-k_2 t)\} \tag{5.37}$$

The concentration-time profiles for a theoretical consecutive reaction are shown in Fig. 5.4 for a theoretical consecutive reaction A→B→C with $k_1 = 0.2$, and $k_2 = 0.1$. Note that the time profile of the intermediate B shows a maximum.

5.2.6 Arrhenius equation, collision theory, and transition state theory

5.2.6.1 *Arrhenius equation*

The rate of a reaction is usually affected by concentration, solvents, and catalysis and, very importantly, by temperature. The Q10 rule, attributed to pioneering physical chemist Jacobus H. van't Hoff, states that the velocity of a chemical reaction increases approximately twofold to threefold for each 10°C rise in temperature. His student, Svante Arrhenius, expressed this more formally as[1]

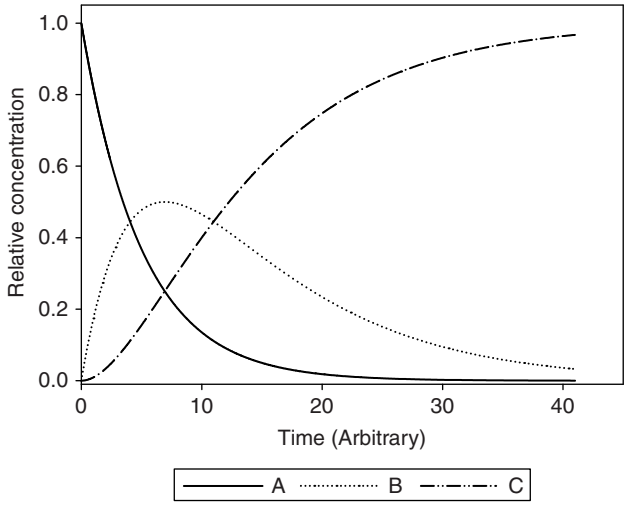

FIGURE 5.4 Concentration-time profiles for a theoretical consecutive reaction.

$$\frac{d\ln(k)}{dT} = \frac{E_a}{RT^2} \tag{5.38}$$

This can be integrated to give the exponential form:

$$\ln(k) = \ln(A) - \frac{E_a}{RT} \quad \text{or} \quad k = A\exp\left(-\frac{E_a}{RT}\right) \tag{5.39}$$

Here, k is the rate constant, A is a constant known as the *Arrhenius frequency factor* (where the limiting rate as the absolute temperature is increased to infinity), E_a is another constant called the *activation energy*, R is the *universal gas constant*, and T is the *absolute temperature*. The frequency factor determines the collision frequency between reacting molecules, while the activation energy is the energy barrier that the molecules must overcome in order to react and form products. Experimentally, the frequency factor and the activation energy can be obtained from the intercept and the slope, respectively, of the Arrhenius plot of $\ln(k)$ versus $1/T$.

Connors et al. pointed out that most drug degradations have activation energies of 12–24 kcal/mol[2]; however, higher activation energies have also been observed.[3] The Q10 rule assumes an activation energy of 13–20 kcal/mol; therefore, it provides a conservative estimate of the effect of temperature on drug degradation rates.

5.2.6.2 *Classic collision theory of reaction rates*

Reactant molecules must collide in order to react. However, not every collision leads to a successful reaction. The classical collision theory of reaction rates postulates that the reaction takes place only if the involved molecules exceed a certain minimum energy (the activation energy). Based on the abovementioned assumptions, an expression of the rate similar to the form in the Arrhenius equation can be derived.

The fraction of molecules with kinetic energies exceeding E_a can be derived using the Boltzmann distribution:

$$f(E_k > E_a) = \exp\left(-\frac{E_a}{RT}\right) \tag{5.40}$$

Here, f is the fraction reacting (or probability of reaction), and E_k is the kinetic energy. Therefore, the rate can be expressed as

$$\text{rate} = ZPC_{E_k > E_a} = ZPC_T \exp\left(-\frac{E_a}{RT}\right) \tag{5.41}$$

Here, $C_{E_k > E_a}$ is the concentration of the reactant molecules with kinetic energy exceeding the activation energy, C_T is the total reactant concentration, Z is the collision frequency, and P is the steric factor ($0 < P < 1$), because not every collision leads to a

reaction. By comparison with the general rate law, one can immediately see that the expression of the rate constant, k, is similar to the Arrhenius equation:

$$k = ZP \exp\left(-\frac{E_a}{RT}\right) \tag{5.42}$$

Here, ZP is identified with the Arrhenius frequency factor A, while E_a is the activation energy.

5.2.6.3 *Transition state theory*

The classic collision theory assumes that the reaction is possible when reactant molecules with sufficient energies collide. It does not answer the question of how they react. The transition state theory, developed around 1935 by Eyring and Polanyi et al. (see the review by Eyring[4]) postulates that in addition to collision, a transition state (or activated complex) must exist in which the reacting molecules have an appropriate configurational geometry for the reaction to occur; furthermore, the transition state is in equilibrium with the reactants. In order for the activated complex to form, a certain energy barrier (the activation energy) needs to be overcome. Once the activated complex is formed, it can decompose to products. In principle, the transition theory provides a means to calculate the rate of a reaction once certain properties of the activated complex, such as vibrational frequency, molecular mass, and interatomic distances, are known. This theory is also referred to as the *absolute rate theory*.

A simplified scheme can be represented as follows:

$$\mathrm{A} + \mathrm{B} \overset{K^{\ddagger}}{\rightleftharpoons} [A\ldots B]^{\ddagger} \rightarrow \mathrm{C} \tag{5.43}$$

The double dagger designates the transition state.

Transition state theory assumes that the decomposition of the activated complex is the rate-determining step of the reaction. Among all the molecular motions of the activated complex, there is one mode of vibration (frequency, designated as ν) that will lead to the formation of the product. Combined with the equilibrium assumption, the rate of the reaction can be written as

$$\text{rate} = \frac{d[\mathrm{C}]}{dt} = \nu[\mathrm{A}\cdots\mathrm{B}]^{\ddagger} = \nu K^{\ddagger}[\mathrm{A}][\mathrm{B}] \tag{5.44}$$

Thus, the rate constant of the reaction, k, has the following form:

$$k = \nu K^{\ddagger} \tag{5.45}$$

Once the vibration frequency ν and the equilibrium constant are known, the rate constant can be calculated. For example, the equilibrium constant can be obtained from statistical thermodynamic treatments of chemical equilibrium, while the frequency of the decomposition vibration can, as shown by Eyring, be approximated by

$$\nu = \frac{k_B T}{h} \tag{5.46}$$

Here, k_B is Boltzmann's constant, h is Plank's constant, and T is the absolute temperature. The final rate constant can be expressed as

$$\begin{aligned} k &= \frac{k_B T}{h} K^{\ddagger} = \frac{k_B T}{h} \exp\left(-\frac{\Delta G^{\ddagger}}{RT}\right) \\ &= \frac{k_B T}{h} \exp\left(\frac{\Delta S^{\ddagger}}{R}\right) \exp\left(-\frac{\Delta H^{\ddagger}}{RT}\right) \end{aligned} \tag{5.47}$$

$\Delta G^{\ddagger}$, $\Delta S^{\ddagger}$, and $\Delta H^{\ddagger}$ are the free energy, entropy, and enthalpy of activation, respectively. In comparison with the Arrhenius equation, it is immediately obvious that

$$\begin{aligned} E_a &= RT^2 \frac{d \ln k}{dT} = RT + \Delta U^{\ddagger} \\ &= RT + \Delta H^{\ddagger} - \Delta(pV^{\ddagger}) \cong RT + \Delta H^{\ddagger} \end{aligned} \tag{5.48}$$

$$A = \frac{k_B T}{h} \exp\left(\frac{\Delta S^{\ddagger}}{R}\right) \tag{5.49}$$

$\Delta(pV^{\ddagger})$ is the change of pV when the activated complex is formed, and this value is negligible for most condensed phase reactions.

The transition state theory provides a better picture of chemical reactivity, and it is still used today. It accounts for the influences on reaction rate by various factors, such as solvent, ionic strength, and dielectric constant. In general, enhancement of the reaction rate is expected if a factor stabilizes the transition state. However, sometimes changing one factor might change the effects of other factors. Therefore, caution must be taken when such exercises are performed.

A schematic representation of the transition state theory is shown in Fig. 5.5a. Fig. 5.5b describes the situation where an intermediate exists. The intermediate is located at a local minimum on the potential energy surface, and in this case, there are two separate activation energies.

5.2.7 Catalysts and catalysis

A *catalyst* is a substance that influences the rate of a reaction without itself being consumed. Positive catalysis increases the reaction rate, while negative catalysis reduces the reaction rate. However, positive catalysis is what is normally considered.

A catalyst changes the rate of a reaction by altering the free energy of activation (or activation energy)

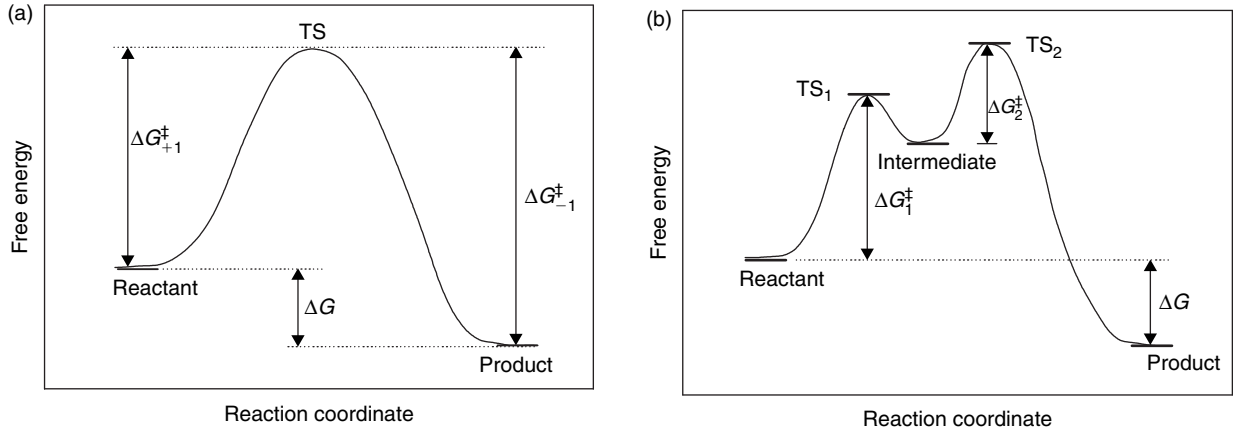

FIGURE 5.5 Schematic potential energy surface along the reaction coordinates; (a) single-step reaction; (b) reaction with an intermediate.

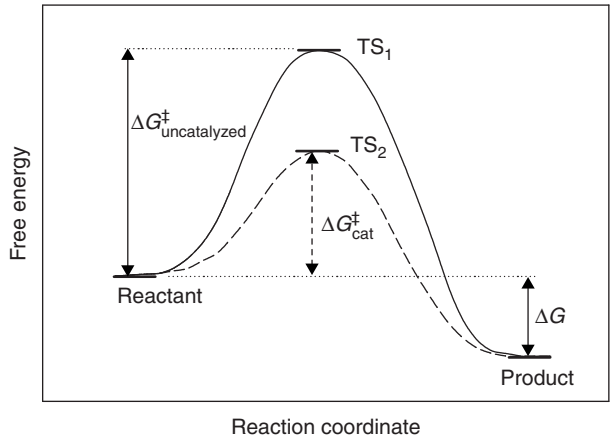

FIGURE 5.6 Schematic potential energy surfaces along a reaction coordinate with a positive catalyst.

without altering the thermodynamic aspects of the reaction. In other words, the equilibrium of a reaction is not changed by the presence of a catalyst. A positive catalyst reduces the free energy of activation, while a negative catalyst increases it. Fig. 5.6 describes the reaction coordinate with a positive catalyst.

The activation energy decreases in the presence of the catalyst; however, the thermodynamics, as indicated by the ΔG of the reaction, are not altered.

5.2.7.1 *Specific acid-base catalysis*

Hydrogen ions and hydroxyl ions are often involved directly in the degradation of pharmaceuticals. In many cases, the concentration of hydrogen ions or hydroxyl ions appears in the rate equation; the reaction is then said to be subject to specific acid-base catalysis.

For example, an ester drug is hydrolyzed in an acidic buffer; the second-order rate equation is

$$\text{rate} = -\frac{d[\text{D}]}{dt} = k\left[\text{H}^+\right][\text{D}] \tag{5.50}$$

Drug degradation studies are often carried out in buffered solutions where concentrations of hydrogen or hydroxyl ions are maintained as constant. In addition, the drug itself is usually the only species whose concentration is monitored over time. As a result, the degradation kinetics is pseudo-first-order when the reaction is catalyzed by hydrogen or hydroxyl ions, with the apparent rate constant, k_{obs}:

$$k_{obs} = k[\text{H}^+] \quad \text{or} \quad \log k_{obs} = \log k - \text{pH} \tag{5.51}$$

For a reaction subject to specific acid catalysis, a plot of the logarithm of the apparent first-order rate constant with respect to pH gives a straight line of slope -1.

Similarly, for specific base catalysis, a plot of the logarithm of the apparent first-order rate constant versus pH gives a line of slope of $+1$:

$$k_{obs} = k[\text{OH}^-] \quad \text{or} \quad \log k_{obs} = \log k + \text{pH} \tag{5.52}$$

Hydrolysis of zileuton is subject to specific acid catalysis, but not base catalysis.[5,6] Hydrolysis of aspirin shows both specific acid- and specific base-catalysis.[7]

5.2.7.2 *General acid-base catalysis*

General acid-base catalysis occurs when the buffering components catalyze a reaction. Either the acidic or basic components of the buffer, or both, can catalyze a reaction.

General acid-base catalysis often causes deviation of the rate-pH profile from the expected behavior. The exact magnitudes of general acid-base catalysis can often be obtained by varying buffer concentration while keeping the remaining conditions (ionic strength,

pH, etc.) constant. A plot of the apparent first-order rate constant versus buffer concentration should be a straight line whose slope corresponds to the catalytic coefficient of the buffer at the studied pH. The intercept of this plot corresponds to the specific rate constant in the absence of general acid-base catalysis.

No distinction between the species responsible for general catalysis can be made by this method. However, it could be achieved if the reaction is studied at different pH values with the same buffer species.

In general, the apparent first-order rate constant can be written as follows, taking into account both specific and general acid-base catalysis:

$$\begin{aligned} k_{obs} &= k_0 + k_H[H^+] + k_{OH}[OH^-] + k_1[\text{buffer species 1}] \\ &\quad + k_2[\text{buffer species 2}] + \ldots \\ &= k_0 + \sum_i k_i C_i \end{aligned} \tag{5.53}$$

Here, k_0 is the intrinsic first-order rate constant in the absence of any catalysis, C_i is the concentration of species i, and k_i is the catalytic coefficient of species i.

The degradation of a number of pharmaceuticals has been shown to be subject to general acid-base catalysis. Degradation of thiamine was found to be catalyzed by acetate ion, but not acetic acid, and is therefore an example of general base catalysis.[8] Citric acid, citrate ions, and phosphate ions all catalyze the decomposition of ampicillin, an example illustrating both general acid and general base catalysis.[9]

5.2.8 pH-rate profiles

The pH-rate profile, sometimes called the *pH-stability profile* or *rate-pH profile*, is the pH dependence of the specific rate constant of degradation of a compound; it is conveniently represented by a log(k) versus pH plot. The pH-rate profiles provide insights into the catalytic nature of a reaction, and they can help in developing more stable solution formulations and lyophilized products. In addition, pH-rate profiles aid in the development of more stable conventional solid oral dosage forms (eg, tablets), although solution stability information is not required to be as detailed in this case.

Many drug degradation reactions follow apparent first-order kinetics and are subject to specific and general acid-base catalysis. The apparent first-order rate constants are usually plotted in a pH-rate profile. One should correct for general acid-base catalysis by buffer components by extrapolation to zero buffer concentration if the catalysis effect is significant.

Analysis of a pH-rate profile can be started by assuming all possible pathways and writing down the corresponding rate equations (eg, Eq. 5.53). The presence or absence of a certain mechanism can then be verified by analyzing the kinetic data. A brief discussion of the more basic pH-rate profiles follows.

5.2.8.1 *V-shaped, U-shaped, and other truncated pH-rate profiles*

Specific acid and base catalysis is common in the degradation of carboxylic acid derivatives, such as esters, amides, substituted ureas, etc. In the absence of other more complicated mechanisms, the pseudo-first-order rate constant can be written as

$$k_{obs} = k_H[H^+] + k_0 + k_{OH}[OH^-] \tag{5.54}$$

Here, k_0 is the intrinsic apparent first-order rate constant, and k_H and k_{OH} are the catalytic coefficients for the hydrogen and hydroxyl ions, respectively. The resulting rate-pH profile plot consists of a straight line with slope of -1 in the acidic region, and another straight line with slope of 1 in the basic region (Fig. 5.7a). Atropine[10,11] and diazepam[12] are examples of compounds with V-shaped pH-rate stability profiles. When k_0 is sufficiently large, the V-shaped pH-rate profile may show a flat region and the resulting plot is U-shaped (see Fig. 5.7b; hydrolysis of the β-lactam ring in cephalothin[13]).

Degradation of some drug substances may show only specific acid- or base-catalysis, but not both (eg, hydrolysis of echothiophate[14]). The plot (Fig. 5.7c or 5.7d) then either has a slope of -1 in the acidic region joined to a flat line extending into the basic region (specific acid catalysis) or a flat line in the acidic region joined to a line with slope 1 in the basic region (specific base catalysis). In some cases, only specific acid-catalysis or specific base-catalysis is observed; therefore, the rate-pH profile consists of only a straight line (Fig. 5.7e and 5.7f; eg, lansoprazole[15]). Fig. 5.7 exhibits these rate-pH profiles where only a single species is reactive with either specific acid- or base-catalysis, or both.

5.2.8.2 *Sigmoidal pH-rate profiles*

Sigmoidal rate-pH profiles usually arise from the dissociation of the drug molecules. Many drug candidates are weak bases or weak acids. In the vicinity of $pH = pK_a$, the species distributions of a weak base or weak acid are sigmoidal when plotted as a function of pH. Therefore, if both the acidic and basic species of the compound can undergo degradation with differing rate constants, the rate-pH profile is expected to be sigmoidal. For example, for the decomposition of weak acid HA:

$$HA \xrightarrow{k_{HA}} \text{product} \tag{5.55}$$

$$A^- \xrightarrow{k_{A^-}} \text{product} \tag{5.56}$$

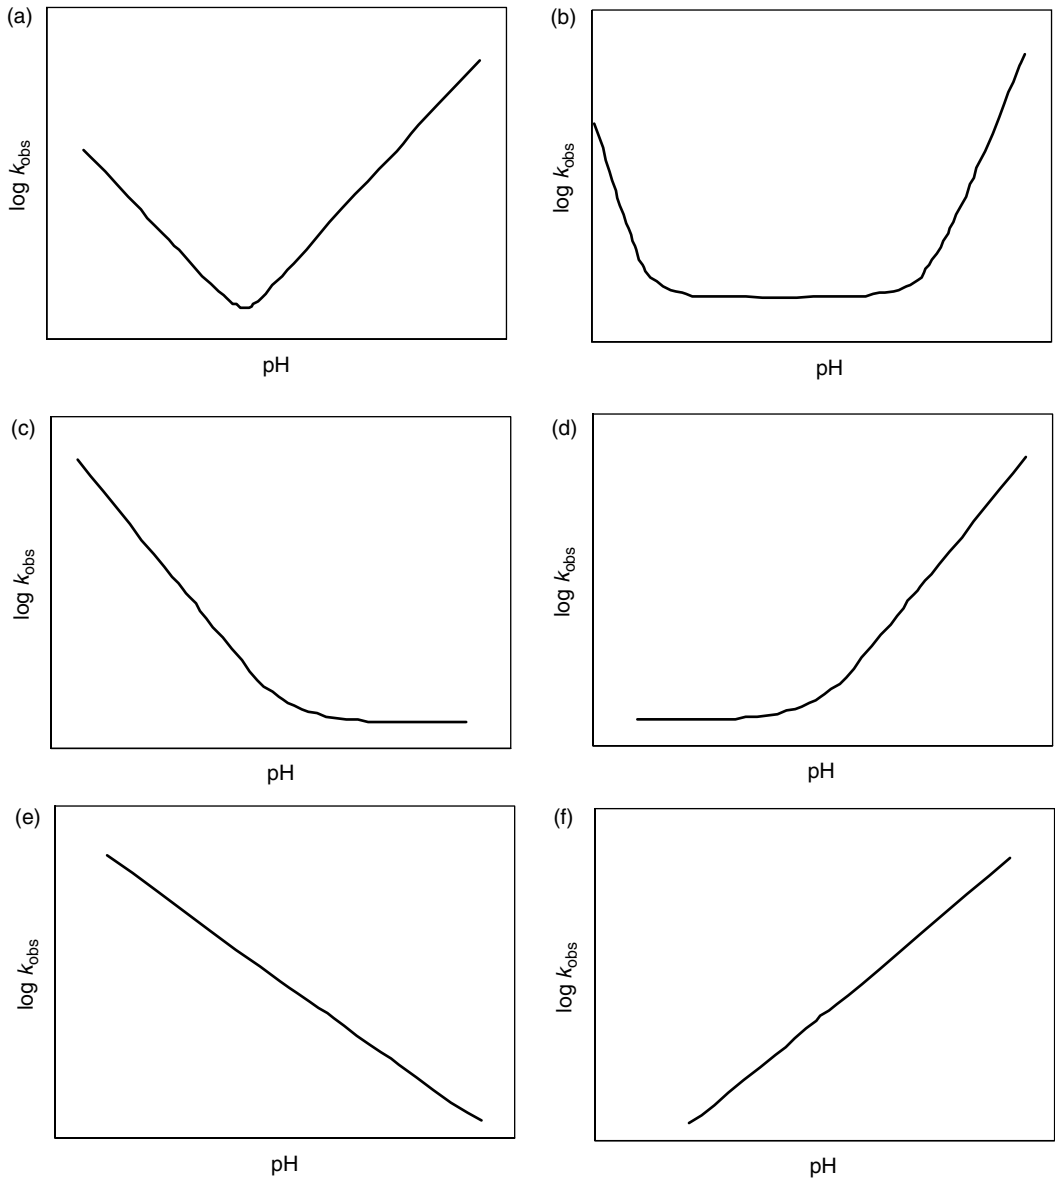

FIGURE 5.7 Schematic rate-pH profiles for reactions involving only a single reactive species with specific acid-, base-catalysis, or both.

When the drug concentration is measured, a distinction between the ionized and unionized species is usually not made. The apparent rate of the reaction is

$$\begin{aligned} \text{rate} &= k_{HA}[HA] + k_{A^-}[A^-] \\ &= \frac{k_{HA}[H^+] + k_{A^-}K_a}{K_a + [H^+]}\{HA\} \end{aligned} \tag{5.57}$$

Here, K_a is the dissociation constant of HA, while {HA} is the total concentration of HA. Therefore, a plot of the apparent rate constant is sigmoidal with respect to pH, so long as the rate constants are not identical. The rate constant of each species can be estimated from the limits of the apparent rate constant at low and high pH, and that pK_a = pH at the inflection point of the sigmoidal pH-rate profile plot. If the change in rate is due to ionization at a single site, the sigmoidal curve will encompass slightly more than ± 1 pH units of the expected pK_a.

In this instance, 5-flurouracil is a weak diprotic acid and has 2 ionization constants with $pK_1 = 7.3$ and $pK_2 = 11.3$. Among the three species, A^{2-} has the highest reactivity, while the neutral molecules H_2A and HA^- possess only slightly different rate constants. Therefore, the sigmoidal pH-rate profile[16] is rather obvious in the pH range 10.5–12.5 (Fig. 5.8a). While the change in rate from pH 6 to pH 8 is only minor, the sigmoid shape can still be seen around the first pK_a.[16] Cycloserine is a zwitterion, with $pK_1 = 4.5$ (acid) and $pK_2 = 7.4$ (base). The three species have different

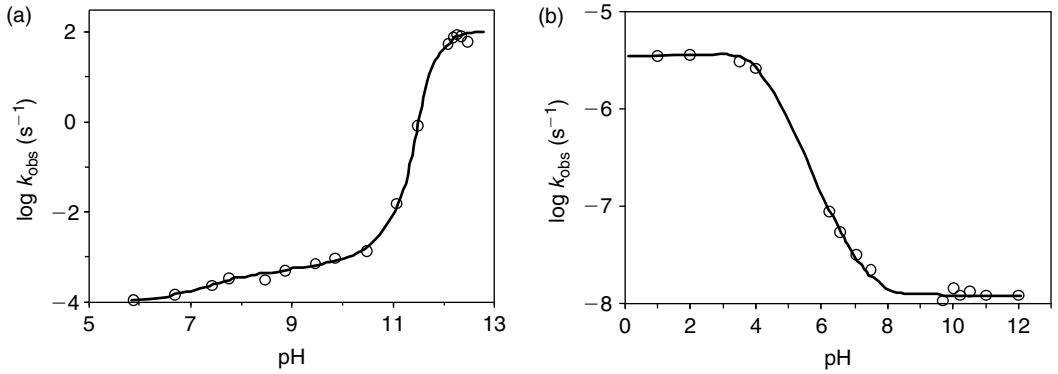

FIGURE 5.8 Sigmoidal pH-rate profiles; (a) 5-fluorouracil; (b) cycloserine at 25°C. *Redrawn from Garrett ER, Nestler HJ, Somodi A. Kinetics and mechanisms of hydrolysis of 5-halouracils.* J Org Chem *1968;**33**:3460–8. Kondrat'eva AP, Bruns BP, Libinson GS. Stability of D-cyclo-serine in aqueous solutions at low concentrations.* Khimiko-Farmatsevticheskii Zhurnal *1971;**5**:38–41, respectively.*

reactivity and follow the following order: $AH^{2+} > AH^{\pm} > A^{-}$. Therefore, a broad sigmoidal pH-rate profile encompassing the pH range 3–9 (Fig. 5.8b) was observed.[17] Degradation of barbital[18] and zileuton[6] also shows similar behavior.

5.2.8.3 Bell-shaped pH-rate profiles

Bell-shaped pH-rate profiles show a minima or maxima. Different scenarios can lead to this kind of pH-rate profile. The most intuitive scenario arises from the existence of two ionizable functional groups in the molecule. For example, for a diprotic acid, H_2A, three species are in solution: H_2A, HA^{-}, and A^{2-}, where the concentration-pH profile of species HA^{-} is bell-shaped. Depending on whether the monoprotic species, HA^{-}, is the most or least reactive, and the corresponding pH-rate profile could show either a maxima or a minima. Based on a similar argument, one can also show that the reaction between an acid and a base can lead to a bell-shaped pH-rate profile. In this case, the two ionizations are on different reactant molecules.

The third scenario occurs when ionization is combined with a change in the rate-determining step. For example, consider a consecutive reaction: A→B→C, where A is a monoprotic acid/base. The two species of reactant A may have very different reactivities with the rate constant of step B→C falling somewhere in between. Therefore, in one pH region (below or above its pK_a), the step A→B is the slowest, whereas B→C becomes the rate-determining step over another pH range. A bell-shaped pH-rate profile then results, with one side of the bell corresponding to the ionization while the other corresponds to the switch of the rate-limiting step. Hydrolysis of hydrochlorothiazide[19,20] was proposed to be such a case (Fig. 5.9). Its profile from pH 7 to 12 was probably caused by its two pK_a values of 8.6 and 9.9, respectively. However, the change from pH 7 to 2 could not be explained by ionization, and was hypothesized to be due to a switch of rate-determining step in the hydrolysis.

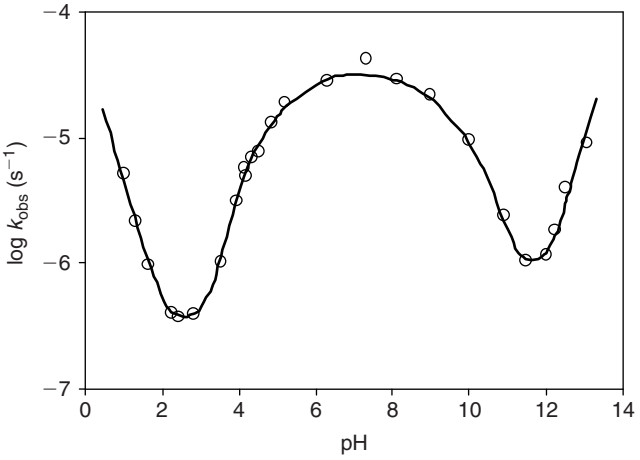

FIGURE 5.9 pH-rate profiles for hydrochlorothiazide at 60°C. *Redrawn from Mollica JA, Rehm CR, Smith JB, Govan HK. Hydrolysis of benzothiadiazines.* J Pharm Sci *1971;**60**:1380–1384.*

5.2.8.4 More complicated pH-rate profiles

The presence of multiple ionization centers can complicate the analysis of a pH-rate profile (Fig. 5.10a). However, their construction is based on similar principles. Depending on how far their pK_a values are isolated, some of the abovementioned features may not be fully developed in a particular pH-rate profile.

Additional features may be identified from a pH-rate profile. The pH-rate profile of aspirin shows evidence for specific acid-catalysis at pH < 2 and specific base-catalysis at pH > 10. The sigmoidal portion (pH 2–9) is due to the different reactivity of the neutral and ionized aspirin species.[7] The broad shoulder at pH 4.5–9 corresponds to the reactivity of ionized aspirin

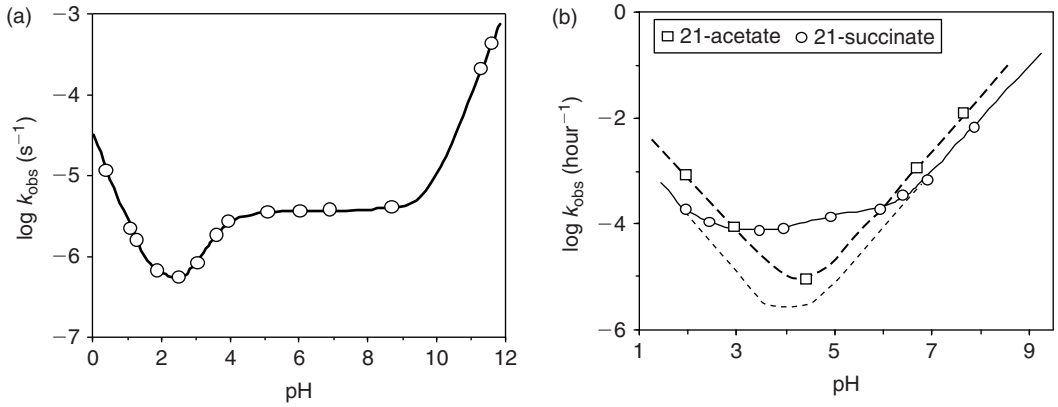

FIGURE 5.10 Complex pH-rate profiles; (a) pH-rate profile for aspirin at 25°C; (b) pH-rate profiles for Methylprednisolone-21-acetate and Methylprednisolone-21-hemisuccinate at 25°C.

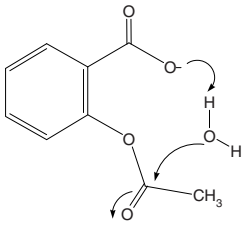
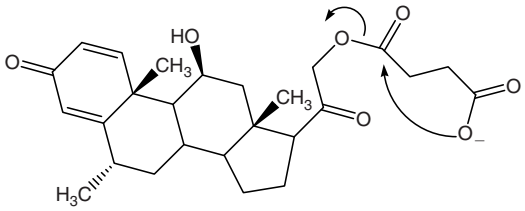
species with water, which is due to intramolecular catalysis:



Anderson et al.[21] studied the hydrolysis of methylprednisolone-21-esters in aqueous solutions. Hydrolysis of methylprednisolone-21-acetate (Fig. 5.10b) showed a V-shaped pH-rate profile, indicating both specific acid- and specific base-catalysis. The structurally similar compound, methylprednisolone-21-succinate, however, showed quite a bit of deviation from that expected in the pH range 2–7. The higher reactivity in this pH range and deviation from the V-shaped pH-rate profile was again caused by intramolecular catalysis:



Information like this not only provides significant insights on the stability itself but is also helpful in designing a stable drug candidate.

5.2.9 Solid-state reaction kinetics

Solid dosage forms are the most common because they are easier to handle, more convenient to patients, and do provide stability advantages in most cases. Degradation of an API in solid state is more complicated than in solution, and a large part of its degradation behavior and kinetics can be attributed to the characteristics of its solid form.

5.2.10 Solid-state kinetic models

Various solid-state kinetic models have been discussed in the research literature, most of which have been applied to relatively simple systems, such as API crystals. These reaction models could be useful in elucidating the route and mechanism of solid-state reactions. The degradation kinetics of an API in a solid dosage form is even more complicated. However, zero- or first-order kinetics may be approximated for the first few percentage points of potency loss, which is most relevant for assessing the stability of a pharmaceutical product. Many so-called solid-state reactions might actually be moisture- or solution-mediated.

The concentration term in solid-state reactions is less clearly defined; therefore the extent of conversion, α, is predominantly used. The quantity α is sometimes called the *fractional conversion* or *fraction converted*. Many different reaction mechanisms have been proposed to describe solid-state reactions, some of which are listed in Table 5.2. Models can be expressed in a differential form $f(\alpha_{t,T})$, as well as an integral form $g(\alpha_{t,T})$ or inverse integral form $g^{-1}(k_{t,T})$.

5.2.10.1 *Reactions involving nucleation*

Most solids contain defects, high-energy spots that can initiate physical and chemical changes. These flaws play important roles when nucleation is the rate-limiting step of a reaction.

5.2.10.2 *Avrami–Erofeev equation*

If the reaction involves random nucleation followed by the growth of nuclei of a defined dimensionality,

TABLE 5.2 Solid-State Reaction Mechanisms and Their Corresponding Kinetic Equations

Reaction mechanisms	Differential form $\frac{\partial \alpha}{\partial t} = k_T f(\alpha_{t,T})$	Integral form $g(\alpha_{t,T}) = k_T t$	Inverse integral form $\alpha_{t,T} = g^{-1}(k_T, t)$
REACTION ORDER MODELS			
(F0) Zero-order	1	α	$k_T t$
(F1) First-order (Mampel)	$1-\alpha$	$-\ln(1-\alpha)$	$1-e^{-k_T t}$
(F2) Second-order	$(1-\alpha)^2$	$(1-\alpha)^{-1}-1$	$1-(1+k_T t)^{-1}$
(F3) Third-order	$(1-\alpha)^3$	$\left(\frac{1}{2}\right)((1-\alpha)^{-2}-1)$	$1-(1+2k_T t)^{-1/2}$
NUCLEATION MODELS			
(P2) Power law	$2\alpha^{1/2}$	$\alpha^{1/2}$	$k_T^2 t^2$
(P3) Power law	$3\alpha^{2/3}$	$\alpha^{1/3}$	$k_T^3 t^3$
(P4) Power law	$4\alpha^{3/4}$	$\alpha^{1/4}$	$k_T^4 t^4$
$\left(P\frac{3}{2}\right)$ Power law	$\frac{2}{3}\alpha^{-1/2}$	$\alpha^{3/2}$	$k_T^{2/3} t^{2/3}$
(A2) Avrami–Erofeev	$2(1-\alpha)[-\ln(1-\alpha)]^{1/2}$	$[-\ln(1-\alpha)]^{1/2}$	$1-e^{-k_T^2 t^2}$
(A3) Avrami–Erofeev	$3(1-\alpha)[-\ln(1-\alpha)]^{2/3}$	$[-\ln(1-\alpha)]^{1/3}$	$1-e^{-k_T^3 t^3}$
(A4) Avrami–Erofeev	$4(1-\alpha)[-\ln(1-\alpha)]^{3/4}$	$[-\ln(1-\alpha)]^{1/4}$	$1-e^{-k_T^4 t^4}$
(B1) Prout–Tompkins	$\alpha(1-\alpha)$	$k_T t_{1/2} + \ln[\alpha/(1-\alpha)]$	$(1+e^{-k_T(t-t_{1/2})})^{-1}$
DIFFUSION MODELS			
(D1) One-dimensional	$1/2\alpha$	α^2	$k_T^{1/2} t^{1/2}$
(D2) Two-dimensional	$[-\ln(1-\alpha)]^{-1}$	$[(1-\alpha)\ln(1-\alpha)]+\alpha$	–
(D3) Three-dimensional (Jander)	$\frac{3(1-\alpha)^{1/2}}{2[1-(1-\alpha)^{1/3}]}$	$[1-(1-\alpha)^{1/3}]^2$	$1-(1-k_T^{1/2} t^{1/2})^3$
(D4) Three-dimensional (Ginstling-Brouhnshtein)	$\frac{3}{2}\left[(1-\alpha)^{1/3}-1\right]$	$1-\frac{2\alpha}{3}-(1-\alpha)^{2/3}$	–
GEOMETRICAL CONTRACTION MODELS			
(R1) Linear contraction	1	α	$k_T t$
(R2) Contracting cylinder	$2(1-\alpha)^{1/2}$	$1-(1-\alpha)^{1/2}$	$1-(1-k_T t)^2$
(R3) Contracting sphere	$3(1-\alpha)^{2/3}$	$1-(1-\alpha)^{1/3}$	$1-(1-k_T t)^3$

No simple algebraic solution obtainable; solve by numerical approximation.

the Avrami–Erofeev equation can be derived and may apply[22–26]:

$$[-\ln(1-\alpha)]^{1/n} = kt \tag{5.58}$$

Here, n takes the value of 2, 3, or 4.

Avrami-Erofeev models have been observed for typical crystallization kinetics.

5.2.10.3 *Prout–Tompkins equation*

The Prout–Tompkins equation[27] is derived based on the assumption of linearly growing nuclei that branch into chains:

$$\ln\left(\frac{\alpha}{1-\alpha}\right) = k(t-t_{1/2}) \tag{5.59}$$

Reaction kinetics of the type: solid → solid + gas often follow the Prout-Tompkins model.[28]

5.2.10.4 *Reactions controlled by diffusion*

In some solid-state reactions, reaction rates are controlled by diffusion of the reactants or products. This situation arises because mass transfer in the solid state is usually slow. Examples include curing of polymeric resins.

If the diffusion-controlled process is one-dimensional, then the one-dimensional equation may be derived[29]:

$$\alpha^2 = kt \tag{5.60}$$

Similarly, the rate may be controlled by two-dimensional diffusion, as in a circular disk[30] or in a cylinder, or by three-dimensional diffusion as in a sphere.[31] The following equations can be derived for each case in turn:

$$(1-\alpha)\ln(1-\alpha) + \alpha = kt \tag{5.61}$$

$$1-\frac{2}{3}\alpha-(1-\alpha)^{2/3} = kt \tag{5.62}$$

A simplified three-dimensional diffusion equation was developed by Jander[32]:

$$[1-(1-\alpha)^{1/3}]^2 = kt \tag{5.63}$$

5.2.10.5 Reactions governed by phase boundaries

Some solid-state reactions involve two or more substances, where phase boundaries are formed between the reactants and the products. In some cases, the advance of the phase boundary so formed determines the rate of such a reaction. When the advance of the phase boundary is one-dimensional, then a zero-order reaction is obtained:

$$1-\alpha = kt \tag{5.64}$$

The two-dimensional phase boundary equation (contracting cylinder), and the three-dimensional phase boundary equation (contracting sphere) can be derived accordingly[29]:

$$1-(1-\alpha)^{1/n} = kt \tag{5.65}$$

Here, n takes the value of 2 and 3, respectively.

5.2.10.6 Higher (nth)−order reactions

These kinetic equations have similar formats as in solution kinetics. Most often, the first- and second-order reactions are used. Higher orders are rare and are difficult to interpret in solid-state reactions. In most cases, these equations provide an opportunity for curve-fitting rather than kinetic interpretation at the molecular level.

5.2.10.7 Bawn kinetics

Sometimes the degradant is a liquid that serves as a solvent for the reactant: solid → liquid + gas. As a result, the reactant degrades both in the solid-state and in the solution state. When the kinetics in both phases is first-order, the Bawn kinetic model[28,33] may be appropriate:

$$\ln(1 + B\alpha) = Bk_s t \tag{5.66}$$

Here, k_s is the first-order rate constant in the solid state, and B is the ratio between the first-order rate constant in solution state and that in solid state. Bawn kinetics ceases to apply when the critical conversion is reached, at which time all of the remaining reactant dissolves.

5.2.10.8 Model-fitting versus model-free approaches

Conventionally, kinetic models in solid-state reactions are determined by a model-fitting approach, where the data are fitted to a number of reaction models, and the best model is then selected using statistical criteria. The process is often assisted by other experimental observations, such as microscopy. Difficulties arise for this model-fitting approach because solid-state reactions are usually more complex, and in many cases, a change of reaction mechanism occurs during the course of the reaction. In addition, statistical distinction between models is not always achievable, such as in nonisothermal studies. A different methodology, called the *model-free approach*, has evolved within the last few decades and found application more recently in pharmaceutical systems.[34–36]

The idea of model-free approaches is evident upon transforming the basic kinetic equation:

$$\frac{d\alpha}{dt} = k(T)\,f(\alpha) = A\exp\left(-\frac{E_a}{RT}\right)f(\alpha) \tag{5.67}$$

Here, $d\alpha/dt$ is the instantaneous rate of a reaction, and $k(T)$ is the rate constant at temperature T, which is related to the activation energy E_a and frequency factor A through the Arrhenius relationship. The term $f(\alpha)$ represents the expression of the kinetic model (a function of the extent of conversion). For a reaction studied under a series of different conditions (eg, different isothermal temperatures and different heating rates), the activation energy can be obtained at a specific extent of conversion, α_i, by transforming Eq. (5.67) into

$$\ln\left(\frac{d\alpha}{dt}\right)_{\alpha_i} = \ln[Af(\alpha)]_{\alpha_i} - \frac{E_{\alpha_i}}{RT_{\alpha_i}} \tag{5.68}$$

It is not necessary to assume an explicit form of the reaction model $f(\alpha)$ because at the same conversion, $f(\alpha)$ is a constant number. The Kissenger[37] plot can be considered a special case of model-free kinetics.

In the model-free treatment, the activation energy is obtained as a function of the extent of conversion. If E_a is constant within experimental error with respect to the conversion, the reaction most likely follows a single kinetic model; otherwise, a change of mechanisms is indicated. With this piece of information,

construction of an underlying reaction model can be achieved for reactions following a single mechanism, while a change of mechanism can also be probed for reactions where E_a varies with conversion. Prediction using the model-free approach is also expected to be more accurate for complex solid-state reactions.

5.2.11 Physical parameters affecting solid-state kinetics

Solid-state reactions were hypothesized to consist of four general steps by Paul and Curtin[38]:

1. Molecular loosening at the reaction site
2. Molecular change
3. Solid solution formation
4. Separation of the product phase

Similar steps have been suggested for physical transformations.[39] The four-step hypothesis can provide some insights to help us understand solid-state reactions.

Like reactions in the solution phase, temperature obviously influences the rate of a solid-state reaction, which can be usually be described by the Arrhenius relationship. Due to the constraint of the crystal lattice, solid-state reactions usually require a higher activation energy compared to solution reactions. The applicability of the Arrhenius relationship to solid-state reactions has been debated, but it has generally been observed over narrow temperature ranges. However, a change of temperature beyond that range could induce phase changes, which could alter the validity of the Arrhenius equation. For example, degradation of an amorphous pharmaceutical is not expected to follow the Arrhenius relationship when its glass transition temperature is crossed.[40] In addition, reaction mechanisms could change as temperature is changed.[41] Therefore, caution must be taken when the effect of temperature on solid-state degradation is studied. Some types of reaction are known not to follow the Arrhenius relationship. Free radical oxidative degradation, both in solution and solid states, is such an example, due to the autocatalytic nature of the process. Photolytic reactions are initiated by light absorption and rarely depend on temperature. Indeed, some photochemical reactions can occur at temperatures near absolute zero.

If one envisions the first step loosing of the molecules at the reaction sites, then the site of initiation of a solid-state reaction may have some amorphous characteristics. Hence, the degree of crystallinity of a solid phase is expected to affect the rate of a solid-state reaction. Solid-state reactions are enhanced by crystal disorder, which is related to the fact that amorphous regions have significantly higher molecular mobility, and hence higher reactivity, than crystalline regions. Even when the degree of crystallinity is not altered, a solid-state reaction can be enhanced by increasing its surface area (smaller particle size), and by increasing defects because solid-state reactions are often initiated by defects at the surface of the material. It is not unusual that mechanical treatments such as milling exacerbate a stability problem by increasing the level of defects. However, there are exceptions to this generalization, which will be briefly touched on in the topochemical reactions described next.

Moisture greatly influences solid-state reactions, which will also be discussed separately. Solid-state reactions can also be affected by other factors. For example, drug formulations may decompose faster in a tablet form than in the powder form, primarily due to more intimate contact.

5.2.12 The role of moisture

Water is ubiquitously present as atmospheric moisture and has a profound effect on solid-state reactions. On the one hand, water can act as a reactant and be involved in the reaction itself, such as in hydrolytic reactions. On the other hand, water is an excellent plasticizer; it increases molecular mobility of reactants and enhances drug degradation. In the worst case, water can form a saturated solution phase and make the solid-state reaction solution-mediated, which adversely affects stability to a great degree.

Various mechanisms exist for water molecules to interact with a solid. Water molecules can be incorporated into crystal lattice through hydrogen bonding, van der Waal's interactions, or both. Generally, lattice water is not a cause of chemical instability. Some compounds rely on the interaction of water to form a stable crystal, thus improving their chemical stability. Water can also be adsorbed onto the surface as a monolayer and as multilayers. Water molecules in a monolayer may behave significantly differently than those in the second or third layers, the latter of which have properties that presumably resemble bulk water. The concept of "bound" and "unbound" water has been suggested to explain solid–water interactions; however, it was found to be overly simplistic in some cases. "Bound" water was perceived to be unavailable for drug degradation, while "unbound water" was viewed as the major source of instability of pharmaceuticals. Various models have been applied to describe water–solid sorption, and some success has been achieved in describing the degradation kinetics resulting from such sorption. However, pharmaceutical solids usually contain various defects and, not uncommonly,

various degrees of disordered, amorphous regions. Water molecules are preferentially absorbed into the interior of these regions. Because water is an efficient plasticizer, it significantly increases molecular mobility in the amorphous phase, which causes the drug degradation process to resemble more that occurring in the solution phase. Moisture adsorption onto crystal surfaces only accounts for insignificant amounts (on the order of 0.1% w/w) of total water content. Hence, the moisture level (a few percent) that is usually seen with bulk pharmaceuticals and formulations is primarily from absorption (into the interior), instead of adsorption (on the surface). In addition, at a relative humidity higher than some critical value, the drug or formulations containing the drug may undergo deliquescence, whereby drug degradation occurs primarily in the resulting solution phase (solution-mediated degradation). A more thorough discussion on water–solid interactions in pharmaceutical systems can be found elsewhere.[42]

The influence of moisture on degradation kinetics is complex, and various models have been proposed. The Leeson–Mattocks[43] model hypothesized that a saturated solution layer exists around solid particles, which sheds some light on the importance of moisture. However, very limited successes have been achieved on the quantitative aspect of moisture effects. Genton and Kesselring[44] initially showed the following equation held for nitrazepam degradation in a solid state:

$$\ln k = \ln A + \frac{E_a}{RT + B} \cdot RH \tag{5.69}$$

Therefore, the Arrhenius relationship holds if RH is held constant. Furthermore, the logarithm of the rate constant changes linearly with relative humidity when temperature is held constant. This observation can be understood in the context that the relative humidity only affects molecular mobility in a reaction, but not the reaction pathways. Waterman et al. and Waterman and Adami[45,46] have confirmed this relationship with a number of additional pharmaceutical systems. However, it should be emphasized that this relationship is not universal, and there are many exceptions.

5.2.13 Topochemical reactions

A true solid-state reaction is a topochemical reaction. This type of reaction can be identified if the reaction does not occur in solution, is much slower in solution, or if the reaction products are different than those obtained in solution. True solid-state reactions depend highly on the molecular arrangements (conformations and configurations) or topologies in the solid-state. Therefore, the crystal structure of a solid phase determines its chemical reactivity. Different solid-state forms (polymorphs, solvates, salts, cocrystals) frequently exhibit different reactivity and demonstrate true solid-state reactions.[47]

The first reported example for a topological thermal reaction is the rearrangement of methyl *p*-dimethylaminobenzenesulfonate to the *p*-trimethylammoniumbenzenesulfonate zwitterion.[48,49] The molecules in monoclinic crystals are oriented almost ideally so as to facilitate reactions in the solid state. On the contrary, the reaction rate is much slower (25 times) in its melt than in the solid state. A pharmaceutical example is the deamidation of the asparagine residue of insulin[50]; in this case, the amorphous state is far more stable than the crystalline state. However, a clear interpretation has not been provided, although it is reasonable to believe that the greater reaction rate observed with crystalline insulin should be related to the crystal packing. There are other examples provided in the text by Byrn et al.[51] that different polymorphs lead to different reactivities; they provide other pharmaceutical examples of topochemical reactions.

5.3 COMMON PATHWAYS OF DRUG DEGRADATION

Despite the diversity of drug candidates, drug degradation follows some common pathways. By examining structural features of a drug molecule, possible degradation routes and products may be predicted to a certain extent, which may aid the design and execution of degradation studies.

Common mechanisms of drug degradation include thermolytic, oxidative, and photolytic. The term *thermolytic degradation* refers to those that are driven by heat or high temperature, which normally follows the Arrhenius relationship. Any degradation mechanism can be considered thermolytic if high temperature enhances the rate; in this case, *thermolytic* is being used loosely. Hydrolysis reactions form a subset of thermolytic degradation reactions and are the most common drug degradation pathways; they will be discussed separately. Other thermolytic degradation pathways include ester/amide formation, rearrangement, isomerization/epimerization, cyclization, decarboxylation, hydration/dehydration, dimerization/polymerization, etc. Oxidation of drugs can proceed with different mechanisms: autoxidation, electrophilic/nucleophilic, and electron transfer reactions. Oxidative degradation reactions do not usually follow the Arrhenius relationship due to their complex nature. Photolytic degradation can occur when a drug or drug product is exposed to light. Photolytic degradation is initiated by light absorption; therefore, temperature has a negligible effect. Photolytic degradation is not uncommon,

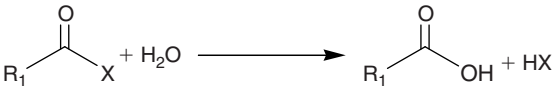
but it may be minimized during the manufacturing, shipping, and storing of drug products in appropriate packaging.

5.3.1 Hydrolysis

Hydrolysis is by far the most commonly encountered drug degradation mechanism, both in solution and in solid state. Many drug molecules contain functional groups derived from relatively weakly bonding groups such as carboxylic acids. Hydrolysis of such derivatives is expected both in solution and in solid state, in the presence of water. In particular, the presence of hydrogen or hydroxyl ions likely catalyzes hydrolytic reactions. In the presence of relevant functional groups, such as alcohols, amines, esters, etc., either as solvent or solvent residuals, or more commonly, as excipients or impurities, the carboxylic acid derivatives can undergo certain types of reactions, such as alcoholysis and transesterification (eg, aspirin-acetaminophen reaction[52]). These reactions follow similar mechanisms to hydrolysis, and will not be treated separately.

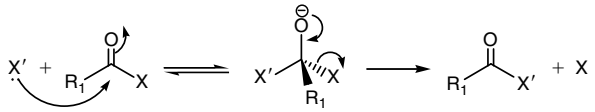
5.3.1.1 *Hydrolysis of carboxylic acid derivatives*

Functional groups derived from carboxylic acid are common in pharmaceuticals. Examples include anhydrides, acyl halides, esters, amides, imides, lactams, lactones, and thiol esters. Esters (including lactones) and amides (including lactams) are among the most commonly seen. Carboxylic acid derivatives are usually prepared by a condensation reaction wherein the carboxylic acid is reacted with the corresponding functional group (alcohol, amine, etc.) with the expulsion of a molecule of water. Since this type of reaction is reversible, the reverse reaction can occur in the presence of added water:



(5.70)

Here X = OCOR, Cl, OR, NR_2, and SR. Sulfonates, sulfonamides, and other sulfonic acid derivatives follow similar pathways. Due to the greater electronegativity of oxygen atoms, the carbonyl group is polarized such that the oxygen atom carries a partial negative charge while the carbon atom carries a partial positive charge. As a result, the carbonyl group can be attacked nucleophilically (by attacking the carbon, using a nucleophile such as OH^-). The hydrolysis of carboxylic acid derivative usually proceeds with a tetrahedral intermediate, as shown here:



(5.71)

In the presence of hydrogen ions, the carbonyl oxygen is protonated, which enhances attack of the carbonyl carbon by weaker nucleophiles such as water. This mechanism explains how the hydrolysis reaction can be catalyzed by either hydrogen or hydroxyl ions (specific acid-base catalysis), as well as by other nucleophiles (general acid-base catalysis).

Insights into the relative hydrolytic stability of carboxylic acid derivatives can be obtained in two aspects: nucleophilic attack of the carbonyl carbon and relative leaving ability of the X group. Hydrolysis will be faster if the nucleophilic attack by X′ is facilitated or if the leaving of X is facilitated, given that other conditions are similar. Electron-withdrawing groups in R_1 increase the electronegativity of the carbonyl group, thus promoting nucleophilic attack on the carbon; electron-withdrawing groups in X increase the basicity of X, stabilize X, and enhance the leaving ability of the X group. On the other hand, electron-donating groups will generally slow down hydrolysis. The effect of electron-withdrawing substituents on R_1 can be seen by comparing the relative hydrolysis rate of a series of substituted benzoate esters, while that of the leaving groups can be seen from the comparison of the hydrolysis rate of different carboxylic derivatives, such as anhydride, ester, amide, and other substances, which usually follows the following pattern: acyl halide > carboxylic anhydride > ester > amide. As a specific example, hydrolysis of phenol esters is much faster than that of corresponding alkyl esters because the phenol anion is a much better leaving group. Because of this, phenol esters are generally more difficult to prepare than the corresponding alkyl esters. More detailed discussion on this topic can be found in a standard organic chemistry textbook, such as Carey and Sundberg.[53]

5.3.1.2 *Hydrolysis of acetals and ketals*

Acetals and ketals are relatively uncommon in pharmaceuticals; however, they are present in some prodrugs. Acetals and ketals are formed by condensation reactions between alcohols and aldehydes and alcohols and ketones, respectively, by removing a water molecule. Due to the unfavorable equilibrium in aqueous solution, and the relative facility of the hydrolysis reaction, they convert back to aldehydes and ketones quickly, particularly in acid solutions:

$$R_2C(OR')_2 + H_2O \xrightarrow{H^+} R_2C{\cdot\cdot}O + 2R'OH \qquad (5.72)$$

The mechanisms of these reactions are the reverse of the formation of the acetals and ketals and are subject to specific acid catalysis, although general acid catalysis is observed in some cases.

5.3.1.3 Hydrolysis of other carbonyl derivatives

A few other types of carbonyl derivatives, such as imines, oximes, hydrazones, and semicarbazones, although not very commonly encountered in drug molecules, can undergo hydrolysis by reversal of the reactions leading to their formation:

$$R_2C{=}NR' + H_2O \rightarrow R_2C{=}O + R'NH_2 \quad (5.73)$$

$$R_2C{=}NOH + H_2O \rightarrow R_2C{=}O + HONH_2 \quad (5.74)$$

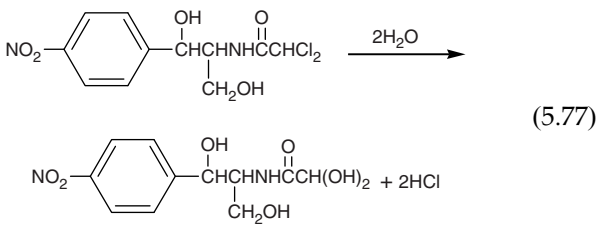
$$R_2C{=}NNHR' + H_2O \rightarrow R_2C{=}O + NH_2NHR' \quad (5.75)$$

$$R_2C{=}NNHC(=O)NH_2 + H_2O \rightarrow R_2C{=}O + NH_2NHC(=O)NH_2 \quad (5.76)$$

Hydrolysis of imines is the most facile of these reactions because the equilibrium constant of formation is unfavorable. On the other hand, oximes, hydrazones, and semicarbazones are usually more stable during hydrolysis because the equilibrium constants for formation are much higher, even in aqueous solution. These hydrolysis reactions are usually catalyzed by both general acids and general bases. Switching of rate-determining steps has also been observed for hydrolysis of imines at different pH values.

5.3.1.4 Miscellaneous hydrolysis reactions

In general, both alkyl halides and aromatic halides are stable to hydrolysis. However, in certain situations, usually when activated by strong electron-withdrawing groups, halides can undergo hydrolysis. An example is chloramphenicol[54]:



(5.77)

The two chlorine atoms are connected to the alpha carbon of the carbonyl, which makes the alpha carbon more nucleophilic, and thus susceptible to hydrolysis.

Ethers hydrolyze to the corresponding alcohols via acidic catalysis. Aryl ethers are particularly unstable under mild acidic conditions, due to the stability of the oxyaryl cation intermediate. Thioethers undergo hydrolysis in a manner similar to ethers. Both ethers and thioethers are relatively stable at neutral or basic pH.

Sulfonamides and sulfonylureas are susceptible to acid hydrolysis. Sulfonamides hydrolyze to the corresponding sulfonic acid and amine, while sulfonylurea decomposes to the amine, carbon dioxide, and sulfonamide. Carbamic esters hydrolyze to the corresponding carbamic acids, which in turn undergo decarboxylation, finally forming the amines. And thiols can hydrolyze to the corresponding alcohols under both acidic and basic conditions.

Epoxides and aziridines are three-member rings, and contain significant strain. Both are susceptible to ring opening reactions via nucleophilic attack by water or other nucleophiles.

5.3.2 Oxidative degradation

Oxidation presents an important drug degradation pathway, second only to hydrolysis. Although its significance to drug stability has been recognized, the study of oxidative stability has not been well developed until more recently, partially due to its complicated nature. This section will briefly discuss the various mechanistic and kinetic aspects of oxidation.

5.3.2.1 Mechanisms of oxidation

Under normal conditions, the reaction between molecular oxygen and an organic molecule, although thermodynamically favorable, proceeds at an insignificant rate. The slow oxidation rate is due to the electronic configuration of molecular oxygen. The valence electrons of the O_2 molecule can be represented, according to molecular orbital theory, as

$$(\sigma_{2s})^2(\sigma^*_{2s})^2(\sigma_{2p_z})^2(\pi_{2p_x})^2(\pi_{2p_y})^2(\pi^*_{2p_y})^1(\pi^*_{2p_z})^1 \quad (5.78)$$

Here, * designates an antibonding orbital. Ground-state molecular oxygen has two unpaired spin electrons in its $\pi^*_{2p_y}$ and $\pi^*_{2p_z}$ orbitals, and therefore it is in a triplet state. Most organic compounds, in contrast, are in a singlet ground state, with all spins paired. Direct reactions between singlet and triplet molecules violate the conservation law of spin angular momentum, and are not favorable. Therefore, for the direct reaction between oxygen and organic molecules to occur, one of the molecules needs to be excited to a state so that the spin states of both molecules match. Triplet ground state oxygen can be excited to the first excited singlet state (singlet oxygen) both chemically and photochemically. Oxidative reactions caused by singlet oxygen will be discussed briefly in the section on photolytic degradation pathways.

Oxidation of organic compounds occurs primarily via one of three mechanisms:

- Nucleophilic/electrophilic processes
- Electron transfer reactions
- Free radical processes (autoxidation)

Nucleophilic/electrophilic processes typically occur between peroxide and an organic reactant. For example, peroxide anion formed under basic conditions can attack drug molecules as a nucleophile. Under normal conditions, a drug will more likely be subject to electrophilic attack by unionized peroxide. Nucleophilic and electrophilic reactions typically follow Arrhenius behavior, and are accelerated at higher temperatures. However, when peroxides are heated, radical processes can be triggered, so non-Arrhenius behavior may be observed above a certain threshold.

In an electron-transfer process, an electron is transferred from a low electron affinity donor to an oxidizing species, which may be catalyzed by transition metals. Single-electron transfer reactions may exhibit Arrhenius behavior when the bond dissociation energy (BDE) of the acceptor molecule is low, but breaking CH bonds requires so much energy that single-electron transfer reactions typically exhibit non-Arrhenius behavior.

The autoxidation process involves the initiation of free radicals, which propagate through reaction with oxygen and drug molecule to form oxidation products. Because of the complexity of the reaction mechanism, non-Arrhenius behavior may be observed. The three stages of autoxidation can be represented as follows:

Initiation:

$$\mathrm{In{-}In} \rightarrow 2\mathrm{In}\bullet \tag{5.79}$$

$$\mathrm{In}\bullet + \mathrm{RH} \rightarrow \mathrm{In{-}H} + \mathrm{R}\bullet \tag{5.80}$$

Propagation:

$$\mathrm{R}\bullet + \mathrm{O_2} \rightarrow \mathrm{ROO}\bullet \tag{5.81}$$

$$\mathrm{ROO}\bullet + \mathrm{RH} \rightarrow \mathrm{ROOH} + \mathrm{R}\bullet \tag{5.82}$$

Termination:

$$\mathrm{R}\bullet + \mathrm{R}\bullet \rightarrow \mathrm{R{-}R} \tag{5.83}$$

$$\mathrm{R}\bullet + \mathrm{ROO}\bullet \rightarrow \mathrm{ROOR} \tag{5.84}$$

$$\mathrm{RO}\bullet + \mathrm{HO}\bullet \rightarrow \mathrm{ROOH} \tag{5.85}$$

In the initiation stage, a pair of free radicals is generated. A variety of processes can generate free radical pairs by cleaving a chemical bond homolytically under the influence of heat or light. Several categories of organic compounds can be used to generate free radicals readily, such as azo compounds, acyl peroxides, alkyl peroxides, and hydrogen peroxide, some of which have been routinely used as free radical initiators in polymerization. For example, the initiation of radicals can be achieved using 2,2′- azobis (*N*,*N*′-dimethyleneisobutyramidine)dihydrochloride (AIBN):

$$(\mathrm{CH_3})_3\mathrm{C{-}N{=}N{-}C}(\mathrm{CH_3})_3 \rightarrow 2(\mathrm{CH_3})_3\mathrm{C}\bullet + \mathrm{N_2} \tag{5.86}$$

The facile dissociation of azo compounds is not caused by the presence of a weak bond, as is the case with peroxides. Instead, the driving force for azo homolysis is the formation of the highly stable nitrogen molecule.

The two steps at the propagation stage are distinct. The first step, the reaction between the drug free radical with oxygen, is fast (on the order of $10^9\ \mathrm{M^{-1}s^{-1}}$ at 300°K).[55] The second step, in which a hydroperoxide is formed and a drug free radical is regenerated, is 8−9 orders of magnitude slower, and it is the rate-determining step. Therefore, the rate of autoxidation is generally unaffected by the oxygen concentration unless the concentration of oxygen becomes significantly low.

The kinetics of autoxidation is complicated due to the multiple steps involved in the process. The reaction order with respect to substrate concentration varies in the range of 0−1. The most noticeable feature of autoxidation kinetics is the lag time, which corresponds to a stage of gradual build up of free radicals.

Besides catalyzing electron transfer processes, transition metals can also react with organic compounds or hydroperoxides to form free radicals:

$$\mathrm{M^{(n+1)+}} + \mathrm{RH} \rightarrow \mathrm{M^{n+}} + \mathrm{R}\bullet + \mathrm{H^+}) \tag{5.87}$$

$$\mathrm{M^{n+}} + \mathrm{ROOH} \rightarrow \mathrm{M^{(n+1)+}} + \mathrm{RO}\bullet + \mathrm{HO^-} \tag{5.88}$$

$$\mathrm{M^{(n+1)+}} + \mathrm{ROOH} \rightarrow \mathrm{M^{n+}} + \mathrm{ROO}\bullet + \mathrm{H^+} \tag{5.89}$$

Typically, multiple mechanisms may occur simultaneously in an oxidative reaction, which introduces further complications.

Stabilization strategies can be developed based on the mechanisms of oxidative degradation for a particular compound.[56,57]

5.3.2.2 *Prediction of oxidative stability*

Oxidative stability of pharmaceuticals can be predicted to a certain extent by theoretical computations.[58] The susceptibility of an organic molecule to nucleophilic/electrophilic and electron transfer oxidative processes can be predicted using frontal molecular orbital (FMO) calculations. According to FMO theory, the site of reaction will occur between the lowest unoccupied molecular orbital (LUMO) of the electrophile and

highest occupied molecular orbital (HOMO) of the nucleophile. Under normal conditions, the nucleophile is usually the organic compound. Therefore, properties of the HOMO of the organic reactant determine its propensity to be oxidized. Computing the HOMO of a reactant could thus yield useful information regarding the most susceptible sites for oxidation by nucleophilic/electrophilic and electron transfer processes.

For oxidative degradation via the free radical process, hydrogen abstraction is usually the rate-determining step for propagation. Therefore, stability of the corresponding free radicals should correlate with their susceptibility to autoxidation. Hence, a BDE calculation could provide insight into sites of potential autoxidation.

5.3.2.3 *Functional groups susceptible to oxidation*

Amines are known to be prone to oxidation. Primary and secondary amines oxidize to hydroxylamines, which can dehydrate to imines or, after further oxidation, to oximes. Oxidation of aryl amines usually produces aryl hydroxylamines, which further oxidize to aryl nitroso compounds. Tertiary amines undergo oxidation, producing *N*-oxides, which are usually the final degradants. Protonation of the amine reduces its propensity to oxidation. However, protonation may not effectively protect against oxidation during long-term storage.

Nitriles are susceptible to oxidation by peroxides under slightly alkaline conditions. Acetonitrile is oxidized to unstable (and oxidizing) peroxycarboximidic acid; this has been known to enhance the susceptibility of organic compounds to oxidation by peroxide when acetonitrile is used as a cosolvent.[59]

Primarily, alcohols can be oxidized to the corresponding aldehydes, and then further to carboxylic acids. Phenols and other aryl hydroxyls are particularly susceptible to oxidation because conjugation in the aryl systems enhances the electron density on the oxygen atoms.

Pyrroles can be oxidized by peroxide to form pyrrolinones. Compounds containing unsaturated double bonds form epoxides by oxidation.

Thiol and thioethers are other examples of readily oxidizable organic functional groups. Thiols can oxidize to disulfide, sulfenic acid, sulfinic acid, and sulfonic acids under a variety of conditions, such as nucleophilic processes (peroxide), autoxidation, and electron-transfer reactions. Due to the affinity of thiols with transition metals, most thiols get oxidized via the metal-catalyzed electron-transfer process. Thioethers undergo oxidation to sulfoxides, and finally to sulfones, a process that also may be catalyzed by transition metals.

A methylene (−CH_2−) or methyne (−CH−group is activated when the corresponding free radical formed by H-abstraction is stabilized by a neighboring group, such as carbonyl, carbon−carbon double bond, aromatic ring, or a heteroatom such as O, N, or S. The activated methylene or methyne group is a potential site of autoxidation, due to the stability of the free radical formed. These sites can be predicted using BDE calculation. Examples include phenylbutazone and benzyl alcohols.

5.3.3 Photochemical degradation

5.3.3.1 *Light*

Light is a form of electromagnetic radiation, the energy of which is given by

$$E = h\nu = \frac{hc}{\lambda} \tag{5.90}$$

Here, h is Plank's constant, c is the speed of light (3×10^8 m/s), ν is the frequency, and λ is the wavelength. Hence, red light (700−800 nm) corresponds to an energy of 30−40 kcal/mol, while far UV light (about 200 nm) corresponds to an energy of 140 kcal/mol. For comparison, the weakest single bonds commonly encountered in organic molecules have a strength of about 35 kcal/mol (such as an O−O bond), and the strongest single bonds have strengths of about 100 kcal/mol (eg, a C−H bond). This simple comparison demonstrates that the energy of light is adequate to potentially lead to degradation of drug molecules if it is absorbed.

No photochemical reaction can occur unless light is absorbed (the Grotthuss−Draper law). The relevant radiation bands that are most likely to be problematic to pharmaceuticals are visible light (λ of about 400−800 nm), and UV light (λ of about 200−400 nm). Sunlight in the wavelength range of 200−290 nm is effectively absorbed by molecular oxygen and ozone in the upper atmosphere, and therefore it is not considered to be important for photolytic degradation of drugs, although many organic substances do absorb strongly in this wavelength range.

5.3.3.2 *Light absorption, excitation, and photochemical reactions*

Accompanying the absorption of UV-visible light by a molecule is a change in its electronic configuration to an excited state. The electrons in the outermost shells of a molecule are the most susceptible ones because these electrons are the least strongly bound to the molecule. From the point of view of FMO theory, electrons in the HOMO will be excited by the absorption of light energy into its LUMO, where they possess higher

potential energy that could cause photochemical degradation of the molecule.

Spin state is a characteristic feature for electron excitation, and it plays an important role in photochemical reactions. Most organic molecules have a ground-state HOMO with paired electrons and are therefore in a singlet state (denoted as S_0, where the subscript 0 refers to the ground state). When one electron is excited from the HOMO to LUMO, its spin can be maintained (first excited singlet state, S_1) or flipped (first excited triplet state, T_1).

The excited electron can drop back to the ground state by giving up one photon; this is called a *photophysical radiative process.* The allowed singlet−singlet ($S_1 \rightarrow S_0$) emission is called *fluorescence,* while the forbidden triplet−singlet ($T_1 \rightarrow S_0$) emission is called *phosphorescence.*

The excited electron can also drop back to the ground electronic state without emitting a photon by photophysical radiationless processes. In most cases, the excited electron falls back to the ground electronic state by releasing heat, which may result from collisions between excited molecules and other molecules (eg, solvent molecules) in their environment. Transitions between states of the same spin (eg, $S_1 \rightarrow S_0 + \text{heat}$) are allowed, and this process is called *internal conversion*; transitions between states of different spins, such as $T_1 \rightarrow S_1 + \text{heat}$ or $T_1 \rightarrow S_0 + \text{heat}$, are forbidden and are called *intersystem crossing.* The energy state diagram shown in Fig. 5.11 describes these photophysical processes.

Not all atoms of a compound absorb UV-visible light, due to the mismatch of the energy of photon and the energetic gap between the ground and excited electronic states. A *chromophore* is defined as an atom or group of atoms that act as a unit in light absorption.

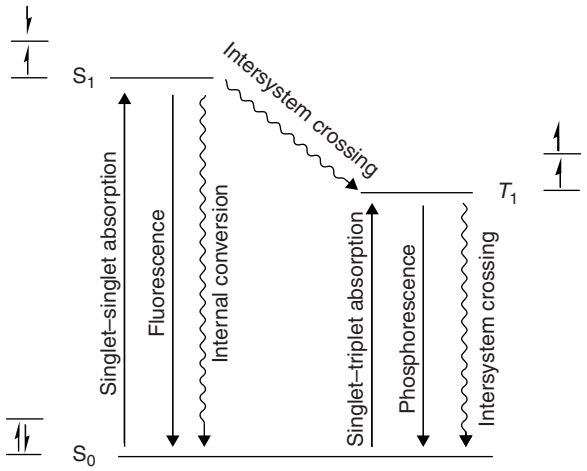


FIGURE 5.11 Schematic energy state diagram for light absorption.

Typical chromophores for organic substances include C:C, C:C, and aromatic groups.

Electronic excitation for C:C bonds involves $\pi \rightarrow \pi^*$ transitions between its electronic orbitals, while for C:C, $n \rightarrow \pi^*$ transitions are involved. Since the electronic occupancy of the excited state is different from that of the ground state, their properties are also different. For example, ethylene is planar in the ground state, while the excited state is twisted. Other properties, such as dipole moments and acid/base dissociation constants, are also changed in the excited state.

Molecules in excited states may undergo chemical reaction with themselves, due to their elevated energy state. The excited molecules may also jump back to ground state via photophysical radiationless routes. The electronic energy is converted to vibrational energy of the molecule in this case, which might be adequate to overcome the activation barrier in the ground state to bond dissociation and trigger chemical degradation.

From the photochemical point of view, most photodegradation reactions observed for pharmaceuticals tend to involve intermediates, and are not concerted in nature. The electronically excited state generated by stretching a σ-bond or twisting a π-bond can result in a diradicaloid structure, where the two half-filled orbitals are nearly degenerate. The interaction of these two degenerated orbitals can then lead to the diradical singlet state, diradical triplet state, and two zwitterionic states (where one degenerated orbital is completely filled while the other is empty). The singlet π, π^* excited state, $S_1(\pi, \pi^*)$, has a significant zwitterionic nature and is expected to form a reactive intermediate via proton or electron transfer reactions, nucleophilic or electrophilic additions, or rearrangement. The triplet $T_1(\pi, \pi^*)$ state, on the other hand, is expected to generate diradical intermediates and undergo primary photoreactions characteristic of radicals (eg, H-abstraction, addition to unsaturated bonds, radicaloid rearrangements, and hemolytic fragmentations). Both $S_1(n, \pi^*)$ and $T_1(n, \pi^*)$ are diradical in nature, and lead to qualitatively similar photochemical products. More detailed discussion of this topic can be found in Turro.[60] Examples of photochemical degradation of drugs can be found in Tønnesen.[61]

5.3.3.3 Photooxidation

Oxidation has frequently been observed in photochemical degradation reactions. Photooxidation can occur when excited triplet state molecules react directly with molecular oxygen because an excited triplet state matches the ground spin state of molecular oxygen. In addition, another process appears to be important in which singlet oxygen is involved, called *photosensitized oxidation.* Photosensitization is a process

whereby an initially light absorbing species (the donor) transfers energy to and excites a second species (the acceptor), provided that the acceptor has a low-lying triplet state. The donor could be a different species (such as a dye molecule), but could also be the drug molecule itself. The acceptor is also called a *quencher* because it quenches the excited state of the donor. Photosensitization allows a nonabsorbing acceptor species to be excited in the presence of a light-absorbing donor molecule.

Two types of photooxidation exist. In Type I photooxidation, the donor transfers an electron or a proton to the acceptor (usually the drug), forming an anion or neutral radical, which rapidly reacts with molecular oxygen. A Type I process is also called an electron transfer or free radical process.

Type II photooxidation involves singlet oxygen. The first excited state of molecular oxygen, $^1\Delta$, lies 22.5 kJ/mol (1270 nm) above its ground state ($^3\Sigma$), which is of much lower energy than the triplet states of most organic molecules. Ground-state molecular oxygen is generally an efficient quencher of the S_1 and T_1 states of organic molecules. The photosensitized singlet oxygen matches the spin states of a majority of organic molecules, which enhances their direct oxidation. Singlet oxygen can be generated using strongly light-absorbing dyes (eg, Rose Bengal, methylene blue) via a photosensitization process.

5.3.4 Other degradation pathways

Hydration (ie, the addition of a molecule of water) can occur at a double bond, which is well known in the case of fumaric acid. Racemization of chiral centers can occur via the formation of a planar intermediate, usually a cation, but a radical or anion intermediate can be involved as well. Decarboxylation often occurs thermally for a β-keto carboxylic acid (eg, norfloxacin[62]).

Amines are common functional groups in APIs, and they are reactive in a variety of ways besides oxidation. Primary and secondary amines can react with counterions in a salt (eg, maleic acid,[63] tartaric acid) or acids/acid derivatives in excipients (eg, stearic acid or magnesium stearate[64]) to form the corresponding amides. Amines react readily with aldehydes (such as formaldehyde, which may present at low levels as a degradation product or impurity in excipients such as polyethylene oxide, polyethylene glycol (PEG), poloxamer, and carbohydrates) to form hemiaminals. The complex series of reactions between a primary or secondary amine and a reducing sugar causes color changes, and is known as the *Maillard browning reaction.*

Other types of degradation reactions have also been observed, such as isomerization (fumaric acid ↔ maleic acid), rearrangements (cephalosporin), dimerization and polymerization (eg, ampicillin and other ß-lactam antibiotics[65]), cyclization (eg, aspartame,[66] moexipril[67]), and deamidation (eg, asparagines residues in peptides and proteins).

5.4 EXPERIMENTAL APPROACHES TO STUDYING THE CHEMICAL DEGRADATION OF DRUGS

Drug degradation studies are a required component of stability testing conducted to support registration of new drug substances and drug products.[68] However, the design and execution of accelerated stability testing methods, while well established in many industries,[69] is still evolving within the pharmaceutical industry. In this section, we survey the current best practices.

5.4.1 Solution thermal degradation studies

In conducting an accelerated thermal degradation study, the investigator typically exposes samples containing the test substance of interest to elevated temperature storage, and then measures the concentration or potency of the test substance remaining after various times. In the past, some methods for the interpretation of data obtained from such studies have focused primarily on the estimation and prediction of reaction rates; however, most users intend to employ these predicted rates to estimate concentrations or potencies at future times at temperatures not tested or to estimate the time until which the concentration or potency will remain within specified limits with a specified probability (shelf life prediction). Although methods that yield estimated rates may be used to obtain point estimates of concentrations, they are incapable of providing useful confidence interval estimates, so this review will focus on methods of obtaining and modeling accelerated degradation experimental data that yield concentration or shelf life estimates directly. Such methods require nonlinear modeling. Because modeling by nonlinear regression is more of an art than a science, previous experience in fitting nonlinear models is helpful.

Chemical kineticists have employed the Arrhenius model for years as a means to determine the energy of activation of a chemical reaction from the temperature dependence of the rate of reaction. Aside from a few studies on biologically derived pharmaceutical preparations,[70] only since the late 1940s did technologists[71–77] in the food and pharmaceutical industries

begin to use the Arrhenius model to study degradation processes. In the mid-1950s, after introductory studies by Garrett, the use of the Arrhenius model to predict the shelf life of a pharmaceutical product at a lower temperature (eg, room temperature) from the kinetics of its degradation studied at higher temperatures became common.[78–86] Prediction of shelf life became a primary focus of thermal stress degradation studies in both the pharmaceutical industry and the food industry, and, over the years, a number of investigators have sought to improve the statistical techniques used to treat the data so as to obtain better estimates of the precision with which shelf life could be predicted. In addition to the use of thermal stress degradation studies to predict shelf life, the time required to determine a reaction rate with a given precision can be reduced by determining the rate at an elevated temperature, where degradation occurs more quickly[87]; thus, Arrhenius models have attracted the interest of chemical engineers and physical chemists.

Early workers in the field of chemical kinetics relied upon graphical methods and simple numerical analysis techniques (such as point-by-point integration) to obtain estimates of the rates of chemical reactions and the effect of changing reaction temperature on these rates. Graphical techniques are important to visualize the data and to form initial judgments as to the overall quality of the data and relevance of the kinetic model; however, they are at best a crude way to obtain kinetic parameters, and are subject to bias on the part of the graphic artist in obtaining the best representation of the data. In addition, graphical methods offer no way to estimate the precision of fitted parameters. Numerical methods based upon point-by-point integration introduce an insidious form of serially correlated error into the final results, as each observation (except the first and last) is used twice. Typical kinetic experiments were run at only a few temperatures, one of which was usually close to ambient. Extraordinary measures to control temperature, and to select very precise analytical methods, are required to employ these methods effectively; in particular, measurement of the energy of activation of a reaction from determination of the rate at only two temperatures about 10°C apart requires temperature control of ± 0.03°C and analytical precision of $\pm 0.1\%$ to obtain an error of $\pm 0.5\%$ in the energy of activation. These methods have been described in detail.[88]

The application of statistical methods, based on modeling by regression analysis to the evaluation of data obtained from accelerated chemical degradation studies in solution, was first applied to a study of the decomposition of a nitrogen-containing compound in 1954 by McBride and Villars.[78] These workers used a two-stage graphical approach, first estimating the rate constants at different temperatures and then plotting the logarithms of the estimated rate constants versus reciprocal absolute temperature in a second step to obtain estimates of the Arrhenius model parameters. Garrett popularized this approach in the pharmaceutical industry in several studies.[77,79,83,84] The use of estimated reaction rates as if they were data reduces the large number of degrees of freedom inherent in the actual data to just a few degrees of freedom in the final model, enormously exaggerating the uncertainty with which interval predictions can be made outside of the time and temperature region studied. Since making such interval predictions is, perhaps, the most important purpose of conducting thermal stress degradation studies, the two-stage modeling approach is wholly unsatisfactory.[89]

Garrett and his followers usually made measurements at linearly spaced time intervals (eg, daily) for a fixed duration (eg, a month or two); measurements at the higher temperatures were terminated when the amount of drug remaining became too low to measure accurately. Most workers also made the same number of measurements at each temperature for each sampling time. This type of design can be called a "Garrett" design. It is not efficient.

Later, Tootill showed that a more efficient design consisted of obtaining measurements at roughly the same extent of decomposition.[90] He was probably the first author to devise a method to use potency remaining at each time and temperature to directly fit an Arrhenius model to kinetic data; however, he did so by imposing strict design constraints. Tootill's 1961 design was actually an extension of the earlier design work of Box and Lucas,[91] who showed that the most efficient design (when percent potency remaining could be measured, the reaction was known to be first order, and the Arrhenius model was known to be correct), was to measure the potency at such a time that 36.8% (100%/e) of the substance remained at both the highest and lowest temperatures that could be studied; this design has properties that statisticians call d-optimal. Davies and coworkers[92,93] showed that the most efficient measurements for the estimation of reaction rates were only obtained after allowing the decomposition reaction to proceed for 1–2 half-lives (50–75% decomposition), in agreement with the finding of Box and Lucas. This recommendation was based solely upon the statistical properties of the data, and ignored potential complications arising from changes in the major reaction pathway caused by the accumulation of degradation products as the reaction proceeds. Thus, Davies and Hudson[93] also recommended designs for which degradation was to be monitored until the same extent of degradation had occurred at each temperature, as previously recommended by Tootill,[90] and by Box and Lucas.[91] Subsequently, such designs will be referred to as "Box-Tootill-Davies" designs. These isoconversional designs are efficient.

Since rates are seldom measured directly, the Arrhenius model can be further integrated to yield, for pseudo-zero-order reactions:

$$P_{hij} = P_0 - t_{ij} A e^{-\frac{E_a}{RT_j}} + e_{hij} \tag{5.91}$$

For pseudo-first-order reactions:

$$P_{hij} = P_0 e^{-t_{ij} A e^{-\frac{E_a}{RT_j}}} + e_{hij} \tag{5.92}$$

Here, P_{hij} is the hth measured potency at time t_{ij} and temperature T_j, P_0 is the estimated initial potency at time $t = 0$, and e_{hij} is the error in measuring P_{hij}. Carstensen and Su introduced this technique in the pharmaceutical field as a method for directly fitting an Arrhenius model to potency data.[94] Nonlinear direct fitting of an Arrhenius model to concentration or potency data was further advanced by the work of Davies and Budgett,[92] who specifically addressed proper weighting of the data. Davies and Hudson later proposed standard methods for the statistical analysis of potency data obtained in the course of degradation studies based on this error analysis.[93] These authors reparameterized the Arrhenius models to explicitly account for the fact that it is the logarithm of estimated rate constants that is approximately normally distributed. Thus, for a pseudo-zero-order reaction:

$$P_{hij} = P_0 - t_{ij} e^{\ln(A) - \frac{E_a}{RT_j}} + e_{hij} \tag{5.93}$$

For a pseudo-first-order reaction:

$$P_{hij} = P_0 e^{-t_{ij} e^{\ln(A) - \frac{E_a}{RT_j}}} + e_{hij} \tag{5.94}$$

Instead of using the logarithm of the rate expected in the limit as the absolute temperature increases to infinity (the Arrhenius frequency factor A), the rate at any other temperature T can be used instead. Thus, one can substitute the following:

$$\ln(A) = \ln(k_{est}) + \frac{E_a}{RT_{est}} \tag{5.95}$$

Furthermore, the rate at any particular temperature is inversely proportional to the time required to achieve a particular fractional degradation f. Thus, for a pseudo-zero-order reaction:

$$k_{T_{est}} = \frac{P_{t=0}(1-f)}{t_{100\ f\%,T_{est}}} \tag{5.96}$$

And for a pseudo-first-order reaction:

$$k_{T_{est}} = \frac{-\ln(f)}{t_{100\ f\%,T_{est}}} \tag{5.97}$$

King et al.[95] independently recommended reparameterization with this additional substitution to estimate shelf life directly. Thus, for a pseudo-zero-order reaction, the Arrhenius model becomes

$$P_{hij} = P_0 - (1-f) P_0 t_{ij} e^{\frac{E_a}{R}\left(\frac{1}{T_{est}} - \frac{1}{T_j}\right) - \ln\left(t_{100\ f\%,T_{est}}\right)} + e_{hij} \tag{5.98}$$

And for a pseudo-first-order reaction, it becomes

$$P_{hij} = P_0 e^{t_{ij}\ \ln(f) e^{\frac{E_a}{R}\left(\frac{1}{T_{est}} - \frac{1}{T_j}\right) - \ln\left(t_{100\ f\%,T_{est}}\right)}} + e_{hij} \tag{5.99}$$

Here, f is the fraction of undegraded drug remaining at time $t_{100f\%}$ at temperature T_{est}.

Simulation studies using a realistic assumed distribution of experimental errors in conjunction with a Box-Tootill-Davies design with $f_{min} = 0.8$ (corresponding to 20% degradation) give remarkably precise estimates of the logarithm of the projected shelf life when either of the abovementioned model equations are used. However, such a design is impractical to execute, since one might need to follow degradation at the lowest temperature included in the accelerated design for a period of time longer than needed to execute a real-time stability study at the temperature of interest T_{est}. Despite this shortcoming, abbreviated studies, in which degradation is not allowed to proceed as far at the lower temperatures, can still give useful results, especially if one's interest is only in projecting whether the projected shelf life at T_{est} is greater than some required minimum (eg, 2 years at $T_{est} = 25°C$).

It is convenient to design accelerated thermal degradation studies so that the temperatures used are selected from a series of equally spaced values on the reciprocal absolute temperature scale (eg, 5°C, 15°C, 25°C, 37°C, 48°C, 61°C, 75°C, 90°C) at temperatures above the final temperature of interest T_{est}. Thus, to project the shelf life at 25°C, one might choose to use the three highest temperatures (eg, 61°C, 75°C, 90°C). If we are only interested in determining whether a drug substance will be stable in solution for 2 years at 25°C, then even this much work is unnecessary. Assuming any reasonable range of expected activation energies, testing at only the two highest temperatures should provide an answer to this question. Of course, the further removed the actual temperatures selected are from the temperature of interest, the larger the error in prediction of the extrapolated value for the logarithm of the shelf life. Nevertheless, reasonable precision is still obtainable using this approach.

It is feasible to design experiments that can be completed in a short period of time (weeks) to determine if the shelf life will be sufficiently long to permit

commercial development of a solution dosage form with storage at either controlled room temperature or under refrigerated storage conditions. All that is needed to design an appropriate experiment is knowledge of the precision achievable by the analytical method that will be used to determine the fraction f remaining undegraded, the allowable extent of degradation f, and the desired storage temperature T_{est}. The design can be validated by simulation prior to execution, and the simulated results can be used to confirm that an adequate number of samples are taken at each temperature. Since most real degradation reactions are pseudo-first-order, sampling times at each temperature should increase exponentially (eg, 0, 1, 2, 4, 7, 14, 28, ... days) so that the change in the fraction remaining will be approximately constant between sampling times. Sufficient samples should be obtained at each temperature to estimate rate constants with equal precision. If one was confident of the order of the reaction, and anticipated degradation rates at each temperature, then the most efficient design would eliminate all intermediate time points, and simply measure the fraction present initially and after some fixed interval storage at each elevated temperature, reducing the analytical workload even further. However, thermal stress degradation studies are usually performed early in the development process, when little is known about the overall stability of the drug substance, so prudent experimenters will want to include samples at intermediate time points to ensure that sufficient usable data is obtained. A pilot experiment, with single samples taken at four temperatures selected from this list on days 0, 1, 2, 4, and 7 (20 samples altogether), will often provide enough information to determine whether additional work is needed. Poorly stable materials can be rejected out of hand, and materials showing no degradation at even the highest temperature require no further study, since no practically achievable activation energy would be consistent with long-term instability if the Arrhenius model holds, and no degradation can be detected after a week of storage at more than 60°C above the intended real-time storage conditions.

Waterman et al. recently extended this concept even further, to incorporate the effects of humidity (Eq. 5.69).[45] These workers have demonstrated that, provided one can design experiments such that the same extent of decomposition is achieved under each of the conditions of temperature and humidity studied (so-called isoconversional conditions), one can estimate both the Arrhenius model parameters and the effect of humidity on the kinetics of decomposition of a drug, either as the API itself or as a component of a formulation, using a small number of measurements with good accuracy. This approach is especially useful for studying solid-state degradation, as isoconversional methods are independent of mechanism.

5.4.2 Solid-state thermal degradation studies

The design of solid-state degradation studies is complicated by the fact that many solid-state degradation reactions do not follow Arrhenius kinetics outside a restricted range. Phase changes (glass transitions, crystalline melting, solvation/desolvation) are expected to radically alter degradation pathways. One must have a thorough understanding of the thermal behavior of the material to be studied prior to undertaking the design of a thermal stress degradation study of a solid material. In most cases, the objective of thermal stress studies on solids is to determine whether moisture will induce hydrolytic degradation. That being the case, the simplest approach is to just add water, stir, and heat.

Isothermal microcalorimetry can be used to study the potential reactivity of solids to water, either alone or in combination with excipients, in relatively short periods of time (days to weeks). Typically, a mixture of the solids and 20% by weight added water is heated to 50−60°C and monitored for thermal reactivity. Hydrolysis reactions are characteristically exothermic and result in the generation of detectable heat signals within the first few days, even for slowly reacting substances. It is prudent to confirm degradation by chemical analysis of any mixture (eg, by high-performance liquid chromatography or liquid chromatography−mass spectrometry) that exhibits the generation of heat. Isothermal microcalorimetry is a completely nonspecific technique that can be used to detect and monitor even the most complex reactions, such as the Maillard reaction between a primary or secondary amine drug and a reducing sugar such as glucose or lactose. This approach is most useful for establishing relative chemical reactivity, such as comparing different potential drug candidates as part of candidate lead selection or for selecting potential excipients to be used in formulation.

A less drastic measure is to store samples of solid materials under conditions of high humidity. Saturated solutions of NaCl maintain essentially 75% relative humidity over a wide range of temperatures, so it is possible to store samples in humidistats (sealed vessels containing a small amount of a saturated solution of NaCl in water) in ovens at different temperatures (eg, 40°C, 60°C, 80°C), provided that no phase changes (such as melting, formation of hydrates, etc.) occur when the samples are heated. Dynamic moisture sorption gravimetric analysis and thermal gravimetric analysis can be used to confirm the absence of hydrate formation at the selected temperatures. Prudent experimenters, not having sufficient test material to perform a thorough characterization of its thermal properties, will opt to begin studies at a lower temperature (eg, 40°C), and progress to studies at higher temperatures

only if it is justifiable to do so when more material becomes available. The very first activity that should be undertaken in the characterization of any new drug substance is to set up a thermal stress degradation experiment for the solid drug substance. This should be started before any other work is undertaken and takes only a few milligrams of material. Samples can be removed from thermal stress conditions at programed times, and stored at low temperature until an analytical method can be developed, assuming larger quantities of material can be obtained later. Often, visual inspection will reveal stability problems, such as color changes and deliquescence, that may dictate storage requirements for the substance being studied. The approach of Waterman and coworkers follows this strategy.[45]

5.4.3 Oxidative degradation studies

Oxidative degradation of drugs is usually caused by impurities (such as peroxide, transition metals, and free radicals) present in the final products. Levels of these impurities are low, variable, and often difficult to control. Hence, oxidation screens are normally conducted in the presence of higher levels of oxidants, catalysts, and other probing reactants. Oxidative testing under these conditions is only prognostic, but not definitive in nature, and quantitative extrapolation to normal storage conditions is challenging and, in most cases, should be avoided. Hydroperoxides, the primary oxidative reagents, may further degrade at elevated temperatures. Therefore, most oxidative tests are carried out at relatively mild temperatures (eg, ambient to 40°C).

As outlined in the section on oxidative degradation, three primary oxidative mechanisms exist: free radical autoxidation, nucleophilic/electrophilic processes, and electron transfer processes. A practical oxidative testing strategy should aim to pinpoint the intrinsic oxidative stability, and the possible oxidative mechanisms. Understanding of oxidative mechanisms allows for stabilization strategies to be developed. Identification of the primary/secondary oxidative degradants also aids in the elucidation of the degradation pathways.

A free radical initiator is frequently used to probe susceptibility of a compound to autoxidation. As mentioned previously, AIBN is a commonly used imitator for this purpose. Its homolytic decomposition half-life in toluene is 10 hours at 65°C, and does not change significantly in different solvents. Tests can be made with molar ratios between AIBN and drug molecule ranging from 0.2 to 1.0. Experiments are often done at 40°C in order to preserve the primary degradants. However, AIBN is not water-soluble. Organic cosolvents, such as acetonitrile and lower alcohols, are necessary for most drug candidates with limited aqueous solubility. Each cosolvent may produce side reactions and has its pros and cons. Water-soluble free radical initiators are available, which have slightly different decomposition kinetics. Examples include 4,4′-azobis(4-cyanopentanoic acid) (ACVA), and 2,2′-azobis(2-amidinopropane) dihydrochloride (AAPH). Antioxidants known to act as free radical trapping agents can also be used to demonstrate radical oxidation in the absence of an added initiator by suppressing oxidation triggered by environmental stress.

Hydrogen peroxide, typically in the concentration range of 0.3−30%, is used to probe the electrophilic/nucleophilic oxidative stability of organic compounds at ambient temperature. Amines, thiols, thioethers, pyrroles, and indoles are functional groups that can be readily oxidized by peroxides. Baertschi[96] stated that, in his experience, a compound is particularly sensitive and could require special efforts for development if a 0.3% solution of hydrogen peroxide induces >20% degradation in 24 hours at room temperature. Alternatively, <5% degradation in 24 hours indicates a relatively stable compound that will likely not present significant challenges to development. Peroxides are present as impurities in many excipients, and some antioxidants are known to be particularly effective as suppressors of peroxide-mediate oxidation. Addition of such antioxidants can help to confirm that peroxide mediated oxidation is responsible for observed degradation.

Many so-called autoxidative degradations may actually be caused by catalysis due to heavy metals, which usually present at very low levels. This is particularly believed for thiols and thioethers, due to their strong interactions with transition metals. In addition, metal ions may react with peroxides, forming reactive hydroxyl radicals. Although levels of heavy metals are low in modern drug substances, their levels may be significant at the early stages. In addition, sensitivity toward metal catalyzed oxidation may be high for certain compounds. Therefore, a transition metal catalysis test still provides valuable information. Compounds that are highly sensitive to these tests may require special processing precautions to avoid metal contamination. Fe^{3+} and Cu^{2+} can be incorporated routinely in oxidative screening at ambient conditions. Chelating agents, such as EDTA, are particularly effective as suppressors of metal-ion catalyzed oxidation. If the addition of chelating agents reduces or prevents oxidative degradation in otherwise untreated samples, metal-ion catalysis due to low levels of contaminating metals is likely to be responsible for the degradation observed.

As an alternative, Tween 80 (or another excipient containing polyoxyethylene moieties), in combination with Fe^{3+} or other transition metals (eg, Mn^{3+}), can be

used to screen the overall oxidative stability of a compound.[96,97] Excipients containing polyoxyethylene moieties, such as Tweens and PEGs, always have low levels of peroxide contaminants. These peroxides react with Fe^{3+}, and produce peroxy radicals that cause the escalation of free radical levels and further oxidation of the excipients. Therefore, the oxidative reaction mechanism in this system could be a combination of all three mechanisms.[97] The Tween test may well be suitable as a first-line oxidative screen. Compounds resisting oxidation in this test could be considered as stable with respect to all three mechanisms of oxidation. For compounds that are susceptible to the Tween test, a further mechanism screen should be carried out using the individual tests.

Susceptibility to singlet oxygen can be tested as a supplement to these oxidative screens, but it is usually not a routine test. A dye (eg, Rose Bengal) can be selected to generate singlet oxygen under light exposure. However, appropriate controls should be applied because many organic compounds are themselves sensitive to photolytic degradation.

In addition to solution tests, a solid-state oxidative screen may provide useful information. Unlike the solution state, reactivity of molecules in the solid state is limited by their crystal packing, and is therefore controlled by their topochemistry. A particular solid form may be stable to oxidative degradation as a solid, even though it is not when dissolved in solution, which can provide criteria to select appropriate polymorphic and salt forms for development. The hydrogen peroxide solvate of urea serves as a convenient source of vapor phase hydrogen peroxide when gently heated, and may be used to supply hydrogen peroxide vapor exposure to solid samples in a manner analogous to the use of saturated salt solutions to supply water vapor at a constant relative humidity.

5.4.4 Photodegradation studies

Photochemical instability is almost never a barrier to successful drug product development. Photochemically labile materials such as sodium nitroprusside are routinely manufactured, distributed, sold, and used to treat patients. The only issue to be resolved experimentally is whether protective packaging may be required, and whether protective lighting systems may be required in laboratory and manufacturing areas.

Photostability testing is required for regulatory approval, and a standard testing protocol for assessing photochemical stability has been established.[98] Pharmacopoeial methods for testing the light resistance properties of proposed packaging materials have also been established.

Commercially available test chambers equipped with an ICH Type I light source, such as a xenon arc lamp, are recommended for initial photochemical stress degradation studies. Chambers equipped with xenon sources typically irradiate samples with more than 2× the required ICH dose of UV radiation when samples are exposed to 1× the required ICH dose of visible light. Unless the test sample absorbs light in the visible region of the electromagnetic energy spectrum, setting the chamber to provide 1× exposure to visible light should provide more than adequate radiation exposure.

In a typical experiment, replicate samples packaged in clear glass containers, clear glass containers wrapped in aluminum foil to exclude all light, and samples in representative colored glass (eg, amber) containers are exposed to the Type I light source following the ICH test conditions. After the exposure has been completed (which may take a few hours, but typically less than 1 day, depending on the intensity of the xenon lamp radiation), the samples are assayed, and any degradation noted. Colored glass containers differ in light transmission properties, so the test should be performed with the least effective (generally the least intensely colored) container being considered. The test may need to be repeated with additional containers having lower specified light transmission.

For the purpose of evaluating laboratory and manufacturing lighting conditions, plastic filter material with defined light transmission properties can be used. A variety of fluorescent lamp tube shields are available commercially that meet this requirement. UV-filter tube shields made of polymethyl methacrylate are available with a cutoff frequency of 395 nm that effectively block all UV light; these are typically sold for use in museums, art galleries, and establishments selling textile products, where fading due to UV light exposure is a potential problem. So-called gold tube shields, designed for use in photolithography manufacturing facilities, effectively block both UV and blue light. Avoid the use of decorative tube shields sold for novelty lighting; many of these transmit some UV light even while blocking almost all blue, green, and yellow visible light. Prepare samples in clear glass containers; place some inside the selected filter tube. Wrap additional samples in aluminum foil to serve as controls. Expose all samples to a Type I light source until the requisite dose of radiation has been achieved. After the exposure has been completed, the samples are assayed. If samples exposed in the clear glass containers show evidence of degradation, but those packaged inside the plastic filter tubes do not, then the plastic filter tubes provide an adequate engineering control that will protect against degradation if installed on lighting fixtures used in production and laboratory areas.

To test for photochemical oxidation, sample containers can be purged with oxygen. Containers purged with an inert gas, such as nitrogen or argon, can serve as controls. A photosensitizing dye, such as Rose Bengal, can be added to test solutions.

Nearly all organic chemicals undergo photochemical degradation if exposed to high-intensity short-wave UV light, such as may be obtained using a high-pressure mercury arc lamp. The degradation products so produced hardly ever reflect those obtained using longer-wave UV or visible light radiation. The use of exotic light sources not likely to be encountered in normal handling and storage is not recommended.

5.5 PHYSICAL STABILITY AND PHASE TRANSFORMATIONS[99]

Physical stability refers to the ability of a solid phase to resist transformation under various conditions. Although in some cases tautomerism may be involved, this section encompasses phase transitions where the chemical entity of APIs remains the same.

As demonstrated in chapter "Crystalline and Amorphous Solids," various solid forms of a chemical entity may have different physicochemical properties. Some of these properties are very relevant to pharmaceutical development, such as solubility/dissolution rate, hygroscopicity, melting point, chemical stability, etc. Extensive efforts are invested early on into the selection of an optimum solid form as an API for downstream development. The understanding of the physical stability of the selected API solid form is minimally necessary to realize the benefit of the selected solid form, to ensure the control during the manufacturing processes, and ultimately to ensure the quality of the finished products.

Transformations among solid forms, mainly as a pure substance, are discussed in detail in chapter "Crystalline and Amorphous Solids," where the applications of these transformations in understanding the interrelationships among the various forms are demonstrated. However, pharmaceutical products consist of many other ingredients, each serving its unique function. Many processing steps are therefore required to bring these ingredients together in a reproducible fashion to achieve certain quality attributes for the finished products. In light of the importance of phase transformations during pharmaceutical processing to preformulation/formulation scientists and processing engineers, the discussions on physical stability in this chapter are biased toward the conditions encountered during pharmaceutical processing.

5.5.1 Types of phase transformations

Various solid forms exist for a certain chemical entity, as categorized in chapter "Crystalline and Amorphous Solids." Many possibilities exist for transformations among these forms. Some phase transformations are thermodynamically favored and are therefore spontaneous. Some phase transformations are thermodynamically disfavored, occur only under stress, and require energy input from the environment. Many phase transformations proceed through a series of individual phase transformations induced by the changes in the environment. Table 5.3 lists the major types of phase transformations.

TABLE 5.3 Major Types of Phase Transformations

Type	Explanation of phase transformation
A	*Polymorphic transition*: Transition between the polymorphs. The crystalline phases include all types of crystalline solids. The composition of the solid remains the same
B	*Hydration/dehydration*: Transition between anhydrates and hydrates or hydrates of different stoichiometry. The compositions of the solids differ by the number of water molecules
C	*Solvation/desolvation*: Transition between solvent-free crystal forms and solvates, solvates of different stoichiometry or solvates of different nature (ie, different solvents are incorporated into the crystalline lattice). The compositions of the solids differ by the nature and number of solvent molecules
D	*Salt/parent conversions or salt/salt exchange*: Transition between the salts (ionic adducts), and the parent unionized compounds (free acids or free bases), between the salts of different stoichiometry or between the different salts. The compositions of the solids differ by the nature and number of counterions
E	*Cocrystal/parent conversions or cocrystal/cocrystal exchange*: Transition between the cocrystals (molecular adducts), and the parent compound (unionized compounds or salts), between the cocrystals of different stoichiometry or between the different cocrystals. The compositions of the solids differ by the nature and number of cocrystal formers
F	*Amorphous crystallization/vitrification*: Transition between crystalline and amorphous phases. The crystalline phases include all types of crystalline solids. Since the compositions of the amorphous phases are usually less well defined, the compositions of the solids change in most cases

5.5.2 Mechanisms of phase transformations

The four underlying mechanisms for phase transformations, and the types of transitions for which these mechanisms could be operating, are listed in Table 5.4. Each of the mechanisms is discussed in further detail.

5.5.2.1 Solid-state transitions

Some phase transitions occur in the solid state without passing through intervening transient liquid or vapor phases. Solid-state reactions have been described previously in Section 5.2.10 and can be mechanistically categorized into four classes: nucleation, geometrical contraction, diffusion, and reaction order models.[100–105] Each model includes several slightly different mechanisms. These mechanisms and their corresponding kinetic equations were summarized in Table 5.2. Recently, a model-free kinetic treatment has been applied to amorphous crystallization,[35] and to dehydration[36] of pharmaceuticals. This new approach is described in detail in Section 5.2.10.6. In summary, this approach provides flexibility in describing the kinetics, and therefore affords better predicting power. Moreover, this approach facilitates the elucidation of the reaction mechanisms, especially those complex ones. In general, the kinetics of phase transition via a solid-state mechanism is influenced by many factors such as the environment (temperature, pressure, relative humidity/partial pressure, etc.), the ideality of the solid phases (the presence and distribution of defects and strains), the physical characteristics of the solid particles (size and distribution, morphology), and the presence of impurities.

5.5.2.2 Melt transitions

When a solid is heated above its melting point and subsequently cooled back to the ambient temperatures, the original solid phase may not be regenerated. Therefore, through this heating/cooling cycle, a phase transition may occur. Among the factors determining the final solid phase are the composition of the melt, relative rates of nucleation, crystal growth, and cooling. Impurities or excipients are also likely to affect the course of crystallization, and thereby the phase transformation. Formulations consist of many components, including API and excipients of different functions. Therefore, it is not only the melting of the API, but also the melting of the excipients that could give rise to phase transitions. In such multicomponent and multiphase systems, it is important to keep in mind phenomena such as melting point depression, eutectic formation among the various components, and the decrease in crystallinity (therefore the melting point) by some upstream pharmaceutical processing.

TABLE 5.4 Underlying Mechanisms of Phase Transformations[99]

Mechanism	Types of phase transformations[a]
Solid-state	A – F
Melt	A, B and C (dehydration/desolvation only), D, E, F (vitrification only)
Solution	A – F
Solution-mediated	A – E, F (amorphous crystallization only); transitions occur only from the metastable phases to the stable phases under the defined conditions

[a]*See Table 5.3 for definitions of types of phase transformations.*

5.5.2.3 Solution transitions

Very often, the solid API will be dissolved, or partially dissolved, in a solvent (typically water) during processing. If subsequent solvent removal induces a transformation, this transformation mechanism is considered a solution mechanism. It is important to note that the transition can be from a metastable phase to the stable phases or vice versa. For instance, the drug may partially dissolve in water during wet granulation or it may completely dissolve in water during freeze-drying or spray drying. Once the solvent is removed, the solid drug will be regenerated from the solution. The regenerated solid may not be the same crystal form as the original phase, and it may consist of a mixture of phases. Thus, through solvent removal, a phase transition may occur. It is also important to realize that only the fraction of drug that is dissolved is capable of undergoing transformation through this mechanism.

The final solid may be a single phase or a mixture of amorphous and crystal forms, depending on the rate of solvent removal, the ease of nucleation and crystal growth of the possible crystal forms under the processing conditions, and the presence of other material in the solution. The undissolved solid drug may serve as seeds and direct the crystallization toward the original crystal form. It may also, together with the insoluble excipients, provide surfaces for heterogeneous nucleation of a different phase. Soluble excipients may have profound effects on the nucleation and crystal growth of the drug, as many crystallization studies have demonstrated.[106]

5.5.2.4 Solution-mediated transitions

As opposed to the solution mechanism, the solution-mediated mechanism only allows the transition from a metastable phase to the stable phases. This type of transformation is driven by the difference in solubility between the two phases. In contrast to the solution mechanism where transformation occurs during drying, the solution-mediated mechanism operates when the metastable phase is in contact with the saturated solution.

Three consecutive steps are involved in a solution-mediated transformation[107–109]:

1. Initial dissolution of the metastable phase into the solution to reach and exceed the solubility of the stable phase
2. Nucleation of the stable phase
3. Crystal growth of the stable phase coupled with the continuous dissolution of the metastable phase

Step 2 or 3 is usually the slowest step. When step 2 is rate-determining, any factor that affects nucleation will influence the overall transformation. These factors include speciation in solution, solubility and solubility difference between the phases, processing temperature, contact surfaces, agitation, and soluble excipients/impurities. When step 3 is the rate-controlling step, the kinetics of the conversion are determined by solubility difference, solid/solvent ratio, agitation, processing temperature, particle size of the original phase, and soluble excipients/impurities.

5.6 PHASE TRANSFORMATIONS DURING PHARMACEUTICAL PROCESSING[99]

5.6.1 Processes for preparing solid dosage forms and associated potential phase transformations

A comprehensive description of the processes used for preparing solid oral dosage forms can be found in many references and textbooks,[110–112] as well as chapters in Section III, design, development and scale-up of formulation and manufacturing process, of this book. Commonly used methods and associated unit operations are summarized in Fig. 5.12. The impact of these processes on solid phase transformations and associated challenges are discussed next.

5.6.1.1 Size reduction

The first step during solid product processing often involves size reduction. Size reduction facilitates subsequent processing and may enhance product performance (eg, through improved morphology/flow properties, minimized segregation, enhanced uniformity, increased surface area, etc.). The principal means for accomplishing size reduction is by milling, which involves shearing/cutting, compressing, and impacting or attrition of drug particles. Impact mills (eg, hammer mills) and fluid-energy mills (eg, jet mills) are widely utilized in the pharmaceutical industry. Other methods for size reduction, such as supercritical fluid technology,[113] are less frequently employed and will not be included in this discussion. Since impact milling typically imparts mechanical stress and often generates heat, it may induce phase transitions, such as polymorphic transitions, dehydration and desolvation, or vitrification via solid-state or melt mechanisms. The rate and extent of these phase transitions will depend on characteristics of the original solid phase, the type of mill, and the milling conditions (such as the energy input). Digoxin, spironolactone, and estradiol are reported to undergo polymorphic transformations during the comminution process.[111] In most cases, the drug substance is milled prior to being mixed with excipients; consequently, the nature and extent of possible phase transformations can be detected more easily relative to the formulation.

5.6.1.2 Granulation/size enlargement

Before a powder can be compressed into a tablet or filled into a capsule, it must possess a number of physical characteristics including flowability, cohesiveness, compressibility, and lubrication. Since most pharmaceutical materials seldom possess all of these properties, granulation methods are frequently used to impart the required characteristics. Wet and dry granulations are the two most commonly used methods of preparing granules for tablet compression or capsule manufacture. Other granulation processes include spray drying and melt granulation, such as high shear melt pelletization, spray-congealing, and melt-extrusion.

5.6.1.2.1 Wet granulation and drying

Wet granulation is most widely used due to its versatility, and the greater probability that the resulting granules will meet the physical requirements for further processing. Wet granulation methods commonly used include low or high shear mixing, fluid-bed mixing, and pelletization (eg, extrusion/spherization).[110] Typical drying methods for the wet granules are tray drying, fluid-bed drying, and vacuum drying. Other methods include microwave drying, tunnel drying, and rotary current drying.[112] Although versatile, wet granulation is especially likely to induce phase transitions. The potential for phase transition of a substance will depend not only on its properties, but also on the conditions and the methods used for granulation and drying.

Conditions such as the amount of liquid used for granulation, the exposure time of the solid to the liquid, airflow, drying temperature, etc., vary with granulation and drying methods. The drug loading, solubility of the drug substance in the granulation liquid, and the procedure for incorporating the drug into the granules will determine whether the starting solid phase is partially or completely dissolved during the granulation process. The subsequent solvent removal rate, which also depends on the method used for granulation and drying, the nature and the concentration of

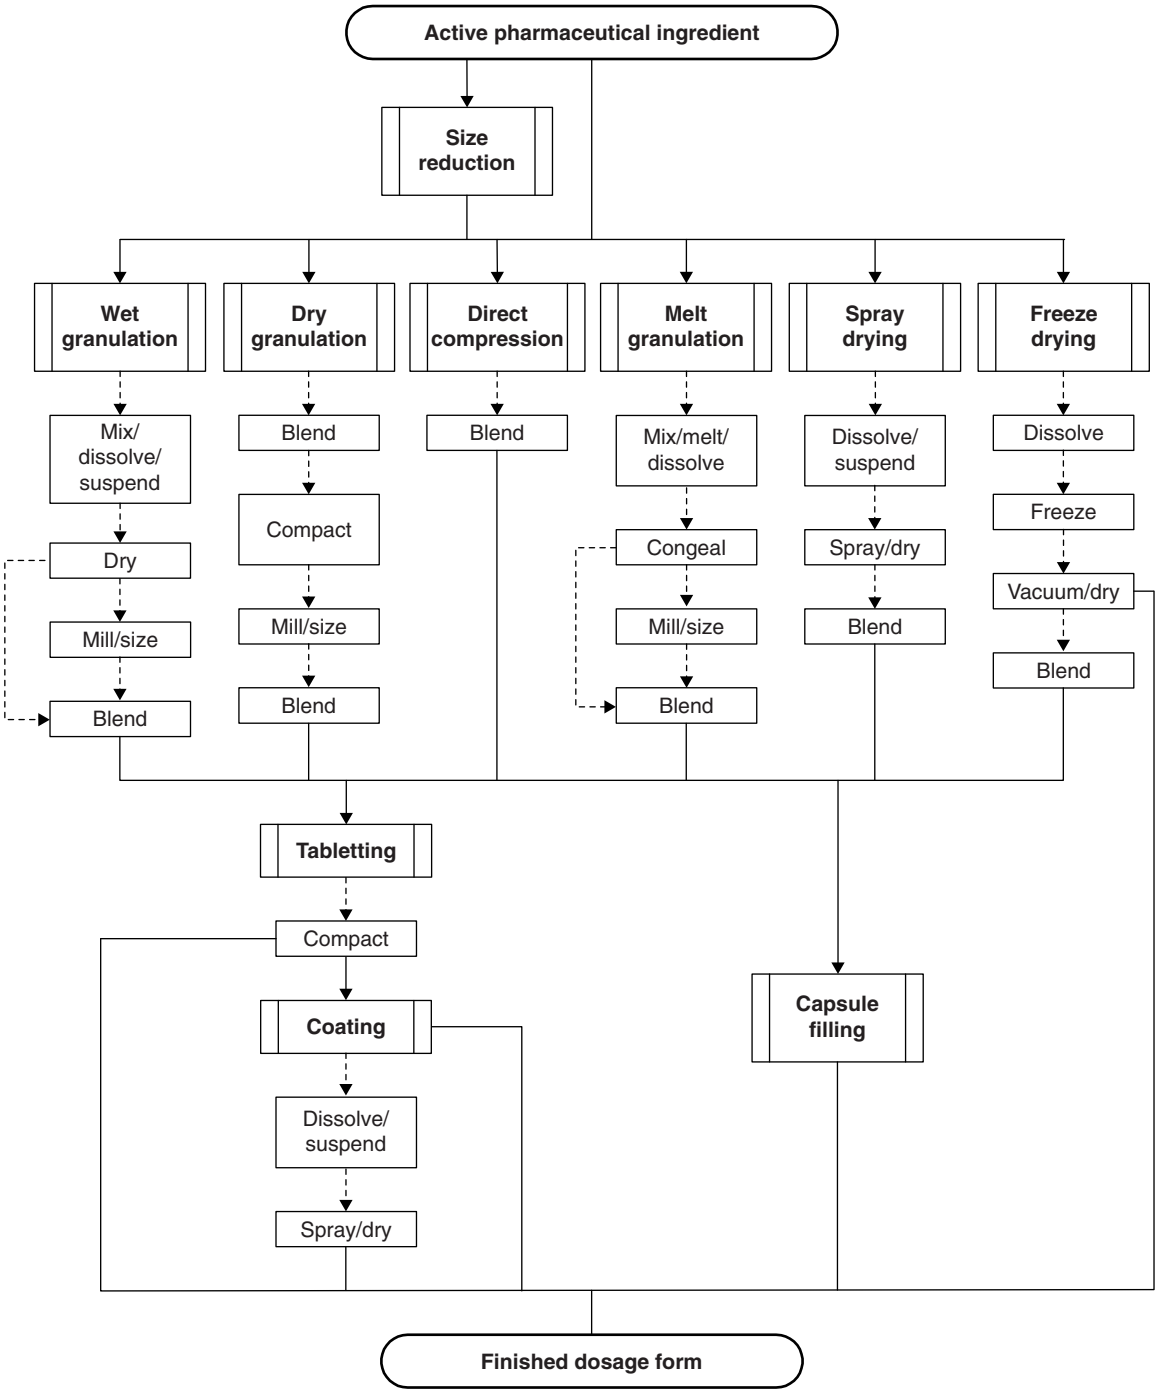

FIGURE 5.12 Common processes for preparing solid oral dosage forms.[99]

the excipient dissolved, may influence the phase formed in the dried granules. Thus, in addition to the properties of the API and the composition of the formulation, the granulating and drying methods and conditions will determine whether solution or solution-mediated phase transformations, such as polymorphic conversion, hydration/dehydration, salt/parent conversion or salt/salt exchange, cocrystal/parent conversion or cocrystal/cocrystal exchange, and vitrification/crystallization will occur. If the drug is completely dissolved in the granulation fluid, the method of drying, as well as the type of excipients used, will determine whether transformation via the solution mechanism will occur. When less soluble drugs are suspended in the granulating fluid, a solution-mediated transformation may occur, leading

to a phase transition from an anhydrous phase to a hydrate, from a salt/cocrystal to its parent, from an amorphous phase to its crystalline counterpart. The ability to detect phase transformations, as well as the number of analytical techniques that can be used for detection, will depend on the drug load in the granules and potential interference from the excipients.

5.6.1.2.2 Dry granulation

Dry granulation is typically used when the formulation ingredients are sensitive to moisture or when they are unable to withstand an elevated drying temperature. It is also used when the formulation ingredients have sufficient inherent binding or cohesive properties. Dry granulation is also referred to as *precompression* or as the *double compression method*.[110] Slugging and roller compaction are the two most commonly used dry granulation methods. The stresses applied during slugging may be lower than those applied by roller compaction because of the differences in dwell time. Since granulating solvent is not used during dry granulation, solution or solution-mediated phase transformations are eliminated, thus the probability of phase transitions with this granulation unit operation is reduced. However, the applied mechanical stresses during processing may lead to phase transformation via the solid-state or melt mechanism. As is the case in the wet granulation process, the ability to detect phase transformations, as well as the number of analytical techniques that can be used, will depend on the drug loading in the granules and on the potential for interference from the excipients.

5.6.1.2.3 Melt granulation

The melt granulation process consists of partially or completely melting solid excipients, and then granulating with the API and other excipients, followed by reducing the mixture to granules by chilling and congealing. During this process, the API is subjected to heat and may be partially or completely dissolved in the molten excipients. If the melting point is relatively low or the heating temperature is sufficiently high, the API may also melt during processing. Partially or completely melted APIs may also serve as binders or congealing carriers. Subsequent cooling could induce phase transitions through the solid-state or melt mechanism. In fact, this process is sometimes used by design for preparing crystalline or amorphous solid dispersions, thus taking advantage of phase transformation through the melt mechanism.

In a spray-congealing process, a low-melting-point carrier is employed to provide the fluidity necessary for spraying. At high temperatures, all or a fraction of the drug may be solubilized in the molten carrier. During spray-congealing, the hot droplets cool rapidly and solidify. Since rapid cooling/congealing is required for the formation of small particles with a narrow size distribution, it is possible that the drug may precipitate as an amorphous phase or as a metastable crystal form, following Ostwald's Rule of Stages.[114,115] In a high-shear-melt granulation, the temperature, extent, and duration of heating, as well as the rate of cooling, are often significantly lower relative to the spray-congealing process. Thus, this process is less likely to initiate phase transitions. Similar to spray-congealing, the melt-extrusion process also requires complete melting of the carrier excipients. Although the rate of cooling is slower, this process is still likely to induce phase transitions.

5.6.1.2.4 Spray drying and freeze-drying

Spray drying produces powder particles that are homogenous, porous, and uniform in size and shape. The technique may also be used for encapsulating or coating drugs to provide protection or release rate control. The process consists of bringing together a highly dispersed liquid and a sufficient volume of hot air to produce uniform droplets. Subsequent evaporation of the liquid leads to particle formation.[110] The feed liquid can be a solution, suspension, or emulsion. This process requires complete or partial dissolution of the drug in a solvent, and thus increases the likelihood for phase transitions involving solution mechanism. Solvent removal from droplets occurs in seconds, and this may lead to rapid crystallization of a metastable phase or the formation of an amorphous phase through the solution mechanism.

Freeze-drying is often used to produce amorphous materials. In this case, extremely low temperatures are used to limit molecular mobility and to prevent nucleation of the drug and the excipients. The conditions for freeze-drying can have a major influence on the solid phase of the drug in the product. Although it is not a commonly used process for manufacturing solid oral dosage forms, freeze-drying has been used to prepare tablets for specific functions (eg, Zydis tablets for rapid dissolution).[116,117]

5.6.1.3 Granulation milling/sizing and blending

A granulated solid is often subjected to milling, and at this stage, the intensity and energy exerted on the API is generally lower than those exerted during initial particle size reduction. Although the risk of phase transition at this stage is less compared to that during API milling and granulation, the presence of excipients makes the detection of phase transitions difficult.

Prior to tablet compression or to encapsulation, granules are directly blended with lubricants and other excipients (eg, lubricants, glidants, and disintegrants) without modifying their physical properties. There is

minimal risk of phase transitions occurring during the blending process.

5.6.1.4 Compression and encapsulation

Lubricated granules are either compressed into tablets or filled into capsules. During tableting, granules may be subject to compression forces as high as 40 kN, with dwell times on the order of a few milliseconds. An energy impact of this magnitude may cause solid phase changes in either the API or the excipients via the solid-state mechanism. For example, caffeine, sulfabenzamide, and maprotiline hydrochloride have been reported to undergo polymorphic transformations during compression.[118] Phase transitions are seldom encountered during the capsule filling process because the solid is experiencing minimal thermal and mechanical perturbations.

5.6.1.5 Coating

When manufacturing finished on the tablet dosage form, a film coating is often applied to each tablet as an aqueous or solvent-based polymer system in coating pans or in a fluid-bed. The function of the coating may be to improve esthetics, mask taste, or modify drug release. Less common coating techniques such as sugar coating, compression coating, or microencapsulation, will not be discussed here. The film coating process involves the application of a thin, polymer-based coating solution to an appropriate substrate (tablets, granules, or crystals) using a spray-atomization technique. To permit uniform distribution of the coating materials and to prevent coating problems (picking, roughness or mottling), film coating parameters are optimized to create a balance between coating solution delivery rate and drying capacity. Rapid drying typically takes place during the application of the film coating. A highly efficient air exchange ensures that there is only a short time between the impingement of the coating liquid onto the tablet surface and the subsequent solvent evaporation. Thus the interaction between the core material and the coating liquid is generally minimal during film coating. In most cases it is unlikely that a phase transition will occur via the solution mechanism during film coating. When necessary, prior to application of the film coat, a polymer-based seal coat may be applied to the surfaces of the tablet cores first. This will prevent extended solid–liquid interactions during the subsequent film coating process.

For some modified release products, a portion of the total dose may be applied as a drug-coating layer. This coat may provide immediate release for fast onset in a biphasic extended release system, or it may provide immediate release in a pulsatile delivery system. The drug layer is typically applied by spraying a drug solution or a drug suspension onto the tablet surface, depending on the drug solubility and dose. Dissolving or suspending the drug in a liquid increases the potential for phase transitions to occur through the solution or solution-mediated mechanism. When a drug solution is used for coating, the probability that such operations will alter the solid phase of the drug is high, similar to that observed in the spray-drying process discussed earlier. That is, rapid solvent removal in this coating process may lead to a transformation to a metastable crystal form or an amorphous phase in the drug layer via the solution mechanism. When a drug suspension is used for coating, if there is a more stable phase in an aqueous medium, the probability that such operations will alter the solid phase of the drug through a solution-mediated mechanism is high. The anticipated risk is higher than that observed in the wet granulation process, and is a result of the following:

- The coating process is usually a much longer process than wet granulation.
- The suspension is usually made with drug particles that are very small (for better suspension, coating uniformity). This leads to faster dissolution to reach supersaturation and, therefore, more time for nucleation of the stable phase to occur.
- The suspension provides a much higher specific solution medium and is usually constantly stirred to ensure the uniformity of the suspension. If nucleation of the stable phase occurs, the conversion to the stable phase will proceed at a much faster rate.

5.6.2 Anticipating and preventing phase transformations in process development

To anticipate and prevent solid phase transitions during manufacturing, it is critical to have a thorough understanding of crystal forms and the amorphous phase of the API and excipients, as well as the interconversion mechanisms and processing options. This integrated knowledge is essential for the rational selection of the physical form of the API, the excipients, the manufacturing process, and for the selection of appropriate handling and storage conditions. In certain cases, even after the solid form and the preferred process are defined, it is advisable to monitor the crystal form of all incoming raw materials and the physical forms present in the final dosage unit. This monitoring is especially important in cases where dissolution or stability of the product is very sensitive to solid phase changes. The rigor used in monitoring will depend on the API, formulation, process, and analytical method. For a highly soluble, stable, and bioavailable molecule, the risk of process-induced phase change on stability and bioavailability may be relatively low. However,

process-induced phase changes in the APIs, excipients, or both may affect manufacturability or disintegration of the dosage form.

In selecting the crystal form of an API for development, the physicochemical, biopharmaceutical, and processing properties must all be taken into consideration. In some cases, it may be necessary to select an alternate crystal form to eliminate stability issues, dissolution rate differences or process-induced phase transitions. It is desirable to choose the crystal form that is least susceptible to phase transformations induced by heat, moisture, and mechanical stresses, provided that the biopharmaceutical and processing characteristics of the API are acceptable. Sometimes an alternate salt having fewer crystal forms may be chosen to minimize process-induced transitions. For example, the authors have encountered a scenario where a new salt form was selected following Phase I studies due to clinical considerations. This change helped us to overcome manufacturing hurdles presented by the complexity of polymorphic phase transitions associated with the original salt form. This change in salt form drastically reduced the number of crystal forms (a single crystal form as opposed to seven processing relevant crystal forms for the original salt, and four processing relevant crystal forms for the parent). This new salt minimized the risk of phase transitions occurring during manufacturing, leading to greater processing flexibility in the development of a solid dosage form for Phase II clinical trials and beyond.

Phase transitions in crystalline excipients, as well as their impact on product performance, also cannot be ignored. For example, process-induced age-hardening in tablets may lead to a decrease in dissolution rates during storage of formulations containing a high level of crystalline excipients such as mannitol. If process-induced hardening is anticipated, variable product dissolution can be minimized through the use of intra- and extra-granular super disintegrants or by selecting alternative excipients.

In designing manufacturing processes for solid dosage forms, process-induced phase transformations can be anticipated based on preformulation studies. These transformations can be controlled and circumvented by selecting the appropriate process. If a solid phase is sensitive to moisture or to solvent, a dry or melt granulation may be used. If a drug substance undergoes an undesirable transition during milling or compression, melt granulation through melt-extrusion may be more desirable provided the drug is thermally stable. It may be possible to avoid milling the drug substance if particle size and shape can be controlled during crystallization. A capsule may be used in place of a tablet dosage form should compression be deemed undesirable. Polymorphic conversion during drying of an enantiotropic polymorph can be avoided by maintaining the drying temperature below the transition temperature. During film coating, solid–liquid interactions at the surface of moisture sensitive cores can be minimized or eliminated by first applying a seal coat that uses a solution of low viscosity at a slow spray rate. Alternatively, an organic solvent-based polymer system can be used for rapid solvent evaporation.

These are just a few examples that illustrate how knowledge of solid-state properties of the APIs and excipients can be applied to formulation design and process selection. Rational formulation and process design can reduce the risk of unpleasant incidents during late stage development and increase the efficiency during new product development. Ultimately, the quality of a solid product manufactured using the chosen process must be confirmed by real-time tests.

Excipient Compatibility and Functionality

A.S. Narang, R.V. Mantri and K.S. Raghavan

Drug Product Science & Technology, Bristol-Myers Squibb, New Brunswick, NJ, United States

6.1 INTRODUCTION

Excipients are pharmacologically inert ingredients added intentionally to a drug product (DP) for various functional roles, such as to enhance dosage form volume or size, disintegration of solid dosage forms, binding of particulates, lubrication during processing, taste masking, or modifying drug release. Excipients play a central role in the design and development of dosage forms.[1] The selection of excipients is vital in the design of a quality DP and is based not only on their functionality, but also on the compatibility between the drug and the excipients. Excipient-compatibility testing and formulation development studies are used in the selection of the excipient type, grade, and concentration in formulation. The formulation development and optimization studies also help in identifying the critical material attributes (CMAs) of excipients and active pharmaceutical ingredients (APIs), which is extremely valuable in management of excipient variability and ultimately the robustness of the DP. Excipients are selected to impart a specified function in the oral solid dosage form. Excipients obtained from a wide range of chemical classes may be produced by varied manufacturing processes either in batch or continuous mode, and could be sourced synthetically or from natural products. Excipients can also have multiple functions in the dosage form. These functions are based on the physical and chemical attributes of excipients that impart functionality specific to a dosage form and application. A thorough mechanistic understanding of excipient functionality and its basis is important in deciding on the grade, vendor, and quality attributes (QAs) of selected excipients.

An incompatibility may be defined as an undesirable drug interaction with one or more components of a formulation resulting in changes in physical, chemical, microbiological, or therapeutic properties of the dosage form. Excipient compatibility studies are conducted to mainly predict potential physicochemical incompatibilities of the drug in the final dosage form. These studies also provide justification for selection of excipients and their concentrations in the formulation as required in regulatory filings. Excipient compatibility studies are often thought to be routine and cumbersome. However, these studies are important in the drug development process, as the knowledge gained from excipient compatibility studies is used to select the dosage form components, delineate stability profile of the drug, identify degradation products, and understand the mechanisms of reactions. If the stability of the drug is found to be unsatisfactory in the presence of certain excipients, strategies to mitigate the instability of the drug can be adopted. These strategies can consist of avoidance of a particular excipient, inclusion of a stabilizer (eg, antioxidant for oxidation instability), modifying the process to minimize drug-excipient interaction (eg, extragranular addition of a disintegrant in a wet-granulation formulation), or modifying the kinetics of degradation (eg, by reducing water activity in the dosage form). The excipient compatibility studies are usually carried out in the worst-case scenario of potential proportion of drug-excipient combination in the DP and exposure to the environment (eg, in terms of both temperature and relative humidity (RH)). Thus, kinetic control of incompatibilities to allow an acceptable shelf-life is often feasible.

Methodical and carefully planned and executed compatibility studies can lead to savings in terms of resources and time delays associated with stability issues arising during late-stage product development. The results from these studies can also be useful in determining the causes of stability issues if and when they surface at later stages of development. From a drug development process perspective, these studies are usually conducted after gaining some understanding of solution

Developing Solid Oral Dosage Forms
DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00006-6

and solid-state stability characteristics of the drug substance (API), but before the formulation development activities. An incompatibility in dosage form can result in any of the following: change in color/appearance, loss in mechanical properties (eg, tablet hardness), changes to dissolution performance, physical form conversion, loss through sublimation, decrease in potency, and increase in degradation products.

Additionally, the regulatory expectations have increased significantly over time. This trend is expected to continue as "Quality by Design" initiatives continue to be advocated. Drug-excipient compatibility data is required to justify the selection of formulation components in development reports that go into filings. There has also been an increased regulatory focus on the "Critical Material Attributes" of excipients and their control strategy because of their impact on the DP formulation and manufacturing process. A thorough understanding of the potential variability in the excipient characteristics and attributes that could potentially affect the DP performance is critically important for the lifecycle of the product.

This chapter will focus on the role of excipient functionality, drug-excipient incompatibility, and material (excipient) variability in the design, development, and control of a robust DP.

6.2 EXCIPIENT FUNCTIONALITY

The choice of excipients in the design of a DP is based on several criteria, including salient elements of the quality target product profile, such as the rate and site of drug delivery; stability/target shelf life, packaging, and storage temperature; and appearance, target patient population, and palatability. These combined with input material properties, including the physicochemical and biopharmaceutical properties of the API, and the manufacturing process help determine the selection of excipients. In the process of DP development, QAs of the DP are determined to identify those that may be critical quality attributes (CQAs). Material attributes (MAs) of selected excipients that help realize this goal are enlisted as target material properties. The dependence of CQAs on MAs and manufacturing process parameters helps determine critical material properties (CMPs) and critical product profiles. These, combined with in-process controls and end-product testing protocols, define the control strategy of a DP. During the course of pharmaceutical development, prototype formulations are processed and tested for various DP QAs to finalize the composition of the DP. Once the composition has been identified, aspects such as excipient variability, identification and control of CMAs, definition of DP CQAs, DP specifications, and DP control strategy are put in place to ensure reproducible and robust manufacture of the DP. Identification, assessment, and control of the functionality determining attributes of excipients form an important cornerstone of this process.

Excipients are added to DP formulations based on their function to aid in large-scale manufacture, stability, consistent appearance, patient compliance, and drug delivery and bioavailability. Excipients used in oral solid dosage form have been classified based on their function into groups such as diluents, disintegrants, binders, glidants, lubricants, release-controlling polymers, stabilizers (such as antioxidants, chelators, and pH-modifiers), film-coating polymers, plasticizers, surfactants, colorants, sweeteners, and flavors.

6.2.1 Compendial standards

The reliable use of excipients in dosage form requires reproducible and robust performance in terms of identity, purity, and functionality. The compendial monographs provide specifications that ensure the identity and purity of the excipient, but not necessarily describe the standards for functionality of the excipients. There has been considerable discussion and debate on the excipient functionality, performance, and the role of compendial monographs.[2,3] USP 34 - NF 29 chapter <1059> summarizes a list of several functional categories, along with a general description of mechanisms by which excipients may achieve their function. It also provides a list of physical and chemical properties that could potentially affect the functionality of an excipient.

The European Pharmacopeia (Ph.Eur.) has begun to introduce nonmandatory, functionality-related characteristics (FRCs) in each of the excipient monographs based on the function (or application) to help in identifying the right excipient QA for a specific purpose. The FRCs are defined as *controllable* physical or chemical characteristics of an excipient that affect its functionality, and they may be understood as the control parameters for a specific use of an excipient. The control of excipient FRCs is intended to help provide an assurance of consistent quality and performance of excipients, as well as of the DPs using those excipients.

Table 6.1 provides a limited list of commonly used excipient functionality categories, with commonly used excipients and a summary of recommended properties from the United States Pharmacopeia (USP) and Ph. Eur. compendial agencies as characteristics of excipients that could provide information regarding the functionality of excipients.

6.2.2 Determining FRCs

Excipients can be multifunctional, and the physical and chemical attributes that afford them their functionality

TABLE 6.1 Excipients, Their Functional Categories and Properties/Characteristics That May Potentially Affect Functionality Based on Compendial Guidance

Functional category	Excipient properties that may affect the functional category (extracted from USP 34 - NF 29 chapter <1059>)	Examples of excipients	Functionality-related characteristics (FRCs) for the specific excipient and function (extracted from nonbinding parts of the monographs listed in Ph.Eur.)
Diluent	Particle size and size distribution, particle shape, bulk/tapped/true density, specific surface area, crystallinity, moisture content, powder flow, solubility, compaction properties for tablet dosage forms; chemical properties, composition, including minor concomitant components and undesirable components	Lactose anhydrous	Particle-size distribution Hausner ratio (bulk and tap density) α-lactose and β-lactose: ratio Loss on drying
		Lactose monohydrate	Particle-size distribution Hausner ratio (bulk and tap density)
		Microcrystalline cellulose	Particle-size distribution Powder flow
Binder	Surface tension, particle size, shape and distribution, solubility, viscosity (nature of the polymer structure, molecular weight, and molecular weight distribution) Chemical properties: polymeric structure, monomer properties and sequence, functional groups, degree of substitution, and cross-linking, variations in their sources (for natural polymers)	Povidone	Molecular mass (viscosity, expressed as *K*-value)
		Hydroxypropyl cellulose (HPC)	Viscosity Degree of substitution Powder flow (as matrix polymer) Particle size (as matrix polymer)
		Pregelatinized starch	Cold water-soluble matter Particle-size distribution Powder flow
Disintegrant	Particle size distribution, water absorption rate, swelling ratio or swelling index, the characterization of the resulting product whether it is still particulate or a gel is formed. Chemical composition and influence of dissolution/disintegration pH and ionic nature of APIs (for anionic disintegrants)	Crospovidone	Hydration capacity Particle-size distribution Powder flow Settling volume (for suspensions)
		Croscarmellose sodium	Settling volume Degree of substitution Particle-size distribution Hausner ratio
		Sodium starch glycolate	N/A
Glidant	Particle size distribution, surface area, hygroscopicity, chemical composition	Colloidal silicon dioxide	Specific surface area
Lubricant	Particle size, surface area, hydration state, polymorphic form; solid-state/thermal behavior, purity (eg, stearate: palmitate ratio) moisture content Chemical properties: composition	Stearic acid	Particle-size distribution Specific surface area
		Magnesium stearate	Particle-size distribution Specific surface area Thermogravimetry

differ based on the application. For example, polyvinylpyrrolidone (PVP) may be used as a binder during wet granulation in one application or may be used for stabilization of amorphous API in a solid dispersion application. The physical, chemical, and mechanical attributes of PVP that contribute to its functionality are different for these two applications. For example, hydrophilicity may be counterproductive to the role of PVP in increasing the physical stability of an amorphous drug in the solid dispersion of a poorly soluble drug, whereas this same attribute helps promote particle adhesion when PVP is used as a binder in wet granulation.

Similarly, the functionality determining attributes of hypromellose (hydroxypropylmethyl cellulose, or HPMC) may differ by the application. The Ph.Eur. proposes different FRCs for two different applications of HPMC—namely, (1) viscosity, degree of substitution, molecular mass distribution, particle-size distribution, and powder flow when applied as matrix polymer for extended release dosage forms and (2) only viscosity and degree of substitution when used as a binder, viscosity-increasing agent, or film-former. Similarly, FRCs for the use of povidone as a solubilizer and stabilizer in liquid dosage form include viscosity and molecular mass, while

molecular mass has been considered sufficient as an FRC when povidone is used as a binder in tablets and granules.

The compendial monographs can be used as the starting point in developing an understanding of the excipient properties that may be relevant from their functionality perspective, but not as prescriptive tests that define the performance of the excipient in a dosage form. In some cases, the same excipient can affect the performance of the dosage form by multiple functions. For example, microcrystalline cellulose (MCC) is generally used in oral solid formulations as a diluent and to promote disintegration. Nevertheless, there are other characteristics of MCC that contribute to the overall performance of the MCC in the DP, including moisture sorption and flow. The former can contribute to the degradation of moisture-sensitive compounds, while the latter can be particularly important for direct compression formulations. Responding to these needs, the excipient industry routinely provides different particle sizes and moisture grades of MCC with relevant specification controls.

Another example of different MAs affecting DPs through different pathways is evident with the lubricant magnesium stearate (MgSt). While a higher specific surface area of MgSt could be useful in lubrication efficiency, it may also negatively affect disintegration or compaction of the solid dosage form. In many cases, selection of the MgSt quantity in the dosage form and the manufacturing process (number of blending revolutions) needs to balance the adverse impact on compactibility or disintegration with the lubricity needed for flow and to avoid picking and sticking during DP manufacturing. In addition, controls on MgSt specific surface area are often required to provide an assurance of reproducible DP manufacture within a predefined design space.

In a perspective paper, Hlinak et al. (2006) proposed a list of powder properties that could qualify as CMAs, along with their potential impact on product attributes and processing (Table 6.2).[4]

Although this list is not comprehensive, it is instructive to show that many physical attributes of a given material could affect the quality and performance of the DP.

6.2.3 Identification of CMAs

The functional role of excipients in a dosage form is based on the underlying chemistry and the functionality that determines attributes of an excipient. In several cases, chemical attributes such as the degree of substitution on a polymeric excipient affects functionality. For example, the degree of substitution of HPC can affect the wetting of drug particles in a solid dosage form and

drug release or dissolution. The ratio of crystalline α and β forms of lactose could affect the flow and compaction properties. However, it is difficult to specify, a priori, a list of all the functional attributes that will be relevant for the specified dosage form. What is of greater importance for a given product is the identification of critical and performance-indicating attributes of excipients that must be assessed and controlled to achieve a consistent and robust product.

A property of an excipient could be considered to be critical when a realistic change in the excipient property leads to a significant impact on DP performance.[5] Identification of these CMAs is accomplished by developing product and process understanding through systematic studies and extending these studies to study the impact of excipient attributes on the product and the interaction of excipient attributes and the manufacturing process. These studies help in devising an appropriate control strategy to ensure conformance of the DP to prespecified criteria in a quality-by-design (QbD) paradigm. Therefore, the formulation scientist must understand the formulation, manufacturing process, and MAs of the API and excipients before the CQAs are identified and controlled. For example, an oral tablet dosage form of the drug brivanib alaninate (BA) was developed using a wet-granulation process.[6–8] QbD formulation and process robustness studies identified the impact of wet-granulation process parameters on tablet dissolution. The effect of API particle size on tablet dissolution was investigated at the worst-case scenario of the combination of wet-granulation process parameters with respect to tablet dissolution to identify appropriate control limits for the API particle size distribution and specification limits for tablet dissolution. This study highlighted the importance of studying the interaction of process parameters and MAs. In addition, the impact of excipient attributes, such as the degree of substitution of the disintegrant, croscarmellose sodium (CCS), were determined within this design space. The role of the degree of substitution of CCS was identified in affecting drug-excipient binding (Fig. 6.1a), which in turn affects the amount of drug absorbed depending on the drug dose and the drug-CCS binding affinity (Fig. 6.1b). This case study highlights that the degree of substitution of CCS could be a CMA in one scenario, but not in another. The simulations further identify the cases (combination of drug dose and the drug-excipient binding affinity) in which the degree of substitution could be a CQA.

In conducting QbD studies to elucidate the impact of excipient attributes on DP CQAs, it should be recognized that the physicochemical properties of an excipient that might qualify as CMAs may sometimes be different from the properties conventionally characterized or reported on the vendor certificate of analyses or those suggested by the compendial monographs. Risk assessment and prior experience can be utilized to prioritize the MAs that need to be studied during the development studies so that the criticality of these attributes toward the DP quality and performance can be established.

6.3 EXCIPIENT COMPATIBILITY

6.3.1 Chemistry of drug-excipient interactions

The most common reactions observed in pharmaceuticals are hydrolysis, dehydration, isomerization, elimination, cyclization, oxidation, photodegradation, and specific interactions with formulation components (excipients and their impurities). The main factors that affect these reactions are temperature, pH, moisture in solids, RH of the environment, the presence of catalysts, light, oxygen, physical form, and particle size of the drug and excipients.

A comprehensive discussion on chemistry of drug stability is out of the scope of this chapter. However, it is important to consider why excipients may alter the stability of drug substances that are prone to certain types of degradation. Some of the common ways by which excipients may affect drug stability in the dosage form are by altering moisture content in the dosage form, changing microenvironmental pH in the dosage form, acting as general acid/base catalysts, directly reacting with a drug, or becoming the source of impurities that can either react directly with drug substances or participate as catalysts in the drug degradation. The excipients can also alter the physical or the chemical form of the drug through, for example, ion-exchange, transformation of polymorphs, and the formation eutectic or solid solutions. The changes in a physical or chemical state may in turn alter the chemical stability of the drug.

In the context of solid-state compatibility testing, two attributes of excipients are especially important to formulation stability and compatibility testing: (1) their ability to absorb water at variable humidity and (2) the pH that the excipients impart.

6.3.1.1 Influence of water and microenvironmental pH

Most drugs and excipients contain water, which may be either bound or unbound. The bound water is the water of hydration or crystallization, which is so tightly incorporated in the physical form of the material that it is practically immobile and is not available for reactions. This is exemplified by the stability of crystalline hydrates of hydrolytically unstable β-lactam antibiotics, wherein the water is incorporated in the crystalline matrix and is

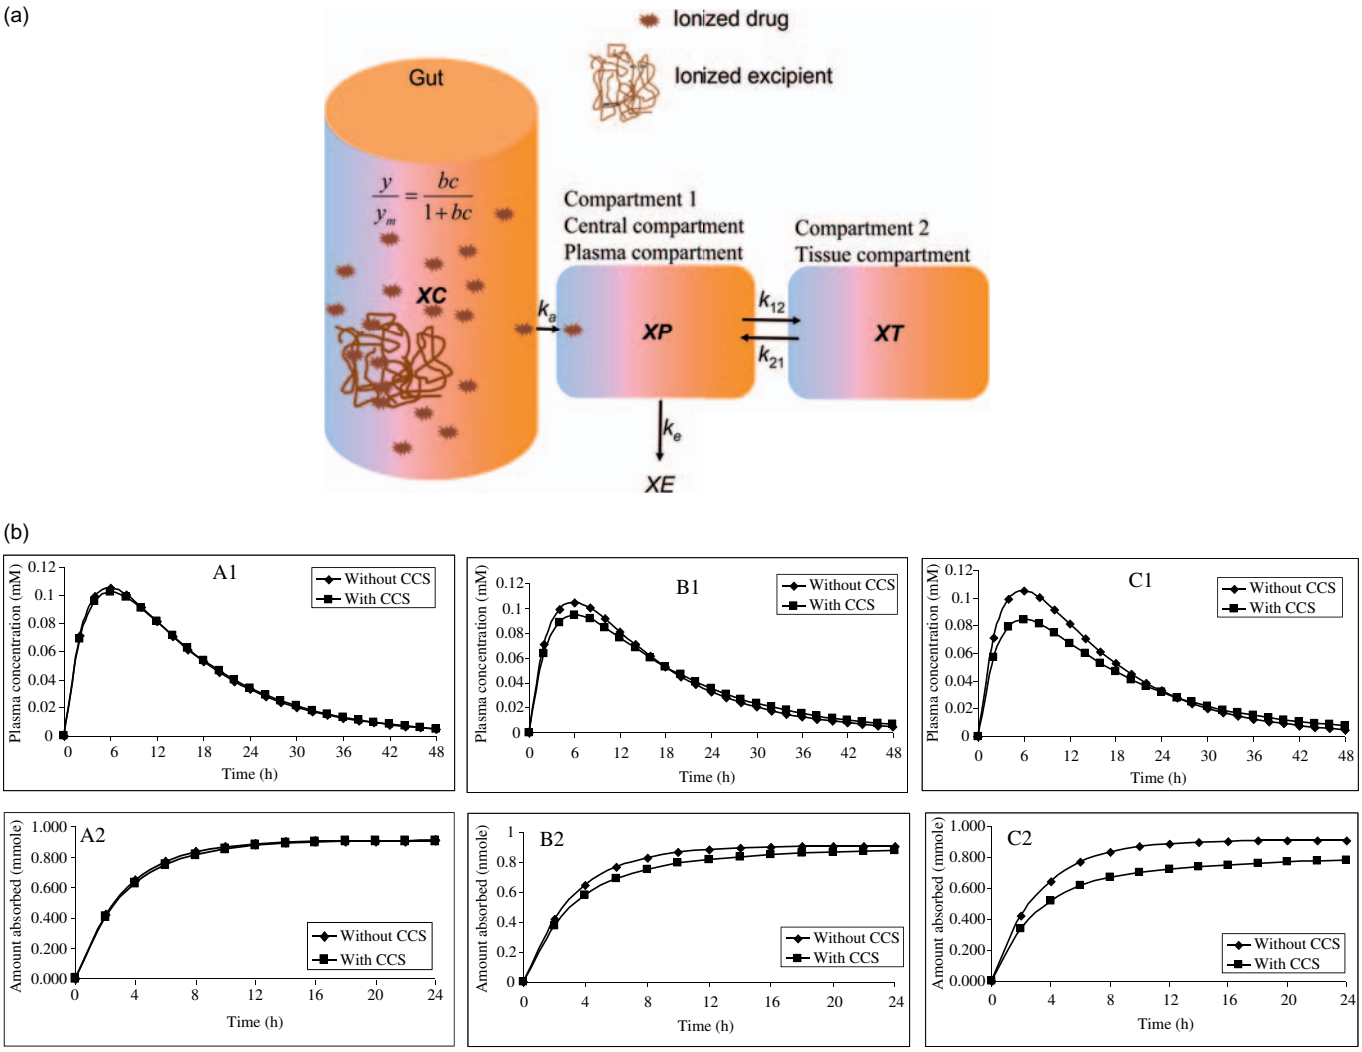

FIGURE 6.1 (a) Pharmacokinetic modeling of the impact of drug-excipient binding on drug absorption from the gastrointestinal (GI) tract; (b) simulation of the effect of drug-excipient binding on oral drug absorption with different degrees of substitution of the excipient, croscarmellose sodium (CCS), affecting pharmacokinetics of the drug, brivanib alaninate (BA), depending on drug dose and binding affinity. The results of simulating the effect of BA-CCS binding on plasma concentration profiles of BA after a single oral dose in the form of a 400-mg tablet using the pharmacokinetic parameters of BA ($V_d = 5.4$ L, $k_a = 0.31$ hour^{-1}, $k_{12} = -0.11$, $k_{21} = 112$, and $k_e = 0.08$) and (A) weak binding ($y_m = 0.5$ mmol BA/mmol CCS and $b = 1$ mM^{-1}), (B) binding parameters observed using Langmuir isotherm ($y_m = 0.85$ mmol BA/mmol CCS and $b = 8.34$ mM^{-1}), or (C) strong binding ($y_m = 2$ mmol BA/mmol CCS and $b = 50$ mM^{-1}). The sub-figures A1, B1, and C1 represent the plasma concentration-time profile. Sub-figures A2, B2, and C2 represent the amount of drug absorbed as a function of time.

not available for reaction. As expected, the stability of these compounds is highly dependent on their crystalline state.[9] In contrast, unbound water usually exists in equilibrium with the atmosphere in an absorbed or adsorbed state by the solid components and has more molecular mobility. The variation in the content of water of an excipient with humidity reflects changes in the unbound water content.

The physical state of water in an excipient or the drug-excipient mixture determines its potential role in drug-excipient interactions. The water sorption-desorption properties of excipients are well documented.[10,11] Presence of water in the solid-state systems has a significant impact on the stability not only in causing the hydrolysis of drugs (eg, of acetylsalicylic acid),[12] but also its role as a reaction medium and in increasing the plasticity and molecular mobility of the system. Excipients that strongly sorb water may prevent drug degradation by scavenging water in a closed system (eg, colloidal silica[13] and silica gel).[14] Excipients with higher adsorption energy can decrease the reactivity of water in the system more than those with lower adsorption energy, as was shown in the case of nitrazepam.[15] On the other hand, water in excipients such as MCC is highly reactive because it is weakly adsorbed.[16]

This was the reason for the higher rate of hydrolytic degradation of aspirin in the presence of MCC versus microfine cellulose.[17] A study of water sorption-desorption of a system as a function of environmental humidity can indicate the strength of sorption of water and its mobility within the system. The mobility of water molecules in a system can be directly measured by nuclear magnetic resonance (NMR) and dielectric relaxation spectroscopy. The mobility of water in the system have been correlated to drug stability in drug-excipient mixtures in several cases; for example, degradation of trichlormethiazide in gelatin gel[18] and of cephalothin in its mixture with MCC.[19]

In addition, water activity is a direct indicator of the amount of free, mobile water in the system. Water activity is proportional to the RH in a closed environment produced in equilibrium with the solid excipient or drug-excipient mixture. Several authors recommend the use of water activity determination for DP stability correlation over the total moisture determination by Karl-Fisher titrimetry, water uptake by weight gain, or both.[20,21] Thus, Burghart et al. correlated the water activity of solid oral dosage forms of levothyroxine and lyothyronine with their chemical stability.[22]

Unbound, weakly adsorbed water contributes to molecular mobility within the system, which is a prerequisite for chemical reactions. Sorbed water plasticizes amorphous solids by reducing the glass transition temperature, Tg.[23,24] The Tg of an amorphous solid represents transition from a highly rigid, less mobile, glassy state to a rubbery, mobile state with higher free volume. Water sorption leading to a reduction in Tg is known in excipients such as starch, lactose, and cellulose,[25] and amorphous drugs such as indomethacin.[26] Molecular mobility of drugs and excipients in the solid state directly correlates with their reactivity.

The pH imparted by the excipient on the microenvironment of the solid state interfaces can have a significant impact on the chemical stability of the drug. For example, the degradation of a fluoropyridinyl drug in a capsule formulation was a function of the pH of the microenvironment facilitating a nucleophilic substitution reaction whereby the fluorine substituent of the pyridine ring was replaced with hydroxyl groups.[27]

Excipients can have an acidic or basic surface pH depending upon their chemical nature and composition. For example, Glombitza et al. measured the surface pH using pH indicator dyes and found that the surface of dicalcium phosphate was more acidic than that of MCC.[28] For soluble excipients, the pH of the excipient solution is a simple indicator of the pH imparted by the excipients in solid state. For insoluble excipients, the pH of 5–20% excipient slurry in water could be used as an indirect indicator. The selection of excipients with compatible pH profiles, based on preformulation solubility and stability studies as a function of pH, is helpful in the design of excipient compatibility experiments. For example, acid labile drugs are expected to be unstable in the presence of acidic excipients such as HPMC phthalate and HPMC-acetate succinate. Similarly, MgSt imparts a basic pH in its microenvironment and may contribute to the instability of base-labile drugs. Stanisz found that the chemical stability of quinapril hydrochloric acid (HCl) in binary drug-excipient mixtures was significantly better with acidic excipients than basic MgSt.[29] This study indicated that both the microenvironmental pH and humidity were significant factors in drug degradation. Thus, the presence of mobile water accelerates the surface pH effects of excipients by creating microenvironmental conditions of dissolved drug on the interacting surfaces.

Most drugs are salts of organic acids or bases, which may exist as free acid or base forms at acidic or basic pH, respectively. Since a minuscule amount of drug may be dissolved in the free water, pH-modifying excipients may result in the formation of the free acid/base form of the drug. If the free acid/base form is more unstable than the salt form, this would lead to enhanced degradation. It may also be volatile and be lost by sublimation from the dosage form, leading to mass balance issues in terms of loss of drug not being accounted for by the presence of degradation products.[30]

6.3.1.2 Reactions with excipients and their impurities

Although generally considered inert, pharmaceutical excipients are organic compounds with functional groups that may undergo chemical reactions in the dosage form, especially with the reactive functional groups of the APIs. Furthermore, pharmaceutical excipients carry trace-level reactive impurities that can either catalyze or directly participate in drug degradation.

A brief review of excipient synthesis, isolation, and purification can give vital clues about their potential impurities and other characteristics that may pose problems in the formulation. However, due to their proprietary nature, the availability of this information is difficult to come by and restricted to informal vendor discussions and perusal of the patent databases in most cases. Several examples of the presence and implication of reactive impurities in pharmaceutical excipients are known in the literature and can be used

as a guiding reference (Table 6.3). Listed here are a few illustrative examples:

- Reactions of reducing sugars (eg, lactose) with primary and secondary amine drugs via Maillard reaction, followed by Amadori rearrangement to produce a multitude of colored products, is well known. The general mechanism of these reactions involves the addition of the amine compound to the open form of the carbohydrate to form an iminium ion intermediate, which can either undergo a ring closure to a glycosamine compound or deprotonate to form the enol version of the Amadori rearrangement product[56] (Fig. 6.2a).
- Even a nonreducing sugar can contain trace levels of reducing sugar. In the case of starch, the terminal glucose was reported to have reacted with hydralazine in the formulation (Fig. 6.2b).[45]
- Formaldehyde and other aldehydes are known impurities in several excipients and packaging components, such as in polyethylene glycol (PEG); see Fig. 6.3. Formaldehyde is known to react with amine drugs to form N-formyl adducts (hemiaminals) that can further react to form dimers (Fig. 6.2c). Adefovir is known to react with formaldehyde to produce the reactive imine, which can further undergo nucleophilic addition with another amine molecule to form a dimer.[21] Nassar et al., showed that BMS-204352 formed an adduct (hemiaminal) with formaldehyde impurity in the solubilizers polysorbate 80 and PEG 300.[22] The impurity of lactose, 5-hydroxymethyl-2-furfuraldehyde, has been reported to react with the carbonyl (ketone) group of haloperidol to form a condensation product (Fig. 6.2d).[31]
- The formyl species could react with amines to form *N*-formamide. For instance, Waterman et al. reported that varenicline, a secondary amine can undergo N-methylation and N-formylation by reactive impurities (formyl and acetyl) found in the polymers used to manufacture osmotic tablets (Fig. 6.2e).[58] Formation of the stearoyl derivative of norfloxacin is attributable to the stearate component of MgSt. Similar to the mechanism shown in Fig. 6.2e, it can be conceived that the secondary amine in norfloxacin would undergo nucleophilic addition to form the stearoyl amide. Seproxetine undergoes a Michael addition reaction with its counterion to form two addition products[59] (Fig. 6.2f).
- The degradation of fosinopril sodium[55] in tablet formulations containing MgSt was attributed to chelation by the magnesium ions.
- Drugs with alcohol groups can form esters with acids (eg, formic acid) or undergo trans-esterification with esters (eg, parabens). Similarly acidic drugs can esterify with excipients containing alcohol groups such as PEGs.
- Trace levels of peroxides and metal ions in formulations are known to accelerate oxidation of drugs. Residual peroxides are also present in PVP, cross-linked PVP, and HPC. Moreover, their content shows both batch-to-batch and manufacturer-to-manufacturer variation.[60] In addition, peroxide levels can change as a function of storage temperature and humidity (Fig. 6.4).[61] The peroxides can cause free radical–initiated oxidation reactions, undergo nucleophilic addition reactions with tertiary amine to *N*-oxide, secondary amine to hydroxylamines, and sulfide to sulfoxide. For example, the hydroperoxide impurity in PVP has been shown to react with a piperazine ring to form N-oxide (Fig. 6.3g).
- Sodium glycolate is a residual reactant in the manufacture of the superdisintegrant sodium starch glycolate, and it has been known to cause degradation of drugs like duloxetine.[62]
- Silicon dioxide may contain significant levels of heavy metal impurities, which may act as catalysts in certain oxidative degradation reactions.

6.3.1.3 *Stabilizing excipients*

Although the focus of compatibility studies is on the identification of potential or seriously destabilizing aspects of drug-excipient interactions, excipients are often also utilized to improve formulation stability. For example, complexation with cyclodextrins has been shown to reduce drug instability in several cases.[63–65] Cyclodextrins internalize the labile drug inside their hydrophobic cavity and shield it from common degradation mechanisms such as hydrolysis, oxidation, and photodegradation.

Stabilization of oxidation-sensitive drugs by the incorporation of antioxidants in the formulation is a well-known strategy. The chosen antioxidants could be water soluble (eg, propyl gallate and ascorbic acid) or water insoluble (eg, butylated hydroxy anisole (BHA), butylated hydroxy toluene (BHT), or α-tocopherol). The choice of antioxidants is based not only on their solubility properties, but also on the mechanism of oxidation. Thus, compatibility studies often involve investigation of the relative efficacy of different antioxidants in mitigating drug degradation.

In addition, the heavy metal–catalyzed degradation reactions in formulations can often be mitigated by the use of chelating agents such as ethylene diamine tetraacetic acid (EDTA) or ethyleneglycol tetraacetic acid (EGTA). For example, EDTA was used to mitigate the oxidative degradation of dextromethorphan in its complexes with the ion exchange resin, divinyl benzene

TABLE 6.3 The Method of Manufacture of Common Pharmaceutical Excipients and Their Potentially Reactive Impurities

Examples of excipients	Method of manufacture	Potentially reactive impurities	Examples of known incompatibilities
Lactose	Lactose is a natural disaccharide consisting of galactose and glucose and is present in the milk of most mammals. Commercially, lactose is produced from the whey of cows' milk, whey being the residual liquid of the milk following cheese and casein production. Cows' milk contains 4.4−5.2% lactose, and it is 38% of the total solid content of milk.[10]	Lactose may contain glucose, furfuraldehyde, formic acid, acetic acid, and potentially other aldehydes.	Maillard reactions, Claissen-Schmidt condensation reaction of its impurity -hydroxymethyl-2-furfuraldehyde,[31] and catalysis of hydrolysis.[32,33]
Microcrystalline cellulose	Microcrystalline cellulose is manufactured by the controlled hydrolysis, with dilute mineral acid solutions of α-cellulose, obtained as a pulp from fibrous plant materials. Following hydrolysis, the hydrocellulose is purified by filtration and the aqueous slurry is spray-dried to form dry, porous particles of a broad-size distribution.[10]	The impurities in microcrystalline cellulose are glucose, formaldehyde, nitrates, and nitrites.	Water sorption resulting in increased hydrolysis,[17] Maillard reaction with residual glucose,[34] adsorption of basic drugs,[35] and nonspecific incompatibilities due to hydrogen-bonding capability.[36]
Povidone and crospovidone	Pyrrolidone is produced by reacting butyrolactone with ammonia. This is followed by a vinylation reaction in which pyrrolidone and acetylene react under pressure. The monomer, vinylpyrrolidone, is then polymerized in the presence of a combination of catalysts to produce povidone. Water-insoluble, cross-linked PVP (crospovidone) is manufactured by a polymerization process where the cross-linking agent is generated in situ.[10]	Povidone and crospovidone contain significant levels of peroxides. Povidone may also contain formic acid and formaldehyde.[37]	Oxidation attributable to peroxides,[38] nucleophilic addition to amino acids and peptides,[39] and hydrolysis of sensitive drugs due to moisture.
Hydroxypropyl cellulose (HPC)	HPC is a water-soluble cellulose ether produced by the reaction of cellulose with propylene oxide.[10]	HPC may contain significant levels of peroxides.	Oxidation of sensitive drugs due to residual peroxides.
Croscarmellose sodium	To produce croscarmellose sodium, alkali cellulose is prepared by steeping cellulose, obtained from wood pulp or cotton fibers, in sodium hydroxide solution. The alkali cellulose then reacts with sodium monochloroacetate to obtain carboxymethylcellulose sodium. After the substitution reaction is completed and all the sodium hydroxide has been used, the excess sodium monochloracetate slowly hydrolyzes to glycolic acid. The glycolic acid changes a few of the sodium carboxymethyl groups to free acid and catalyzes the formation of cross-links to produce croscarmellose sodium. The croscarmellose sodium is then extracted with aqueous alcohol and any remaining sodium chloride or sodium glycolate removed. After purification, croscarmellose sodium of greater than 99.5% purity is obtained. The croscarmellose sodium may be milled to break the polymer fibers into shorter lengths and hence improve its flow properties.[10]	Monochloroacetate, nitriles, and nitrates. Monochloroacetate can react with nucleophiles.	Weakly basic drugs can compete with the sodium counterion, thus getting adsorbed on the surface of the disintegrant particles.[40,41] Drug salt form conversion has also been reported.[42]

(*Continued*)

TABLE 6.3 (Continued)

Examples of excipients	Method of manufacture	Potentially reactive impurities	Examples of known incompatibilities
Sodium starch glycolate	Sodium starch glycolate is a substituted and cross-linked derivative of potato starch. Starch is carboxymethylated by reacting it with sodium chloroacetate in an alkaline medium, followed by neutralization with citric, or some other acid. Cross-linking may be achieved by either physical methods or chemically, by using reagents such as phosphorus oxytrichloride or sodium trimetaphosphate.	Monochloroacetate, nitriles, and nitrates are potentially reactive impurities.	Adsorption of weakly basic drugs and their salts due to electrostatic interactions.[43,44] In addition, the residual monochloroacetate may undergo S_N2 nucleophilic reactions.
Starch	Starch is composed of amylose and amylopectin, polymers of glucose connected by α 1,4 glycosidic linkages (in contrast to cellulose β1,4 linkages). Amylopectin has occasional branch chains connected by α 1,6 glycosidic linkages. Starch is extracted from plant sources through a sequence of processing steps involving coarse milling, repeated water washing, wet sieving, and centrifugal separation. The wet starch obtained from these processes is dried and milled before being used in pharmaceutical formulations. Pregelatinized starch is a starch that has been chemically or mechanically processed to rupture all or part of the starch granules and so render the starch flowable and directly compressible. Partially pregelatinized grades are also commercially available.	Starch may contain formaldehyde, nitrites, and nitrates.	Terminal aldehydes in starch have been known to react with the hydrazine moiety of hydralazine HCl.[45] Starch may also be involved in moisture-mediated reactions, may adsorb drugs, and may react with formaldehyde, resulting in reduced functionality as a disintegrant.[46,47]
Colloidal silicon dioxide		May contain heavy metal impurities.	May act as a Lewis acid under anhydrous conditions and may adsorb drugs.[48,49]
Stearic acid	Stearic acid is made via hydrolysis of fat by continuous exposure to a countercurrent stream of high-temperature water and fat in a high-pressure chamber. The resultant mixture is purified by vacuum-steam distillation and the distillates then separated using selective solvents. Stearic acid also may be made via hydrogenation of cottonseed and other vegetable oil; by the hydrogenation and subsequent saponification of oleic, followed by recrystallization from alcohol; and from edible fats and oils by boiling with NaOH, separating any glycerin and decomposing the resulting soap with sulfuric or hydrochloric acid. The stearic acid is then subsequently separated from any oleic acid by cold expression.		Stearic acid is incompatible with most metal hydroxides and may be incompatible with oxidizing agents. Insoluble stearates are formed with many metals; ointment bases made with stearic acid may show evidence of drying out or lumpiness due to such a reaction when compounded with zinc or calcium salts. A number of differential scanning calorimetry studies have investigated the compatibility of stearic acid with drugs. Although such laboratory studies have suggested incompatibilities (eg, naproxen), they may not necessarily be applicable to formulated products. Stearic acid has been reported to cause pitting in tablets coated using an aqueous film-coating technique; the pitting was found to be a function of the melting point of the stearic acid. Stearic acid could affect the hydrolysis rate of API if the degradation is pH dependent. It could also potentially react with an API containing a primary amine to form a stearoyl derivative.[50,51]

(*Continued*)

TABLE 6.3 (Continued)

Examples of excipients	Method of manufacture	Potentially reactive impurities	Examples of known incompatibilities
Magnesium stearate	Magnesium stearate is prepared either by chemical reaction of aqueous solution of magnesium chloride with sodium stearate, or by the interaction of magnesium oxide, hydroxide, or carbonate with stearic acid at elevated temperatures. The raw materials used in manufacturing of magnesium stearate are refined fatty acids, which is a mixture of palmitic and stearic acid with certain specifications. A fatty acid splitting (hydrolysis) process takes place first, where glycerin and fatty acids are separated. The fatty acids are then further refined to yield tallow acid. Magnesium stearate can be prepared through two processes:1. Fusion—Simple acid-base interaction between tallow acid and magnesium hydroxide2. Saponification—Tallow acid is saponified first with sodium hydroxide, making a sodium tallowate (salt), then magnesium sulfate is added to the sodium tallow solution, followed by pH adjustment, dilution with water, washing, and drying.	Magnesium oxide is a known reactive impurity.	Magnesium stearate can form hydrates with water and exists in four hydration states—monohydrates, dehydrates, and trihydrates.[52] MgO impurity is known to react with ibuprofen.[53] In addition, magnesium stearate provides a basic pH environment and may accelerate hydrolytic degradation.[54] The magnesium metal may also cause chelation-induced degradation.[55]

sulfonic acid.[66] EGTA has a much higher affinity for calcium and magnesium ions than EDTA.

Stabilization of hydrolysis-sensitive drugs intuitively disallows the selection of excipients with high residual moisture content and high water sorption capacity. Nonetheless, excipients with affinity for water might mitigate moisture sensitivity of the formulation by preferentially taking up the moisture permeating through the package during shelf-life and accelerated storage. For example, edible silica gel, Syloid, was used to stabilize extremely moisture sensitive potassium clavulanate in oral solid dosage forms.[67] An interesting case was presented by Perrier and Kesselring of the stabilization of nitrazepam in binary mixtures with excipients as a function of their nitrogen adsorption energy.[15] The authors assumed that the binding energy for water followed the same rank-order correlation as that of nitrogen. The use of excipients with higher binding energy was hypothesized to sequestrate any available moisture and act as a stabilizer. Similarly, it can be hypothesized that the use of excipients that act as sorbents (eg, MCC and amorphous silica) might sequestrate reactive trace impurities (eg, formaldehyde and formic acid and volatile residues such as methanol, ethanol, and isopropyl alcohol) from the formulation.[68] These strategies may be tested in applicable cases by spiking studies in the binary compatibility experiments or the use of mini-formulation designs that combine the offending and the protecting excipients.

Exposure to light can cause drug degradation by various mechanisms such as addition reactions in unsaturated systems, polymerization, isomerization, photo-oxidation, and substitution reactions. The use of light-resistant packaging, for example, amber glass and opaque high-density polyethylene bottles, are standard practices for photolabile drugs. In addition, to protect the drug during processing and packaging operations, light-resistant film coatings and the use of excipients such as cyclodextrins, dyes, and colored additives is often helpful. In addition, photolabile excipients can be used in the formulation of photosensitive drugs just as antioxidants are used for oxidation-sensitive drugs. In this case, substantial overlap of the ultraviolet (UV) absorption spectrum of the excipient with the drug has been shown to improve the drug stability in several cases (eg, stabilization of nifedipine by using riboflavine or curcumin and the stabilization of sulphisomidine by using oxybenzone).[68]

6.3.2 Current practices

Compatibility studies involve a series of activities designed to identify key drug-excipient incompatibilities and their causes (Fig. 6.5). Compatibility studies on new

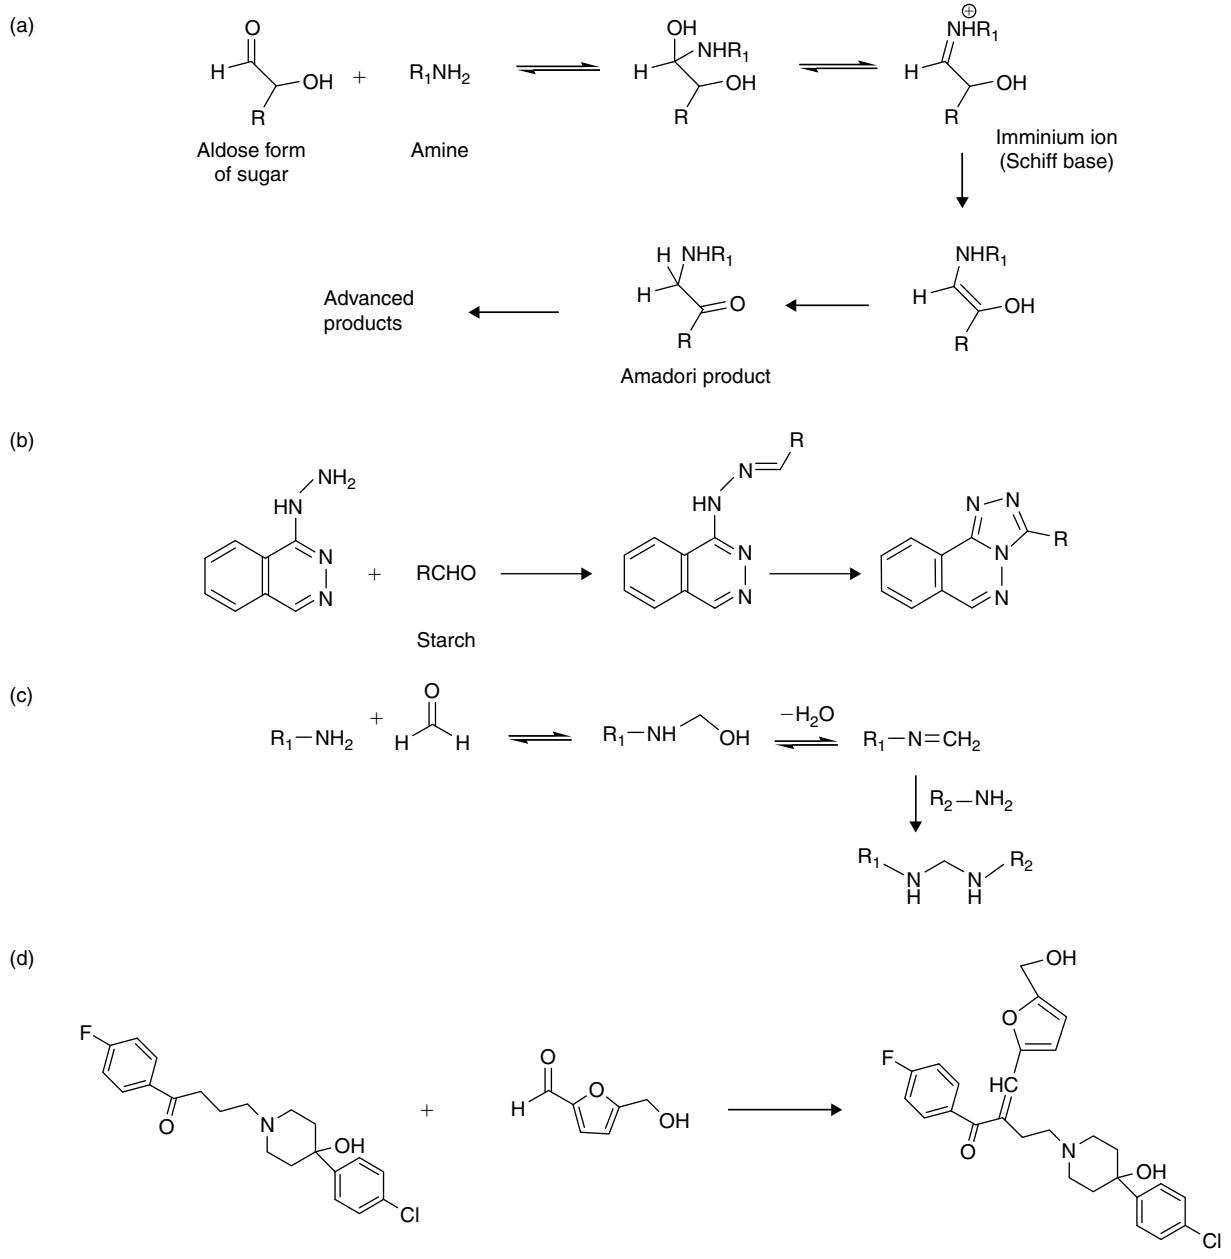

FIGURE 6.2 Examples of reactions of drugs with pharmaceutical excipients and their reactive impurities; (a) reaction of primary amine with a reducing sugar; (b) reaction of hydralazine with terminal aldehydes of starch residue; (c) reaction of an amine with an formaldehyde; (d) reaction of haloperidol with the impurity 5-hydroxymethyl-2-furfuraldehyde (HMF) found in lactose; (e) addition of formic acid to (f) addition of amine to maleic acid; (g) formation of N-oxide from hydrogen peroxide impurity.

molecular entities invariably start with the evaluation of existing information and paper chemistry of the drug candidate to identify "soft spots" in the molecule. The presence of reactive or unstable functional groups, pK_a value, and known reactivity of similar compounds provides useful information for the selection of excipients. In addition to the general literature, several computational programs have recently become available that can help predict potential degradation pathways of a drug candidate (eg, CAMEO, SPARTAN, EPWIN, and Pharm D[3]). Many pharmaceutical companies also have internal databases and software programs. Furthermore, preformulation studies on the physicochemical characterization and forced-degradation of the drug molecule are used to modulate the design of compatibility studies to detect the presence and extent of known reactivity.

The design of compatibility studies might involve the use of mixtures of drugs with one or more excipients. These mixtures may be incubated at different stress conditions as physical mixtures per se or after

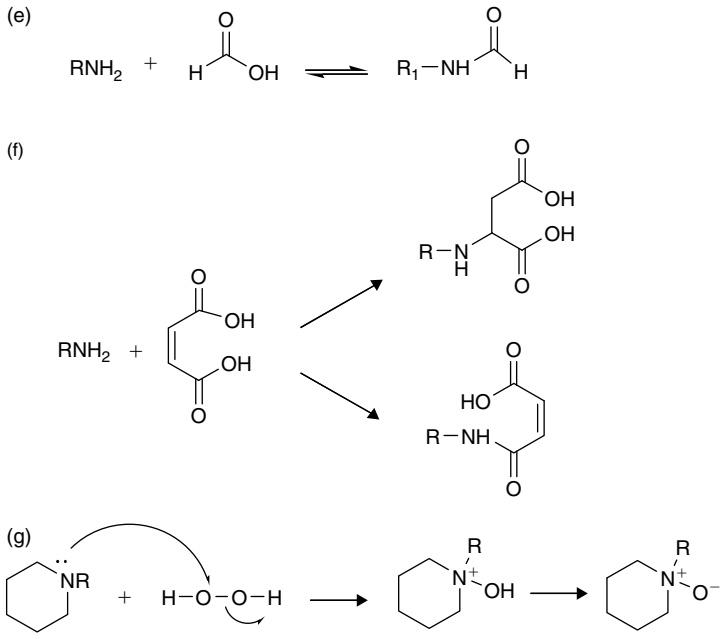

FIGURE 6.2 (Continued)

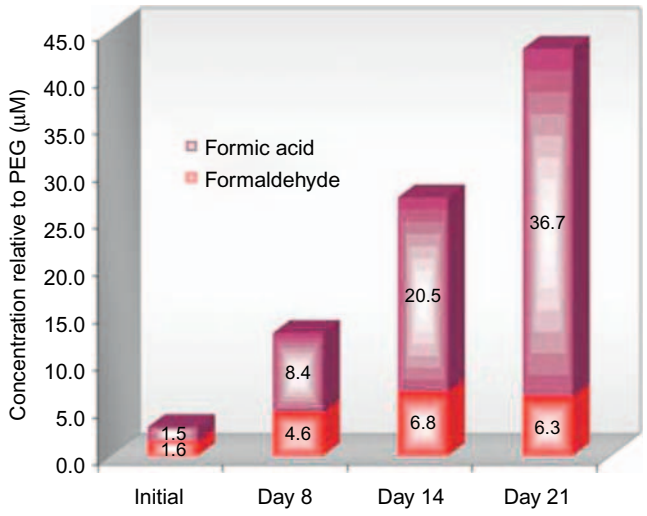

FIGURE 6.3 Generation of formaldehyde and formic acid in poly (ethylene glycol) (PEG) 400 mixed in a 1:1 w/w ratio with water when stored in glass vials with aluminum-crimped rubber septa at 40°C for up to 21 days.[57]

compaction. Often water is added in these systems to evaluate its role in accelerating drug-excipient interactions. The addition of other ingredients, such as hydrogen peroxide to induce oxidative stress, is based on the background information of the molecule's sensitivities. The compatibility study samples are typically stored at elevated temperatures and analyzed for physical and chemical changes in the drug at predetermined time intervals. In addition, binary mixtures of drug and excipients are analyzed by thermal methods such as differential scanning calorimetry (DSC) and isothermal microcalorimetry (IMC) for rapid assessment of potential incompatibilities. In short, compatibility studies involve several choices for each stage of testing depending on the drug candidate, available literature, and the goals of the study. The following sections of this chapter will highlight the basis for some of these decisions.

6.3.2.1 *Experimental design*

Compatibility studies are commonly carried out by accelerated stress testing and evaluation of its effect on the binary or multicomponent drug-excipient mixtures. The design of experiments (DoE) is governed by the potential formulation choices and excipient preferences. These decisions are made in conjunction with all the other available preformulation data, API characteristics, and marketing preferences. These also determine the types of pharmaceutical excipients that are evaluated. For example, compatibility studies for a liquid formulation of an insoluble compound would differ widely (eg, include excipients such as surfactants and suspending agents) from the studies designed for a highly soluble compound.

6.3.2.1.1 Two-component or multicomponent systems

Proactive preformulation compatibility studies are traditionally carried out as binary or ternary systems. Binary mixtures of drug and common pharmaceutical excipients such as diluents, or ternary mixtures of drug, a diluent, and excipients used in lower proportions such as disintegrants and lubricants are incubated at

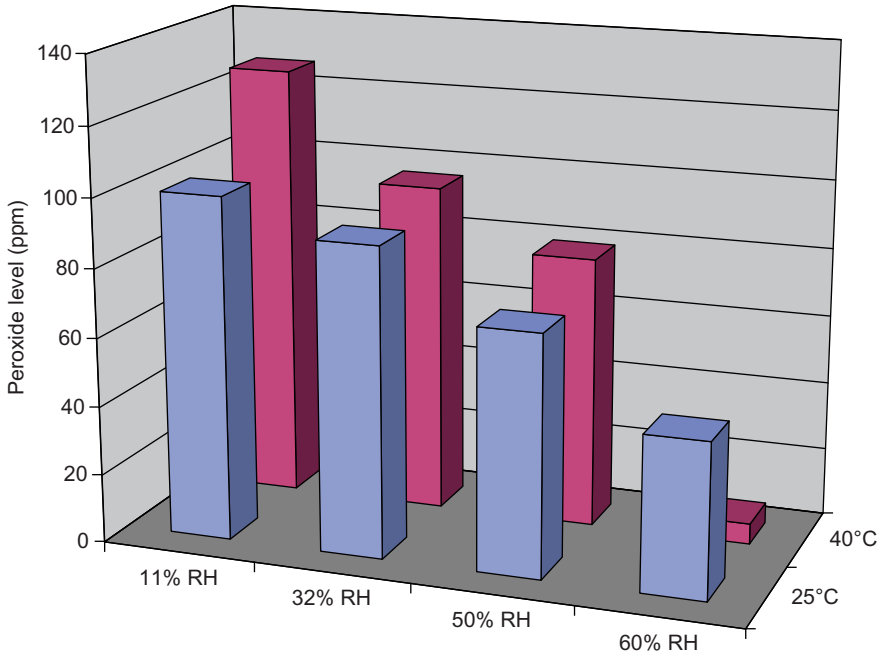

FIGURE 6.4 Effect of storage temperature and humidity (under open-dish conditions) on peroxide levels in povidone (initial level = 80 ppm).[61]

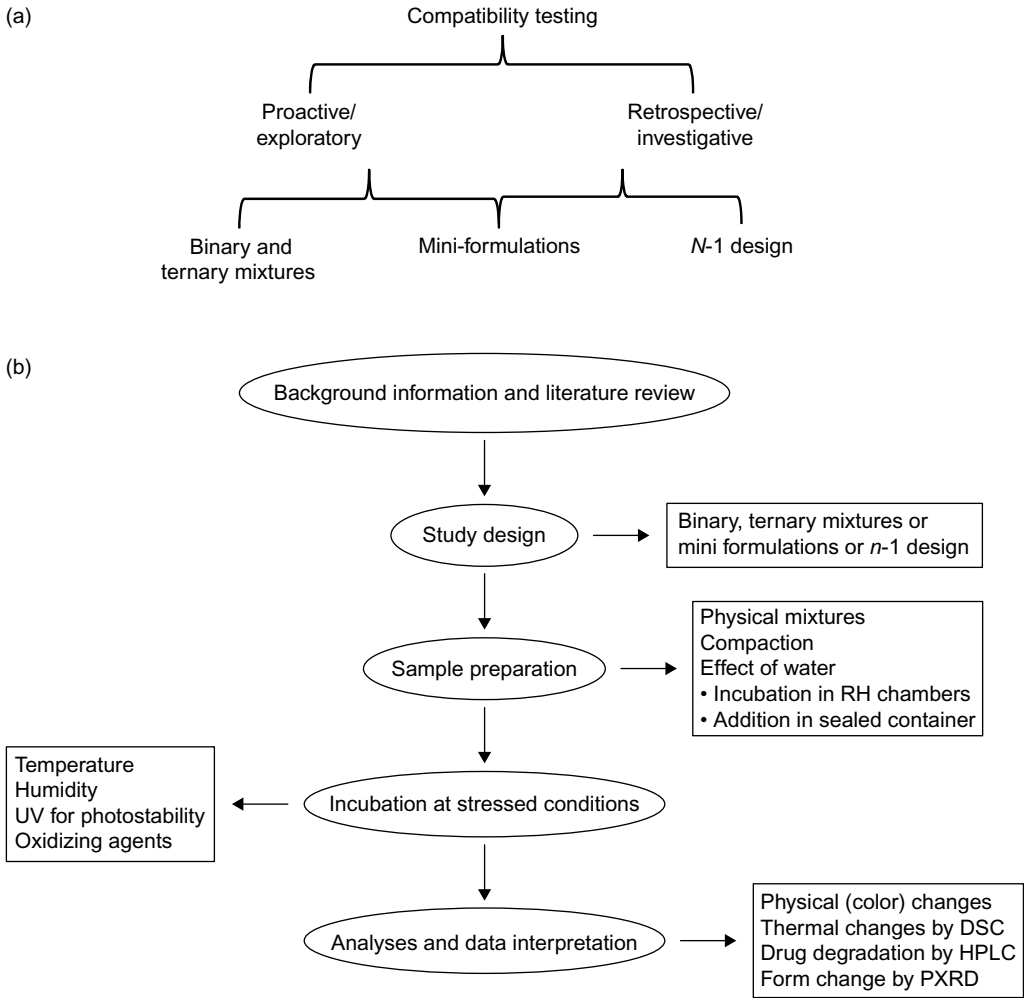

FIGURE 6.5 Typical modalities of compatibility testing (a) and the study execution (b). Various stages of the compatibility testing are highlighted in ovals, and the key decisions and variables involved in each stage are in square boxes.

accelerated conditions of temperature and humidity for extended periods of time, using the drug alone and the excipient alone as controls. Additional aggravating conditions, such as light and peroxides, are incorporated in the study design depending upon the characteristics of the drug molecule. Incompatibilities are physically identified by visual observation for color or physical form changes and spectroscopic and calorimetric methods, and chemically quantified by analytical assays for drug content and impurities.

Wyttenback et al. used binary design to study the excipient compatibility of acetylsalicylic acid or fluoxetine HCl in binary mixtures with 7 excipients using bilevel factors of temperature (40°C and 50°C), humidity (10% and 75% RH), and time (1 and 4 weeks), for a total of 56 experimental runs for each drug.[69] The total impurity content of each run was measured by high-performance liquid chromatography (HPLC) to determine the effect of each excipient on drug stability. In addition, they grouped together all excipients as a factor and interpreted the data by analysis of variance using F-ratio to test whether the means of normally distributed populations are equal, and then calculated the *P*-value. The data presented interesting insights into the relative stability of the two drug substances as a function of these factors and their interactions.

6.3.2.1.2 The $n-1$ design and mini-formulations

Compatibility studies are often aimed at solving formulation stability issues. In such cases, studies are carried out with the exclusion of only one component in each sublot to identify the source of incompatibility. Often, mini-formulations are prepared with the exclusion of noncritical, quantitatively minor, or easily interchangeable ingredients (eg, colors and flavors from solutions and suspensions). Compatibility studies for the development of liquid formulations are invariably mini-formulation studies since they require prior pH solubility and stability evaluation to use the appropriate buffer system in compatibility testing and base formulations.

The Plackett–Burman design may be used to design studies involving mini-formulations, although it is rarely used in practice. This design minimizes the number of experimental runs and is capable of finding the excipients that cause major incompatibilities. It can examine n excipients in $n+1$ experimental runs.[70] This design was utilized by Durig and Fassihi to investigate the compatibility of pyridoxal HCl with 11 excipients at two temperature (25°C and 55°C) and humidity (11% and 75% RH) conditions using only 16 experimental runs.[71] In this study, they included eight experiments over the minimum required to study the effect of "pseudovariables" to account for random experimental variation. This approach, however, does not take into account the variation in the concentration of excipients depending upon the number of components present in the mixture.

6.3.2.2 *Sample preparation and storage*

Sample preparation for compatibility studies depends on the physical nature of the ingredients and the conceptualization of the final formulation. The selection of appropriate drug-to-excipient ratios for binary compatibility studies is often carried out on a weight or molar basis of their expected usage in the final formulation. In the absence of a defined dose of the drug, as is often true of new molecules in the early stages of development, the worst-case scenarios of the lowest drug-to-excipient ratios are tested.

The lowest drug-to-excipient ratio is expected to provide the highest rate of possible drug-excipient interactions. For example, the amorphous calcium salt of the Merck compound L-649,923, a leukotriene D_4 antagonist, degraded by intramolecular esterification to form a γ-lactone. Its degradation rates were higher at lower drug doses with both MCC and pregelatinized starch as excipients.[72] These observations are in line with the hypothesis that reactions happen at the interface of the drug and the excipients. A higher rate of drug degradation with lower-particle-size excipients further supports this hypothesis. Thus, hydrolysis of acetylsalicylic acid in tablets containing dibasic calcium phosphate dihydrate showed a rank-order correlation with the particle size of the excipient.[73] Similarly, powdered MgSt showed higher levels of drug degradation than its granular form.[54]

6.3.2.2.1 Sample preparation

Binary mixture designs for solid-state samples often involve only physical mixing. Attention must be paid to the use of fine particles of both the drug and the excipient, as well as deagglomeration of either component, if needed. Often, coscreening through a mesh is utilized to effect intimate mixing. Compaction of drug-excipient mixtures is carried out in solid-state compatibility testing. Milling and compaction of crystals can lead to the formation of an amorphous state.[74] Process stresses such as compaction, grinding, and drying may also lead to release of bound water from actives and excipients. For example, grinding was shown to dehydrate the crystal water of theophylline hydrate[75] and affected the solid-state stability of ampicillin trihydrate[76] and sodium prasterone sulfate.[77] Similarly, cifixime trihydrate showed a reduction in crystallinity and dehydration upon grinding in a ball mill.[78] Thus, compatibility studies involving grinding and compaction are helpful for moisture-sensitive and low-melting compounds, as is also the case for drug substances for which milling is envisaged for particle-size reduction.

The presence of water often accelerates degradation kinetics. In addition, sorbed moisture can accelerate isomerization, crystallization, or both. One of the important goals of preformulation compatibility testing is to determine the feasibility of processing conditions such as wet granulation and the moisture resistance need for packages. Thus, it becomes important to determine the case and extent of moisture sensitivity of the drug in the presence of excipients. To this end, water is often added to drug-excipient binary mixtures in closed systems to create a high-RH environment.[78] Alternatively, the compatibility mixtures are stored in open containers at different temperature and RH conditions. Care must be exercised in comparing the data across these designs since the potential volatilization and escape of reactive components in the open-container storage conditions might give an indication of stability that may not hold true in the final dosage form.

Compatibility study experiments tend to be labor intensive due to their exhaustive design. Automation of compatibility studies is often undertaken during the early development stages.[79] The automated systems can be used for determining drug solubility, forced degradation, and compatibility testing. Reactor blocks, consisting of an array of samples, can be prepared using automated liquid handlers and powder dispensers such as Autodose and Gilson liquid handler. The blocks can be stored in different stress conditions. Automated sampling at predetermined time points can be accomplished using robotic systems such as Jaba. These operations also may be performed with fully automated systems such as the Symyx Automated Forced Degradation System. This system can accurately weigh given quantities of excipients and actives in blocks of vials. The blocks are then robotically transferred to controlled environmental chambers and removed at a predetermined time for analysis. The use of automated systems improves efficiency and broadens the experimental space, allowing the execution of exhaustive, statistically robust experiments and generation of knowledge. This, when coupled with scientific rigor, could significantly reduce or even avoid the appearance of drug-excipient incompatibilities during later stages of DP development.

The selection of accelerated environmental storage conditions for compatibility testing is based upon the nature of the API and the expected stresses during the storage of the finished dosage form. These include storage at elevated temperatures, higher humidity, and exposure to UV irradiation, peroxides, etc. While the International Council on Harmonization (ICH) and the regulatory authorities provide guidelines on the selection of accelerated storage conditions for the finished dosage form for confirmatory stability studies based on the target label storage requirements, the selection of accelerated conditions for compatibility studies is at the formulator's discretion.

6.3.2.2.2 Thermal stresses

Isothermal stress testing (IST), or incubation of samples at constant higher temperatures as stress conditions, is almost universal for compatibility studies. It is based on the underlying assumption that the kinetics of degradation reactions follows Arrhenius kinetics. The Arrhenius equation states the reaction rate dependence on temperature:

$$k = A \times e^{-E_a/RT}$$

where T is the temperature (in Kelvin), R is the gas constant with a value of 8.314 J/(K × mol), E_a is the activation energy in KJ/mol, k is the reaction rate constant, and A is the Arrhenius constant.

The selection of higher temperatures is designed to accelerate reaction rates significantly so that even relatively slow reactions become evident in a short period of time. For example, assuming the mean activation energy for solid state reactions to be 105 kJ/mol,[80] the amount of drug degradation observed at 25°C in approximately 5 years would be evident in about 3 weeks at 60°C. Certain implicit assumptions of IST include:

- Temperature independence of activation energy and reaction mechanism
- Absence of equilibrium or autocatalytic reactions
- Activation energies for different reactions of pharmaceutical relevance in a relatively close range
- Stability of API per se under the stress conditions.

The temperature is often maximized to increase reaction rate and decrease testing time. However, care must be exercised in the judicious selection of temperature since above a certain temperature, the system may exceed the activation energies of alternative degradation pathways, resulting in nonrepresentative data. A shift in the primary degradation processes is often indicated by the appearance of additional impurity peaks in the HPLC chromatogram. For example, while exploring accelerated degradation conditions for an experimental compound, Sims et al. observed that while temperatures up to 80°C resulted in the formation of the same impurities as controlled room temperature and 60°C, samples stressed at 100°C showed many unrelated peaks.[81]

Therefore, usually more than one stress condition is chosen to determine if the degradation reactions observed at elevated temperatures might be the ones that have such high activation energies that they occur only under pharmaceutically irrelevant conditions.

6.3.2.2.3 Humidity and water content

The use of high moisture content for compatibility studies is intended to uncover not only the reactions in which water participates directly (eg, hydrolysis), but also to investigate whether water increases reactivity in the solid state. Water adsorption on solid surfaces

can enhance reactivity by acting as a medium or a plasticizer for the reacting species. The presence of water in the solid component mixtures provides the molecular mobility required for reactions to occur between the two solid components.

Water can be incorporated in the excipient compatibility samples in several ways: (1) preparation of a slurry or suspension; (2) addition of water, usually 20% of solids, in a closed system[81]; and (3) exposure of the system to controlled humidity conditions.

Each of these methods has advantages and disadvantages. While the slurry experiments provide useful information for the simulation of suspension dosage forms and rapid assessment of aqueous sensitivity of the drug substance, they often do not simulate conditions in solid dosage forms, which could be important to data interpretation in retrospective or investigational compatibility studies. The addition of a fixed proportion of water to the drug-excipient mixture in a closed system controls the initial amount of water in the system and partly simulates wet-granulation conditions. Nevertheless, the water content in a sample changes depending on the water uptake kinetics and equilibrium moisture content of the sample at the storage temperature. Moreover, the same amount of water in the air results in lower RH at elevated temperatures. In contrast, incubation of samples under controlled humidity conditions ensures consistent maintenance of equilibrium moisture levels in the solid system, enabling the investigation of degradation reactions where water acts as a medium or just to increase the molecular mobility of reacting species.[81] However, the open-container studies may lead to loss of reactive volatile impurities from the mixture, possibly altering the reaction pathways. In addition, storage of samples in constant humidity chambers (eg, open dish) can lead to increased induction times compared to water addition (or slurry experiments), thereby complicating kinetics.

Given the pros and cons of each modality of testing, the formulation scientist must select appropriate conditions for each compatibility study design based upon the available preformulation data.

6.3.2.2.4 Mechanical stress

Mechanical stress is often an unavoidable part of DP processing conditions (eg, milling and compaction). These stresses may lead to the formation of amorphous pockets of drug or crystal defects in the crystalline drug molecule, or simply increase the intimacy and surface area of contact between the drug and the excipients in the mixture. Thus, mechanical stresses may lead to increased rates of degradation reactions. For example, milling of Procaine Penicillin G almost doubled its rate of degradation in compatibility studies with Emcompress and Avicel as compared with the unmilled drug-excipient mixtures.[82] Similarly, Badawy et al. observed more than threefold higher hydrolytic degradation of an investigational compound DMP-754 in compacts with anhydrous lactose as compared to uncompacted binary mixtures.[83]

In addition to chemical reactivity, compaction may have an effect on the physical form of the drug. Thus, Guo et al. observed a loss of crystallinity of quinapril hydrochloride, whose crystalline form exits as an acetonitrile (ACN) solvate, with ACN loosely incorporated into the crystal lattice channels. Loss of ACN was observed upon compaction, with concomitant loss of crystallinity and increase of the cyclized degradant. This was attributed to the significantly reduced activation energy for the cyclization reaction in the amorphous state than the crystalline state.[84]

Investigations of the effect of mechanical stresses are undertaken when instability is suspected in the investigational drug (eg, in situations such as the use of a metastable polymorphic form or known chemical reactivity of the molecule). Simulation of mechanical stresses in compatibility studies involves such procedures as grinding using a ball mill and comilling of drug-excipient mixtures. In addition, a Carver press for the preparation of compacts is often utilized to simulate the compaction during tableting and dry granulation.

6.3.2.2.5 Oxidative stress

Oxidation is one of the most common causes of drug degradation in pharmaceutical systems. Oxidative degradation often presents unique patterns of drug degradation (eg, rapid growth of impurities following an induction period and sensitivity to trace amounts of free radicals). If preformulation or API characterization studies reveal sensitivity to oxidation, the compatibility studies may be designed to comprehensively assess the extent of oxidation sensitivity as well as to find ways to mitigate the same. These methodologies include, for example, one or more of the following:

- Spiking drug-excipient mixtures with different levels of oxidizing agents, such as hydrogen peroxide; metal impurities (copper and iron salts); or free radical initiators commensurate with the levels seen in excipients[85]
- Comparing drug degradation in compatibility samples stored under air, oxygen, and nitrogen or argon in hermetically sealed containers
- Incorporation of free-radical scavengers and heavy metal chelating agents[85]
- Packaging configurations that include the incorporation of oxygen scavenger inserts and the minimum permeability materials of construction[86]
- Use of different batches of excipients known to have residual peroxide content (eg, PVP, cross-linked PVP, HPC, polysorbate 80, and PEG 400)[38]

- Studies with different antioxidants (eg, BHA, BHT, α-tocopherol, propyl gallate, and ascorbic acid)[87]

For these studies, sample preparation conditions, such as compaction, should be carefully controlled. Furthermore, peroxide impurities in excipients usually show batch-to-batch variation, thus necessitating the testing of batches with high- and low-level impurities. Spiking experiments are often carried out to quantify the acceptable limits of peroxide impurities in excipients, which may then be used to set incoming material specifications.[38]

6.3.2.3 Sample analysis and data interpretation

The desired tests for a given set of compatibility studies and the key outcome measures depend not only on the envisaged final dosage form and product configuration, but also on the background data available on the chemistry and preformulation studies on the drug candidate. Most compatibility studies include visual inspection for any color changes, compact/tablet integrity, and deliquescence; and quantitative chemical analysis for monitoring drug degradation. In addition, form changes of the active are monitored in samples of short-listed excipients.

6.3.2.3.1 Monitoring for drug degradation

Physical observation of stressed compatibility samples involves the observation of changes in color, odor, deliquescence, powder/compact flow characteristics, and other characteristics. The inherent subjectivity in these observations is partly overcome by making rank-order correlations with control, refrigerated, samples. Furthermore, UV-visible spectroscopy may be utilized to quantify changes in color. This method, however, suffers from the limitation that small changes in absorbance may not appear to be significantly different and the degradants may retain the chromophores of the drug, leading to negligible or no change in absorbance even in the presence of degradation. Nevertheless, when significant differences are seen, these observations are often a good indicator of incompatibility between the components.

Several drugs show such evidence of discoloration as an indication of instability, incompatibility, or both, including promethazine, phenylephrine, potassium clavulanate, cefuroxime axetil, and terbinafine. A common example is the discoloration (often browning) of formulations containing primary or secondary amines with reducing sugars such as lactose.[88] This is associated with the Maillard reaction, whose end products can undergo Amadori rearrangement to form several colored intermediates and end products.[56]

HPLC with UV detection is by far the most commonly used method to quantify drug degradation by measuring drug potency, total impurities, or the growth of a selected impurity over time and as a function of the storage conditions. Measurements of growth of a single impurity or all impurities are often preferred over the quantification of loss in potency. This is because a small change in a large number reduces the sensitivity in the interpretation of the data; for example, a potency drop from 99.5% to 99.2% would likely be considered insignificant, but not an impurity level increase from 0.02% to 0.32%.

It is important that the sample extraction, along with the analytical methodology, is sound. Particular attention should also be paid to the lack of mass balance issues, which can arise either due to poor extraction or retention of degradation products on the column or due to reduction in the response factor of the degradation products. When extraction problems are suspected, alternate solvents and agitation techniques should be utilized. To ensure that the column retention is not an issue, HPLC systems with a wide polarity range and longer run times can be employed. If the mass balance issue is severe, the relative response factors of drug and impurities may be assessed by taking the ratio of absorbance of the degraded sample to that of the initial (reference) sample measured by UV alone. This ratio should be identical to the ratio of total area counts for the degraded and initial sample as determined by HPLC-UV. The main disadvantage of this method is that it is useful only when there is a severe mass balance issue. Although not used in routine analyses, alternative detectors such as evaporative light scattering detector, refractive index detector, mass spectrometry, Corona charged aerosol detector, chemiluminescent nitrogen detector, or LC/NMR can be used when UV detection is not effective.

6.3.2.3.2 Thermal methods

The use of a quantitative, stability-indicating analytical method such as HPLC may not be feasible during the early stages of drug development. In such cases, thermal methods may provide a quick, nonspecific, and less labor-intensive screening tool. It must be noted that results obtained from thermal methods are often not conclusive and must be confirmed by another independent observation.

Thermal methods for compatibility testing rely on exothermic or endothermic energy changes in the sample. The most commonly applied thermal technique for compatibility studies is DSC. It involves heating or cooling the sample in a controlled manner and measuring the heat released or absorbed by the sample as the temperature of the sample and a reference standard are equally changed over time. IMC, on the other hand, measures heat flow from the sample compared to a reference vessel as the two are maintained at a

constant temperature. IMC can be applied to detect extremely slow reactions since this technique allows the measurement of very low amount of heat changes. This allows the ability to monitor reactions in drug-excipient mixtures at room or low temperatures. Thus, reactions that are relatively slow and affect the formation of impurities in DP over prolonged shelf-life storage (ie, reactions of real-life significance) can be monitored using IMC.[89,90]

DSC analyses for compatibility evaluation involves recording the thermograms of the individual excipient, the drug, and their physical mixture at a standard heating rate, usually under a nitrogen atmosphere. A simple superimposition of these curves is then interpreted to determine whether the thermal properties of the mixture are a sum of the individual components, an assumed fundamental property of noninteracting components. An interaction is, thus, identified as changes in the appearance or disappearance of a transition peak and through changes in transition temperature, peak shape, and peak area. Nonetheless, caution should be exercised in interpreting the results of DSC for determining excipient compatibility and it should be in conjunction with simultaneous application of other techniques such as infrared (IR) spectroscopy and IST. For example, Verma and Garg utilized physical observations, IR spectroscopy, and IST in conjunction with DSC to determine excipient compatibility.[91]

IMC can measure thermodynamic events in powder mixtures at real-time storage conditions, thus potentially pointing to the degradation reactions that are of relevance in the long-term stability studies of the DP. For example, it can pick up reactions that may lead to only 1−2% degradant accumulation over a year of storage at room temperature. The high sensitivity of this technique necessitates careful control of sample preparation (eg, the uniformity of particle size of different samples, adequate mixing, and the effects of moisture). Schmitt et al. used IMC to study the compatibility of an experimental compound ABT-627 in binary mixtures with excipients.[92] Selzer et al. reported IMC studies on drug-excipient mixtures as powders, granules, and compacts.[93,94]

6.3.2.3.3 Monitoring for form changes

The drug discovery and early-stage development work is aimed at selecting not only the right molecule, but also its most preferred solid form. The physical form of the drug, polymorphic and salt form, has a significant impact on the physical, chemical, mechanical, and biopharmaceutical properties of the drug candidate. For example, a state with higher thermodynamic activity (eg, the amorphous phase) generally has higher apparent solubility and diffusion-controlled dissolution rate, as well as higher hygroscopicity and chemical reactivity. It also has a tendency to crystallize to a more stable form. The mechanisms underlying phase transformations have been discussed in the literature.[95,96] It is important to ensure that dosage form composition and processing conditions do not alter or destabilize the physicochemical form of the drug. It must be noted that although these investigations are not a routine part of compatibility testing, they become very important if a metastable form is taken up for development or if there is data on the API stability that warrants monitoring for form changes.

Several analytical techniques can be utilized for the characterization of drug's form in the solid state, for example, powder X-ray diffraction (PXRD), single crystal X-ray diffraction, IR and near-infrared (NIR) spectroscopy, Raman spectroscopy, solid-state NMR spectroscopy, solvent sorption, polarized microscopy, and hot stage microscopy. An example of the application of instrumental techniques to identify the impact of excipients on potential form change of the drug during wet processing was presented by Airaksinen et al. using nitrofurantoin as a model drug.[97] Nitrofurantoin exists in two anhydrous (designated α and β) and two monohydrous (designated I and II) forms. High-humidity storage and processing conditions (eg, wet granulation) may lead to the conversion of the anhydrous to the monohydrate form. The authors used PXRD and NIR spectroscopy to investigate form transformation of nitrofurantoin in physical mixtures with selected excipients. Their interpretation of PXRD data focused on the appearance of a peak specific to the monohydrate form that indicated form conversion. Similarly, NIR data was interpreted for the appearance of the absorption maxima for the water of crystallization in the monohydrate form. Such data sets help in establishing the rank order relationships of the tendency of excipients to support or inhibit form conversion of the drug. The authors correlated the water sorption capacity and the amorphous/crystalline nature of the excipients with their role in moisture-induced form change of nitrofurantoin during processing. Their work demonstrates the utility of these techniques in investigating drug form changes as a part of the compatibility studies.

6.4 EXCIPIENT VARIABILITY

The drug-excipient and excipient−excipient interactions in dosage forms can significantly affect both the stability[98] and the bioavailability[99] of the drug substance or the API.[100] The mechanistic basis of such effects could be a direct interaction between the drug and the excipient, reaction of an API with the reactive impurities that may be present in excipients,[101,102] or indirect effect of excipients on DP attributes such as the water

activity of the dosage form[103] and its densification.[104,105] Variability in excipient properties that contribute to their effect on DP attributes can, therefore, lead to batch-to-batch variability in DP QAs. To obviate these possibilities, as a rule of thumb, simple formulations that minimize the use of excipients to essential functional ingredients is preferred.[106] In addition to a thorough mechanistic understanding of physicochemical interactions in a DP, identifying relevant excipient properties that contribute to critical product attributes and delineating their normal acceptable and generally observed variation is critical to robust DP design.

QAs of excipients do vary—not only between different grades and types of excipients, but also within the same excipient. Variability of excipient attributes could be source-to-source variability or lot-to-lot variability for the same grade and source of excipients. These have also been termed *intersource* and *interlot variability*, respectively. Intersource variability is much easier to control. It is usually done by establishing and controlling the source of raw materials. Interlot variability, however, can be difficult to identify, understand, and control, especially when these are outside the types of material properties reported on the vendor's certificate of analysis (CoA). Such properties may include, for example, compression properties of Elcema G250, an α-cellulose product,[107] lubrication properties of MgSt,[108–110] and compaction properties of starch.[111] The extent of lot-to-lot variability could be different from one supplier to another. For example, when Williams et al.[112] studied different particle-size grades of MCC using six different suppliers and two lots per supplier, they observed greater lot-to-lot differences with the material supplied from some suppliers than others. This section primarily focuses on the interlot variability of excipients and suggests a set of approaches that can be proactively adopted to understand and account for the lot-to-lot variability encountered with excipients when designing robust DPs and input material control strategies.

Addressing excipient variability during DP development has the following components[113]:

1. Identification of critical excipients in a given DP
2. Understanding of the mechanistic basis of functional role of the critical excipients
3. Identification of CMAs of the excipient that affect DP performance
4. Developing an understanding of the range of excipient QAs that are or may be routinely encountered during DP development
5. Building a DP design space or QbD strategy that incorporates the observable differences in excipient QAs

6.4.1 Identification of critical excipients

Pharmaceutical development of new DPs routinely address the effect of formulation composition (both qualitative and quantitative) and process parameters on DP QAs.[6] Excipients are utilized in the DPs to aid in the bioavailability, stability, or manufacturability of a dosage form. Most functional excipients utilized in the DP fulfill one or more of these roles. At the same time, the criticality of an excipient is usually assessed with respect to the influence of variability in excipient attributes on the patient-centric QAs. Certain excipients, such as colloidal silicon dioxide, are added to oral solid dosage forms as functional excipients that help with the flow and prevention of sticking of the granulation during manufacture. These excipients are important for developing a robust DP manufacturing process. At the same time, they may not directly affect a patient-centric QA of the DP. Therefore, it is important to determine the excipients that are critical with respect to patient-centric QAs and differentiate these from the excipients that may be critical from the process robustness or manufacturability perspectives. Early identification of excipients critical to the DP manufacturability (such as process robustness) can influence the selection of formulation components to not only build robust processes, but also reduce the impact of excipient variability on formulation QAs or manufacturability.

6.4.2 Understanding the mechanistic basis of functional role

Functional excipients are typically added to the DP for a well-defined objective. For example, immediate release tablet dosage forms typically include a disintegrant to promote rapid tablet and granule disintegration to facilitate drug release. Sustained release tablets may have a hydrophobic core matrix to slow the rate of drug release. Formulation and process development studies are typically carried out to determine the effect of excluding or replacing a particular excipient (qualitative composition change) or the concentration of an excipient (quantitative formulation change) in controlled, often statistical, DoE studies. These studies result in a robust definition of factor-response relationships with an additional delineation of two-way or three-way interactions. Such studies, however, do not provide adequate information about the critical attributes of the excipient that is important to its functionality.

The mechanistic basis of the functional role can be better understood using excipients in the same

functional class, but with well-controlled and -defined differences in material properties. For example, certain excipients can show noncovalent interactions with drugs in the dosage form that can affect drug release in the dissolution medium. The effect of drug-excipient binding on a drug's bioavailability, however, would depend on the strength and extent of binding of the drug. For example, CCS, a common superdisintegrant in immediate-release oral solid dosage forms and an anionic polyelectrolyte excipient, can form noncovalent interactions with basic amine drugs. A source of interlot and intervendor variability in CCS stems from the degree of cross-linking within the polymer network. A comprehensive set of modeling and experimental studies[8] indicated that the relevance of drug-excipient binding to a drug's bioavailability depends on the drug's dose and the affinity of binding (Fig. 6.1b).

6.4.3 Understanding the range of variability of excipient attributes

A DP manufacturer has very little control over the intrinsic lot-to-lot variability within a single grade of each excipient in a given formulation, as the source of this variability is dictated by the degree of process control implemented by each excipient vendor.[114] Several lots of excipients are typically used during formulation design, formulation and process development, process scaleup, and clinical DP manufacture, which sample the range of typical variability expected in the excipient attributes. In addition, several lots of commonly used excipients are routinely procured and utilized by the pharmaceutical industry. The exposure to different lots and manufacturers of excipients provides opportunities to test the range of variability observed in different lots of excipients for a particular product QA. The quantitation of the range of excipients' QAs encountered during the development of a DP may be used to build a baseline database of excipient attribute experience-space[115] that can be helpful for establishing formulation and process robustness, and to study the effect of potential deviations from this experience space in the future batches. Risk assessment may be used to shortlist the attributes to be monitored in building the database of excipient attribute experience-space.

A common approach is collating data, and establishing statistical parameters, from the information provided in the CoA by the vendor. This approach can sometimes be combined with Bayesian statistical methods, which can enable continuous development of a statistical database as representative batches of the DP are manufactured over a period of time. For example, Kushner et al. reported discernible variability of Avicel PH 102 manufactured at two different sites although all data was within specifications.[116]

Developing an understanding of the effect of excipient attributes on DP MAs represents an inherently multivariate to potentially more than one response. The use of chemometric methods with statistical multivariate analyses tools such as principal component analysis and multiple linear regression have been proposed for this purpose.[117] These tools can allow better understanding of the effect of MAs on in-process material properties, which are ultimately linked to DP CQAs, and process outcomes—thus enabling the development of a robust multivariate advanced process control strategy.

6.4.4 Generating or obtaining excipient lots with a range of known MAs

A traditional approach to determine the impact of excipient QAs on DP performance is to select the known MAs that may affect product performance based on literature, functional role of the excipient in the formulation, or prior experience, and to investigate the effect of a range of those excipient attributes on product CQAs in controlled experimental studies. Such an experimental investigation of the effect of selected *potential* CMAs of excipients on predefined DP CQAs relies on the ability to obtain excipients with a wide-enough range of those potential CMAs. For example, to examine the impact of excipient material property variability for three common excipients on the performance and manufacturability of an immediate-release, dry granulated, solid oral dosage form, Kushner et al. selected the material QAs that were known to affect product performance.[114] These were the particle size of MCC, spray-dried lactose, and MgSt, as well as the polymorph and specific surface area of MgSt. The authors obtained samples of different batches of these excipients from vendors with differences in selected QAs for this study. The authors observed that the particle size of MCC and lactose affected blend particle size, blend flow, granulation particle sizes, roller compaction ribbon tensile strength, and tablet hardness. Specific surface area of MgSt affected ribbon tensile strength and tablet hardness. The authors concluded that despite the observation of statistically significant effects, the range of particle sizes examined were not sufficiently large to adversely affect the CQAs studied.[114] This conclusion highlighted that even though variation in an MA had a statistically significant impact on in-process MAs during DP manufacture, it did not adversely affect the CQAs of the finished DP.

A frequently cited limitation of this approach is the availability of a given excipient with sufficiently large variation in the QAs that can cover the range of variability listed as a specification on the official CoA provided by the vendor. The manufacture of excipients in bulk using highly controlled processes results in a few batches of excipients manufactured annually and those batches being very tightly controlled in terms of the QAs under investigation. Two approaches are suggested when such limitations make experimental verification of excipient variability impact on DP CQAs challenging:

- Using different grades or suppliers of excipients that would represent greater variation in the selected MAs than within grade, thus qualifying as a worst-case scenario for the selected MA
- Spiking or using storage conditions that result in modifications to the MAs under investigation

6.4.4.1 Different grades or suppliers of excipients as a worst-case scenario

When it is difficult to obtain samples of different batches of an excipient with adequately wide differences in selected MAs *and* such MAs vary across different grades of an excipient, different grades of the excipient can be selected for an experimental investigation of the role of selected MAs on potential DP CQAs and manufacturability as a worst-case scenario.

A caveat of this approach is that the range of variation in the MA examined may be wide enough to significantly affect DP CQA or manufacturability when the range of variability routinely expected within a grade of an excipient may not have affected DP CQA or manufacturability. For example, Alvarez-Lorenzo et al. described interlot (ie, two lots) and intersource (ie, two suppliers) variability in the properties of HPC and its implications on drug release from theophylline swellable matrix tablets.[118] The authors compared two lots of a high-viscosity grade of HPC, which showed differences in the molecular weight, molecular structure, particle size distribution, particle shape, and water affinity. These parameters were seen to affect the rate of drug release from tablets, with the impact of interlot variability being lower than intersource variability. In another study, Doelker et al. investigated the tableting characteristics of 16 different lots of MCCs produced by 7 different manufacturers.[119] These grades were compared with respect to moisture content, particle size distribution, bulk and tap densities, flow properties, and sensitivity to lubricant. The authors found greater intersource than interlot differences. These studies indicate that the results of studies conducted with different grades or suppliers of excipients as a surrogate for the extent of lot-to-lot variability within a grade or supplier should be interpreted with caution. This approach (intersource or intergrade variability as a worst-case scenario for interlot variability) is generally more valuable for ruling out a potential MA as a CMA than identifying a particular MA as a CMA.

6.4.4.2 Mixtures of different grades of excipients

A modification of the approach of using different grades of excipients to delineate the impact of wide variations in MAs on product QAs is to use the mixtures of excipients that provide material properties within the range of the specifications of target material. This approach was utilized by L'Hore-Gaston et al.,[120] who prepared physical mixtures of different grades of polyethylene oxide excipients to simulate product viscosities across the range of the standard product specification of the target material the authors were planning to use. The authors used two standard poly (ethylene oxide) polymers (POLYOX 205 NF Water-Soluble Resin and POLYOX N-12K NF Water-Soluble Resin) to develop a series of samples across the viscosity specification range of another standard product (POLYOX 1105 NF Water-Soluble Resin), which has a viscosity between these two grades.

For this study, the authors had preidentified the MAs to study (polymer viscosity and particle size distribution), the DP of interest (an extended release matrix system), and the product QAs as responses (tablet mechanical strength and drug dissolution).[120] The approach of mixing the two different grades of excipients as producing results similar to an intermediate viscosity grade was verified by comparing drug dissolution profiles from matrix tablets. Utilizing this approach, the authors were able to make reasonable inferences of the properties of the polymer on drug release from the matrix extended release tablet. Where feasible, such an approach can be a valuable tool to study the acceptable range of variation in material properties that can result in a truly QbD raw material control strategy.

6.4.4.3 Spiking or using storage conditions to modify MAs

Reactive impurities in excipients that react with the drug substance or API in a formulation can lead to safety concerns about the drug degradants. This section describes potential methodologies to test the effect of variability in excipient impurities on DP stability when excipients with different concentrations of reactive impurities are not readily available from the vendor. These approaches consist of storing excipients under particular conditions or spiking excipients with known reactive impurities. For example, reactive

formyl impurities in PEG increase upon storage at high temperature (Fig. 6.2).[57,121] Reactive peroxide impurities in povidone increase upon storage under low-RH and high-temperature conditions.[61] Thus, storage of excipients under conditions that lead to an increase in the reactive impurities under investigation can be useful to experimentally study the effect of reactive impurities in excipients on DP stability in a controlled manner, using the same lot of excipient stored under different conditions.

The strategy of spiking known reactive impurities in excipients has been utilized in certain cases such as spiking hydrogen peroxide in povidone and crospovidone or formic acid and heavy metals in PEG, polyvinyl alcohol (PVA), or coating materials comprised of these polymers (eg, Opadry II from Colorcon). Spiking strategies, however, have inherent limitations. For example, the reactive impurities' species present in the excipient resulting from natural formation under routine manufacture and storage conditions can be very different and diverse compared to the spiked species. For example, spiking of formic acid in PEG or Opadry II coating material may not reproduce the variety and extent of formyl esters present in the polymer networks when the impurities are formed inherently. Spiking of formaldehyde has practical limitations, in that formaldehyde is a gas available as a 37% aqueous solution. Spiking of hydrogen peroxide in povidone does not address the organoperoxide impurities that are present inherently. In addition, the uniformity of distribution of minor quantities of spiked impurities within the excipient sample and how well or deeply the spiked impurities are embedded within the polymer network is always questionable.

6.4.5 Controlled experiments with a range of known MAs

Once different lots of excipients have been obtained with differences in MAs of interest, experimentation is undertaken to investigate the impact of the known differences in MAs on the selected product QAs.

6.4.5.1 MA comparison at target formulation and process parameters

Investigation of the effect of MAs—of one or more components of a formulation—is typically carried out without studying the interaction with the formulation composition or process parameters. In most cases, the effect of changes in the MAs are studied at the center point of the target formulation composition and process parameters. These experiments seek to compare the responses due to potential excipient lot-to-lot variability, while keeping all other formulation and process parameters constant. A limitation of such experiments is lack of information about the implications of interactions of variability in more than one excipient or the interaction of excipient variability with process parameters. These studies can sometimes incorporate the variability in more than one excipient to study their interactions. In certain cases, focused experiments are carried out to study the impact of two or three variables simultaneously. For example, the effect of surface area or particle size of MgSt in two different lots can be studied concurrently with the number of revolutions during the lubrication mixing operation in a 2^2 full-factorial design to identify the interaction between the formulation (lot-to-lot variability) factor and the process factor.

6.4.5.2 Statistical DoE studies that combine MAs with formulation and/or process parameters

Generating an extended experimental space using systematic statistical DoE with different lots of several excipients combined with some formulation and or process variables, although feasible, becomes prohibitive in material, time, and effort requirements. The feasibility and challenges encountered in such a study were highlighted by the work of Gabrielsson et al.,[122] who used multivariate design to study the robustness of a tablet formulation. The authors investigated the impact of lot-to-lot variability in excipients in a formulation consisting of 10 ingredients (9 excipients and 1 API). These studies were conducted at two different drug loads. Utilizing 3–7 lots of each of the 10 ingredients, the authors manufactured and characterized 50 DP batches in a first multivariate characterization study. Another multivariate characterization was performed on 30 batches, 3 from each of the 10 components of the formulation. The results of this study were subject to principal component analyses to determine the principal properties. A Plackett–Burman design was applied to the principal properties. Regression analysis was used to study the relationship between design factors and two selected DP responses (mean disintegration time and mean crushing strength). The relatively lean saturated statistical study design allowed the delineation of only the main effects. These studies allowed the authors to generate multivariate characterization models for each of the main effects studied in the design.

Another example of multivariate statistical DoE study that incorporated excipient attributes with formulation and process variables is provided by Kushner et al.,[123] who studied within grade and intergrade variations in excipient particle size along with API type, API particle size, drug loading, manufacturing method, and a range of diluent to lubricant particle size ratios in a 2^{5-1}

fractional factorial statistical design. The authors conducted 28 experimental runs with a variety of response measurements, and noted that the variation in excipient particle size distribution parameter, reported d[4,3] value, had the greatest impact on the blend and granulation particle size and flow responses.

DoE studies that encompass formulation and process variables along with the excipient attribute differences can be relatively large and demanding in terms of material, time, and effort requirements. At the same time, these studies also tend to be limited in terms of the variables that can be investigated. The investigator needs to select the most pertinent formulation and process variables for study, as well as the excipients within the formulation and their range of variables that can be studied.

To design a robust DP formulation, pharmaceutical scientists need to take into account the physicochemical properties and variability of the API; the performance advantages, limitations, and variability of the excipients; the advantages, limitations, and variability of the unit operations; the influence of input and in-process material storage conditions and DP packaging components; and interactions among these variables.[124] Thus, a holistic understanding of influence of excipient impurities on DP QAs can allow the development of a control strategy with the DP focus. For example, for excipients that show increase in the concentration of impurities during storage, such as PEG[57,121] and povidone,[61] the packaging configuration and storage conditions may be more fruitful than tight specifications on reactive impurity concentration in the initial input material. An increase in reactive impurities in excipients during storage stability in a DP can sometimes be mitigated by avoiding the concurrent use of excipients that can increase the rate of formation of certain reactive impurities through excipient–excipient interactions, as, for example, the use of PVA and PEG in conjunction in a drug product.[125,126]

Process parameters may interact with excipient attributes to generate reactive impurities in DP that can be controlled by establishing adequate process control strategies. For example, Reed et al. reported on increase in organoperoxide-mediated degradation in a DP that correlated with fluid bed granulation process parameters[127] and the photosensitivity of a drug that correlated with light exposure during manufacturing and packaging processes in addition to the concentration of iron in the excipients.[128] Hemenway et al. demonstrated that, in certain cases, the rate of drug degradation in a DP may be a function of water activity of the DP,[103] which can be kinetically controlled using packaging strategies such as the use of desiccants.

These studies highlight the need to quantitatively understand the variability in excipients and holistically address their impact on DP QAs taking into account the mechanism and kinetics of interactions between excipients, other formulation ingredients, packaging components, and DP manufacturing process. A robust control strategy can then be developed with the DP focus. Development of a control strategy for DPs and excipients to address potential effects of excipient variability needs to take into account the interaction of process with the excipient attributes.

Establishing tight specification controls on excipients is inherently challenging. A majority of pharmaceutical excipients are supplied by the food and chemical industry.[129] Excipients not only originate from diverse sources and constitute diverse material types (liquids, solids, semisolids, and gases), they are also used in diverse dosage forms and routes of administration. The varied uses create different performance expectations for each excipient. Compendial specifications for excipients are focused on safety and purity. With the increasing recognition of the functionality-related tests and the variability in excipients, the pharmacopeias have started to add elements of functionality testing to the excipients. As discussed earlier, the Ph.Eur. has included an FRC section to certain monographs, although compliance with these FRCs is not mandatory. The USP has included an Excipient Performance Chapter (<1059>) as an informational monograph that provides an overview of typical MAs associated with certain functional categories of excipients.[130] Moreton has published a series of articles discussing the functionality and performance of excipients in a QbD world[124,131,132] that address excipient attributes from the perspectives of excipient manufacturers. These articles highlight practical considerations that play a role in the design of excipient control strategies and the options available to the pharmaceutical scientists in understanding and incorporating excipient attribute variability within DP formulation design and development. Moreton and Carlin affirmed that tighter raw-material control is unlikely to be viable in practice and propose strategies such as robust formulation design and end-point adjustments within the manufacturing process that encompass the natural range of variability expected within excipients.[133]

6.5 RISK ASSESSMENT OF DRUG-EXCIPIENT INCOMPATIBILITIES AND MITIGATION STRATEGIES

Drug-excipient interactions can complicate and compromise a development program or the viability of a commercial product. Many of these interactions can take a long time to manifest and are not always predicted by stress and preformulation studies. However,

it is possible to reduce the probability of occurrence of such undesirable and costly scenarios by a careful risk assessment. This should be based on sound knowledge of the degradation pathways of the drug. A good awareness of excipient reactivity based on knowledge of reactive impurities that takes into account the nature, variability, and fate of these impurities is important. A well-designed and -executed drug-excipient compatibility study based on API properties such as reactivity and solid form, environmental factors of pH and moisture, formulation, and process design is essential. Early identification of drug-excipient incompatibilities followed by designing a DP that can tolerate excipient variability is the best approach to avoid undesirable surprises late in development and commercialization of the product.

There are several mitigation strategies one can adopt on a case-by-case basis to address the impact of drug-excipient incompatibilities. The reactive impurities in excipients may either be residues from excipient manufacturing process or degradation products of excipients and very often, the manufacturing process used by excipient vendors is a trade secret. Additionally, the pharmaceutical industry is relatively a smaller customer base for these excipients relative to the food and cosmetic industries, where demand is high and stringency requirements are relatively low. So the ability to influence the excipient vendor to modify the manufacturing process to suit the needs of pharmaceutical product manufacturers is limited requiring strong interaction. Changing the source of the excipient is another option, but it is often challenging. Where possible, avoiding the excipient is the best option. Many times that is not a viable option. In such situations, one can take other measures such as modifying the API form, formulation, and manufacturing process depending on where the issue resides. These can be through the use of stabilizers, pH modifiers that affect the microenvironmental pH, the solid form of the drug, or the formulation process, just to mention a few. Modifying packaging and storage conditions without modifying the formulation is another option. For example, desiccants such as silica gel can be copackaged with the dosage form. There are predictive models such as the sorption desorption moisture transfer model to simulate the effects of desiccants and determine the appropriate level of desiccant usage.

When changes to the formulation and packaging cannot be made, setting acceptance criteria for incoming material is another approach because it is not reasonable to expect compendial limits to address product-specific requirements. This can be done by an understanding of how changes in the reactive impurity level affects DP stability. There are challenges to this as well—for example, obtaining excipient samples with different levels of impurities from vendors is not easy. Analytical methods of these trace level impurities are another challenge. Finally, there are the cost considerations.

6.6 CONCLUSIONS

This chapter highlighted the cornerstones of excipient compatibility, functionality, and variability. Excipient compatibility studies are conducted with the primary goal of selecting dosage form components that are compatible with the drug. Methodically conducted experiments also provide additional information on stability profile of the drug, identify degradation products and mechanisms. Furthermore, if the stability of the drug is found to be lacking, strategies to mitigate the instability of the drug can be adopted. The guidelines and principles presented in this chapter would be useful in the appropriate design, conduct, and interpretation of compatibility studies to help accelerate formulation development activities and prevent or minimize surprises in drug development. Additionally, a clear understanding of excipient functionality in a DP, the underlying material properties that dictate the desired functionality, and the variability encountered in common excipients is expected to further enable the efficient development of DPs with sound control strategy and scientifically based specifications.

7.1 INTRODUCTION

The introduction of polymer excipients has been crucial in advancing modern formulation design and solid oral drug delivery technologies over the past 50 years. Polymeric materials are widely used in a broad range of pharmaceutical products and constitute essential components of modern solid oral dosage forms. Therefore, it is important to understand polymer properties and characterization methods in order to enable rational design and development of oral solid drug delivery systems and manufacturing processes.

The word "polymer" is derived from the Greek πολυ *(polu)* for "many" and μέρος *(meros)* for "part," meaning a long-chain consisting of many parts. The combination of repeating units to form long chains with widely variable length and structure is essential in determining the properties and applications of the resulting polymers, as the diversity of polymer properties is attributed to the simple fact that each polymer molecule consists of many parts with individual variations in sequence of repeating units and chain length.

In contrast to substances comprised of small molecules that are well defined and identified by a set of system variables, including basic physical properties, states, or characteristics with unique and discrete values, polymers are less well defined or characterized in the conventional sense. This applies to even the simplest of polymeric systems. For example, substances comprised of small molecules have a distinct molecular weight, with each molecule having exactly the same nominal mass, neglecting, for the moment, the multiple natural isotopes possible for the atomic constituents. Polymers, on the other hand, are characterized by a diverse population in which there is a broad distribution of molar masses across the entire chain population. This is well known and clearly understood, since polymers are simply chains of many monomeric residues covalently linked together. For small molecules, it can be clearly defined if a molecule is in solution or not. Such a clear distinction may not be applied to polymers. It is quite possible for extended segments of a long polymer chain to effectively reside in bulk solution, while other parts still reside in a bulk polymer solid phase. Conceptually, the polymer chain is not completely in solution, yet the behavior of this system is clearly very different from the one where an unswollen polymer sample is sitting unsolvated in a sea of solvent. The state of an unswollen polymer is not a fluid or solution by traditional definition. Distributions in properties, states, and characteristics are what set the behavior of many polymers apart from small molecules in general. Understanding the operational impact of this difference is the first step in rational characterization and applications of polymeric materials.

This chapter will emphasize some of the pragmatic consequences of continuous distributions in composition, molecular weight, and molecule state in the use of polymeric materials and the impact on their functionality. Since the basic literature of polymer chemistry is readily available,[1–6] we will strive not to duplicate that information here. Rather, this chapter should be viewed as an operational entry point into the practical utilization of polymeric materials. While we will attempt to maintain a firm foot in fundamental science, each of the major subsections of this chapter could constitute a monograph in its own right. As such, the approach taken is to cover the information that will be of immediate value to a user of polymeric excipients. This necessitates a somewhat limited but focused scope of coverage. In addition, we do not wish

Developing Solid Oral Dosage Forms
DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00007-8

to be distracted by equations that only approximately describe the major features of polymeric systems and often obscure important underlying operational principles. Where possible, we will resort to experimental rather than theoretical examples to illustrate specific points. Our objective is to provide the user and formulator of polymeric materials an operational and pragmatic guide upon which to base formulation decisions and understand the molecular origins of these performance metrics.

In this chapter, we will consider basic structural issues surrounding polymeric materials. One general aspect to appreciate is that two samples with identical average molecular weight and composition may display very different behavior in specific applications. Since a polymer is comprised of chains of monomer units, the total number of monomers per chain (ie, the molecular weight), the gross topology of the chain (linear vs branched), and the microstructural monomer sequence within and across the chains (ie, block A−B copolymer vs random A−B copolymer vs a physical mixture of polymers A and B, see Fig. 7.1) all impact the final properties of the material.

Determination of the average monomer composition and molecular weight of a polymeric sample are experiments routinely carried out using a variety of well-known techniques. Other attributes of polymeric materials, for example, branching or large-scale composition heterogeneity across chains, may require some level of experimental finesse but can be addressed in broad terms. However, detailed questions regarding monomer sequencing within chains can be all but impenetrable in most instances and often require appeal to indirect challenge/response using experimental probes to even qualitatively address them. This fine detail is of significant importance in current research, since key performance properties can often be directly related to this elusive structural parameter.

7.1.1 Definition, structure, and nomenclature

The gross architecture of a polymer chain can be readily assessed by asking whether the chain or chain assembly can be mapped onto a one- (linear), two- (branched), or three- (cross-linked network) dimensional object (Fig. 7.2). In general terms, these distinctions reflect the natural spatial connectivity imparted by these chains when placed into a volume element, either in formal solution, a melt, or the solid state.

How a polymeric chain mechanically couples to and transports within a medium comprised of either other polymeric materials or low molecular weight solvent is determined in part by the gross topology of the chain system. Ultimately, the key physical attributes are the length, scale, and nature of connectivity between volume elements in solution, gel, melt, or solid states and how that connectivity propagates through space.

If one takes a linear chain and stretches it, a simple line is obtained. By the same token, the lowest

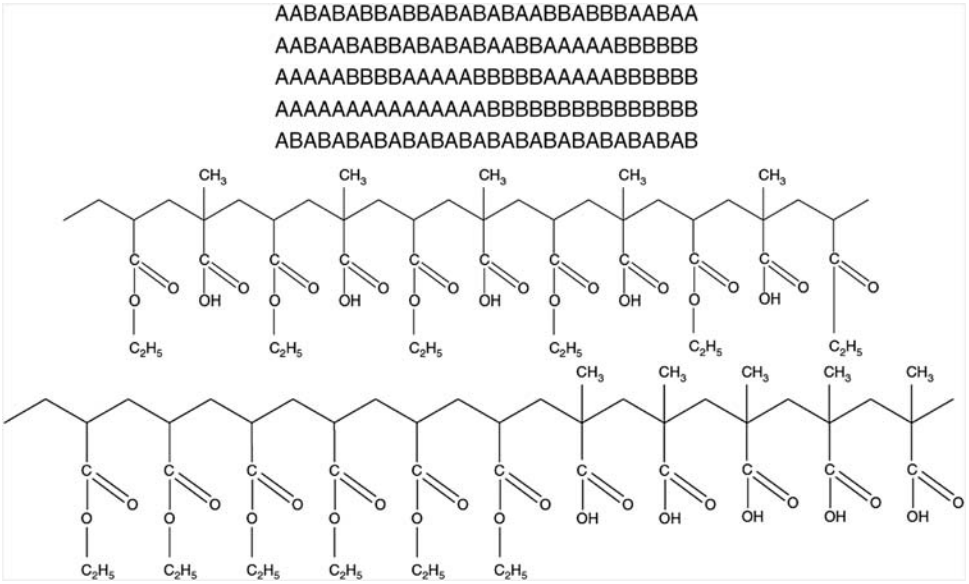

FIGURE 7.1 Examples of AB type copolymers in which the composition is the same (50:50 A:B), but the sequence of A and B monomers differ. Prototype copolymer structures shown top to bottom represent random, block graft, multiblock, diblock, and alternating AB copolymer systems. As a specific chemical example, consider the case of a 50:50 copolymer comprised of ethyl acrylate and acrylic acid as either an alternating, or diblock, architecture. The solution properties of these two materials, which have equal composition and molar mass, would be expected to be vastly different, as would solid state and melt properties.

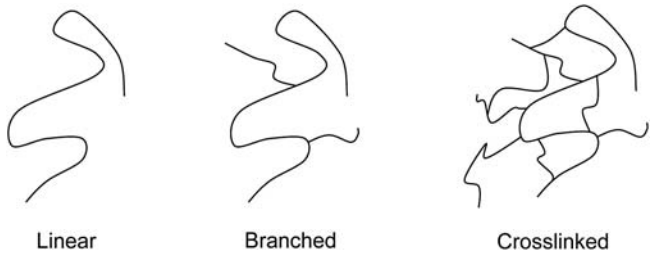

FIGURE 7.2 Diagrammatic examples of prototype chain architectures. A linear chain has been depicted as a random coil, although rigid or semirigid rods are also possible. The branched example is comprised of a main backbone with two extended long-chain branches, while more extensive branching and linking to other main backbones have been used to depict a typical cross-linked polymeric system.

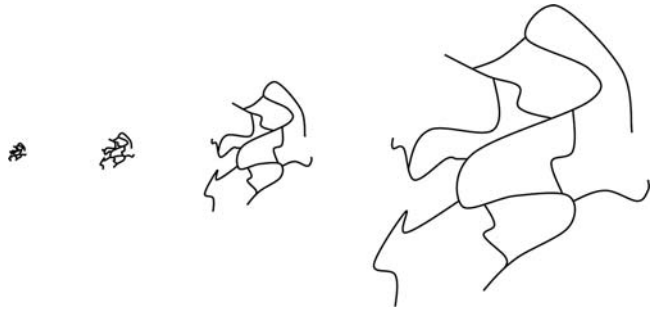

FIGURE 7.3 Depending upon the length and the flexibility of chain segments between covalent cross-links, a cross-linked polymer may be a very rigid and nonswelling solid (short, rigid segments between cross-links) or very highly swelling (low cross-link density between very flexible and solvent compatible segments) under the appropriate solvent conditions. In some cases, for example with a change of pH from highly acid to neutral or basic for a cross-linked polyacrylic acid system, conversion between collapsed and highly swollen states is readily and reversibly accomplished.

dimensional object that a simple branched structure will yield under deformation, in the simplest case, is a two-dimensional planar object. A cross-linked network will yield a three-dimensional volume element under any applied deformation. In this sense, these three classes of chains are topologically and dimensionally distinct. As in any discussion involving polymeric species, the evolution between types is continuous rather than discrete even when involving dimensional extent; simple characteristics, lengths, scales along principle axes are critical.

For example, as a simple linear chain is grafted with an increasingly long side chain in the midsection of the molecule, the evolution from a purely linear to a branched planar structure occurs in a continuous fashion. Likewise, as multiple chains having a two-dimensional architecture receive additional grafts on side chains, a similar transition from two- to three-dimensional character occurs. It is critical to appreciate that even aspects that appear firmly rooted in discrete representations, dimensionality in this example, may take on some attributes of a continuous variable if viewed from specific contexts.

The chain types shown in Fig. 7.2 are assumed to represent covalently linked permanent structures. Polymeric materials of a given intrinsic topology may also assume a higher apparent dimensionality via dynamic self-association. This association can involve either similar or compositionally distinct partners. Both types of examples exist in use, with self-association of a hydrophobically modified polymer[7] reflecting the former case, while the interaction of xanthan and locust bean gum or sodium carboxymethyl cellulose and hydroxyethyl cellulose are examples of the latter.[8] Finally, simple physical entanglements at high polymer concentrations can be viewed as a type of dynamic cross-link, since many of the essential properties of cross-linked systems (structural robustness, high elasticity, slow transport of polymer, and/or constituent polymer) will be achieved, particularly at relatively short timescales (minutes to hours).

Gross chain topology has an influence on the flow and mechanical properties of polymer melts and solutions, as well as over the timescales of structural relaxation. In general, as a system transitions from pure linear to highly cross-linked, the balance between the viscous and elastic nature of a solution or melt tends towards more elastic. This transition is similar in kind to that observed as the molecular weight of a polymer is increased. In terms of gross phenomenology, the basic causes are tied to similar origins, with the understanding that in a cross-linked or branched polymer sample permanent covalent linkages dominate the situations, while with high-molecular-weight linear polymers dynamic interchain entanglements, which can be akin to a transient cross-link, control system response.

In addition to extensively cross-linked pure polymer systems, an intermediate type of system is exemplified by cross-linked swellable microparticulates—the most common of these being provided by cross-linked acrylic acid-based systems prepared in a microparticulate form. These are often used to control the flow properties of systems by simply encapsulating substantial fractions of the total system volume but keeping it segregated into rather small length scale packets (see Figs. 7.3 and 7.4). With large swelling ratios, relatively small amounts of particulate mass can basically encapsulate large volumes of liquid. This is often useful to build in a yield stress while maintaining a relatively low-shear viscosity, since the propagation of shear forces is basically constrained to simple soft sphere hydrodynamic effects (vs chain entanglement for a molecular dissolved system), with a net length

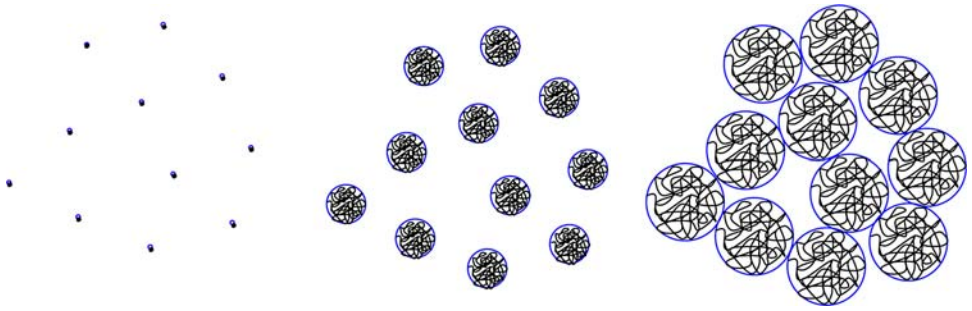

FIGURE 7.4 In addition to bulk cross-linked systems, the swelling of cross-linked microparticulate polymeric systems provides interesting opportunities for rheology control. As the particles swell, they first occupy a significant volume fraction of the dispersed phase and then reach a point at which all discrete swollen particles start to overlap and touch. Diameter ratios of 1:10:20, yielding a net 8000-fold volumetric swelling, is depicted.

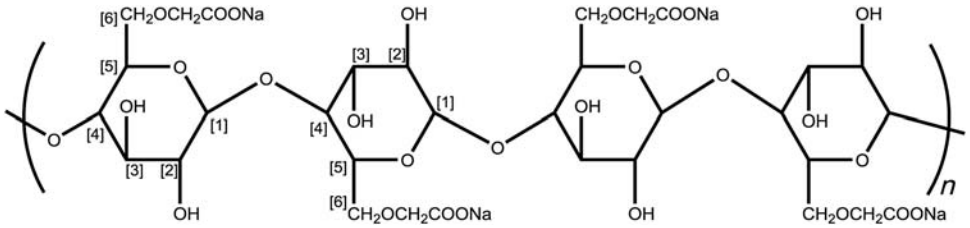

FIGURE 7.5 Representative structure of sodium carboxymethyl cellulose. For graphic convenience, only substitution at the six-position is explicitly shown. However, all three hydroxyl positions are available for substitution, and a real polymer will be comprised of a mixture of primarily unsubstituted, monosubstituted, or disubstituted monomer residues. This example is an idealized DS = 1 sodium carboxymethyl cellulose.

scale established by the dimensions of the swollen particle. In general, our attention will be restricted to linear polymers, since they comprise the majority of systems of direct interest.

7.1.2 Types of homopolymers and copolymers

In dealing with polymeric materials, cautious delineation of whether a material is a homopolymer or a more complex copolymer is an extremely critical initial step in understanding the range of properties that can emerge in everyday use. In general, most of the polymeric materials that we deal with are much more profitably handled and understood if it is explicitly recognized that they are copolymeric in reality, and the detailed sequence of the various residues is an important variable that can influence application properties in use. In some cases the distinctions are clear, while in others they are not.

As a specific example of the potentially significant impact that a sequence can have on a material, consider a simple AB copolymer that possesses equal molar amounts of A and B (Fig. 7.1). For the same average chemical composition, molecular weight, and gross architecture, a significant range of structural archetypes can be prepared by manipulating only the sequence of the monomer units. That sequence can run from purely random to somewhat blocky, from multiblock to diblock, and to purely alternating structures. If the monomer residues possess differing solution properties, for example consider a case in which one residue is relatively hydrophobic while the other is very hydrophilic, the sequence can have an overwhelming influence on properties such as solubility, phase behavior, and packing in the solid state. As a specific case, consider poly(*co*-ethyl acrylate-methacrylic acid) (Fig. 7.1). The alternating and diblock architectures will yield vastly different physical properties (solubility, mechanical properties) and performance traits despite the equivalence of molecular weight and average composition. Naturally, the argument can be extended to include a physical mixture of the two homopolymers, which provide the same average molecular weight and composition values. Again, one has a system of near-identical molecular weight and composition, but the performance is anticipated to be distinctly different. In fact, the component polymers would likely be immiscible in the melt state and prone to segregate if deposited from the solution state in, for example, a coating application.

As a second example, consider the simple case of sodium carboxymethylcellulose with an average degree of substitution (DS) of one. In total, carboxymethyl substitution can occur at up to three hydroxyl positions on any anhydroglucose residue (Fig. 7.5).

In principle, a sodium carboxymethylcellulose chain can be comprised of unsubstituted anhydroglucose, have monosubstitution at either the two, three, or six hydroxyl positions, disubstitution at the 2/3, 2/6, or 3/6 positions, or be a fully trisubstituted monomer. Even if the added detail of positional substitution is ignored and we consider only unsubstituted, monosubstituted, disubstituted, and trisubstituted monomers as distinct entities, the system has to be considered as an ABCD copolymer. As noted, the detailed sequence distribution of the A, B, C, and D monomer residues can have an impact on the final properties of the material if the intrinsic properties of those constituent monomers (polarity, hydrophobicity/hydrophilicity, charge state, propensity to participate in interchain hydrogen bond association) differ significantly. Obviously, the solution and solid-state behavior of a neutral sugar (anhydroglucose) will be different from a trianion salt (sodium tricarboxymethyl anhydroglucose) due to the ionic charge and steric packing requirements of the latter and the facile possibility for hydrogen bond formation for the former.

As illustrated by the examples, one expectation is that microstructural sequence variations will impact the local chemical nature of subsections within a polymer chain. In the case of poly(*co*-ethyl acrylate-methacrylic acid), we see a transition from a nominally hydrophilic alternating copolymer to a system with distinct hydrophobic and hydrophilic blocks. In terms of expected solubility in water, the hydrophobic block will not find an aqueous environment amenable. Depending on the net balance of segment lengths and position along the backbone, this may manifest itself as anything from partial insolubility with a high propensity to swell, complete solubility with a tendency to adsorb onto surfaces, a tendency to self-associate in solution, or as gross insolubility in pure solvents with a decided need to employ binary solvent mixtures to achieve complete dissolution. A reality with polymeric materials is that all of these possibilities can, in principle, be expressed by materials of the same average composition via adjustment of molecular weight and chain microstructure sequence.

The case with synthetic copolymers is fairly obvious and readily understood on the basis of the respective behavior of the constituent monomers. It is a less obvious situation with derivatized cellulosics, even though the underlying issues are identical and similar trait differences for nominally similar compositions are possible, although the underlying physical phenomena are somewhat distinct. With cellulosic derivatives, aside from the cases of cellulose esters and ethyl cellulose, the possible constituent monomers are all fairly hydrophilic. However, similar issues remain and tend to be tied to the potential formation of hydrogen bonding junction zones in structurally regular domains of the material. These structurally regular domains can be due to short runs of contiguous unsubstituted anhydroglucose or uniformly substituted contiguous run lengths. In both cases, the underlying feature is a structurally regular domain that can be annealed into a highly ordered domain for which the primary events of dissolution (solvent penetration and separation of the packed chains) are kinetically unfavorable due to cooperative multipoint hydrogen bond association.

This added level of complexity, which is intrinsic with derivatized cellulosic excipients but an important operational detail for many polymeric samples, needs to be appreciated in order to understand why materials that possess very similar average compositions can display rather diverse end use performance attributes in different applications.

7.2 BASIC CONCEPTS AND CHARACTERIZATION OF POLYMERIC MATERIALS

Some specific example polymers were described in Section 7.1, as were some of the key traits used to characterize these polymers. In this section we'll delve somewhat deeper into the measurement of these traits and the interrelationships between them.

At the most basic level, a polymeric material is defined by the average molecular weight distribution and average composition. As has already been seen with molecular weight, the net range in molecular weight sampled is enormous. This can have important consequences. Traits that are dependent on properties showing variation, take molecular weight as a specific example, may display particular sensitivity to specific portions of the molecular weight distribution. What this means is that those traits that are molecular-weight dependent may differ between materials with nominally the same average molecular weights. A specific example would be the complete shear rate dependent flow curve of a blend of high and low molecular weight materials with that which is a pure intermediate molecular weight.

7.2.1 Polymer composition

At the basic level, polymers are characterized by average composition variables that reflect either the total level of secondary substitution for derivatized systems (eg, cellulose ethers) or the level of constituent monomers for a synthetic or natural copolymer system.

For example, cellulosic derivatives are compositionally characterized by the percent weight of the functional group attached to the backbone, the degree of substitution (DS) per anhydroglucose, or the total molar substitution (MS) per anhydroglucose residue. These three modes of characterization are largely interchangeable with the preferred quantity often dependent on historical legacy and whether the substituent can form an oligomeric pendant group. In the latter case, the DS would not fully characterize the net amount of substituent on a chain.

It is important to recognize that the definition of an operational functional group may include contributions from both the anhydroglucose residue and the added functional reagent, leading to apparent percentage of weight function groups that may appear inordinately high. A good example of this would be ethyl cellulose, in which the average composition is typically expressed as the percentage of ethoxyl content. In this case, the ethyl portion of the ethoxyl group is derived from the derivatizing reagent (ethyl chloride), while the oxygen atom is provided by the anhydroglucose residue. For a typical N or standard type ethylcellulose, a DS of 2.5 corresponds to a weight percentage of ethoxyl of 48.5. However, the actual percentage of mass imparted by the added ethyl group is 31.3%, with the remainder contributed by the oxygen atom that is already a part of the main backbone polymer.

The second manner to characterize the composition of cellulosics is to speak of the DS. Each anhydroglucose residue along a cellulosic backbone possesses three reactive hydroxyl groups, located specifically at the C2, C3, and C6 positions. The average DS of a material quantifies the average number of hydroxyl groups that are derivatized per anhydroglucose. The maximum DS of any cellulosic material is 3, at which point all reactive hydroxyl functionality will have been consumed. The C2 and C6 positions are the most reactive sites and will generally carry the bulk of the substituents.

When the derivatization reagent effectively caps the reactive hydroxyl functionality (eg, methyl, ethyl, or carboxymethyl functionality), the amount of bound functionality quantifies both the degree of hydroxyl substitution and total MS. However, as already noted, if the substituent is able to oligomerize, as is the case with hydroxyethyl or hydroxypropyl substitution, the connection between DS and MS starts to diverge. Furthermore, in principle, the net MS provided by an oligomerizing functional group is not bound to an upper limit determined by the number of backbone reactive sites, although steric constraints and reaction efficiency do provide a pragmatic limit. Of all available cellulosics, hydroxypropyl cellulose (HPC) is the most highly substituted system, with MS levels routinely in the vicinity of four.

In the case of synthetic copolymers, composition is typically determined by the average mole percent or weight percent of the various copolymer constituents, and/or the charge state for a titratable functionality. In general, this is controlled by the charge composition of the reaction mixture used to prepare the product.

In either case, there are a variety of experimental techniques that can be used to quantify the mean composition of the material. These techniques include direct functional group analysis, in the case of the derivatized cellulosics, while the average monomer composition is generally the target for synthetic copolymer systems. In part, this is related to the potential complexity with cellulosics that possess chain-extended pendant groups.

One significant compositional difference between polymers and low-molecular-weight materials is that the detailed sequence distribution of the constituents at equivalent average compositions can have a significant impact on the final solution and solid-state properties of the polymer.

In contrast to the situation that exists with the determination of the average material composition, there is a dearth of direct experimental techniques that provide information on the sequence of monomers in a copolymer system. In general, one is left with fairly indirect experimental probes to assess monomer sequence.

In broad strokes, these indirect probes fall into two general classifications. First, there are the techniques that degrade the polymer to an oligomeric species and then analyze the compositional heterogeneity of these oligomeric materials. While this approach provides insight into the compositional heterogeneity of the system, ascribing the difference observed between interchain and intrachain sequence variations is sometimes quite ambiguous, since one is unable to trace the fragments back to the originating polymers.

The second strategy is to examine the response of the system to the applied challenges. Specific examples would include examining the solubility behavior in a variety of pure and mixed solvent systems, characterizing solubility as a function of temperature (cloud point) or using site-directed cleavage as an approach to probe specific structural motifs. An example of the latter would be enzymatic degradation, which is selective to the presence of short runs of contiguous unsubstituted anhydroglucose. Both approaches have appeared in the literature.[9–13]

In each case, an indirect response is used to provide qualitative insight into the presence or absence of specific run sequences. The utility of this approach is that it provides insight into the origins of observable performance differences between materials that have the same average composition and molecular weight.

At this stage, the information derived from these types of measurements remains semiquantitative.

7.2.2 Molecular weight

Owing to the dispersity in chain lengths and potentially number of substituents per residue of an assembly of polymeric molecules, molecular weights must be discussed in terms of distribution averages. Three distinct types of averages are generally considered: the number, the weight, and z-average molecular weights.

Defining relationships for these three quantities are as follows:

$$M_n = \frac{\sum_i n_i M_i}{\sum_i n_i} = \frac{\sum_i w_i}{\sum_i \frac{w_i}{M_i}}$$

$$M_w = \frac{\sum_i n_i M_i^2}{\sum_i n_i M_i} = \frac{\sum_i w_i M_i}{\sum_i w_i}$$

$$M_z = \frac{\sum_i n_i M_i^3}{\sum_i n_i M_i^2} = \frac{\sum_i w_i M_i^2}{\sum_i w_i M_i}$$

with

$$w_i = n_i M_i$$

where:

w_i is the mass of the fraction of polymer chains with molecular weight M_i;
n_i is the number of these chains.

For a perfectly monodisperse polymer sample, $M_w = M_n$. One more frequently speaks of the population polydispersity or M_w/M_n, which is equal to 1.0 for a perfectly monodisperse sample, since all the chains in that sample have precisely the same molecular weight. For the materials being discussed here, sample polydispersities will generally fall in the range of 10–20, dropping down to values of 3 or so for rather low-molecular-weight materials, and occasionally rising above 20 if the systems of differing viscosity grade have been blended. In understanding the performance of polymeric materials, high-molecular-weight polydispersity can often be a decided benefit. The most extreme example of this would be a synthetic polymer in which a residual monomer serves as an integrated plasticizer of the polymeric solid to help control mechanical properties of the system. To varying extents, most low-molecular-weight constituents (including moisture and low-molecular-weight oligomers) can serve this type of role.

While the three molecular weight averages may appear to be a simple mathematical construct to characterize a polydisperse population, the origin of these relations resides in the different classical methods that one can employ to experimentally determine the absolute molecular weight of a polymer and the distinct averaging schemes operative in these methods. The various techniques used to measure polymer molecular weight are well described in the literature.[14–16]

Colligative property measurements of absolute molecular weight (vapor pressure lowering, boiling point elevation, osmotic pressure) are sensitive to the number average molecular weight. Techniques such as light scattering can, under certain circumstances, yield the weight-average molecular weight. Finally, ultracentrifugation-based methods yield z-average molecular weight. In other words, the differing physical response for each of the measurement approaches provides intrinsically different forms of averaging within the polydisperse population. In addition to these absolute methods for determining molecular weight, any physical observable that possesses a molecular weight dependence, for example, solution viscosity at a fixed concentration can be used as an indirect proxy for a molecular weight determination, with operational correlation methods providing the needed link to the actual molecular weight.

In recent years, size exclusion chromatography (SEC) has largely replaced these classical approaches for routine absolute molecular weight determination. SEC has a distinct advantage over the classical measurements in that it is able to provide direct information on the complete molecular weight distribution via a direct separation based on the hydrodynamic size of the molecules in solution. There are some additional pragmatic issues that potentially improve the robustness of the SEC-based measurement including:

- Since a separation is performed, contamination of the sample with low-molecular-weight impurities has an inconsequential impact on the final result, since their contribution can be ignored at the data processing step.
- As a corollary, the sample concentration does not need to be accurately known in order to obtain a viable measurement. This can be of enormous help when dealing with in-process or formulated product samples.
- There are minimal sample requirements. Typical injected samples are 100–200 μL with a net concentration in the mg/mL range. This can be advantageous when a sample is limited (say in debugging processing details), but it can have a

negative side with respect to preparing a representative sample for analysis, as the material is very heterogeneous. Naturally, subsampling of a large parent solution can readily address this issue.

The hydrodynamic size of a chain in solution with fixed topology (ie, linear or branched) will scale with molecular weight, so the operational separation is effectively one of molecular weight and provides for estimation of the various distribution quantities. Since the common detection schemes are generally concentration sensitive, the *i*th weight fraction (w_i) is the experimentally determined quantity, thus M_w is based on the actual analytical measurement results. In contrast, M_n and M_z rely on derived calculations from the acquired analytical with heavy weighting at either the low- or high-molecular-weight wings of the distribution, which significantly lowers the precision of their determination. For a well-controlled and calibrated system, long-term variability of M_w determinations are generally better than $\sim$5% relative with M_n, and M_z often $\sim$10–15% precision. Note that these are rough results. Observed precision is composition dependent. Sample requirements, such as the need to employ a binary mobile phase to obtain a fully soluble form, can impact precision. Finally, shear forces in an analytical SEC column can be quite high. SEC system flow rates suitable for low- and moderate-molecular-weight materials (1.0 mL/minutes for typical $\sim$7–8 mm inner diameter SEC columns) may yield in situ shear degradation of the higher-molecular-weight grade materials available. The obvious approaches of either lowering the flow rate (to 0.25–0.50 mL/minutes) or using SEC packing materials with a larger particle size will remedy this problem.

By and large, routine SEC-based molecular weight determinations generally yield molecular weight averages that refer to chemically distinct narrow molecular weight distribution calibration standards used in calibrating the chromatographic system elution volume–molecular weight relationship. As such, reported molecular weights are often referred to as relative or equivalent molecular weights. Values provided by many laboratories adhere to this methodology. Finally, while most materials mentioned (aside from sodium carboxymethyl cellulose) are nominally nonionic, it is always strongly recommended that users employ some level of dissolved indifferent electrolyte in the SEC mobile phase. The reason for this is that even nominally nonionic polymers may possess low levels of carboxylate functionality due to adventitious oxidation events during preparation or aging. In the absence of screening indifferent electrolytes, chains that possess even a low level of charge may be electrostatically excluded from the internal pore volume of the packing material. In the absence of molecular weight-sensitive detection, this occurrence can yield incorrect molecular weights, since the elution of the sample is now influenced by factors outside of size alone.

More recently, SEC separations have been combined with molecular weight-sensitive detection schemes (online light scattering, online viscometry) to enable integrated development of operational absolute molecular weight–elution volume calibration of the system and online determination of absolute molecular weight information. The potential compositional complexity of the copolymeric systems used as pharmaceutical excipients renders light scattering determinations of molecular weight rather more complex than simple characterization of typical synthetic homopolymer systems. While the absolute nature of light scattering molecular weight determinations are often touted, that ideal is often not completely realized with the complex copolymeric systems discussed here. Furthermore, absolute molecular weight determinations are quite dependent upon the determination of an accurate, specific refractive index increment (dn/dc). Inspection of the literature for tabulated values of this quantity often shows a wide range of values in rather similar solvent systems. Ultimately, the accuracy of absolute molecular weights often relies on the quality of this secondary quantity. Under well-controlled conditions using purified samples, dn/dc can be determined with high precision. The usual secondary issue associated with this is how strongly dn/dc varies with composition and to what extent composition of the samples also varies.

While productive use of molecular weight-sensitive detection relies on judicious understanding of all the factors required to generate quality data, one overriding value of the approach is that if adsorption of the analyte occurs on the stationary phase packing material, the result is unaffected to the degree that elution zones may overlap with genuinely low-molecular-weight material. In routine SEC, which relies on the use of a secondary calibrant to allow creation of a MW/elution volume calibration curve, there is no direct indication if analyte is adsorbing to the stationary phase, and this will naturally have an enormous impact on any calculated results.

Although SEC is certainly one of the most used approaches to polymer molecular weight determination, the batch classical methods are still used.

Colligative property measurements include both vapor pressure and membrane osmometry. While both measurements rely on colligative effects, in a practical sense, they complement one another rather well.

Owing to the physical limitations of membranes, membrane osmometry is ill suited for relatively

low-molecular-weight polymers (M_n <25,000 Da), and finds its main utility with relatively high-molecular-weight materials and, under carefully controlled conditions, polyelectrolytes. Since low-molecular-weight contaminants are able to equilibrate across the membrane, membrane osmometry is insensitive to low-molecular-weight contaminants. It is also insensitive to chemical heterogeneity, which is a major advantage in the analysis of copolymeric materials.

In contrast, vapor pressure osmometry tends to excel in the lower-molecular-weight region (M_n <20,000 Da), for which membrane osmometry is ill suited. However, the technique is very sensitive to the presence of any low-molecular-weight impurities, which requires the use of highly purified samples and is inapplicable to polyelectrolyte systems.

Although colligative property measurements have a well-founded physical basis, any methodology that allows an experimentalist to count molecules in an assembly can be used to provide an estimate of M_n. Other techniques that have seen utility in the literature include end group analysis, in which unique functionality or reactivity or end groups are used as a mechanism to count the total population of chains in a sample.

At the other end of the spectrum, analytical ultracentrifugation can be used to quantify the M_z of a sample population. While this technique has seen substantial use in the analysis of proteins and other biologically derived polymers and has had a recent resurgence with the commercial rerelease of the Beckman Coulter Optima XL-A series of instruments, it remains something of a niche technology despite the appreciable technical benefits (lack of a potentially adsorptive stationary phase as in SEC, wide range of solution conditions possible, ability to assess complicated equilibria, and ability to handle ultrahigh molecular weight and colloidal systems under conditions of very low sample shear).

The measurements of M_w averages tend to dominate molecular weight characterization of polymers. For the sake of this discussion, we will consider methods that directly measure M_w together with methods such as viscometry, which yield a response that generally tracks M_w.

For the determination of an absolute M_w, light scattering, either alone or in conjunction with SEC, is the primary experimental approach. The use of SEC with either narrow distribution molecular weight standards or inline viscometric detection with universal calibration transformation, provides results that can range from a simple relative molecular weight, if the calibration standards are chemically distinct from the analyte, to near absolute M_w results.

Potential pitfalls of light scattering include the possible impact of dust or suspended precipitates for batch-style measurements, association phenomena that result in the inflation of the experimental results, the use of binary solvents to improve polymer solubility or the lack of strict adherence to constraints required to guarantee that absolute results are obtained (chemical homogeneity of the chain populations, maintaining constant chemical potential of counterions for polyelectrolyte samples (often approximated by the use of "swamping" electrolyte in large relative excess), accurate values of dn/dc).

Pairing light scattering with a prior SEC separation adds substantial power to both techniques. While SEC provides a means to separate material according to its hydrodynamic volume in solution, it also provides an excellent means to filter the analytical sample to eliminate dust and other artifacts from the light scattering signal.

While the underlying fundamental physical quantity of interest is the molecular weight of a material, and most performance traits are related to the molecular weight, most materials are classified in a more operational manner via grade classification according to a viscosity measurement under specified conditions. Naturally, viscometry or rheology can be used as a method to quantify polymer molecular weight, as well as to provide other insights into the nature of the material.

7.2.3 Rheological properties

Rheology is the study of the deformation and flow of a material when subjected to an applied force. The practical consequences of rheology play out in everyday experiences: in the kitchen as one thickens a water-based fluid with starch or forms a jelly through the use of gelatin dissolved at high temperature. In both extremes, the mechanical properties of the final preparation are manipulated through the judicious addition of a polymeric material. The science of rheology attempts to quantify the material changes exemplified by these systems. Detailed treatments of the complete scope of rheology are readily available.[17–20] Dealy has also prepared a convenient summary of official nomenclature and basic terms related to rheological science.[21]

In assessing the response of a material to an applied force, it is critical to appreciate that the applied force can span many orders of magnitude, ranging from simple gravity acting upon a particle suspended in a fluid medium to the very high shear rates experienced in high-speed mixing or high deformation rates experienced in high-speed conveyance and manufacture of solid products. Depending upon the particular details in manufacture and of usage, this entire range of shear

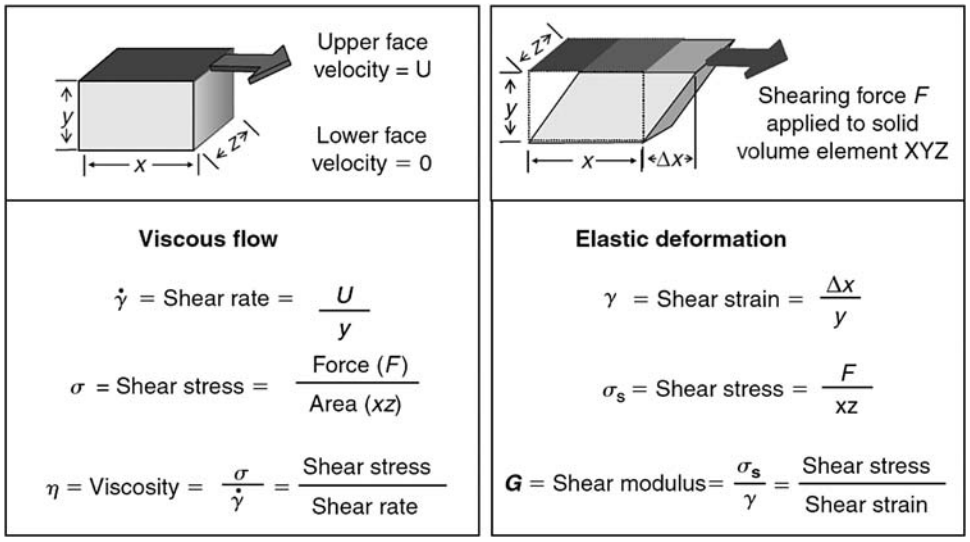

FIGURE 7.6 The basic mechanics of the flow of viscous liquids and deformation of elastic solids. In viscous flow, the energy input into the system is dissipated, while it is stored in the pure elastic deformation of a solid. Real materials are viscoelastic in nature, displaying both viscous and elastic character, with the balance determined by both the magnitude and duration of the applied force.

or deformation rates may be sampled at various points in routine usage.

Rheology considers not only the viscous flow of liquids but the elastic and plastic deformation of solids. In terms of the essential mechanics, the physical situations are quite similar (see Fig. 7.6). Real materials possess both elastic and viscous traits, with the key feature being the timescale over which the shear force is applied relative to the intrinsic relaxation time for the material.

In most cases, the response of a system is quantified by measuring the shear stress (σ, Pa) that develops in a system under the conditions of a controlled and specified shear rate ($\dot{\gamma}$, second^{-1}) for viscous flow or shear strain (γ) for pure elastic deformation. Typically, one speaks of the viscosity (η) of a fluid, which is simply the ratio of the shear stress divided by the shear rate:

$$\eta = \frac{\sigma}{\dot{\gamma}}$$

or the shear modulus (G):

$$G = \frac{\sigma}{\gamma}$$

in the case of solids.

If we restrict our attention to liquid systems for the moment, in the simplest case, which experimentally applies to simple, low-molecular-weight, nonassociating liquids, flow is directly proportional to the applied force. Equivalently, the ratio of the shear stress to applied the shear rate is a constant independent of the applied shear rate (see Fig. 7.7). Systems that behave in this fashion are termed Newtonian. Although it is not explicitly noted, Newtonian fluids will also display a time invariant viscosity. If the shear rate is maintained constant over time, the temperature is maintained constant, and chemical degradation of the sample does not occur, the shear stress that results, and hence the measured viscosity, is also constant. Although most common Newtonian liquids are also low viscosity, these two traits are not inexorably tied together. For example, concentrated sucrose solutions possess substantial viscosity and also exhibit Newtonian flow.

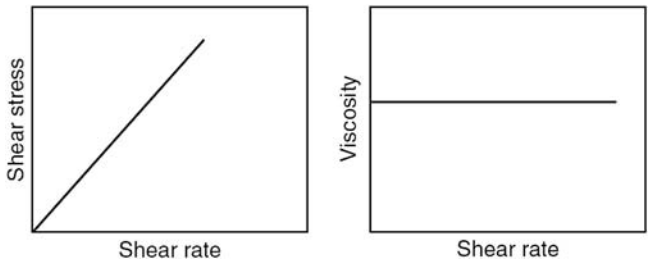

FIGURE 7.7 The simplest case for fluid flow is provided by a simple Newtonian liquid. In this case, the fluid viscosity is independent of the applied shear rate. Common low-molecular-weight unassociated liquids and solutions are Newtonian.

When a polymer is dissolved in a low-molecular-weight Newtonian solvent, the rheological response can become decidedly more complex. The most significant effect is that one observes that the solution viscosity is no longer independent of the applied shear rate under all conditions. One will generally observe that at vanishingly small shear rates, there will be a limited low-shear Newtonian plateau over which the solution viscosity appears independent of the applied

shear rate. As the applied shear rate is increased, one will enter a shear-thinning regime in which the apparent viscosity drops as the shear rate is increased (see Fig. 7.8). Finally, at very high shear rates, one may observe the reestablishment of a regime in which the apparent viscosity is again independent of the applied shear rate, yielding a limited high-shear Newtonian plateau.

An example with actual data is provided in Fig. 7.9. This profile shows the shear-thinning behavior of various viscosity grades of 2.0 wt.% hypromellose in water. Note that even at rather low effective shear rates, achievement of a well-defined low-shear Newtonian plateau is not assured. Finally, the fairly strong shear rate dependence

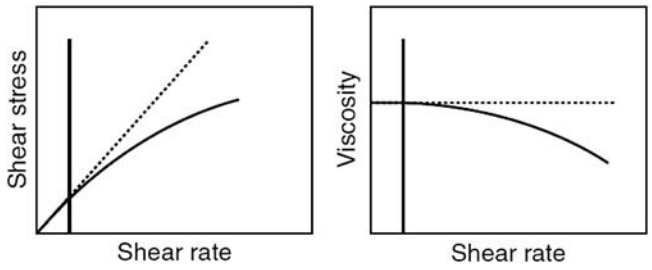

FIGURE 7.8 Most solutions of polymers exhibit some degree of non-Newtonian flow behavior. Simple shear thinning is the most straightforward case. In this example, the system is Newtonian until a critical shear rate is achieved. Above this critical shear rate, the apparent viscosity drops with further increases in shear rate.

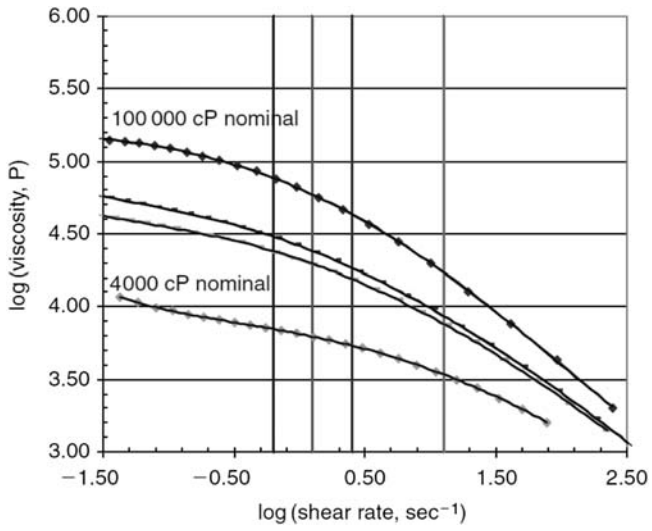

FIGURE 7.9 Typical shear-thinning behavior exhibited by 2 wt.% hypromellose solution in water. The minor apparent upturn in the apparent viscosity of the 4000 cP nominal viscosity sample is an instrumental artifact due to a low analytical signal. The vertical lines indicate (left to right) the effective shear rate applied in a Brookfield rotational viscometer equipped with a cylindrical fixture at 3, 6, 12, and 60 revolutions per minute (rpm).

in the measured viscosity of a polymeric solution can have very practical consequences. As can be observed from the estimated shear rates for a determination of viscosity using a simple Brookfield rotational viscometer under rotational speeds commonly employed in laboratory work (3, 6, 12, and 60 rpm), for a shear-thinning fluid, precise adherence to specified conditions is a clear requirement if the direct comparison of results is desired. For example, the apparent viscosity of the 100,000 cP (grade designation based on 2% Ubbelohde viscosity using the USP methodology) would appear to be roughly 75,000 cP if measured at with a cylindrical spindle at 3 rpm, while the apparent viscosity is less than 20,000 cP if measured at 60 rpm. This is the reason that the shear rate of the measurement needs to be known in assessing viscometric results, particularly when the sample is in the semidilute regime. Furthermore, while factors such as spindle rotation rates obviously impact the shear rate applied to a system, less obvious factors such as vessel size (if small relative to the rotational fixture in a Brookfield viscosity measurement) can also contribute to the actual shear rate applied to the sample.

In addition to the pronounced shear rate dependence in the apparent viscosity, the concentration dependence can be broken into two regimes for nonelectrolyte polymers, with some added complexities apparent in the case of polyelectrolytes. If one views the state of a discrete polymer chain as the concentration of a system is increased, the solvated chain will rotationally sweep out a distinct and large volume element of the solvent. In a dilute solution, on average, all of the chains will be able to rotationally average their motions without any hindrance from neighboring polymer chains. However, as the concentration is increased, one will reach a point at which the rotationally averaged volume elements first touch, then overlap. Once these volume elements start to overlap, the chains start to entangle with one another. When this occurs, the concentration dependence of the apparent viscosity at constant shear rate increases substantially. This regime, under which polymer chains overlap and entangle with one another, is referred to as the semidilute concentration regime. If one were to examine the profile of apparent viscosity against concentration in log–log coordinates, two distinct power law regimes are generally apparent in the dilute and semidilute regimes. Power law exponents are generally close to 1 in the dilute regime and increase to 3–4 as one transitions to the semidilute regime (see Fig. 7.10). From a fundamental basis, characterization of the apparent viscosity dilute and semidilute regimes is best done using results extrapolated to zero shear rate (ie, reflective of the low-shear Newtonian plateau). However, operationally, these analyses and general guides also apply with reasonable fidelity under

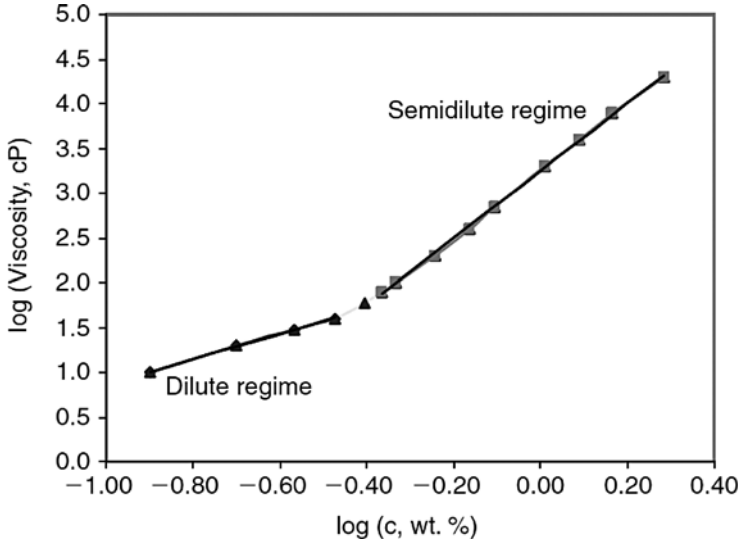

FIGURE 7.10 Example of the concentration dependence of viscosity for sodium carboxymethyl cellulose (DS ~ 0.7, 7H type) as concentration is varied from roughly 0.10 to 2.0 wt.%. Clear distinction of the dilute and semidilute regimes is apparent. The solutions represented in this example were prepared using pure water as the solvent, hence the ionic strength of the solution is not held constant as the polymer concentration is increased. This results in a slight lowering of the power law slope in both the dilute and semidilute regimes.

conditions of finite shear. The distinction is important, since most workers will have access to a Brookfield rotational viscometer to characterize these materials, with this style of measurement generally being practiced at effective shear rates well above that needed to observe the low-shear Newtonian plateau.

In the case of polyelectrolyte, additional complications exist due to the strong dependence of the expansion of a solvated chain on the net ionic strength of a solution. Fig. 7.11 depicts the dependence of the intrinsic viscosity of a sodium carboxymethyl cellulose sample as a function of ionic strength in dilute solution. As one would anticipate, the addition of an indifferent electrolyte screens the repulsion of like charges along a polyelectrolyte backbone, allowing the chain to adopt a more relaxed random coil configuration in solution. The net result is a drop in viscosity in the system. As depicted in Fig. 7.11, the drop in viscosity can be relatively large for modest changes in ionic strength.

In a solution with no added indifferent electrolyte, the general viscosity behavior of polyelectrolytes is similar to nonelectrolytes, with the added feature of the progressively increasing screening of bound charge sites yielding an apparent lowering of power law exponents in both the dilute and semidilute regimes, since the apparent ionic strength increases with polymer concentration. This complexity can be suppressed by the addition of an indifferent electrolyte to maintain a nearly constant net ionic strength in solution. Naturally, this can further suppress viscosity build in the system.

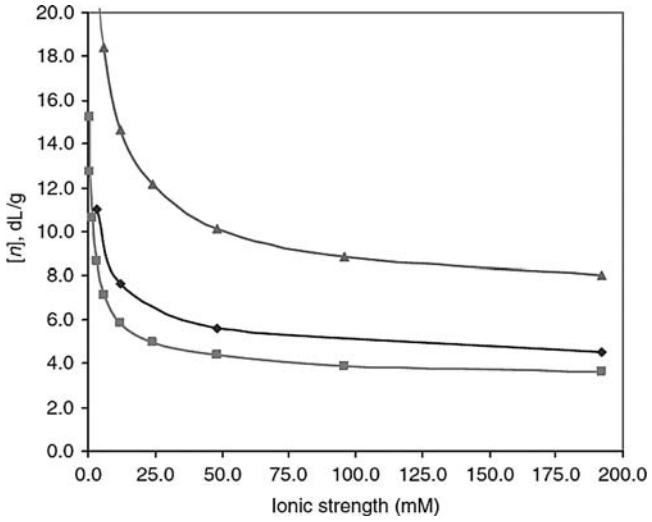

FIGURE 7.11 Impact of an added electrolyte on the intrinsic viscosity of a typical polyelectrolyte, in this case sodium carboxymethyl cellulose (NaCMC). (Original data from Pals, D. T. & Hermans, J. J. (1952). Rec. Trav. Chim. Pays-Bas, 71, 433–443.) At low ionic strength, the NaCMC chains adopt a relatively rigid, rod-like conformation due to electrostatic repulsion between adjacent chain-bound anionic charges. As the ionic strength is increased, this repulsive interaction is screened, and the polymer adopts a less rigid conformation.

Finally, in addition to solution shear thinning due to alignment of chains by the applied shear field, the presence of labile association aggregates can yield a time-dependent apparent viscosity that is dependent on the recent shear history of the sample (see Fig. 7.12). This characteristic is termed "thixotropy," and it arises

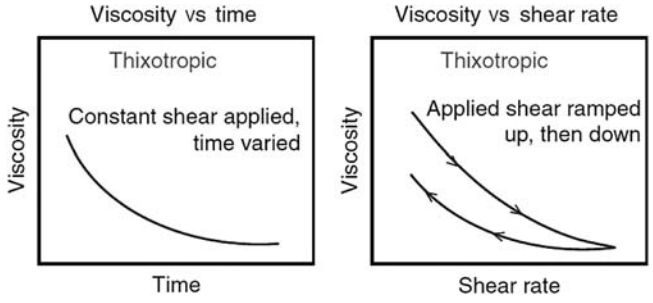

FIGURE 7.12 Polymeric systems in which reversible interpolymer association is possible display a characteristic known as thixotropy. Basically, the mechanical stress applied to the system causes reversible disassembly of the aggregate network. Under conditions of steady shear, this yields a slow decrease in the apparent viscosity over time. The extent of disassembly is dependent on the net force applied to the system, hence the drop in viscosity can occur from either a quiescent state or if a sheared system is subjected to a higher shear rate. By the same token, on a decrease in applied shear rate, the apparent viscosity exhibits recovery. The magnitude of the effect is generally quantified by measuring the disparity in flow curves obtained in a simple experiment in which the shear rate is ramped up then down with continuous recording of the viscosity.

from the association-dissociation of aggregates, which is much slower than the timescale of the measuring experiment.

Although relating solution rheology to molecular weight is best pursued using extrapolated zero shear values, the use of power law relationships in the semidilute concentration regime at finite shear typically yields operationally useful relationships for the quick estimation of molecular weight. Owing to pragmatic instrumental limitations, these experiments generally involve data acquired over a range of shear rates. This can lower the overall quality of the correlation, but it is still useful for routine estimates.

Power law relationships of the form:

$$\log(M_w) = a + b * \log\left[\frac{\eta}{c^{\alpha}}\right]$$

are often found to operationally model the data. In the equation above, M_w is the average molecular weight, while η is the solution viscosity at concentration c. The constants a, b, and α can be viewed simply as mathematical fitting constants, although α is related to the power law concentration exponent in the semidilute regime. An example of this treatment is shown in Fig. 7.13 for three types of cellulosic derivative. The specific relationships shown are as follows:

HPC:

$$\log(M_w) = 5.08 + 0.305 * \log\left[\frac{\eta}{c^{3.2}}\right]$$

Hydroxyethyl cellulose:

$$\log(M_w) = 5.00 + 0.306 * \log\left[\frac{\eta}{c^{3.1}}\right]$$

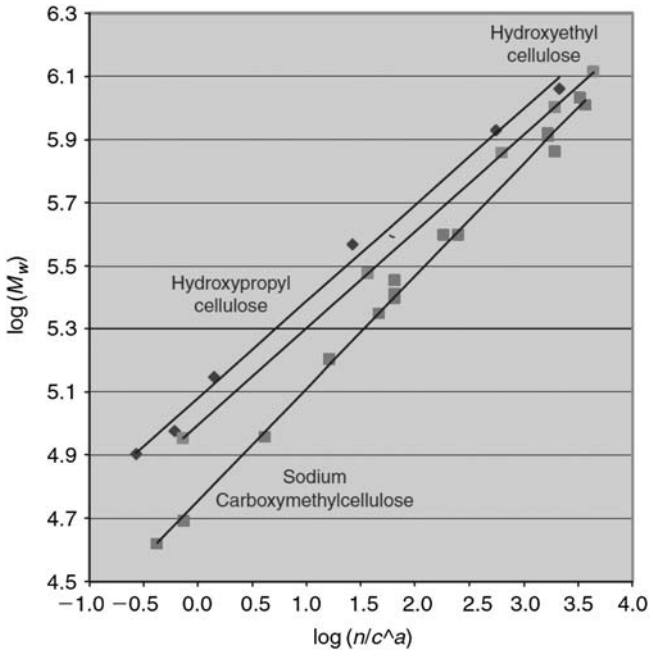

FIGURE 7.13 Polymer master viscosity/concentration/M_w profiles for cellulose ether excipients using Brookfield viscosity values at variable concentration and assuming a simple power law relationship. Separate curves for HPC, hydroxyethyl cellulose, and sodium carboxymethyl cellulose are shown. These curves span the entire product range viscosity for the derivative types shown and listed in Table 7.8, later in this chapter.

Sodium carboxymethyl cellulose:

$$\log(M_w) = 4.78 + 0.356 * \log\left[\frac{\eta}{c^{3.1}}\right]$$

where:

M_w is the nominal material molecular weight;
η is the solution Brookfield viscosity;
c is weight percentage polymer concentration.

Naturally, these relations can be rearranged to yield initial estimates of the concentration of any specific grade of polymer required to achieve a target of viscosity.

There are a few key points related to rheology and polymers that are worth noting:

1. Since the rheology of a polymer solution is molecular-weight dependent, rheology/viscometry can be used as an indirect proxy to monitor molecular weight.
2. Although, strictly speaking, one should use the apparent viscosity extrapolated to zero shear in modeling the molecular-weight dependence of polymer solution viscosity, reasonably good master curves obtained at finite shear rates and at variable concentration can be used to provide decent pragmatic estimates of the molecular weight of a polymer sample.

3. Owing to the very strong concentration dependence, the actual polymer concentration needs to be accurately known. Since the power law exponent of viscosity–concentration curves in the semidilute region have a log–log slope of 3–4, an x% error in specifying the concentration yields a 3x%–4x% error in the calculated viscosity.
4. Solution viscometric experiments generally provide information related to the average M_w of a system. No information on the breadth of the molecular weight distribution is provided.
5. The magnitude of the exponent in the power law dependence in viscosity as a function of concentration, as seen in Figs. 7.10 and 7.13, is the origin of typical rules of thumb used to estimate viscosity at different concentrations. For example, a doubling in weight percentage concentration often yields an increase in viscosity of roughly 10-fold, which follows directly from the type of power law behavior shown in Fig. 7.10.

7.2.4 Polymers in solution

Understanding the unique solution behavior of polymers mainly resides primarily in appreciating a few key points.

First, the high molecular weight of a polymeric solute significantly lowers the entropy of mixing for a polymer solvent binary system, lowering this component of the net free energy of solution. This was treated some time ago by Flory[6] and more recently by Sanchez and Lacombe,[22–24] which captures the essential results.

At an ideal level, taking a solution as a simple lattice model, we find:

$$\Delta S_{\text{mix}} = -R(n_1 \ln(\varphi_1) + n_2 \ln(\varphi_2))$$

or

$$\Delta S_{\text{mix}} = -R\left[\frac{\varphi_1}{DP_1}\ln(\varphi_1) + \frac{\varphi_2}{DP_2}\ln(\varphi_2)\right]$$

As is apparent from the inverse dependence of the prelogarithmic factor of each term on the degree of polymerization (DP) or, equivalently, the molecular weight of the components in the mixture, if either one or both of these components is a high-molecular-weight material, the magnitude of the entropy is lowered as the molecular weight is increased. In broad strokes, as the molecular weight increases, the free energy driving force for dissolution is lowered, since the gain in entropy by the polymer on dissolution is quite low.

One direct consequence of the lowered entropy of solution is that in a chemically homogeneous system precipitation of a polymeric solute, as solvent conditions transition from good to poor, it starts with the high-molecular-weight portion of the distribution and proceeds with decreasing molecular weight. This provides a relatively facile manner to perform crude molecular weight-based preparative isolation. It also suggests that for a partially soluble material (again, assumed to be chemically homogeneous), the undissolved fraction is typically enriched in the high-molecular-weight fraction.

Secondly, most polymers under consideration here are copolymeric materials, for which the various component monomers have rather different intrinsic solubility. For example, in the case of HPC, a single unsubstituted anhydroglucose moiety is quite hydrophilic, while a heavily hydroxypropylated anhydroglucose residue is rather hydrophobic. The constituent monomers in a real sample will span a wide range in hydrophobic nature, thus their distinct distribution across chains (interchain heterogeneity), and within chains (intrachain heterogeneity). The net result is that at any specific solvent composition a situation can arise in which subpopulations of entire chains may be soluble or insoluble, or discrete subsections of single chains may be solvated or unsolvated.

Thirdly, the linear array of monomer groups provides a spatial template upon which relatively low-energy intermolecular forces can operate in a cooperative fashion to yield fairly strong interchain associations. A specific example of this would be the interchain association of unsubstituted anhydroglucose runs in sodium carboxymethyl cellulose to yield textured solutions and thixotropic rheology.

With respect to gross solution behavior, the same basic rules that guide the dissolution of low-molecular-weight species also apply to polymers. As with low-molecular-weight materials, “like dissolves like.” This is captured somewhat more quantitatively in the extended solubility parameter approach,[25–27] in which the cohesive energy of a material is divided into contributions arising from distinct types of intermolecular interactions (dispersive, polar, hydrogen bonding). While the usual admonishment that “like dissolves like” is somewhat more quantitatively expressed within the solubility parameter approach as a matching of the cohesive energy densities of the two materials (solubility is maximized when the cohesive energy densities of the solvent and solute are equal and decreases as they become increasingly disparate), the categorization of the extended solubility parameter approach places a rationale around the basic picture in terms of discrete interaction mechanisms that exist between molecules.

Unlike the situation with low-molecular-weight liquids, one cannot experimentally determine the molar

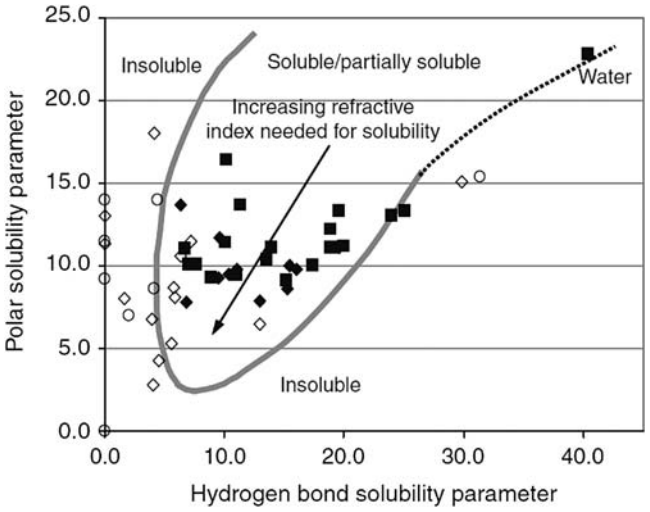

FIGURE 7.14 Solubility characteristics of hydroxypropyl cellulose as a function of polar and hydrogen bond solubility parameters. In this solubility map, the solid curve is the soluble/insoluble phase boundary presented in reference.[28] The dashed line is an interpolated boundary taking into account water solubility characteristics. Points shown represent the specific solvents listed in references[27–29] as yielding solutions, described as clear and smooth/soluble (■), moderately granular and/or hazy/partially soluble (◆) or insoluble (○), or uncharacterized systems of unknown solubility (◇).

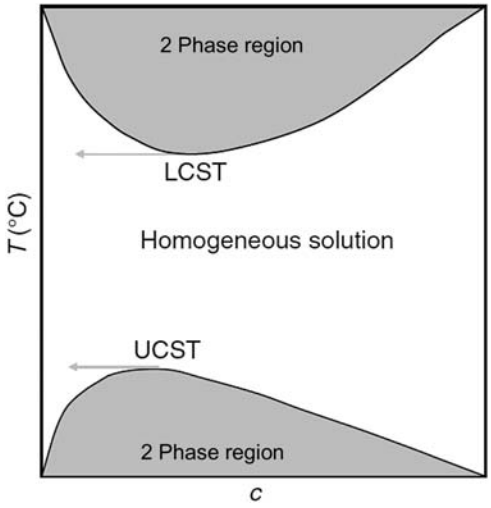

FIGURE 7.15 Schematic representation of upper and lower critical solution temperatures, UCST and LCST respectively. A UCST exists when a polymer transitions from partially soluble to soluble as temperature is raised, while an LCST occurs when a single homogeneous phase splits into two phases with the same increase in temperature. An LCST is often seen with relatively hydrophobic materials, while UCST behavior tends to be observed with systems involved in specific self-association phenomena.

energy of vaporization of polymers and using the molar volume calculate a direct cohesive energy density ($\delta = (E_{vap}/V)^{0.5}$). However, one can perform challenge–response experiments to assess the solubility behavior of a polymer in a number of low molecular weight liquids (insoluble, partially soluble/swellable, soluble) and use those observations to construct solubility parameter-based maps, which can aid in the selection of optimum solvent systems for dissolving a polymeric material. As a specific example, consider HPC.[28,29] Fig. 7.14 contains the qualitative solution behavior of HPC in a variety of solvents presented as a two-dimensional solubility map in terms of the polar and hydrogen bond solubility parameters. As is apparent, there is a reasonably clear demarcation between the insoluble and partially or completely soluble regions. Note that the partially soluble and soluble regions exhibit a substantial overlap. This is largely a consequence of the two-dimensional nature of the plot, which neglects the explicit contribution of dispersive interactions to solubility. The specific solvents for which HPC exhibits good solubility at low polar and/or hydrogen bond solubility parameters tend to be high refractive index liquids (aromatic or halogenated), which increases the dispersive contribution of the net solution energy.

The dissolution characteristics of the polymeric species become complicated when the constituent monomers have vastly different solvation requirements. In that case, the usual recommendation of "like dissolves like" may only apply to a portion of a given polymer chain. In this case, the use of binary and/or ternary solvent mixtures can often yield solutions not possible from any of the pure solvent components.

One other aspect of polymer solubility is the existence of upper and lower critical solution temperatures, referred to as UCST and LCST, respectively, seen in aqueous solutions of many of these polymers. The situation is diagrammatically shown in Fig. 7.15. In the case of an LCST, the system splits into a two-phase system comprised of polymer-rich and polymer-lean compositions at high temperature. As the temperature is lowered, the composition of these two phases approaches one another and then merges into a single phase at the LCST. Similar behavior occurs with the UCST, except that the transition from a two-phase to a one-phase system occurs as the temperature is raised.

In the current application settings, one typically observes an LCST from the perspective of a cloud point, which is simply due to performing the experiment in reverse—starting with a homogeneous solution in the single-phase region and raising the temperature until the solution splits into two phases. This occurs uniformly throughout the volume of solution, which typically yields small droplets of the polymer-rich phase dispersed in the polymer-lean phase. This generates a high level of scattered light, rendering the fluid opaque, and is the origin of the term "cloud point."

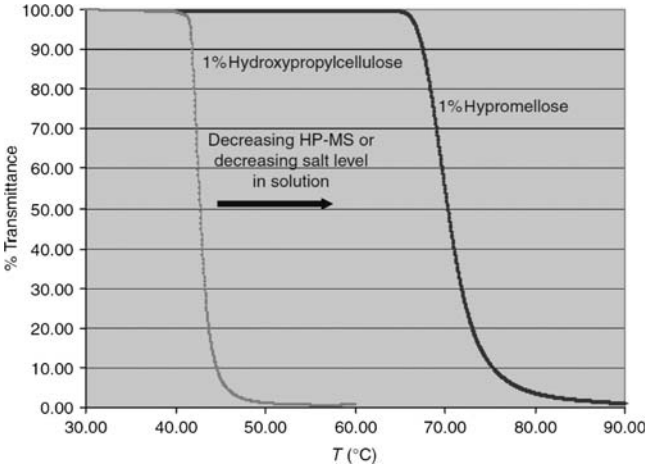

FIGURE 7.16 Cloud point curves for typical high-viscosity grades of hydroxypropyl cellulose and hypromellose (hydroxypropylmethyl cellulose). The major difference in cloud points between these two materials is reflective of the differing hydrophobicities (determined by a combination of hydroxypropyl and methoxyl groups for hypromellose). In addition to the native polymer composition, addition of an indifferent electrolyte can lower the cloud point by a few degrees for typical physiologically relevant ionic strength.

Fig. 7.16 provides an example of two chemically similar systems, HPC and hypromellose, both as 1% solutions in water. The substantial difference in cloud points is related to the substantially different hydrophobicity of these two materials. As is typical for marginally soluble hydrophobic materials, the addition of an electrolyte will move the cloud point to a lower temperature, as would an increase in the hydroxypropyl content of either system or the methoxyl level of the hypromellose sample.

7.2.5 Polymer morphology and physical properties

Polymers may consist of both crystalline and amorphous regions; the degree of crystallinity is usually expressed in terms of a weight fraction or volume fraction of the crystalline portion. The crystallinity of polymers is characterized by their degree of crystallinity and, in principle, can range from zero for a completely noncrystalline or amorphous polymer to one for a theoretical completely crystalline polymer; however, it typically ranges from 10% to 80% in real polymers.[30] Therefore, such crystalline polymers are often called semicrystalline. The properties of semicrystalline polymers are determined by the degree of crystallinity and by the size and orientation of the polymer chains. Polymers containing microcrystalline regions (ie, semicrystalline polymers) are generally tougher (can be bent more without breaking) and more impact-resistant than totally amorphous polymers.

The term melting point, when applied to crystalline polymers, suggests a transition from a crystalline or semicrystalline phase to an amorphous melt phase. Although abbreviated as simply T_m, it may be more properly called the crystalline melting temperature. Among synthetic polymers, crystalline melting is only associated with linear thermoplastic polymers, as highly cross-linked thermosetting polymers will decompose at high temperatures rather than melt.

In an amorphous state, the arrangement of the polymer chains is completely random. There is no restriction to chain movement from the lattice ordering of partially crystalline polymers. Therefore, amorphous polymers do not have sharp melt points; instead they soften gradually with increasing temperature. The physical properties of amorphous polymers are related to the extent of their molecular mobility in the material, which is governed by the chain flexibility and the temperature of the system.

On cooling, rubbery materials undergo a liquid-glass transition, which has also been called a rubber-glass transition. The temperature at which this transition occurs is termed the glass transition temperature (T_g), which describes the temperature at which amorphous polymers undergo a second-order phase transition from a rubbery, viscous amorphous solid to a brittle, glassy amorphous solid. Drastic changes in the physical properties, such as hardness and elasticity, can be observed during this transition as it reflects the onset of changes in the cooperative thermal motion of the polymer backbone segments. These changes are completely reversible, since the transition is a function of molecular mobility rather than polymer structure. At temperatures above T_g, the polymer chains are in relatively rapid thermal motion. The chain movement becomes progressively slower as the temperature is lowered. At T_g, the polymer chains are essentially locked in the conformation they possessed before reaching T_g. Below T_g, the polymer is virtually frozen in a glassy state with a completely random structure. The T_g of a polymer depends largely on the chemical structure of the polymer chain. The glass transition temperature may be modified by altering the chain flexibility, monomer structure and copolymer composition, degree of branching or cross-linking in the polymer, or by the addition of plasticizers. Long-chain branches may increase polymer strength, toughness, and the T_g due to an increase in the number of entanglements per chain. Increasing chain length tends to decrease the chain mobility and increase the glass transition temperature (T_g). This is a result of an increase in polymer chain interactions such as van der Waals attractions and entanglements associated with increased chain length. These interactions tend to immobilize individual chains more strongly in situ,

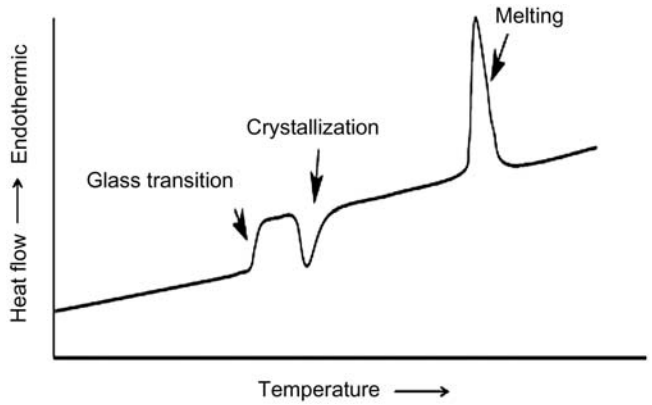

FIGURE 7.17 Typical differential scanning calorimetry (DSC) scan.

resulting in better resistance to deformation and matrix breakup, both at higher stresses and higher temperatures.

The glass temperature of a polymer can be characterized experimentally by measuring basic thermodynamic, physical, mechanical, or electrical properties as a function of temperature. Thermal method such as differential scanning calorimetry (DSC) is used routinely for this purpose. A typical DSC scan is shown in Fig. 7.17 where the heat flow is plotted against the average temperature. In addition to sharp peaks corresponding to crystallization and melting events, the change of slope of this scan occurs at the glass transition temperature, which can be related to the enthalpy change associated with this transition.

7.2.6 Structure–property relationships

In polymer chemistry and materials engineering, it is common to design novel materials and formulated systems with improved functional properties based on detailed study and understanding of how the structure of a material impacts the physical and chemical properties that are critical to the end use. In the pharmaceutical industry, it is common to apply this type of approach to the design of drug molecules. For example, quantitative structure–activity relationships are studied to enable the design of drug molecules with optimal therapeutic efficacy. A further example is the optimization of drug solubility and stability through the selection of appropriate salt and crystal forms. Similarly, a good appreciation of structure–property and structure-function relationships is also essential if formulators are to make rational, science-based choices when selecting polymers and other excipients as formulation components. Structure–property and structure–function relationships can be defined as understanding how the chemical or molecular structure of a polymeric excipient impacts the physical and chemical properties that are critical to the end use functionality. These concepts are gaining increasing significance in the context of quality by design (QbD). QbD is defined as a systematic, scientific, risk-based, and holistic approach to pharmaceutical development that begins with predefined objectives and emphasizes product and process understanding and process control. A requirement of QbD is to identify critical material attributes (CMAs), which are defined as the physical, chemical, and biological properties of an input material that should be within specific limits to ensure desired quality. For polymeric excipients, this essentially requires the understanding of structure-function and structure-property relationships.

The following section will attempt to illustrate some of the major, generally applicable structure–property relationships that are of practical use and specifically relevant to pharmaceutical polymers and their use in solid oral controlled-release dosage forms. These include the impact of MW, substitution, and copolymerization on solution, gel, mechanical, and thermal properties. While the general principles are applicable across a wide range of polymers, many of the examples given here will focus on cellulose derivatives and vinylpyrrolidone polymers, as these are the most commonly used classes of polymers in oral solid dosage form design.

7.2.6.1 Molecular weight effects

7.2.6.1.1 Effect of molecular weight on solution viscosity

Many polymer properties are molecular-weight dependent, including solution and melt viscosity, glass transition temperatures, mechanical properties, and gel strength. Perhaps the most important and frequently applied structure–property relationship is the correlation between dilute solution viscosity and molecular weight. As a longer polymer chain gyrates in solution, it can be visualized to occupy a larger volume of the solvent, collide, and overlap more frequently with other long polymer chains as compared to shorter polymer chains. The initial fundamental observation and prediction that solution viscosity is proportional to polymer molecular weight was made by Staudinger and Heuer.[31] For linear polymers, the Mark–Houwink equation provides an empirical model for this is relationship:

$$\eta = kM^a$$

where:

η is the specific viscosity;
M is the weight-average molecular weight;
K and a are polymer, solvent, and temperature dependent.

Generally, a varies between 0.5 and 1. For poor solvents in which the polymer remains coiled, $a = 0.5$. For good solvents, a varies between 0.65 and 0.8. For stiff, asymmetrical molecules in good solvents, a may approach 1. It should be noted this specifically applies to linear polymer molecules. Highly branched, bush-shaped polymer structures may have a large molecular weight but occupy proportionally smaller volumes in their solvated state.

7.2.6.1.2 Effect of molecular weight on mechanical and thermoplastic properties

Many physical properties of amorphous polymers, including mechanical and thermoplastic properties, show strong molecular-weight dependence. Frequently, a general relationship applies where molecular weight changes in the lower middle molecular weight range result in large changes in the physical property of interest. However, as shown in Fig. 7.18, after reaching a threshold level in molecular weight, further molecular weight increases result in only minor changes in the physical property of interest.

Often these phenomena can be explained on the basis of chain end concentration, that is, lower-molecular-weight polymer chains are shorter, and thus for the same amount of material, there is a proportionate increase in the number of molecules and thus chain ends. The chain ends tend to be associated with a greater degree of mobility and free volume as compared to the middle segments of a polymer chain. Consequently, lower molecular weight is generally associated with greater plasticity and lower glass transition temperatures. In contrast, longer polymer chains (lower chain end concentration) are generally associated with increased elasticity and flexibility.

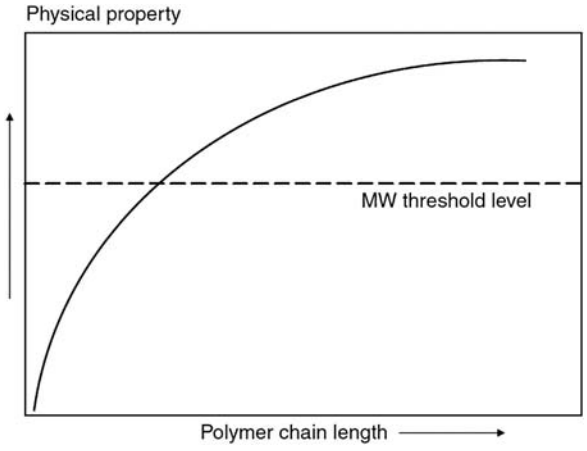

FIGURE 7.18 General relationship between polymer chain length (molecular weight) and physical properties such as tensile strength and T_g.

7.2.6.1.3 Mechanical strength of films

One of the most useful mechanical tests for polymeric and pharmaceutical materials in general is to determine its tensile strength and the accompanying stress–strain curve. This is generally done by using a mechanical testing machine and continuously measuring the force developed as the material is elongated at a constant rate of extension. Fig. 7.19 illustrates a typical stress–strain curve. Important mechanical properties of a material include the modulus (slope of the initial curve), which is a measure of the material stiffness; yield stress; strength; ultimate strength; elongation at break; and toughness (area under the curve).

For practical purposes, it is often useful to divide polymeric materials into five common classes depending on their stress–strain behavior. These common classes are illustrated in Table 7.1.

For polymer films, an increase in molecular weight tends to increase film tensile strength, elongation, and flexibility. This can be explained on the basis that longer polymer chains exhibit greater flexibility and elasticity. They can thus be extended further before rupture, as compared with short polymer chains.

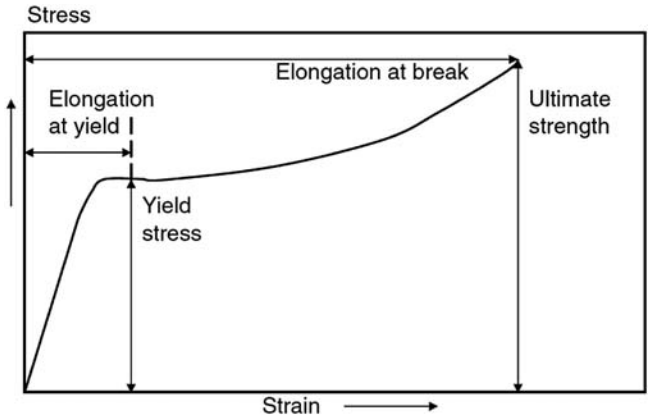

FIGURE 7.19 Typical tensile stress–strain curve for a polymer specimen tested in tension.

TABLE 7.1 Common Classes of Materials Based on Their Stress–Strain Curve Characteristics (Ref. 32)

Class	Modulus	Yield stress	Ultimate strength	Elongation at break
Soft and weak	Low	Low	Low	Moderate
Soft and tough	Low	Low	Moderate	High
Hard and brittle	High	None	Moderate	Low
Hard and strong	High	High	High	Moderate
Hard and tough	High	High	High	High

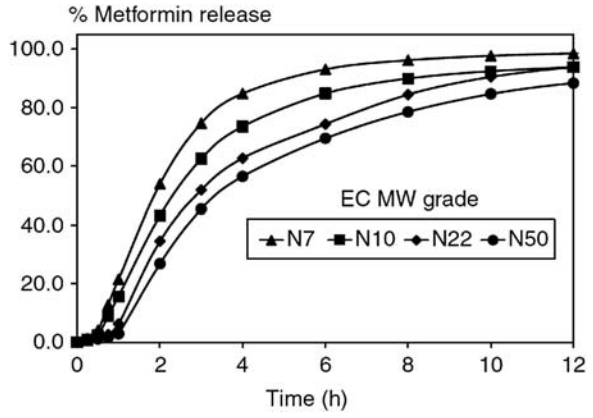

FIGURE 7.21 Drug release from metformin HCl pellets coated with various molecular weight grades of Ashland N Pharm ethyl cellulose (EC).[33] N7, N10, N22, and N50 refers to different molecular weight grades with 7, 10, 22, and 50 cps solution viscosity (5 wt.% solution in 80:20 toluene:ethanol), respectively.

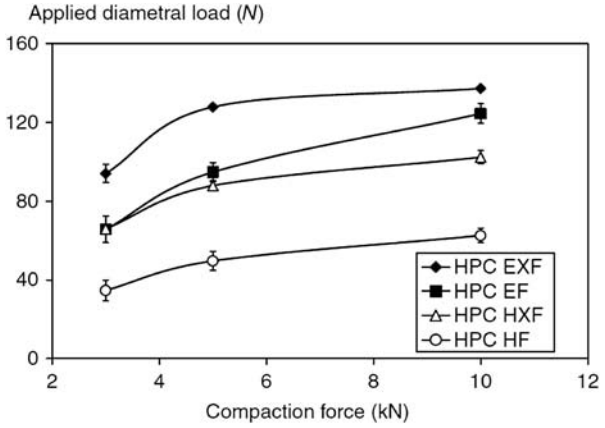

FIGURE 7.22 Compactability for various molecular weight and particle size types of hydroxypropyl cellulose. Klucel™ EXF Pharm HPC (80 kDA, 70 μm average particle size) Klucel™ EF Pharm HPC (80 kDA molecular weight, 200 μm average particle size), Klucel™ HXF Pharm HPC (1000 kDA molecular weight, 70 μm average particle size), Klucel™ HF Pharm HPC (80 kDA, 200 μm average particle size); 300 mg pure polymer tablets were compressed on a Manesty BetaPress using 7/16″ round flat-faced tooling.

A general relationship describing this behavior is given by the following equation:

$$\text{Tensile strength} = a - \frac{b}{M_n}$$

where a is the tensile strength threshold, beyond which further molecular weight increases become ineffective; b is a material-dependent constant; and M_n is number average molecular weight.[32] An example of this is given in Fig. 7.20, which shows the viscosity (MW) dependence of ethyl cellulose film properties.

Film strength is of significance in membrane reservoir controlled-release dosage forms such as multiparticulates or tablets coated with ethyl cellulose controlled-release films. It has been shown that the drug-release kinetics of such systems are directly proportional to the film strength and, by inference, polymer molecular weight (Fig. 7.21). This is due to the fact that the drug release from membrane–reservoir systems is osmotic pressure dependent. As the water enters the dosage forms via osmosis and builds up hydrostatic pressure in the core, it increasingly exerts a stress on the membrane until fissures and cracks open up, resulting in the release of the drug due to osmotic pumping.[33–35]

Similar examples of increasing film strength with molecular weight are known for the majority of pharmaceutical polymers. A further example is the report by Prodduturi et al., describing the increased mechanical strength of drug-loaded buccal films with increasing molecular weight of HPC used.[36]

7.2.6.1.4 Mechanical strength of tablets

As previously indicated, longer polymer chains impart greater elasticity, while the greater chain-end concentration found with decreasing molecular weight results in greater plasticity and molecular mobility. For directly compressed tablets, lower polymer molecular weight, therefore, results in less postejection elastic recovery and greater permanent deformation. For example, low-molecular-weight HPC grades have been reported to yield stronger tablets than high-molecular-weight HPC due to greater plasticity and lower postcompaction ejection.[37] However, this disadvantage of high-molecular-weight polymers can be partly neutralized by using fine-particle-size HPC (Fig. 7.22).[38] Similar observations have also been made for ethyl cellulose matrix tablets.[39]

7.2.6.1.5 Glass transition temperature, melting point, and melt index

The glass transition temperature (T_g), melting point temperature, and melt index are fundamental characteristics related to thermoplastic behavior. Similar to mechanical properties, a negative inverse relationship has also been postulated for T_g and molecular weight[40]:

$$T_g = T_g^{\infty} - \frac{k}{M_n}$$

where T_g^{∞} is the glass transition at infinite molecular weight, and k is a constant. The greater flexibility and lower T_g of lower-molecular-weight polymers are attributed to the greater concentration and mobility of polymer chain ends versus the chain middle. Due to their greater mobility and the effective defect in material packing that they create, chain ends are associated with greater excess free volume. In a series of equally substituted polymers, lower-molecular-weight polymers will thus have a greater concentration of chain ends, resulting in greater excess free volume, greater molecular mobility, and a lower T_g. A good example of this is provided by poly(vinyl pyrrolidone) (PVP), a simple, linear, polymer molecule with additional side chains or cross-linking. Table 7.2 Illustrates the inverse relationship between T_g and molecular weight. Additionally, Fig. 7.23 shows the change in T_g as a function of solution viscosity (as an indirect proxy for molecular weight) for a series of ethyl cellulose polymers.

T_g is an important fundamental property of amorphous and semicrystalline polymer systems, and it is frequently correlated with properties such as plasticity, ductility, film-forming ability, and stickiness. While polymer molecular weight is a major factor determining T_g values, numerous other structural factors will impact molecular rigidity and order, and, by implication, T_g. Some of these factors are summarized in Table 7.3.

Similarly to T_g, melting point temperatures and melt viscosity increase with increasing molecular weight. Operationally, polymer flow is typically characterized using a melt flow index, which is an inverse measure of melt viscosity. These properties are especially critical in modified-release dosage form design in the context of thermal processing, such as melt extrusion and injection molding. Frequently, higher melt flow index polymers are required for thermal processing in the range at or below 100°C in order to avoid thermal degradation of drug and acceptable throughput rates. Fig. 7.24 shows the variation of melt flow indices for different molecular weight grades of HPC, a thermoplastic polymer that is commonly used in melt extrusion processes, such as the manufacture of oral film strips and other extruded drug delivery devices.

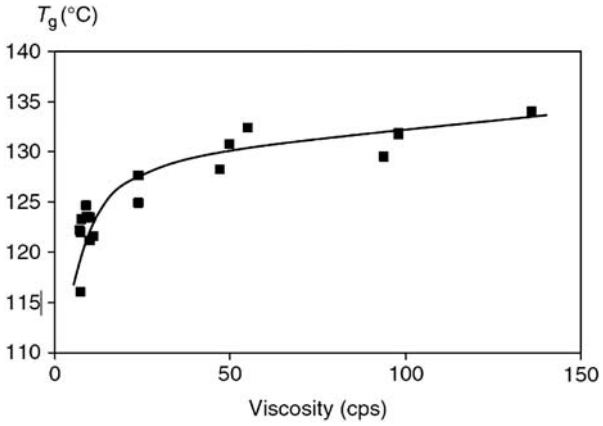

FIGURE 7.23 Glass transition temperature (T_g) as a function of solution viscosity (an indicator of molecular weight) for a series of Ashland ethyl cellulose polymers. In all cases, substitution was between 49.8 and 51 wt.% ethoxyl content.

Increased cross-link density	Higher

7.2.6.1.6 Effect of molecular weight on gel strength

The relationship between gel strength and polymer molecular weight is of particular importance in the field of modified-release dosage form design. For hydrophilic matrix tablets, the gel strength will determine the erodibility of the matrix system. Erosion can

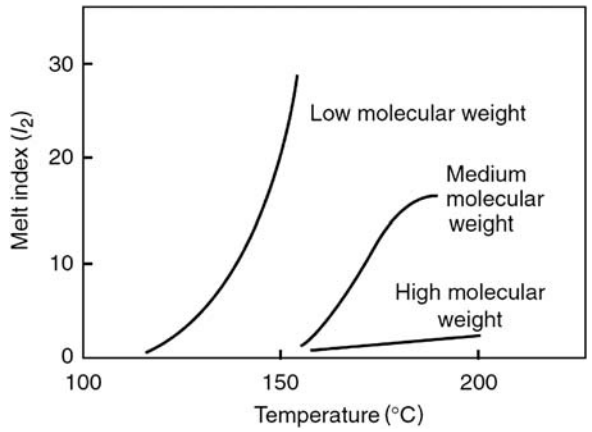

FIGURE 7.24 Melt index, I_2, as a function of temperature and Klucel™ hydroxypropyl cellulose molecular weight. The melt index is defined as the grams of molten material that is extruded under standard American Society for Testing and Materials (ASTM)-defined conditions in 10 min at a given temperature and applied load.

be described as polymer dissolution or the disentanglement of polymer chains from the gel surface and transfer of the polymer to the bulk solution. Erosion can be used to the formulator's advantage when designing a delivery system for insoluble drugs. Here, erosion is the main mechanism facilitating transfer of the insoluble drug out of the tablet matrix and into the dissolution medium. However, poor release characteristics such as variable burst release and dose dumping may be expected for a highly soluble drug that is formulated in a highly erodible dosage form.

For hydrophilic polymers such as hypromellose and HPC compressed into matrix tablets, the disentanglement concentration of the polymer follows a nonlinear, inverse relationship with molecular weight.[41] Furthermore, the polymer matrix erosion rate has also been shown to vary with the molecular weight in a nonlinear, inverse manner[42]:

$$\text{Erosion rate} = kM_n^{-a}$$

It should be noted that the opposite relationship applies to matrix swelling, that is, swellability increases with molecular weight up to a limiting threshold level. The rate and extent of polymer matrix swelling and erosion and the drug solubility and concentration are the dominant compositional factors determining drug-release kinetics from matrix tablet systems. Figs. 7.25–7.27 show the impact of the polymer molecular weight on the matrix tablet erosion, swelling, and drug release for a typical sparingly soluble compound, nifedipine.

7.2.6.2 *Side-chain substitution effects*

The structure of the side-chain substituents on the polymer backbone is a major compositional factor

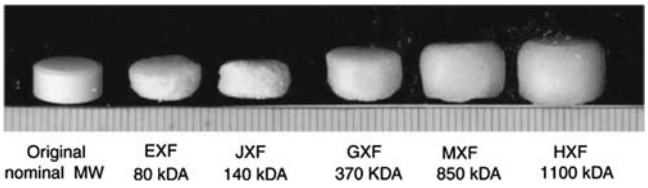

FIGURE 7.25 Effect of Klucel™ Pharm HPC molecular-weight grade on erosion and swelling behavior of nifedipine matrix tablets subjected to dissolution testing for 4 h. Formulation: 20% nifedipine, 30% HPC, 49.5% microcrystalline cellulose, and 0.5% magnesium stearate.

impacting polymer functionality. Important aspects of substitution are the chemical structure of the substituents, the extent of backbone substitution, and the uniformity of substitution. In this section, we will mainly focus on the impact of substituent type and the extent of substitution on the functionality in modified-release systems.

7.2.6.2.1 Side-chain structure (substituent type)

Effect of side-chain structure on polymer solubility. In most cases, substitution of less polar groups for hydrogens or hydroxyls on a polymer chain leads to a reduction in crystallinity and, usually, also a reduction in melting points. Such changes are thus generally expected to improve thermoplasticity and polymer solubility. A good example is presented by cellulose, a naturally occurring polymer comprised of anhydroglucose units. Native cellulose has considerable microcrystalline character. When the free hydroxyls on the anhydroglucose backbone are substituted with hydroxyalkyl side chains, for example, hydroxypropyl or hydroxyethyl groups, the crystallinity of the resultant hydroxypropyl or hydroxyethyl cellulose is below the limit of reliable quantification (<10%). Moreover, unlike microcrystalline cellulose, the derivatized cellulose ethers are freely gelling and soluble in water. Polymer water solubility can be further enhanced by deliberate inclusion of highly polar, ionizable substituents. Sodium carboxymethyl cellulose (NaCMC) is an example of this.

Unlike small drug molecules, it is not useful to describe the solubility of a polymer in a given solvent system in terms of saturation concentration values (eg, g/mL). Among the more useful methods, solubility parameters can be used to evaluate the solubility and compatibility between a polymer and solvent or other additives with solvent-like properties. Additionally, for water solubility, equilibrium moisture content (hygroscopicity) and cloud point are useful indirect measures of water solubility. The solubility parameters for a series of differently substituted cellulose ether molecules and other materials of interest to formulators are shown in Table 7.4.

For many polymers including cellulose, the relationship between water solubility and the nature of the side chain or substituent chemistry can be understood in terms of hydrogen bonding between the hydrogen atoms of water and the polar oxygen atoms present in the polymer backbone and on the side chains. Studying a series of alkali celluloses of similar molecular weight, Klug[43] showed that polymer hydrophilicity increases as the oxygen content of the derivatized cellulose increases due to either the type or the extent of substitution. Sodium carboxymethyl cellulose is an exception due to its ionic character. The increased hydrophilicity impacts numerous important properties such as hygroscopicity, cloud point, matrix tablet swelling ability, and matrix gel strength. The general relationship is shown in Fig. 7.28.

TABLE 7.4 Solubility Parameters for a Series of Cellulose Ethers and Other Materials of Interest

Polymer or drug molecule	Average solubility parameter,[a] δ ($MPa^{½}$)
EC (2.7 DS)	19.2
HPC (3.8 MS)	23.2
HPMC (1.9 MS)	23.6
HEC (2.5 MS)	25.0
NaCMC (0.7 DS)	28.9
Cellulose	31.1
PVA	30.2
PEO	19.3
Metformin HCl (highly water-soluble drug)	27.2
Itraconazole (low water-soluble drug)	19.5

[a]*Calculated as the Average of the Hildebrand, Hansen, Fedors, and van Krevelen Solubility Parameters.*

Effect of side-chain structure on gel strength, swelling, and erosion in matrix systems. From Fig. 7.28, it can be seen that the differently substituted cellulose derivatives can be ranked in the following order of ascending hydrophilicity: HPC < MC < HPMC < HEC and CMC. The difference in hydrophilicity due to substitution on the polymer backbone is particularly important for the functionality of hydrophilic matrix systems. As shown in Fig. 7.29, polymer hydrophilicity, in combination

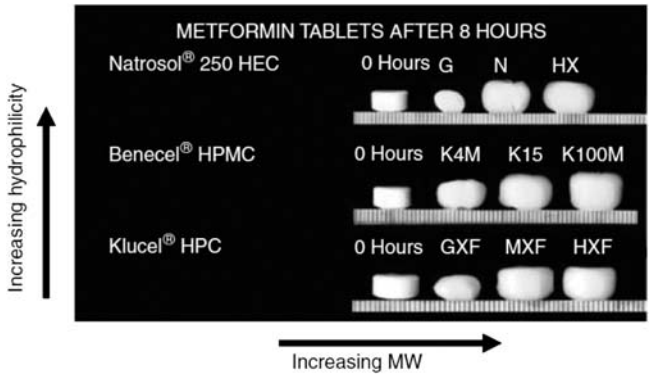

FIGURE 7.29 Matrix tablet swelling and erosion behavior as a function of hydrophilicity (cellulose ether substitution) and molecular weight.

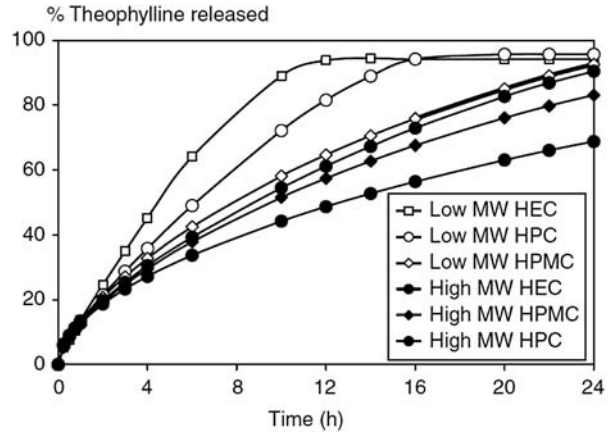

FIGURE 7.30 Drug release from matrix tablets as a function of cellulose ether chemistry and molecular weight.

with molecular weight, has a major impact on matrix swelling and erosion behavior. For medium and low-soluble drugs, these factors are the main determinants of release mechanism and release kinetics (Fig. 7.30).

Effect of side-chain structure on mechanical properties. The nature of the side-chain substituent type also significantly impacts mechanical and thermoplastic properties. HPC and ethyl cellulose (EC) are significantly more thermoplastic than HPMC and HEC. The compactibility of matrix-forming cellulose ethers has been reported to increase in the following rank order: HEC < HPMC < HPC.[44]

7.2.6.2.2 Extent of side-chain substitution

In addition to the identity of the side-chain structure, the amount of side-chain substitution on the polymer backbone can also exert a significant effect on physical and chemical properties of the polymer.

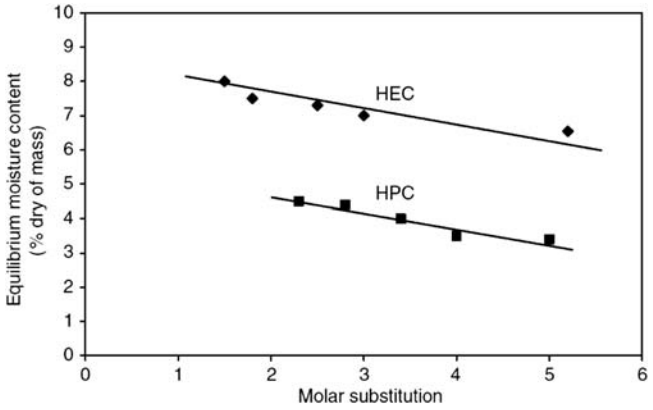

FIGURE 7.31 Effect of substitution level on the equilibrium moisture content of hydroxypropyl and hydroxyethyl cellulose at 50% relative humidity. *Adapted from Klug, E.D. Some properties of water soluble hydroxyalkyl celluloses and their derivatives. J Polym Sci Part C 1971;36:491–508.*

7.2.6.2.3 Effect of extent of substitution on solubility

When highly polar hydroxyl groups on crystalline cellulose are substituted with hydroxyalkyl groups to manufacture HPC or HEC, water solubility initially increases due to a reduction in crystallinity and hydrogen bonding between the cellulose backbone chains. However, as the amount of hydroxyalkyl substitution continues to increase, the polymer becomes increasingly hydrophobic. As shown in Fig. 7.31, the equilibrium moisture content steadily decreases as MS increases from 2.0 to 5.0 for both HEC and HPC. A similar relationship has also been demonstrated for the cloud point.[43] An exception to this behavior is polymers with ionic groups in their side chains. In this case, increasing the level of highly polar substituents will increase water solubility. For example, when the DS for sodium carboxymethyl cellulose is increased from 0.7 to 1.2, the equilibrium moisture content at 50% relative humidity increases from 13% to 18%.[43]

7.2.6.2.4 Effect of extent of substitution on amorphous solid dispersion properties

As explained, the amount of side-chain substitution or the ratio of different substituents will affect the relative hydrophilic-hydrophobic balance of the polymer. When using polymers as carriers for amorphous solid dispersion of poorly soluble drugs, this has the potential to affect the polymers' ability to undergo hydrogen bonding with drug molecules in the solid state, as well as to undergo hydrophobic interaction with drug molecules in the saturated solution state. For example, as shown in Fig. 7.32, HPMCAS is available in three different acetyl/succinyl substitution ratios.

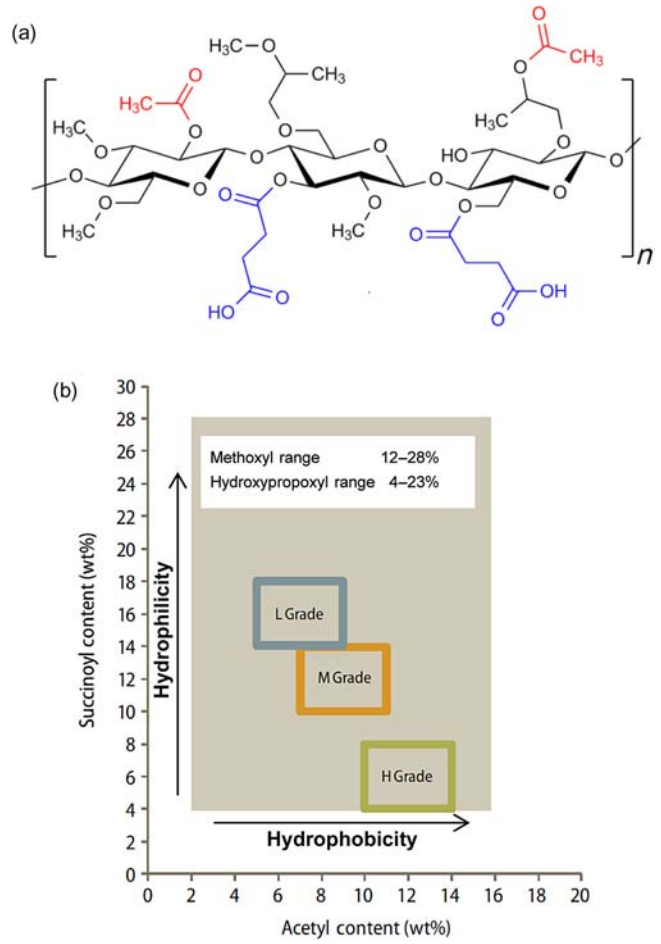

FIGURE 7.32 (a) Idealized chemical structure of HPMCAS. (b) Schematic showing acetyl and succinoyl substitution ranges and effect on hydrophilic/lipophilic balance for different commercial grades of Aquasolv™ HPMCAS.

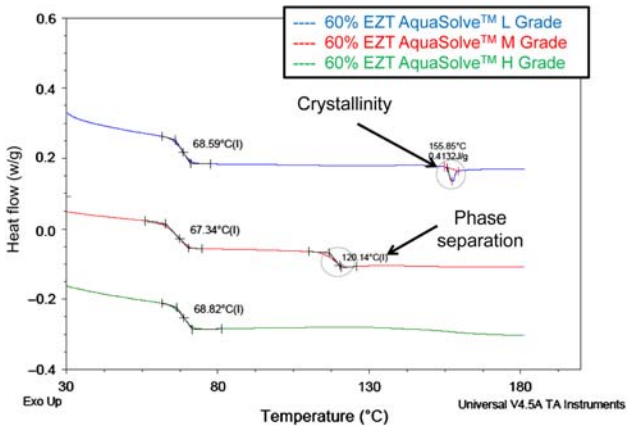

FIGURE 7.33 DSC thermograms for ezetimibe: Aquasolv™ HPMCAS solid dispersions aged for 65 h in open dish conditions at 40°C and 75% relative humidity.

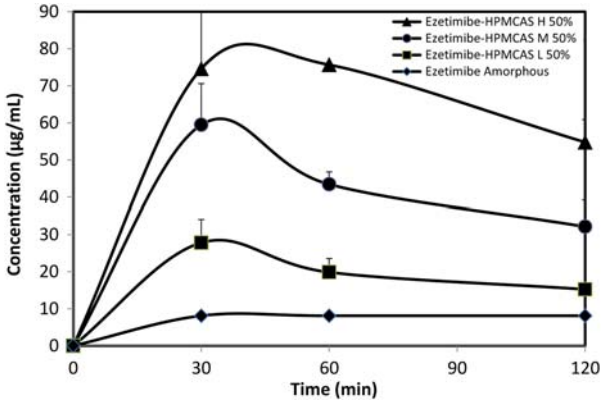

FIGURE 7.34 Nonsink condition dissolution profiles of amorphous ezetimibe and ezetimibe-Aquasolv™ HPMCAS solid dispersions equivalent to 500 µg/mL ezetimibe in 20 mL FaSSIF media at 37°C and 300 rpm using fiber-optic dissolution profiler, µDISS Profiler. At 30, 60 and 120 min, samples ($n = 4$) were centrifuged at 3700 rpm for 5 min, and the supernatant was analyzed for drug concentration.

These different substitution grades can stabilize amorphous solid dispersions to varying degrees, depending on drug properties. Fig. 7.33 shows that H grade is significantly better at preventing recrystallization of rapid recrystallizer ezetimibe in the solid amorphous state than M and L grade, both of which have higher succinoyl content. This can be related to the ability of HPMCAS H grade to undergo better hydrogen bonding.[45]

In addition, the acetyl/succinyl substitution level also affects precipitation inhibition in saturated drug solutions that occurs after the amorphous dispersion is dissolved. Fig. 7.34 shows that HPMCAS with high acetyl, that is, greater hydrophobicity, is more effective at preventing ezetimibe precipitation from saturated solutions. This can be related to an improved hydrophobic interaction and drug-polymer binding capability.[46]

7.2.6.2.5 Effect of extent of substitution on mechanical properties

In addition to increased hydrophobicity, an increase in the amount of less polar substituents generally also results in an increase in polymer plasticity. As shown in Fig. 7.35, in the case of tensile film strength, this manifests in lower ultimate tensile strength but greater elongation and film flexibility. In contrast, increasing the amount of highly polar, ionic side chains tends to result in an increased T_g, a markedly less thermoplastic material. As a result, films will tend to exhibit relatively high tensile strength but will be very brittle and inflexible, with minimal elongation at break. Sodium carboxymethyl cellulose shows this behavior and, as a result, requires high levels of added plasticizer if useful, defect-free films suitable for tablet or particle coating are to be achieved.

[a]*275 mg pure ethyl cellulose tablets compressed on a Manesty BetaPress at 25 kN.*

For polymers compressed into tablets, increasing the number of nonpolar substituents generally results in increased plasticity, lower elastic recovery after compression and ejection, and consequently denser compacts with higher diametral crushing strength (tensile failure). Similarly, decreasing the number of more polar substituents will have the same effect. The compaction behavior of a series of hypromellose and methyl cellulose grades with varying levels of methoxyl (less polar, hydrophobic substituent) and hydroxypropyl (more polar, more hydrophilic substituent) groups illustrates this.[47] As can be seen in Table 7.5, as the percentage of methoxyl in the polymer increases and the percentage of hydroxypropyl decreases, for a series of similar viscosity polymers, the tablet strength significantly increases.

An additional example of the significant effect that an increase in the number of nonpolar substituents can have is provided by ethyl cellulose (EC). It has been reported that a higher compactability of EC was associated with high ethoxyl content and low molecular weight (low viscosity) (Fig. 7.36).[92]

High substitution and low molecular weight were also correlated with significantly higher crystallinity and higher melting points, while the amorphous regions had lower glass transition temperatures (Table 7.6). Compaction simulator studies showed that the net effect of this unique solid-state structure is a marked reduction in postcompaction elastic recovery of the polymer (Fig. 7.37). Less energy of compaction was therefore lost due to postcompaction axial expansion, resulting in denser compacts with lower porosity. This had a significant effect on drug diffusion from nonswelling, porosity-controlled matrix tablets. Additionally, the reduced viscoelasticity resulted in lower strain rate sensitivity (10% vs typically 20–25% for other EC types).

7.2.6.3 Copolymerization

7.2.6.3.1 Thermal properties of copolymers

When the monomers of two crystalline homopolymers are combined, the degree of crystallinity and the

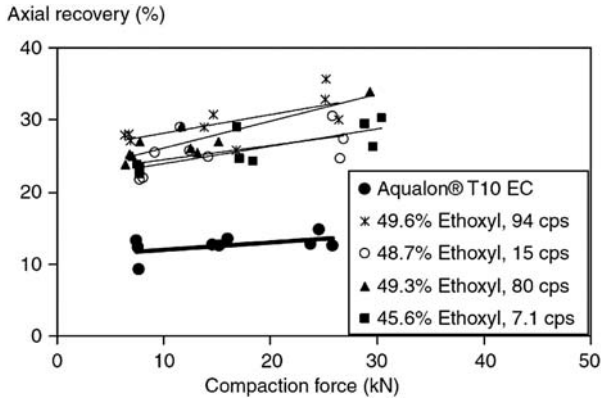

FIGURE 7.37 Effect of ethoxyl content and viscosity on postcompaction axial recovery. High ethoxyl, low-viscosity Ashland T10 EC has the lowest axial recovery.

melting point are usually depressed. The following relationship frequently applies:

$$\frac{1}{T_m} = \frac{1}{T_m^0} - \frac{R}{\Delta H_m}\ln(n)$$

where:

n is the mole fraction of crystalline constituent;
T_m is the melting point of the copolymer;
T_m^0 is the melting point of the pure homopolymer;
ΔH_m is the heat of fusion.[2]

In contrast, the glass transition temperature, T_g, of random copolymers usually falls into the range between that of the two corresponding homopolymers. This difference between how T_m and T_g of a copolymer are affected can be attributed to the fact that crystal structure disruption is not relevant to T_g of the amorphous polymer domains. Frequently, a simple weight-average mixing rule of the following type can be applied to get an approximate idea of the resultant T_g of the copolymer:

$$a_1 w_1 (T_g - T_{g1}) + a_2 w_2 (T_g - T_{g2}) = 0$$

where:

T_{g1} and T_{g2} refers to the individual homopolymers;
w_1 and w_2 are weight fractions of monomers 1 and 2;
a_1 and a_2 depend on monomer type.[48]

The 60:40 random copolymer of vinylpyrrolidone and vinyl acetate (copovidone) is a good example of this phenomenon. As shown in Fig. 7.38, the addition of vinyl acetate to vinylpyrrolidone results in a T_g of 105°C, which intermediate between polyvinylpyrrolidone (povidone) of similar molecular weight (165°C) and polyvinyl acetate (70°C) and a significant T_g reduction when compared to polyvinylpyrrolidone alone.

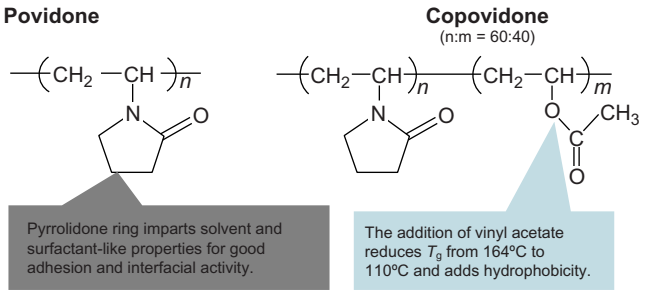

FIGURE 7.38 Schematic structures of povidone and copovidone.

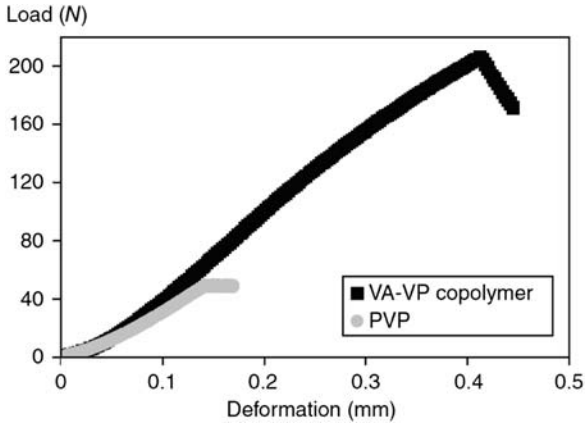

FIGURE 7.39 Load–deformation plots for the pure polymer tablets of povidone ($T_g \sim 161$°C and copovidone ($T_g \sim 101$°C) subjected to diametral compression.

7.2.6.3.2 Mechanical properties of copolymers

The decrease in T_g, and T_m as a result of adding a comonomer to an amorphous or crystalline generally results in an increase in copolymer plasticity and flexibility. Therefore, copolymers are frequently better film formers and tablet binders than the initial homopolymer. Povidone (PVP) and copovidone, the 6:4 random copolymer of vinylpyrrolidone and vinyl acetate (VP–VA copolymer) present a relevant pharmaceutical example. PVP, although frequently used as a tablet binder, is relatively stiff, brittle, and hygroscopic. The brittleness and stiffness are reflected in the relatively high T_g of approximately 164°C. In contrast, the VP–VA copolymer has a significantly lower T_g of approximately 110°C, is a lot more flexible and plastic, and has lower moisture uptake than PVP. This results in a significantly improved compactibility, as seen in Fig. 7.39.

7.3 COMMONLY USED POLYMER EXCIPIENTS IN SOLID ORAL PRODUCTS

Polymers are widely used as excipients or sometimes even active ingredients in pharmaceutical applications. The selection of excipients for a particular

application will depend on the therapeutic target, route of administration, dosage forms, and drug-release profile, in addition to the cost, availability, and complexity of related pharmaceutical unit operations.

The basic architecture of polymeric excipient materials to be considered consists of a relatively simple linear polymer structure. This includes cellulosic derivatives and most major synthetic polymers used as formulation components. Aside from a limited number of cross-linked polymers such as croscarmellose, lightly cross-linked poly (acrylic acid) (Carbopol), and crospovidone, most polymeric materials used as excipients are not branched or cross-linked. However, a number of materials do participate in reversible self-association that can result in the formation of dynamically branched or physically cross-linked system, and this secondary association equilibrium can exert an influence on the usage properties of the material.

Polymeric excipients are numerous and very diverse of natural, semisynthetic, or synthetic origin, depending on the source and method of preparation. They can be classified according to their source of origins: natural polymers and synthetic polymers. They can also be classified alternatively according to their chemical composition, chain shape, comonomer sequence, and their performance.

Biopolymers or natural polymers refer to polymers of natural origin, such as polysaccharides. They are produced by living organisms or from biomass derived from monomers such as sugars for polysaccharides. Natural polymeric materials such as shellac, amber, and natural rubber have been in use for centuries. A variety of other natural polymers exist, such as cellulose and hydrocolloids. Natural polymers can also be chemically modified to produce semisynthetic polymers. Commercially important semisynthetic polymers include ethyl cellulose (EC), hydroxypropyl cellulose (HPC), hydroxypropyl methylcellulose (HPMC), hydroxypropyl methylcellulose phthalate (HPMCP), hydroxypropyl methylcellulose acetate succinate (HPMCAS), and methyl cellulose (MC) for pharmaceutical applications.

Synthetic polymers are man-made by chemical synthesis from monomers. Polyacrylates, polyvinylpyrrolidone (PVP), polyvinyl alcohol (PVA), poly(lactic-*co*-glycolic acid) (PLGA), poly(ethylene glycol) (PEG), and polyethylene (PE) are typical examples of synthetic pharmaceutical polymers. Synthetic and semisynthetic polymers have a potential advantage over natural polymers due to their consistency and reproducibility in quality and functional properties.

Rather than presenting a comprehensive coverage of the molecular properties of all classes of polymeric excipients used in pharmaceutical formulations, we will focus our attention primarily on an overview of those typically used in solid oral drug products. These polymeric excipients are used to fulfill a variety of functions in solid oral dosage forms such as binders, disintegrants, coatings, and drug-release, rate-controlling polymers.

The chemical structure and applications of a number of important pharmaceutical polymer excipients for oral dosage forms are shown in Table 7.7.

7.3.1 Cellulose and cellulose derivatives

Cellulose is abundant in nature and exists in plant-based foods. It is a safe material for oral drug formulations based on a long history of human consumption. Cellulose and its derivatives (ether and ester) (Fig. 7.40) are among the excipients most frequently used in solid oral dosage forms. A number of overviews of polysaccharide chemistry in general,[49] and cellulose derivatives in particular,[50] are readily available, and these classic references remain worthwhile resources towards understanding key aspects of the chemistry.

The simplest modification of cellulose is size reduction. Powdered cellulose is produced by the purification and mechanical size reduction of α-cellulose obtained as a pulp from fibrous plant materials. It occurs as a white or almost white, odorless, and tasteless powder of various particle sizes, ranging from a free-flowing fine powder or granular dense powder to a coarse, fluffy, nonflowing powder. Powdered cellulose is used as a tablet diluent and filler in two-piece hard capsules.[51,52] Powdered cellulose has acceptable compression properties. Low-crystallinity powdered cellulose has exhibited properties that are different from standard powdered cellulose materials, and it has shown potential as a direct-compression excipient. In soft gelatin capsules, powdered cellulose may be used to reduce the sedimentation rate of oily suspension fills. It is also used as the powder base material of powder dosage forms and as a suspending agent in aqueous suspensions for peroral delivery. It may also be used to reduce sedimentation during the manufacture of suppositories.

In order to improve the compactability of cellulose and make it useful as dry binder for roller compaction and tableting by direct compression, cellulose is modified by controlled hydrolysis with dilute mineral acid solutions of α-cellulose, obtained as a pulp from fibrous plant materials. Following hydrolysis, the hydrocellulose is purified by filtration, and the aqueous slurry is spray dried to form dry, porous particles of a controlled size distribution and moisture content for different applications. This process converts cellulose to microcrystalline cellulose (MCC). MCC is purified, partially depolymerized cellulose that occurs

TABLE 7.7 List of Polymeric Excipients for Oral Dosage Forms

Polymers	Major functionality	Applications	Typical use levels (%)	IID or IIG limit[a]
WATER-INSOLUBLE NATURAL/MODIFIED POLYMERS				
Cellulose, microcrystalline (MCC) $(C_6H_{10}O_5)_n$, $n \sim 220$	Binder/filler	Tablet and capsules	10–90	789.6 mg
Cellulose, powdered $(C_6H_{10}O_5)_n$	Filler	Tablet and capsules	5–40	391.7 mg
Cellulose, silicified, microcrystalline (SMCC), $(C_6H_{10}O_5)_n$. SiO_2	Binder/filler	Tablet and capsules	10–90	N/A
Cellulose acetate (CA) $(C_6H_7O_2(OH)_3)_n$	Coating for osmotic pump	Osmotic pump	1–20	47.49 mg
Ethyl cellulose (EC) $C_{12}H_{23}O_6(C_{12}H_{22}O_5)_nC_{12}H_{23}O_5$	Coating/binder	Extended-release coating/ matrix former	1–30	308.8 mg
Croscarmellose sodium (NaCMC) $(C_8H_{16}O_8)_n$	Disintegrant	Tablet and capsules	0.5–25	180 mg
Sodium starch glycolate (SGS) $(C_{24}H_{44}O_6N_a)_n$	Disintegrant	Tablet and capsules	2–8	876 mg
WATER-INSOLUBLE SYNTHETIC POLYMERS				
Crospovidone $(C_6H_9NO)_n$	Disintegrant	Tablet and capsules	2–30	340 mg
Polyacrylic acid (carbomer; Carbopol), $(C_3H_4O_2)_n$	Rheology modifier/controlled release	Tablets, suspension	0.1–30	90 mg
Polymethacrylate, cationic	Coating/binder	Extended-release coating/ matrix former	5–50	161 mg
Polymethacrylate, neutral	Coating/wet binder	Extended-release coating/ matrix former	5–50	187.3 mg
WATER-SOLUBLE NATURAL/MODIFIED NATURAL POLYMERS				
Hydroxyethyl cellulose (HEC) $[C_6H_7O_2(OH)_x(OC_2H_5)_y[O(CH_2CH_2O)_mH]_z]_n$	Coating/rheology modifier	Tablet, suspension, pellets	2–50	400 mg
Hydroxypropyl cellulose (HPC) $(C_{36}H_{70}O_{19})_n$	Binder/coating/controlled-release matrix, extrusion aid	Tablet, capsules, pellets	1–50	240 mg
Hydroxypropyl methylcellulose (HPMC or hypromellose) $(C_{56}H_{108}O_{30})_n$	Binder/coating/controlled-release matrix	Tablet, capsules, pellets	1–75	480 mg
Methyl cellulose (MC) $C_6H_7O_2(OH)_x(OCH_3)_y$	Coating/binder/rheology modifier	Tablet, suspension, capsules	0.5–20	30 mg
Sodium alginate $(C_6H_7O_6Na)_n$	Coating/controlled-release matrix/ rheology modifier	Tablet, capsules, pellets	1–40	350 mg
Sodium carboxymethyl cellulose (NaCMC) $(C_8H_{15}NaO_8)_n$	Binder/coating/controlled-release matrix/rheology modifier	Tablet, capsules, pellets	0.1–90	2000 mg
WATER-SOLUBLE SYNTHETIC POLYMERS				
Polyethylene glycol (PEG), $C_{2n}H_{4n+2}O_{n+1}$	Plasticizer, solubility enhancer	Coating, tablet, softgel, capsules	1–40	960 mg
Polyethylene oxide (PEO), $C_{2n}H_{4n+2}O_{n+1}$	Mucoadhesion, tablet binder, matrix former, thickener	Tablets, coating	5–50	393.46 mg
Polyvinyl alcohol (PVA), $(C_2H_4O)_n$	Film former, thickener	Tablets, coating, microspheres	0.5–20	79.4 mg
Polyvinylpyrrolidone (PVP), $(C_6H_9NO)_n$	Coating, binder, solubility enhancement	Tablet, capsules, pellets	0.5–90	853.8 mg
POLYMERS WITH pH-DEPENDENT WATER SOLUBILITY				
Cellulose acetate phthalate (CAP)	Enteric coating	Tablet and capsules	0.5–9	75.6 mg
Hydroxypropyl methylcellulose acetate succinate (HPMCAS)	Enteric coating, solubility enhancement	Tablet and capsules	0.5–90	560 mg
Polymethacrylate, anionic	Enteric coating, solubility	Enteric coating, solubility	0.5–30	430.8 mg

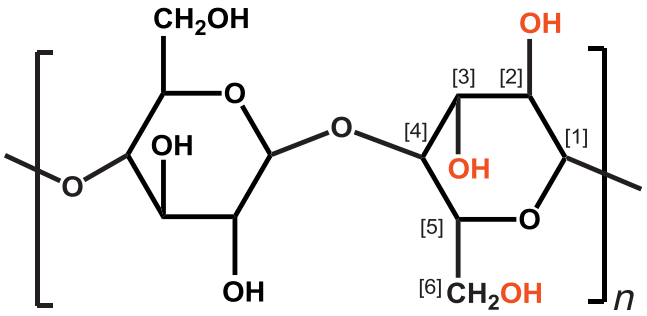

FIGURE 7.40 Basic structure of cellulose, which is used as the starting material for any cellulosic derivative. Each anhydroglucose residue possesses three potentially reactive hydroxyl groups. These are indicated and numbered in the second residue according to the associated carbon on which they reside. For most reaction schemes, the 2 and 6 positions are more reactive than the 3 position.

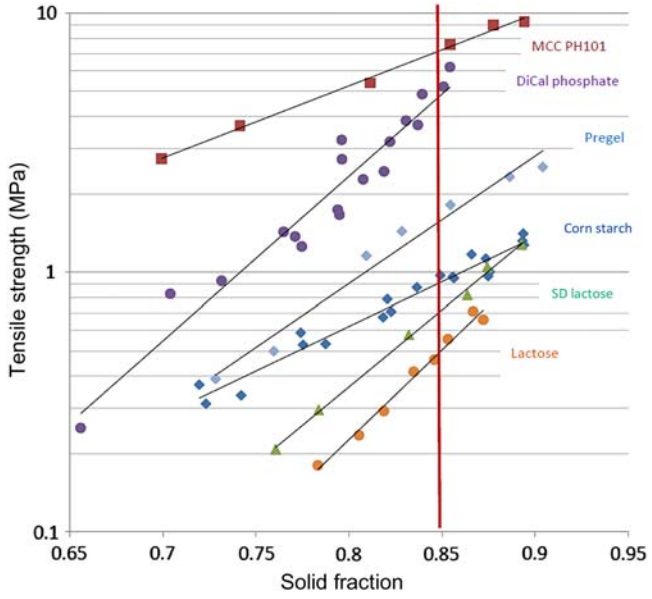

FIGURE 7.41 Comparison of tensile strength of tablets made from different materials at a solid fraction of 0.85, an average value for commercial tablets. *Adapted from Amidon, G.E. Compaction and the properties of mixtures, presented at Compaction Simulation Forum, Cambridge, MA, November 13–14, 2012, http://people.clarkson.edu/~ccetinka/CompactionPresentation/1%20Amidon%20UMichigan.pdf.*[61]

as a white, odorless, tasteless, crystalline powder composed of porous particles. The properties and applications of MCC depend on the particle sizes and moisture grades of MCC.[53–55] MCC is widely used in pharmaceuticals, primarily as a binder/diluent in oral tablet and capsule formulations where it is used in both wet-granulation and direct-compression processes. In addition to its use as a binder/diluent, MCC also has some lubricant and disintegrant properties that make it useful in tableting. A comparison of tensile strength of tablets made from different materials at various solid fractions is shown in Fig. 7.41 where it can be seen that microcrystalline cellulose is the most compactable filler. Therefore, it is not surprising that MCC has been a widely used excipient for tablets.[56–60]

Cellulose can also be mixed with other ingredients to form coprocessed excipients. One of the most widely used coprocessed cellulose is silicified microcrystalline cellulose (SMCC).[62–64] Silicified microcrystalline cellulose is a synergistic, intimate physical mixture of two components: microcrystalline cellulose and colloidal silicon dioxide. It is manufactured by cospray drying a suspension of microcrystalline cellulose particles and colloidal silicon dioxide such that the dried finished product contains 2%w/w colloidal silicon dioxide. The colloidal silicon dioxide appears physically bound onto the surface and inside the silicified microcrystalline cellulose particles. Extensive studies using different spectroscopic methods have not detected any form of chemical interaction.

Cellulose has also been coprocessed with lactose, mannitol, and sodium carboxymethyl cellulose for applications in direct compression for tablets as binder/filler and in oral suspensions as a suspension vehicle.

In order to improve the chemical and physical properties of cellulose for food and pharmaceutical applications, chemical modifications have been applied to cellulose to produce a diverse range of cellulose derivatives for pharmaceutical applications.

As the name implies, cellulose derivatives are all based on cellulose provided by a variety of starting furnishes (wood pulp, chemical cotton). The starting biopolymer, cellulose, is a β-1–4 linked linear polymer of anhydroglucose (Fig. 7.40). Due to the relatively stiff main chain backbone, the array of available hydrogen bonding sites per monomer residue, and structural order inherent in the natural system, cellulose molecules form crystalline microfibrils that are mechanically strong and highly resistant to enzymatic attack. Cellulose is, therefore, insoluble in water and indigestible in the human body. Dissolution of cellulose normally requires exotic solvent systems or in situ derivatization to cap self-associating hydroxyl groups.

The reaction chemistry used in the production of cellulosic derivatives[50] is based on removing that hydrogen bond-mediated order from the system via activation of purified cellulose with a strong caustic, followed by reaction with appropriate alkylating agents (typically alkyl halides) and/or etherifying agents (eg, propylene oxide or ethylene oxide) to introduce various hydrophilic and/or hydrophobic substituents. This derivatization reaction introduces point-packing defects along the main backbone and prevents the reestablishment of the higher level of order that was present in the native cellulose. The overall result is that the material is rendered soluble in a

TABLE 7.8 Structure of Cellulose and Its Derivatives Based on Fig. 7.40

variety of solvents, with the preferred solvents being dependent on the substituents bound to the backbone. The overall molecular weight of the cellulose derivative is largely controlled by the specific selection of starting cellulose furnish for the higher-molecular-weight grades, with either in situ or post-derivatization oxidative or hydrolytic glycosidic chain scission being used to prepare the lower-molecular-weight members of a given chemical class (Table 7.8).

Much of the solution chemistry of cellulose derivatives can be organized by understanding the interplay of the substituent as a defect in the native cellulose packing structure to increase solubility with the use of substituent hydrophobicity and/or charge to tailor compatibility with nonaqueous or binary water/nonaqueous solvents.

Cellulose derivatives can be further classed according to whether or not the substituents can undergo a chain extension oligomerization (either in free solution or once grafted onto the cellulose backbone). Hydroxypropyl and hydroxyethyl substituents are able to undergo chain extension through the inherent hydroxyl group, whereas carboxymethyl, methyl, and ethyl substituents effectively cap the reactive hydroxyl site when they are grafted onto the chain. In cases where the substituent is able to undergo chain extension, the degree of substitution (DS = number of substituent capped hydroxyls per anhydroglucose) and total molar substitution (MS = number of substituent moles per mole of anhydroglucose) will differ with MS > DS. Note, for any cellulose derivative, the maximum value for DS cannot exceed three, as each anhydroglucose unit only has three hydroxyl groups available for reaction (ie, DS < 3), whereas the MS can be greater than 3. For example, for most water-soluble cellulose ethers, the DS values are in the range of 0.4–2, whereas for water-insoluble polyether such as ethyl cellulose, the DS values are between 2.3 and 2.8. On the other hand, typical MS values for hydroxyalkyl ethers of cellulose are between 1.5 and 4.0.

Cellulose derivatives are generally graded according to their viscosity under defined concentration conditions, which is ultimately tied to their molecular weight and substitution levels as expressed by the DS, MS, or percent mass of grafted substituent. Note that in some cases (ethyl cellulose would be a specific example), the substituent used to quantify the mass loading of derivatizing reagent on the polymer, $-OCH_2CH_3$, reflects the combination of the oxygen atom from anhydroglucose with the ethyl group from the ethyl chloride used in the derivatization reaction. Typical data of the various grades of cellulose ethers shown in Table 7.9 indicate that the range in average molecular weight represented in these polymers is extremely large—ranging from 50,000 Da on the low side to 1,200,000 Da for the highest molecular weight materials available. This is a factor of 24 in net molecular weight. Owing to the variable content in residue formula weight provided by the pendant groups, a direct comparison of the differences in the DP will differ slightly. In this case, net degrees of polymerization, basically the number of discrete monomer residues on average per chain, range from a low of roughly 215 for low-molecular-weight sodium carboxymethyl cellulose to a high of about 4700 for the highest molecular weight grade of hydroxyethyl cellulose. Again, the total dynamic range that chain length varies is by about a factor of 20.

The broad range in the average molecular weight, or equivalently, the DP, tells only part of the story. These ranges reflect the wide variability in the population average values. Within a given population, in other words, for a given molecular weight, there is also a very disparate population of overall chain lengths present. For example, in a size exclusion chromatographic characterization of any of the high-molecular-weight cellulosics, the net range of molecular weights encompassed by the population of a given moderate- to high-molecular-weight sample will typically span a range from a few hundreds to thousands up to a few million. In other words, the net diversity in chain lengths is extremely broad and easily spans a net range of two to three orders of magnitudes as the high- and low-molecular-weight portions of the distribution are accounted. A typical example is shown in Fig. 7.42. More typically, the polydispersity of a polymeric material is quantified by the ratio M_w/M_n. In cellulose

TABLE 7.9 Viscosity Grade Molecular Weights for Various Cellulose Derivatives

Viscosity grade (cP, at listed concentration)	Concentration (wt.%)	Viscosity measurement conditions	Approximate molecular weight (M_w, Daltons)
HYDROXYPROPYL CELLULOSE (HYDROXYPROPYL MS ~3.4–4.1)

[a] *Estimated, based on viscosity data.*

derivatives, depending on type and viscosity grade, this ratio can range from 3 to values of 20 or so.

Typical examples of commonly used cellulose ethers and esters include the following[65]:

7.3.1.1 Hydroxypropyl cellulose

HPC is an ether of cellulose where some of the hydroxyl groups on the cellulose backbone have been hydroxypropylated (Fig. 7.43).

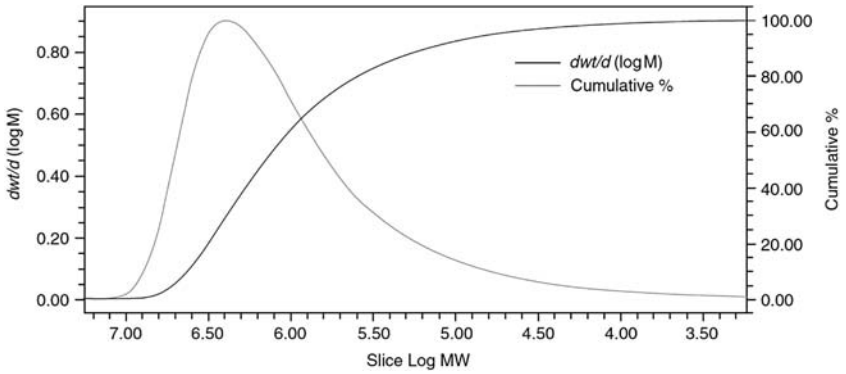

FIGURE 7.42 Representative molecular weight distribution profile of a high-viscosity grade (1500–3000 cP, 1% solution in water) sample of HPC. The molecular weight scale calibration in this example refers to narrow distribution polyethylene oxide/polyethylene glycol. Note that in this example, the net range of material spans roughly 2000–10,000,000 Da from the start to the end of the complete molecular weight distribution. This is a fairly typical situation for high-molecular-weight polymers.

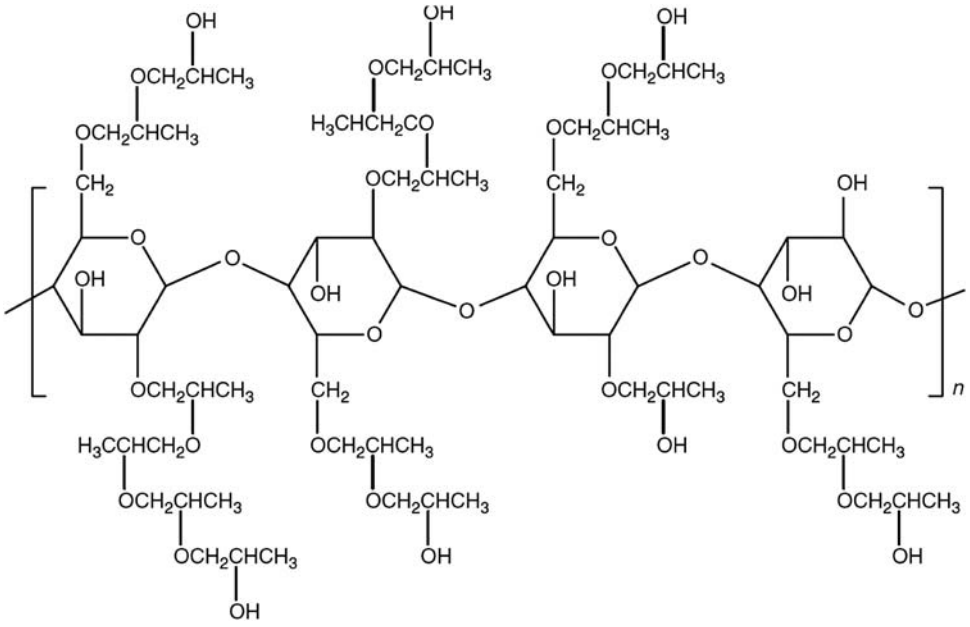

FIGURE 7.43 Typical structure for hydroxypropyl cellulose. The net molar substitution in this example is 4.0. Note that there is a distribution in the hydroxypropyl chain length for the pendant groups added to the base cellulose polymer. The relatively high hydroxypropyl content yields a somewhat hydrophobic thermoplastic polymer, which is sparingly soluble in hot water.

As mentioned earlier, because each of the added hydroxypropyl group introduces a secondary hydroxyl group, this can also be etherified during the preparation of HPC, giving rise to additional chain extension. When this occurs, the number of moles of hydroxypropyl groups per anhydroglucose ring, the molar substitution MS, will be higher than the degree of substitution DS (Fig. 7.43). To overcome the crystallinity of cellulose, HPC usually needs to have a MS about 4 in order to produce good solubility in water. Due to the high level of hydroxypropylation (around 70%), HPC is relatively hydrophobic, so it exhibits a LCST at 45°C. At temperatures below the LCST, HPC is readily soluble in water; however, above the LCST, HPC is not soluble. HPC is widely used in solid oral dosage forms as a binder, a film coating, controlled-release matrix former, and as extrusion aid. HPC is commercially available in six different viscosity grades corresponding to average molecular weights from 80,000 to 1,150,000 Da (Table 7.9).

7.3.1.2 *Hydroxypropyl methylcellulose*

Hydroxypropyl methylcellulose (HPMC or hypromellose) is a partly *O*-methylated and *O*-(2-hydroxypropylated) cellulose ether derivative (Fig. 7.44).

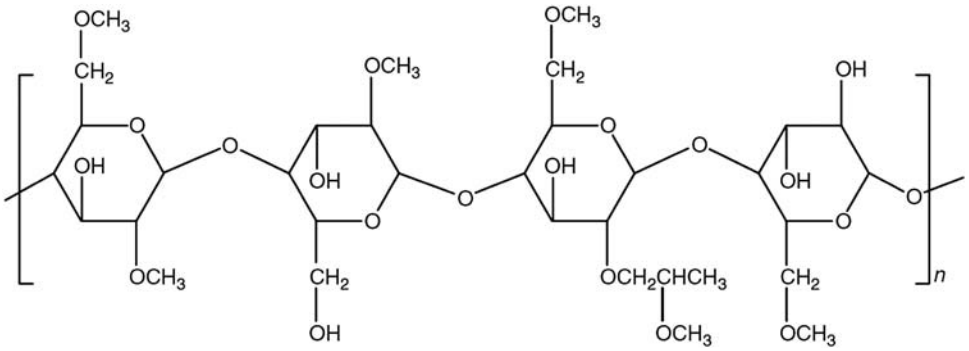

FIGURE 7.44 Typical structure for hydroxypropyl methylcellulose. This is an example of a mixed derivatized cellulosic containing both hydroxypropyl and methoxyl functionality. The specific system shown has a hydroxypropyl DS of 0.25 (~9.6 wt.%) and methoxyl DS of 1.5 (~23 wt.%). Due to the lower content of bound hydrophobic functionality relative to HPC shown in Fig. 7.38, this material will generally display better water solubility at higher temperatures.

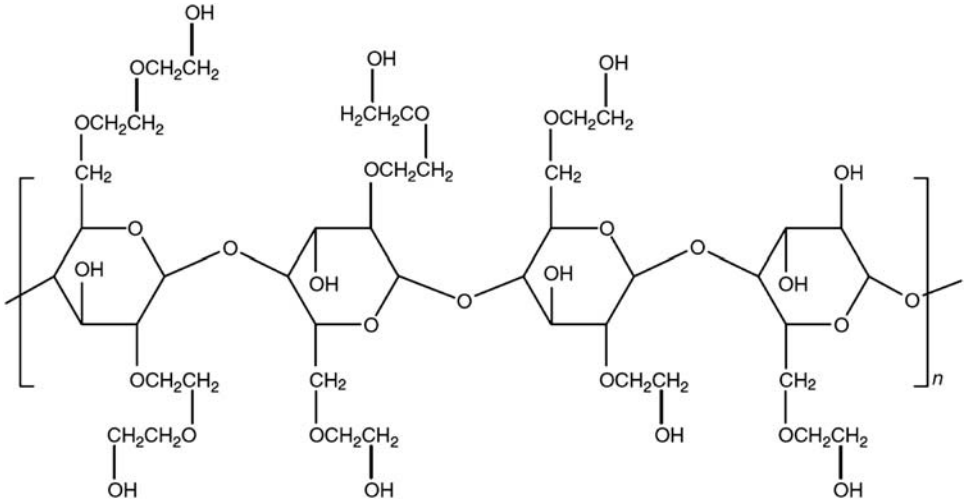

FIGURE 7.45 Typical structure for hydroxyethyl cellulose. As with hydroxypropyl cellulose, a distribution in hydroxyethyl oligomer chain lengths exists. In this example, the hydroxyethyl cellulose segment shown has a net molar substitution (MS) of 2.5, while the degree of substitution (DS) is 1.75 (=7/4).

HPMC is also widely used in solid oral dosage forms as a binder, a film coating, and a controlled-release matrix.[66,67] It is often the polymer of choice in the preparation of hydrophilic matrix tablets because of its rapid formation of a uniform, strong, and viscous gel layer, which protects the matrix from disintegration and controls the rate of drug release. It is commercially available in several types with different DS and MS; here the added hydroxypropyl group introduces a secondary hydroxyl group that can also be etherified during the preparation of HPMC, giving rise to additional chain extension. Currently, the USP/NF and other compendia provide definitions for different substitution types of HPMC using a four-digit number: for example, hypromellose 2208, hypromellose 2906, and hypromellose 2910, respectively, where the first two digits refer to the approximate percentage content of the more methoxy group (OCH_3), and the second two digits refer to the approximate percentage content of the more hydroxypropoxy group ($OCH_2CH(OH)CH_3$). Such variations in the ratios of methoxy and hydroxypropoxyl substitutions and molecular weight affect their properties such as organic solubility, thermal gelation temperature in aqueous solution, swelling, diffusion, and drug-release rate. In practice, hypromellose 2208 (also known as K chemistry or grade) and hypromellose 2910 (also known as E chemistry or grade) are the most widely used types of HPMC in modified-release formulations. These two types of HPMC are commercially available in many different viscosity grades corresponding to average molecular weights from 80,000 to 1,200,000 Da (Table 7.9).

7.3.1.3 *Hydroxyethyl cellulose*

HEC is a partially substituted polyhydroxyethyl ether of cellulose (Fig. 7.45).

It is used in ophthalmic and topical formulations as a viscosity-modifying agent and as a binder, controlled-release matrix former, and as a film-coating

agent in solid dosage forms. Similar to the synthesis of HPC, each of the added hydroxyethyl group introduces a secondary hydroxyl group that can be further etherified during the preparation of HEC, giving rise to an additional chain extension. In this case, the number of moles of hydroxyethyl groups per anhydroglucose ring, the molar substitution MS, will be higher than the degree of substitution DS. A typical structure of HEC with substitution sites on the anhydroglucose rings, giving rise to MS value of 2.5 and DS value of 1.75, is illustrated in Fig. 7.40. HEC dissolves quickly in water (hot or cold) to form a clear and smooth solution, which does not gel or precipitate even when heated to the boiling point of water. HEC is available commercially in several grades that vary in viscosity and DS, corresponding to average molecular weights from about 90,000 to 1,300,000 Da (Table 7.9).

7.3.1.4 Ethyl cellulose

Ethyl cellulose (EC) is a partly *O*-ethylated cellulose ether derivative (Fig. 7.46).

It is insoluble in water but soluble in a variety of solvents. EC is widely used in oral pharmaceutical formulations as a coating agent for tablets and granules to regulate the drug-release rate and to mask unpleasant taste, as well as in microencapsulation and in matrix tablets to achieve modified release. EC films can be applied from organic solvent systems, but this has largely been replaced by the use of a more environmentally friendly aqueous dispersion of EC without the need for organic solvents.[68–71] The substitution level or the ethoxyl content directly impacts the properties of the resulting EC. A typical structure of EC with a DS value of 2.5 corresponding to a 48.5 wt.% ethoxyl content is shown in Fig. 7.46. If the DS of EC is increased to 2.8, a largely insoluble material would result, underscoring the interplay of solid-state packing defects in modulating the solubility of cellulose derivatives. Currently, USP-NF and EP define the ethoxyl content of EC to be between 44.0 and 51.0 wt.%. EC is available commercially in several types that vary in viscosity and ethoxyl content, corresponding to average molecular weights from about 65,000 to 215,000 Da; the most widely used is the standard or *N* type that has 48.0–49.5 wt.% ethoxyl content (Table 7.9). EC can also be used as a binder/matrix former for matrix tablet formulations for modified-release applications.[72]

7.3.1.5 Methyl cellulose

Methyl cellulose (MC) is a methyl ester of cellulose (Fig. 7.47) that contains 27.5–31.5% of the methoxy groups. A typical structure of MC with DS value of

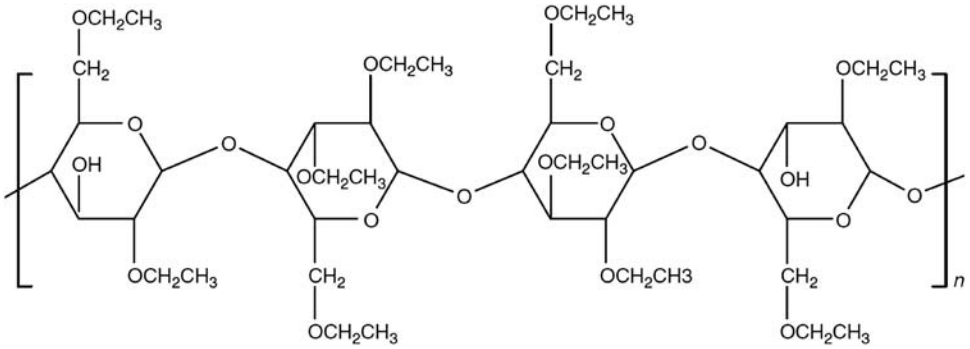

FIGURE 7.46 Typical structure for ethyl cellulose with a net degree of substitution of 2.5. This corresponds to a wt.% ethoxyl of 48.5, which is representative of an *N* or standard grade of this material. If the net DS of the ethyl cellulose is substantially increased to the order of 2.8, a largely insoluble material results, underscoring the interplay of solid-state packing defects in modulating cellulose derivative solubility.

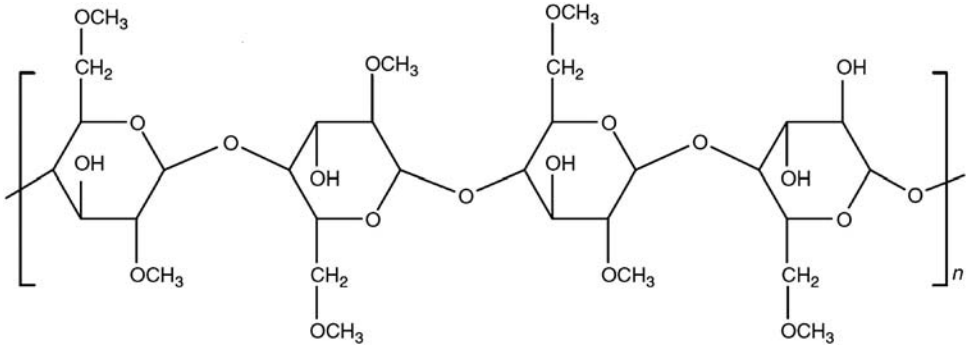

FIGURE 7.47 Typical structure for methyl cellulose with a net degree of substitution of 1.75, which corresponds to a wt.% methoxyl level of 29.1.

1.75 corresponding to 29.1 wt.% methoxyl content is shown in Fig. 7.47. MC is soluble in water, and its aqueous solution exhibits thermal gelation properties. A wide range of viscosity grades (5–75,000 cP at 2%) corresponding to average molecular weight range of 10,000–220,000 Da are available commercially. MC is widely used in oral solid pharmaceutical formulations as a binder, a coating agent, and a disintegrant for tablets, as well as in matrix tablets to achieve sustained release.

7.3.1.6 Sodium carboxymethyl cellulose

Sodium carboxymethyl cellulose (NaCMC) is the sodium salt of the carboxymethyl ether of cellulose, an anionic derivative (Fig. 7.5).

It is widely used in oral, ophthalmic, injectable, and topical pharmaceutical formulations, primarily for its viscosity-increasing and gelling properties. For solid dosage forms, it is mostly used as a binder or matrix former. Pharmaceutical grades of NaCMC are available commercially at DS values of 0.7 and 0.9, with a corresponding sodium content of 6.5–9.5 wt.% (USP/EP), and at a DS value of 1.2 with sodium content of 10.4–12 wt.% (USP). NaCMC is highly soluble in water at all temperatures, forming clear solutions with viscosities depending on the substitution grade and concentration. NaCMC is available in several different viscosity grades, corresponding to average molecular weights from about 49,000 to 725,000 Da (Table 7.9).

7.3.1.7 Cellulose acetate

Cellulose acetate (CA) is cellulose with its hydroxyl groups partially or completely acetylated (Fig. 7.48).

It is insoluble in water but soluble in a variety of organic solvents. CA is available in a wide range of acetyl contents (29.0–44.8%) and chain lengths, with molecular weights ranging from 30,000 to 60,000. CA is widely used in pharmaceutical formulations as semipermeable coatings on osmotic tablets to regulate the osmotic water influx, thereby controlling the drug-release rates.[73–76] With appropriate additives, it is also used as coatings on tablets or granules or as shell material for microcapsules to achieve controlled drug release, or as coatings on tablets or granules for taste-masking purposes. CA can also be employed to formulate matrix tablet prepared by direct compression.

7.3.1.8 Cellulose derivatives with pH-dependent solubility

HPMCAS (Fig. 7.49) is produced by the esterification of HPMC with acetic anhydride and succinic anhydride in a reaction medium of a carboxylic acid, such as acetic acid, and using an alkali carboxylate, such as sodium acetate, as catalyst.

HPMCAS retains the structure diversity of the starting material HPMC where the added hydroxypropyl group introduces a secondary hydroxyl group, which can also be etherified during the preparation of HPMC, giving rise to an additional chain extension. It is available in several grades with varying extent of substitution, mainly of acetyl (2.0–16.0%) and succinoyl (4.0–28.0%) groups with molecular weights ranging from 55,000 to 93,000 Da. HPMCAS is insoluble in gastric fluid but starts to swell and dissolve at a pH above 5 depending on the extent of substitution. The dissolution pH increases as the ratio of acetyl over succinoyl substitution increases. Traditionally, HPMCAS has been used in enteric film coating of tablets and multiparticulates.[77] For aqueous film-coating formulations, a dispersion of HPMCAS fine powder and triethyl citrate (as a plasticizer) in water is commonly utilized. Organic solvents can also be used as vehicles for applying this polymer as a film coating. However, today HPMCAS is the most widely utilized amorphous solid dispersion polymer for drug solubilization. It is most easily used via spray drying, but hot-melt extrusion is also becoming increasingly common.[78,79]

Cellulose acetate phthalate (CAP) (Fig. 7.50) is a product of esterification of cellulose acetate (CA) with phthalic anhydride in the presence of a tertiary organic base such as pyridine or a strong acid such as sulfuric acid containing 21.5–26.0% of acetyl groups

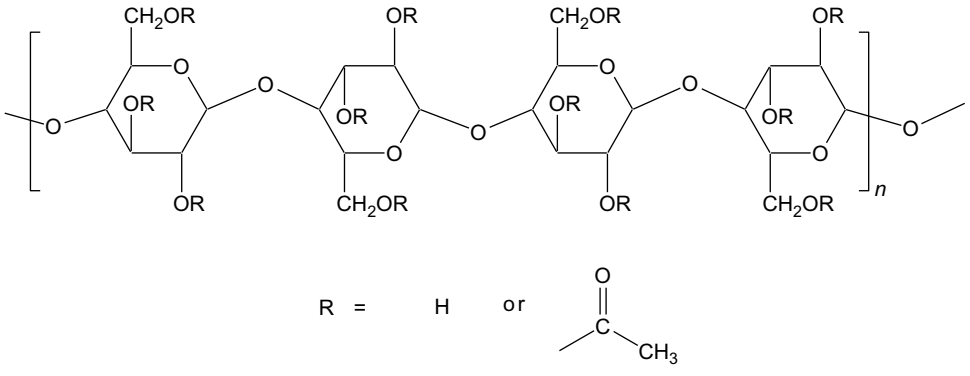

FIGURE 7.48 Typical structure for cellulose acetate (CA).

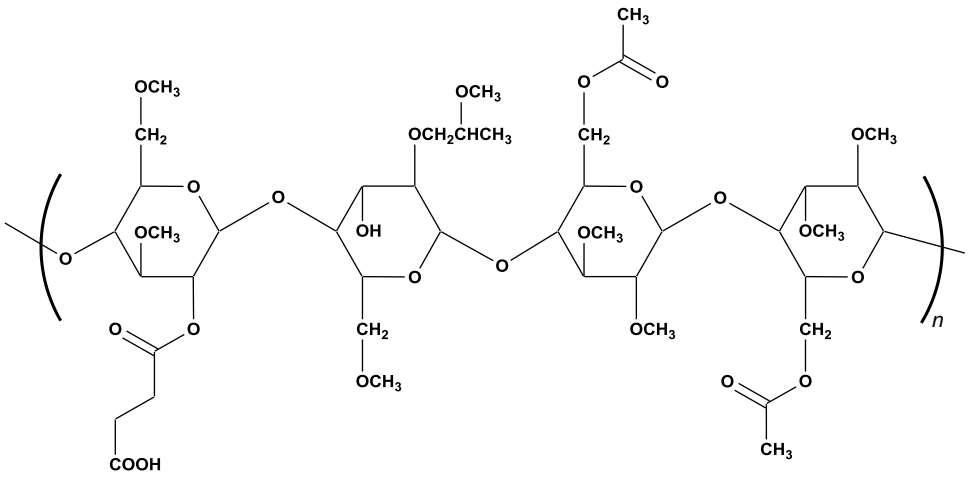

FIGURE 7.49 Typical structure for hydroxypropyl methylcellulose acetate succinate (HPMCAS).

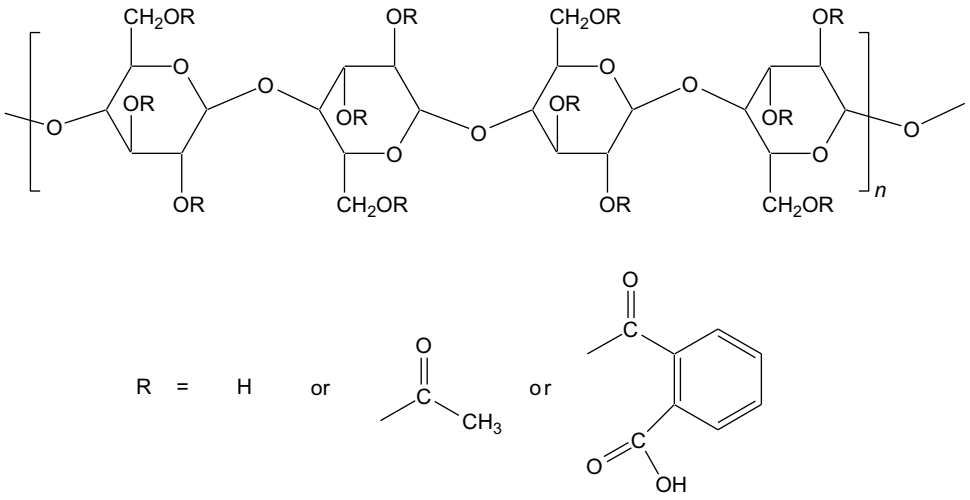

FIGURE 7.50 Typical structure for cellulose acetate phthalate (CAP).

and 30.0–36.0% of phthalyl groups with a viscosity (15% in acetone) ranging from 50 to 90 cP.

CAP has pH-dependent solubility and is soluble in aqueous solutions at a pH above 6. CAP is mainly used as an enteric film-coating material or as a matrix binder for tablets and capsules. It provides protection of API in the strongly acidic gastric fluid, but it dissolves in mildly acidic or neutral intestinal environment to make the drug available for absorption. CAP is commonly applied to solid-dosage forms either by coating from an aqueous dispersion or a solution of organic solvent or by direct compression.

7.3.2 Synthetic polymers

7.3.2.1 Acrylic acid polymers

Synthetic polymers based on acrylic, especially methacrylic acids, have found extensive applications in the oral solid formulations to protect the active ingredients as versatile film former for coatings or to release the drug in a controlled manner as a matrix former or a diffusion barrier for a reservoir system.

Such polymers can be made as cationic, anionic, and neutral (nonionic) polymers.

7.3.2.1.1 Polyacrylic acid (carbomer; carbopol)

Carbomers (Fig. 7.51) are synthetic high-molecular-weight polyacrylic acids cross-linked with allyl sucrose or allyl pentaerythritol and contain between 56 and 68% w/w carboxylic acid groups. The molecular weight of carbomer is estimated to be at 7×10^5 to 4×10^9 Da. As three-dimensionally cross-linked microgels, carbomers do not dissolve but swell to a remarkable extent in water after neutralization to form a gel.[80] Carbomers are used in liquid or semisolid pharmaceutical formulations as rheology modifiers. Carbomers having low residual solvent content, such as Carbopol 971P NF or

Carbopol 974P NF, may be used in oral solid dosage forms as binders or matrix tablet formers.[81–84]

7.3.2.1.2 Polymethacrylate

Polymethacrylates (Fig. 7.52) are synthetic linear copolymers prepared by free-radical polymerization. They may exist as cationic, anionic, and neutral (nonionic) polymers depending on the starting monomers for preparing the polymers. The functionality and applications of such polymers depend on the structures and ionic charges of the polymers.[85–88]

Anionic polymers: Anionic polymethacrylate polymers contain methacrylic acid functional groups, which dissociate and render the polymer soluble at the higher pH of the small intestine and colon. Anionic polymers containing methacrylic acid–ethyl acrylate copolymer (1:1) in coating products (eg, Eudragit® L 30-D or Kollicoat® MAE 30 DP) are soluble from a pH 5.5 but insoluble at the low pH in the stomach. Such polymers offer enteric protection to many active ingredients in oral solid formulations in the gastric environment and trigger drug release at a selected pH for targeted drug delivery in the GI tract. Anionic copolymers of methacrylic acid and methyl methacrylate at a ratio of approximately 1:1 (Type A; eg, Eudragit L) and approximately 1:2 (Type B; eg, in Eudragit S). Both polymers are readily soluble in neutral to weakly alkaline conditions (from pH 6 for

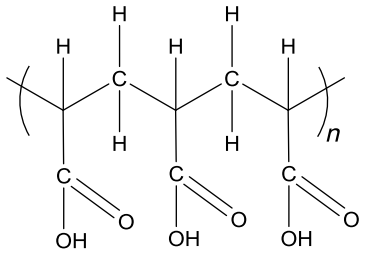

FIGURE 7.51 Typical structure for carbomers.

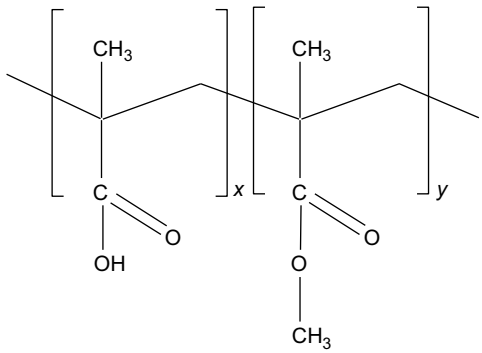
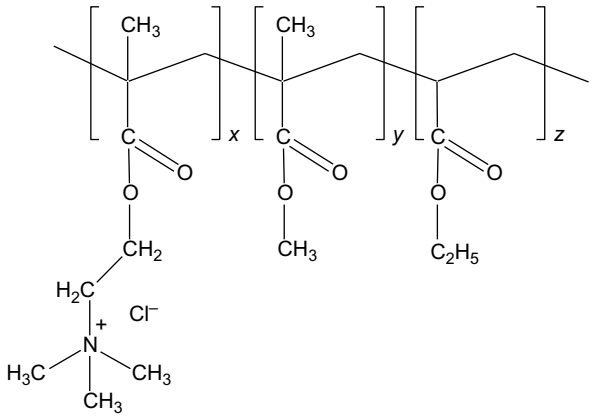
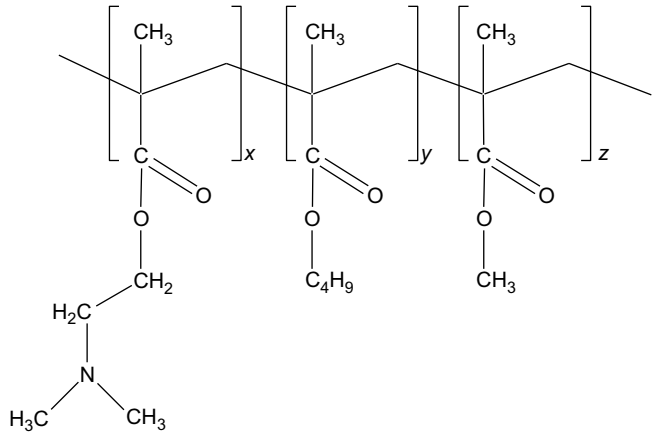


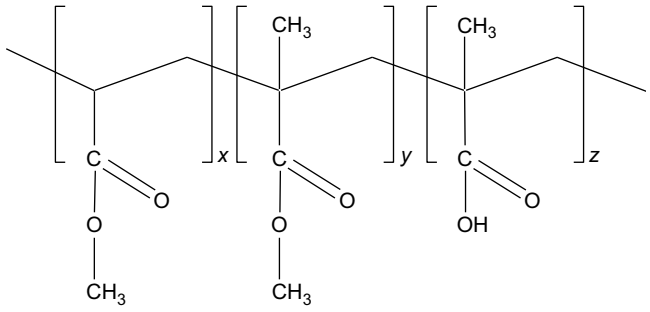
Methacrylic acid—methyl methacrylate copolymer (1:1 or 1:2)



Poly(ethylacrylate-co-methyl methacrylate-co-trimethylammonioethyl methacrylate chloride) (1:2:0.2 or 1:2:0.1)



Poly(butyl methacrylate-co-(2-dimethylaminoethyl) methacrylate-co-methyl methacrylate) (1:2:1)



Poly(methyl acrylate-co-methyl methacrylate-co-methacrylic acid) (7:3:1)

FIGURE 7.52 Typical structure for polymethacrylates.

Type A and from pH 7 for Type B); the latter enables drug delivery to the colon, since the polymers becomes soluble at pH >7.0.

Cationic polymers: Cationic polymethacrylate polymers typically consist of copolymers of ethyl acrylate, methyl methacrylate, and a low content of methacrylic acid ester with quaternary ammonium groups. The ammonium groups are present as salts, which increase the polymer swelling in aqueous media, thereby making the polymers more permeable. Cationic polymethacrylate containing more quaternary ammonium groups (eg, Eudragit RL 100) is, therefore, more permeable than the one containing less quaternary ammonium groups (eg, Eudragit RS 100) as a consequence. Both polymethacrylate polymers are commercially available as a fine powder (eg, Eudragit RS PO), a solution in organic solvents (eg, Eudragit RS 12.5), or an aqueous dispersion (eg, Eudragit RS 30 D). Both polymethacrylate polymers can be mixed in any ratio to modulate the drug-release rate in addition to well-known strategies of varying coating thickness and incorporation of pore formers.

Another available cationic polymethacrylate is a copolymer based on dimethylaminoethyl methacrylate, butyl methacrylate, and methyl methacrylate (eg, Eudragit E 100). It is soluble in gastric fluid below pH 5 but becomes swellable and permeable, but not soluble, above pH 5. This cationic polymethacrylate can be used for taste-masking applications.

Neutral polymers: Neutral polymethacrylates based on copolymers of ethyl acrylate and methyl methacrylate (2:1) do not contain ionic groups and, therefore, only swell in aqueous media independently of pH without dissolving. These are generally available as aqueous dispersions with a solid content at 30% and 40% respectively (eg, Eudragit NE 30 D and Eudragit NE 40 D). Films prepared from these are insoluble in water but will swell and become permeable when they are in contact with water and exhibit pH-independent drug permeability. Such neutral polymethacrylate aqueous dispersions can be used for controlled-release coatings and wet-granulation binders.

7.3.2.2 Polyvinylpyrrolidone

7.3.2.2.1 Povidone

Povidone (Fig. 7.53) is a linear polymer of 1-vinyl-2-pyrrolidinone monomer with different degrees of polymerization, which results in polymers of a wide range of molecular weights (2,500−3,000,000 Da).

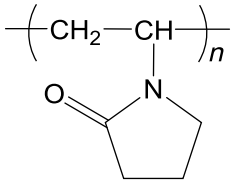


FIGURE 7.53 Chemical structure for polyvinylpyrrolidone (PVP).

Povidone is water soluble, with the maximum concentration being limited only by the solution viscosity. Being nonionic, the viscosity of povidone in an aqueous solution is unaffected by the pH or salt concentration. Povidone is widely used in solid-dosage forms. In tablet formulations, povidone solution is used as wet-granulation binder. Povidone can also be incorporated to powder blends in the dry form and granulated in situ by the addition of water, alcohol, or hydroalcoholic solutions. Povidone may be used as a dissolution-enhancing agent in oral formulations for poorly soluble drugs involving processes such as spray drying and hot-melt extrusion.[79,89] Povidone is a well-known complexing agent; for example, the ability to complex with iodine is of particular commercial importance, providing an antibacterial povidone iodine solution and powder that are widely used in medical and hospital settings. Povidone solutions may also be used as a film former for coating formulations or as binders for drug layering onto a substrate such as sugar or microcrystalline cellulose beads. Povidone is additionally used as a suspending, stabilizing, or viscosity-increasing agent in a number of oral suspensions and solutions. Increasingly due to its advantageous solubility in PEG 400 and glycerin, povidone is also used as a viscosifying and stabilizing agent in liquid-filled gelatin capsules.

7.3.2.2.2 Crospovidone

The preparation of vinylpyrrolidone for crospovidone is similar to povidone. The vinylpyrrolidone is polymerized in solution using a catalyst to produce crospovidone by a popcorn polymerization process. Crospovidone is a white, free-flowing, practically tasteless and odorless, hygroscopic powder.

Crospovidone is a cross-linked, water-insoluble superdisintegrant. It is usually incorporated dry in the running powder of a tablet formulation, but it can also be processed by wet and dry granulation methods. Typical use levels in tablet formulations range from 2% to 5%, but in orally disintegrating tablets in particular and some capsule formulations, crospovidone is used at much higher levels up to 30%. Similar to sodium starch glycolate, crospovidone disintegrates tablets mainly by swelling, with little tendency to form gels. Crospovidone can also be used for solubility enhancement of poorly soluble drugs in the process of coevaporation. This process enables the drug adsorption onto crospovidone in the presence of a suitable solvent, and the solvent is then evaporated to provide a solid mixture with a faster drug dissolution rate.

7.3.2.3 *Polyvinyl alcohol (PVA)*

Polyvinyl alcohol (PVA) is produced through the hydrolysis of polyvinyl acetate. The repeating unit of vinyl alcohol is not used as the starting material because it is unstable and cannot be isolated. The hydrolysis of polyvinyl acetate proceeds rapidly in methanol, ethanol, or a mixture of alcohol and methyl acetate, using alkalis or mineral acids as catalysts.

PVA occurs as an odorless, white to cream-colored granular powder. It is a linear water-soluble polymer represented by the formula $(C_2H_4O)_n$ (see structure in Fig. 7.54). The value of n for commercially available PVA is between 500 and 5000, equivalent to a molecular weight range of 20,000−200,000. Various grades of PVA are commercially available. The DP and the degree of hydrolysis are the two key factors affecting their physical properties. Typically, pharmaceutical grades are partially hydrolyzed materials.[65]

The predominant commercial use of polyvinyl alcohol in solid oral dosage forms is as an immediate-release, film-coating polymer. It is also used as a viscosity-enhancing agent in ophthalmic and topical formulations.

7.3.2.4 *Polyethylene oxide (PEO) and polyethylene glycol (PEG)*

Polyethylene oxide (PEO) and polyethylene glycol (PEG) have the same CAS registry number 25322-68. Both PEO and PEG are nonionic homopolymers of ethylene oxide, sharing the same formula $(CH_2CH_2O)_n$ (Fig. 7.55) where n represents the average number of oxyethylene groups, with $n = 5-182$ for typical PEGs (avg. MW 200-8000) and much larger n's for PEOs (avg. MW 100,000 up to several million).

7.3.2.4.1 Polyethylene glycol (PEG)

Polyethylene glycol (PEG) is formed by the reaction of ethylene oxide and water under pressure in the presence of a catalyst.

PEG is soluble in water and miscible in all proportions with any other grade of PEG (after melting, if necessary). Liquid PEGs are soluble in acetone, alcohols, benzene, glycerin, and glycols. Solid PEGs are soluble in acetone, dichloromethane, ethanol (95%), and methanol; they are slightly soluble in aliphatic hydrocarbons and ether but insoluble in fats, fixed oils, and mineral oil. Aqueous solutions of higher-molecular-weight grades may form gels.

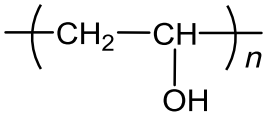

FIGURE 7.54 Chemical structure for polyvinyl alcohol (PVA).

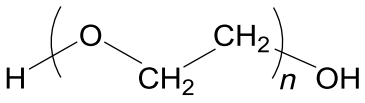

FIGURE 7.55 Chemical structure for polyethylene glycol (PEG) and polyethylene oxide (PEO).

In tablet formulations, PEGs of a high molecular weight can enhance the effectiveness of tablet binders and impart plasticity to granules when it is used in conjunction with another binder. PEG may prolong disintegration if used above 5% w/w. Polyethylene glycol grades with molecular weights of 6000 and above can be used as lubricants, particularly for soluble tablets. The lubricant action is not as good as that of magnesium stearate, and stickiness may develop if the material becomes too warm during compression.

In coating formulations, low-molecular-weight PEG is mainly used as a plasticizer. Higher molecular weights can be useful as hydrophilic polishing materials. Solid PEGs are also used to enhance the ductility of the coating membrane and avoid rupture of the coating film when the coated microcapsules are compressed into tablets. The presence of PEGs in film coats, especially of liquid grades, tends to increase their water permeability and may reduce protection against low pH in enteric-coating films.[65]

PEGs may also be used to enhance the aqueous solubility of poorly soluble drugs by making solid dispersions with an appropriate grade of polyethylene glycol by either spray drying or hot-melt extrusion.

Polyethylene glycols have been used in the preparation of urethane hydrogels, which are used as controlled-release agents. Polyethylene glycol has also been used in insulin-loaded microparticles for the oral delivery of insulin; it has been used in inhalation preparations to improve aerosolization.

7.3.2.4.2 Polyethylene oxide (PEO)

Polyethylene oxide (PEO) is prepared by the polymerization of ethylene oxide with the use of a suitable catalyst.

PEO is soluble in water and some commonly used organic solvents such as acetonitrile, chloroform, and methylene chloride. It is insoluble in aliphatic hydrocarbons, ethylene glycol, and most alcohols. It may contain up to 3% of silicon dioxide or suitable antioxidant.

Higher-molecular-weight PEO is predominantly used in extended-release formulations as a hydrophilic matrix former at levels ranging from 5% to 75%. PEO can be used as a tablet-and-extrudate forming material or an aid in hot-melt extrusion. The relationship between the swelling capacity and the molecular

weight is a good guide when selecting products for use in immediate- or sustained-release matrix formulations. Polyethylene oxide has also been shown to have mucoadhesive properties. PEO films exhibit good lubricity under wet conditions.[65]

PEOs are an effective viscosity enhancer at low-use level, although alcohol is usually added to water-based formulations to provide improved viscosity stability.

7.3.2.5 *Ion-exchange resins*

Ion-exchange resins are generally made from methacrylic acid, sulfonated styrene, and divinylbenzene (DVB). A generic structure of such cation-exchange resin is shown in Fig. 7.56.

Cation exchangers are anionic polymers that contain carboxyl or sulfate groups with hydrogen, potassium, and sodium as counterions. Cation exchangers with weak acidity are made from a polymer of methacrylic acid (containing COOH) cross-linked by DVB. The counterion of the acidic carboxyl group is either hydrogen (as in polacrilex resin) or potassium (as in polacrilin potassium). To make a cation-exchange resin with a stronger acidity, water-insoluble styrene is used to prepare the polymer, which is sulfonated to make it hydrophilic. DVB is also used to cross-link the polymer, and the counterion of the sulfate group (SO_3) is generally sodium.

Ion-exchange resins swell in an aqueous medium. The DVB–cross-linked potassium methacrylate copolymer possesses such a high swelling capacity that it is used as a disintegrant for oral solid formulations.

Ion-exchange resins have fixed ionic functional groups that can provide binding of ionic drugs. Release of the bound drugs requires an exchange with counterions such as hydrogen or sodium, which are

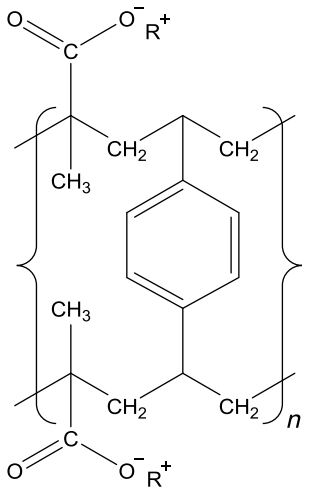

FIGURE 7.56 Generic structure of a cation-exchange resin based on polymethacrylic acid, where R = hydrogen for polacrilex resin, R = potassium (partial) for polacrilin potassium.

available in the gastrointestinal tract. Because of their unique properties, the ion-exchange resins are generally used for taste masking, drug stabilization, and sustained-release applications or a zero-order release due to their high swelling capacity.[90,91]

The commercial product of sodium polystyrene sulfonate (Amberlite™ IRP69) is used to treat hyperkalemia. On the other hand, cationic ion-exchange resins with the ability to exchange anions carry quaternary ammonium groups, $-N^+(R)_3$ with chlorine as a counterion. Cholestyramine resin (Duolite™ AP143) is cationic styrene DVB polymer that is an anion exchanger and is used to reduce cholesterol or to sequestrate the bile acid.

7.4 CONCLUSION

In many respects, polymeric materials have a preeminent position among excipients, as they form the backbone of modern pharmaceutical practice and drug-delivery technologies in particular. With the exception of a few technologies, the majority of bioavailability enhancement, modified-release, and controlled-release technologies rely on the unique properties of polymers to achieve drug-release control through a variety of mechanisms. These may include dissolved drug diffusion through water-insoluble, polymeric film coatings or diffusion and erosion from water-soluble, hydrogel-forming polymeric systems. Some of the obvious, inherent properties of polymers that continue to enable the development of new technologies include their large molecular weight, which facilitates entanglement and network formation, thus allowing diffusion control. Also important is the availability of large numbers of different polymers, which are generally regarded as safe and which have good processing and manufacturing properties such as solubility in aqueous systems and common nonaqueous solvents, good stability, good plastic deformation and compaction properties, and excellent film-forming properties.

As highlighted in this chapter, the key to understanding and productively using polymeric materials in solid dosage form design and general industrial practice is to appreciate their unique properties as compared to well-defined, discrete small molecules. In particular, unlike small molecules with a well-defined and discrete structure, state, and properties, polymers are best viewed in terms of a continuum and distribution of structural and physical property characteristics and states. Furthermore, while structure–property relationships are frequently complex and multifactorial, we hope to have conveyed that even with the application of only a small set of relatively simple rules and principles, it is possible to make

more rational and science-based decisions with regard to polymer selection to achieve the desired effects and robust systems. This is particularly important in the context of the current industry focus on QbD and the fact that polymeric materials frequently comprise a significantly greater proportion of the modern dosage form than does the drug. Looking to the future, it is clear that polymers will continue to be a tool in the development of solid oral dosage forms.

[1]Imperial College London, South Kensington Campus, London, United Kingdom
[2]University of Otago, Dunedin, New Zealand [3]Abbvie Inc., North Chicago, IL, United States

8.1 INTERFACES

In the pioneering work "Graphical methods in the thermodynamics of fluids" by Prof. J. Willard Gibbs,[1] he makes the argument that:

> It may occur, however, in the volume-entropy diagram that the same point represents two different states of the body. This occurs in the case of liquids which can be vaporized.

This work, the first integrated mathematical description of interfacial phenomena, sparked the development of a new research area dealing with the phenomena at the boundaries between phases.

The interface is the boundary between any two phases.[2] This definition implies that the two phases can be of the same state or even to be identical. For the sake of convenience, interfacial interactions are distinguished by the states of matter of two contacting phases, solid (S), liquid (L) and vapor (V). Therefore, six possible interfaces arise as a result of the combination of contacting phases: S-S, S-L, S-V, L-L, L-V, V-V. However, the existence of an interface between two vapor phases is unlikely, thus, it is omitted in this chapter. Additionally, the L-V interface is of less practical importance to solid dosage forms. Therefore, it will not be included in this chapter either. In all succeeding discussions, it is important to keep in mind the dynamic nature of these interfaces; for example, when a solid particle is dissolving in a liquid medium, the S-L interface decrease upon dissolution until it vanishes.

S-S interactions (commonly known as contact mechanics): Contact mechanics describe the cohesive and adhesive properties of particles implicating their processability during manufacturing. In particular, S-S interface influences the flow of powders,[3,4] mixing, and blending operations,[5,6] including coating and deaggregation processes.[7] Furthermore, milling and micronization processes,[8–12] which are very important for the size reduction of active pharmaceutical ingredients (APIs) for dry powder inhalers (DPIs), will have an impact on the API-excipient S-S interactions. Formulation processes such as fluidization and tableting are subjected to the effects of S-S interfaces as well.

S-L interactions: These are of particular importance in operations like wet milling and wet granulation,[13] where liquids are used to enhance the process efficiency. Interfacial properties will determine the wetting of solids in liquids, an important step in the formation of granule nuclei leading to successful granulation processes. Solid–liquid interactions will also determine the dissolution behavior of solid dosage forms, in vitro and in vivo.[14]

S-V interactions: Moisture uptake can lead to the accumulation of liquid on solids either in the form of bound or unbound water. The adsorption mechanisms are susceptible to changes in solid properties such as surface energy, porosity and physical form (amorphous vs crystalline), as well as the changes in the environment. Morphological changes and recrystallization[15,16] have been reported as a result of moisture uptake. Moisture removal is just as important as moisture uptake. It is widely reported that the formation of polymorphs through dehydration/desolvation hinges on drying conditions and dehydration/desolvation mechanisms.[17,18]

L-L interactions: Emulsification processes are employed in delivering insoluble drugs and in preparing drug delivery carrier particles. These are two important examples of the application of L-L interactions.

Developing Solid Oral Dosage Forms

8.2 FUNDAMENTAL INTERMOLECULAR FORCES

In his Nobel Lecture on December 12, 1910,[19] Johaness Diderik van der Waals challenged Boyle's law, stating:

> As you are aware the two factors which I specified as reasons why a nondilute aggregate of moving particles fails to comply with Boyle's law are firstly the attraction between the particles, secondly their proper volume.

This statement has been interpreted mathematically by the well-known van der Waals equation of state:

$$\left(p + \frac{a_{\mathrm{VdW}}}{v^2}\right)(v - b_{\mathrm{VdW}}) = RT \tag{8.1}$$

where a_{VdW} describes the adhesive (van der Waals) forces between the molecules, b_{VdW} corresponds to the exclusion volume of a molecule of the fluid and the rest of the parameters have the same meaning as in the ideal gas law. As a_{VdW} and b_{VdW} tend to zero, the van der Waals equation reduces to the ideal gas law. This condition is in line with the fundamental assumptions of ideal gas law, assuming that the gas molecules are volumeless and molecules do not interact.

8.2.1 Van der waals forces

Van der Waals forces can be categorized, on the ground of the molecules involved in the interaction, to: Keesom forces, Debye forces, and London (dispersion) forces, summarized schematically in Fig. 8.1. For Keesom forces, two polarized molecules interact because of the inherent difference in charge distribution. In the case of Debye forces, a molecule with a permanent dipole induces charge redistribution to neighboring molecules with no dipole moments. Finally, London forces arise in molecules without permanent dipoles. The fluctuations on the electron cloud lead to temporary changes in the charge distribution inducing a charge redistribution to neighboring molecules. The mathematical formulation of all three components has the general form:

$$U(r) = -\frac{C}{r^6} \tag{8.2}$$

where C is a constant changing slightly for each component and r is the intermolecular distance.

Apart from van der Waals forces, there exists an interaction between electron poor and electron rich atoms, via the sharing of a lone pair of free electrons from the latter to the former, called *dipole-dipole interactions*. When a hydrogen atom is involved in this interaction, the interaction is called hydrogen bond. Due to its nature, it is characterized by directionality and short-range action, meaning that the electron poor and the electron rich sites should "face" one another at a close distance. Directionality leads to the formation of weak structures of molecules held together via the bonds formed through the sharing of lone pairs of free electrons. The effect of these bonds is affected by the proximity of the molecules. Thus, it changes depending on the state of the matter. In particular, as matter moves from vapor to liquid or solid states, the importance of them increases. The physical chemical property of ice is the most striking manifestation of the effects of these forces.

Additionally, Coulombic forces develop between charged atoms or ions. The nature (attractive or repulsive) and magnitude of the interaction depend on the sign (positive or negative), the ionic charge of the contributing elements, the distance, and the medium separating them. For instance, two oppositely charged ions exhibit attractive interactions, the magnitude of which is given by the following relation:

$$U(r) = \frac{Q_1 Q_2}{4\pi\varepsilon_0 r^2} \tag{8.3}$$

where Q_1 and Q_2 are the charges, r is the distance between them, ε_0 is the dielectric constant of the medium separating these ions.

8.2.2 Thermodynamics of dispersion forces

From the aforementioned van der Waals forces, London dispersion forces account for the majority of the van der Waals interactions. In the following section, two main approaches for the derivation of them will be discussed: Hamaker's and Lifshitz's approaches.

8.2.2.1 Hamaker's approach[20,21]

If a single spherical molecule is suspended above a flat, solid surface (Fig. 8.2), it can be assumed that the total interaction to be given by the summation of all the intermolecular interactions between the molecule and the flat surface. Assuming simple additivity

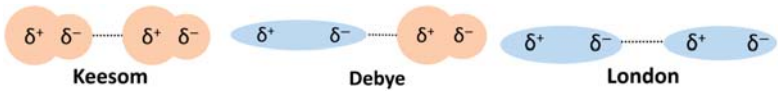

FIGURE 8.1 Schematic representation of the three components of van der Waals forces.

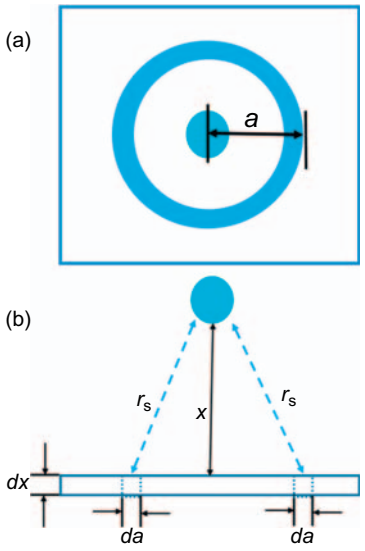

FIGURE 8.2 Schematic representation for the derivation of potential energy equation by Hamaker's approach (a) top view, (b) side view.

between them and n number of molecules on the surface then the potential energy, U, can be written as:

$$\frac{dU}{dn} = -\frac{3\alpha^2 h\upsilon}{4(4\pi\varepsilon_0)^2 r_s^6} \tag{8.4}$$

where r_s is the geometric term shown in Fig. 8.2, α is the polarizability, h stands for the Planck constant, υ is the frequency of fluctuation and ε_0 is the dielectric permittivity in vacuum.

The number of molecules, assuming a spherical shape, can be calculated further by the following equation:

$$dn = 2\pi\ \rho da\ dx \tag{8.5}$$

where ρ is the concentration of molecules on the surface.

Upon combining the two equations and integrating, the following relation for the potential energy can be obtained:

$$U = \int_H^\infty \int_0^\infty -\frac{3a^2 h\upsilon}{4(4\pi\varepsilon_0)^2 (x^2+\alpha^2)^3} 2\pi\ \rho d\alpha\ dx = \frac{3a^2 h\upsilon}{4(4\pi\varepsilon_0)^2}\frac{\pi\rho}{6H^3} \tag{8.6}$$

As can be seen in Fig. 8.2, α is the radius of the flat solid surface, x is the variable used to describe the distance between the molecule and the surface and finally H is the actual distance between the molecule and the surface.

For a system of two parallel plates the number of molecules is given simply by $dn = \rho \cdot dh$, so the potential is given by:

$$U = \frac{3a^2 h\upsilon}{4(4\pi\varepsilon_0)^2}\frac{\pi\rho^2}{12H^2} \tag{8.7}$$

Hamaker conducted pairwise summation of the dispersion energies and proposed that the interaction between two similar macroscopic bodies at short distances can be given by:

$$A_{ii} = \beta\pi\rho^2 \tag{8.8}$$

where β stands for the pairwise interaction coefficient.

where A_{ii} is the Hamaker constant.

As such, the dispersive intermolecular energy or the free energy of interaction between two parallel plates can be rewritten as

$$U = \Delta G = -\frac{A_{ii}}{12\pi r_s^2} \tag{8.9}$$

where r_s is the interplate separation.

In the case of two bodies of different materials, Berthelot's principle states that the interaction can be estimated by the geometric mean of the interaction between each of the same materials. Thus, the Hamaker constant for their interactions is written as:

$$A_{ij} = \sqrt{A_{ii}A_{jj}} \tag{8.10}$$

where A_{ii} and A_{jj} are the Hamaker constants of each material in vacuum.

Similarly for two bodies (1, 2) interacting in a third medium (3), the Hamaker combination rule gives the following expression:

$$\begin{aligned} A_{132} &\approx A_{12} + A_{13} - A_{13} - A_{23} \\ &= \left(\sqrt{A_{11}} - \sqrt{A_{33}}\right)\left(\sqrt{A_{22}} - \sqrt{A_{33}}\right) \end{aligned} \tag{8.11}$$

8.2.2.2 *Lifshitz's approach*[22]

Lifshitz avoided the problems associated with additivity proposed by the earlier approaches of Hamaker. Lifshitz's approach ignores the atomic structure and treats the forces between large bodies as continuous media. The Lifshitz theory is derived from dielectric constants and refractive indices. Nonetheless, the full derivation is out of the scope of this chapter as it requires extensive understanding of quantum mechanics.[23,24] The Hamaker constants, for unlike bodies interacting in a medium, evaluated by the Lifshitz approach are given by

$$\begin{aligned} A_{132} = {} & \frac{3}{4}kT\left(\frac{\varepsilon_1-\varepsilon_3}{\varepsilon_1+\varepsilon_3}\right)\left(\frac{\varepsilon_2-\varepsilon_3}{\varepsilon_2+\varepsilon_3}\right) \\ & + \frac{3h\upsilon}{8\sqrt{2}}\frac{\left(n_1^2-n_3^2\right)\left(n_2^2-n_3^2\right)}{\sqrt{\left(n_1^2+n_3^2\right)\left(n_2^2+n_3^2\right)}\left(\sqrt{\left(n_1^2+n_3^2\right)}+\sqrt{\left(n_2^2+n_3^2\right)}\right)} \end{aligned} \tag{8.12}$$

where n_i and ε_i stand for the refractive index and dielectric constant of material i, respectively.

The main limitation to the Lifshitz approach is that the theory is based on the continuum theory, which is true only when the interacting surfaces are farther apart than their molecular dimensions. The practical use of this theory is dependent on the availability of the dielectric constants for the materials of interest.

8.3 THERMODYNAMICS OF PARTICLES IN ELECTROLYTE SOLUTIONS

8.3.1 DLVO theory[25,26]

Let's now consider an electrolyte containing solution with negatively charged particles in it, with D being the distance between two particles. For the sake of convenience, it is first assumed that only counterions (positive ions with respect to the negatively charged surfaces) exist in the solution. The surfaces of the particles are treated as flat since in a microscopic point of view curvature effects can be neglected. The chemical potential of the ions can be written as:

$$\mu = ze\psi + kT\log(\rho) \tag{8.13}$$

where z corresponds to a particular valency number, ψ stands for the electrostatic (zeta) potential, ρ is the number density of ions with valency z at a distance x from the midpoint (Fig. 8.3).

The repulsive forces between charged particles in a solution can be described according to the following equation:

$$W_{\text{rep}}(D) = 2\pi Rk\varepsilon_0\varepsilon_{\text{R}}\psi_0^2\exp(-\kappa D) \tag{8.14}$$

where R is the radius of the sphere, ε_0 is the electric permittivity in vacuum, ε_{R} is the dielectric constant of the liquid, κ is a constant characterizing the width of the electrical double layer, and D is the distance between two particles.

8.3.2 Steric stabilization of particles

Polymer adsorption on particles surface is used to stabilize colloidal systems. The adsorbed polymers create a layer around the particle. When two particles come close, their polymer layers interact and the arising steric forces prevent coagulation, stabilizing the system. Both enthalpic and entropic phenomena contribute to the steric potential, the former associated with the elastic deformation of the polymer layer and the latter with the osmotic phenomena in the polymer layer. The enthalpic and entropic contributions act additively, as shown in the following equation (Fig. 8.4):

$$W_{\text{steric}} = W_{\text{enthalpic}} + W_{\text{entropic}} \tag{8.15}$$

The interaction between the polymer chains increases the local concentration of polymer inducing

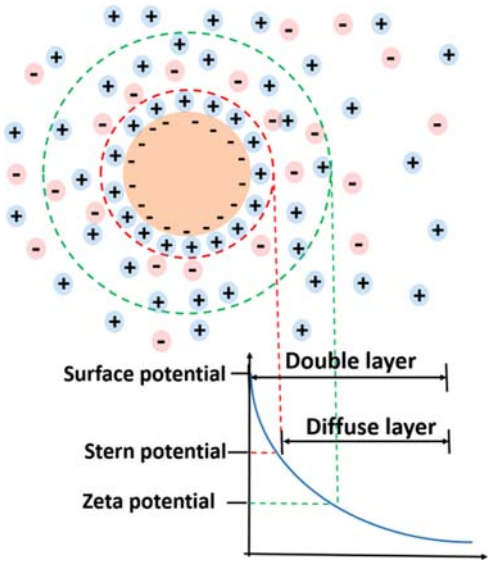

FIGURE 8.3 Schematic showing the double layer around a negatively charged particle and the corresponding graph showing the change in the magnitude of the potential at different distances away from the surface of the particle.

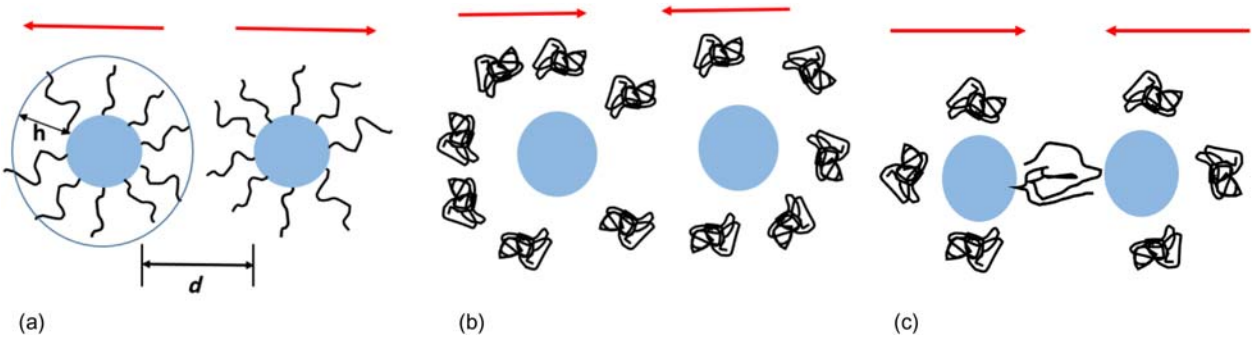

FIGURE 8.4 Illustration of three possible interactions between polymers and particles (the red arrows show whether the particles come closer or move further away): (a) Particles coated with sufficient amount of polymer repel each other, stabilizing the system, (b) If the polymer does not adsorb on the particles, the steric interactions are not sufficient, then there are not enough steric interactions and particles attract each other, and (c) If the amount of adsorbed polymer is not sufficient, bridges are formed attracting the particles.

an osmotic force driving solvent molecules to diffuse toward the gap between the two particles, forcing the two particles to disjoin. Moreover, the interaction between the polymer chains reduces the conformational entropy of the polymer, increasing the free energy of the system enhancing its stability. A coherent mathematical interpretation of this phenomenon can be given in terms of Fischer's work[27]:

$$W_{\text{steric}} = 2\pi RkT\Gamma^2\left(\mathrm{N_A}\left(\frac{V^2_{\text{polymer}}}{V_{\text{solvent}}}\right)\left(\frac{1}{2}-\chi\right)S_{\text{osmotic}} + \frac{1}{\Gamma}S_{\text{entropic}}\right) \tag{8.16}$$

In this equation, Γ is the amount of adsorbed polymer, V_{polymer} and V_{solvent} are the molar volumes of the polymer and the solvent, respectively, and R is the radius of the particle. The term χ is the Flory–Huggins parameter discussed in Section 2.7, S_{osmotic} and S_{entropic} are geometric terms determined by the particle size and the polymer behavior of the polymer layer.

As can be seen, the strength of the solvent is driving the mixing component of the steric potential. If the solvent is strong, meaning that it can dissolve a large amount of material, then $\chi < 0.5$, the overall steric potential has constantly a positive value, favoring good dispersion of the particles. On the other hand, if $\chi > 0.5$, then there would be a competition between osmotic and entropic phenomena. Furthermore, molar-density appears to be quite important. In good solvent conditions, low density polymers enhance mixing, and the reverse happens for bad solvent conditions.

In the context set here, the total potential for sterically stabilized colloid particles is given by the summation of the entropic and enthalpic phenomena with the effects of van der Waals forces described earlier in this chapter:

$$\begin{aligned} W_{\text{total}} &= W_{\text{enthalpic}} + W_{\text{entropic}} + W_{\text{Van der Waals}} \\ &= 2\pi RkT\Gamma^2\left(\left(\frac{V^2_{\text{polymer}}}{V_{\text{solvent}}}\right)\left(\frac{1}{2}-\chi\right)S_{\text{osmotic}} + \frac{1}{\Gamma}S_{\text{entropic}}\right) \\ &\quad + W_{\text{Van der Waals}} \end{aligned} \tag{8.17}$$

If the thickness of the layer is not sufficient, then S_{osmotic} decreases rapidly as the interparticle distance increases. This can result in negative values of W corresponding to a flocculating system.

8.4 SURFACE TENSION AND SURFACE ENERGY

8.4.1 Fundamentals

In the bulk of a material, at any state, molecules interact symmetrically with the rest as shown in Fig. 8.5.

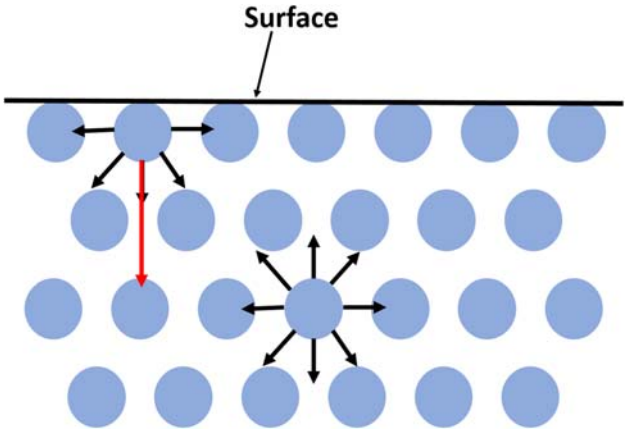

FIGURE 8.5 Interactions for molecules in bulk and molecules on the surface of a material. For the resultant forces shown on one of the surface molecules with a red arrow, there is an equal magnitude and opposite direction force corresponding to the surface tension.

However, the molecules on the surface of the bulk exhibit anisotropic interactions leading to a net force toward the bulk of the material. This force imbalance gives rise to the concept of surface tension (for liquids) or surface energy (for solids). This force imbalance is the energy needed to create a unit surface area of a material.

Consider the interface between a liquid and a vapor having a height h and surface area A; then its volume is given according to the relation $V = h \cdot A$. The work needed (W) to create a unit area of this interface should be the sum of the effects of surface energy and volume expansion:

$$dW = \gamma\, dA - P\, dV \tag{8.18}$$

where γ is the surface tension of the liquid and P is the pressure of the system.

The internal energy of the system is then given by:

$$dU = dQ + dW = TdS + \gamma\, dA - P\, dV \tag{8.19}$$

Furthermore, the expression for Gibbs free energy comes as follows:

$$\begin{aligned} dG &= dH - d(TS) = dU + d(PV) - d(TS) \\ &= TdS + \gamma\, dA - P\, dV + PdV + VdP - SdT - TdS \\ &= \gamma\, dA + VdP - SdT \end{aligned} \tag{8.20}$$

If the system is at constant temperature and pressure, then the Gibbs free energy equation collapses further, to

$$dG = \gamma\, dA \Longrightarrow \gamma = \left(\frac{\partial G}{\partial A}\right)_{\text{T,P,V}} \tag{8.21}$$

The derived relation proposes a "thermodynamic" definition for surface tension to be the change in Gibbs free energy per change in surface area at constant pressure, temperature and volume.

If constant pressure and surface area are assumed, then the change in Gibbs free energy is:

$$dG = -SdT \tag{8.22}$$

Since it is known that Gibbs free energy and surface tension are identical, then this can be rewritten as

$$S = -\left(\frac{dG^s}{dT}\right)_P = -\left(\frac{d\gamma}{dT}\right)_P \tag{8.23}$$

The negative sign in the relation indicates that the free energy at the surface results in attractive forces between materials. For two separate and different bodies, the work associated with holding them together at an interface is termed the adhesive work, W_A while the work associated to holding together bodies of the same kind is called the cohesive work, W_c.

8.4.2 Surface energy components

As previously mentioned, the surface energy of a material is the energy required to create a unit area of the material. In this sense, it can be described in physicochemical terms, according to Fowkes' hypothesis,[28] as the sum of intermolecular forces the system is composed of. Mathematically this corresponds to Eq. 8.24, where n stands for the major surface energy components (dispersion forces, hydrogen bonds, dipole-dipole interactions, ion-dipole interactions, etc.). This equation is usually written in a simplified form as described by Owens–Wendt,[29] with one term accounting for the apolar (Lifshitz–van der Waals) interactions, γ^{LW}, and one term accounting for the polar interactions, γ^P:

$$\gamma = \sum_n \gamma^n = \gamma^{LW} + \gamma^P \tag{8.24}$$

The polar component comprises acid-base interactions and hydrogen bonds. On the other hand, the Lifshitz–van der Waals components not only include dispersion (London) forces,[30] but also the forces induced by the orientation of the interacting molecules (Keesom forces) and by the interactions between a polar and a nonpolar molecule (Debye interaction).[21] Nevertheless, for convenience, γ^{LW} is called the *dispersive component of surface energy*.

The manifestation of surface energy in the macroscopic world can be seen, as mentioned, through the work of adhesion. Let's assume two dissimilar surfaces, i and j, trying to join each other. The total work (W_{ij}) needs to be done is given by

$$W_{ij} = \gamma_i + \gamma_j - \gamma_{ij} \tag{8.25}$$

In this equation, γ_i and γ_j, correspond to the surface energy of the surfaces i and j, respectively, where γ_{ij} stands for the surface energy of the interface. To calculate the value of γ_{ij}, the fundamental equation of surface energy is applied in the context of an interface.

$$\gamma_{ij} = 2\left(\sqrt{\gamma_i^{LW}\gamma_j^{LW}} + \sqrt{\gamma_i^P\gamma_j^P}\right) \tag{8.26}$$

For this document, a geometric mean approach (the Girifalco-Good equation) is selected to calculate the value of the surface energy of the interface.[31] However, another model has been suggested by Wu, using a harmonic mean approximation in the calculations as shown in the following equation[32]:

$$\gamma_{ij} = 4\left(\frac{\gamma_i^{LW}\gamma_j^{LW}}{\gamma_i^{LW}+\gamma_j^{LW}} + \frac{\gamma_i^P\gamma_j^P}{\gamma_i^P+\gamma_j^P}\right) \tag{8.27}$$

The polar component of Eq. 8.27 can be further analyzed according to van Oss-Chaudury-Good (vOCG) method.[24] The polar components are separated to take in account the electron acceptor (γ^+) and donor (γ^-) interactions between the two surfaces, giving us the following:

$$\gamma_{ij} = 2\left(\sqrt{\gamma_i^{LW}\gamma_j^{LW}} + \sqrt{\gamma_i^+\gamma_j^-} + \sqrt{\gamma_i^-\gamma_j^+}\right) \tag{8.28}$$

In cases where polar interactions are negligible, the polar components get a zero value. When the surfaces i and j are the same, then $\gamma_i = \gamma_j$. We refer to this situation as energy of cohesion.

8.4.2.1 *Acid-base interactions*

As has been discussed in the previous section, the vOCG approach accounts for the short-range forces in terms of acid (γ^+) and basic (γ^-) parameters. The hydrogen bonding geometric mean approximation for compounds like ethers, esters and aromatics was challenged.[33] This is due to the hydrogen bonding component of the work of adhesion of these compounds with hydrogen donors, even though their structure does not permit the formation of hydrogen bonds (corresponding to $\gamma_{AB}^{hydrogen} = 0$). Instead of this erroneous approximation, Fowkes and Mostafa proposed the following relation for the acid-base component of the work of adhesion as follows:

$$W^{AB} = -f * N^{AB} * \Delta H^{AB} \tag{8.29}$$

In this relation, ΔH^{AB}stands for the enthalpy of adhesion, N^{AB} for the number of acid-base pairs per unit area and f for a conversion constant used to normalize the units. This equation implies experimental calculation of ΔH^{AB}. In this direction, two different models have been proposed.

The first, developed by Drago,[34] is a combination of Mulliken's work on molecular complexes and the Hard-Soft Acid-Base theory.[35] According to this model, enthalpy can be measured in terms of the tendency of

the acidic or the basic components of electrostatic interactions and covalent bonding. Mathematical formulation of it is given in the following form:

$$\Delta H^{AB} = -(E_A E_B + C_A C_B) \tag{8.30}$$

To avoid any misconception, it is important to specify that for this equation the two terms with subscript A correspond to the electrostatic (E) and covalent (C) parameters of the acidic components, respectively, and those with B subscript to the same terms of the alkaline component. The ratio of the two terms, E and C, of each component defines the hardness of the corresponding component. Iodine is used as the reference, giving a ratio equal to 1. The validity of this method for solids with a very high or very small hardness ratio has been disputed.

The second method for the determination of the acid-base component of the surface energy, was proposed by Gutmann.[36] This theory is represented mathematically as follows:

$$\Delta H^{AB} = -(K_A DN + K_B AN^*) \tag{8.31}$$

In this equation, the K's are parameters characterizing the acidic (A) and alkaline (B) capacity of the solid, respectively. In addition, DN and AN^* stand for the donor and the corrected acceptor number, respectively. The first one, DN, is a parameter measuring the electron donor characteristics. It is measured based on the heat of mixing of the compound in a solution of antimony pentachloride and dichloroethane. The corrected acceptor number (AN^*) is a parameter calculated indirectly from the acceptor number (AN). Acceptor number is measured based on the shifts the compound causes on the P-NMR spectrum of tri-ethyl phosphine. The correction was introduced to account for the effects of van der Waal forces on the shift. Using solvent probes with different acid-base properties, a plot of $\Delta H^{AB}/AN^*$ against DN/AN^* can be constructed. The slope would correspond to K_A and the interception with the y-axis is K_B.

8.4.3 Fundamentals of self-assembly of soft Structures

Poorly water-soluble drug substances, as well as those degrading in water, are often formulated with the aid of soft structures[37] such as microemulsions.[37,38] These structures are primarily constructed by amphiphilic molecules, the structure of which encompasses hydrophobic and hydrophilic parts, such as surfactants and copolymer. The main aim of this section is to provide an overview of the thermodynamic principles underlying self-assembly phenomena creating soft structures out of amphiphilic molecules. The abundance of possible structures of soft structures arises from the anisotropic nature of the amphiphiles and from the spatial arrangement of the functional groups contributing to self-assembly via attractive interactions.

Considering a system of amphiphiles creating soft structures comprising N monomers, the chemical potential of the system can be written as follows:

$$\begin{aligned}\mu &= \mu_1^o + kT\log(X_1) = \mu_2^o + \frac{1}{2}kT\log\left(\frac{1}{2}X_2\right)\\ &= \ldots = \mu_N^o + \frac{1}{N}kT\log\left(\frac{1}{N}X_N\right)\end{aligned} \tag{8.32}$$

where μ_i is the chemical potential of species i, X_i stands for the concentration of i.

Self-assembly is taking place in solutions, in case of equilibrium in this solution the chemical potential of the micelles should be equal to the chemical potential of the free amphiphiles in solution. From the thermodynamic derivation, it is clear that for stable micellization the following condition should be fulfilled:

$$\Delta\mu = \mu_{\text{micelle, N}} - \mu_{\text{solution}} < 0 \tag{8.33}$$

So, as the size of the structure increases, the total chemical potential of the system decreases. However, it is expected that the spatial conformation of the soft structures affect the chemical potential of the system. In this direction, it is important to be able to distinguish the implications associated with geometry, from first principles. Starting from simple one-dimensional (1D) structures, such as rods, comprising of N components it is implied that the change in chemical potential decreases linearly with increasing value of N. Similarly, for two-dimensional structures like circles and sheets, the decrease is proportional to $N^{1/2}$, and for three-dimensional micelles to $N^{1/3}$.

$$\Delta\mu_N = \frac{\alpha kT}{N}(1\ D) \tag{8.34}$$

$$\Delta\mu_N = \frac{\alpha kT}{N^{\frac{1}{2}}}(2\ D) \tag{8.35}$$

$$\Delta\mu_N = \frac{\alpha kT}{N^{\frac{1}{3}}}(3\ D) \tag{8.36}$$

Term α in these equations is a positive constant related to the different geometries.

The changes in system properties occurring above critical micelle concentration (CMC) are used to study micelle formation. At concentrations below CMC, there is a linear increase in monomer concentration as total concentration increases. Beyond CMC, however, the monomer concentration does not change any more. All added molecules self-assemble in the form of micelles, leading to the changes in a range of properties of the system. This sharp change is reflected in changes in a wide range of physical properties, including but not limited to, osmotic pressure, turbidity and surface

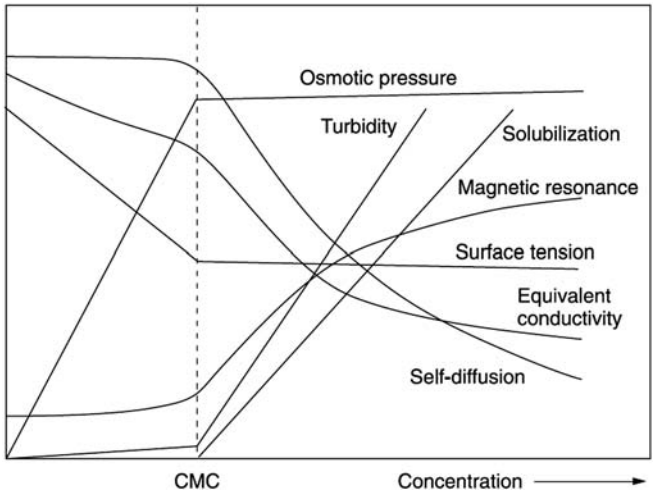

FIGURE 8.6 Change in physicochemical properties of system as a function of surfactant concentration.

tension, as shown in Fig. 8.6. Thus, the micelle concentration can be assessed indirectly by measuring these properties with well-established appropriate techniques.

Nonetheless, properties such as turbidity are affected by the size distribution of the aggregates, as real systems do not exhibit monodispersed aggregates, with a certain value of N, but structures with a range of sizes. To appreciate the relative abundance of different aggregate sizes, it is important to understand the thermodynamic principles governing aggregation of structures with different size. For convenience, in terms of mathematical manipulations, 1D structures comprising an N number of monomers is assumed.

Starting from the fundamental thermodynamic equations for self-assembly leading to

$$\mu_1^{\circ} + kT\log(X_1) = \mu_N^{\circ} + \frac{1}{N}kT\log\left(\frac{1}{N}X_N\right) \rightarrow X_N = N\left(X_1\exp\left(\frac{\mu_1^{\circ}-\mu_N^{\circ}}{kT}\right)\right)^N \quad (8.37)$$

Appropriate mathematic manipulation of these equations, a parabolic equation can be derived describing the change in chemical potential of a system in terms of assemblies comprising N number of micelles and the average number of micelles in each assembly (M):

$$\mu_N^{\circ} - \mu_M^{\circ} = \Lambda(\mathrm{N}-\mathrm{M})^2 \quad (8.38)$$

where Λ is a geometric constant.

8.5 THERMODYNAMICS OF WETTING

8.5.1 Fundamentals

As shown in Section 8.4, the surface tension of a liquid can be defined as the change in Gibbs free energy of a system of changing surface area at constant temperature, pressure and volume. Consider a liquid i spreading over a solid surface j, new interfaces ij are created during this wetting process. This process is interpreted mathematically as follows:

$$\partial G = \left(\frac{\partial G}{\partial A_i}\right)_{T,P} dA_i + \left(\frac{\partial G}{\partial A_j}\right)_{T,P} dA_j + \left(\frac{\partial G}{\partial A_{ij}}\right)_{T,P} dA_{ij} \quad (8.39)$$

Using the definition of surface energy/tension, this equation can be written as

$$-\left(\frac{\partial G}{\partial A_i}\right)_{T,P} = S_{ij} = \gamma_j - \gamma_i - \gamma_{ij} \quad (8.40)$$

where S_{ij} is the spreading coefficient, also related to the work of cohesion and adhesion. Since the work of cohesion can be expressed in terms of surface tension energy by the equation $W_C = 2\gamma_i$, then the work of adhesion can be calculated as follows:

$$S_{ij} = W_A - W_C = \gamma_j - \gamma_i - \gamma_{ij} \quad (8.41)$$

$$W_A - 2\gamma_i = \gamma_j - \gamma_i - \gamma_{ij} \quad (8.42)$$

$$W_A = \gamma_j + \gamma_i - \gamma_{ij} \quad (8.43)$$

8.5.2 Experimental techniques

8.5.2.1 Sessile drop contact angle

Sessile drop contact angle measurements employ the fundamentals of liquid spreading to determine the surface energy of a solid. It is grounded on the observations presented in Young's pioneering work on the cohesion of fluids[39] and can be summarized in the following statement, adapted from that work:

> It is necessary to premise one observation, which appears to be new, and which is equally consistent with theory and with experiment; that is, that for each combination of a solid and a fluid, there is an appropriate angle of contact between the surfaces of the fluid exposed to the air, and to the solid.

The fundamentals of it are described with the aid of Fig. 8.7. Consider a droplet resting on a solid surface. If the mass of the droplet is not big, the gravity effects can be omitted and the forces acting on the system are as shown, γ_{SL} stands for the solid–liquid interfacial energy, γ_{SV} is the interfacial energy between the solid and the air (the one that needs to be determined usually), γ_{LV} is the interfacial energy between the liquid and the air (commonly known as surface tension) and θ_c is the contact angle. The effects of the three-phase interfacial energy have also been neglected. Assuming that the droplet is in equilibrium, the resultant force on the system would be zero. So, Young's equation[40] can be written as

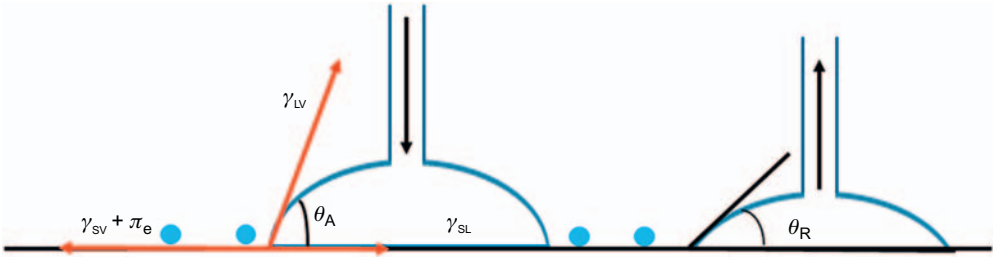

FIGURE 8.7 Schematic representation of the concept of advancing and receding contact angle measurements, indicating the relevant surface tensions, according to Young's equation and the spreading pressure.

$$\gamma_{SL} = \gamma_{SV} - \gamma_{LV}\cos\theta_c \tag{8.44}$$

However, experience leads to the conclusion that droplets do not have a unique contact angle, corresponding to a unique equilibrium position but they experience a wide range of contact angles. Studies conducted on this topic reveal that this broad spectrum is related to the structural and chemical heterogeneity of the material.[21,41,42] The effects of structural heterogeneity on wetting have been investigated in depth, with an example application in the development of biomimetic surfaces.[43–46] Theoretically, a clean and perfectly smooth ideal surface would lead to a single equilibrium position. Contact angles on nonideal surfaces can exhibit a maxima or minima, referred to as the *advancing* and *receding contact angle,* respectively, shown in Fig. 8.7.[47]

Experimentally, the droplet is placed on the surface and is inflated through pumping liquid into it. Simultaneously, measurements of the advancing contact angle are taken at regular, constant time intervals. It is important not to overinflate the droplet, because the effects of gravity become significant and it may collapse (the stick-slip phenomenon). When the droplet reaches a sufficiently large volume, liquid is removed from the droplet and simultaneously receding contact angle is measured. The average of the advancing (θ_A) and receding (θ_R) contact angles is often calculated from Eqs. 8.45–8.47 to calculate the "real" contact angle (θ_c). The difference between the advancing and receding contact angle is known as the contact angle hysteresis.

$$\theta_c = \arccos\left(\frac{r_A\cos\theta_A + r_R\cos\theta_R}{r_A + r_R}\right) \tag{8.45}$$

where r_A and r_R are given by:

$$r_A = \left(\frac{\sin^3\theta_A}{2 - 3\cos\theta_A + \cos^3\theta_A}\right)^{\frac{1}{3}}; \tag{8.46}$$

$$r_R = \left(\frac{\sin^3\theta_R}{2 - 3\cos\theta_R + \cos^3\theta_R}\right)^{\frac{1}{3}}; \tag{8.47}$$

Semiempirical models based on equations of state have been proposed for the measurement of the contact angle. These models introduce a new term, based on the degrees of freedom of the system, to account for the deviations from Young's equation. Li and Neumann[48,49] have proposed the following equation:

$$\cos\theta_c = -1 + 2\sqrt{\frac{\gamma_{SV}}{\gamma_{LV}}}\exp\left(-\beta\left(\gamma_{LV} - \gamma_{SV}\right)^2\right) \tag{8.48}$$

The term β has been determined experimentally, by fitting of a large number of experiments. This equation has been successfully used in polymeric systems. Nevertheless, its applicability on pharmaceutical solids has been disputed.[50]

8.5.2.2 *Beyond the sessile drop measurements*

Sixty years after Young's work, Wilhelmy[51] developed an experimental approach for the determination of the contact angle using the immersion of a solid into a liquid and measuring the force exerted on the solid due to capillary forces.

Because of the experimental setup, this technique is particularly useful for the measurement of the surface energy of thin films or fibers, but not very suitable for particulate materials. However, studies exist trying to apply this technique on compressed pharmaceutical powder disks and on glass slides with adhering pharmaceutical powders.[52] Glass slides were first sprayed with a liquid adhesive, and powder was adhered on the slide by shaking slides briefly in a container of the test powder. Theophylline and caffeine powders were studied in this work. Dove and coworkers found that the surface energy values obtained from the powder plates were more realistic compared to results obtained from compressed powder disks. This difference was attributed to possible changes in the surface properties of the powders during the preparation of the compacted powder disks. The effect of compression on surface chemistry has always been a point of concern for samples prepared in this manner. While the adhesion of powders onto slides overcomes some difficulties faced by compacted samples, it introduces other variables such as surface roughness as well as a potential contribution by the adhesive to the results obtained.

Washburn, Bartell, and Osterhof[53] use the same notion as Wilhelmy to develop a method measuring the surface energy of particulate materials using the rate of penetration of a liquid in the powder bed. Nevertheless, this approach includes numerous assumptions based on idealized conditions and may not be applicable to real particulate materials, especially for porous material.[54–56]

8.5.2.3 *Effects of surface roughness*

Advancing and receding contact angles are a result of surface chemical and structural heterogeneity, and have been first addressed by Cassie[57,58] and Wenzel,[59] respectively. Wenzel suggested that the measured contact angle can be correlated with the actual one based on a roughness parameter ($r_w > 1$).

$$r_w \cos(\theta_{actual}) = \cos(\theta_{measured}) \tag{8.49}$$

As can be seen from the equation, if the surface energy of the material corresponds to a $\theta > 90^\circ$ then increasing the roughness parameter (rougher surface) would result in an increase in the measured contact angle. The opposite happens with surfaces where $\theta < 90^\circ$.

Further studies lead to the development of the Cassie–Baxter equation, describing the contact angle on composite faces:

$$\cos(\theta) = \sum_{i=1}^{n} f_i \cos(\theta_i) \tag{8.50}$$

where f_i stands for the relative surface coverage of component i on the surface of interest and θ_i is the contact angle of the probe on pure component i. There is suggestion that advancing-receding contact angle measurements can be indicative of the surface energy, even for the presence of concentrated impurities. However, it seems that these kinds of measurements can be hardly extended to particulate materials owing to experimental limitations related with the wetting perimeter. Furthermore, the anisotropic nature of particulate materials, imposing energetic anisotropy and heterogeneous distribution of roughness, limits the accuracy of this type of measurements. Vapor sorption measurements,[60] using the notions developed by Anvir and Pfeifer on the fractal nature of surface roughness,[61,62] have been used to assess the roughness of powder materials, including pharmaceutical solids.[60] These sort of measurements can potentially be helpful for the determination of surface energy in terms of Wenzel equation.

Ambient humidity condensates on asperities forming capillaries, on the ground of Kelvin equation. These capillaries influence the cohesion and adhesion behavior of particles. Surface force apparatus and atomic force microscopy have been used extensively to characterize the effect of asperities in interparticle interactions.[63–66] Nonetheless, these measurements cannot, usually, account for a statistically significant number of particles and the corresponding interactions. Adsorption based techniques, such as finite dilution inverse gas chromatography, have been used[67,68] to overcome these problems. Ghoroi has investigated extensively the properties of coated and uncoated pharmaceutical particles. Some of the key findings are that increasing roughness leads to reduced moisture uptake leading to higher bulk density and less change of volume upon compression. Most importantly, it seems that coated pharmaceutical particles exhibit less sensitivity to their properties upon changing in relative humidity (RH).[69–71]

8.5.3 Implications of solid–liquid interfaces

8.5.3.1 *Interfacial thermodynamics in dissolution*

Dissolution of particles, surrounded by a solvent, is a multistep process during which a homogeneous solute–solvent/solution mixture is created with the mass transfer from the particles to the bulk. Thus, both interfacial and hydrodynamic parameters are involved. Hydrodynamic issues of particle dissolution have been extensively investigated both from a modeling and experimental perspective.[72]

From a microscopic (interfacial) perspective, dissolution is initiated by the solvation of molecules at the surface of the particles, which then moves to the solid–liquid interface. Then, the corresponding diffusion mechanism transfers the material to the bulk. The enthalpic component of the change in Gibb's free energy associated with solvation process arises from the average potential energy interactions whereas the entropic component is determined by the spatial conformation of the components taking part in the reaction. The breaking of the bonds in order to create the solid–liquid interface requires large enthalpic penalties. On the other hand, for the solvation of molecules requiring the extensive formation of hydrogen bonds, characterized by specific spatial arrangement, the entropic term dominates the process.[73] It is clear that the spatial orientation of the molecules in a solid particle affects the dissolution process. For example, in a crystalline particle, the exposure of functional groups promoting the formation of hydrogen bonds on the crystal planes may enhance dissolution.[74]

The Gibbs free energy per molecule at the interface between a solute molecule and the bulk solvent can be written in terms of a hard sphere model (assuming spherical solute molecules):

$$\frac{\Delta G}{4\pi R^2} \approx \frac{pR}{3} + \gamma\left(1 - \frac{2\delta}{R}\right) \tag{8.51}$$

where R is the radius of the solute, p is the pressure of the system, γ is the tension in the solute−solvent interface and δ is a length scaling parameter indicating the asymptotic behavior of the surface tension. Theoretical calculations based on this model show that for solute molecules with $R << 1$ nm, the free energy increases proportionally with the solute size. However, for $R > 1$ nm, a shift is observed, leading the free energy to grow slower, proportionally to the surface area of the solute, approaching a limiting value. This crossover marks the formation of an interface between large solute molecules and the solvent. Molecular dynamics simulations, conducted on aqueous systems, reveal that this interface formation is favored by the tendency of water molecules, held together via hydrogen bonds, to move away from the large solute molecule, to minimize the number of unformed hydrogen bonds. On average, less than one hydrogen bond is sacrificed, out of the four a water molecule can form, due to this shift. These studies verify the Stillinger's theory stating among others that[75]:

> Although liquid water might properly be described as a random, three-dimensional, hydrogen-bond network, it surely cannot have invariant fourfold coordination. Instead, some of the hydrogen bonds must be broken and others severely strained in length and direction.

8.5.3.2 *Surfactant enhanced wetting*

Surfactant-containing liquid droplets exhibits high spreading even on highly hydrophobic surfaces. The phenomenon where a liquid spreads rapidly on a surface is called superspreading.[76] The exact mechanism behind this is still unclear, nevertheless various attempts have been made to explain it using theoretical,[77] computational[78,79] and experimental tools. Despite the lack of understanding, surfactants are extensively used industrially to aid spreading, including in pharmaceutical formulations.[80]

8.5.3.3 *Effect of additives in crystallization*

The paper published by Michaels and Colville in 1960[81] sets the basis for the understanding of the role of ionic additives in crystal growth and habit. An adsorption based mechanism has been proposed to explain the changes in crystal growth. The notions of this study have been expanded for the effects of surfactants and polymers on crystal growth. Empirical and semiempirical approaches have mainly been employed, based on the functional groups and the molecular weight of the additives. However no mechanistic approach exists describing these phenomena. Recently, Kestur[82] proposed an explanation for the effects of polymers molecular weight and concentration. Nonetheless, the role of the intermolecular interactions arising from the functional groups remains unclear.

In the field of surfactant additives, apart from the changes in supersaturation driven by the increase in solubility due to the effects of surfactants, micelle formation appearing above the CMC may lead to some interesting effects. In two independent studies, one on organic[83] and the other on inorganic materials,[84] it has been shown that crystallization in solutions with surfactant concentration above the CMC, the crystal habit is significantly different. Carbamazepine dihydrate recrystallized from a solution of anhydrous carbamazepine (form III) produces elongated planar crystals with high aspect ratio. As the concentration of surfactant increases, there is a shift to a planar shape with lower aspect ratio. When the surfactant concentration is above the CMC, the shape becomes prismatic. From a theoretical perspective, the attachment energies of carbamazepine dihydrate favor the formation of the elongated shape minimizing the morphological importance of the {200} facet. This change is due to the presence of soft micellar structures.

The emergence of nonclassical nucleation[85–87] schemes could provide the tools to understand the effects of macromolecules and additives in general in crystallization. In this direction, the discovery of an intermediate liquid phase, called the *polymer-induced liquid phase*, used by organisms in biomineralization proved to be of great importance.[88,89] As discussed by Evans, features of this phenomenon can be extended in the crystallization of organic molecules with the aid of proteins via the formation of an amorphous organic phase.[90]

Coming from a different pathway, researchers have investigated the crystallization of organic compounds from the corresponding amorphous organic glasses.[91] The high energetic amorphous phase appears to enhance crystallization. In particular, even when the material is below its glass transition temperature the molecular mobility could be enough to promote nucleation and crystal growth.[92] A more intrinsic feature is that the growth rates in the bulk and the surface of the amorphous material are different, with the latter being orders of magnitude faster.[93,94] Many potential mechanisms were examined including the effects of surface tension, surface ordering, and surface mobility.[95]

Recent investigations have revealed the correlation of the growth mechanism with the fluidity at the crystal−amorphous interface.[96] Crystal growth in such a system occurs due to the expansion of the crystalline front and not because of the nucleation on the amorphous side. The crystalline side advances fast enough so to overcome diffusion phenomena arising from the fluidity of the amorphous materials. In this direction, the ratio of the diffusivity of the glassy material to the crystal growth should be less than seven picometers.

An increase in the fluidity of the amorphous material would lead to an increase of the diffusivity, resulting in crystal growth cessation.

8.6 SOLID–VAPOR INTERFACE

8.6.1 Introduction

The phenomenon of gaseous molecules attaching themselves to a solid surface can occur via two general mechanisms, physisorption and chemisorption. Of course, fundamentally this distinction is arbitrary and cases exist which are difficult to classify as being simply physisorption or chemisorption. The latter involves the formation of chemical bonds of which the enthalpy involved is comparable to the heat of reaction. In physisorption, the energy involved is similar to those required for liquefaction and is completely reversible for a nonporous solid. The third mechanism for vapor–solid interactions can also occur whereby the vapor molecules are "dissolved" into the interior of the solid, and the phenomenon is referred to as absorption. The term sorption is usually used to describe a process in which both adsorption and absorption occur. The solid is termed the adsorbent, while the vapor molecules are the adsorbate.

8.6.2 Adsorption fundamentals

Adsorption-based techniques can be employed for the determination of surface energetics of various types of materials,[97] including but not limited to polymers,[98,99] metals, and of course crystalline organic materials.[68] In this section, a brief introduction to some concepts of adsorption processes, associated with the concepts already established in the chapter, is provided. The International Union of Pure and Applied Chemistry (IUPAC) definition of adsorption is

> An increase in the concentration of a dissolved substance at the interface of a condensed and a liquid phase due to the operation of surface forces. Adsorption can also occur at the interface of a condensed and a gaseous phase.

This definition is supported mathematically by the Gibb's adsorption isotherm[100] shown in Eq. 8.52, where γ stands for the surface tension, Γ for the surface excess, μ for the chemical potential, and i for the number of components. As can be seen, this definition does not refer to solids at all.

$$d\gamma = -\sum \Gamma_i \, d\mu_i \tag{8.52}$$

In 1937, two seminal papers were published by Bangham and Radzouk, pioneering the studies of vapor–solid adsorption systems.[101,102] After that, much work on the development of new mathematical models to describe adsorption isotherms corresponding to different conditions has been undertaken. Table 8.1 summarizes some of the most well-known isotherms describing their main attributes (chronological order is followed, going from the oldest to the most recent).

8.6.3 Heterogeneous adsorption

Because of the energetic anisotropy of crystalline particles, pharmaceutical particles (as well as other materials used in engineering applications) are characterized by energetic heterogeneity. Taking into account this

TABLE 8.1 Summary of Some of the Most Important Adsorption Isotherms Available

Name	Equation	Comments
Freudlinch (1909)	$\theta_e = K_0 P_e^{\frac{1}{n}}$	Equation used on the chemisorption on activated carbon. It can describe multilayer problems
Langmuir (1918)	$\theta_e = \frac{Q_0 b P_e}{1 + b P_e}$	Well established equation suitable for chemical adsorption problems, limited to monolayer situations
BET (1938)	$\theta_{monolayer} = \frac{C P_e}{(1 - P_e)[1 + (C - 1)P_e)}$	It is used extensively for the characterization of particulate materials
Fowler-Guggenheim (1939)	$K_{FG} P_e = \frac{\theta_e}{1 - \theta_e} \exp\left(\frac{2\theta_e W}{RT}\right)$	One of the first approaches taking into account lateral interactions
Temkin (1940)	$\theta_e = \frac{RT}{\Delta Q} \ln(K_0 P_e)$	A quasi logarithmic isotherm, attempting to capture the surface heterogeneity of the material of interest
Kiselev (1958)	$K_1 P_e = \frac{\theta_e}{(1 - \theta_e)(1 + k_n \theta_e)}$	It is used extensively for the characterization of porous materials
Elovich (1962)	$\frac{q_e}{q_{monolayer}} = K_E P_e \exp\left(-\frac{q_e}{q_m}\right)$	One of the pioneer efforts for the systematic understanding of multilayer adsorption
Hill de Boer (1968)	$K_1 P_e = \frac{\theta_e}{1 - \theta_e} \exp\left(\frac{\theta_e}{1 - \theta_e} - \frac{K_2 \theta_e}{RT}\right)$	Similar to Fowler–Guggenheim, derived from van der Waals equation of state

heterogeneity parameter, the following equation has been suggested:

$$\int_0^{\infty} \chi(\varepsilon)\, d\varepsilon = 1 \tag{8.53}$$

The term $\chi(\varepsilon)$ is the probability distribution of having an energy site with energy ε on the surface of a given material. Combining the aforementioned equation with any isotherm equation, the fundamental equation of adsorption on heterogeneous surfaces is derived.[97]

$$\theta(T,p) = \int_0^{\infty} \theta_e(\varepsilon,T,p) * \chi(\varepsilon)\, d\varepsilon \tag{8.54}$$

In Eq. 8.54, θ denotes for the surface coverage and θ_e for the adsorption isotherm.

Similarly, an integral equation can be developed for the mean surface energy of adsorption:

$$\overline{E} = \int_{\overline{E}_{min}}^{\overline{E}_{max}} \varepsilon * \theta_e(\varepsilon,T,p) * \chi(\varepsilon) d\varepsilon \tag{8.55}$$

The solution of theses equations provides an insight to the energetic heterogeneity of the material under investigation. Many attempts have led to solution schemes involving different isotherm. However, there is not a universal solution scheme. Here, the attention is given to the development of a solution framework describing the adsorption phenomena on organic crystalline materials, as it takes place in IGC. The fundamentals of this effort have been set in the work of Jefferson et al.[103] and Smith et al.[104]

Jefferson's and Smith's approaches are based on the Henry's law model, implying a linear relation between surface coverage (θ) and vapor pressure. Despite the oversimplistic nature of this argument, it may be considered valid, particularly at low partial pressures. This is because pharmaceutical organic powders, at low surface coverage (<10%), will typically have an IUPAC type II isotherm, similar to BET. As can be seen, the Brunauer-Emmett-Teller (BET) equation at low pressure collapses to Henry's law.

Using the kinetic model proposed for gas adsorption on crystalline solids, Henry's constant (C) was given in the following terms:

$$C = \frac{v_0}{n_0\sqrt{2\pi mkT}} \exp\left(\frac{-\Delta G_{ads}}{kT}\right) \tag{8.56}$$

In this equation, v_0 corresponds to the mean stay time of an adsorbed molecule on the surface (ie, it measures the tendency of the molecules to desorb), n_0 stands for the concentration of surface sites, m is the mass of an adsorbed molecule, ΔG_{ads} is the adsorption surface energy, k is the Boltzmann constant, and T the temperature.

Assuming that the adsorbent molecule is a van der Waals fluid with negligibly small polar component, then the energy of adsorption per molecule is given as follows:

$$\Delta G_{ads} = -2a_m\sqrt{\gamma^{LW}_{surface}\gamma^{LW}_{adsorbate}} \tag{8.57}$$

On the surface of a crystal a finite number of patches/facets with specific surface energy value, depending on the facet, the relative coverage between two different patches is given by the ratio of the Henry's constant corresponding to each facet. In this context, it can be assumed that the concentration of surface sites is facet independent, as it is determined by the crystal lattice parameters. The adsorption of van der Waals fluids is driven only by the dispersive component of surface energy (physisorption). The mean stay time, in this case, is approximately 10^{-2} seconds. Taking into account these two assumptions, the mathematical formulation of the relative surface coverage takes the following form:

$$\frac{C_1}{C_2} = \exp\left(\frac{-\Delta G_{ads,1} + \Delta G_{ads,2}}{kT}\right) = \exp\left(\frac{2a_m\sqrt{\gamma^{LW}_{adsorbent}}\left(\sqrt{\gamma^{LW}_{surface,1}} - \sqrt{\gamma^{LW}_{surface,2}}\right)}{kT}\right) \tag{8.58}$$

8.6.3.1 *Mapping of energetic surface Heterogeneity*

Smith et al. used the analysis described previously to solve the integral equations to deconvolute representation of the dispersive surface energy profiles, assuming Gaussian distribution of surface energies. The integral equations were solved using point-by-point integration as suggested by Thielmann.[105] The underlying idea of this method is that the integral equations are solved for different combinations of the energy density distribution function ($\chi(\varepsilon)$), until an agreement is reached between model and experimental data. For example, let's assume a sample of powder χ containing crystals with four different facets $A-D$, each one with a different surface energy value (let's call it μ). Assumptions are made for the relative contribution of each of the facets to the total surface area (this fraction would be called w) of the sample. If a Gaussian distribution of the energetic sites is assumed, then the following equation for $\chi(\varepsilon)$ can be formulated:

$$\chi(\varepsilon) = \sum_{i=A}^{D} \frac{w_i}{\sigma_i\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{\gamma_i^d - \mu_i}{\sigma}\right)^2} \tag{8.59}$$

In fact, since the values for μ are known from contact angle experiments, only the values of w can be varied in this equation. By inspection of the IGC data, is possible to obtain some good predictions for them.

This deterministic approach for the solution of adsorption problems is grounded on two over simplistic arguments. The first one is that Boltzmann distribution is adequate to describe, energetically, the behavior of gas molecules in a microscopic level. The second argument is that each adsorption site corresponds to a certain energetic threshold value, determined by the surface energy of the sites. If the adsorbent particles carry enough energy to overcome this threshold, then this site will be filled.

Employing arguments similar to those Einstein used to explain the stochastic nature of Brownian motion,[106] adsorption can be classified as a stochastic process. The stochastic nature of adsorption implies that even if the energy of an adsorbate does not exceed the threshold value of the adsorption site, there are still probabilities to adsorb on it. These probabilities govern both the adsorption and desorption phenomena.

8.6.4 Inverse gas chromatography (IGC)

As mentioned, particulate materials are energetically heterogeneous. Thus, adsorption methods can be used to characterize their surface properties since these techniques can provide an idea for the values of surface energy at different values of surface coverage. Inverse gas chromatography is one of those methods. The application of this method in the field of the particulate materials has started in the mid-1970s.[107–110] The name of this process is indicative of its fundamental features. It is exactly the inverse of a conventional gas chromatography, developed by the Russian botanist Mikhail Tswett[111] at the beginning of the 20th century. A known gas probe is injected into a column packed with the material of interest. The time needed for the gas to exit the column (retention time) is used to determine the net retention volume, which in turn is used to determine a material's physicochemical properties, including the surface energy.

The infinite dilution regime of IGC, corresponds to the situation where a small amount of probe is injected into the system covering only a small amount of the surface of the solid. The back tailing regime corresponds to relatively high surface coverage ($>25\%$) of macroscopic materials, the isotherm of which corresponds to type II and IV IUPAC isotherms. The fronting situation is one corresponding to either type III or V IUPAC isotherms.[112] These isotherms characterize materials with low surface energy. This situation is usually undesirable. Low surface energy materials do not adsorb the injected probes well. Desorption phenomena prevail, and usually the results are not reliable. In cases like this, the best option is to run the experiment at a lower temperature until the fronting effects are minimized.

From the chromatograms obtained, the retention time of each injected probe can be estimated. If a Gaussian chromatogram is produced, then the retention time is taken as the time at which the maximum peak occurs. If the peak is skewed, then the center of mass should be taken. The retention volume can be estimated from the following equation:

$$V_N = \frac{j}{m_s} w(t_R - t_0)\left(\frac{T_s}{T_{Ref}}\right) \tag{8.60}$$

The retention time (t_R) can be implemented in the equation given here to calculate the elution volume (V_N). In the same equation, j stands for the James–Martin pressure drop coefficient. This parameter acts as a correction factor accounting for the compressibility of the injected probes. Parameter m_s is the specific surface area of the material under investigation in m^2 per unit mass, w is the carrier gas flow rate in standard cubic centimeters per minute, t_0 is the dead time, the time takes for an inert probe molecule to pass through the column, T_s is the temperature at which the experiment is performed, and T_{Ref} is the reference temperature, which is usually taken to be 273.15 K.

Taking into account the aspects outlined in the surface energy section of this chapter, it is clear that the selection of the probes is important in this method. Usually, linear alkanes are used for the determination of the dispersive component of the surface energy. Due to the differences in adsorption behavior of each of them, a series of n-alkanes is used (usually C6-C11). The results can be analyzed based either on the Schultz[113,114] or the Dorris and Gray[115] methods, to calculate the dispersive surface energy of the sample. The results obtained from the two methods are similar, and there is not a rational way to select which is most appropriate for each case.[115,116]

Similarly for the determination of the polar component of the surface energy, polar probes are used.[117] The experimental results from different temperatures can be plotted based on the fundamental thermodynamic equation shown here:

$$\Delta G_{ij}^0 = \Delta H_{ij}^0 - T\Delta S_{ij}^0 \tag{8.61}$$

To determine the enthalpy of adsorption for the acid-base components, experiments should be performed as a function of temperatures. More recently, the use of monopolar probes such as ethyl acetate and dichloromethane have been proposed by Das et al. to determine the acid-base properties by IGC.[118]

8.6.5 Implications of solid–vapor interfaces

8.6.5.1 Moisture content in solid-state materials

Solid-state formulations are exposed in high moisture environment during processing and/or storage. Water in crystalline solids can be present as bound or unbound water. The term bound water indicates that the water molecules are incorporated into the crystal lattice or in channels. On the other hand, unbound water is either adsorbed on the crystal facets or trapped in voids. This distinction is useful in distinguishing moisture containing pharmaceutical formulations, but can be misleading.[119,120]

For crystalline materials, when adsorption is dictated by van der Waals forces (physisorption), then multiple layers of adsorbate molecules can be formed. In this context, BET and Hill de Boer adsorption isotherms are particularly attractive for use in sorption studies. On the other hand, when chemical (short-range) forces dominate, then monolayer adsorption prevails where the Langmuir isotherm is adequate. It is important to appreciate that because of the nature of the interactions, physisorption is a slower process, requiring a longer time for equilibrium to be established. Experience has shown that the validity of these equations is confined in a certain range. Nonetheless, more complicated equations which may provide a larger validity range may require careful determination of the associated parameters.

In amorphous solids, above the T_g, the adsorbed moisture diffuses in the bulk of the material. In this case, the system is treated in terms of liquid–liquid mixing models (Flory–Huggins)[121,122] or models describing the solvent diffusion in amorphous polymers (Vrentas–Vrentas).[123] In any case, it should be mentioned that moisture absorption in amorphous solids is not uniform. It has been shown that, depending on the conditions, solvent clusters can be formed in the solid. Of course, the use of these models is not limited to moisture sorption studies, but it has been extensively used in the characterization of polymer-drug interactions.[124–126]

The hysteresis behavior of the adsorption isotherms observed in sorption studies provides information on the amorphous content and the porosity of the material under investigation, apart from the details on the water uptake capacity. Generally speaking, hysteresis can occur due to the porosity of the material, but also on structural defects and chemical impurities on the surface of the material of interest. In Fig. 8.8, some examples of hysteresis behavior are shown. Crystalline macroporous materials exhibit no or marginal hysteresis; porous materials have a larger hysteresis and amorphous materials lead to an open loop hysteresis. The shape of the hysteresis loop is dependent on the size and geometry of the pores and is categorized by the IUPAC classification. In amorphous materials, the open loop indicates that the water bound in the bulk of the material cannot be released with just reversing the RH.

8.6.5.2 Drying

Moisture removal includes simultaneous heat and mass transfer; energy is transferred from the surroundings to the particle leading to the evaporation of the moisture. Due to the different states at which moisture is bound in the solid, drying processes exhibit different stages. During the initial heating period, the fluid is heated to evaporation. Then there is a constant drying rate phase the moisture adsorbed on the surfaces is removed until a critical moisture content value corresponding to the tightly bound water content. The vapor pressure of the moisture bound in capillary structures can be significantly lower due to the effects of confinement described by the Kelvin equation.

In the case of crystalline solids, the exposure of crystal planes to ambient moisture after drying may induce

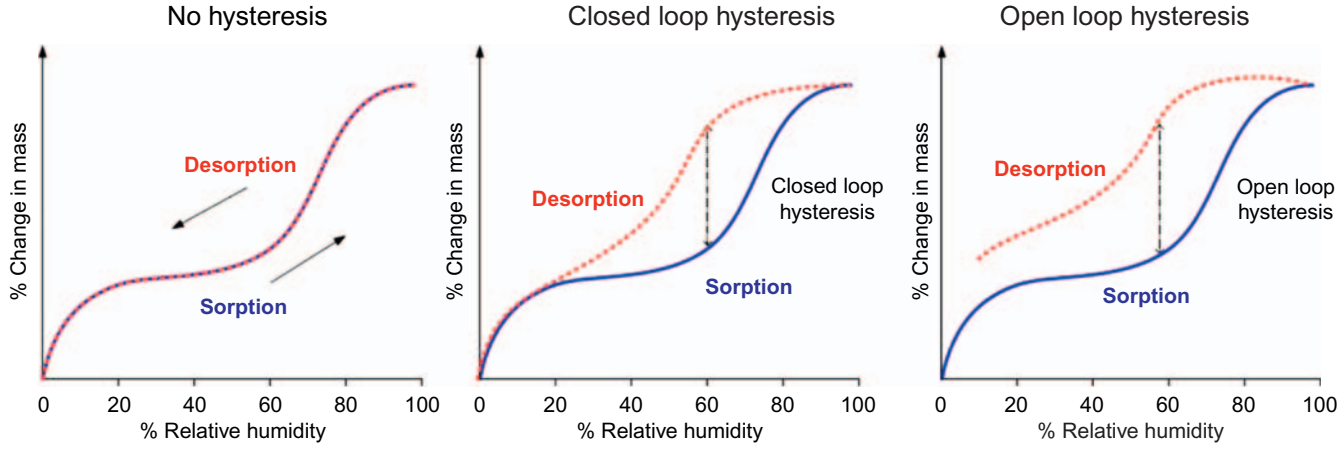

FIGURE 8.8 Sorption desorption isotherms for different hysteresis cases.

either changes on the surface patterning or increase in nucleation density. The increase in surface roughness associated with the latter is a common feature of hydrated compounds. An example obtained from the dehydration of carbamazepine dihydrate is shown in Fig. 8.9. However, no literature findings support the facet-specific dependence of this process, although crystal defects can affect this process.[127–129]

Crystal defects can be distinguished in three different categories[130]:

1. Point defects: this case includes situations when atoms or molecules are literally missing from a point of the crystal lattice, creating a vacant point, or when an extra atom appears on a random position on the lattice.
2. Linear defects: this is when a group of atoms/molecules is misplaced in the lattice creating screw or edge dislocations.
3. Planar defects: in this case defects appear in the region between two homogeneous crystal planes

Defects can arise randomly during crystallization or can be induced by thermal or mechanical stress. They are characterized by higher energy than the bulk of the material, and thus, they are sites of preferential reaction (either via Lifshitz–van der Waals or chemical interactions). When hydrates are dried under vacuum, the nucleus of the anhydrous form is initially formed in the area around the crack (Fig. 8.10). The moisture removed from the material provides the molecular mobility on the interface between anhydrous and hydrated material to facilitate the anhydrous material growth. If the moisture removal is too fast (eg, under vacuum conditions), then the crystal lattice cannot withstand the stress associated with the removal of bound water molecules and collapses to an amorphous state.[131] The amorphous, nonequilibrium, material seeks to recrystallize. However, recrystallization is not necessarily taking place toward the most stable anhydrous polymorph, but toward the one with the energy minimum of closest proximity.[132] Thus, it could turn to an intermediate form which would then turn to the most stable one under the effect of Ostwald's rule, which can be summarized by the following excerpt from Threlfall[133]:

> At a sufficiently high supersaturation, the first form that crystallises is the most soluble form. This transient state then transforms to the more stable form through a process of dissolution and crystallization.

Apart from the conventional drying approaches, spray drying and freeze drying allow moisture removal combined with the transition from crystalline phase to amorphous. This transition directly affects the molecular arrangement in the bulk and the surface of the solid, since amorphous solids are characterized by a lack of thermodynamic equilibrium. Existing studies, are limited in the use of infinite dilution inverse gas chromatography for the determination of the surface energetics of spray and freeze-dried materials, meaning that they are taking into account only a negligibly small amount of surface area of the material under investigation. The data obtained from these studies show negligible changes in the surface energy. Nonetheless, further studies should be conducted on the ground of finite dilution inverse gas chromatography to provide us with positive results for the effects of spray and freeze drying on the surface energetics of solids.[134]

The dynamic behavior of suspensions in a spray dryer can lead to the formation of particles with a wide range of characteristics. The mechanism for the formation of these hollow particles is determined by the heat and mass transfer processes described by the Peclet number. Suspensions are injected into the spray drying chamber and under the proper conditions the habit of the dried particles, at the outlet of the spray

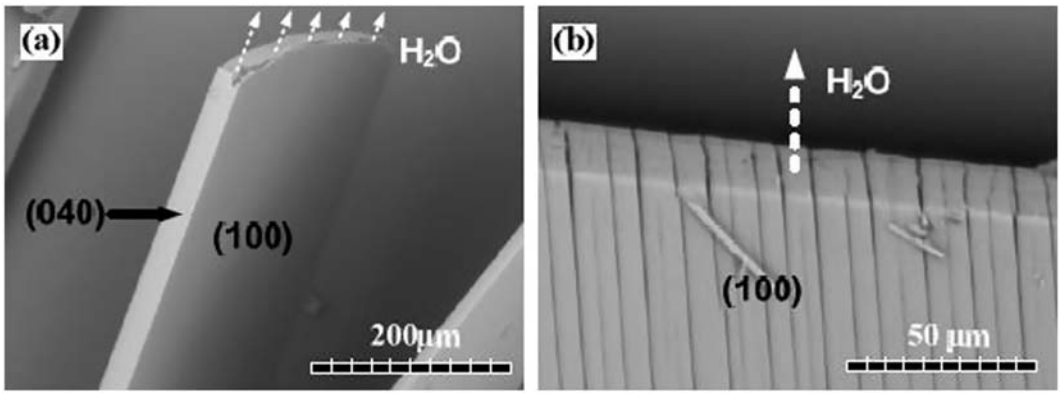

FIGURE 8.9 The effects of drying on the surface roughness of carbamazepine dihydrate, the cracks are induced by the removal of bound water.[127]

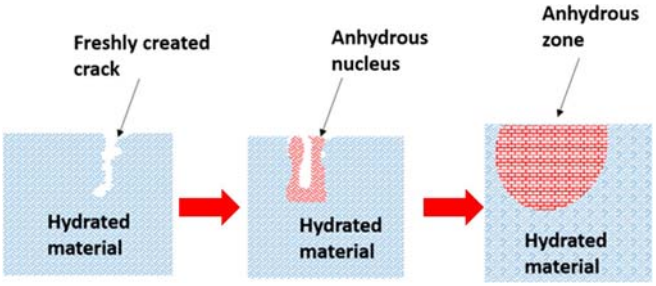

FIGURE 8.10 The development of an anhydrous form during dehydration at the cracks of the surface of a hydrated crystalline solid.

dryer, can be engineered. The dimensionless Peclet number, providing the ratio of the change in surface area of a particle containing bubble with the diffusion coefficient of the solids in the liquid droplet can be modified with the use of coated particles with different diffusion coefficients.

In his works on spray drying, Vehring prove the applicability of this process in the manufacturing of hollow particles to be used in drug delivery systems. The formation of hollow particles can also lead to the decrease in the bulk density of the product; though can be susceptible to breakage. The versatility of spray drying opens the possibility for particle engineering and product design, including pharmaceutical solids.[135,136]

8.7 INTERFACIAL PHENOMENON (SOLID–SOLID)

8.7.1 Fundamental thermodynamics

When solid particles interact, the behavior of the resultant system is greatly influenced by their interfacial interparticulate interactions. This interaction may be defined by adhesion or cohesion forces. The attractive force between particles of different compounds is regarded as adhesion while the attractive force between particles of the same compound is termed as cohesion. Adhesion and cohesion forces are the sum total of van der Waals forces, capillary forces, mechanical interlocking and solid bridging in addition to minor contributions from contact potential and Coulombic forces. Van der Waals forces are considered to be the principal forces for particulate adhesion or cohesion that include interactions like dipole-dipole, dipole-induced dipole and induced dipole-induced dipole. Adhesion forces have been discussed in the section on fundamental intermolecular forces, however, they are briefly mentioned here in the context of powdered solids.

The relative contribution of these forces is mainly determined by material properties such as hydrophilicity or hydrophobicity, particle size and local environmental conditions, such as RH.[137] These factors are particularly important for DPIs, as micronized powders are highly susceptible to interparticulate forces because of their high specific surface area.

Surfaces of pharmaceutical powder particles are often rough. Particle interactions can thus be reduced by surface roughness since the latter increases the distance between particles and consequently decreases contact and van der Waals forces. However, if the surface is excessively rough, for example, crevices and holes are present on the surface, they may interlock which can in turn dramatically increase interparticular interactions by mechanical interlocking. In addition, if a small particle is trapped in a depression on a large particle, the attractive forces are more than the required detachment forces due to intermolecular and electrostatic interactions.[138]

The presence of moisture has a significant effect on interparticulate interactions. Although van der Waals forces exist in both low and high humidity, low level of moisture can enhance the dissipation of triboelectric charge and decrease interparticulate interactions. At high RH, water vapor moving through interparticulate spaces can condense and form liquid bridges and influence interparticulate forces by at least three different mechanisms such as by changing surface energy, surface conductivity through electron mobilization and surface tension.[139] The presence of high level of moisture can develop capillary forces and increase interparticulate interactions.

The development of capillary forces and their contribution to overall adhesion forces is governed by several factors. Firstly, capillary forces are not significant at an RH of less than 50%, and they are the dominant contributor to adhesion at an RH of above 65%.[140] Secondly, capillary forces develop more easily for hydrophilic compounds than hydrophobic compounds. Liquid bridges can be formed by the moisture condensed between particles. If the lifetime of these bridges is high, they can start dissolving the particles. Due to evaporation of the moisture, the dissolved solid is recrystallized to form solid bridges. Solid bridges increase the interparticulate interactions significantly.

Solid bridges can also be formed by mineral bridges between particles of the same material; chemical interaction or reaction between particles; partial melting of low melting point solids caused by friction or heat and subsequent cooling. Although solid bridging is rare in practice, they become important during long-term storage of hydrophilic compounds.[141] Liquid bridges are often followed by solid bridges due to recrystallization.[142]

The surface energy of particles plays an important role in their behavior. The term surface energy is sometimes confused with adhesion/cohesion. In the previous section, it has been clearly shown how surface energy is related with adhesion/cohesion forces. Adhesion force can be calculated from surface energy by using contact mechanics models. The history of these models dates back to 1881 when Hertz[143] published his influential work accurately describing the deformations on macroscopic systems, but not taking in account the effect of adhesion forces. Numerous advancements have been made, and different models have been proposed since then and concentrated especially on the effects of adhesion in smaller scales.[144–146] The two most well-known models are the Derjaguin-Muller-Toporov (DMT) model[25] and Johnson-Kendall-Roberts (JKR) model.[147]

In the JKR model, the forces outside the contact area between the two bodies are considered negligible. In addition, at the edges of the contact area, the elastic stress tends to infinity meaning that the strength of the system increases unboundedly with decreasing size of the sphere.[148,149] On the other hand, in DMT model, the surrounding forces appear to have an effect on the adhesion, nevertheless they do not affect the shape of a sphere which is deformed according to Hertz's model. This discussion can simplistically be summarized by the statement that JKR model is more appropriate for larger systems where the sphere has a large enough contact surface area to make the effect of the surrounding forces negligible, and smaller systems are better treated through DMT model.[150] In this context, the more frequent question is what can be considered being large and what being small. Maugis attempts to answer this question in his work. Using a more general model developed by Dugdale, it proves that the aforementioned models are specific cases of Dugdale's model and has related the two models with dimensionless parameters.[148]

8.7.2 Experimental techniques

For the quantitative determination of adhesion force, atomic force microscope (AFM) is widely used. Inverse gas chromatography can be used to calculate adhesion/cohesion forces by measuring surface energy. However, scanning electron microscope (SEM) and other imaging techniques are also used to understand the interparticulate interactions qualitatively.

8.7.2.1 Atomic force microscope

AFM has been extremely useful for measuring adhesion force. Prior to the introduction of AFM, optical microscope was used to image a surface. The AFM is a type of scanning probe microscope that has a resolution in the order of nanometer. It has revolutionized the imaging of particulate surfaces, thus has been useful in manipulating particulate surface in the nanometer range. The AFM has also been used to determine adhesion forces and surface energy from DMT/JKR models.[151,152]

The cantilever is made of a well-characterized material, and its Hooke's law (spring) constant is known. The tip of the cantilever is of known shape, and its material properties are also known. A small force slowly pushes the tip of the cantilever toward the surface of the material. The movement of the cantilever from the moment it approaches the surface enough to feel the attractive forces until it gets pushed back is used to calculate the force via Hooke's law. The force-to-distance behavior is displayed in Fig. 8.11 in conjunction with the cantilever surface relationship.

Initially, the tip approaches the surface when is in a distance where the attractive forces start to become significant, it bends. As it bends, the effect of attractive forces becomes more profound until the tip attaches to the surface. Then the tip is pulled back slowly until it is totally dispatched from the surface.

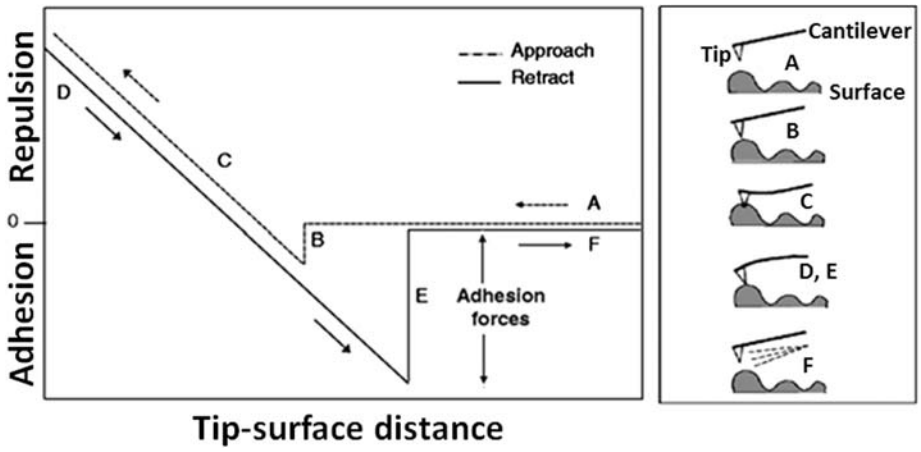

FIGURE 8.11 Schematic showing the force curve during an AFM experiment in conjunction with cantilever surface relation.

8.7.2.2 Scanning electron microscope

SEM helps the qualitative identification of drug-carrier interactions on the surface of the particle. In normal SEM, a vacuum is necessary, which was not possible to see the changes made by different environmental humidity on powders. The introduction of environmental SEM in the 1980s has made now possible to study powder sample controlling temperature and RH.[153]

8.7.3 Pharmaceutical implications

Solid dosage forms dominate all the other dosage forms, with oral solid dosage forms constituting over 80% of the market. Solid dosage forms include tablets, capsules, suppositories and dry powder for reconstitution or inhalation. In many phases of their production process, understandings of the interfacial interparticulate interactions are important. The processes include but not limited to milling, flowability, mixing, tabletting, etc. The influence of solid–solid interfacial interactions will be discussed in the following section.

8.7.3.1 Flowability

Flowability is an important bulk powder characteristic. The term "Flowable" means an irreversible deformation of a powder to make it flow due to the application of external energy or force. Various parameters such as angle of repose, Carr's index, Hausner ratio, flow function (ff) are used to express flowability of powders.

The angle of repose is the simplest method to express the flowability of powders. The angle of the heaped cone of a free standing powder is the angle of repose. When a powder is allowed to fall on a flat surface from a funnel positioned at a certain height, the funnel is gradually moved upward in order to maintain a fixed height between the powder tip and the bottom of the funnel. The angle produced by the powder on the surface is the angle of repose. The other way is to allow powder from a central hole of a flat-bottomed container. The slope produced by the remaining powder in the container bottom is the angle of repose. Furthermore, rotating drum can be used to measure the angle of repose. The material is placed, homogeneously, in the drum and left to rotate for a number of revolutions. Then the angle is measured.

Another refined method to measure flowability is the ff, defined as the ratio of consolidation stress (σ_1) to unconfined yield strength or uniaxial compression stress (σ_c).

The flow of powder particles is influenced by interparticulate interactions which include adhesion/cohesion, frictional forces, mechanical forces due to interlocking. A range of other factors can also influence flowability of powders. For example, particle size and size distribution, particle shape and shape distribution, porosity, density, moisture content, surface composition, substances present in powder.

The lower the adhesion/cohesion forces, the greater will be the flowability. Flowability can be improved by using both hydrophilic such as aerosol and hydrophobic substances such as magnesium stearate, sodium stearate, magnesium silicate and calcium silicate, etc. Hydrophobic additives can increase flowability of powders by decreasing interparticulate interactions by reducing van der Waals forces at low RH. In contrast, hydrophilic additives may decrease flowability by increasing interparticulate interactions by developing capillary forces. The use of low cohesive, hydrophobic lubricants has, already, been employed to improve powder's flowability.

One of the challenges of increasing the flowability by using flow additives is to disperse the flow additives on the surface of host particles since very fine particles of flow additives might prefer to agglomerate themselves. Flow additives are added either by mixing or by mechanofusion. The processes of mixing and mechanofusion is discussed in the following.

8.7.3.2 Mixing or blending

Mixing or blending is a widely used process in pharmaceutical industries to blend a multicomponent particular system. In the formulation of tablets, active ingredients are mixed with excipients before granulation. Different glidants and lubricants are mixed with granules after granulations and before tabletting. Similarly, drugs are mixed with various excipients for other solid dosage forms such as capsules, dry powders for inhalation and powders for reconstitution. The mixing is carried out using different mixers or blenders, for example, V-mixer, Cone mixer, rotating cylinder, etc. It is expected that a mixture will be homogeneous meaning the different components will be distributed in a uniform manner throughout the system.

If drug particles are small in size, they are cohesive and can form agglomerates. The mixing mechanisms involve two stages: the breakdown of agglomerates to primary particles and the dispersion of primary particles. An ideal mixing process may break down these agglomerates to primary particles and disperse throughout the system in a manner that they are evenly distributed, and it will be maintained for a long time after mixing so that the ultimate dosage forms such as tablets and capsules have uniformity in drug content. In practice, it is not possible to have a completely uniform (ideal) mixture. Often, a "satisfactory level of random mixing" is achieved, where the

average (mean) of each type of particles in a series of samples is close to the ideal mean and the variability in drug content is low.

There are three main procedures of solid mixing: diffusive mixing, convective mixing, and shear mixing. In diffusive mixing, individual particles move to change position relative to neighboring particles in a random way. This type of mixing is possible for free-flowing powders and is facilitated by the differences in density and particle size. In convective mixing, a portion of the mixture is taken from one place and deposited in another. Finally, in shear mixing, particles are forced to move past each other. In this type of mixing, usually large agglomerates are broken up but not small agglomerates. This is determined by the relative strength of agglomerates and the shear applied.

Demixing (segregation) can occur at the same time as mixing occurs when the external mixing procedure stops. The factors promoting segregation include differences in particle size, shape and density. If the particles are uniform in size, shape and density, and the surface is smooth, achieving uniformity of mixture is still extremely difficult when the drug concentration is very low in the mixture, and the drug or excipients are highly cohesive resulting in very strong agglomerates of drug or excipients.[154,155]

In order to improve the homogeneity of a powder mixture containing a very low concentration of a drug, ordered mixing process was introduced by John Hersey.[156] This technique was initially developed for producing tablets of highly potent drugs. Later on, it has been regularly used to produce carrier based DPIs where only a small percent of drug is mixed with large carriers. Each "ordered unit" of a mix will be similar or almost identical in composition to all other ordered units in the mixture. Ordered mixing is achieved by dividing and recombining the powder bed in different ways such as preblending and geometric dilution; "doubling."

When the drug is mixed with carriers, the homogeneity ultimately depends on the balance between cohesiveness of drugs and excipients and the adhesion between drugs and excipients. It is expected that adhesion between drug and excipients will be higher than cohesive forces of drugs.

Measuring the surface energy of powder mixtures, using inverse gas chromatography, is not a straightforward process. The differences between physically mixed and coated samples can be identified. Following the discussion conducted in the solid–vapor interface section of this chapter, it is easy to appreciate that inverse gas chromatography study of mixtures comprising materials with significantly different surface energy involves certain limitations arising from the nature of the technique. The fluid probes interact preferentially with the material exhibiting higher energy adsorption sites on the basis of a Boltzmann distribution, leaving the adsorption sites of the lower energy material uncovered. Thus, especially at low values of surface coverage, only one of the materials may take place in the measurement.

The surface energy of a powder after mixing might be different due to the creation of new surfaces due to attrition/fracturing.[157] Recently, surface energy profile determination explained the mixing phenomenon even better. The nonpolar surface energy profile of the salbutamol sulfate (SS)–magnesium stearate (MgSt) mixture to be positioned between those of SS and MgSt and it was within 5% range of nonpolar surface energy profiles of MgSt, indicating that the surface of SS was covered by MgSt during the mixing process.[158] Similarly, the surface energy profiles of two blends of fine lactose (LH210) and large lactose (LH250) at different ratios were found to be positioned between those of LH210 and LH250.[159]

Interparticulate interactions were also studied by using AFM to understand the influence of mixing two or more components on the mixture especially in the context of DPI performance. It was concluded that one of the mechanisms on how the inclusion of fines improves performance of drugs from a career based formulation is that when fines are mixed with large carriers, the highly active sites are occupied by the fines, making the less active sites available for drugs that can be easily dispersed.[160]

8.7.3.3 *High-shear mixing or dry coating*

Mechanofusion is a process of mechanical dry coating in which submicron-sized guest particles directly attach onto relatively larger, micron-sized host or core particles. This process uses shear and compression to produce a thin continuous film of the guest material on the surface of the host. This high-shear mixing process has been used to change the surface properties of powders by coating a material with hydrophobic materials to modify the surface energy and reduce particle interactions.[161]

Dry coating can be performed by using a magnetic assisted impaction coater (MAIC) or a hybridizer (HB)[162], or by using a mechanofusion apparatus.[163] Magnesium stearate, traditionally used as a lubricant, has been widely used in coating by mechanofusion. Dry coating of powders such as fine lactose, salbutamol sulfate, triamcinolone acetonide, and salmeterol xinafoate with a low cohesive material such as magnesium stearate has been very successful at increasing the deagglomeration of those powders.[7,164] Mechanofusion of lactose with MgSt has been shown to improve flow properties and dispensability dramatically compared with conventional mixing of MgSt with lactose in a turbular mixer.[165]

Other materials include hydrophobic and hydrophilic silica. Coating of cornstarch with different silicas using MAIC has shown to improve flowability. Hydrophobic silica was found to be more effective than hydrophilic silica, especially by reducing the liquid bridge formation.[162]

Recently, the Resonant Acoustic Mixer was developed to improve mixing and dispersion processes. It applies resonance phenomenon to effectively transfer energy to the content in the mixing container. In the case of mixing particulate materials, the powders are accelerated as high as 100 times of the gravitation force. Numerous particle-particle and particle-vessel collisions lead to the effectiveness of the process. Its application in dry powder coating of pharmaceuticals was demonstrated by Mullarney and coworkers using several drugs.[166] Flexibility in mixing scale (from subgram to hundreds of kilogram), the ability to contain the mixing contents, and the availability of the continuous version of the mixer make this technology a great prospect for applications in pharmaceutical development.

8.7.3.4 Milling

Micronization and milling are commonly used pharmaceutical processes for reducing particle size of pharmaceutical materials.[167–171] A reduction in size is extremely important in the case of DPI since particles of $<5\,\mu m$ size can reach lower respiratory tracts which are the primary sites of drug delivery through inhalation. In general, micronization of large drug particles is used to produce particles of an inhalable size and then mixed with a large carrier in a carrier-based formulation for inhalation. It is also important to increase the dissolution of solids since the reduction in particle size can improve surface area, and thereby, the dissolution rate of the materials. In tablet manufacturing, drug is micronized before wet granulation with excipients. Micronization can be carried out using high-energy air jet mill while ball milling is used. The process is influenced by many factors, such as the nature of starting material, temperature, RH and energy input, etc.

Micronization introduces new interfaces by fracturing particle, creating lattice defects, or by producing amorphous materials. These new interfaces may have different exposed surface groups than the surface of the original material. These processes, therefore, may increase or decrease the surface energy of materials based on the exposed surface groups. In general, an increase in dispersive or nonpolar surface energy was observed upon micronization of compounds, such as paracetamol Form I,[109] salbutamol sulfate,[172] salmeterol xinafoate, and crystalline α-lactose monohydrate.[173] Increase in surface energy may result in increased agglomeration due to their cohesive forces exceeding the gravitation forces, thus, creating new challenges in drug delivery. Milling of DL-propranolol initially increased dispersive surface energy until a particular point, brittle to ductile the transition point, followed by a decrease with further milling.[174] Similar change was observed for ketoconazole and griseofulvin.[175]

However, micronization of compounds showed mixed effects (increase or decrease) on polar surface energy. For example, the acidic component of polar surface energy was found to decrease for DL-propranolol,[174] salbutamol sulfate,[172] salmeterol xinafoate and α-lactose monohydrate,[176] but it increased for acetaminophen upon micronization. The basic component of surface energy was increased for DL-propranolol,[177] salbutamol sulfate,[172] and α-lactose monohydrate,[176] but it decreased for acetaminophen upon micronization or milling. Micronization and milling may expose new surfaces, created by the formation of lattice defects or because of the formation of amorphous sites.[172,178–180] In all the aforementioned studies, surface energy was determined at infinite dilution using an inverse gas chromatography and results may only provide a limited description of powder properties as such measurements do not fully describe the heterogeneity of crystalline solids.

The particle surface energy characteristics were revealed in more detail with the determination of surface energy (heterogeneity) using finite dilution IGC. The distribution of nonpolar surface energy was more heterogeneous for milled lactose than untreated α-lactose monohydrate.[67] The milled lactose had significantly higher nonpolar surface energy than untreated (before milling) α-lactose monohydrate at infinite dilution (zero surface coverage). However, at higher surface coverage, the milled lactose had lower surface energy than the untreated α-lactose monohydrate. In another study, it was observed that, compared to ibipinabant before micronization, the nonpolar surface energy of ibipinabant after micronization was smaller at low surface coverages whereas it was larger at higher surface coverages.[181] The increase in nonpolar surface energy was attributed to the generation and redistribution of high energy sites on micronization.

8.7.3.5 Tableting

The ability of a powder to form a tablet of adequate mechanical strength is termed as tabletting. It is important that a tablet remain intact during its manufacturing, packaging and transportation processes until it is consumed by the patient. It is also important that the tablet is not excessively strong so that it does not undergo disintegration and dissolution after oral administration. The mechanical strength of a tablet is expressed as the tensile strength which is the minimum force required to break a tablet.[182,183] The tensile

strength of a tablet depends on many characteristics of the consolidating granules or powders, such as particle size, shape, density, surface area and interparticulate interactions.[184]

A tablet is produced by compression of granules or powders of drugs with or without excipients. When a powder is compressed, it undergoes processes such as particle rearrangement, particle fracture, and particle deformation. Interparticulate interactions play a major role in tabletting. Interparticulate interactions such as van der Waals forces, hydrogen bonding may exist between molecular solids while ion-dipole, ion-induced dipole or Coulombic forces may exist for ions. During the early compression process, powder particles come closer due to rearrangement of particles. The interparticulate interactions such as van der Waals forces increase when the distance between particles decreases. As the compression force is increased, the particles fracture (depending on the brittle-ductile nature and the strength of the particles). Again the strength of an individual particle depends on the interparticulate interactions of the molecules and ions they are made of. The last phase of consolidation by compression is particle deformation which involves plastic and elastic deformation with an increase in interparticulate interactions by increasing particle contact area. The ultimate success of tabletting depends on interparticulate interactions of powder particles, material properties, and compression process.

8.7.3.6 Triboelectrification

When two materials undergo friction, the particles may be charged or electrified due to the transfer of electrons from one particle to the other; this charging is called *triboelectric charging*, *tribo-charging*, or *frictional electrification*.[185] *Contact charging* denotes the charging which arises due to the transfer of electrons when two different materials come in contact and are separated. Charging due to short contact for collision is called *impact charging*. It is practically difficult to differentiate the purposes of charge transfer; therefore, *triboelectric charging* is commonly used to refer to all three of these processes.[186]

Triboelectric charging could be generated due to the direct transfer of electrons between two materials in contact due to the difference in their work functions (as in metal-metal contact) or surface charges. It may also arise due to the transfer of ions or materials from surfaces during contact, frictions or impact. For a metal-metal contact, the amount of charge transferred (ΔQ_c) can be calculated as the product of the contact potential difference (V_c) and the capacitance (C_0) between the two bodies.

Since the particles collide with each other, or with the wall of the container, or particles are abraded during production and handling of powdered solids (eg, milling, micronization, sieving, mixing, coating and spray drying), triboelectric charge generation in the particles is common.[187] This can be both problematic and beneficial. The negative impact of triboelectrification of particles includes particle adhesion during manufacturing, particle accumulation on equipment surface, segregation and altered dose uniformity.[188–192] In contrast, the positive impact of electrostatic charging includes the production of ordered mixtures of charged powder particles exploiting the opposite polarity.[193] This type of ordered mixture is more stable and may improve content homogeneity more than other powder processing techniques.[190,193,194] Factors that influence triboelectric charge production include particle size, shape, surface roughness,[195,196] surface chemistry, presence of functional groups and chemical structure[197–199] and electrical properties of powders and contacting surfaces.[200,201]

Triboelectric charge is affected by the presence of moisture (ie, environmental RH and temperature), nature of contacting material, and velocity of particles.[186] At a specific temperature, the triboelectric charge decreases with increasing RH probably due to increased leakage for decreased electrical resistance on the surface.[202] It also decreases with increasing temperature.

In order to minimize triboelectric charging, particle surface is coated with different materials. The irradiation using ultraviolet rays and plasma processing are the two methods commonly used to change surface charge of polymers. In electrophotography, two types of materials, charge control agents and charge stabilizers are used to minimize charging. Fumed silica and polyvinylidene fluoride are used as surface charge control agents while amines or quaternary ammonium salts are bulk charge control agents which are blended with polymers to control charging. Polyester salts are used as charge stabilizers.

Triboelectric charges can be characterized by different techniques. One of these techniques is a cascade method.[203] The triboelectric charges are produced on particles when they are allowed to fall down from the top of a reference plate which is kept tilted at a certain angle. The charge is measured by a Faraday cage. Higashiyama et al.[204] described a slightly different technique. In their technique, particles are allowed to fall from one end of a charging plate to the other end through vibration where the charge of the particles is measured by a Faraday cage. Luga et al.[205] used a fluidized bed to develop triboelectric charges and a charge spectrometer to measure charge distribution.

8.8 FUTURE DIRECTIONS—OPINIONS

The interfacial properties and behavior of solid-state pharmaceutical formulations are complex, though

ubiquitous in the manufacture, handling, formulation and delivery of pharmaceuticals. However, much of the current descriptors employ semiempirical approaches, and there is a need in providing the framework for more fundamental understanding. The ability to develop linkages between quantum and nanoscale phenomena with their manifestations in the microscale will lead to major scientific advances and have significant industrial relevance. Molecular modeling tools and population balance equations could play a significant role in bridging these gaps. Development of theoretical models across lengthscales; from molecules to particles to process,[206,207] are currently undertaken, some of which are already resulting in more accurate descriptions and useful insights.

Many fundamental equations consider the ideal case where particles are spherical and the surfaces are flat and smooth. In reality, such ideal cases do not exist, and surface morphology such as surface roughness and shape should be considered in describing interfacial phenomena. It is plausible that the inclusion of the anisotropic nature of crystalline solids[208,209] into current theoretical models will leads to a better understand and ultimately predictability of powder processability. In parallel, advancement in characterization techniques is also necessary. Approaches to describe heterogeneity or distribution of particle properties are crucial, as single average value do not accurately explain powder behavior. For example, advances in determining surface energy heterogeneity, crystal size and crystal shape distribution of powders have been made over the last decade.

Recently developed imaging techniques allow the determination of both the size and shape distribution of particles.[210,211] Significant steps have been made toward the fundamental understanding of the mechanisms leading to the crystallization of particles with different crystal habits under different conditions.[212–214] The surface energy deconvolution of powders is also a useful tool in the understanding of the effects of surface anisotropy. However, these advancements have not matured enough to be implemented in the existing mechanistic models describing macroscopic phenomena like aggregation and attrition.

Whilst not addressed exhaustively in this chapter, novel formulation methods including but not limited to amorphous solid dispersions, nanodispersions, porous nanoparticles and liposomes exhibit interesting interfacial phenomena. Since some of them rely on particles in the submicron scale and/or self-assembly interactions it is, also, obvious that interfacial phenomena would probably dictate the corresponding product/process development into a great extent. Thus, the question is not if we would need to go deeper in understanding the implications of interfaces in pharmaceutical formulations but if we would be able to progress fast enough to reach the demands for more advanced formulations. We are in a more advantageous position compared with the pioneers in the field of interfaces. Novel experimental techniques enable us to go achieve a level of accuracy that our predecessors did not enjoy. Also, we have tools to develop and solve more sophisticated mathematical models to describe interfacial phenomena, than anyone could imagine back in Gibbs's era, in the late 19th century. Nonetheless, interfaces remain a challenging field where significant work should be done to bridge different length scales and provide integrated understanding for their behavior.

9.1 FUNDAMENTAL OF DIFFUSION

9.1.1 Introduction

In nature, particularly in the gas and liquid phases, molecules are frequently colliding with conservation of momentum. Collisions cause changes in the direction of movement of molecules or small particles, resulting in their random motion. Collisions between molecules and the walls of a container generate pressure in a gas or hydrostatic pressure in a liquid. Random motion of a particle caused by random bombardment by solvent (or gas) molecules due to thermal motion is known as *Brownian motion*. *Diffusion* is the process by which atoms, molecules, or small particles are transported from a region of higher concentration to a region of lower concentration due to random motion. In the absence of convection, Brownian motion or diffusion is a primary transport mechanism for small particles ($<0.1\,\mu m$) or molecules when the transport distance is small (ie, $<$ a few millimeters). Over larger distances, diffusion is a slow process for material transfer, and other factors like convection are important to obtain significant transport of material in a reasonable time period (ie, <1 day). In dissolution testing, diffusion and convection are combined processes that generate dissolved drug in solution, in which convection is the dominating mechanism.

The diffusion process is driven by entropy change (ie, $\Delta S > 0$ for diffusion). The process is an example of the second law of thermodynamics; no enthalpy is required in the process (ie, no heat or work is required, but heat can affect the rate of diffusion). Diffusion is irreversible because it can occur in only one direction—from high to low concentrations.

The exact movement of any individual molecule (or small number of molecules) is completely random. The overall behavior (ie, macroscopic) of a large population of molecules ($>10^6$) is quite predictable. Diffusion is a process of mass transport that involves the movement of one molecular species through another (ie, a drug in a gel or solution). It occurs by random molecular motion from one point to another, and it can occurs in gas, liquid, or solid states. Diffusion in liquid, gel, or polymeric systems is of primary interest in the pharmaceutical sciences.

The subject of diffusion has been well studied, and a variety of models and their mathematical expressions related to pharmaceutical applications are available in the literature.[1–6] The first part of this chapter provides a review of the fundamental theory and the basic equations of diffusion to facilitate the further application of diffusion theory in pharmaceutical sciences.

9.1.2 Basic Equations of Diffusion

The two basic equations describing the diffusion process are Fick's first and second laws.

Fick's first law: The rate of transfer (dQ/dt) of a diffusing substance through the unit area (A) in one dimension (x) is proportional to the concentration gradient, $\partial C/\partial x$, as described in Eq. (9.1).

$$J = \frac{dQ}{Adt} = -D\frac{\partial C}{\partial x} \tag{9.1}$$

where:

J is the flux (rate of diffusion)
D is the diffusion coefficient
C is concentration
$\partial C/\partial x$ is the concentration gradient.

DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00009-1

The negative sign indicates that diffusion occurs from high concentration to low concentration.

Fick's second law: The rate of solute accumulation or concentration change, $\partial C/\partial t$, in an element volume, dV, is proportional to the flux gradient of the solute in the element, dJ/dV. In other words, the rate of change of number of molecules in the volume element equals the difference between the flux of molecules entering the element and the flux of molecules leaving the element.

The mathematical form of Fick's second law can be developed from the first law by the following approach: molecules entering and leaving a volume element by diffusion can occur in three dimensions. The contribution of diffusion in one of the dimensions, x, to the concentration change in the volume element is depicted in Fig. 9.1, where the surface area for diffusion remains constant along the diffusional path. By mass balance, the rate of change of molecules in the element by one dimension diffusion can be described by Eq. (9.2).

Thus, the concentration change in this volume element can be formulated as the difference in fluxes into and out of the element, as shown here:

$$\frac{\partial C}{\partial t}dV = (J_{\text{in}} - J_{\text{out}})dA \tag{9.2}$$

Utilizing the relationship of $dV = dAdx$ and replacing dx (in the flux expression) with ∂x, the rate of concentration change in one-dimensional diffusion can be written as

$$\frac{\partial C}{\partial t} = \frac{-\partial J}{\partial x} = D\frac{\partial^2 C}{\partial x^2} \tag{9.3}$$

Similar equations can be derived for diffusion in the other two dimensions, assuming that the diffusion coefficient in the volume element is constant. The rate of concentration changes can thus be written as the sum of contributions in three dimensions as

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} + D\frac{\partial^2 C}{\partial y^2} + D\frac{\partial^2 C}{\partial z^2} \tag{9.4}$$

Eqs. 9.2–9.4 are derived for the case where the surface area for diffusion remains constant. If the surface area for diffusion changes, such as the radial diffusion in a cylinder or in a sphere, the area changes must be taken into account. For diffusion in a sphere, Fick's second law is

$$\frac{\partial C}{\partial t} = D\left(\frac{\partial^2 C}{\partial r^2} + \frac{2}{r}\frac{\partial C}{\partial r}\right) \tag{9.5}$$

For radial diffusion in a cylinder, Fick's second law can be expressed as

$$\frac{\partial C}{\partial t} = D\left(\frac{\partial^2 C}{\partial r^2} + \frac{1}{r}\frac{\partial C}{\partial r}\right) \tag{9.6}$$

Diffusion can reach a steady state where concentration in a volume element does not change with time, but material still diffuses through the element. Using this criterion, the rate of change of the concentration gradient in the element is zero at steady state according to Fick's second law. For a one-dimensional system with constant surface area, the concentration gradient ($\partial C/\partial x$) at steady state is constant (the concentration profile is linear with distance along the diffusional path in the system).

If one views Fick's first law as an equation for the rate of mass transfer, then Fick's second law expresses the acceleration (or deceleration) of mass transfer.

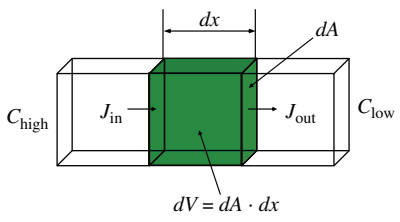

FIGURE 9.1 Volume element.

9.1.3 Solutions for Diffusion Equations

The most fundamental diffusion equation, Fick's second law, is a partial differential equation that must be solved for specific conditions before it can be used for practical problems. Mathematical solutions for actual systems can be obtained by taking the initial and boundary conditions of the real systems into consideration. Assuming that the diffusion coefficient is a constant, solutions for many systems with different initial and boundary conditions have been derived, either in the form of an error function (or a series of error functions) or of a Fourier series. These solutions can be found in the literature,[1–6] eliminating the need to derive them again. One can thus select the corresponding solution from the literature to fit the specific initial and boundary conditions for a particular system. These can be either infinite or finite systems, with or without perfect mixing (ie, sink conditions) for the boundary conditions. A number of these cases will be presented and discussed next.

9.1.3.1 Diffusion from a plane source into an infinite medium

If a finite amount of solute, M, is deposited on an infinitely thin plane in the middle of an infinite tube of medium (ie, water or gel), and the solute diffuses

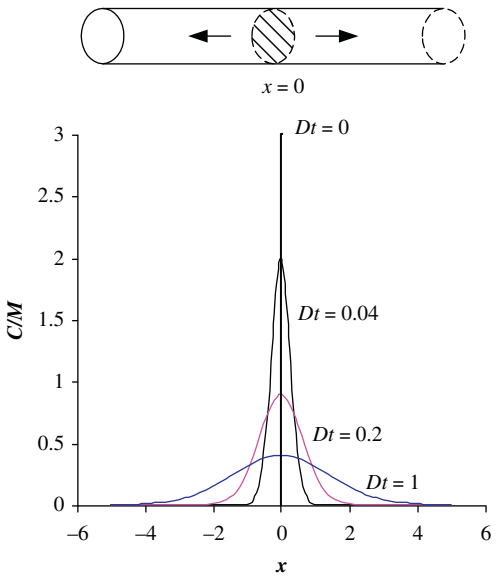

FIGURE 9.2 Plane-sourced, one-dimensional diffusion system and the relative concentration profiles as a function of distance and time.

axially toward each end of the tube (ie, one-dimensional diffusion) without mixing, as depicted in Fig. 9.2, Eq. (9.7) is the solution to Fick's second law for this one-dimensional system, assuming that the diffusion coefficient D is constant at constant temperature:

$$C(x,t) = \frac{M}{2\sqrt{\pi Dt}} \exp\left(\frac{-x^2}{4Dt}\right), \quad t > 0 \tag{9.7}$$

As indicated in Fig. 9.2, the concentration at $x = 0$ becomes smaller with time. At other points where $|x| > 0$, concentration increases with time when $\partial^2 C/\partial x^2 > 0$ and decreases when $\partial^2 C/\partial x^2 < 0$. The area under the concentration distribution curve is constant because the entire initial mass, M, is retained. However, as t approaches infinity, C becomes infinitely small over all distance values.

9.1.3.2 *Diffusion between two infinite regions in contact*

This system consists of two regions in contact with one of the regions (ie, $x > 0$) initially containing solute at concentration C_0, and the other region is free of solute (ie, $C = 0$). Solute diffuses from the initially loaded region into the empty region without mixing. This system can be considered an extended version from the plane source system described previously by treating the system as containing an infinite number of plane sources of thickness, $\Delta\alpha$, each with an initial concentration, C_0, as shown in Fig. 9.3.

The initial conditions are

$$t = 0, \quad C = 0 \quad \text{for } x < 0, \quad \text{and} \quad C = C_0 \quad \text{for } x > 0$$

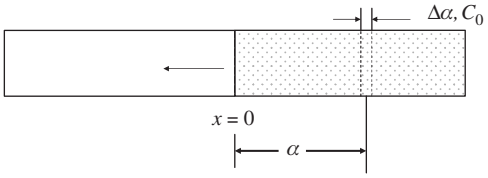

FIGURE 9.3 Infinitely extended region of uniform initial distribution.

Obviously, the amount of diffusing molecules in each segment is $C_0\Delta\alpha$, and diffusion from each infinitely thin segment to the point α can be expressed as follows:

$$C(x,t) = \frac{C_0\Delta\alpha}{2\sqrt{\pi Dt}} \exp\left(-\frac{(x-\alpha)^2}{4Dt}\right) \tag{9.8}$$

By superposition, diffusion from the entire region with initial distribution C_0 can be obtained by integrating over all the infinitely small elements to obtain:

$$C(x,t) = \int_0^\infty \frac{C_0}{2\sqrt{\pi Dt}} \exp\left(-\frac{(x-\alpha)^2}{4Dt}\right) d\alpha \tag{9.9}$$

Eq. (9.9) can be rewritten in the form of an error function:

$$C(x,t) = \frac{C_0}{2}\left[1 + erf\left(\frac{x}{2\sqrt{Dt}}\right)\right] \tag{9.10}$$

Eq. (9.10) shows that at the interface where $x = 0$, the concentration is constant at $C_0/2$.

The net amount of material transferred from the initially loaded region into the unloaded region (ie, across $x = 0$) over time can be calculated as follows:

$$Q_t = AC_0\sqrt{\frac{Dt}{\pi}} \tag{9.11}$$

where A is the cross-sectional surface area of the entire system. Note that Eqs. (9.10) and (9.11) are applicable for infinite regions in contact or a short time approximation of finite systems with the same initial conditions as the infinite systems. As a short time solution, it is assumed that the initially loaded region maintains C_0 at some distance from $x = 0$, and the initially unloaded region is still essentially free of solute at some distance from $x = 0$. The derivation of Eqs. (9.10) and (9.11), as well as the properties of the error function, were reviewed in the previous edition of this book.[7]

9.1.3.3 *Diffusion in semi-infinite systems*

If a semi-infinite polymeric gel or a large planar piece of biological tissue initially free of drugs is in

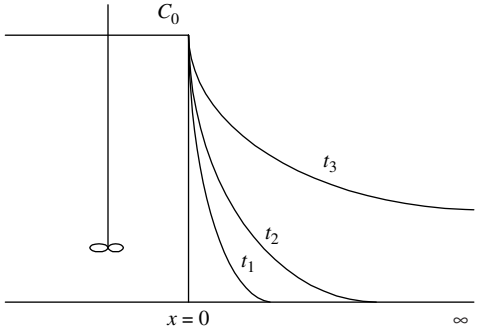

FIGURE 9.4 Diffusion in a semi-infinite system.

contact with a well-stirred saturated drug solution, as depicted in Fig. 9.4, the initial conditions are given by

$$C = 0, \quad x > 0, \quad t = 0$$
$$C = C_0, \quad x = 0, \quad t > 0$$

where C_0 is the drug solubility at the interface of the solution and the gel or tissue surface.

Under these conditions, the drug concentration profile that has diffused into the gel or tissue up to time t can be described by

$$C(x,t) = C_0\left\{1 - erf\left[\frac{x}{2\sqrt{Dt}}\right]\right\} \tag{9.12}$$

The amount of drug that has diffused into the gel over time can be described by

$$Q_t = 2AC_0\sqrt{\frac{Dt}{\pi}} \tag{9.13}$$

Comparing Eqs. (9.11) and (9.13), it can be seen that the rate of diffusion is doubled when half of the diffusion system is well mixed, and maintained at a constant concentration compared to the unstirred system, with all other conditions being the same.

In infinite and semi-finite systems, the concentration profiles are a function of diffusion distance and time; the thickness of the system does not affect the concentration profile until concentration begin to change at either boundary in the semi-infinite system.

9.1.3.4 Diffusion in finite planar systems

When a planar gel of thickness $2h$, initially loaded with a solute at $C = C_0$, is placed in a well-stirred medium maintained at zero concentration, drug release occurs with an initial condition of

$$C = C_0, \quad -h < x < h, \quad t = 0$$

and boundary conditions of

$$C = 0, \quad x = \pm h, \quad t > 0, \quad \text{and} \quad \frac{\partial C}{\partial x} = 0, \quad x = 0, \quad t > 0$$

For this finite system, the thickness of the gel affects drug release. The complete solution for the concentration in the gel as a function of time and distance is

$$C(x,t) = C_0\left\{1 - \sum_{n=0}^{\infty}(-1)^n erfc\left(\frac{(2n+1)h - x}{2\sqrt{Dt}}\right) - \sum_{n=0}^{\infty}(-1)^n erfc\left(\frac{(2n+1)h + x}{2\sqrt{Dt}}\right)\right\} \tag{9.14}$$

The amount of drug released from the gel over time is

$$Q_t = 2AC_0\sqrt{Dt}\left\{\frac{1}{\sqrt{\pi}} + 2\sum_{n=1}^{\infty}(-1)^n ierfc\left[\frac{nh}{\sqrt{Dt}}\right]\right\} \tag{9.15}$$

For a small period of time when $nh/\sqrt{Dt}$ is large, the *ierfc* terms become negligible, and Eq. (9.15) can be simplified to Eq. (9.13), which is useful for a drug release of not more than approximately 60%. This approximation can be understood by considering the fact that for short periods, the middle of the gel is still at C_0, so the system can be viewed as a semi-finite system. Therefore, Eq. (9.15) can be reduced to Eq. (9.13) for short time approximations, even though the systems differ in size.

Using the method of separation of variables,[7] the concentration in the finite planar systems can be expressed by a series of trigonometric distance and exponential time functions, known as *Fourier series*, as shown here:

$$C = \frac{4C_0}{\pi}\sum_{p=0}^{\infty}\frac{(-1)^p}{2p+1}\cos\frac{(2p+1)\pi x}{2h}\exp\left(-\frac{(2p+1)^2\pi^2 Dt}{4h^2}\right) \tag{9.16}$$

The total amount of drug released from both sides of the gel with a total surface area of $2A$ is described by

$$Q = \frac{8AC_0h}{\pi^2}\left\{\frac{\pi^2}{4} - \sum_{p=0}^{\infty}\frac{1}{(2p+1)^2}\exp\left(-\frac{(2p+1)^2\pi^2 Dt}{4h^2}\right)\right\} \tag{9.17}$$

Eq. (9.17) is useful for drug releases of more than approximately 60%, and can be considered a useful long-term solution. The Fourier series in this case is not a convenient short-term solution because it requires too many terms to be calculated in the series to obtain accurate concentration profiles, but at longer times, only a few terms (or possibly only the first term) are needed for accurate calculations.

9.1.3.5 Diffusion across a planar barrier

In membrane permeation studies, it is common to place a homogenous barrier membrane of thickness h

between a donor solution and a receiver solution. The solutions on both sides are well mixed such that the concentration is maintained constant at C_0 in the donor solution, and essentially at zero in the receiver solution (called *sink conditions*). Under these conditions, solute will diffuse from the donor solution through the barrier membrane and pass into the receiver solution. The initial condition for this system is

$$C = 0, \quad 0 < x < h, \quad t = 0$$

and the boundary conditions are

$$C = C_0, \quad x = 0, \quad \text{and} \quad C = 0, \quad x = h, \quad t > 0$$

Assuming a constant diffusion coefficient at constant temperature, the concentration profile of solute in the membrane can be found by separation of variables and proves to be

$$C = C_0 - \frac{xC_0}{h} - \frac{2C_0}{\pi}\sum_{n=1}^{\infty}\frac{1}{n}\sin\frac{n\pi x}{h}\exp\left(-\frac{n^2\pi^2 Dt}{h^2}\right) \tag{9.18}$$

At the early stage of diffusion when time is short, the concentration gradient in the membrane is not yet steady, and it changes with respect to time and distance. During this stage, sorption of solute by the membrane is the dominant process because the rate of solute entering the membrane is much greater than the rate leaving the membrane on the receiver side. At longer times, such as $t \to \infty$, the sorption rate by the membrane reaches a constant, and the rate of solute entering the membrane is the same as that leaving the membrane. At this point, the solute concentration profile in the membrane becomes linear with distance and does not change with time. This stage is commonly referred to as *steady state*.

Regardless of the time, the general equation for the amount of solute passing through unit surface area of membrane up to time t can be calculated by deriving the expression for the concentration gradient (dC/dx), calculating the flux (J) at $x = h$, and then integrating the flux at this point over time. The resulting equation is:

$$Q = \frac{DC_0 t}{h} - \frac{hC_0}{6} - \frac{2hC_0}{\pi^2}\sum_{n=1}^{\infty}\frac{(-1)^2}{n^2}\exp\left(-\frac{n^2\pi^2 Dt}{h^2}\right) \tag{9.19}$$

As $t \to \infty$ as steady state is reached, the exponential term in Eq. (9.19) becomes negligible and the rate of solute diffusing through the membrane becomes constant with time, as described by the first two terms of Eq. (9.19), shown here:

$$Q = \frac{DC_0}{h}\left(t - \frac{h^2}{6D}\right) \tag{9.20}$$

By extrapolating the linear profile back to $Q = 0$, an intercept on the time axis is obtained:

$$t_L = \frac{h^2}{6D} \tag{9.21}$$

t_L is commonly referred to as the *lag time*. Steady state is reached asymptotically and is within about 99% of exact steady state at $t = 2.7t_L$, which can be used as a guideline for membrane permeation studies to ensure that steady state is reached, if such a state is desired.

Eqs. (9.18)–(9.21) in fact apply to a unique case in which the membrane is initially free of solute. In general, the membrane may initially contain a solute at a concentration of C_i such that the initial conditions are

$$C = C_i, \quad 0 < x < h, \quad t = 0$$
$$C = C_0, \quad x = 0; \quad C = 0, \quad x = h, \quad t \geq 0$$

Crank[2] showed that the general equation for the amount of solute that has diffused through a unit area of membrane is

$$Q = \frac{DC_0}{h}\left(t + \frac{C_i h^2}{2DC_0} - \frac{h^2}{6D}\right) - \frac{2hC_0}{\pi^2}\sum_{n=1}^{n=\infty}\frac{(-1)^n}{n^2}\exp\left(-\frac{n^2\pi^2 Dt}{h^2}\right) - \frac{4C_i h}{\pi^2}\sum_{m=0}^{m=\infty}\frac{1}{(2m+1)^2}\exp\left(\frac{-(2m+1)^2\pi^2 Dt}{h^2}\right) \tag{9.22}$$

If $C_i = C_0$, as $t \to \infty$, Eq. (9.22) approaches the linear function:

$$Q = \frac{DC_0}{h}\left(t + \frac{h^2}{3D}\right) \tag{9.23}$$

A burst time t_B (actually, this is also a lag time) can be obtained by extrapolating the linear release profile to $Q = 0$:

$$t_B = \frac{-h^2}{3D} \tag{9.24}$$

9.1.3.6 Diffusion in a sphere

Diffusion in a sphere is a three-dimensional process. The surface area for diffusion changes as mass diffuses radially. Taking this geometry into consideration, the differential equation for Fick's second law of diffusion in a sphere is

$$\frac{\partial C}{\partial t} = D\left(\frac{\partial^2 C}{\partial r^2} + \frac{2}{r}\frac{\partial C}{\partial r}\right) \tag{9.25}$$

Setting $u = Cr$, it can be shown that

$$\frac{\partial u}{\partial t} = r\frac{\partial C}{\partial t}(\partial r/\partial t = 0),$$
$$\frac{\partial^2 u}{\partial r^2} = 2\frac{\partial C}{\partial r} + r\frac{\partial^2 C}{\partial r^2},$$

and Eq. (9.25) can be written as

$$\frac{\partial u}{\partial t} = D\frac{\partial^2 u}{\partial r^2} \tag{9.26}$$

This is exactly the same form as Eq. (9.3) and can be solved in the same fashion as for one-dimensional planar diffusion.

For a homogeneous permeable sphere of radius R, initially free of solute and placed in a well-stirred solution such that $C = C_0$ at $r = R$, the concentration profile in the sphere is given by

$$C = C_0\left\{1 - \frac{2}{\pi}\sum_{n=1}^{\infty}\frac{R}{r}\frac{(-1)^{n+1}}{n}\sin\frac{n\pi r}{R}\exp\left(-\frac{n^2\pi^2 Dt}{R^2}\right)\right\} \tag{9.27}$$

The total amount of solute that has entered the sphere up to time t is

$$Q = \frac{8R^3C_0}{\pi}\left\{\frac{\pi^2}{6} - \sum_{n=1}^{\infty}\frac{1}{n^2}\exp\left(-\frac{n^2\pi^2 Dt}{R^2}\right)\right\} \tag{9.28}$$

9.1.3.7 Diffusion in a cylinder

Assuming that axial diffusion through the two ends of a cylinder is negligible, the radial diffusion in a cylinder is a two-dimensional diffusion system. The partial differential equation for this case has been given by Eq. (9.6). Similar to the one-dimensional diffusion problems, solutions for radial diffusion in a cylinder can be derived using an error function or by separation of variables, which results in Bessel function solutions. These solutions may appear more complicated than those derived for the one-dimensional diffusion systems, but there are expressions available for numerous cylindrically symmetrical systems. Interested readers are referred to the research literature for detailed mathematical treatments for general solutions. A simple case discussed here is the steady-state radial diffusion through the wall of a hollow cylinder.

For outward diffusion through the wall of a hollow cylinder with inner radius a and outer radius b, and with the concentration profile maintained constant at C_0 at $r = a$ and $C = 0$ at $r = b$, the steady-state expression is

$$D\left\{\frac{\partial^2 c}{\partial r^2} + \left(\frac{1}{r}\right)\frac{\partial c}{\partial r}\right\} = 0 \tag{9.29}$$

The general solution is

$$C = A + B\ln r \tag{9.30}$$

From the boundary conditions, it can be determined that

$$B = \frac{C_0}{\ln(a/b)}, \text{ and } A = -\frac{C_0\ln b}{\ln(a/b)}$$

Therefore, the steady-state concentration profile in the wall is

$$C = \frac{C_0\ln(r/b)}{\ln(a/b)} \tag{9.31}$$

The quantity of drug released (Q) through $r = b$ into a perfect sink as a function of time is given by

$$Q = \frac{ADC_0 t}{\ln(a/b)} \tag{9.32}$$

Eq. (9.32) shows that, at steady state, the rate of diffusion through the wall of a hollow cylinder is constant, as expected, but the concentration profile in the wall as given by Eq. (9.31) is nonlinear.

9.1.3.8 Diffusion combined with other processes

Diffusion and adsorption

Adsorption of diffusing molecules in some systems, such as in a reinforced polymer matrix or onto solids in suspensions, can occur during the diffusion process. For example, silicon dioxide or other fillers in reinforced polymeric membranes can adsorb the diffusant during membrane permeation. Adsorption leads to the immobilization of some of the diffusing substance, hence reducing the driving force and diffusion rate until adsorption reaches equilibrium with the free solute concentration at each position in the membrane. Typically, the amount of substance immobilized by the adsorbent is determined by the adsorption isotherm, which is a function of the free concentration of the diffusant. To account for the adsorption, Fick's second law for one-dimensional diffusion is modified to give

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} - \frac{V_f}{\varepsilon}\frac{\partial A_f}{\partial t} \tag{9.33}$$

where: A_f represents the sorption isotherm of the adsorbent, V_f is the volume fraction of adsorbent in the membrane, and ε is the porosity of the continuous polymeric phase.

In this case, the lag time for diffusion has been shown[8] to be

$$t_L = \frac{\tau^2 h^2}{6D} + \frac{1}{DC_0}\frac{V_f}{\varepsilon}\int_0^{\tau h} xA_f d_x \tag{9.34}$$

where: h is the thickness of the membrane and τ is the tortuosity due to the presence of the impermeable filler.

Eq. (9.34) shows that lag time for membrane diffusion can be increased significantly due to increasing tortuosity and adsorption by the filler. The effects of filler on lag time have also been verified by experimental results. Chen studied the diffusion of 2-hydroxypyridine through polydimethylsiloxane (PDMS) membranes with different levels of silica filler. It was shown that lag-time increased by about 10-fold by adding 23% silica filler into the PDMS membrane with thickness similar to the unfilled one.[9] The lag time calculated agreed well with the predicted value from Eq. (9.34). The filler effect on steady-state flux, on the other hand, is substantially less than the effect on lag time. After adsorption reaches equilibrium at each point in the membrane, the steady-state flux through the membrane containing 23% of the filler is about 50% of the unfilled one (Fig. 9.5).

Diffusion and chemical reaction

If a slow chemical reaction occurs simultaneously with diffusion, the reaction reduces the free diffusant concentration. Similar to the adsorption problem, the expression of Fick's second law is reduced by the reaction rate, R, as described by

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} - R \tag{9.35}$$

If the rate of reaction is simple (ie, first-order), and is directly proportional to the rate of concentration change as a function of time ($R = k\partial C/\partial t$), Eq. (9.35) can be rewritten as

$$\frac{\partial C}{\partial t} = \frac{D}{1+k}\frac{\partial^2 C}{\partial x^2} = D'\frac{\partial^2 C}{\partial x^2} \tag{9.36}$$

where D' is the reduced diffusion coefficient due to reaction. It can be seen from Eq. (9.36) that the mathematical solution for diffusion coupled with a simple first-order reaction is the same as a simple diffusion process without reaction, except that the diffusion coefficient is reduced. It should be noted that if $k \gg D$, diffusion may not be detectable.

For reaction rates other than this simple case, more complex solutions can be developed based on the applicable rate law and the initial and boundary conditions for the diffusion-reaction process. Readers are referred to the research literature[1–6] for details on more complicated diffusion-reaction problems.

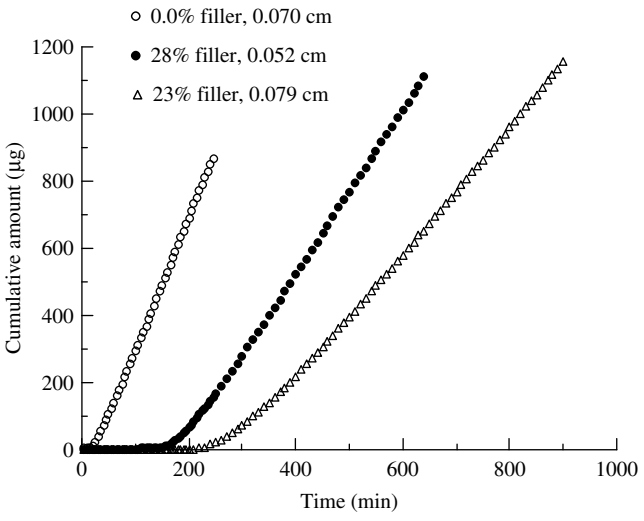

FIGURE 9.5 Flux of 2-hydroxypyridine through polydimethylsiloxane membranes with different levels of silica filler.

9.1.4 The Diffusion Coefficient and Its Determination

From Fick's first law, the diffusion coefficient D can be defined as the rate of transfer of the diffusing substance across unit area and unitary concentration gradient of the diffusing substance. From this definition, it can be shown that the diffusion coefficient has units of length^2/time, which is commonly expressed in cm^2/s. The diffusion coefficient is a property of a solute in a specific medium or matrix at a constant temperature and pressure. It is dependent on temperature, viscosity, and the size of solute, as described by the Einstein equation

$$D = \frac{k_B T}{6\pi\eta r} \tag{9.37}$$

where:

k_B is the Boltzmann's constant
T is absolute temperature
η is the medium viscosity
r is the solute radius.

If all the values of the parameters on the right side of Eq. (9.37) are known, the diffusion coefficient can be calculated.

For a given solute in a given medium, the dependency of diffusion coefficient on temperature is described by

$$D = D_0 \exp\left(-\frac{E_a}{RT}\right) \tag{9.38}$$

where D_0 is the hypothetical diffusion coefficient at infinite temperature and E_a is the activation energy of diffusion.

Assuming that the diffusion coefficient is not affected by solute concentration, the diffusion

coefficient can be determined from steady-state fluxes or lag times from a membrane permeation study, or from release data of other well-defined systems at constant temperature. These methods are discussed next.

9.1.4.1 Steady-state flux method

As discussed earlier, for membrane permeation with constant surface concentration, diffusion reaches steady state when the solute concentration profile in the membrane becomes linear with respect to distance. At steady state, the flux is proportional to the diffusion coefficient and concentration gradient as shown here:

$$J_{ss} = Dk\frac{\Delta C}{h} \tag{9.39}$$

where:

J_{ss} is the steady-state flux
k is the partition coefficient
ΔC is the concentration difference between the donor and the receiver solutions.

If membrane permeation is conducted in aqueous solution, the membrane may be covered by stagnant aqueous layers at the membrane-solution interfaces, either due to a significant partition rate limitation between the membrane and the aqueous solutions or the poor hydrodynamics of mixing at the interfaces. Assuming that the thicknesses of the stagnant layers on both sides of the membrane are the same, a general flux equation is given[10] by

$$J_{ss} = \frac{\Delta C}{h_m/D_m k + 2h_a/D_a} = \frac{\Delta C}{(1/P_m) + (2/P_a)} \tag{9.40}$$

where the subscripts m and a indicate membrane and aqueous solutions, respectively; and P is the permeability coefficient.

Eq. (9.40) shows that flux could be determined for the membrane with the stagnant diffusion layers, and depending on the properties of the membrane (ie, thickness and partition coefficient), the aqueous diffusion layers may or may not contribute significantly to the overall flux. If $h_m/D_m k \gg 2h_a/D_a$, diffusion is controlled by the membrane. If $h_m/D_m k \ll 2h_a/D_a$, diffusion is controlled by the stagnant diffusion layers. It has been reported that under some common study conditions, the thickness of the stagnant aqueous diffusion layers are about 100 μm. However, the thickness of these stagnant layers decreases as the agitation rate increases. If a membrane has a sufficient thickness and the study is conducted with a high stirring rate, the boundary layer effects may be negligible, although this assumption must be verified by experimentation. Once it is proved that the boundary layer effects are negligible, the diffusion coefficient in a homogeneous polymer membrane can be calculated from the steady-state flux data, as shown here:

$$D_m = \frac{J_{ss}h}{k\Delta C} \tag{9.41}$$

If the effect of the boundary layer is not negligible, additional experimentation must be conducted in order to obtain a reliable membrane diffusion coefficient. By determination of the total apparent permeability at constant temperature and constant stirring rate for membranes of different thicknesses,[10] the intrinsic membrane permeability can be calculated from the intercept of a graph of the reciprocal of apparent permeability coefficient P_{total} against the reciprocal of membrane thickness, as described by

$$\frac{1}{P_{total}} = \frac{1}{P_m} + \frac{2h_a}{D_a}\frac{1}{h_m} \tag{9.42}$$

In order to obtain accurate diffusion coefficients, it is also important to carry out the membrane permeation experiment for a sufficiently long time to ensure that a steady state is reached. As a general guide, flux data used for calculation should be determined to be greater than 2.7 × lag time.

If the membrane is heterogeneous with impermeable inert domains, the measured value from steady-state flux data is an apparent diffusion coefficient of the composite material. The volume fraction (V) and the tortuosity (τ) of the continuous polymer phase must be accounted for in order to calculate an accurate diffusion coefficient of the continuous membrane phase according to

$$D_{eff} = D\frac{V}{\tau} \tag{9.43}$$

9.1.4.2 Lag time method

As discussed previously, when a membrane initially free of solute is used to conduct a permeation study with the concentration in the donor solution kept constant, and the receiver solution is kept at essentially zero concentration, the diffusion coefficient can be calculated from the lag time by

$$D = \frac{h^2}{6t_L} \tag{9.44}$$

If the membrane contains inert fillers, lag time is increased by the tortuosity, which must be considered for the calculation of diffusion coefficient as follows:

$$D = \frac{\tau^2 h^2}{6t_L} \tag{9.45}$$

Care should be taken when a thin membrane is used to conduct diffusion research in aqueous solution. As

discussed previously, diffusion may be controlled by the aqueous boundary diffusion layers for some systems. In the extreme case when $h_m/D_m k \ll 2h_a/D_a$, the lag time is determined by the boundary layers as

$$t_L = \frac{2h_a^2}{3D_a} \tag{9.46}$$

Obviously, the diffusion coefficient of the membrane could not be calculated from the lag time when the process is controlled by the stagnant layers.

If the membrane is initially equilibrated with the donor solution prior to the initiation of permeation study, there will be a negative burst time t_B, which is also lag time, and the diffusion coefficient can be calculated by

$$D = \frac{-h^2}{3t_B} \tag{9.47}$$

When the membrane contains adsorptive fillers or some other domains capable of binding the diffusing substance, the lag time is the combined result of diffusion in the polymer and adsorption or binding in the system; hence, Eqs. (9.44)–(9.46) are no longer valid for calculation of the diffusion coefficient. This is particularly important for biological membranes because in many cases, protein in biological membrane can bind many kinds of organic compounds. For adsorptive and binding systems, the effects of adsorption or binding on lag time (and hence the diffusion coefficient) must be accounted for by using Eq. (9.34) or modified versions of it.

If the adsorption isotherm of the filler is a simple linear equation as a function of the steady-state concentration distribution (C_s) in the membrane as follows:

$$A_f = bC_s = bC_0\left(1 - \frac{x}{h}\right) \tag{9.48}$$

then Eq. (9.34) can be integrated. The result of the corrected lag-time relationship with tortuosity and adsorption due to the presence of filler is given by

$$t_L = \frac{\tau^2 h^2}{6D}\left(1 + b\frac{V_f}{\varepsilon}\right) \tag{9.49}$$

Thus, the diffusion coefficient can be expressed as

$$D = \frac{\tau^2 h^2}{6t_L}\left(1 + b\frac{V_f}{\varepsilon}\right) \tag{9.50}$$

9.1.4.3 *Sorption and desorption methods*

Data from either absorption by a planar polymer matrix or release/desorption from the matrix have frequently been used to determine the diffusion coefficient in the polymer. The exponential series given by Eq. (9.17) can be used to determine the diffusion coefficients by curve fitting.

The short time approximation for Eq. (9.15), as in Eq. (9.13) using the initial sorption or desorption data, is more convenient to use for the determination of the diffusion coefficient than from using Eq. (9.17). From the slope of the Q_t versus $\sqrt{t}$ plot for the early release or sorption data, the diffusion coefficient can be calculated as follows:

$$D = \frac{\pi k^2}{4C_0^2} \tag{9.51}$$

where:

k is the slope of the Q_t versus $\sqrt{t}$ plot
C_0 is the initial concentration in the matrix in the case of release, or the surface concentration in the case of sorption.

For a heterogeneous system with impermeable domains, Eq. (9.51) must be corrected for porosity and tortuosity as follows:

$$D = \frac{\tau\pi k^2}{4\varepsilon^2 C_0^2} \tag{9.52}$$

Theoretically, different methods should yield the same value of diffusion coefficient for the same solute in the same polymer. However, if the polymer contains adsorptive domains, the results may not agree with each other, due to the difference in the effective concentration of the solute available for diffusion in the polymer phase at the time of the experiment. This is because adsorption or binding may be effective during the initial sorption study, but not during the early release stage. Therefore, it is important to understand and characterize the system before valid conclusions can be drawn.

9.1.5 Pharmaceutical Application of Diffusion Theory

Much study has been conducted on the application of diffusion theory in different fields of pharmaceutical science, especially in the study of controlled release drug delivery systems, dissolution of particles and dosage forms, and passive drug absorption processes. Vast information is available in the literature for numerous specific cases. A review of detailed applications is beyond the scope of this chapter. However, these authors believe that it is important to acknowledge several seminal applications of diffusion theory in pharmaceutical science for the study of drug delivery and dissolution of particles, as these applications have led to the development of models that are

playing critical roles in advancing the pharmaceutical sciences. For drug delivery, the application of the fundamental equations of Fick's first and second laws enabled the development of different equations to describe the drug release profiles for systems of different geometries and conditions, such as the Higuchi equations[11,12] and the Langer equation.[13] Similarly, several models were developed for studying the dissolution rates of particles with different particle sizes, including the diffusion layer model by Noyes and Whitney[14] and Nernst,[15] the cube-root model for describing the dissolution profiles of large particles by Hixson and Crowell,[16] the two-thirds-root equation for dissolution of fine particles by Higuchi and Hiestand,[17] and the unified general model developed by Wang and Flanagan[18] for describing the dissolution profiles of small and large spherical particles. The application of diffusion theory for the development of different equations for particle dissolution will be discussed in more detail in the following parts of this chapter.

9.2 FUNDAMENTALS OF DISSOLUTION

9.2.1 Introduction

Orally administered solid dosage forms generally undergo disintegration, dissolution, and absorption to enter the bloodstream and reach the site of action. For drugs with low solubility, dissolution is often the rate-limiting step that directly affects the rate and extent of drug absorption. Various dissolution tests have been developed and have become tools for predicting in vivo performance and monitoring product quality. The basic theoretical aspects of solid dissolution are covered in this chapter, and this discussion is focused on the dissolution of small drug molecules in aqueous media.

9.2.2 Mechanism and theories of solid dissolution

A prerequisite for drug molecules to be transported into the bulk solution is that they detach from the solid surface and form solvated molecules. This process is called *solvation*, which is a pseudochemical reaction. Solvated molecules then need to transfer from the solid–liquid interface to the bulk solution, which is a mass transport process. Both the solvation and the mass transport process can control the dissolution rates. Diffusion usually plays a key role in the transport process, while convection also is important in cases of agitated media.

9.2.2.1 *Thermodynamic considerations*

Whether a solid is crystalline or amorphous, neighboring molecules are closely associated with each other through intermolecular forces. Dissolution involves the breaking of these existing intermolecular interactions and the formation of new interactions with the solvent (usually water). The solid dissolution process generally involves two sequential steps. The first step is the interaction between solid and solvent molecules to form solvated molecules (solvation), which takes place at the solid–liquid interface. The second step is the mass transport of solvated molecules from the solid–liquid interface to the bulk solution. These two steps govern the rate and extent of solid dissolution. Solubility, a basic property for solids, controls the first step. Transport, on the other hand, usually controls the second step, which is generally slower than the first step. Overall, dissolution is governed by solubility and transport processes.

The first step of dissolution can be viewed as a pseudochemical reaction that is governed by the same principles as regular chemical reactions. The solvation process is reversible, and solubility is reached when the reaction reaches equilibrium. This process can be described by its Gibbs free energy (ΔG):

$$\text{Drug} + \text{Solvent} \leftrightarrow \text{Solvated Drug} \tag{9.53}$$

$$\Delta G = \Delta H - T\Delta S \tag{9.54}$$

This reaction involves both the breakage of existing intermolecular interactions (drug-drug, solvent-solvent) and the formation of new intermolecular interactions (drug-solvent). The net entropy (ΔS) change for this reaction is generally positive (dissolution causes an increase in disorder), which is favorable for dissolution. Therefore, the extent of dissolution is often determined by the net enthalpy change (ΔH). If the net enthalpy change is negative or close to zero, the reaction will continue until all the available solids are dissolved. The empirical rule, "like dissolves like," therefore, has a thermodynamic basis. On the other hand, if the net enthalpy change (ΔH) is positive, the reaction will progress until equilibrium is reached ($\Delta G = 0$). A saturated solution is obtained.

The reaction rate V is described kinetically by

$$\begin{aligned} V &= k_1[\text{Drug}][\text{Solvent}] \\ k_1 &= A\mathrm{e}^{-E_a/RT} \end{aligned} \tag{9.55}$$

The overall rate of dissolution is controlled by the slower step of the two-step dissolution process. Thermodynamically, the activation energy E_a for the formation of a solvated drug should be less than the energy to break water-water or drug-drug intermolecular interactions. Since hydrogen bonding is among the strongest intermolecular interactions, the activation

energy for reaction (Eq. 9.53) in many cases should be less than the energy of the water-water hydrogen bond, which is about 19 kJ/mol. In liquid water, hydrogen bonds are constantly being broken and reformed because thermal energy is sufficient to cause cleavage of these interactions. Therefore, at room temperature, the rate of solvation is generally so fast that equilibrium is also instantaneous. Compared to the rate of solvation, mass transport from the solid–liquid interface to bulk solution involves molecules moving a great distance compared to molecular dimensions, which is usually much slower and becomes the rate-limiting step.

9.2.2.2 *Dissolution by pure diffusion*

For solid dissolution processes, convection generally accompanies diffusion in transporting dissolved molecules. Dissolution through pure diffusion without any contribution from some form of convection is rare. Even without mixing, density gradients caused by concentration differences or thermal effects due to the heat of solvation can lead to natural convection. However, we can consider a hypothetical situation in which dissolution is purely diffusional.

Assume that a small drug particle is placed at the bottom of a large beaker full of water. The water is kept unstirred so that there is no convection. The drug particle may dissolve by diffusion, which is equivalent to having a diffusion layer of growing thickness. In this case, dissolution becomes a pure diffusional phenomenon.

When a particle dissolves by pure diffusion, the concentration at every point away from the solid–liquid interface rises, but the concentration gradient at any distance from the particle decreases with time. The overall dissolution rate of the particle becomes slower. Depending on the solubility and solvent volume, there can be two possible results. If the amount needed to saturate the solvent is equal to or more than the particle weight, the particle will eventually completely dissolve; if the amount needed to saturate the solvent is less than the particle weight, a saturated solution will eventually form, which coexists with the smaller particle.

No matter what the final result is, we will not be able to see the formation of a pseudo-steady state in this dissolution process. A pseudo-steady state can be reached if during some finite time in the dissolution process, the concentration gradient becomes relatively constant with time. The existence of a pseudo-steady state would make the dissolution rate expression simpler mathematically. However, in this case, the concentration gradient may be constantly changing, and we may not be able to apply the pseudo-steady state treatment. Later in this chapter, we will see cases where a pseudo-steady state is applicable.

9.2.2.3 *Diffusion layer model*

Noyes and Whitney first proposed the basic transport-controlled model for solid dissolution.[14] They suggested that when surface area is constant, the dissolution rate is proportional to the difference between solubility and the bulk solution concentration:

$$\frac{dQ}{dt} = k(C_s - C_b) \tag{9.56}$$

where: dQ/dt is the dissolution rate, k is a constant (mass transfer coefficient), C_S is solubility, C_b is bulk solution concentration.

Nernst[15] and Brunner[19] then suggested that rapid equilibrium (ie, saturation) is achieved at the solid–liquid interface during dissolution, and then diffusion occurs across a thin layer of stagnant solution, called the *diffusion layer*, into the bulk solution. Diffusion across this diffusion layer is rate-controlling in most cases, which effectively converts the heterogeneous dissolution process into a homogeneous process of liquid-phase diffusion. This model, as shown in Fig. 9.6, is also called the *film model*. Dissolution rate can be expressed as

$$\frac{dQ}{dt} = DA\frac{(C_s - C_b)}{h} \tag{9.57}$$

where:

D is diffusion coefficient,
A is solid surface area,
h is diffusion layer thickness.

Nernst's and Brunner's concept of a diffusion layer being a stagnant or unstirred layer of liquid adhering to the solid surface is hydrodynamically unrealistic but allows the complex dissolution processes to be analyzed in a tractable fashion. The diffusion layer model is widely used due to its simplicity and applicability to

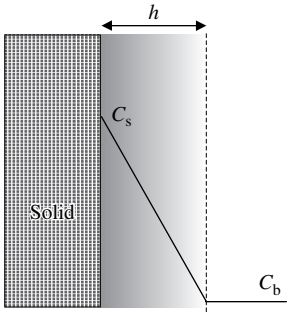

FIGURE 9.6 Diffusion layer model for a planar surface dissolution. (C_S is solubility, C_b is bulk solution concentration, h is diffusion layer thickness.)

a wide range of dissolution phenomena. However, the notion of a stagnant liquid layer near the solid surface is not supported by fluid dynamics. Liquid motion was observed at distances from solid surfaces that are much closer than with a typical diffusion layer thickness. Therefore, the diffusion layer is actually a boundary layer with a concentration gradient, as well as a velocity gradient. Another limitation of the diffusion layer model is that it does not give a means to calculate a diffusion layer thickness independently based on hydrodynamics. Thus, it does not allow computation of the diffusional flux, a priori. Diffusion layer thicknesses can be obtained only by fitting equations to experimental data.

9.2.2.4 Convective-diffusion model

Due to the limitations of the diffusion layer model, further examination of the dissolution process is necessary in order to develop an improved model. There are two mechanisms for the transport of solute molecules from a solid in a moving liquid. First, there is molecular diffusion as a result of a concentration gradient; second, solute molecules are carried along by the moving solvent (ie, convection). Dissolution is usually a combination of these two mechanisms, which is called *convective diffusion*. In convective-diffusion models, the contribution of both convection and molecular diffusion are taken into account. The general equation for convective diffusion in three dimensions is given here:

$$\frac{\partial C}{\partial t} = D\left(\frac{\partial^2 C}{\partial x^2} + \frac{\partial^2 C}{\partial y^2} + \frac{\partial^2 C}{\partial z^2}\right) - v_x\frac{\partial C}{\partial x} - v_y\frac{\partial C}{\partial y} - v_z\frac{\partial C}{\partial z} \tag{9.58}$$

where v_x, v_y, and v_z are liquid velocities in the x-, y-, and z-directions in Cartesian coordinates.

This equation is an extension of Fick's second law of diffusion with the addition of convection terms. It is a second-order partial differential equation with variable coefficients. To determine the net concentration change at a particular point at any time, we also need to know the liquid flow pattern and the boundary and initial conditions. This equation can be solved exactly for only a very limited number of special cases. Some of these cases will be discussed later in this chapter.

In the convective-diffusion model, solvent stream movement depends on its distance from the solid surface. At distances far from the solid surface, convection dominates over diffusion for transport of solute molecules. At distances very close to the solid surface, the solvent stream movement is slow, while the concentration gradient is large. In such regions, the contribution of diffusion to the solute molecule movement is comparable to or larger than convection. This region is also called the *diffusion layer*, but it is different from Nernst's concept. Levich pointed out the following differences between Nernst's layer and the convective diffusion-based diffusion layer[20]:

1. Solvent in Nernst's layer is considered stagnant, while it has a velocity gradient in the convective-diffusion model.
2. In Nernst's model, mass transport in the direction parallel to solid surface is disregarded. In convective-diffusion theory, convection and diffusion both across and along the diffusion layer are taken into account.
3. Nernst's layer is considered to have a constant thickness everywhere, while the thickness of the diffusion layer based on convective diffusion theory varies substantially along the solid surface depending on position and solvent motion. In fact, the diffusion layer has no clear-cut boundary; it is simply a region where the concentration gradient is at a maximum.

Unlike Nernst's diffusion layer model, the convective-diffusion model is more hydrodynamically realistic, which does allow us to predict solid dissolution rates. However, it is usually complicated to apply convective-diffusion to derive accurate expressions for solid dissolution because of the need to describe the fluid dynamics accurately.

9.2.3 Planar surface dissolution

Modeling planar surface dissolution is easier than modeling particulate dissolution because the mathematics is simpler. The simplest expression describing planar surface dissolution is the empirical Noyes-Whitney equation. The diffusion layer model is almost as simple. Measuring dissolution rate from a well-defined surface has been a popular way to characterize pharmaceutical solids. Determination of intrinsic dissolution rate is one example. Although the Noyes-Whitney equation is capable of describing such a process, planar surface dissolution can be more accurately described with convective-diffusion models based on different hydrodynamic conditions.

9.2.3.1 Convective-diffusion model for a rotating disk

When other parameters, such as agitation intensity and surface area, are fixed, dissolution rate can be viewed as a property of the solid. This loosely defined property is called the *intrinsic dissolution rate*. Due to the close relationship between the intrinsic dissolution rate and solubility, measuring the intrinsic dissolution rate becomes an alternative method for solubility estimation when equilibrium solubility cannot be easily

obtained experimentally. For example, measurement of intrinsic dissolution rates is a powerful tool for the evaluation of solubility differences between polymorphs or solvates. The equilibrium solubility of an anhydrous crystal form may not be determined if it converts to a hydrate when in contact with water. The solubility difference of an anhydrous versus hydrate crystal form can be estimated by studying the difference in initial intrinsic dissolution rates as the conversion occurs.

Since dissolution rate is always affected by agitation intensity, surface area, and container configuration, determination of intrinsic dissolution rates requires a method with good reproducibility. The rotating disk method, which is schematically demonstrated in Fig. 9.7, is often the method of choice. The disk is compressed from pure material and has a planar surface. The compressed disk is put into the holder so that only one flat surface is in contact with the solvent. The disk is then rotated at either a constant or varying speed, and the dissolution rate is measured. When a diffusion layer model is applied, a diffusion layer thickness can be easily determined from the dissolution rate data.

The hydrodynamics for a rotating disk system presents a good case of applying a convective-diffusion model. According to Levich, using a convective-diffusion model, the solvent flow pattern can be depicted as shown in Fig. 9.8.[21,22] Far from the disk, the fluid moves axially toward the disk. In a thin layer near the disk surface, the liquid acquires a rotating motion and moves radially away from the center of the disk. This system is one of the few cases that can be solved exactly with convective-diffusion theory. The dissolution rate (dQ/dt) is given by

$$\frac{dQ}{dt} = 1.95D^{2/3}C_s u^{-1/6}\omega^{1/2}R^2 \tag{9.59}$$

where:

D is the diffusion coefficient,
C_S is the solubility,
u is the kinematic viscosity,
ω is the rotational speed,
R is the disk radius.

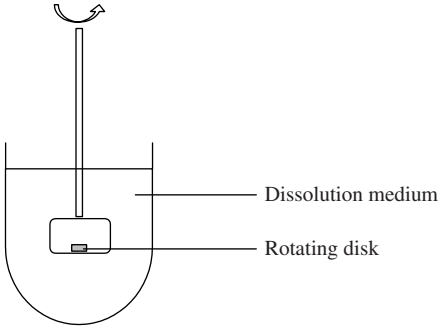

FIGURE 9.7 Rotating disk apparatus for measuring intrinsic dissolution rate.

The convective-diffusion model for dissolution of a rotating disk also provides a means to estimate the diffusion layer thickness as shown here:

$$h = 1.61D^{1/3}u^{1/6}\omega^{-1/2} \tag{9.60}$$

An interesting study using the rotating disk is by McNamara and Amidon, who applied convective-diffusion models to reactive dissolution.[23,24]

9.2.3.2 *Convective-diffusion model for flow past a planar surface*

In addition to dissolution from a rotating disk, there is the case of planar surface dissolution that can be modeled with relative ease. When the solvent flows parallel to a flat surface of a solid, there is a velocity gradient, as shown in Fig. 9.9. Both molecular diffusion normal to the surface and the forced convection

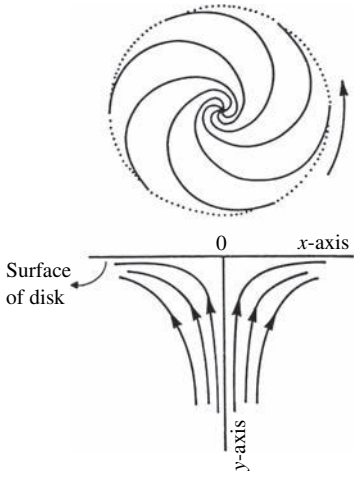

FIGURE 9.8 Liquid flow pattern around a rotating disk apparatus.

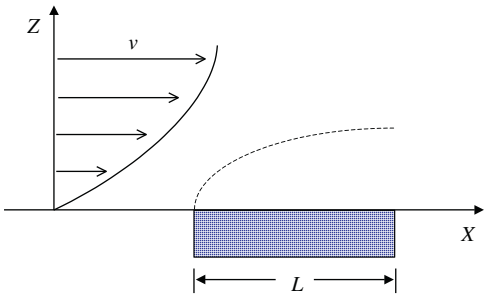

FIGURE 9.9 Convective-diffusion model for dissolution of a planar surface with liquid flow parallel to the surface. (The dashed curve indicates the boundary layer region. X and Z are coordinate axes, L is the solid surface length, and v is the bulk fluid velocity.)

parallel to the surface contribute to the dissolution of the solid. For such a flat surface, the diffusion boundary layer is well characterized and can be used to calculate the dissolution rate. An equation derived by Levich can be applied to the dissolution of a rectangular tablet of length L (in the direction of flow) and width b[25]:

$$\frac{dQ}{dt} = 0.68D^{2/3}C_s u^{-1/6} v^{1/2} b L^{1/2} \tag{9.61}$$

where:

D is the diffusion coefficient,
C_s is the solubility,
u is the kinematic viscosity,
v is the bulk fluid velocity.

Nelson and Shah also developed a convective-diffusion model for planar surface dissolution under parallel flow.[26–29] For rectangular tablets with length L (in the direction of flow) and width b, the dissolution rate is

$$\frac{dQ}{dt} = 0.808D^{2/3}C_s \alpha^{1/3} b L^{2/3} \tag{9.62}$$

where:

α is the rate of shear in the boundary layer,
b is the tablet width (normal to flow),
L is the tablet length (parallel to flow).

If the tablet is circular with a radius of r, the equation becomes

$$\frac{dQ}{dt} = 2.157D^{2/3}C_s \alpha^{1/3} r^{5/3} \tag{9.63}$$

The results obtained by Nelson and Shah were confirmed by Neervannan et al. using numerical methods to solve the convective-diffusion equations.[30]

9.2.4 Particulate dissolution

Modeling planar surface dissolution is important for understanding dissolution mechanisms. However, dissolution of solid dosage forms usually involves solid particles. Most rapid release oral dosage forms first disintegrate into small particles, which then dissolve in order for the drug to be bioavailable. The same dissolution theories that apply to planar surface dissolution are also applicable to particle dissolution. However, the dissolution of solid particles is more complicated because of surface area changes during dissolution. Also, particles have various shapes and size distributions, which make modeling their dissolution process even more complicated.

9.2.4.1 *Diffusion layer–based dissolution models*

Three diffusion-controlled models for monosized spherical particle dissolution under sink conditions are given by

$$W^{1/3} = W_0^{1/3} - K_{1/3}t \quad K_{1/3} = \left(\frac{4\pi\rho N}{3}\right)^{1/3} \frac{DC_s}{\rho h} \tag{9.64}$$

$$W^{1/2} = W_0^{1/2} - K_{1/2}t \quad K_{1/2} = \left(\frac{3\pi\rho N}{2}\right)^{1/2} \frac{DC_s}{k'\rho} \tag{9.65}$$

$$W^{2/3} = W_0^{2/3} - K_{2/3}t \quad K_{2/3} = \left(\frac{4\pi\rho N}{3}\right)^{2/3} \frac{2DC_s}{\rho} \tag{9.66}$$

where:

W is the particle weight at time t,
W_0 is the initial particle weight,
$K_{1/3}$, $K_{1/2}$, and $K_{2/3}$ are composite rate constants,
ρ is the density of the particle,
N is the number of particles,
D is the diffusion coefficient,
C_s is the solubility,
h is the diffusion layer thickness,
k' is a constant.

Eq. (9.64), reported by Hixson and Crowell, is known as the *cube-root law*.[16,31] It was derived originally based on the assumption that dissolution rate is proportional to the surface area of spherical particles. It can also be derived using a simple diffusion layer model. Eq. (9.65) is a semiempirical expression reported by Niebergall et al. and has a square-root dependency on weight.[32] Eq. (9.66) has a two-thirds-root dependency on weight and was derived by Higuchi and Hiestand for the dissolution of very small particles.[17,33]

Each of these three particle dissolution models gives a satisfactory fit to certain experimental dissolution data.[31–33] However, the choice of the model to fit experimental data is somewhat arbitrary. Although they appear different in form, the three equations are often difficult to distinguish when applied to experimental data. Pedersen and Brown evaluated these three models experimentally by studying the dissolution of tolbutamide powder.[34] By taking into account the particle size distribution in their computer model, they found that the cube-root model worked best with the smallest mean squared deviation for the fitted curve. However, the fitting results of the cube-root and the square-root models were almost equally good.

By accounting for the curvature of the concentration gradient in the diffusion layer around a spherical particle, Wang and Flanagan derived a general solution for diffusion-controlled particle dissolution (Eqs. (9.67) and (9.68)).[18] Their analysis shows that the concentration gradient inside a diffusion layer is not linear

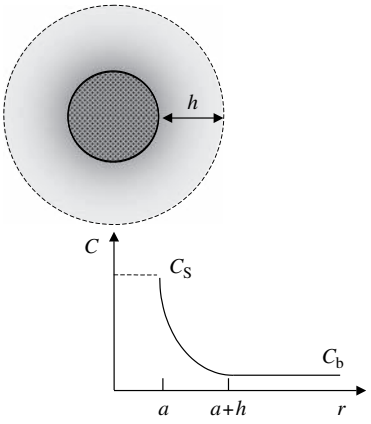

FIGURE 9.10 Pseudo-steady state concentration gradient around a spherical particle.

(Fig. 9.10). Mathematical analysis shows that the three classical particle dissolution rate expressions are approximate solutions to the general solution. The cube-root law is most appropriate when the particle size is much larger than the diffusion layer thickness, the two-thirds-root expression applies when the particle size is much smaller than the diffusion layer thickness. The square-root expression is intermediate between these two models:

$$\frac{DC_s}{\rho h}t = a_0 - a - h\ln\frac{h+a_0}{h+a} \tag{9.67}$$

$$\frac{DC_s}{\rho h}t = \left(\frac{3w_0}{4\pi\rho}\right)^{\frac{1}{3}} - \left(\frac{3w}{4\pi\rho}\right)^{\frac{1}{3}} h\cdot\ln\frac{h+\left(\frac{3w_0}{4\pi\rho}\right)^{\frac{1}{3}}}{h+\left(\frac{3w}{4\pi\rho}\right)^{\frac{1}{3}}} \tag{9.68}$$

In deriving the general solution for diffusion-controlled particle dissolution, pseudo-steady state is an important assumption. For example, dissolution from a planar surface under sink conditions reaches steady state when the dissolution rate becomes constant; hence, the concentration gradient in the diffusion layer becomes time-invariant. In any short time interval, the number of molecules moving into the diffusion layer from one side equals the number of molecules moving out of the diffusion layer from the other side.

For particle dissolution, a similar state can often be reached in which the number of molecules moving into the diffusion layer from one side approximately equals the number of molecules moving out of the diffusion layer from the other side. This assumption requires that within the time for an average molecule to cross the diffusion layer, the change of particle surface area is negligible.

An interesting result derived from the general particle dissolution model is given by Eq. 9.69, which demonstrates that the dissolution rate per unit surface area (surface-specific dissolution rates) depends upon particle size, with smaller particles having higher surface-specific dissolution rates. Bisrat and Nystrom[35] and Anderberg et al.[36,37] reported a dependence of surface-specific dissolution rates upon particle size (with radius of a). Their results showed the same trend as predicted here. The surface-specific dissolution rate increased (after correcting for solubility dependence on particle size) with decreasing particle size. This increase was especially pronounced for particle sizes below about 5 μm:

$$J = DC_s\left(\frac{1}{h}+\frac{1}{a}\right) \tag{9.69}$$

9.2.4.2 *Convective-diffusion-based particulate dissolution model*

The convective diffusion model has the advantage of being more hydrodynamically realistic. Applying convective diffusion to spherical particle dissolution has the potential of being able to predict dissolution rate more accurately.

Levich derived an equation for convective diffusion from a sphere. Assuming that liquid flow around a particle is in creeping motion while the boundary layer is small compared to particle size, Levich derived an expression for mass transport to a free-falling sphere based on convective diffusion.[21] This expression is applicable when the Reynolds number is much less than 1 while the Peclet number is much larger than 1. When this expression is applied to spherical particle dissolution, it can be written as

$$\frac{dQ}{dt} = 7.98\cdot C_s D^{2/3} v^{1/3} a^{4/3} \tag{9.70}$$

where:

Q is the amount dissolved,
t is time,
C_S is solubility,
D is the diffusion coefficient,
v is the bulk solvent velocity,
a is the particle radius.

The dissolution rate per unit area (J) is obtained by normalizing the total dissolution rate (Eq. 9.70) by particle surface area ($4\pi a^2$), which leads to

$$J = 0.635\cdot C_s D^{2/3} v^{1/3} a^{-2/3} \tag{9.71}$$

The significance of Eq. 9.71 is that the dissolution rate per unit area depends on surface curvature. For the same total surface area, smaller particles have higher dissolution rates. Although the expressions are different, this conclusion qualitatively agrees

well with the previous general diffusion layer model for spherical particle dissolution (Eq. 9.69). Applying this equation for diffusional flux under such flow conditions leads to the following equation for particle weight undissolved (w) with time:

$$w^{5/9} = w_0^{5/9} - 2.35 \cdot C_s D^{2/3} v^{1/3} \rho^{-4/9} t \tag{9.72}$$

For dissolution of N monosized spherical particles, the equation becomes

$$w^{5/9} = w_0^{5/9} - K_{5/9} t \quad K_{5/9} = 2.35 \cdot C_s D^{2/3} v^{1/3} \rho^{-4/9} N^{5/9} \tag{9.73}$$

For dissolution of a polydisperse particle system, the overall dissolution profile can be obtained by summing the contributions from each particle:

$$W_t = \sum_{i=1}^{N} W_{ti} \tag{9.74}$$

where:

W_t is the total particle weight remaining at time t,
w_{ti} is the weight remaining of particle i at time t,
N is the number of particles.

Since all the parameters in Eq. 9.73 can be determined independently, it is possible to calculate particle dissolution profiles a priori without resorting to parameters that must be calculated from the dissolution data (ie, diffusion layer thickness).

The derivation of Eq. 9.73 based on Levich's expression is a novel approach to modeling particle dissolution. Independent of the chapter authors, Abdou[37] and Shah et al.[38] presented equations similar to Eq. 9.73. Their equations were slightly different from Eq. 9.73, possibly due to editorial errors.

9.2.4.3 Dissolution under nonsink conditions

For solid dissolution, a changing bulk solution concentration complicates the modeling of this process. The assumption of sink conditions makes the mathematical derivation easier. The particle dissolution models summarized in this chapter are such examples. However, many dissolution processes take place under nonsink conditions, particularly for sparingly soluble compounds.

If the change of solvent volume (V) during dissolution is minimal, the concentration in the bulk solution can be expressed as

$$C_b = \frac{Q}{V} \tag{9.75}$$

where:

Q is the amount dissolved,
V is the solvent volume.

For spherical particle dissolution, concentration in the bulk solution is expressed as

$$C_b = \frac{\frac{4}{3}\pi\rho(a_0^3 - a^3)}{V} \tag{9.76}$$

By introducing Eqs. 9.75 and 9.76 to the abovementioned particle dissolution models, the particle dissolution models discussed here can be extended to nonsink conditions. Hixson and Crowell actually derived equations for particle dissolution under nonsink conditions. They also discussed a special situation in which the initial total particle weight is equal to the saturation capacity of the solvent. However, their equations were presented in a way that was inconvenient to apply.[16] These equations were later derived and discussed by Short et al.[39] and by Pothisiri and Carstensen.[40] Patel and Carstensen found that these nonsink condition models were valid up to 80–90% dissolved for the dissolution of p-hydroxybenzoic acid and sodium chloride.[41]

9.2.4.4 Effects of particle shape

All three classical particle dissolution models discussed in this chapter were developed for spherical particles. Obviously, real pharmaceutical powders usually have irregular shapes. It is desirable to know how much deviation irregular particle shapes can contribute to the dissolution profile. Pedersen and Brown investigated this problem theoretically.[42] Assuming exact isotropic dissolution, they derived the equations governing the dissolution profile for 10 common crystal shapes and found that the dissolution of each crystal shape can usually be approximated by a hypothetical spherical particle dissolution. The deviation became large after a large portion of the particle had dissolved.

Dali and Carstensen studied the effect of particle shape on dissolution behavior using single potassium dichromate crystals.[43] They incorporated a semiempirical shape factor to fit the dissolution profile of a crystal to that of a spherical particle of equivalent volume. Assuming that deviations from the cube-root law were completely due to the shape factor, they found that the shape factor is not constant; rather, it changes as a particle dissolves.

9.2.4.5 Polydispersity effects

Classical particle dissolution models, like the cube-root law, are intended only for single- or monodisperse-particle dissolution. However, pharmaceutical powders are composed of particles of various sizes. Sieve cuts from powders have often been used in dissolution experiments. Based on theoretical calculations, Brooke pointed out that, when treated as monosized powders, the error can be as much as 3% for the narrowest sieve cuts depending on particle size distribution across the cut. For wider sieve cuts, errors of 6–10% are possible.[44] Therefore, a theoretical treatment for polydispersity

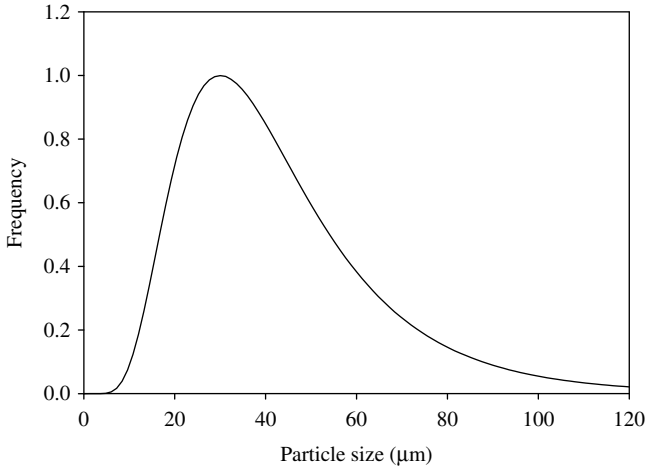

FIGURE 9.11 Typical log-normal particle size distribution for pharmaceutical powders.

effects is necessary even for fairly narrowly distributed powders. Most pharmaceutical powders are produced by milling and, as a result, tend to give skewed particle size distributions, as shown in Fig. 9.11. Such a distribution can be converted to a Gaussian distribution by plotting the x-axis on a logarithmic scale. Such a distribution is log-normal. Most theoretical investigations for polydispersed particle dissolution assume the particle size distribution to be log-normal.

Higuchi et al. studied the dissolution of a polydispersed methylprednisolone powder by approximating a log-normal distribution with a simpler function.[33] By convoluting the approximate particle size distribution function with the two-thirds-root particle dissolution model, the total particle dissolution profile was calculated. Reasonably good agreement between experimental results and theory was obtained in the study of methylprednisolone powder dissolution.

Brooke derived an exact equation for the dissolution of a log-normal distributed powder based on the cube-root single-particle dissolution model.[45] Although the calculations are tedious, they can be performed with a calculator and a normal distribution table. Brooke's expression is

$$\begin{aligned} W_\tau = {} & \mathrm{re}^{3(\mu+3\sigma^2/2)}\left(1-F\left[\frac{\ln(\tau)-(\mu+3\sigma^2)}{\sigma}\right]\right) \\ & -3\mathrm{r}\tau\mathrm{e}^{2(\mu+\sigma^2)}\left(1-F\left[\frac{\ln(\tau)-(\mu+2\sigma^2)}{\sigma}\right]\right) \\ & +3\mathrm{r}\tau^2\mathrm{e}^{(\mu+\sigma^2/2)}\left(1-F\left[\frac{\ln(\tau)-(\mu+\sigma^2)}{\sigma}\right]\right) \\ & -r\tau^3\left(1-F\left[\frac{\ln(\tau)-\mu}{\sigma}\right]\right) \end{aligned} \tag{9.77}$$

where

$$F(x)=\frac{\sqrt{2}}{2\pi}\int_{-\infty}^{x} e^{-x^2/2}dx$$

and

$$\tau=\frac{2\mathrm{k}C_\mathrm{s}}{\rho t}$$

W_τ is the weight undissolved,
μ is the mean particle diameter,
σ is its standard deviation,
$r = \pi\rho N/6$,
C_S is the particle solubility,
ρ is the particle density,
k is a constant.

Brooke also pointed out that many actual powders follow truncated distributions. Therefore, it is possible that applying an untruncated distribution or ideal log-normal distribution would lead to errors. If the exact equation is used to represent a distribution that is truncated, the result is erroneously adding some larger or smaller particles that do not actually exist. However, the error due to the addition of smaller particles is minimal, while the error due to the addition of larger particles can be significant. This arises because for the same number of particles, the total weight of the larger particles is much higher than that for smaller particles. Brooke then presented an equation for the dissolution of truncated log-normal distributed powders, which is applicable before the critical time (ie, before the smallest particles disappear).[46] Pedersen and Brown and Pedersen presented complex expressions for polydispersed powder dissolution under sink or nonsink conditions based on the three classical single-particle dissolution models.[47–49]

With faster computational tools, it is less important to have a single equation convolving a size distribution function with a particular basic particle dissolution model to predict a dissolution profile. So long as the size distribution is available, the total dissolution profile can be calculated by treating each narrow size fraction separately and adding the contributions of each fraction together. The additional advantage for this approach is that particle size does not need to follow any specific distribution. Several powder dissolution studies have been conducted using this method, and satisfactory results were obtained.[50–52]

In all of the methods dealing with polydispersed particles discussed in this chapter, it is assumed that each particle dissolves independently. This may not be true under certain experimental conditions. A commonly encountered problem in particle dissolution is aggregation. In such cases, the dissolution of one particle is affected by the existence of other particles. The

abovementioned multiparticle dissolution expressions do not apply to such situations.

10.1 INTRODUCTION

As timelines become tighter, internal and external pressures abound for the pharmaceutical industry. The cost of drug development continues to rise at an alarming rate (with an average cost to market of $1–2 billion per drug), making it imperative to develop drugs in more effective ways to reduce cost and time. Historically, early drug product development has focused on using the design of experiments to manufacture numerous "kilogram size batches" to optimize the formulation, and gain a complete understanding of the manufacturing process. This method may produce a high-quality product, but requires the use of large quantities of expensive active pharmaceutical ingredient (API), and results in lengthy timelines.

Since most compounds do not make it through the development stages, a different approach is needed for product development. Hence, efforts have focused on using material-sparing strategies to develop early solid dosage forms. These materials—sparing formulations are developed by characterizing particle, powder, and compacts of API, excipients, and formulations at small-scale (50–200 g). Such characterization, coupled with predictive tools, allows scientists to understand the important physical, chemical, and mechanical properties of materials (eg, critical material attributes) to design robust formulations quickly at a relatively low cost and achieve acceptable exposure in clinical studies. Some of the characterization methods discussed in this chapter are summarized in Table 10.1.

There are advantages and disadvantages to the material-sparing paradigm. Using smaller amounts of material results in a lower cost, but may increase the risk of working with a nonrepresentative sample, which may result in errors. To reduce resource requirements, we have proposed strategies to decrease method development time and introduced some general guidelines to maximize the chances of success.

10.2 PARTICLE SIZE CHARACTERIZATION

Particle properties such as size, size distribution, shape, and texture are important considerations in the development of formulations using the material-sparing approach. This is true for API, excipients, and formulations (blends and granulations). When characterizing API, excipients, or formulations, a representative sample must be obtained. The sample needs to be correctly and reproducibly prepared, and necessary parameters must be correctly used for the analysis.[1] Each particle sizing method, replete with its assumptions, results in a unique measure of particle size and distribution since a sample exhibits a range of shapes and sizes and, of course, the complexity is compounded when analyzing multicomponent systems such as formulations. Since no two methods of particle sizing will result in the same "numbers," it becomes important to distinguish between different methods and to use the same type of analysis when comparing lots of API, excipients or formulations, examining differences in performance that process changes make, among other things. While many types of analyses for particle characterization are available and possible, this discussion focuses on those methods used in the material-sparing paradigm. Table 10.2 outlines the various techniques used for particle characterization in a material-sparing formulation development process. For those interested in more detailed information on particles size measurements, standard textbooks are recommended.[2]

TABLE 10.1 Material-Sparing Characterization Methods

Method	Measured parameters
PARTICLE CHARACTERIZATION	
Light microscopy	Size, shape, roughness, size range
Polarized light microscopy	Crystallinity
Scanning electron microscopy	Size, shape, roughness, size range
Sieving	Size, size distribution
Light diffraction particle size	Quantitative size, distribution, span
POWDER CHARACTERIZATION	
Helium pycnometry	True density
Bulk/tapped density	Bulk and tapped density, compressibility index
Shear cell	Powder flow parameters, flow function coefficient, unconfined yield strength, cohesion, effective angle of internal friction
COMPACT CHARACTERIZATION	
Tablet compaction	Compaction pressure, solid fraction
Indentation test	Deformation pressure, elastic deformation
Tensile test	Tensile strength, compromised tensile strength
TABLET CHARACTERIZATION	
Tabletability	Tensile strength—solid fraction relationship
Compactibility	Tensile strength—compression pressure relationship
Compressibility	Solid fraction—compression pressure relationship
Manufacturability	Tablet crushing force—compression force relationship

TABLE 10.2 Summary of Material-Sparing Particle Characterization Techniques

Method	Min, micron	Max, microns	Distribution	Shape	Texture	Grams	Crystallinity
MICROSCOPY							
Light	1	1000	Yes	Yes	Yes	<0.1	No
Polarized	1	1000	Yes	Yes	Yes	<0.1	Yes
SEM	0.02	1000	Maybe	Yes	Yes	<0.1	No
Dynamic image analysis	1	10000	Yes	Yes	No	2–5	No
LIGHT SCATTERING							
Laser—wet	0.02	2000	Yes	No	No	1–2	No
Laser—dry	0.02	2000	Yes	No	No	1–2	No
OTHER							
Sieving	25–50	2000	Yes	No	No	3–5	No

Particle size measurements vary in difficulty depending on the shape of the particle. Spherical particles, for example, can be fully defined by their diameter. In reality, most particles are far from spherical; however, for certain analyses (such as laser light diffraction (LD), discussed later in this chapter) a solid particle is considered to approximate a sphere. Since this measurement is based on a hypothetical, not

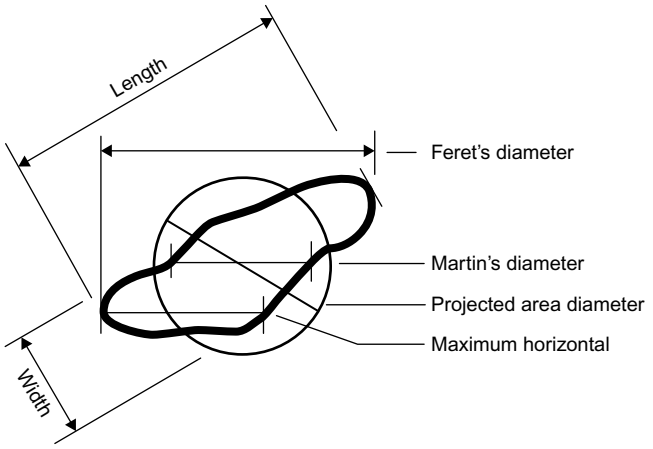

FIGURE 10.1 Particle shape parameters.

actual, sphere and is only an approximation of the true particle shape, it is referred to as the equivalent spherical diameter of the particle.[3]

For other analyses of irregularly shaped particles (such as microscopic evaluation), information about both size and shape is needed. Several different particle diameters can be used for the evaluation of particle size; the most common of these are illustrated in Fig. 10.1.[4] While length and width are diameters more often used in microscopic evaluation, the equivalent spherical diameter is widely used in laser LD analyses. Another descriptor of particle diameter used in early formulation development is the sieve diameter, which is the width of the minimum square aperture through which a particle passes.

Descriptors of particle shape include acicular, columnar, flake, plate, lath and equant, and should be included in the characterization of irregularly shaped particles. Degree of particle association (eg, aggregate, agglomerate), and surface characteristics (eg, cracked, smooth, porous), should also be noted.[4]

Since most APIs, excipients, and formulations are found in a range of sizes, size distribution of the materials is critically important and must also be determined. When a bell-shaped curve resembling a normal distribution can describe particle size distribution (PSD), it can be described by the mean particle size and standard deviation. Again, however, many pharmaceutical powders do not fall into a bell-shaped distribution. Some are skewed toward the upper end of the particle size range. These powders are often better described using a log-normal distribution that, when the data are plotted using a log scale for the size axis, resembles a normal distribution curve. When using a log-normal representation, the geometric mean standard deviation, and geometric median particle size, are used to describe the distribution. Other pharmaceutical powders cannot be characterized by a single distribution, and may have bimodal or multimodal distributions. Cumulative frequency distribution curves may also be generated by adding percent frequency values to produce a cumulative percent frequency distribution. Sieving data is often presented in this manner.

10.2.1 Light Microscopy

Light microscopy is perhaps the ultimate material-sparing characterization technique and forms the basis of the material-sparing approach as it pertains to particle characterization. With only a few milligrams of material, appearance, shape, the extent of particle association, and texture information may be quickly obtained. With a polarizing light microscope, extent of crystallinity may also be assessed. PSDs may be generated from microscopic evaluation, although it is a tedious and time-consuming process. Laser diffraction has become increasingly popular for PSD as discussed later in the chapter. More recently, dynamic image analyzers have been developed which automate the analysis of particle size and shape by capturing images with a camera, transmitting them to a computer system, and then analyzing them electronically. Average particle size, size distribution, and shape information may be generated using this technique. Image analysis may be used for particles in the size range of 1 μm−10 mm, but requires up to several grams of material depending on the difficulty of method development, and thus far has not been routinely used during the material-sparing formulation process.

For a compound light microscope, the type of microscope used, the practical size range is 1 μm−1 mm. This type of microscope is used when fine detail must be resolved. The clarity or resolving power of the image depends on the sharpness of the image produced by the objective lens. Resolving power is defined as the smallest distance between two points such that the two points can be distinguished.[5] The sample is usually mounted in a medium that has sufficient contrast to the sample, and in which the sample is insoluble. The particles should all be in the same plane, be adequately separated from each other, and should represent the size and distribution of the entire sample population (Retrieved from http://www.authorstream.com/Presentation/naveen.gokanapudi-1764246-preformulatio).

10.2.2 Scanning Electron Microscopy

Scanning electron microscopy (SEM) is another technique where only milligram quantities of material may be used to determine particle size, shape, and texture.

In SEM, a fine beam of electrons scan across the prepared sample in a series of parallel tracks. The electrons interact with the sample, and produce different signals which can be detected and displayed on the screen of a cathode ray tube (Retrieved from http://www.authorstream.com/Presentation/naveen.gokanapudi-1764246-preformulatio).[2] Particles less than 1 nm can be viewed and, since the depth of focus is so much greater than that of the light microscope, information on surface texture can be generated. SEM requires more time-consuming sample preparation than optical microscopy and cannot distinguish between crystalline and noncrystalline materials. It is also more difficult to generate a PSD using SEM since, while the information obtained is visual and descriptive, it is usually not quantitative since only a few particles are seen in the viewing field at one time. However, when SEM is used with other techniques (Retrieved from http://www.authorstream.com/Presentation/naveen.gokanapudi-1764246-preformulatio), it can provide additional valuable information that may help to explain powder properties such as agglomeration or flow problems.

10.2.3 Sieving

Sieving is a simple method that is used for determining the PSD of a powder. It is often the preferred method of choice for formulators since it is a straightforward analysis that can be done during the formulation development process (eg, after mixing or granulation of a formulation). This technique is most often used for intermediate processed materials such as granulations, formulations or excipients since larger quantities are needed (3–5 g are needed to perform an analysis using small-scale sonic sifting). API is not always evaluated by sieving due to the particle size limitations, as well as their more irregular particle shapes. Sieving is most suitable for powders whose average particle size is greater than 25–50 μm.[1]

For material-sparing sieving, a sonic sifter using 3-inch sieves is employed. Sonic sieving combines two motions to separate the particles: a vertically oscillating air column to lift particles and carry them back against mesh openings at several thousand pulses per minute, and a repetitive tapping pulse to help reduce sieve blinding (Retrieved from http://www.authorstream.com/Presentation/naveen.gokanapudi-1764246-preformulatio). Tapping also helps to deagglomerate samples with electrostatic, hygroscopic, or other adhesion problems.[6] The raw data can be converted into a cumulative weight distribution, and the data presented as a percentage of the sample retained on each sieve (histogram) or a cumulative distribution as a function of sieve size. When data is plotted on a log–log plot (sieve size vs cumulative percent), unimodal versus polymodal distributions can also be determined. A detailed procedure for analytical sieving may be found in the United States Pharmacopeia (USP) General Chapter <786>, Method I (dry sieving).[7]

10.2.4 Light diffraction

Laser LD is a preferred method for the determination of PSD of pharmaceutical materials. This technique can be quite material-sparing, often using 1–3 g of a material for a complete evaluation. Even less material may be used if combined with a microscopic or SEM evaluation to determine particle size, morphology, and fragility of the sample. There are several advantages to LD methods. Analysis time is short, robust methods can be developed with a minimum of material, results are reproducible, calibration is not required, and a wide range of measurement is possible. LD technology is divided into two general methods. High angle light scattering is appropriate for very small (submicron) particles and falls outside the scope of this discussion. Low angle light scattering is used for pharmaceutical materials in the micron size range or greater. Determination of particle size using low angle technology is only effective if one has a model to use to interpret it. For particles much larger than the wavelength of light any interaction with those particles causes the light to be scattered with only a small change in angle. This is known as Fraunhofer diffraction, and produces light intensity patterns that occur at regular intervals and are proportional to the particle diameter that produces this scatter. Fraunhofer diffraction-based instruments are applicable for particle size ranges of about 1–2000 μm, depending on the lens used.

Both wet and dry laser diffraction methods are possible and are used in a material-sparing process. For dry dispersion LD, initial conditions such as pressure and lens size are determined by microscopy, with a short series of trial runs to assess correct pressure for dispersing particles without fracturing them and to confirm lens size. Too high a pressure may break down some fragile particles. With small tray accessories, these dry methods can use 500 mg or less for a complete analysis. Initial conditions for a wet method rely on a small set of standardized generic methods and microscopy. For wet methods, it is important to choose a suspension medium where the sample has low solubility (hexane is often used) that will also disperse the sample adequately. Surfactants are occasionally used to facilitate dispersion and

inhibit flocculation of the sample, but it is important to prevent particle dissolution in the surfactant solution. A filtered saturated solution can be used as the dispersing medium to effectively prevent particle dissolution in the medium. Sonication may be needed to break up aggregates, but the fragility of the sample must be assessed since sonication may fracture individual particles and skew the results. Sample load is also important as a higher percentage of the sample in the dispersing solvent may cause aggregation.

Whether a wet or dry method is used during material-sparing formulation development depends on several factors, the most important of which are the properties of the material to be tested. Wet dispersion is frequently used for API characterization since it is a one-component system, easily screened for the appropriate nonsoluble dispersant. Multicomponent systems, such as mixes or granulations, are more amenable to dry dispersion techniques. There is no need to test the solubility of each component in the dispersant since the dispersant for dry techniques is air. Dry dispersion techniques tend to be used when there is plenty of material available, since developing a method is straightforward with sufficient trial runs. Other factors that determine which method is utilized include operator experience, equipment availability, and personal preference.

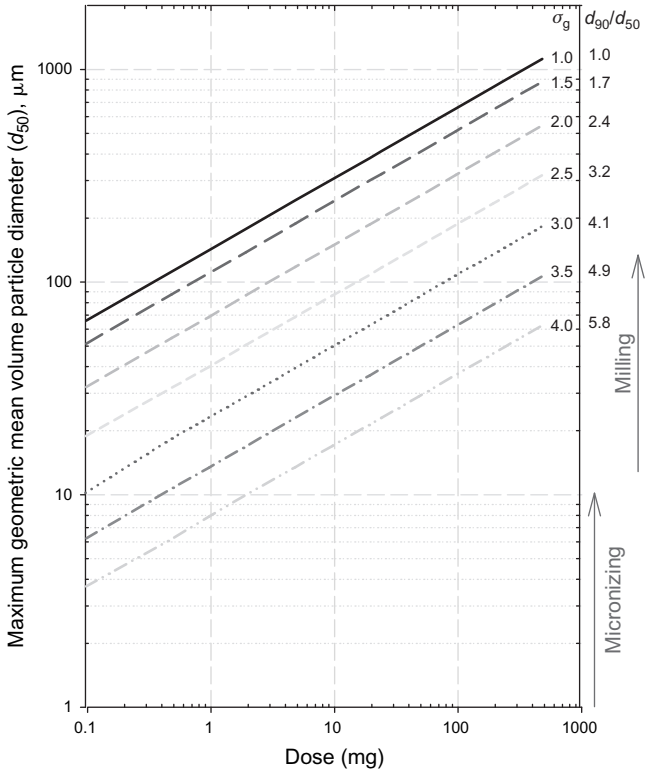

FIGURE 10.2 Content uniformity prediction as a function of particle size, distribution, and dose.

10.2.5 Importance/impact of particle size characterization

Understanding a pharmaceutical powder's particle size, shape, and distribution is an important component of material-sparing formulation development. When working with the API, a few large or small particles in a batch can alter the final tablet's content uniformity (potency, segregation), dissolution profile, and/or processing (eg, flow, compression pressure profile, and granulating properties if it is for dry granulation). Rohrs et al. have shown that with only the predicted API dose and the geometric standard deviation, an estimate of the API particle size can be obtained having a 99% probability of passing USP Stage I content uniformity criteria.[8] This is displayed graphically in Fig. 10.2. It is useful for determining approximate parameter values for particle size requirements, including whether additional API processing such as milling is necessary. API particle size and distribution data information can also help decide whether a direct compression formulation or dry granulation approach is most suitable. Examination of the API can also reveal inter- and intrabatch differences and/or trends. If for example, the PSD has changed from one batch of API to the next, this could significantly impact the processing of the final formulation.

Particle size and size distribution are also important from a dosage form performance point of view in that they are critical parameters in assuring that the desired dissolution rate is achieved for oral dosage forms. Several theoretical models for dissolution of powders have been developed.[9–11] Using a Noyes–Whitney type expression as a starting point, Higuchi and Hiestand,[10] as well as Hintz and Johnson,[11] derived expressions for dissolution of spherical particles as a function of time. While details are beyond the scope of this chapter, it is possible to predict the dissolution rate of polydispersed PSDs by summing up the predicted dissolution rate of individual size fractions of the powder. For example, using this approach, the predicted particle diameter necessary to achieve 80% dissolved in a USP dissolution apparatus in 30 minutes under sink conditions as a function of solubility and PSD is shown in Fig. 10.3.[12] With this information, selection of an appropriate particle size and distribution needed to achieve the desired dissolution rate may be estimated.

Particle characterization of the in-process or final-formulation is also critical. Flow characteristics of formulations (which will be discussed later in the chapter) are based, among other factors, on shape, size, and size distribution of particles. Large, spherical particles flow better than smaller, irregularly shaped materials, for example.

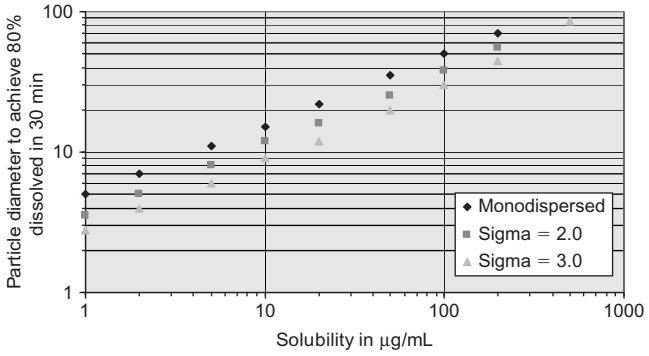

FIGURE 10.3 Predicted particle diameter necessary to achieve 80% dissolved in a USP dissolution apparatus in 30 min under sink conditions as a function of solubility and particle size distribution (sigma = geometric standard deviation of a log-normal distribution).

10.3 POWDER CHARACTERIZATION

10.3.1 Density

10.3.1.1 True density

The true density of a substance is the average mass of the particles divided by the solid volume, exclusive of all the voids that are not a fundamental part of the molecular packing arrangement; therefore, it should be independent of the method of determination.[13] There are three basic methods for determining true density:

- gas pycnometry or displacement;
- liquid displacement; and
- flotation in a liquid.

Gas pycnometry is often used in the material-sparing paradigm for determination of true density as a small amount of material is used (usually 1–8 g), the method is easy, reproducible and reliable, and the method is nondestructive: that is, the material may be reused after testing is complete.

The true density, ρ, can be calculated using Eq. (10.1).

$$\rho = \frac{w}{V_p} \tag{10.1}$$

where:

w is the weight of the sample
V_p is the powder volume.

Since the measured density is a volume-weighted average of the densities of all the individual powder particles, errors may be introduced if the gas adsorbs onto the powder or if volatile contaminants escape from the powder during the measurement. Sorption may be prevented by using an appropriate gas, usually helium or nitrogen. Volatile components may be removed during purging of the sample, and sample weight is taken before and after purging to determine if volatile contaminants were removed. True density is an essential parameter for process development and solid dosage manufacturing. As discussed in more detail later in the chapter, true density is used to calculate the solid fraction (SF) of tablets.

10.3.1.2 Bulk density

Bulk density is the mass per unit volume of a loose powder bed. The unit volume includes the spaces between the particles, and the envelope volumes of the particles themselves. The method used to fill the material into that volume can affect the degree to which the powder is compressed and can thus influence the bulk density value.[14,15] Bulk density can be calculated using Eq. (10.2), where M = mass in grams and V_o = untapped apparent volume in milliliters.

$$\text{Bulk Density } (g/\text{mL}) = \frac{M}{V_o} \tag{10.2}$$

The loose or "aerated" bulk density can be determined by allowing a defined amount of material to fill a container with a known volume under the influence of gravity.[16] The amount to which the particles collapse and fill voids between the particles depends on some powder properties, including particle shape, PSD, interparticle friction, and cohesion.

Bulk density is typically measured by gently introducing a known sample mass into a graduated cylinder, and carefully leveling the powder without compacting it. The apparent untapped volume is then read to the nearest graduated unit. As most pharmaceutical powders have densities in the range of 0.1–0.7 g/mL, a 25-mL graduated cylinder filled at least 60% full calls for a sample mass of approximately 2–11 g. (Since this test is nondestructive, the material may be reused.) USP requirements dictate a minimum graduated cylinder size of 25 mL.[16] However, if a material is in short supply, a 10-mL graduated cylinder may be used. Although wall effects could be observed, this approach provides a reasonable estimate of the bulk density.

Bulk density is an essential parameter for process development and solid dosage manufacturing. It is used in determining the amount of powder that can fit in a space such as a blender or a hopper on a tablet press or capsule filler. It is also used to determine the amount of powder that can be fitted into a capsule. Previous work has suggested that the effective bulk density of the same material will vary under different dynamics.[14,15]

10.3.1.3 Tapped density

Tapped density of a powder is the ratio of the mass of the powder to the volume occupied by the powder

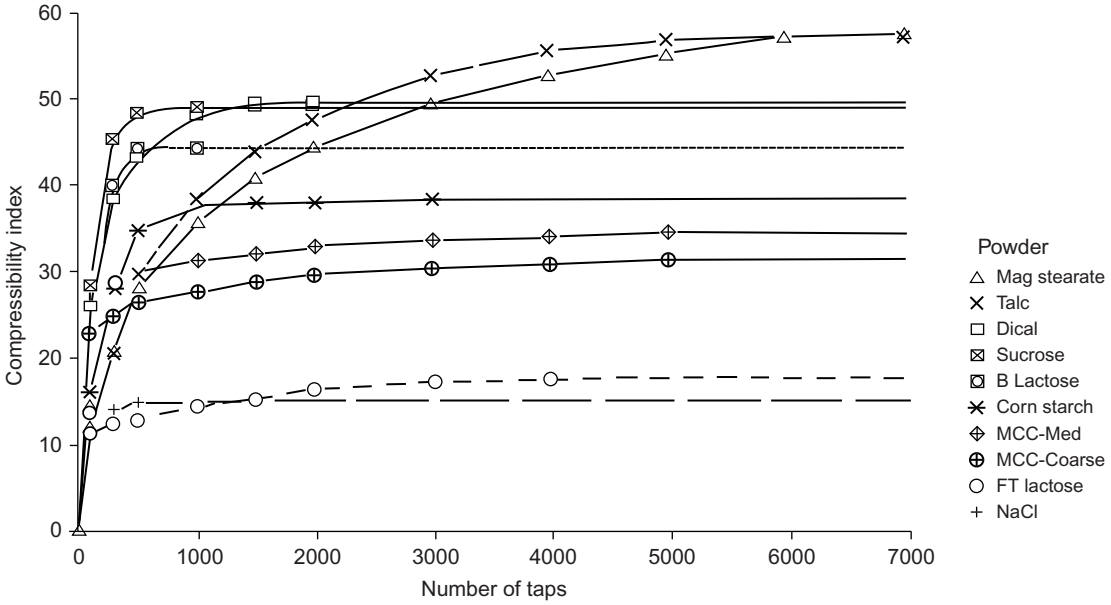

FIGURE 10.4 Influence of number of taps on the compressibility index.

after it has been tapped for a defined period of time. The tapped density of a powder represents its random dense packing. Tapped density can be calculated using Eq. (10.3), where M = mass in grams, and V_f = the tapped volume in milliliters.

$$\text{Tapped Density } (g/\text{mL}) = \frac{M}{V_f} \tag{10.3}$$

Tapped density values are higher for more regularly shaped particles (ie, spheres), as compared to irregularly shaped particles such as needles. PSD has been shown to affect the packing properties of fine powders.[17] The packing properties of a powder can affect operations critical to solid dosage manufacturing, including bulk storage, powder flow, and compaction.

Tapped density is measured by first gently introducing a known sample mass into a graduated cylinder and carefully leveling the powder without compacting it. The cylinder is then mechanically tapped by raising the cylinder and allowing it to drop under its own weight using a suitable mechanical tapped density tester that provides a suitable fixed drop distance and nominal drop rate (Retrieved from http://www.authorstream.com/Presentation/naveen.gokanapudi-1764246-preformulatio). There are two methods for measuring tapped density in the USP with different drop distance and drop rates.[16] The tap density of some pharmaceutical materials is shown in Fig. 10.4.[18] As with bulk density measurements; a material-sparing approach can be undertaken by using a 10-mL graduated cylinder (1−4 g sample requirement). This test is also nondestructive.

10.3.2 Flow

Flow assessment of APIs, excipients, and formulations are routinely completed as part of solid dosage form development. Assessments must be made to ensure powder flows adequately through processing equipment such as a roller compactor, hopper, or tablet press. Poor flowability can lead to the inability to feed powder into the dies of a rotary tablet press and can also cause tablet weight variation.

Due to the complexity of powder flow and the factors that influence it, no single measure is currently adequate for defining a flow. Unsurprisingly, many ways to measure flow currently exist, ranging from simple, qualitative methods, to more quantitative methods utilizing specialized technology. Factors such as the relative humidity of the environment, previous storage conditions, and degree of consolidation have a large impact on flowability, any of which can alter the test results.

The influence of physical and mechanical properties on powder flow is a subject of interest to formulation scientists. Factors such as PSD and particle shape have been shown to influence flow.[19–21] Additional properties such as bulk and tapped density, bonding index (BI), and internal friction coefficient are also thought to be contributors. An understanding of the effects of physical and mechanical properties on powder flowability can decrease the need to perform powder flowability analysis on some materials, resulting in significant time and resource savings.

An attempt has been made to model flowability based on physical and mechanical properties using

complex methods such as artificial neural networks, discrete element method, and constitutive models.[22–24] While these models have demonstrated a correlation between certain physical properties and the results of various methods for measuring flow, more work is required.

10.3.2.1 Compressibility Index and Hausner ratio

The compressibility index (CI) is a measure of the propensity of a powder to consolidate.[25] As such, it is a measure of the relative importance of interparticulate interactions. In a free-flowing powder, such interactions are less significant, and the bulk and tapped densities becomes closer in value. For poorer flowing materials, there are frequently greater interparticle interactions; bridging between particles often results in lower bulk density and a greater difference between the bulk and tapped densities. These differences in particle interactions are reflected in the CI. A general scale of powder flow using the CI is given in Table 10.3.[25] CI can be calculated as shown in Eq. (10.4), where V_o = untapped apparent volume, V_f = tapped apparent volume.

$$\mathrm{CI}(\%) = 100 \cdot \frac{(V_o - V_f)}{V_o} \tag{10.4}$$

Although this method cannot be used as a sole measure of powder flowability, it has the advantage of being simple to perform and it provides a quick comparison between API, excipients, and formulations. If bulk and tapped density measurements have already been performed, no additional material or experimentation is required to calculate the CI. CI has been correlated to manufacturing performance on machines such as capsule fillers. Podczeck et al. for example demonstrated a correlation between the minimum coefficient of fill weight variation and CI.[26]

The Hausner ratio (HR) is closely related to CI.[27] It can be calculated using Eq. (10.5), where V_o = untapped apparent volume and V_f = tapped apparent volume.

$$\text{Hausner Ratio} = \frac{V_o}{V_f} \tag{10.5}$$

Scales of flowability for CI and HR are included in Table 10.3.

TABLE 10.3 Scale of Flowability for Compressibility Index and Hausner Ratio[31]

Flow character	Compressibility index	Hausner ratio
Excellent	≤10	1.00–1.11
Good	11–15	1.12–1.18
Fair	16–20	1.19–1.25
Passable	21–25	1.26–1.34
Poor	26–31	1.35–1.45
Very poor	32–37	1.46–1.59
Very, very poor	>38	>1.60

10.3.2.2 Angle of repose and flow through an orifice

The angle of repose has long been used to characterize bulk solids.[28–30] Angle of repose is a characteristic related to interparticulate friction or resistance to movement between particles. According to the USP, it is the constant, three-dimensional angle (relative to the horizontal base) assumed by a cone-like pile of material formed by any of several different methods. Due to the high dependence of angle of repose measurements on testing conditions, angle of repose is not a very robust means of quantifying powder flow.[31]

Flow rate through an orifice is generally measured as the mass of material per unit time flowing from any of a number of types of containers (cylinders, funnels, hoppers). It is thought to be a more direct measure of flow than measurements such as angle of repose or HR, because it more closely simulates flow of material from processing equipment such as from a tablet press hopper into a die. Measurement of the flow rate is heavily dependent on test set-up, such as orifice diameter.[32] Both angle of repose and flow rate through an orifice methods require 5–70 g of material, and therefore are not aligned with material-sparing strategies.

10.3.2.3 Shear cell methods

Shear cell methods measure flow on a more fundamental basis than the simple methods discussed above, providing more robust flow results. Shear cell methods allow the assessment of flow properties as a function of consolidation load and time, as well as powder–hopper material interactions.[33] Various types of shear cells exist, including rotational and translational cells.[34–36] While shear cell measurements are more time-consuming than the methods discussed above, they offer a higher degree of experimental control, leading to more reproducible results. They are used extensively in multiple industries, and significant advances in automation have occurred in the past 5 years.[28,37,38]

Detailed descriptions of shear cell methods and data analysis are available in the literature.[39] The shear cell analysis method is as follows: a bulk solid sample is carefully loaded into a container or "cell," taking care not to consolidate the powder during loading. The

powder bed is typically preconsolidated at a defined load normal to the powder bed. As the load is applied, the powder bed is sheared until a uniform state of consolidation is reached (ie, powder starts to "flow" and shear stress reaches a constant value). This value of the shear stress represents the shear strength of the powder at those conditions. Once preconsolidation is achieved, the normal load is reduced, and a normal load less than the preconsolidation load is applied. The bulk solid is sheared until the shear force goes through a maximum value. This maximum value represents the shear strength of the powder bed under those conditions. This process of preconsolidation, and subsequent consolidation at a reduced load is repeated multiple times at different normal loads. This process is sometimes referred to as a yield locus test. A yield locus is constructed based on the shear data; it passes through the points defined by the shear and normal stress values during preshear and shear. Fig. 10.5 shows the yield loci of three different materials, constructed using a simplified (translational) shear cell. The yield locus is characteristic of the physical and mechanical properties of the powder, as well as a number of environmental factors (a list of some of these factors is included in Table 10.4). Some of the most commonly reported shear cell flow properties reported in the literature are the angle of internal friction and the flow function.[40,41]

Because shear methods provide quantitative, reproducible results, the properties defined in Table 10.5 can be used to compare the flowability of different drug substances, excipients, and formulations. To properly compare data, the environmental factors listed in Table 10.4 should be kept constant. For example, Moreno-Atanasio et al. demonstrated an increase in the unconfined yield strength with an increase in preconsolidation stress using a uniaxial compression test. Shear cell methods are also used to characterize the performance of materials on equipment such as capsule-filling machines,[42] and tablet presses.[43] They are extensively used to design hoppers for feeding powders, and to study the effect of storage time on flowability.[44,45] Jenike developed a mathematical methodology for determining the minimum hopper angle and opening size for mass flow from conical and wedge-shaped hoppers.[46]

Several different types of shear cell testers are available. The Schulze Ring Shear Tester is an annular or rotational shear tester. The bulk solid sample is contained in an annular shear cell containing a ring at the bottom and a baffled lid. Ring shear testers are considered to be relatively easy to operate, and provide good reproducibility.[40] A single yield locus test can be performed in approximately 30 minutes (of which the operator must be present about one-third of the time).

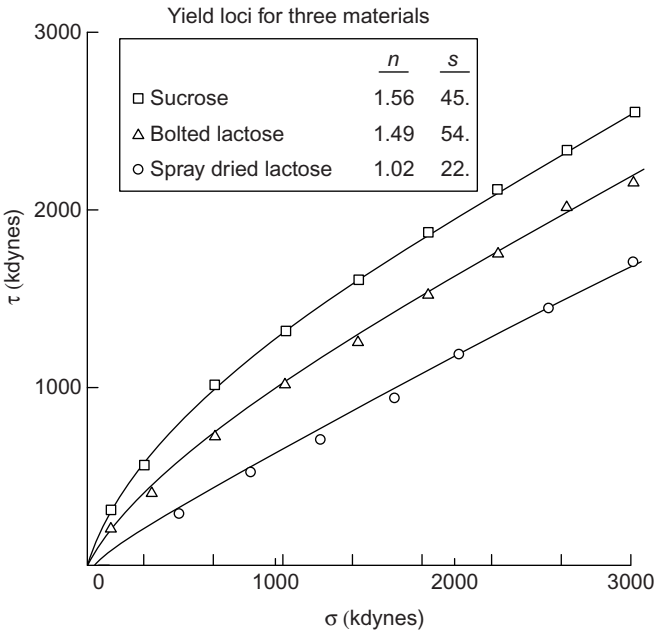

FIGURE 10.5 Yield loci for three materials.

TABLE 10.4 Physical and Mechanical Properties and Environmental Factors Influencing Flowability

Physical and mechanical properties	Environmental effects
Particle size distribution	Consolidation load
Particle shape	Consolidation time
Bulk/tapped density	Shear effects (direction & rate)
Particle density	Particle/wall interactions
Moisture content	Air permeability
Crystallinity	Compressibility (a function of load and time)
Polymorphic form	Humidity/powder moisture content
Surface area	Packed density
Electrostatic charge	
Surface energy	
Elasticity	
Plasticity (ductility)	
Viscoelasticity	
Brittleness	

Multiple shear cell sizes are available. Depending on the particle size of the powder specimen a small, 10-mL shear cell can be used, allowing for a significant reduction in sample requirements. Medium and large shear

TABLE 10.5 Shear Cell Flow Property Names and Definitions

Flow property	Definition
Major consolidation stress (σ_1)	Defined by the major principal stress of the larger Mohr stress circle
Unconfined yield strength/stress (σ_c)	Defined by the major principle stress of the smaller Mohr stress circle. It is the stress at which the sample will break (flow) after a vertical stress has been applied to a consolidated sample
Flow function coefficient (*FFC*)	The ratio of the major consolidation stress to the unconfined yield strength at a defined normal load
Flow function	A flow function curve can be constructed by plotting the FFC values obtained by performing multiple yield locus tests at different preconsolidation normal loads
Slope angle of the linearized yield locus (φ_{lin})	The angle defined by the linearized yield locus. The linearized yield locus is the line that is tangential to both Mohr stress circles
Effective angle of internal friction (φ_e)	The angle defined by the line that runs through the origin of the diagram, and is tangent to the larger Mohr stress circle
Angle of internal friction at steady state flow (φ_{sf})	The arctangent of the ratio of shear stress to normal stress of the preshear point (ie, steady state flow). It characterizes the internal friction at steady state flow in the shear plane
Cohesion (τ_c)	The shear stress at yield under zero normal stress, that is, the intersection of the yield locus with the ordinate

cells are also available, which can accommodate samples with larger particle sizes. These cell sizes require sample volumes greater than approximately 31 and 73 mL, respectively.[47] A standard test method for using the Schulze Ring Shear Tester can be found in ASTM Method D 6773.[48]

The Jenike Shear Tester is a translational tester. The shear cell is cylindrical and is split horizontally, forming a shear plane between the lower stationary base and the upper movable portion. It consists of a closed ring at the bottom, a ring of the same diameter lying above the bottom ring, and a lid.[49] An advantage of the Jenike cell over the ring shear tester is that the powder bed is shared more uniformly.[49] Disadvantages of the Jenike Shear Tester include the amount of material required and the time required for a test. Depending on the powder, and the operator's skill, 1–2 hours per yield locus (during which the operator has to be present) are required. Results generated using the Jenike Shear Tester have been shown to correspond to those generated using the ring shear tester.[39] A standard test method for using the Jenike Shear Tester can be found in the ASTM Method D 6128.[50]

10.3.2.4 Additional shear testers

Schulze ring shear and Jenike shear cell testers are used extensively due to their commercial availability, though other shear cells are available. Plate or "simplified" shear cells have also been designed, which consist of a thin sandwich of powder between a lower stationary rough surface and an rough upper surface that is movable.[18,51] Uniaxial, biaxial, and triaxial testers have also been used for flow analysis, and have been discussed in the literature. The measurement principle of the uniaxial tester is similar to that of shear cells.[35,49]

10.3.2.5 Dynamic test methods

Avalanche testers assess the flowability of powders by measuring their avalanching behavior, which is related to powder cohesivity and flowability. Unlike shear cell methodology, this type of assessment is dynamic in nature,[52] which may be more applicable to low-shear processes such as blending, in which avalanching behavior of powder promotes mixing. Avalanche testing can be carried out in different types of equipment, including rotating drums and vibratory feeders.[53,54] Avalanche testing has been shown to distinguish between freely flowing powders, blends, and granulations.[55,56]

One limitation of the avalanche tester is the qualitative nature of determining the regimes of avalanche flow in the rotating drum. Boothroyd et al. argued that the ideal flow regimes necessary for meaningful data analysis for pharmaceutical powders were the "rolling" and "cascading" regimes.[57,58] Another limitation of the system is the method development required before analysis. Rotational speed, measurement duration, and sample size must be optimized, as they have a great degree of influence over the measurement results.[53] A third limitation is the amount of material required, which limits the use of this technique in a material-sparing approach to formulation development. Hancock et al. proposed a sample size of 50 mL.[53]

Bhattachar et al. developed a vibratory feeder method for assessing avalanche behavior that requires a smaller sample size than for the Aeroflow (1.2 g). Results compared to those generated using the

Aeroflow.[59] Despite the small sample size requirements, this method is not widely used. The instrument is not commercially available and has not been extensively tested.

10.4 COMPACT (MECHANICAL PROPERTY) CHARACTERIZATION

Many investigations have demonstrated the importance and impact of the physical and chemical properties of materials on powder processing. Physical properties such as particle size and shape clearly influence powder flow for example. The previous sections of this chapter provide some recommendations for how to proceed with characterization using limited quantities of materials. However, mechanical compact properties (ie, those properties of a material under the influence of an applied stress) are also of great importance for solid dosage form development and manufacturing, particularly for tablet formulation. This section describes the importance of the mechanical properties of materials, as well as some basic principles and methodologies that can be used to investigate the influence of these properties on compaction. For this discussion, physical properties are considered to be those properties that are "perceptible especially through the senses" (ie, properties such as particle size, and shape). In contrast, mechanical properties are those properties of a material under an applied load: elasticity, plasticity, viscoelasticity, bonding, and brittleness.

Table 10.4 lists some of the physical and mechanical properties that influence powder properties and compaction. For example, surface energy and elastic deformation properties influence individual particle true areas of contact. Plastic deformation likely occurs to some extent in powder beds depending on the applied load, and almost certainly it occurs during the compaction of powders into tablets. Certainly at asperities, local regions of high pressure can lead to localized plastic yielding. Electrostatic forces can also play a role in powder flow, depending on the insulating characteristics of the material and environmental conditions. Particle size, shape, and size distribution have also been shown to influence flow and compaction. A number of environmental factors such as humidity, adsorbed impurities (air, water, among others), consolidation load and time, direction and rate of shear, and storage container properties are also important. With so many variables, it is not surprising that a wide variety of methods have been developed to characterize materials. The focus of this chapter is on those useful methods that require limited amounts of material (bulk drug or formulation) and provide the most valuable information.

What holds particles together in a tablet? A detailed discussion is beyond the scope of this chapter, and excellent references are available in the literature.[60,61] However, it is important to realize that the forces that hold particles together in a tablet or powder bed are the very same forces discussed in detail in introductory physical chemistry texts. There is nothing magical about particle–particle interactions; the forces involved are London dispersion forces, dipole interactions, surface energy considerations, and hydrogen bonding. The consolidation of powders brings particles into proximity, and these fundamental forces can begin to act effectively to produce strong particle–particle interactions (eg, bonding). Particle rearrangement, elastic and plastic deformation of material can establish large areas of true contact between particles; if the resulting particle–particle bonds are strong, a strong and intact tablet is produced.

10.4.1 Important mechanical properties

Materials used in the pharmaceutical industry can be elastic, plastic, viscoelastic, hard, tough, or brittle in the same sense that metals, plastics, or wood are. The same concepts that mechanical engineers use to explain or characterize tensile, compressive, or shear strength are relevant to pharmaceutical materials. These mechanical properties of materials can have a profound effect on solids processing.

The mechanical properties of a material play an important role in powder flow and compaction. These properties are critical properties that influence the true areas of contact between particles. Therefore, it is essential to characterize the properties. Reliable mechanical property information can be useful in helping to choose a processing method such as granulation or direct compression, selecting excipients with properties that will mask the poor properties of the drug or helping to document what went wrong, for example, when a tableting process is being scaled-up or when a new bulk drug process is being tested. Since all of these can influence the quality of the final product, it is to the formulator's advantage to understand the importance of the mechanical properties of the active and inactive ingredients and to be able to quantify the properties.

10.4.1.1 Elastic deformation

In general, during the initial stages of deformation, a material is deformed elastically. A change in shape caused by the applied stress is completely reversible, and the specimen will return to its original shape on

release of the applied stress. During elastic deformation, the stress–strain relationship for a specimen is described by Hooke's law (Eq. 10.6):

$$\sigma = E \cdot \varepsilon \tag{10.6}$$

where:

E is referred to as Young's modulus of elasticity
σ is the applied stress
ε is the strain ($\varepsilon = (l - l_o)/l_o$).

The region of elastic deformation of a specimen is shown graphically in Fig. 10.6. The reader is directed to standard texts in material science and engineering for detailed discussions of elastic deformation. As long as the elastic limit is not exceeded, only elastic deformation occurs.

The elastic properties of materials can be understood by considering the attractive and repulsive forces between atoms and molecules. Elastic strain results from a change in the intermolecular spacing and, at least for small deformations, is reversible.

10.4.1.2 Plastic deformation

Plastic deformation is the permanent change in shape of a specimen due to applied stress. The onset of plastic deformation is seen as curvature in the stress–strain curve shown in Fig. 10.7. Plastic deformation is important because it "allows" pharmaceutical excipients and drugs to establish large true areas of contact during compaction that can remain on decompression. In this way, strong tablets can be prepared.

Plastic deformation, unlike elastic deformation, is not accurately predicted from atomic or molecular properties. Rather, plastic deformation is often determined by the presence of crystal defects such as dislocations, grain boundaries, and slip planes within crystals. While it is not the purpose of this chapter to discuss this in detail, it is important to realize that dislocations and grain boundaries are influenced by factors such as the rate of crystallization, particle size, the presence of impurities, and the type of crystallization solvent used. Slip planes may exist within crystals due to molecular packing arrangements that result in weak interplanar forces. Processes that influence these (eg, crystallization rate, solvent, temperature) can be expected to influence the plastic deformation properties of materials, and hence the processing properties. The reader is directed to standard texts in material science and engineering for detailed discussions of plastic deformation.

The plastic properties of a material are often determined by an indentation test.[62] Both static and dynamic test methods are available, but all generally determine the pressure necessary to cause permanent and nonrecoverable deformation.

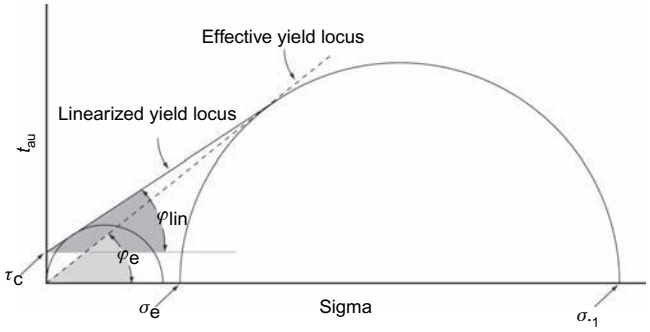

FIGURE 10.6 Yield locus and Mohr stress circle diagram.

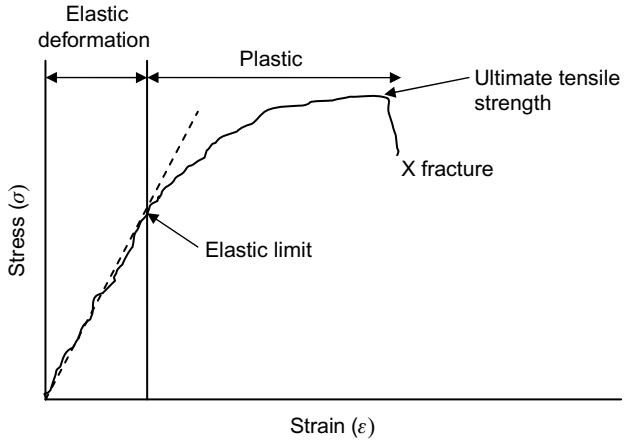

FIGURE 10.7 Stress–strain curve.

10.4.1.3 Brittle and ductile fracture

In addition to plastic deformation, materials may fail by either brittle fracture or ductile fracture; fracture being the separation of a body into two or more parts. Brittle fracture occurs by the rapid propagation of a crack throughout the specimen. Conversely, the ductile fracture is characterized by extensive plastic deformation followed by fracture. Ductile failure is not typically seen with compacts of pharmaceutical materials. The characteristic snap of a tablet during hardness testing is indicative of brittle fracture.

10.4.1.4 Viscoelastic properties

Viscoelastic properties can be important; viscoelasticity reflects the time-dependent nature of stress–strain. A basic understanding of viscoelasticity can be gained by considering processes that occur at a molecular level when a material is under stress. An applied stress, even when in the elastic region, effectively moves atoms or molecules from their energy equilibrium state. With time, the rearrangement of atoms or molecules can occur.

The stress–strain relationship can, therefore, depend on the time frame over which the test is conducted. In compacting tablets, for example, it is frequently noted that higher compaction forces are required to make a tablet with a given strength when the compaction speed is rapid. All pharmaceutical materials are viscoelastic; the degree to which their mechanical properties are influenced by rate depends on the material.

10.4.2 Overview of methods

Characterizing mechanical properties has been an active area of pharmaceutical research for decades. The application of classic "engineering" methodologies to characterize pharmaceutical materials dates to the 1950s or before. With the advent of high-speed computer control, and monitoring of processes such as tablet compaction, the era of "dynamic" characterization of pharmaceutical materials was ushered in. Sophisticated instrumentation of rotary tablet presses and, in particular, the design of tablet compaction simulators with seemingly infinite control of the compaction process, has offered scientists an unprecedented opportunity to study the mechanics of materials at speeds representative of production tablet compaction. Even today, both dynamic testing and the classic "quasi-static" engineering testing approaches offer opportunities to understand pharmaceutical materials. In this regard, dynamic and quasi-static testing are complementary tools. Both quasi-static and dynamic test methodologies will be discussed in the following sections. One key advantage of quasi-static testing is the ability to "independently" dissect out and investigate the various mechanical properties of a material. As aforementioned, pharmaceutical materials can be elastic, plastic, viscoelastic, hard, tough, or brittle. Ultimately, these individual components that cumulatively describe a pharmaceutical material determine its compaction properties in a dynamic compaction process.

The consolidation of powders into intact tablets is a process of reducing pores in a powder bed while creating interparticle bonds. During compression, materials experience complex stresses, the structure of the powder bed changes, and consolidation is brought about mainly by particle rearrangement, plastic deformation, and fragmentation.[63] The deformation of pharmaceutical materials is time dependent, and this dependency is related to the consolidation mechanism and dynamics of the consolidation process.[64–68] Under compression, for example, brittle materials are considered to consolidate predominantly by fragmentation; plastic materials deform by plastic flow. The time dependency of this process arises from stress relaxation for materials undergoing primarily plastic deformation. However, the compaction of brittle materials is often less influenced by speed because fragmentation is rapidly achieved and prolonged exposure to the force has a limited effect on tablet properties.

Several researchers have previously identified the utility of SF in describing tablet properties. Armstrong and Palfrey[69] concluded that differences in the tensile strength of tablets compressed at different speeds could be accounted for by differences in tablet porosity. Hancock and coworkers[70] found that tablet strength and disintegration time for tablets made on an eccentric press and a rotary press were comparable when considering a comparable SF. Maarschalk and coworkers[71] found that tablet tensile strength of sorbitol as a function of tablet porosity was independent of compression speed. Finally, Tye and coworkers[63] extended this work to show that tablet SF was the primary factor determining tablet strength for several pharmaceutical excipients (both brittle and ductile) over an extremely wide range of compaction speeds (dwell times from $<$10 milliseconds to 90 seconds).

The SF of a compact can be calculated based on the true density (ρ_{true}) of the material (typically determined using pycnometry), the tablet volume (ν), and the tablet weight (Wt) (Eq. 10.7):

$$SF = \frac{Wt}{\rho_{true} \cdot \nu} \tag{10.7}$$

The relationship between the SF, also referred to as relative density, and porosity (ε) is:

$$\varepsilon = 1 - SF \tag{10.8}$$

10.4.3 Quasi-static testing

Quasi-static testing typically applies variations of traditional engineering and material science testing methods to compacts (ie, test specimens) of pharmaceutical materials. There are, for example, a number of variations of indentation, tensile, flexural, compression, and brittle fracture tests in the pharmaceutical literature.[72] The quantity of material required for testing varies from 1 to 100 g. Methods for characterizing the elastic, plastic, and brittle properties of compacts of organic materials have, for example, been developed by Hiestand and coworkers.[73–77] These measures of tableting performance assess several key mechanical properties of compacted materials that have been shown to relate to tableting. Currently available methods typically require from 10 to 60 g for complete mechanical property characterization using Hiestand's methods.

10.4.3.1 Test specimen preparation

It is important to prepare test specimens of pharmaceutical materials properly so that quasi-static test results are not improperly influenced by "flaws" that may exist in the test specimen itself. Of the methods defined in the literature, the most refined method is to make square compacts using triaxial compression and decompression.[73] A split die (Fig. 10.8) is used to make compacts that are substantially free of defects that may occur if a conventional compaction process were to be used. The split die permits triaxial decompression such that the pressure applied to all three axes is essentially equal during the decompression process.[73] This is achieved by computer control of the decompression process. The stresses in the compact are more uniformly relieved in three dimensions, and this minimizes the production and propagation of flaws within the compact. Using this approach, defect free compacts of essentially any pharmaceutical material is possible, something not obtainable with uniaxial decompression.

10.4.3.2 Importance of the solid fraction

It is imperative to realize and address the fact that the mechanical properties of a compact are very much influenced by SF. A change in SF of 0.01 (ie, a change in *SF* from 0.85 to 0.86) can result in a mechanical property change of 10–20%. For this reason, it is critical to compare the properties of a material at a "reference" SF to ensure that one is "comparing apples to apples." Hiestand and coworkers[73] defined their reference SF as 0.9 (ie, porosity = 0.1% or 10%) while others have used a SF of 0.85 or even extrapolated to a SF of 1.0 (eg, zero porosity). In comparing results from the literature, it is important to keep this in mind. It is recommended that a SF in the range typical of tablet compaction be used. For compacts of organic materials, a reference SF of 0.85 is in the mid-range of those typically observed. For inorganic materials (such as dicalcium phosphate) SFs in the 0.6–0.75 range are often observed for tablets. The wide range of mechanical properties observed means no ideal value can be identified for all materials, but 0.85 is often appropriate for materials of organic origin.

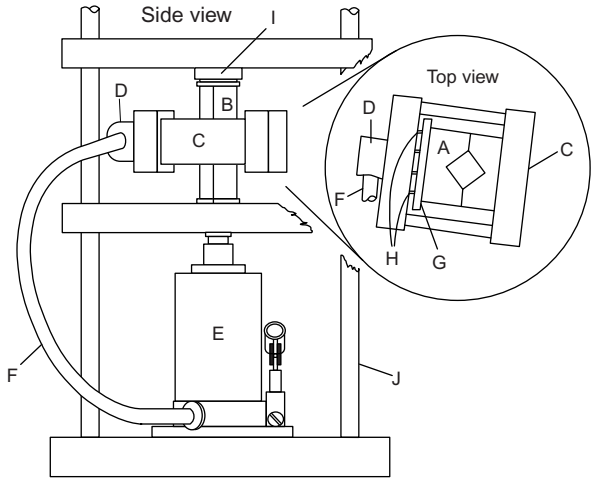

FIGURE 10.8 Schematic drawing of a simple triaxial press with a split die.

10.4.3.3 Tensile strength determination

The tensile strength, σ_T, of a square test specimen provides extremely useful information. Several methods for determining it are available and include traditional tablet hardness testing and transverse compression or square compacts. In transverse compression, specimens are compressed with platens 0.4 times the width of the compacts in the tensile testing apparatus.[73] The force necessary to cause tensile failure (tensile forces are maximum at the center of the tablet) is monitored by a load cell, and the magnitude of the force at fracture is determined. Testing of square compacts has advantages over the testing of circular compacts; however, circular compacts can be used. Conventional hardness testing of tablets can result in a measurement of tensile strength.[78] Similar results are obtained for round and square compacts when tensile failure is achieved. It is extremely important to compare measured properties such as tensile strength at the same SF. Tensile strength values more than 1 MPa (typical range 0.1–4 MPa) are typically desired for tablets.

10.4.3.4 Pendulum Impact Device

A simple schematic of a pendulum impact device (PID) is given in Fig. 10.9. This equipment permits the permanent deformation pressure of a compact of material to be determined under dynamic conditions.[73,74] Flat-faced, square tablets of the test substance are compressed at different compression pressures and then subjected to impact with a stainless steel ball in the PID. The rebound height of the ball and the chordal radius of the dent are carefully measured and used to calculate the permanent deformation pressure. In a simple sense, one is measuring the energy necessary to make the permanent deformation (the difference between the initial height of the ball and the rebound height). By measuring the volume of the dent, one can calculate the deformation pressure—the energy divided by the volume. The permanent deformation pressure is the pressure (ie, stress) necessary to cause plastic deformation. This permanent deformation pressure, *H*, has been shown to be related to the yield pressure obtained using dynamic testing methods and

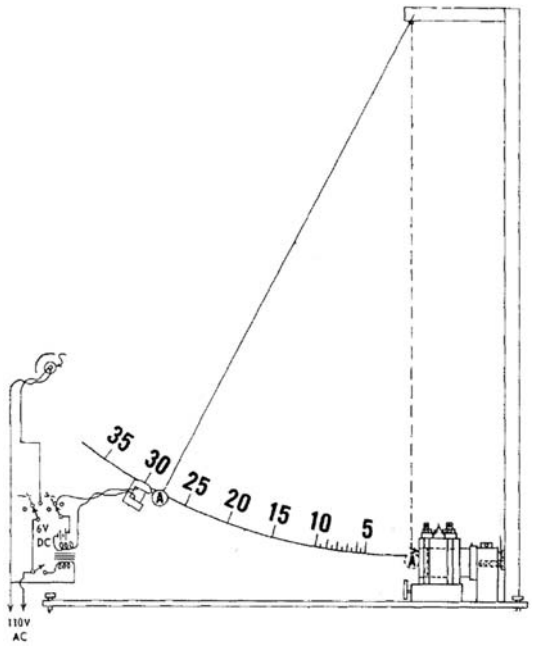

FIGURE 10.9 Pendulum impact device.

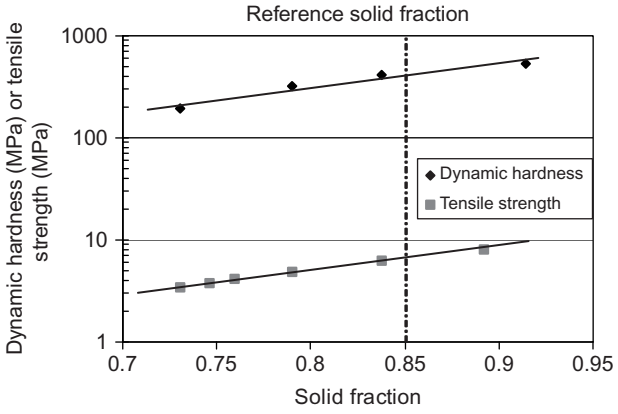

FIGURE 10.10 Dynamic hardness and tensile strength as a function of solid fraction.

Heckel analysis.[79] The dynamic hardness and tensile strength are shown in Fig. 10.10 as a function of SF for a common pharmaceutical excipient. One can clearly see the impact of SF on the measured mechanical properties.

10.4.3.5 Tableting indices

Using the methodology described above, several indices of tableting performance have been developed by Hiestand and coworkers.[60,75] These indices provide relative measures of properties (ie, dimensionless numbers) that reflect the performance of materials during processing.

10.4.3.6 Bonding Index

The purpose of the BI is to estimate the survival of strength during decompression[75]; it is defined in Eq. (10.9):

$$\mathrm{BI} = \frac{\sigma_T}{H} \tag{10.9}$$

where:

σ_T is the tensile strength of the compact at a given SF (typically 0.85 or 0.9 as defined by the user)
H is the permanent deformation pressure (ie, hardness) of a compact at the same SF.

The BI is, in essence, a measure of the ability of a material, on decompression, to maintain a high fraction of the bond that was created during compression. At maximum compression pressure, the bonded areas are at a maximum, because the right areas of contact are maximized. During decompression, some of that area and bond is "lost" due to elastic recovery. A high BI indicates that relatively speaking, a larger portion of the strength remained intact after decompression. A low BI indicates that less of the strength remains. The term BI, then, is a good description since it, in effect, characterizes the tendency of the material to remain intact after it has been compressed. Tablets made of materials with poor bonding characteristics may be quite friable. Compacts made of materials with good bonding indices may, conversely, make strong tablets. A BI in excess of 0.01 (range 0.001−0.06) is typically desired.

10.4.3.7 Brittle Fracture Index

The brittle fracture index (BFI) is a measure of the brittleness of a material. It is a measure of the ability of a compact to relieve stress around compact defects by plastic deformation. The BFI is determined[73,74] by comparing the tensile strength of a compact, σ_T, with that of a compact with a small hole (stress concentrator) in it, σ_{To}, using the tensile test described above. A hole in the center of a compact weakens it. If a material is very brittle, theoretical considerations show that the tensile strength of a tablet with a hole in it will be about one-third that of a "defect free" tablet. If, however, the material can relieve stress, then the strength of the compact with a hole in it will approach that of a compact with no hole. The BFI is defined such that very brittle compacts have a *BFI* of 1, and very nonbrittle materials have a *BFI* close to 0; it is calculated in Eq. (10.10).[73] *BFI* values less than 0.3 (range 0−1) are indicative of relatively nonbrittle materials.

$$BFI = 0.5 \cdot \left[\frac{\sigma_T}{\sigma_{To}} - 1\right] \tag{10.10}$$

10.4.3.8 Viscoelastic index

Hiestand and coworkers have further refined the concept of BI to include both a worst-case and a best-case BI.[75] The BI is determined under different experimental conditions: the rate at which the permanent dent is made in a compact is varied such that the viscoelastic properties of the material are assessed. If a material is very viscoelastic, there is substantial stress relaxation with time. It is reasonable to expect, then, that tablets that are slowly deformed during the determination of the hardness, H, may retain more of the bonded area than tablets that are rapidly deformed (ie, as in the PID). This is because some of the stresses developed during compaction will have a chance to be relieved. The dynamic bonding index (BI_d), sometimes called the worst case BI, is determined using a the PID for measuring the indentation hardness (H_d). On the other hand, the quasi-static bonding index (BI_{qs}), also sometimes referred to as the best case BI, is measured using a "quasi-static" or slow method for measuring indentation hardness (H_{qs}). The dynamic and quasi-static BI is calculated as previously described. The viscoelastic index (VE) is defined as the ratio of the dynamic to quasi-static indentation hardness:

$$VE = \frac{H_d}{H_{qs}} = \frac{BI_{qs}}{BI_d} \tag{10.11}$$

10.4.3.9 Application of Quasi-static testing to formulation development

The application of quasi-static testing methods and interpretation has been discussed extensively in the scientific literature. In addition to the pioneering work of Hiestand and coworkers,[60–62,73–77] additional research discussing the application of this methodology is available.[33,63,80–89] Benefits of a complete characterization of the mechanical properties of both the active ingredient and the excipients used in the formulation include:

- fundamental understanding of critical mechanical properties of the active ingredient and excipients;
- identification of mechanical property deficiencies and attributes;
- selection of excipients that can overcome deficiencies of active ingredient;
- identification of lot-to-lot variations in materials;
- identification of potential manufacturing problems associated with tableting process (Retrieved from http://www.authorstream.com/Presentation/naveen.gokanapudi-1764246-preformulatio).

The reader is directed to the literature for a thorough discussion of the application of mechanical property characterization to formulation development. A fundamental understanding of the mechanical properties is essential to understanding compaction properties and the tableting process.[60,61,75–77,79] Development of mathematical models of mixtures has been used by Amidon,[90,91] and others,[86,87,92] to identify the type and quantity of excipient required to produce tablet formulations that have acceptable manufacturing properties. Fig. 10.11 shows mechanical properties of binary mixtures of microcrystalline cellulose and lactose spray process.[90,91,93] From this figure, one can see that the mechanical properties of a mixture may be estimated knowing the mechanical

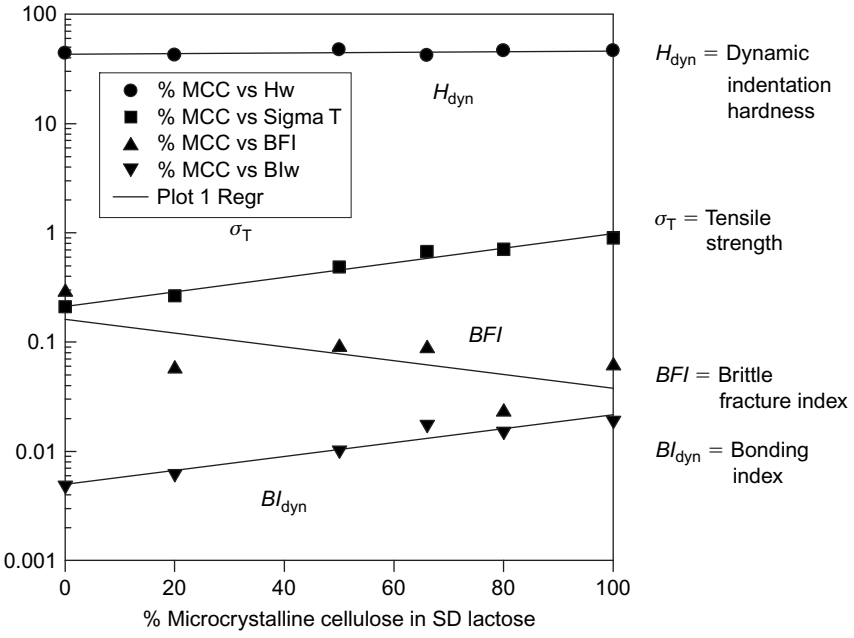

FIGURE 10.11 Mechanical properties of mixtures of microcrystalline cellulose and lactose spray process.

properties of the two individual components. While the mechanical properties of mixtures are complicated,[94,95] estimating the properties of mixtures has been successfully used to identify suitable excipient types and quantities. A simplified equation for binary mixtures is given in Eq. (10.12) or Eq. (10.13):

$$\Phi_{\text{mixture}} = x(\Phi_A) + (1-x)(\Phi_B) \tag{10.12}$$

$$\log(\Phi_{\text{mixture}}) = x\log(\Phi_A) + (1-x)\log(\Phi_B) \tag{10.13}$$

where:

Φ_{mixture} is the mechanical property of interest for the mixture at the reference SF
Φ_A, Φ_B are the properties of the pure components of the binary mixture at the same reference SF
x is the fraction of component A.

While either equation may be used, experience has shown that the log-linear relationship shown in Eq. (10.13) often produces better predictions for mixtures of common lactose-microcrystalline cellulose-based formulations. Further work is needed, however, to explore the science and predictability of mixtures.

For ternary mixtures, that is, for mixtures containing an API as one component and a second "placebo" component containing two excipients, it is possible to estimate the mechanical properties of a mixture by extending this concept, as shown in Eq. (10.14).

$$\log(\Phi_{\text{formulation}}) = y\log(\Phi_{\text{API}}) + (1-y) \cdot([x]\log(\Phi_A) + [1-x]\log\Phi_B) \tag{10.14}$$

where:

y is the fraction of API in the blend
$(1-y)$ is the fraction of the blend that constitutes the placebo component.

While a simplification, this approach has been used to predict the properties of mixtures.[90,91,93] An example of the predicted mechanical properties of a ternary blend of API, and a placebo component consisting of microcrystalline cellulose and lactose spray process, is shown in Fig. 10.12. A sound understanding of the mechanical properties of the individual components, and the range of desirable mechanical property values, allows for a rational selection of excipient types, grades and quantities.

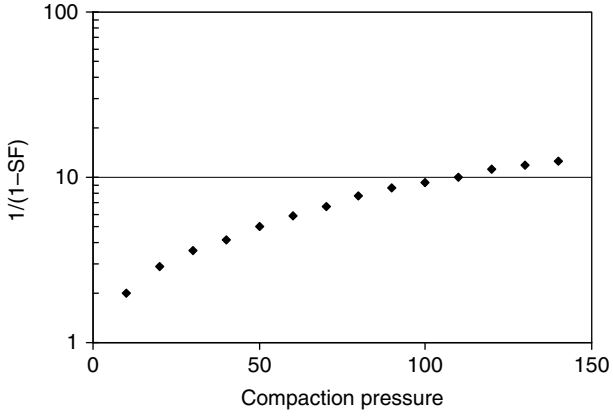

FIGURE 10.12 Heckel plot.

10.4.4 Dynamic testing

The most commonly used methods of studying the mechanical properties of solids under dynamic conditions include the use of the following instrumented equipment:

- Hydraulic press;
- Eccentric (single station) tablet press;
- Rotary tablet press;
- Compaction simulator;
- Compaction emulator (eg, Presster).

Accurate measurements of force and distance require careful construction of equipment and placement of instrumentation; several publications are available discussing these aspects.[96,97] Appropriate care is also needed during calibration, and for correction of measurements due to machine dimensional changes; tablet punches, for example, deform elastically, and these changes should be considered.

While any of these instrumented presses may be used, the most commonly used for dynamic testing is the compaction simulator. The compaction simulator,[98] because of its sophisticated control and monitoring of the compaction process, offers the greatest flexibility in compression conditions. It is possible, for example, to carry out compression under constant velocity conditions for the compression and decompression phases (ie, saw-tooth compression profile)—something not possible with other presses. Also of particular note is the demonstrated utility of a "linear" tablet press emulator (Presster), that offers many of the advantages of a conventional compaction simulator in ease of use and experimental flexibility, as well as its ability to simulate virtually any commercially available rotary tablet press.[99] One limitation of the Presster, though it may also be viewed as a benefit, is that it uses compression rolls of the same dimensions as those on a rotary tablet press. Therefore, compression profiles are limited to those described by conventional tablet press geometries of the tablet punch tooling as it moves under the compression rolls.

With proper instrumentation, "in die" or "at pressure" measurements may be made during the compaction process. For example, the compaction pressure versus tablet porosity (compressibility) may be determined for a single tablet. This information, obtained under

these dynamic testing conditions, can be used to generate an "in die" Heckel plot. Alternatively, measurements may be made on compacts after the tablet is removed from the die. These are "out of die" or "at zero pressure" measurements. Both in die and out of die methods have their advantages. Among the advantages of out of die measurements is that they represent the "final product" after decompression and ejection. The out of die properties are those by which the dosage form are ultimately judged by the formulator, by quality assurance, and by the consumer.

A variety of pressure–porosity equations have been derived over the years.[100–102] The most commonly referenced of them is that of Heckel.[102] The Heckel equation (sometimes referred to as the Athy–Heckel equation) was derived assuming that the change in SF (ie, relative density) with compaction pressure is proportional to the porosity of the compact. Therefore, as porosity approaches zero, the change in SF with compaction pressure, $d\rho/dP$, approaches zero. Therefore:

$$\frac{d\rho_r}{dP} \sim \varepsilon = (1-\rho_r) \tag{10.15}$$

And, integrating Eq. (10.15), results in the classic Heckel equation:

$$\ln\left(\frac{1}{1-\rho_r}\right) = kP + A \tag{10.16}$$

where k is a measure of the plasticity of the material. It is related to the yield strength, Y, of a material by Eq. (10.17).[102,103]

$$k = \frac{1}{3y} \tag{10.17}$$

The constants in the Heckel plot are typically determined by regression analysis of the terminal linear portion of a plot of $\ln(1/(1-\rho_r))$ versus P (see Fig. 10.13). The yield strength, Y, of the material under the dynamic conditions of the test is a measure of the deformability. In addition to yield strength, the shape of the Heckel plot has been used to distinguish volume reduction mechanisms.[104] Three types or families of curves are considered to reflect materials that undergo consolidation primarily by: (1) plastic deformation, (2) fragmentation, or (3) a variation of (1) which is plastic flow with no initial particle rearrangement.

Additional information regarding the compaction process may be obtained using dynamic testing conditions, including work of compaction, work recovered during decompression, work to overcome die wall friction, etc. A detailed discussion of these opportunities is beyond the scope of this chapter, and the reader is directed to the literature for further information. While very valuable as a research tool, the quantitative use of pressure–porosity measurements and analysis beyond the determination of yield pressure does not appear to be used routinely during formulation development and optimization.

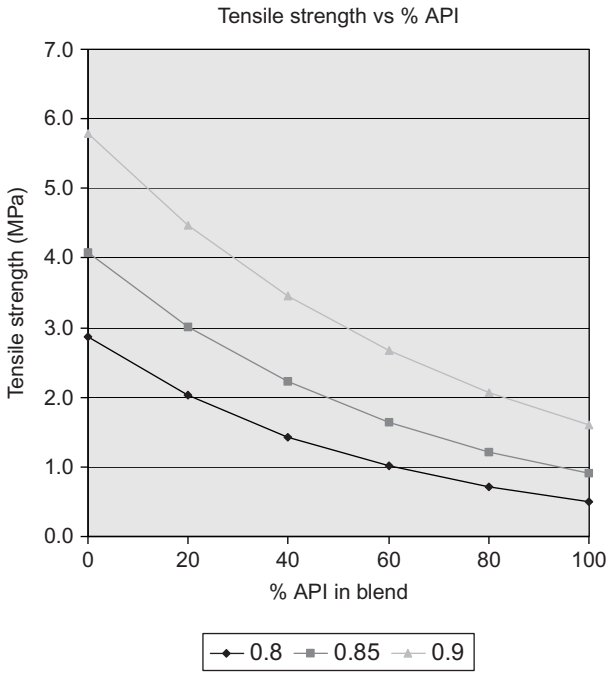

FIGURE 10.13 Predicted mechanical properties of a ternary blend of API, micro crystalline cellulose and lactose spray process.

10.4.4.1 Application of dynamic testing to formulation development

There are a number of reports of the use of dynamic testing of active ingredients and excipients in the literature. There are two key benefits of dynamic testing: (1) the properties can be determined under dynamic conditions representing those in a production environment and (2) small quantities are typically required (2–10 g). In contrast, disadvantages include the difficulty of factoring out the individual mechanical property "components" that, combined, determine how a material behaves during compaction.

The relationships between compaction pressure, tensile strength, and SF are critical to understanding and characterizing the compaction process. The relationship between these three parameters is described as:

- Compactibility: relationship between tensile strength and SF;
- Tabletability: relationship between tensile strength and compression pressure;
- Compressibility: relationship between compaction pressure and SF or porosity;
- Manufacturability: relationship between tablet crushing force and compression force.

Representative compactibility, tabletability, compressibility, and manufacturability profiles for a compactable excipient are shown in Figs. 10.14–10.17. The compactibility, tabletability, and compressibility profiles form the three faces of a three-dimensional plot as shown in Fig. 10.18.[63] The Presster compaction emulator was used for these studies, although other properly instrumented presses can also be used. The compaction emulator was set up to emulate a Killian RST tablet machine (250 mm compression rolls) with a 27 ms dwell time (corresponding to 28,800 tablets/hour) using 10 mm diameter flat-faced round punches with no precompression force.

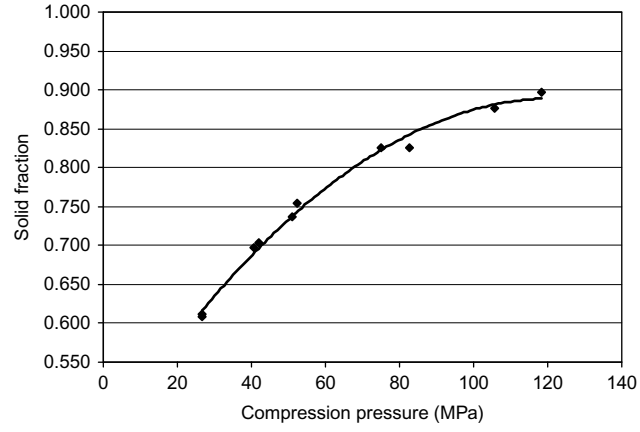

FIGURE 10.16 Compressibility profile using a compaction emulator.

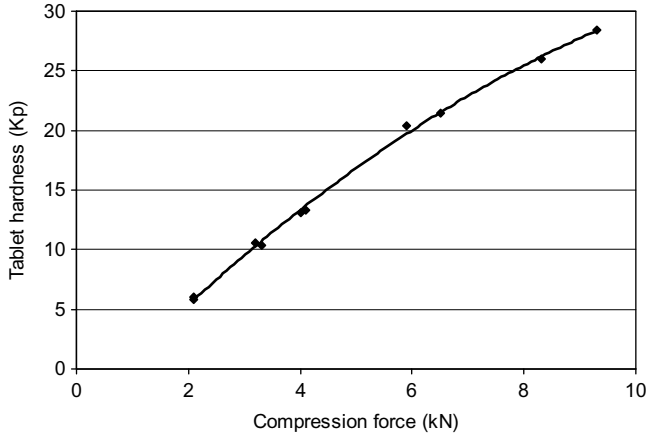

FIGURE 10.17 Manufacturability profile using a compaction emulator.

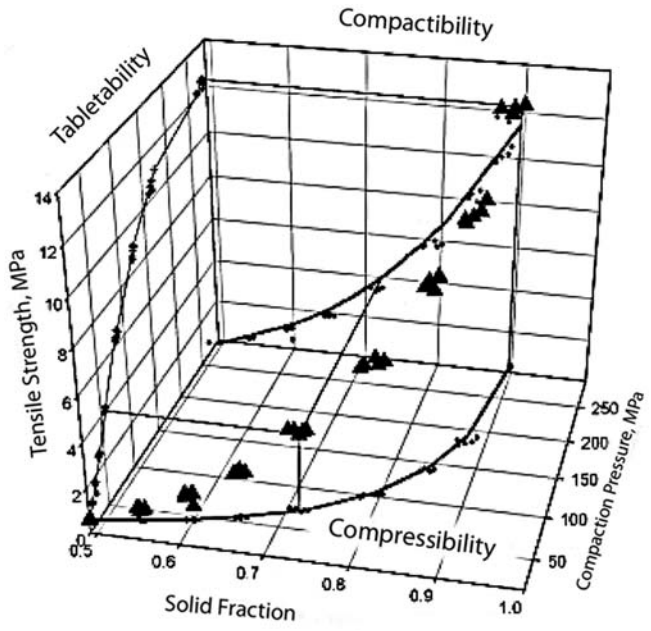

FIGURE 10.18 Three-dimensional tablet tensile strength, solid fraction, and compaction pressure curve.

Compactibility is the ability of a powder to be transformed into tablets with a resulting strength.[105] It is represented by a plot of tensile strength versus SF. The compactibility is the most valuable of the three properties since it reflects the two most important effects of applied pressure: tablet strength, and SF. A representative compactibility profile of an excipient is shown in

Fig. 10.14. If one can achieve an acceptable tensile strength at an acceptable SF with the application of pressure, a satisfactory tablet can be produced. Compactibility plots are largely independent of the process by which compacts are made since only measured tablet properties (tensile strength and SF) are involved. Compactibility plots are useful as a tool to compare formulations made on different equipment. If the formulations are the "same," then the "same" compactibility plots will be obtained.[63]

Tabletability is the capacity of a powder to be transformed into a tablet of specified strength under the effect of compaction pressure.[105] It is represented by a plot of tensile strength versus compaction pressure. Tabletability describes the effectiveness of the applied pressure in increasing the tensile strength of the tablet, and demonstrates the relationship between the cause (the compaction pressure), and the effect (the strength of the compact) (see Fig. 10.15). Normally, a higher compaction pressure makes a stronger tablet. However, this relationship is often found to be speed dependent. Also, at high pressures, some materials may have lower tensile strength due to overcompaction.[106] Characterization of the tabletability provides excellent insight into the compaction process and mechanical properties of a material.

Compressibility is the ability of a material to undergo a reduction in volume as a result of an applied pressure.[105,107] It is a measure of the ease with which a powder bed undergoes volume reduction under compaction pressure; it is represented by a plot showing the reduction of tablet porosity (ie, the increase in SF) with increasing compaction pressure (Fig. 10.16). Compressibility is often described by the Heckel equation.[102] Heckel plots, for example, have been widely used to assess the mechanism of deformation, and as a tool to estimate yield pressure. It is also well-known that tablet porosity is an important parameter, for example, in tablet disintegration and dissolution, since some porosity is often necessary to facilitate liquid penetration into tablets.[103,108]

Manufacturability, a plot closely related to tabletability, shows the relationship between the tablet crushing force (related to tensile strength), and compaction force (related to compression pressure). The manufacturability profile (Fig. 10.17) is commonly considered by formulation scientists since it reflects the "measured" properties of a dosage form during manufacturing (tablet crushing strength and compression force). In general, however, pressure and tensile strength are preferred parameters to consider.

In summary, characterization of the compactibility, tabletability, compressibility, and manufacturability of a formulation provides valuable information of the compaction process and the prospects for a successful tableting process in manufacturing. Obtaining tablets with adequate tensile strength at a reasonable SF with acceptable compression pressure is the key to success. Robust formulations must not be on the "edge;" that is, they should provide the manufacturing scientist with the ability to adjust compression pressure to achieve the desired tensile strength and still maintain the SF in a desirable range, such that the tablet performs as required.

10.5 CONCLUSIONS

As timelines become tighter and shortened, it has become more important than ever to quickly and efficiently characterize the critical properties of materials that will influence product development and performance. In this chapter, a discussion of those particle, powder, and compact properties that are most important in developing solid dosage forms has been discussed. The focus has been on methods that yield important information, yet require small quantities of materials. With a sound understanding of these properties, formulation development can proceed most efficiently and scientifically with greater success. Tomorrow's formulation and process scientists will require a sound understanding of these pharmaceutical material science principles, and must be able to apply them to the design and development of dosage forms in an efficient and scientifically rigorous way. The beauty of science is the knowledge and ability it gives us to predict the future reliably. As formulation and process scientists, the future we need to predict accurately is that of a consistent, reliable, manufacturable product that performs as expected.

11.1 BARRIERS TO ORAL DRUG DELIVERY

Oral drug delivery is the most popular and economical route of drug administration. Barriers to oral drug delivery include solubility and dissolution, absorption, presystemic metabolism, and excretion. For drugs whose targets are easily accessible, the portion of drugs reaching systemic circulation after overcoming all of these barriers is considered bioavailable. Certain drugs that must reach hard-to-access target organs, such as the central nervous system (CNS) and drug-resistant cancer cells; and must be transported across additional barriers (eg, the blood–brain barrier) to their targets. Consequently, these barriers may represent an additional hurdle that should be overcome for delivering orally administered drugs.

All oral drugs must generally be dissolved in the aqueous environment of the gastrointestinal (GI) tract before they can be absorbed. This seemingly simple process is actually a significant challenge to the development of new oral drugs, especially lipophilic molecules that are poorly soluble in aqueous solutions. Several chapters in this book deal with this issue; thus, we will not discuss them in detail here. An important issue to recognize is that the transit time for solid-dosage forms or undissolved drug solids in the upper GI tract (ie, stomach and small intestine) typically ranges from 2 to 6 hours.[1] Therefore, dissolution rates must be sufficiently high to dissolve these solids for absorption.

Once dissolved in the gastric fluid, drug molecules must stay soluble throughout the GI tract. This requirement is not trivial because the pH of the GI tract changes from highly acidic (pH1.5) in the stomach to slightly basic (pH8) in the lower small intestine and colon; as this change could alter the solubility of numerous drugs, this factor should be considered when designing solubility and dissolution experiments.

Dissolved drugs are absorbed via different transcellular and paracellular pathways across the intestinal tract. A paracellular pathway is defined as drug transport between cells, whereas a transcellular pathway is defined as drug transport across the cells (through apical and basolateral membranes). Transcellular pathways include passive diffusion and carrier-mediated transport, whereas paracellular pathways mainly involve passive diffusion.

Drugs are primarily absorbed in the small intestine, where the absorption area is very large (100 m^2 or an area equivalent to that of a tennis court). Absorption in the colon is generally limited and can be highly variable because of undigested materials, bacteria, and variable water content. Given these factors, GI transit plays a significant role in the absorption of drugs.

Developing Solid Oral Dosage Forms
DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00011-X

After absorption into intestinal cells, some drugs may be subjected to first-pass metabolism by various intestinal metabolic enzymes. Escaping the intestinal metabolism does not guarantee bioavailability because the drugs absorbed from the stomach and intestine (large and small), with the exception of those absorbed at the terminal rectum, are subject to additional first-pass metabolism by the liver. Metabolites formed in the intestinal cells can be directly or indirectly excreted back to the lumen after they are taken up by the liver cells and excreted via bile. Metabolites formed in hepatocytes can also be excreted via bile. Alternatively, all metabolites formed in enterocytes or hepatocytes may stay in the blood, where they are eliminated via the kidneys.

11.1.1 Intestinal barrier

The intestinal tract is traditionally recognized as an organ for absorption. However, absorption in this organ does not occur without selection, which is based on several factors. The first factor is the size of the molecules. Large molecules are not absorbed unless their quantities are minute, such as in the case of antigen delivery (eg, polio vaccine). Hepatic, pancreatic, gastric, and intestinal enzymes will degrade typical macromolecules, such as proteins, polypeptides, and polysaccharides, into much smaller molecules. These smaller molecules are often hydrophilic and require the assistance of protein transporters in order for uptake into the cells to occur. This size restriction is enabled by the mechanical barrier of the intestinal cells, which is made of mucus, cell membranes, and tight junctions.

Several small molecules can diffuse into the circulatory system with ease via passive diffusion, but others cannot because of the presence of efflux transporters (eg, P-glycoproteins (P-gps)), which prevent the entrance of certain lipophilic substances. Small molecules that are taken up by the intestinal cells can be rapidly metabolized by the phase I and phase II enzymes in the enterocytes. Phase II enzymes appear to be the major metabolic enzymes that are capable of deactivating a large number of polyphenols and phenolics.[2] The excretion of phase I metabolites is usually straightforward, with the vast majority using the same pathway as the parent compound. The excretion of many phase II metabolites, especially those that are highly hydrophilic, requires the action of efflux transporters.[2] These transporters are often coupled to the phase II enzymes to achieve optimal functionality.

Finally, the expression of enzymes and transporters is highly region-dependent. Duodenal expression of an enzyme or a transporter is usually, if not always, different from those of the terminal ileum and colon.[3,4] These region-dependent expression levels can often be used as indicators that a transporter or enzyme is involved in drug uptake via experimental systems (eg, regional intestinal perfusion) that take advantage of this fact.

11.1.2 Hepatic barrier

The hepatic barrier is distinctly different from the intestinal barrier, in that the liver tends to be relatively uniform. The primary barrier of the liver is the presence of vast amounts of metabolic enzymes, which tend to inactivate lipophilic substances absorbed from the intestine that also escape intestinal metabolism. Both phase I and phase II enzymes are expressed in abundant quantities and varieties in the liver. The main phase I enzymes in the liver belong to the cytochrome P450 superfamily. These enzymes often produce metabolic products that can be further conjugated (via phase II enzymes) to hydrophilic moieties so that the final metabolites are highly hydrophilic. Then hydrophilic metabolites are often excreted to bile or carried to the kidneys for elimination.

Another important component of the liver barrier is the presence of various efflux transporters that line the bile canalicular membrane.[5] These transporters are capable of excreting parent compounds, phase I metabolites, and phase II metabolites out of the hepatocytes. Similar to the phenomena in the intestine, the functions of enzymes and efflux transporters can be interdependent, thereby resulting in significantly faster and more extensive metabolism than predicted. These coupling processes have been labeled as *double jeopardy* and *revolving door* mechanisms; explanations of these processes are provided later in the chapter.

11.2 PATHWAYS OF DRUG ABSORPTION

Absorption is the process of transferring chemical substances from the GI tract through its wall into the bloodstream and lymphatic stream. In general, absorption does not differ between drugs and food, but different mechanisms of absorption and differences in absorption rates occur in different parts of the GI tract. The absorption of drugs depends on physicochemical factors, including formulation factors (eg, rates of disintegration and rates of drug release from polymeric dosage forms), drug factors (eg, solubility and lipophilicity), and biological factors (eg, stomach-emptying rate and GI membrane permeability).

The two main mechanisms of drug transport across the GI epithelium are transcellular (ie, across cells) and paracellular (ie, between cells). The transcellular pathway is further divided into simple passive diffusion,

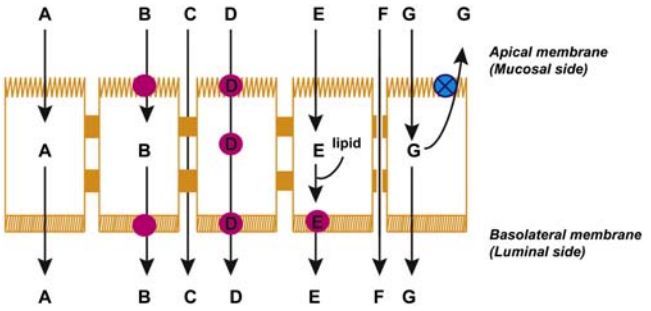

FIGURE 11.1 Potential modes of absorption of drug molecules across the intestinal epithelium: A, transcellular passive diffusion; B, carrier-mediated transcellular diffusion; C, paracellular diffusion; D, transcellular diffusion by endocytosis; E, transcellular diffusion and incorporation into lipid particles; F, paracellular diffusion with a modulator of tight junctions; G, transcellular diffusion modified by a polarized efflux mechanism.

carrier-mediated transport (active transport and facilitated diffusion), and endocytosis. These pathways are illustrated in Fig. 11.1. Transport across the healthy intestinal epithelium by the paracellular route (pathway C) is minimal because of the presence of tight junctions. Only small hydrophilic molecules are allowed to pass between cells unless a modulator of the tight junctions (pathway F) is present.[6,7] Transcellular transport of a molecule can occur via a passive mechanism (pathway A) or by a specific carrier (pathway B). For passive flux to occur, a molecule must have the correct physicochemical properties (eg, size, charge, lipophilicity, hydrogen-bonding potential, and solution conformation) to cross the lipophilic apical and basolateral membranes and diffuse through the cytoplasm, which is an aqueous environment separating the two membranes.[8] However, compounds that are absorbed by this route may be substrates for intracellular metabolism and apically polarized efflux mechanisms (pathway G), such as P-gps, which transport compounds from inside the cell back into the intestinal lumen.[8,9] Compounds may also be transcellularly absorbed by utilizing naturally occurring carriers that will transport the compounds from the lumen into the cell. Some drugs are absorbed via carrier-mediated pathways. For instance, L-dopa and oral cephalosporins are absorbed by amino acid and dipeptide transporters, respectively.[10,11] Endocytosis of compounds (pathway D) is minimal in the adult small intestine and is not a probable mechanism of drug absorption by the intestine. Most orally administered drugs are absorbed by passive transport.[8]

11.2.1 Paracellular diffusion

The paracellular pathway involves the transport of materials between cells rather than across cells. The pathway differs from all the other absorption pathways described later in this chapter. In the intestine, the cells are joined together via closely fitting tight junctions on their apical side. The intercellular spaces occupy only about 0.01% of the total surface area of the epithelium. The tightness of these junctions can considerably vary between different epithelia in the body. The paracellular pathway decreases in importance downstream of the GI tract because the numbers and sizes of the junctional gaps between the epithelial cells decrease.

The paracellular route of absorption is important for the transport of ions, such as calcium, and the transport of sugars, amino acids, and peptides at concentrations above the capacity of their transport carriers. Small hydrophilic and ionized drugs are not distributed into cell membranes, and they cross the GI epithelium via the paracellular pathway. The molecular weight cutoff for the paracellular route is usually considered to be 200 Da, although some larger drugs have been shown to be absorbed via this route, albeit usually at exceedingly small quantities. The paracellular pathway can be divided into a convective (solvent drag) component and a diffusive component. The convective component is the rate at which the compound is carried across the epithelium as the result of the water flux.

11.2.2 Passive diffusion

Passive diffusion is the preferred main route of absorption; thus, it is more likely to be used by low-molecular-weight lipophilic drugs. In the process, drug molecules pass the lipid membrane via passive diffusion from a region of higher concentration in the lumen to a region of lower concentration in the blood. This lower concentration is primarily maintained by the blood flow. The rate of transport is determined by the physicochemical properties of the drug, the nature of the membrane, and the concentration gradient of the drug across the membrane. The process initially involves the partitioning of the drug between the aqueous fluids within the GI tract and the lipoidal-like membrane of the epithelial membrane. The drug in the membrane diffuses across epithelial cells or cells within the GI barrier to the blood in the capillary network of the lamina propria. Upon reaching the bloodstream, the drug is rapidly carried away by blood flow, thereby maintaining a much lower concentration at the basal side than that at the apical side, thereby maintaining the so-called sink effect. If the cell membranes and fluid regions of the GI-blood barrier are modeled as a single membrane, the stages of GI absorption could be represented by the model in

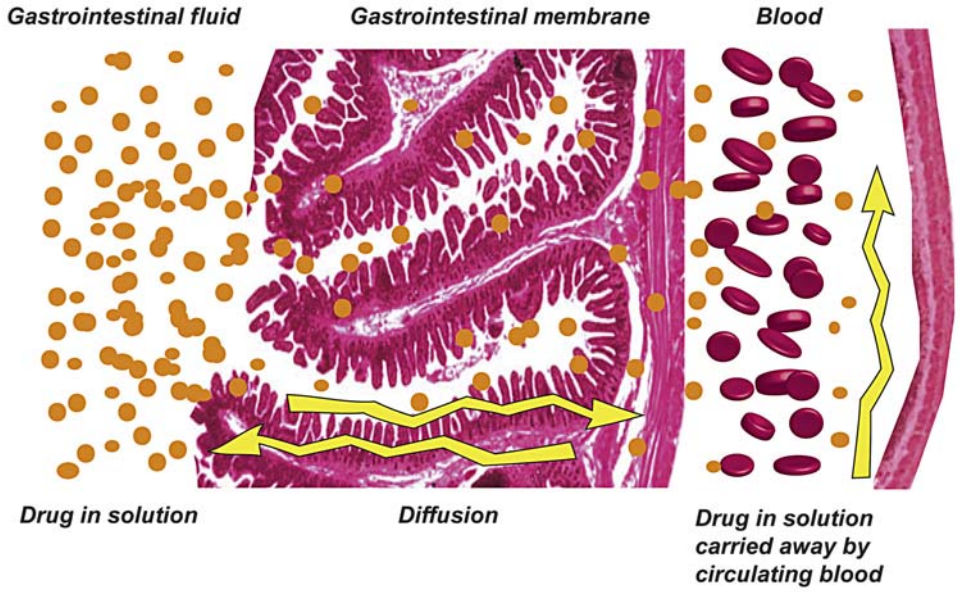

FIGURE 11.2 Diagrammatic representation of absorption via passive diffusion.

Fig. 11.2. The mechanism of the passive pathway follows Fick's law, where the absorption rate is proportional to the drug concentration gradient and the surface area. Given the notably different lipid and protein compositions of the apical and basolateral membranes, the rate of passage across these two barriers could be different for the same molecule.

The pathway has been assumed to exist solely in one single absorbable species. However, many drugs are weak electrolytes that exist in aqueous solution as two species: the unionized species and the ionized species. The unionized form of a weak electrolyte drug exhibits greater lipid solubility compared with the corresponding ionized form, and the GI membrane is more permeable to the unionized species. Thus, the rate of passive absorption of a weak electrolyte is related to the fraction of the total drug that exists in the unionized form in solution in the GI fluids at the site of absorption. This fraction is determined by the dissociation constant of the drug (eg, its pK_a) and by the pH of the aqueous environment. According to the pH-partition hypothesis, if the pH on one side of a cell membrane differs from the pH on the other side of the membrane, then the drug (weak acid or base) will be ionized to different degrees on the respective sides of the membrane. Moreover, the total drug concentration (ionized plus unionized drug) on either side of the membrane will be unequal, with the compartment in which the drug is more highly ionized containing the greater total drug concentration. For these reasons, a weak acid will be rapidly absorbed from the acidic environment (such as pH1.2), whereas a weak base will be poorly absorbed from the acidic environment.

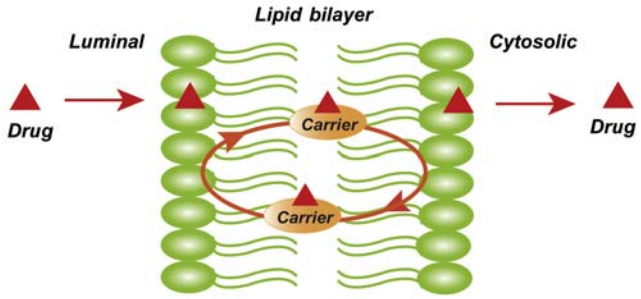

FIGURE 11.3 Schematic representation of the carrier-mediated transport of a drug across the intestinal membrane.

11.2.3 Carrier-mediated transport

Theoretically, a lipophilic drug may pass through a cell or move around cells during the absorption process. If the drug has a low molecular weight and is lipophilic, the lipid cell membrane is not an effective barrier to drug diffusion and absorption. For hydrophilic drug molecules, numerous specialized carrier-mediated transport systems, present in the body (especially in the intestine), may be used for their absorption. Normally, these carriers are utilized for the absorption of ions and nutrients and involves specific interaction between the molecule and the transporter or carrier in a saturable mechanism, as shown in Fig. 11.3. Two types of transport exist: active and passive carrier-mediated transport. The active carrier-mediated transport is either Na^+- or H^+-linked with bifunctional carriers. This process requires metabolic energy and can work against a concentration gradient of the substrate. By contrast, passive carrier-mediated

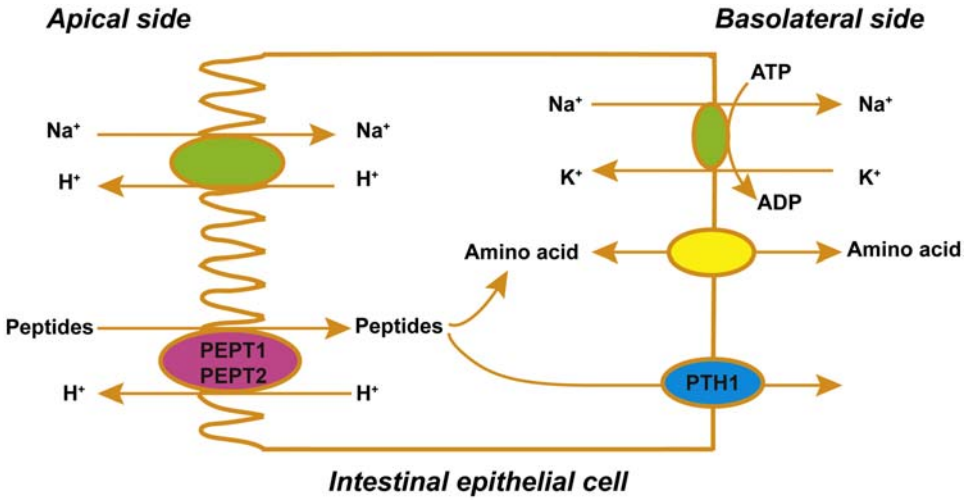

FIGURE 11.4 Accepted model for intestinal transepithelial peptide transport.

transport does not require metabolic energy and is driven by the concentration gradient of substrate. These carrier-mediated mechanisms are utilized by some drugs as pathways for entering cells. The best documented examples are β-lactams and cephalosporin antibiotics,[12] which are substrates for proton-driven dipeptide transporters. Peptide mimetic angiotensin-converting enzyme inhibitors, such as captopril, are also absorbed by carrier-mediated systems.[13]

11.2.3.1 *Active transport*

Compared with passive diffusion, active transport is an energy-consuming process where compounds can be transported against a concentration gradient across a cell membrane (ie, transport can occur from a region of lower concentration to one of higher concentration). This process is illustrated in Fig. 11.3. The energy arises either from the hydrolysis of adenosine triphosphate (ATP) or from the transmembrane ion gradient, electrochemical potential, or both. Numerous carrier-mediated active transport systems or membrane transporters are available in the small intestine and can be present on either the apical or basolateral membrane. These membrane transport systems include peptide transporters; nucleoside transporters; sugar transporters; bile acid transporters; amino acid transporters; organic anion transporters (OATs); efflux transporters of multidrug-resistant (MDR) proteins, such as MDR1, multidrug-resistant associated proteins (MRPs), and breast cancer resistant protein (BCRP); and vitamin transporters.

Unlike passive absorption, where the rate of absorption is directly proportional to the concentration of the absorbable species of the drug at the absorption site, active transport only proceeds at a rate that is proportional to the drug concentration at low concentrations. The carrier mechanisms may become saturated at higher concentrations, and further increases in drug concentration may not increase the rate of absorption (ie, the rate of absorption remains constant).

Competition occurs between two similar substrates for the same transport mechanism, and inhibition of absorption of one or both compounds is another characteristic of carrier-mediated transport. Some substances may be absorbed by simultaneous carrier-mediated and passive transport processes. Generally, the contribution of the carrier-mediated process to the overall absorption rate decreases with concentration and is negligible at a sufficiently high concentration.

In summary, the characteristics of active transport mechanisms are as follows: (1) The process must have one or multiple carrier transporters, (2) the process must be activated by ATP energy, (3) the process shows temperature dependence, and (4) active transport can be competitively inhibited by substrate analogs or specific inhibitors. Active transport also works to excrete several drugs in the intestine, kidney, liver, and bile.

11.2.3.1.1 Peptide transporters

As described previously, most oral chemical drugs rely on passive diffusion to cross cell membranes. However, some orally administered peptidomimetic drugs are absorbed through the intestinal peptide transport system[14,15] (Fig. 11.4). In this transport process, the proton gradient provide the driving force for peptide uptake into intestinal epithelial cells via proton-dependent peptide transporters located in the apical membranes.[16] Peptides that are resistant to hydrolysis by intracellular peptidases are transported across the basolateral membrane via the basolateral peptide transporters.[17] The Na^+/H^+-exchanger generates and

maintains the inward proton gradient on the luminal surface, while the Na^+/K^+-ATPase present in the basolateral membrane maintains a low intracellular sodium concentration. Protons are cotransported with peptides across the epithelial membrane; thus, this system is also referred to as the H^+-dependent peptide cotransport system.[16] Peptide transporters can accept dipeptides and tripeptides as physiological substrates, thereby indicating their much broader substrate specificity than other nutritional transporters. Consequently, drugs and xenobiotics with structures resembling small peptides (eg, β-lactam antibiotics), are recognized by the peptide transporters. Therefore, peptide transporters work as nutritional transporters and drug transporters (Fig. 11.4).

Currently, the peptide transporters are divided into two types: those localized at the brush-border membranes of epithelial cells, and those localized at the basolateral membrane of intestinal and renal epithelial cells. Two-border-type peptide transporters have been identified and designated as PEPT1 and PEPT2. These polytopic integral membrane proteins have 12 predicted membrane-spanning domains (MSDs) and NH_2- and COOH-terminal ends facing the cytosol. Western blot analysis of protein preparations of the intestine and kidney have identified PEPT1 and PEPT2 via immunoreactivity as glycosylated proteins with molecular masses of about 75 and 100 kDa, respectively.[18,19] The mammalian PEPT1 protein is comprised of 701−710 amino acids, depending on the species, and is highly glycosylated.[20−22] Digestion of PEPT1 (about 75 kDa) with endoglycosidase A shifts its mass significantly to 63 kDa.[22] The PEPT2 gene encodes a 729−amino acid protein[19] and shares 48% amino acid identity with PEPT1 predominantly in transmembrane domains (TMDs). PEPT1 and PEPT2 share the lowest identity in the large extracellular loop connecting TMD9 and TMD10, perhaps signaling some difference in substrate-binding recognition. The PEPT2 protein is also glycosylated; the molecular mass of the mature protein is about 107 kDa and its nonglycosylated mass is 83 kDa.[23] The genomic organization of peptide transporter genes has also been elucidated. Human PEPT1 and PEPT2 genes, for example, have been mapped to chromosomes 13q33-34 and 3q13.3-q21, respectively.[21,24]

Peptide/histidine transporter 1 (PHT1) have substrate specificity similar to that of PEPT1 and PEPT2 but possess other distinct functional properties. Unlike PEPT1 and PEPT2, these transporters are localized at basolateral membranes of intestinal and renal epithelial cells.[25] Absorption of peptidelike drugs through the intestinal epithelial requires the crossing of two distinct membranes; that is, uptake by epithelial cells from the lumen across the brush-border membrane (presumably by PEPT1/PEPT2), followed by transfer to the bloodstream across the basolateral membrane (presumably by PHT1). Although orally active β-lactam antibiotics are efficiently taken up from the intestine, these compounds are difficult to move across the basolateral membranes by passive diffusion because of their hydrophilicities. This leads to the study of the basolateral peptide transporter in the intestinal epithelial cells. The characterization of peptidelike drug transport via the basolateral membranes of Caco-2 cells grown on microporous membrane filters demonstrated that the PHT1 transporter, which is distinguished from PEPT1, is expressed in the basolateral membranes of intestinal epithelial cells.[26,27]

The intestinal peptide transporters, especially PEPT1, have been key target molecules for prodrug approaches.[28] Under this scheme, appropriately designed molecules in the form of dipeptide or tripeptide analogs can be absorbed across the intestinal brush-border membranes via PEPT1 and may be absorbed intact or hydrolyzed intracellularly by peptidases or esterases prior to exiting the cells. In addition to PEPT1, the intestinal basolateral PTH1 transporter has the ability to transport nonpeptidic compounds such as δ-ALA, which is a precursor of porphyrins and heme. Here, δ-ALA plays an important role in the production of heme-containing proteins.[27] The transport of δ-ALA by PEPT1 and the basolateral peptide transporter has been reported to explain the good bioavailability of δ-ALA (approximately 60% in humans).[27,29]

11.2.3.1.2 Amino acid transporters

The endothelial lining of blood vessels provides a barrier for the exchange of nutrients and is actively involved in the local control of vascular homeostasis. Multiple transport systems mediate the influx of cationic, neutral, sulfonic, and anionic amino acids across the plasma membrane of mammalian cells. Molecular cloning approaches have led to the identification of Na^+-dependent and Na^+-independent amino acid transport systems. Table 11.1 summarizes the nomenclature used to designate these amino acid transport systems. Note that the ionic dependency and K_m corresponding to the different transport systems were compiled from the cited publications and do not necessarily reflect the transport properties of all cell types.[30]

The different carrier proteins mediating transport of cationic amino acids include the Na^+-independent systems y^+, y^+L, $b^{0,+}$, and b^+, as well as the Na^+-dependent system $B^{0,+}$. System b^+ was originally described in mouse blastocysts and is highly specific for cationic amino acids, whereas the other systems also can transport neutral amino acids. System y^+ is the principal cationic amino acid transport system expressed in NO-producing cells and most likely plays a key role in regulating L-arginine supply for NOS. Although

TABLE 11.1 Mammalian Amino Acid Transport Systems and Identified Transporters[30]

Transporter system	Associated protein or cDNA	SLC number	Amino acid selectivity	Ionic dependency	K_m, μM
CAT-ASSOCIATED TRANSPORT					
y^+	CAT-1	SLC7A1	Cationic	No	70–250
	CAT-2A or CAT-2/2α	SLC7A2	Cationic	No	2150–5200
y^+	CAT-2B or CAT-2/2β	SLC7A2	Cationic	No	38–380
$y^{+?}$	CAT-3	SLC7A3	Cationic	No	40–120
	CAT-4	SLC7A4	Cationic (Arg)	No	450–910
HETERODIMERIC GLYCOPROTEIN (4F2HC, CD98)–ASSOCIATED TRANSPORT					
y^+L	y^+LAT1	SLC7A7	Neutral/cationic	Na^+ (neutral)	340
y^+L	y^+LAT2	SLC7A6	Neutral/cationic	Na^+ (neutral)	6–10
L	LAT1/LAT2	SLC7A8	Large neutral	No	30–300
x_c^-	xCT	SLC7A11	Cystine/glutamate	No	40–92
Asc	Asc-1	SLC7A10	Small neutral	No	9–23
rBAT-ASSOCIATED TRANSPORT					
$b^{0,+}$	$b^{0,+}$, AT	SLC7A9	Neutral/cationic cystine	No	88
UNKNOWN HEAVY CHAIN–ASSOCIATED TRANSPORT					
asc	Asc-2	SLC7A10	Small neutral	No	2.9
NA^+ AND/OR CL^- OR H^+–ASSOCIATED TRANSPORT					
A	ATA1/2/3(SAT1/2/3 or SA 1/2/3)	SLC38A1	Neutral/N-Me group	Na^+	> 200
N	SN 1/2/3	ASNS	Gln, Asn, His	Na^+/H^+	150–1600
ASC	ASCT 1/2[a]	SLC1A4	Neutral	Na^+	9–464
$B^{0,+}$	$ATB^{0,+}$	SLC6A14	Neutral/cationic	Na^+/Cl^-	23–140
Pro	PROT[a]	SLC6A7	Praline	Na^+/Cl^-	6
Gly	GLYT 1/2[a]	SLC6A5/9	Glycine	Na^+/Cl^-	17
Betalike	mTAUT[a]	SLC6A6	β-amino-acids	Na^+/Cl^-	3–13
	GAT-1-3	SLC6A11/12	GABA and/or β-amino acid	Na^+/Cl^-	1–20
	BGT-1				
	EAAT1-5[a]	SLC1A3/2/1/4/5	Glu and/or Asp	Na^+, OH^-/HCO_3	18–97
X^-_{AG}			Glu, Asp	Na^+	About 200
x^-_{AG}			Glu	No	About 230

[a]*Cloned high-affinity amino acid transporters from the brain or retina that may not exhibit kinetic properties described in other peripheral cell types. Lowercase nomenclature for the classical transport systems denotes Na^+-independence.*

Summary of the classical nomenclature for the majority of amino acid transport systems and the nomenclature adopted for recently cloned amino acid transport proteins. The substrate specificity, ionic dependency, and Michaelis constant (K_m) values included in this table were compiled from the cited references and reviews.

Ala, alanine; Ser, serine; Cys, cysteine; Gln, glutamine; Asn, asparagine; His, histidine; Glu, glutamate; Asp, aspartate.

information on ASCT-, PROT-, GLYT-, TAUT-, and EAAT-associated amino acid transport in vascular cells is limited, recent evidence indicates that bovine aortic endothelial cells express a taurine transporter sharing a high degree of sequence homology with that of the mTAUT complementary DNA (cDNA) isolated from the brain.[31]

Similarities between the transport of cationic amino acids in renal proximal tubules and the small intestine have been recognized. In patients with the renal abnormality cystinuria, lysine and ornithine transport in the intestinal tract is also defective. For this reason, and with considerable prescience, the genetic defect underlying cystinuria is also evident in the small intestine. This

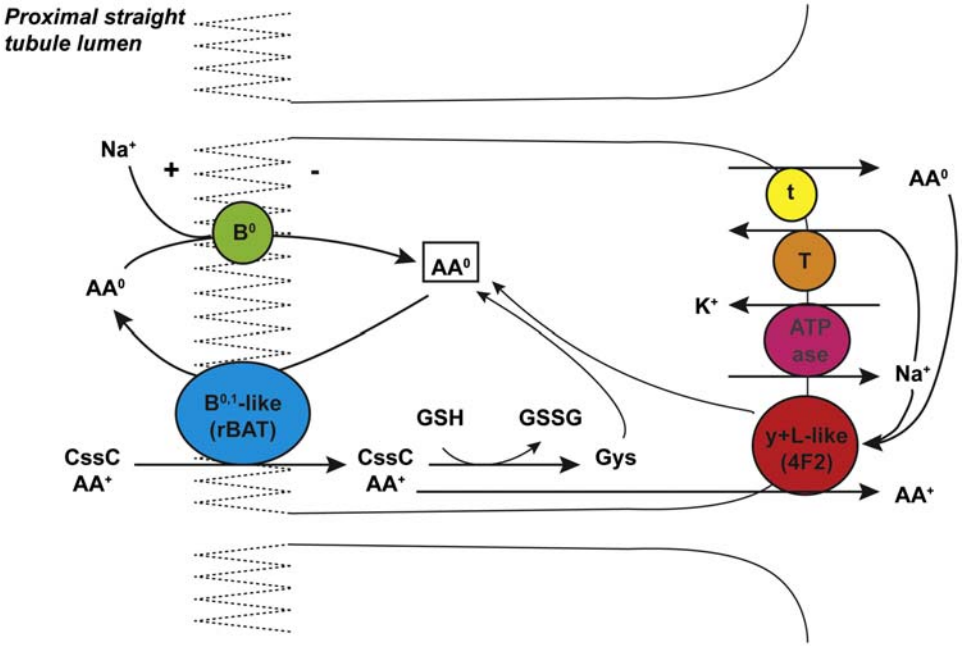

FIGURE 11.5 Model for renal reabsorption of cationic amino acids (AA^+) and cysteine (CssC). Participation of various broad-scope systems ($b^{0,+}$, y^+L, and $B^{0,+}$) and interactions with neutral amino acids (AA^0) are indicated. Note the proposed functions of rBAT ($b^{0,+}$) and 4F2 (y^+L) proteins in apical and basal membranes, respectively. *GSH*, glutathione; *GSSG*, oxidized glutathione. *Source: Redrawn from Deves R, Boyd CA. Transporters for cationic amino acids in animal cells: discovery, structure, and function.* Physiol Rev *1998;78:487–545.*

notion is compatible with the findings of early studies, which indicated that net transport of three basic amino acids against a concentration gradient occurs in the hamster intestine in vitro, and that these amino acids share the same transport system as cysteine.[32]

The Na^+-dependent and Na^+-independent transport systems for cationic amino acids have been identified in the brush border of the small intestine. Evidence also shows that efflux across the basolateral membrane constitutes a rate-limiting step of transepithelial cationic amino acid transport. During lysine transport across the intact epithelium, the intracellular amino acid concentration may be up to fivefold higher than that in the lumen; by contrast, the accumulation of solute in tissues is much less for neutral amino acids.[33,34]

The principles of transepithelial cationic amino acid transport exemplified in the intestine are also applicable to the kidney. In the kidney, the Na^+ dependence and electrogenicity of the brush-border transport of cationic amino acids are controversial. Thus, various studies with membrane vesicles conclude that Na^+-dependent secondary active transport occurs,[35] that transport is electrogenic but Na^+-independent,[36] and that electroneutral transport takes place in the absence of Na^+.[37] A model for the reabsorption of cationic amino acids in the kidney was recently proposed and is shown in Fig. 11.5.[32]

11.2.3.1.3 Organic anion-transporting peptides

OATs and organic cation transporters (OCTs) are two of the major transporter families responsible for the absorption, distribution, and elimination of environmental xenobiotics, plant or animal toxins, and drugs. Although both transport systems have distinct substrate preferences, OAT is for those carrying negative charges and OCT is for those carrying positive charges. Both share several common features, including similar predicted transmembrane topology, interaction with numerous structurally and pharmacologically diverse compounds, and broad expression patterns in tissues, such as kidney, liver, intestine, brain, and placenta. Six members of the OAT family have been identified thus far: OAT1, OAT2, OAT3, OAT4, OAT5, and URAT1. These OATs have primary structures of 526–568 amino acid residues and a predicted secondary structure of 12 TMDs. These multispecific transporters are expressed in a variety of tissues, including the kidney, liver, brain, and placenta, with a wide range of recognized substrates. Six members of the OCT family have been identified: OCT1, OCT2, OCT3, OCTN1, OCTN2, and OCTN3. Based on their primary structures, OCTs and OCTN3 are distinct subfamilies within the OCT group. Like OATs, common structural features of OCT family members include 12 TMDs, a large hydrophilic loop between TMDs 1 and 2 carrying several potential glycosylation

sites, and multiple potential phosphorylation sites localized on the large intracellular loop between TMDs 6 and 7.[38]

OAT1 and OAT3 transporters belong to the classically described OATs in the kidney proximal tubules, which utilizes a tertiary transport process to move organic anions across the basolateral membrane into the proximal tubule cells for subsequent exit/elimination across the apical membrane into urine. This tertiary process in the basolateral membrane includes the following steps:

1. Na^+ K^+-ATPase pumps Na^+ out of the cells and generates an inwardly direct Na^+ gradient.
2. This Na^+ gradient then moves dicarboxylates into the cells through an Na/dicarboxylate cotransporter ($SDCT_2$). This process, in conjunction with an ongoing cellular metabolic activity, sustains an outwardly directed dicarboxylate gradient.
3. The dicarboxylate gradient transfers organic anions into the cells via OAT1 and OAT3, which serve as organic anion/dicarboxylate exchangers.

Whether other members of the OAT family, such as OAT2 and OAT4, use a similar transport mechanism remains unknown. Oat5 is exclusively localized in the kidney. Oat5 urinary excretion was recently proposed as a potential early biomarker of acute kidney injury.[39]

After being transported across the basolateral membrane into the proximal tubule cells, organic anions exit across the apical membrane into the urine for elimination. However, the mechanism for this apical step is not yet well understood.[40,41]

The characteristics of organic cation transport by OCT1, OCT2, and OCT3 are electrogenicity, reversibility of transport direction, and independence from Na^+.[42] For OCTNs, the transport modes depend on the substrates; and hOCTN1 and rOCTN1 mediate pH-dependent and Na^+-dependent transport of trimethylamine or TEA.[43,44] However, mOCTN1 mediates carnitine transport in an Na^+-dependent manner.[45] OCTN2, which has significant affinity for carnitine and TEA, transports carnitine in an Na^+-coupled manner. However, OCTN2 transports other organic cations, including TEA, in an Na^+-independent manner.[46,47] OCTN2-mediated transport is also pH-dependent and electrogenic, as was recently demonstrated by the two-electrode voltage clamp technique.[48] By contrast, the OCTN3-mediated transport of carnitine is Na^+-independent.[45]

Three synthetic opioid peptides: DPDPE, DADLE, and deltorphin II are transported by certain members of the OATP/Oatp family, including rodent Otap1, Oatp2, and Oatp4[49,50] and human OATP-A, OATP-C, and OATP-8.[50–53] Enkephalins may also be recognized by some of these transporters. The primary location of most of these transporters is the basolateral membrane of hepatocytes.[49,51,54–56] Therefore, these transporters play a critical role in the uptake of opioid peptides by the liver for subsequent elimination into bile. OATP-A is located in the brain capillary endothelial cells in humans[50,53] and may be expected to be an important determinant of the transfer of opioid peptides across the blood–brain barrier. Evidence of marked changes in the ability of OATP-A to transport opioid peptides due to genetic polymorphisms has been reported.[53]

11.2.3.2 Facilitated transport

Facilitated transport is a carrier-mediated process that differs from active transport because the facilitated process cannot transport a substance against its concentration gradient. Therefore, facilitated transport does not require energy input but does require a concentration gradient as the driving force, which is similar to passive diffusion. In facilitated diffusion, substances are transported down the concentration gradient at a much faster rate than would be anticipated based on the molecular size and polarity of the molecule for pure diffusion. The facilitated process, like active transport, is saturable and subject to inhibition by competitive inhibitors. Facilitated diffusion seems to play a very minor role in drug absorption.

11.2.3.2.1 Nucleoside transporters

Nucleosides are precursors for nucleic acid synthesis, which is fundamental to the control of growth and metabolism in all living systems. Nucleosides are hydrophilic and diffuse slowly across cell membranes. To facilitate the salvage of these precursors for nucleotide biosynthesis, cells employ a complex transport systems consisting of multiple carrier proteins known as the *nucleoside transporters*. The physiologic roles of these transporters include the salvaging of precursors for DNA and RNA synthesis and the regulation of adenosine-mediated neuromodulation by controlling its concentrations at the receptor site. Several therapeutic nucleoside analogs rely on nucleoside transporters to enter or exit cells. Consequently, the expression and functional characteristics of these transporters in the absorptive/excretory organs and target/nontarget cells exert an important effect on the pharmacokinetics, efficacy, and toxicity of nucleoside analogs.[57]

Two major classes of nucleoside transport systems, equilibrative and concentrative, have been identified. The equilibrative system comprises facilitated carrier proteins, whereas the concentrative system consists of Na^+-dependent secondary active transporters. Multiple subtypes with distinct substrate specificity and inhibitor sensitivity exist within each major class.

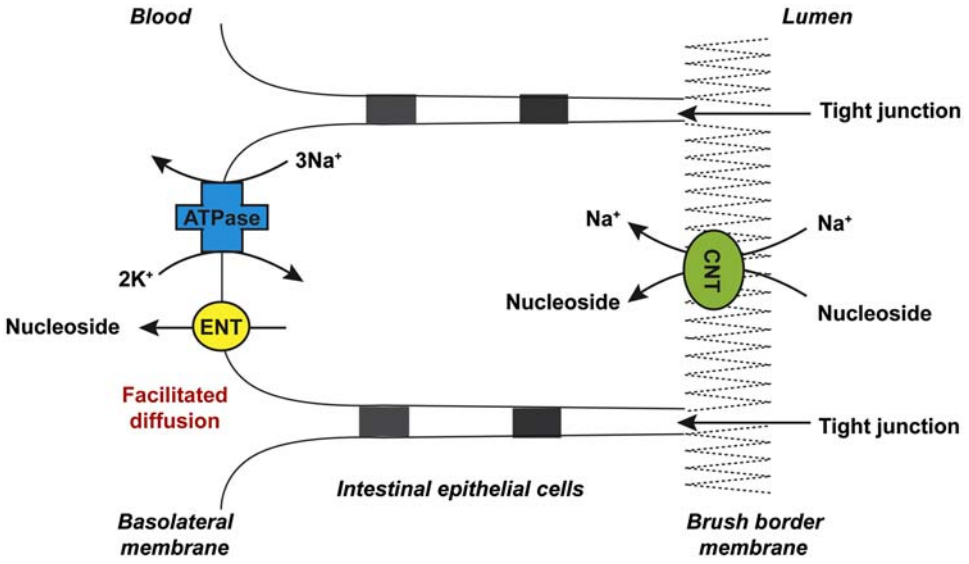

FIGURE 11.6 Model of transepithelial nucleoside flux mediated by Na^+-dependent nucleoside transporters (CNTs) and ENTs in the lumen of the intestine.

Cloned equilibrative nucleoside transporters (ENTs) share significant sequence homology and belong to a so-called ENT gene family, whereas genes encoding Na^+-dependent nucleoside transporters belong to a concentrative nucleoside transporter (CNT) gene family.

In polarized cells, such as renal and intestinal epithelia and hepatocytes, ENTs and CNTs are asymmetrically distributed between the apical and basolateral membranes to mediate the vectorial-transepithelial flux of nucleosides (Fig. 11.6). ENTs mediate the facilitated diffusion of nucleosides across membranes and bidirectionally function according to the substrate concentration gradient. Based on sensitivity to nitrobenzylthioinosine (NBMPR), which is a tight-binding and highly specific inhibitor, ENTs have been classified into two subtypes: *es* (equilibrative sensitive) and *ei* (equilibrative insensitive). The *es* subtype binds to NBMPR with high affinity via noncovalent interactions at a high-affinity binding site on the transporter protein. By contrast, the *ei* subtype is not affected by NBMPR at nanomolar concentrations and becomes inhibited only at high NBMPR concentrations.[58] Both *es* and *ei* transporters exhibit broad substrate selectivity and are widely distributed in different cell types and tissues. More recently, the two transporters were renamed as ENT1 and ENT2 according to their characteristics and belong to a large NET gene family, the members of which are also found in yeast, protozoans, insects, and plants.[59]

Moreover, two new mammalian ENT members (ENT3 and ENT4) with unknown function have been identified from the public sequence database. Compared with ENTs, which mediate the passive downhill flux of nucleosides, CNTs mediate the active uphill transport of nucleosides. These transporters utilize the inwardly directed Na^+ gradient established by the ubiquitous Na^+/K^+-ATPase to move substrates into cells against their concentration gradients. Unlike ENTs, Na^+-dependent nucleoside transporters exhibit distinct substrate selectivity for purine or pyrimidine nucleosides to regulate various physiological processes, including neurotransmission and cardiovascular activity.

Based on functional studies in cell and tissue preparations, five Na^+-dependent nucleoside transporter subtypes (N1–N5) have been identified. The N1 (or *cif*) subtype is mainly purine-selective but also transports uridine. The N2 (or *cit*) subtype is pyrimidine-selective but also transports adenosine. The N3 (or *cib*) subtype is broadly selective and transports both purine and pyrimidine nucleosides. The N4 subtype transports pyrimidine and guanosine and is characterized in brush border membrane vesicles isolated from the human kidney. The N5 subtype, which is NBMPR sensitive and transports formycin B and cladribine, is described only in human leukemia cell lines. To date, the genes encoding N1–N3 transporters have been cloned, and these genes belong to a CNT gene family. The genes encoding N4 and N5 transporters have not been identified.[57]

The clinical significance of nucleoside transporters can be summarized as follows:

- A number of anticancer nucleoside analogs rely on nucleoside transporters to enter cells to reach their cellular targets. For these drugs, the expression of nucleoside transporters on cancer cells is a

prerequisite for the cytotoxicity of nucleoside analogs. Loss of nucleoside transporters in tumor cells can lead to drug resistance.
- If a drug is a substrate for nucleoside transporters, the distribution of these transporters in various tissues and organs (particularly absorptive and excretory organs) may influence its pharmacokinetic and toxicological properties.
- Nucleoside transporters themselves could serve as drug targets.

In conclusion, nucleoside transporters are critical in determining the intracellular bioavailability and systemic disposition of therapeutic nucleoside analogs. Knowledge of nucleoside transporters is important in the evaluation and prediction of the kinetics, targeting, efficacy, and toxicities of nucleoside-derived drugs.

11.3 PATHWAYS OF DRUG METABOLISM

Drug metabolism usually involves a variety of enzymes, which by definition (from a biochemical perspective) typically helps increase efficiency (by acting as a catalyst) to biotransform a substrate into a product by reducing the required threshold energy for the reaction. Two categories of drug metabolism are well recognized in the field today—namely, phase I and phase II metabolism. In general, phase I metabolism acts as the first step in the drug metabolic process, in which its product often becomes a substrate for phase II metabolism. When lipophilic endobiotics and xenobiotics enter cells through passive diffusion or uptake transporters, phase I enzymes often facilitate the first enzymatic reaction that acts to clear them from the body. The phase II reactions are the true detoxification pathways and produce metabolites that are generally highly water-soluble and can be readily excreted from the body in the form of bile or urine.

11.3.1 Phase I metabolism

Phase I drug-metabolizing enzymes (DMEs) can catalyze a wide array of chemical reactions that facilitate xenobiotic metabolism and elimination. A common theme apparent for all phase I enzymatic reactions is that the final products are usually modified to contain a chemically reactive functional group (ie, hydroxyl, amine, sulfa, and carboxylic acid).[60]

This property supports the well-documented concept that phase II metabolism (ie, glucuronidation, glycosidation, sulfation, methylation, acetylation, glutathione conjugation, amino acid conjugation, fatty acid conjugation, and condensation) is the true detoxification step for xenobiotic elimination in the body (discussed in detail next). Because phase I reactions add functional groups onto a substrate for phase II metabolism to occur, phase I metabolism becomes a necessary prerequisite for the detoxification of xenobiotics.

Phase I metabolism also occurs during nutrient digestion, which typically involves hydrolysis reactions. These reactions include the hydrolysis of proteins, polysaccharides, and polymeric nucleotides and nucleosides[61,62] and typically provide nutrients useful to the human body. Additional phase I reactions include hydrolysis of the ester bond, which is necessary for the processing of fatty acids and their derivatives, to produce monoglyceride and fatty acids for absorption.[63] We emphasize here that some drugs may also undergo hydrolysis in the GI tract and the liver, but these drugs are uncommon.

11.3.1.1 Oxidative metabolism

Many drugs and other xenobiotics are biotransformed by oxidative reactions, which are defined as reactions that remove electrons from a molecule. Two types of enzymatically mediated oxidation reactions are known:

- Oxygen is incorporated into the drug molecules by the insertion of a hydroxyl group (−OH). Hydroxylation is the most common reaction type in phase I metabolism and usually produces a chemically stable and more polar hydroxylated metabolite than the drug.
- Hydroxylation sometimes creates unstable compounds that spontaneously split into small molecules by losing parts of the drug molecules. Different biotransformation processes, such as dealkylation and deamination, are mediated by this basic mechanism.

When most experts in the drug metabolism field are asked about phase I metabolism, typical conversations focus on oxidation metabolism involving the cytochrome P450 (CYP) enzyme family because CYP oxidation reactions are very important and highly diverse; thus, these reactions have received a considerable amount of research focus. However, oxidation reactions not related to CYP are also observed and typically involve the metabolism of endogenous substrates. The list of common names for oxidative metabolism via hydroxylation include dehydrogenases (eg, alcohol dehydrogenase), oxidases (eg, amine oxidase), and aromatases (eg, P450arom).[64]

11.3.1.1.1 Cytochrome P450 enzymes

The majority of research on phase I metabolism has focused on cytochrome P450 (CYP) proteins (the number 450 reflects the absorption maxima of the enzymes

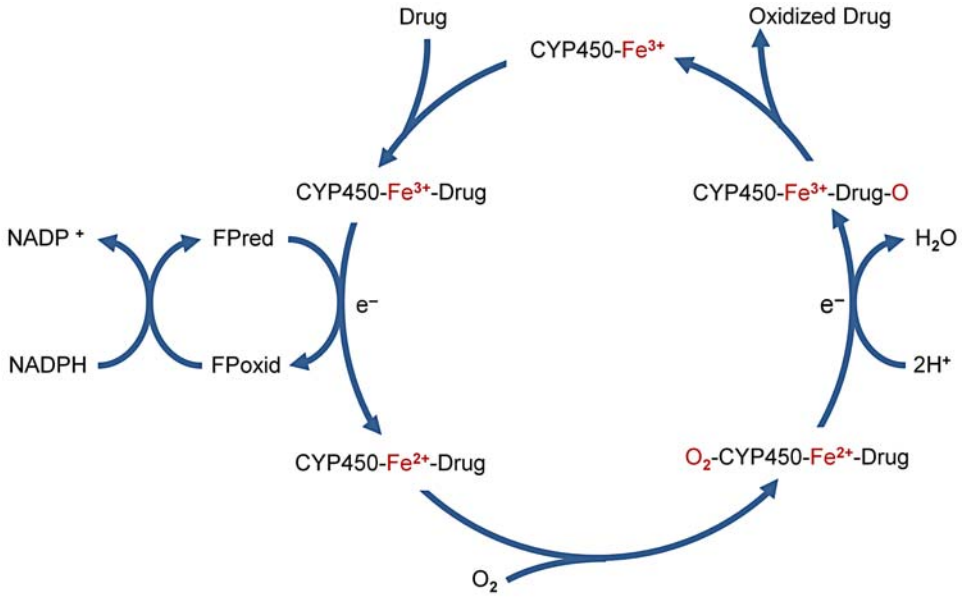

FIGURE 11.7 Generalized catalytic cycle for cytochrome P450-mediated oxidation.

at 450 nm using the CO-binding spectrum). As a superfamily of enzyme proteins, CYP plays a very important role in the phase I oxidative metabolism of drugs.

Because CYPs are responsible for the primary metabolism of a large variety of drugs in vivo,[65] determination of the mechanisms of CYP reactions has been emphasized. The importance of CYP can be observed from various perspectives. From a basic research perspective, CYP eliminates xenobiotics by preparing a substrate for phase II metabolism through addition of reactive functional groups. However, this does not mean that phase I metabolites cannot be excreted or eliminated from the body through either active or passive efflux. From the point of view of drug design, a thorough understanding of CYP behavior and its activities with xenobiotics can help predict possible adverse reactions of drugs and provide solutions to improve drug efficacy and administration.[66] Therefore, the US Food and Drug Administration (FDA) has paid a significant amount of attention to this subject. In a recent draft from the agency providing guidance on drug interaction studies, the need to define the metabolism of a new investigational drug clearly during early drug development was stressed.

CYPs are located in the endoplasmic reticulum, which can oxidize various xenobiotics. Because CYPs have a prosthetic group known as *iron protoporphyrin IX*, they are categorized as heme-containing enzymes. Heme iron is bonded to the rest of the enzyme by four pyrrole nitrogen atoms of protoporphyrin IX and two axial ligands to the porphyrin plane. The two axial ligands (known as the *fifth* and *sixth ligands*) and their complex configuration states enable CYPs to hydroxylate a wide variety of substrates. The overall main catalytic function of CYPs is to insert one atom of oxygen into a substrate (oxygenation) (Fig. 11.7).

11.3.1.1.2 Nomenclature of CYP

The nomenclature for CYP is essentially based on the degree of structural similarity among different enzyme isoforms. Current nomenclature guidelines suggest that members of CYP families share $\geq 40\%$ amino acid identity, while CYP enzymes in the same subfamily share $\geq 55\%$ amino acid identity. Individual enzymes within the same subfamily are identified based on their catalytic specificity, which is often defined using a so-called probe substrate. Virtually all CYP enzymes are designated with the root *CYP*, followed by an Arabic numeral for the gene family (eg, CYP3), a capital letter for the subfamily (eg, CYP3A), and another Arabic number for a particular gene (eg, CYP3A4).

Because of the wide variety of CYPs that exist in nature, the classification of these enzymes is also a rather complex issue because newly found isoforms are continuously published in the literature. Amidst this confusion, Dr David R. Nelson developed and maintained an updated website that reports all known CYP genes across species. In addition to this database, sequence alignments and information about known structures are also available on the Internet (http://drnelson.uthsc.edu/CytochromeP450.html). Humans have 57 genes and over 59 pseudogenes divided into 18 families and 41 subfamilies of CYP genes (Fig. 11.8). Most drugs are metabolized by CYP families 1, 2, and 3.

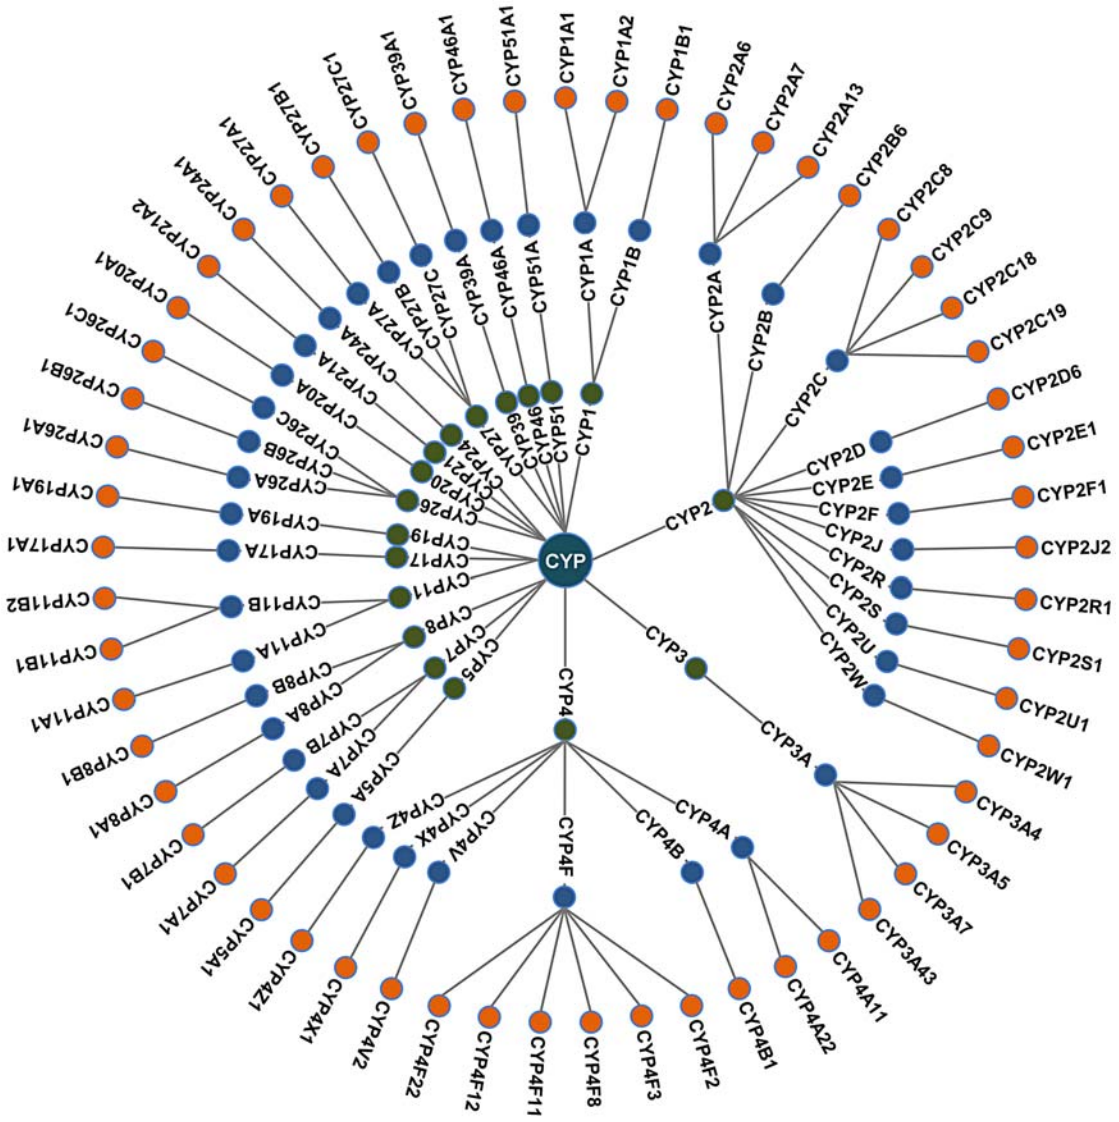

FIGURE 11.8 Phylogenetic tree representing human CYP proteins.

Despite the highly diverse amino acid compositions and enzyme mutations (commonly point mutations, such as single nucleotide polymorphisms) of CYPs that occur quite frequently in nature, the structures of CYPs are so well conserved that their catalytic functions can be well preserved. However, some mutations can cause serious damage to the catalytic capacity of CYP enzymes, leading to complicated pathologies such as Antley-Bixler syndrome.[60] Another example in which polymorphism greatly affects patient reaction to drugs is seen in the case of warfarin (ie, the S enantiomer form has higher activity than the R form). CYP2C9 is the main isoform responsible for S-warfarin metabolism. Patients with polymorphisms, particularly CYP2C9*2 and CYP2C9*3 (both heterozygous and homozygous), have major deficiencies in S-warfarin metabolism, making them susceptible to a higher incidence of life-threatening bleeding.[67]

11.3.1.1.3 Hydroxylation

Hydroxylation reactions are typically very common reactions for compounds that have aromatic rings in their chemical structures. Because many drugs and xenobiotics consist of aromatic rings, hydroxyl derivatives are quite commonly seen in nature for both drugs and xenobiotics. Another very common hydroxylation reaction is seen in aliphatics. Of interest to cancer research are epoxidation reactions where unstable intermediates are formed. Although sometimes derived from polycyclic compounds, epoxide formation is important, as it is often the first step in

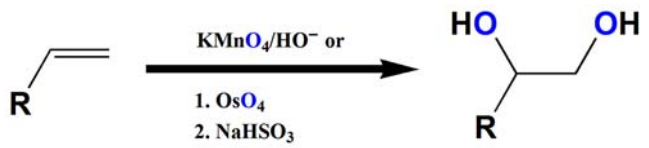

FIGURE 11.9 Chemical equation of alkene oxidization from donated hydroxyl groups.

aromatic hydroxylation, which may lead to carcinogen activation.

The essential formula that underlies all hydroxylation reactions is seen as chemically modified with the addition of one or more hydroxyl groups (−OH). In the example given in Fig. 11.9, alkene (starting compound) is oxidized through the addition of hydroxyl groups.

11.3.1.2 *Reductive metabolism*

Reductive metabolism in mammalian species is quite rare and seldom occurs in the metabolism of drugs and xenobiotics. However, reductive metabolism and ring fission frequently occur in the intestinal microflora.[68] The essential formula that underlies all reduction reactions is seen when a chemical is modified in two ways: (1) addition of hydrogen and (2) removal or reduction of oxygen. The commonality that exists for reductive metabolism is that it requires nicotinamide adenine dinucleotide phosphate (NADPH) as a necessary component in the reaction mixture but is generally inhibited by oxygen. This observation differs from mixed-function oxidase reactions, where oxygen is required for reaction.

The major groups of compounds metabolized by reductive reaction are compounds with nitro or azo functional groups. These compounds are reduced to their amines—for example, conversion of 3′-azido-3′-deoxythymidine (zidovudine) to 3′-amino-3′-deoxythymidine (Fig. 11.10). Aldehydes and ketones are also reduced to their corresponding alcohols by aldoketoreductases (Fig. 11.11). Reductive dehalogenation of halothane to 2-chloro-1,1-difluoroethylene (Fig. 11.12) is another important reductive reaction in the mammalian liver, especially under anaerobic conditions.

11.3.1.3 *Hydrolysis*

11.3.1.3.1 Necessity of hydrolysis

The necessity for hydrolysis with regard to both absorption and metabolite conversion (to parent compound) can be exemplified by the intestinal disposition pathways for compounds such as isoflavones. Natural isoflavones exist predominantly in the form of glycosides. In order for them to be absorbed, the lactase phlorizin hydrolase that resides on the surface of the intestinal lumen must be utilized to cleave the sugar

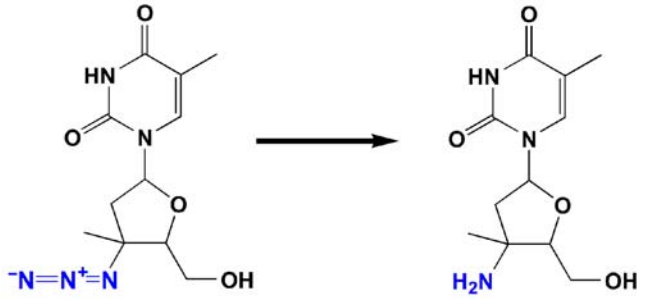

FIGURE 11.10 Chemical equation of azo-reduction of zidovudine.

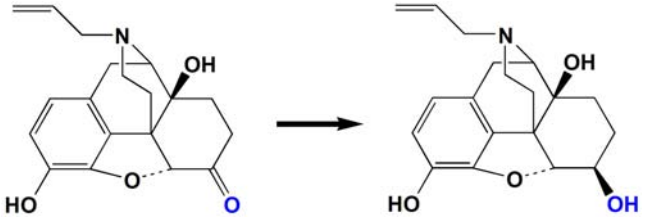

FIGURE 11.11 Chemical equation of reductive reaction of naloxone.

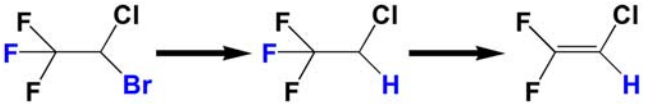

FIGURE 11.12 Chemical equation of reductive dehalogenation of halothane.

(ie, glucose) group from the isoflavone glycoside.[69,70] Only then can the isoflavone aglycone (no sugar group attached) be substantially absorbed into the intestine. Furthermore, hydrolysis by β-glucuronidases derived from bacteria in the colon or enterocytes of the upper small intestine is also a necessary step in the enteric recycling and local recycling of isoflavones. This step hydrolyzes the phase II metabolites of isoflavones back to the isoflavone aglycone form in the intestine, which can be reabsorbed.

11.3.1.3.2 Common hydrolysis substrates

Three main groups of compounds subjected to hydrolysis are amides, carbamates/hydrazides, and esters. Some important compounds metabolized in this way are aspirin (Fig. 11.13), lidocaine (Fig. 11.14), and isoniazid (Fig. 11.15). Hydrolysis of esters usually takes place through both nonspecific and specific esterases. Amides can also be hydrolyzed via nonspecific esterases in the plasma. However, amidases in the liver are more specific and have shown greater amide-hydrolyzing capacity. Hydrazide and carbamate

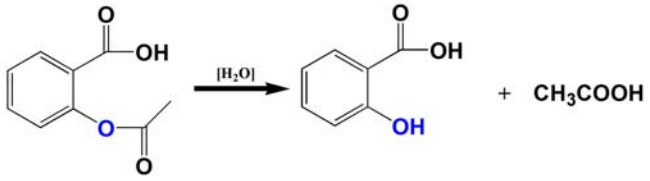

FIGURE 11.13 Chemical equation of ester hydrolysis, using aspirin as an example.

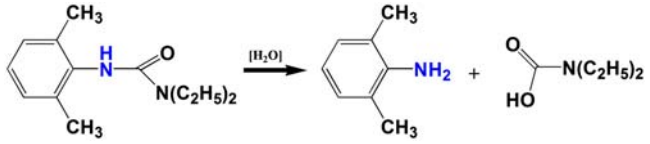

FIGURE 11.14 Chemical equation of amidehydrolysis, using lidocaine as an example.

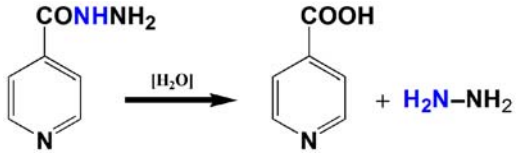

FIGURE 11.15 Chemical equation of hydrazide hydrolysis, using isoniazid as an example.

groups are the least common functional groups subjected to hydrolysis.

11.3.2 Phase II metabolism

Phase II enzymes catalyze conjugating reactions in the classification of drug metabolic pathways. Although drugs can undergo phase I and phase II reactions simultaneously, one pathway typically dominates. For most prescription drugs and drug candidates under development, the predominant pathway is not phase II metabolism. Instead, phase II metabolism often occurs following phase I metabolism, which serves to eliminate drug molecules from the body.

The main metabolic pathways of some compounds involve phase II conjugations. For example, the major metabolic pathway of polyphenol is phase II conjugation. Once absorbed, polyphenols are subjected to three types of conjugation (namely, glucuronidation, sulfation, and methylation).[2,71–73] Glucuronidation and sulfation metabolize polyphenols into very hydrophilic conjugates, whereas methylation produces metabolites that are similarly (if not slightly more) lipophilic than the substrates.[2] Upon methylation, the products (which are still phenols) are usually conjugated subsequently into glucuronides and sulfates since methylation primarily occur on catechols. Therefore, conjugation enzymes that catalyze the formation of hydrophilic metabolites significantly affect the bioavailability of drugs or xenobiotics.

11.3.2.1 *UDP-glucuronosyltransferases or UGTs*

Human UDP-glucuronosyltransferase (UGT) enzymes mainly catalyze the reaction referred to as *glucuronidation*, which involves the covalent linkage of glucuronic acid, derived from the cofactor UDP-glucuronic acid (UDP-GA), to a substrate bearing a suitable functional group (Fig. 11.16). Nucleotide sequences encoding 22 human UGT proteins have been identified, and these sequences have been classified into four gene families, including UGT1 on human chromosome 2q37, UGT2 on chromosome 4q13, UGT3 on chromosome 5p13.2, and UGT 8 on chromosome 4q26. The UGT1 and UGT2 families are the most important in terms of drug metabolism, with the highest efficiency obtained using UDP-GA as the glycosyl donor. By contrast, UGT3 and UGT8 enzymes are generally inactive with UDP-GA as the sugar donor, instead, they utilize UDPGlc, UDPGlcNAc, or UDPGal. Evidence suggests that the enzymes of these two families are unlikely to contribute significantly to drug metabolism.[74]

At the cellular level, all UGTs are membrane-bound proteins located in the smooth endoplasmic reticulum of many tissues.[75] The liver has been well established to contain the most diverse and abundant UGT enzymes. With the exception of UGT1A5, 1A7, 1A8, 1A10, and 2A1, all members of the UGT1 and UGT2 families are expressed in the human liver. In addition to hepatic expression, UGT1A and 2B enzymes are differentially expressed in other tissues, including the kidneys and GI tract, which are considered the most important sites of extrahepatic drug metabolism. The general patterns of UGT expression in the small intestine and colon closely resemble that in the liver, each with a large number of significantly expressed enzymes that sometimes overlap. However, the expression of UGT2B4, the most abundant isoform in the liver, is limited throughout the GI tract; UGT1A7, 1A8, and 1A10, which are essentially absent from the human liver, are expressed in the small intestine and colon.[74] Significant interindividual variability is notably present in UGT tissue expression.

11.3.2.2 *Sulfotransferases or SULTs*

Sulfotransferases (SULTs) are soluble and highly active cytosolic enzymes. They catalyze the transfer of a sulfate moiety from 3′-phosphoadenosine-5′-phosphosulfate to a hydroxyl group on various substrates.[76,77] Compared with UGT isoform-catalyzed metabolism, much less is known about how SULT isoforms metabolize their substrates and the relationships

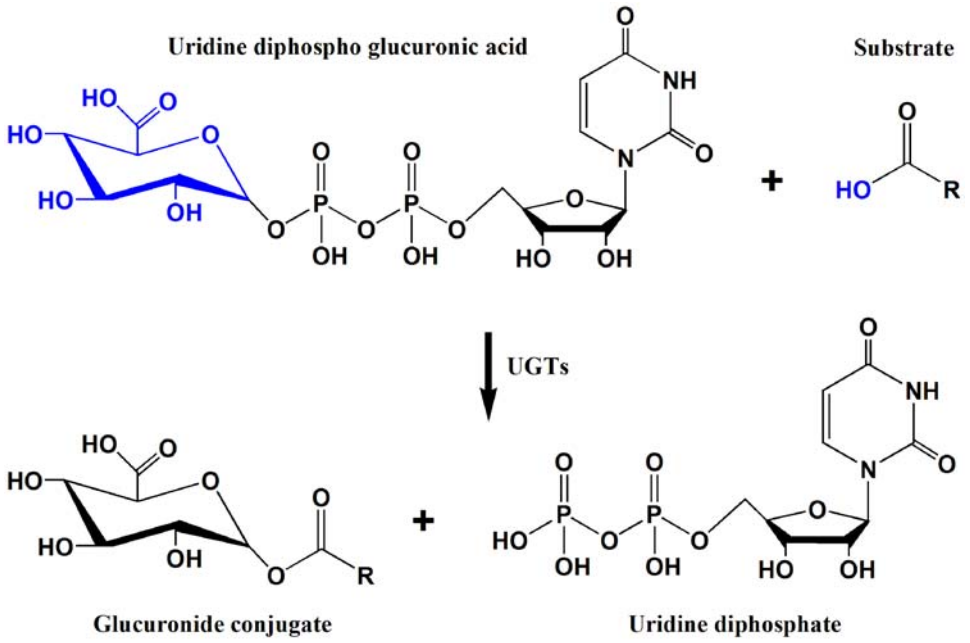

FIGURE 11.16 Glucuronidation reaction scheme.

of structural activities involved. The latter may be due to the following facts: sulfation is often the secondary metabolic pathway (to glucuronidation and other phase II reactions), only a handful of isoforms are commercially available, and commercially available SULTs are much more expensive than UGTs. Therefore, isoforms that are specifically involved in the conjugation of polyphenols have yet to be clearly identified. However, sulfation can still account for a large percentage of the phase II metabolism at lower concentrations and may serve as the primary metabolic pathway for certain compounds such as resveratrol.[78]

11.3.2.3 *Glutathione transferases or GSTs*

Similar to UGTs and SULTs, glutathione transferases (GSTs) are also important in the detoxification process.[79,80] The metabolic products of GSTs are very polar and require the assistance of efflux transporters to exit the cells. More important, glutathione depletion can significantly affect the function of this enzyme. Compared with UGTs and SULTs, GSTs appear to be superior in detoxifying carcinogenic and oxidizing agents. Xenobiotics and natural polyphenols are capable of inducing GSTs, which is critical to maintain an organism's ability to fight oxidative stress and cancer (in mammals).[79,81]

11.3.2.4 *Other conjugating enzymes*

Unlike UGTs and SULTs, methyltransferases such as catechol-*O*-methyltransferase catalyze the *O*-methylation of several catechol-containing polyphenols, thereby forming metabolites that are just as polar as or slightly less polar than the parent compound.[80] This *O*-methylation reaction is subjected to strong inhibitory regulation by *S*-adenosyl-L-homocysteine, which is formed in large quantities during the *O*-methylation of tea polyphenols. Although methylation may not be the major metabolic pathway, its importance in the mechanisms of tea polyphenols cannot be underestimated; methylated metabolites tend to have different activities and some may resist inactivation via UGTs and SULTs.

Similar to methyltransferases, many other phase II enzymes such as acetyltransferases also produce fewer hydrophilic molecules. However, glutamyltransferases and other transferases produce more hydrophilic metabolites to facilitate their elimination.

11.4 PATHWAYS OF DRUG ELIMINATION

The absorptive transport of foods, drugs, or xenobiotics across the intestinal lumen is the first step for them to become bioavailable. As stated previously, the three general routes of absorptive transport include passive transport, facilitated diffusion, and active transport. The actual transport route of these molecules typically depends on their sizes and respective chemical polarities. In general, small hydrophobic molecules are passively transported across the lumen, whereas many hydrophilic nutrients are transported via protein transporters (as discussed earlier in this

chapter). Traditionally, research has focused on how to facilitate the absorptive transport of drugs.

More recently, more attention has been paid to active transport, by which molecules can be actively effluxed out of the intestinal lumen. In addition to excreting or eliminating absorbed molecules, these transporters may be responsible for eliminating phase I and/or phase II metabolites of drugs (as described in detail in the earlier sections of this chapter). To date, several processes of active efflux have been identified. Active transport proteins, such as P-gps, MRPs, and other OATs s, play a major role in governing the intestinal absorption and metabolism of drugs, together with the action of hepatic enzymes and efflux transporters, which determine the bioavailability of drugs and xenobiotics.

11.4.1 P-Glycoprotein

11.4.1.1 Introduction to P-gp

The history of P-gp goes hand in hand with human cancer and chemotherapy. Upon the discovery of cytotoxic drugs that can destroy cancer cells, researchers also discovered that drug resistance (for multiple drugs) can impede the effects of these drugs. P-gp was the first active transporter protein to be discovered, over 30 years ago. Two research groups greatly contributed to the discovery of P-gp and determined this transporter as the major culprit responsible for multidrug resistance (MDR). In 1968, the Ling Lab at the University of Toronto initially used somatic cell genetics to investigate colchicine resistance in Chinese hamster ovary cells, which linked P-gp to MDR.[82] In the meantime, Dr Michael Gottesman's lab at the National Cancer Institute was able to clone the amplified DNA sequences related to the MDR phenotype in cell lines.[83] From both of their works, we now know that MDR and P-gp genes are identical. Today, we know that P-gp and other more recently identified proteins act as efflux transporter pumps with a broad specificity for a variety of substrates.

11.4.1.2 Structure of P-gp

P-gp is a member of a diverse family (over 50 members) of ATP-binding cassette (ABC) transporters that efflux xenobiotics and certain endogenous substances such as bile acids and bilirubin. Dependent on ATP, the P-gp structure shares extensive sequence homology and domain organization compared with other members of this superfamily. The most conserved region is the ABC domain range, approximately between 200 and 250 amino acids consisting of two nucleotide-binding domains (NBDs) located toward the cytoplasmic face of the membrane.[84] More specifically, P-gp contains 12 transmembrane regions split into two halves, each of which contains an NBD.

11.4.1.3 Nomenclature of ABC transporters

P-gp and other members of the MDR-type transporters are organized and classified under the MDR/TAP (transporter associated with antigen processing) protein subfamily. Within the ABC superfamily, MDR-type transporters, such as P-gp (also known as MDR1), MDR3, and BSEP (bile salt export pump, also known as the sister of P-gp), are grouped within the B subfamily and are designated as ABCB1, ABCB4, and ABCB11, respectively.

11.4.1.4 Substrates for P-gp

Substrates for P-gp are typically lipophilic and cationic. As previously mentioned, a large number of compounds are substrates/inhibitors for P-gp, including anticancer agents, antibiotics, antivirals, calcium channel blockers, immunosuppressive agents, and plant chemicals normally found in the human diet.[85]

11.4.1.5 Disruption of P-gp activity

The nature of P-gp is to limit the absorption of compounds by driving the efflux back into the lumen, which in turn limits the bioavailability of these compounds. Data from both in vitro and in vivo studies use human intestinal epithelial cell lines[86] and P-gp-knockout mice,[87] respectively, showed that disruption of P-gp activity could lead to potentially hazardous consequence with regard to drug disposition. Essentially, disruption of P-gp means elimination of a compound in the body via excretion will be substantially decreased (if the compound is predominantly eliminated by P-gp), thereby increasing sensitivity to toxicity as a result of a net increase in compound exposure.

11.4.2 Multidrug-resistance associated proteins

11.4.2.1 Introduction to MRPs

MRPs were discovered much later compared with P-gps. For instance, MRP1 was first cloned in 1992 from a human small cell lung cancer cell line that did not express P-gp.[88] MRP2 was later cloned in 1996 from rat liver and designated as cMRP,[89] as well as from human liver, and designated as a canalicular multispecific OATs.[90] MRP3 was discovered later and was found to be most closely related to MRP1, sharing 58% amino acid identity.[91] In general, all currently known MRPs (MRP1-9) were discovered later than P-gp, and relatively little information exists regarding the function and expression patterns of the more recently discovered MRPs (MRP7-9).

11.4.2.2 Structure of MRPs

As mentioned in the section entitled "Structure of P-gp," earlier in this chapter, the general structure of P-gp and MRPs comprises 12 transmembrane regions split into two halves, each of which contains an NBD. MRP structures are only slightly more complex than P-gp. MRP1-3 and MRP6-7 have a total of 17 transmembrane regions, with another 5 transmembrane regions at the N-terminus. However, these 5 regions do not have an additional NBD. More interestingly, MRP4 and MRP5 do not have these additional regions and thus resemble that of P-gp, which has only 12 transmembrane regions.

11.4.2.3 Nomenclature of MRPs

The nomenclature of MRPs is consistently updated because more novel MRP transporters are being discovered. The subfamily that incorporates MRPs is called the MRP/CFTR (cystic fibrosis transmembrane conductance regulator), which includes MRP1−MRP9, CFTR, and sulfonylurea receptors 1 and 2.

11.4.2.4 Substrates for MRPs

The substrates of MRPs differ among each individual isoform and their localization. However, the overall mechanistic function of MRP is to eliminate compounds from the cell through efflux. For MRPs, studies have shown that this transporter can confer resistance to cytotoxic drugs such as vincristine,[92] peptides,[93] heavy metal anions,[94] and endogenous metabolites such as bilirubin glucuronides.[95] More specifically, MRP2 is centrally involved in the detoxification process through its ability to secrete metabolites into bile. The importance of MRP2 is clearly seen in patients who suffer from Dubin-Johnson syndrome, with defective MRP2 that impairs the ability to secrete glutathione and its conjugates, as well as bilirubin glucuronides.[96] MRP3 exhibits affinity for bile salts and is especially important in mediating bile salt reabsorption. While it is clear that some major overlaps exist with regard to substrate specificity for these MRPs, they do seem to have specific roles in the disposition of xenobiotics and endogenous compounds. Much has yet to be discovered with regard to the substrate specificities and functions of the recently discovered MRP transporters (MRP7-9).

11.4.2.5 Disruption of MRP activity

As previously mentioned, the substrate specificity of MRPs can differ, as can their localization in the cell. Therefore, the effect of the disruption of MRP activity on the disposition process of xenobiotics or endogenous compounds can differ greatly. In general, various MRPs seem to overlap with regard to substrate specificity. Thus, disruption of a specific MRP isoform, such as MRP3, will probably not result in major physiological dysfunction because MRP1 (if expressed and functional) functions similarly to MRP3. However, this is not the case for all MRPs, as certain isoforms (ie, MRP2) seem to be more critically important to the body than others. As mentioned in the previous section, dysfunction of MRP2 in humans can cause Dubin-Johnson syndrome.[96] Data from our laboratories also illustrate the vital role of MRP2 in the efflux of metabolite conjugates with respect to the enterohepatic-recycling process of isoflavones and flavonoids.[101−104]

11.4.3 Breast cancer resistance protein

11.4.3.1 Introduction to BCRP

Human BCRP is one of three major ABC proteins involved in drug disposition. It is encoded by the *ABCG2* gene, which is located on chromosome 4q22. The gene was named as such because it was initially cloned from an MDR breast cancer cell line, where it was found to confer resistance to chemotherapeutic agents. BCRP is physiologically expressed in a variety of tissues, most abundantly in the GI tract, liver, kidney, brain endothelium, mammary tissue, testis, and placenta. It has a significant role in limiting oral bioavailability and transport across the blood−brain barrier, blood-testis barrier, and the maternal-fetal barrier of certain drugs and substrates.[105,106] The role of BCRP in drug disposition can now be fully appreciated because of its wide distribution, expression, and broad substrate and inhibitor specificity. BCRP is recognized by the FDA to be one of the key drug transporters involved in the disposition of clinically relevant drugs.

11.4.3.2 Structure of BCRP

BCRP is a "half ABC transporter" consisting of 655 amino acids and 6 TMDs.[107] It is a member of the subfamily G of the human ABC transporter superfamily, which, in humans, consists of five homologous half transporters, with the ABC domains located toward the N-terminus of the polypeptide chain. BCRP contains only one NBD and one MSD; these features distinguish the protein from P-gp and MRP1, which contain two tandem-repeated halves. In addition, the NBD in BCRP precedes its MSD, a domain organization contrasting that of P-gp and MRP1.[108,109]

11.4.3.3 Nomenclature of BCRP

BCRP is the second member of the subfamily G of the human ABC transporter superfamily; hence, it is also named ABCG2. BCRP was also independently cloned by two other groups named ABCP (for the

human placenta–specific ABC gene)[110] and MXR.[111] MXR is cloned from mitoxantrone-resistant S1-M1-80 human colon carcinoma cells.

11.4.3.4 Substrates for BCRP

ABCG2 is a drug transporter with a broad range of endogenous and exogenous substrates, including both positively and negatively charged and large amphiphilic molecules. Substrates of BCRP were initially reported to include a wide range of chemotherapeutics, such as mitoxantrone, camptothecin derivatives, flavopiridol, and methotrexate.[108] In addition to chemotherapeutics, drugs including prazosin, glyburide, cimetidine, sulfasalazine, and rosuvastatin have been shown to be BCRP substrates.[108,112] Recently developed tyrosine kinase inhibitors such as imatinib, gefitinib, and nilotinib are also known BCRP substrates.[108] A variety of photosensitizers, including pheophorbide A, protoporphyrin IX, and related compounds, are also BCRP substrates.[113] Besides transporting neutral substrates, BCRP transports conjugated organic anions, particularly sulfated and glucuronide conjugates and organic conjugates of drugs, xenobiotics, and endogenous substances.[108] Other BCRP substrates include chemical toxicants, phototoxic compounds, and flavonoids.[108,112] Collectively, BCRP has a broad range of substantially overlapping substrate specificity, which is distinct from that of P-gp or MRP1.

11.4.3.5 Disruption of BCRP activity

As previously mentioned, BCRP actively excretes a wide variety of chemically unrelated compounds from the cells. This protein protects mammalian cells and tissues against various xenobiotics and has a crucial role in the intestine, liver, placenta, and the blood–brain barrier. Disruption of BCRP activity can differ greatly with respect to drug toxicity or the prevention of drug toxicity. Moreover, the role of BCRP in drug disposition is now fully appreciated because it resembles P-gp in tissue distribution and expression. Similar to P-gp, BCRP has a broad substrate specificity. Thus, disruption of BCRP activity could lead to potentially hazardous consequences with regard to drug disposition (ie, drug-drug interactions).

11.4.4 Organic anion transporters

11.4.4.1 Introduction to OATs

The discovery of OATs began almost 70 years ago. At that time, the anionic dye phenolsulphophthalein was observed in very high concentrations in the renal convoluted tubules, which suggested a tubular secretion process. This finding essentially gave rise to the discovery of organic anion (and cation) transport.

11.4.4.2 Structure of OATs

Organic anion transporter 1 (OAT1) was first cloned from rat kidney in 1997 and functionally identified as an OAT.[114,115] OATs and OCTs share a predicted 12-TMD structure with a large extracellular loop between TMD 1 and 2, carrying potential *N*-glycosylation sites. Conserved amino acid motifs exhibited a relationship with the sugar transporter family within the major facilitator superfamily.

11.4.4.3 Nomenclature of OATs

Although the type I and type II classifications of OCTs are formally recognized, this is not the case with OATs. Currently, the most useful method is to acknowledge that OATs can be separated and classified with respect to molecular weight, net charge, and hydrophobicity. Therefore, type I OATs are relatively small (generally <400 kDa) and associated with monovalent compounds such as *p*-aminohippurate. Type II OATs are bulkier (generally >500 kDa), polyvalent in nature, and associated with compounds such as calcein.

11.4.4.4 Substrates of OATs

Substrates for OATs typically include weak acids that have a net negative charge on carboxylate or sulfonyl residues at physiological pH. Although OATs can perform endogenous transport via active secretion of the proximal tubule of compounds, such as riboflavin, the principal function of OATs is to eliminate excess levels of xenobiotic agents.[116] This includes many of the products of phase I and phase II hepatic biotransformation, as well as anionic drugs.[117]

11.4.4.5 Disruption of OAT activity

Disruption or alteration of OAT activity because of underexpression or overexpression is reflected in its pathophysiological states. Essentially, accumulation of uremic toxins (of which many are organic anions) in the kidney as a result of OAT dysfunction will lead to general renal disease.[118]

11.5 COUPLING OF ENZYMES AND EFFLUX TRANSPORTERS

Until recently, conjugating enzymes such as UGTs and their ability to metabolize compounds (phase II metabolism) were believed to be the most important steps in the disposition of xenobiotics. The ability of UGTs to biotransform a lipophilic compound into a more hydrophilic metabolite (via the addition of a glucose sugar molecule) was initially believed to be the major biological barrier to the entry of xenobiotics/

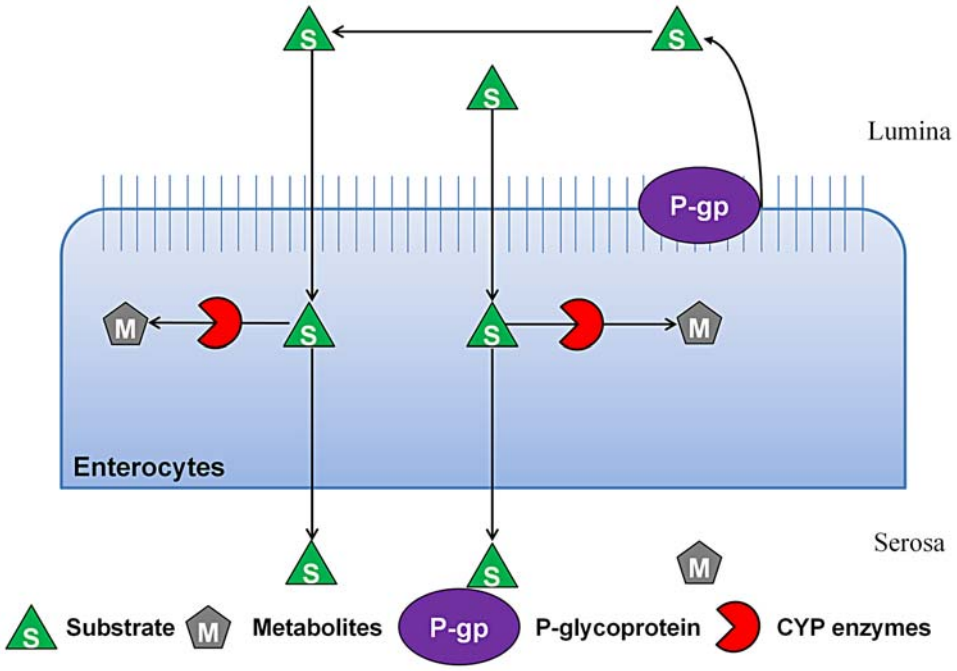

FIGURE 11.17 Schematic representation of the double jeopardy theorem. Substrates are represented by triangles, whereas the products of enzymes or metabolites are represented by pentagons or hexagons.

drugs into systemic circulation, representing one of the main pathways for their elimination.[2] However, this belief places great emphasis on UGT activity and does not comprehensively cover the overall disposition of xenobiotic/drugs. The fallacy lies in the fact that many conjugates are hydrophilic and cannot permeate the cell membrane once biotransformed by UGTs. While UGT metabolism is a highly necessary component for the disposition process of xenobiotics/drugs, more focus has been placed on various transporters that are capable of transporting negatively charged hydrophilic conjugates across the cellular membrane. In this section, we discuss three theories that explain the mechanistic details and complexities of this coupling process.

11.5.1 Double Jeopardy theorem

The double jeopardy theorem, in a slightly different form, was originally proposed to explain the mechanistic details that describe the coupling phenomenon between a phase I metabolic enzyme, such as CYP3A4, and an efflux transporter, such as P-gp (Fig. 11.17). The theorem was originally intended by Benet and coworkers to explain the pharmacokinetic behavior of certain drugs that are substrates of both CYP3A and P-gp.[115,116]

11.5.1.1 Mechanistic description of the theorem

The mechanism of action for this coupling theory is slightly less complex than the revolving door theorem (discussed next). In essence, the substrate is assumed to be absorbed (at the apical side of the membrane) and metabolized by the enzyme CYP (typically CYP3A4). Afterward, P-gp can take this one-time metabolized substrate and transport it via efflux back into the intestinal lumen. It is important to note that this one-time metabolized substrate can pass through the other side (basolateral) of the membrane and thus reach the systemic circulation. However, if this one-time metabolized substrate is effluxed back into the intestinal lumen via P-gp, it can be absorbed one more time at the apical side of the membrane (further down the intestinal tract), metabolized again by the same enzyme CYP (albeit in a different cell), and subjected to the same metabolism. Owing to these two repeats of "prosecution," the theory merits the term "double jeopardy."[121,122]

11.5.1.2 Consequences of disruption

In general, the consequences of the disruption of this mechanism and any other coupling mechanism can vary depending on the substrate in question. Given differences between substrate disposition profiles, the toxicity and interactions of certain drugs with other drug mechanisms, as well as the compensatory mechanism or effects by other enzymes or transporters in the system, will vary accordingly. In terms of the double jeopardy theorem (and, more specifically, CYP and P-gp), disruption of P-gp activity would result in

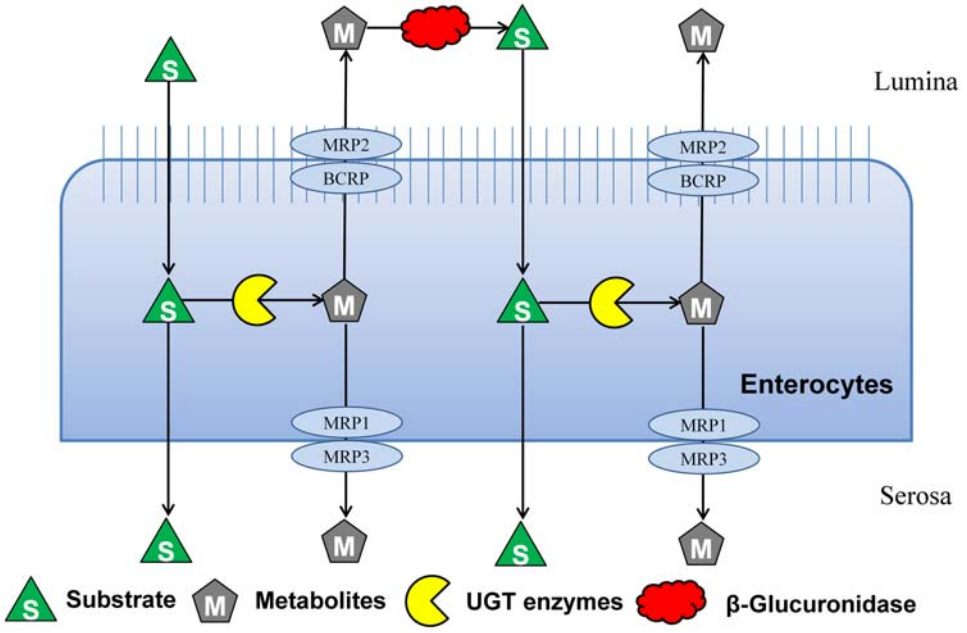

FIGURE 11.18 Schematic representation of the revolving door theorem. Substrates are represented by triangles, whereas products of enzymes or metabolites are represented by pentagons.

less exposure time of the substrate in question at the apical membrane. This shorter exposure time leads to higher substrate concentrations inside the intestine (ie, increase in absorption) and could potentially decrease the bioavailability of the substrate, its metabolite in the systemic circulation, or both. On the other hand, if CYP activity was disrupted, the amount of metabolite available would decrease severely, allowing more substrates to reach the systemic circulation.

The revolving door theorem, recently proposed, hypothesizes that efficient coupling of conjugating enzymes (UGTs) and efflux transporters enables enteric recycling processes.[2] Therefore, unlike the previous theory, the revolving door theorem emphasizes the importance of efflux transporters and their ability to solely enable the cellular excretion of hydrophilic metabolites (Fig. 11.18). This theory also recognizes the transport of hydrophilic metabolites to both apical and basolateral sides of the membrane. This latter point adds complexity to the theory and its mechanism (discussed next).

11.5.2 Revolving door theorem

11.5.2.1 Mechanistic description of the theorem

The mechanism of the revolving door theorem is best illustrated step by step for a model compound, such as the soy isoflavone, genistein (aglycone). When absorbed into the intestinal lumen, genistein undergoes two possible immediate fates. First, genistein passes through the basolateral side of the membrane and reaches the systemic circulation. However, research has found that this fate is not always the case, as bioavailability is extremely low for this compound upon ingestion.[123] Second, in the intestinal lumen, genistein is likely to be extensively metabolized by UGTs.[123,124] After biotransformation by UGTs, the genistein metabolite again has two fates. One, as an organic anion, the genistein metabolite can be transported by efflux transporters (MRP1 and/or MRP3) located at the basolateral side of the lumen and eventually reach the systemic circulation. Second, the metabolite can be transported back across the apical side of the intestinal lumen by efflux transporters, such as MRP2 (or perhaps BCRP). According to our research,[125] this efflux step is most likely the rate-limiting step of this coupling process. In other words, the amount of metabolites produced by UGTs may not significantly alter or influence the disposition of genistein or its metabolites because of the dependence on the efflux step by transporters. This dependence is ultimately the theme of the revolving door theorem, which places emphasis on the rate of the efflux step (ie, the speed at which the revolving door is spinning) as the determining factor for the disposition of genistein and its metabolite.

Upon efflux into the intestinal lumen, genistein metabolites are converted back to the genistein aglycone through bacterial hydrolysis and can thus reenter the intestinal lumen. This entire process, which occurs at the intestinal level, is known as *enteric recycling*. This

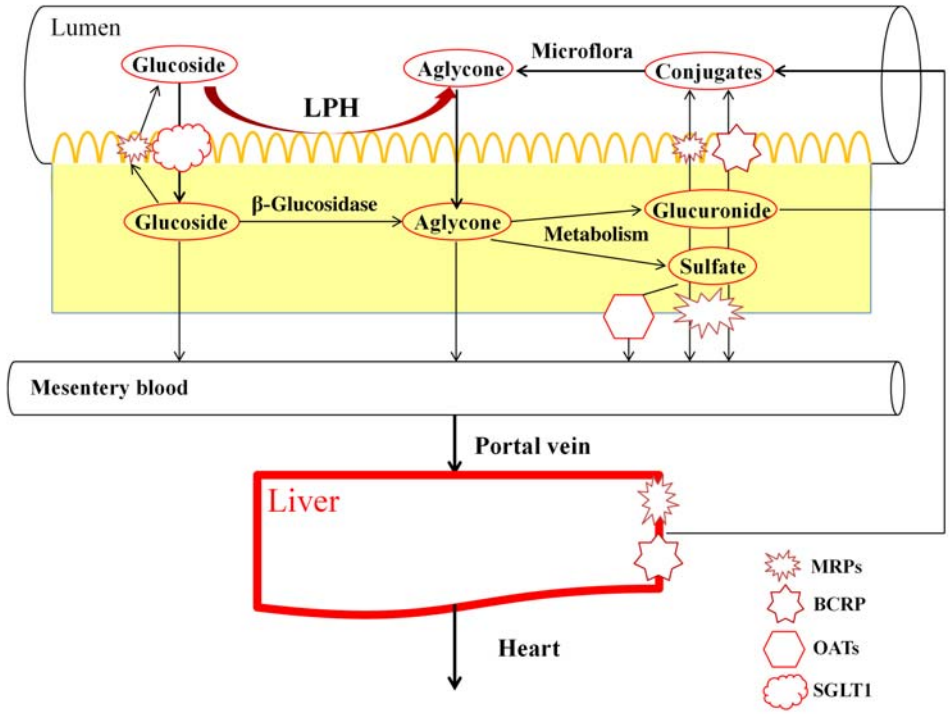

FIGURE 11.19 Schematic representation of both enteric and enterohepatic recycling with that isoflavone aglycone as an example. Isoflavones are typically subjected to rapid hydrolysis with intestinal gut hydrolase. Absorption of aglycone occurs rapidly, and the isoflavone is subjected to UGT metabolism with metabolites that typically efflux at both the intestinal and hepatic levels. Further hydrolysis from conjugates back to the aglycone form completes the cyclical recycling process, which features repeated absorption, followed by metabolism and eventual efflux.

extensive metabolism at the enteric level is also known as *first-pass metabolism*. Regarding the liver, genistein passing UGTs in the intestine is subjected to liver UGTs. These metabolites, as well as any metabolite that passes through the intestinal level, will again be secreted in bile into the intestinal lumen, hydrolyzed, and become ready for absorption. This process is known as *enterohepatic recycling*; once again, the revolving door theorem is considerably involved (Fig. 11.19).

11.5.2.2 Consequences of disruption

The consequences of disruption of this coupling theory depend on the substrate and its metabolites in question, as the body possesses an elaborate system of various metabolic enzymes (ie, UGTs and SULTs) and efflux transporters (ie, MRPs, BCRP, and OATs) with overlapping substrate specificities. Considering that detoxification is an essential function for organism survival, we have developed a highly complex system through evolution featuring multiple enzymes and efflux transporters that can compensate if any particular member becomes dysfunctional. Therefore, a wide number and variety of enzymes (ie, both UGTs and SULTs) must be made dysfunctional to disrupt coupling severely.

11.5.3 Enteric and enterohepatic recycling

Besides metabolism, various recycling or circulation processes are known to affect the oral bioavailability of certain phenolics (including flavonoids) and their conjugates. In addition to enteric recycling, excretion could occur in the liver when mediated by efflux transporters. In the liver, metabolites could be excreted into the intestinal lumen via bile. After hydrolysis of the metabolites to substrates, the substrates could then be reabsorbed. Enterohepatic recycling restricts the entry of substrates into systemic circulation but extends the systemic exposure time, which could explain the poor systemic bioavailability but reasonably long half-lives of certain phenolics that participate in recycling (Fig. 11.20).[126]

The mechanism of enterohepatic recycling can be best illustrated by using flavonoids as model compounds. The phase II metabolites of flavonoids formed in hepatocytes are hydrophilic. Therefore, flavonoids have difficulty penetrating the cell membrane by passive diffusion. Like enterocytes, hepatocytes possess basolateral and apical sides.[127] The expression of transporters on the basolateral and apical sides of hepatocyte membranes is obviously different. MRP3, MRP4, MRP5, and MRP6 are located on the basolateral side, whereas P-gp, BCRP, and MRP2 are located on the apical side.[128] In general, details of the

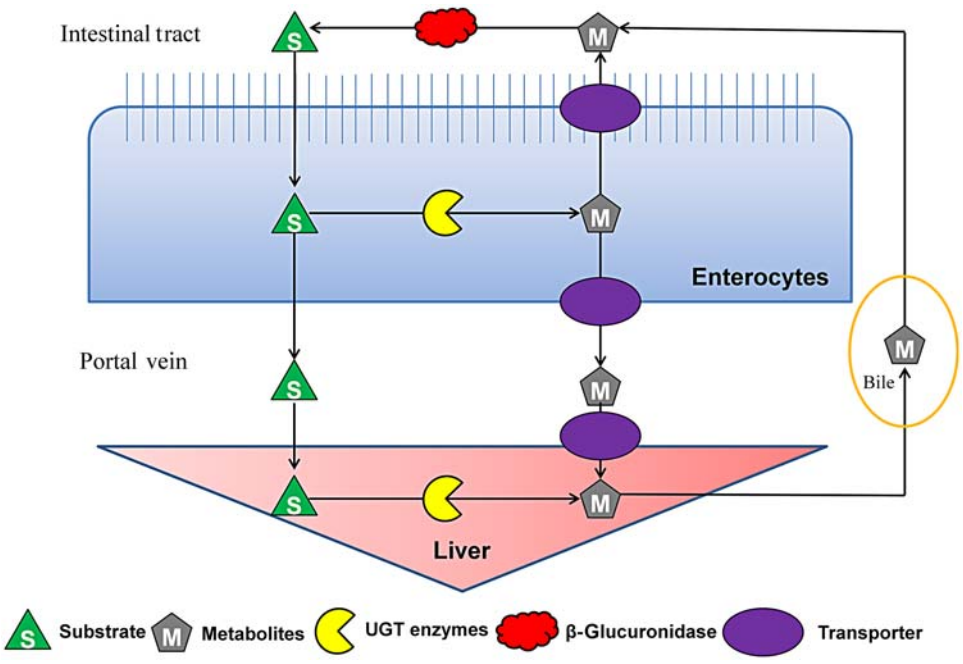

FIGURE 11.20 Schematic representation of enteric and enterohepatic recycling. Substrates are represented by triangles, whereas the products of metabolism or metabolites are represented by pentagons.

efflux of flavonoid metabolites by transporters are revealed less in hepatocytes. However, as the same transporter is expressed in both hepatocytes and enterocytes, we can assume that the same transporters perform these functions. Phase II metabolites of flavonoids are commonly excreted via bile. After duodenal administration, high concentrations of flavonoid metabolites could be detected in the bile.[129] In the rat intestine perfusion model, considerable amounts of metabolites could be recovered from the bile.[126,130,131] Enterohepatic recycling of phase II conjugates of flavonoids is common. Glucuronides and sulfates in flavonoids could be converted back to aglycones by hydrolases and reabsorbed in the intestinal tract, completing a process called *enterohepatic circulation*. Enterohepatic recycling contributes in part to the prolonged presence of relevant radioactivity in plasma, which may enhance the efficacy of flavonoid metabolites.[132]

11.6 REGULATION OF TRANSPORTERS AND ENZYMES BY NUCLEAR RECEPTORS

11.6.1 Nuclear receptors

Nuclear receptors (NRs) are ligand-inducible transcription factors that specifically regulate the expression of target genes involved in metabolism, development, and reproduction.[133] NRs include the pregnane X receptor (PXR; NR1I2), constitutive androstane receptor (CAR; NR1I3), liver X receptors α and β (LXR; NR1H3 and NR1H2), farnesoid X receptor (FXR; NR1H4), and peroxisome proliferator-activated receptors α, β/δ, and γ (PPAR; NR1C1, NR1C2, and NR1C3). Most of the NRs share common structural features, which comprise two essential functional domains that include the N-terminal DNA-binding domain (DBD) and a C-terminal ligand-binding domain (LBD). The conserved DBD encompasses two DNA-binding zinc-finger motifs that bind to distinct target genes. The LBD, which is connected to the DBD through a hinge region, folds to form a hydrophobic pocket, into which the ligand binds.[134] In the absence of xenobiotics, the basal expression level of proteins mediated by NRs is low. On ligand binding, the NRs transcriptionally regulate the expression of target genes involved in the biotransformation and homeostasis of both exogenous and endogenous substances by the recruitment of coactivators or corepressors (Fig. 11.21).

11.6.2 Pregnane X receptor and constitutive androstane receptor

PXR and CAR both belong to the NR superfamily and are well-established xenobiotic sensors that are capable of binding to various structurally diverse chemicals. They are predominantly expressed in the liver, and both are involved in the regulation of drug metabolism, bile acid transport, cancer, and cholesterol metabolism, among others. When bound to and activated by ligands,

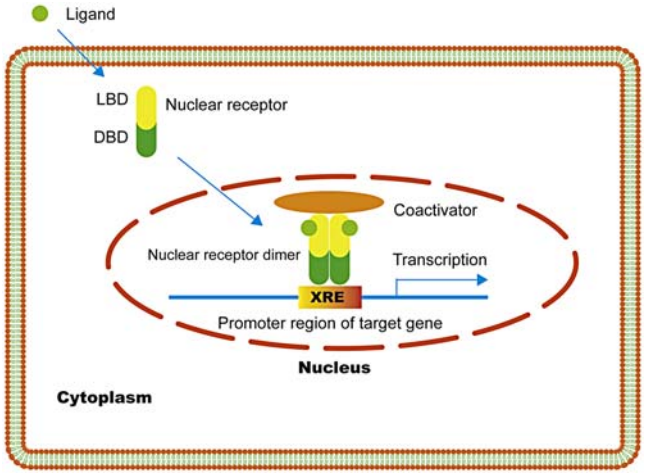

FIGURE 11.21 Model of nuclear receptor signaling. *Source: Derived from Sugatani J, Kojima H, Ueda A, Kakizaki S, Yoshinari K, Gong Q.H, et al. The phenobarbital response enhancer module in the human bilirubin UDP-glucuronosyltransferase UGT1A1 gene and regulation by the nuclear receptor CAR.* Hepatology (Baltimore, MD) *2001;33:1232–8.*[135]

the sensors translocate from the cytoplasm to the nucleus of cells, where they bind to DNA response elements as a heterodimer or heterotetramer with the retinoid X receptor (RXR).[136] Upon ligand binding, PXR and CAR are activated to control the expression of a large number of target proteins involved in the biotransformation and homeostasis of both exogenous and endogenous substances, including DMEs and transporters, thereby influencing the detoxification of xenobiotics.

11.6.3 Regulation of transporters and enzymes by PXR

PXR is one of the NRs that are originally identified as xenobiotic receptors that regulate CYP gene expression. CYP3A4, the most highly expressed CYP enzyme in human liver, is highly inducible by a wide variety of xenobiotics. CYP3A induction by xenobiotics is now believed to be largely due to xenobiotic binding and activation of PXR. Originally, PXR/RXR heterodimers were observed to bind efficiently to DR3-type xenobiotic response elements (XREs) present in the proximal promoters of rat *CYP3A23* and *CYP3A2* genes.[137] PXR/RXR heterodimers were later found to bind to a DR3 element in the human CYP3A4 gene enhancer and an ER6 element located in the proximal promoter of the *CYP3A4* gene.[138,139] In addition to CYP3A family members, PXR regulates other phase I enzyme genes, including *CYP2B6*, *CYP2B9*, *CYP2C8*, *CYP2C9*, and *CYP2C19*. Phase II enzyme genes regulated by PXR include those in the GST, SULT, UGT, and carboxylesterase families. The expressions of certain transporters, including OATP1A4, OATP2 (OATP1B1), MRP2, and MDR1, are also influenced by PXR (Table 11.2).

TABLE 11.2 PXR Target Genes Involved in Phase I, II, and III Metabolism

Phase	Target genes	Species
Phase I	*Aldh1a1*	Mouse
	Aldh1a7	Mouse
	CYP1A1	Mouse, human
	CYP1A2	Human
	CYP1A6	Human
	CYP2B1	Rat
	CYP2B2	Rat
	CYP2B6	Human
	CYP2b10	Mouse
	CYP2C8	Human
	CYP2C9	Human
	CYP2C19	Human
	CYP3A1	Rat
	CYP3A2	Rat
Phase II	*CYP3A4*	Human
	CYP3a11	Mouse
	CYP3A23	Rat
	CYP3a44	Mouse
	CYP7A1	Human
	CYP11A1	Human
	CYP11B1	Human
Phase III	*UGT1A1*	Mouse, human
	UGT1A3	Human
	UGT1A4	Human
	UGT1A6	Human
	UGT2b5	Mouse
	GSTA1	Mouse, rat
	GSTA2	Mouse, rat
	Gstm1	Mouse, rat
	Gstm2	Mouse
	SULT2A1	Mouse, human
Phase IV	*MDR1*	Mouse, human
	MRP2	Mouse, rat, human
	MRP3	Mouse, human
	OATP1A4	Mouse, rat
	OATP2 (OATP1B1)	Mouse, rat

11.6.4 Regulation of transporters and enzymes by CAR

Similar to PXR, CAR is another NR that was originally identified as a xenobiotic receptor that regulates CYP gene expression. CAR regulates gene expression through the phenobarbital responsive element module (PBREM), in the promoter regions of target genes. In humans, *CYP2B6* is responsible for the metabolism of a large number of drugs. *CYP2B6* is highly inducible not only by phenobarbital (PB), but also by a large number of other compounds.[140] CAR response elements have been shown to be located in human *CYP2B6* and mouse *Cyp2b10* gene promoters. CAR-/- mice fail to display *Cyp2b10* induction in response to PB treatment.[134] In addition to *CYP2B6*, hCAR can regulate the expression of other CYPs, including *CYP2B6*, *CYP2C9*, *CYP2C19*, *CYP3A4*, and *CYP3A5*. UGT1A1 is an important phase II enzyme, the expression of which has been reported to be dually regulated by hCAR. UGT1A1 was initially identified as a CAR target gene when CAR is activated by PB.[141] GST, another phase II conjugation enzyme, is modestly induced by PB[141] and TCPOBOP,[142] thus suggesting that CAR may regulate the expression of GSTs. Besides its regulation of the phase I and II DMEs, CAR regulates the expression of drug transporters, such as P-gp, OATP2 (OATP1B1), and MRP2-4 in mouse liver (Table 11.3).

TABLE 11.3 CAR Target Genes Involved in Phase I, II, and III Metabolism

Phase	Target genes	Species
Phase I	*Aldh1a1*	Mouse
	Aldh1a7	Mouse
	CYP1A1	Mouse
	CYP2a4	Mouse
	CYP2A6	Human
	CYP2B1	Rat
	CYP2B2	Rat
	CYP2B6	Human
	CYP2b10	Mouse
	CYP2C6	Rat
	CYP2C7	Rat
	CYP2C9	Human
	CYP2C19	Human
	CYP3A1	Rat
	CYP3A4	Human
	CYP3a11	Mouse
Phase II	*UGT1A1*	Mouse, human
	UGT2B1	Rat
	GSTA1	Mouse, rat
	GSTA2	Mouse, rat
	GSTA3	Mouse, rat
	Gstm1	Mouse, rat
	Gstm2	Mouse
Phase III	*MDR1*	Mouse, human
	Mrp1	Mouse
	MRP2	Mouse, rat, human
	MRP3	Mouse, human
	Mrp4	Mouse
	OATP2 (OATP1B1)	Mouse, rat

Derived from Sugatani J, Kojima H, Ueda A, Kakizaki S, Yoshinari K, Gong Q.H, et al. The phenobarbital response enhancer module in the human bilirubin UDP-glucuronosyltransferase UGT1A1 gene and regulation by the nuclear receptor CAR. Hepatology (Baltimore, MD) *2001;33:1232–8.*

11.6.5 Regulation of transporters and enzymes by other NRs

In addition to PXR and CAR, other NR members perform important functions in the regulation of DMEs and drug transporters. For example, aryl hydrocarbon receptor, which shares several significant characteristics with CAR and PXR, mainly enhances the gene expression levels of *CYP1A1*, *CYP1A2*, *CYP1B1*, *UGT1A1*, *UGT1A3*, *UGT1A4*, *UGT1A6*,[143] *MDR1/3*, and *MRP2/3*.[144] Vitamin D receptor is related to the expression of several CYP genes, such as *CYP2C9*, *CYP2B6*, *CYP3A4*,[145] and transporter MDR1.[146] Nuclear factor erythroid 2-related factor 2 (Nrf2) mainly regulates the expression of phase II enzymes (GST),[147] as well as transporters such as MDR1, BCRP, MRP2, and MRP3.[148] Peroxisome proliferator-activated receptors (PPARs) mainly affect phase II enzymes, such as SULTs, UGTs,[143] and transporter BCRP.[149]

11.7 PHYSICOCHEMICAL FACTORS AFFECTING DRUG ABSORPTION

We classify the physicochemical characteristics of a drug molecule or particle into those that are solely related to chemical structures and those that are related to physical shape (eg, crystalline forms). Considering the biological constrains posed by GI barriers, we must consider the following physicochemical properties: lipophilicity, size, charge, solubility, dissolution, and ionization.

11.7.1 Lipophilicity

The lipophilicity of a drug or drug candidate molecules is a major concern in the development of dosage forms because drug molecules must penetrate the lipid bilayer of most cellular membranes, including that of enterocytes. Therefore, drug molecules should be lipophilic to allow good absorption.

The lipophilicity of uncharged molecules can be estimated experimentally via a straightforward method of measuring the partition coefficients in a water/oil (eg, water/octanol) bi-phase system. For molecules that are weak acids or bases, one must consider the pH at which the majority of the species remain uncharged versus the pH at which the majority of the species are charged. Based on the pH partition theorem, absorption is favored when a molecule is uncharged, which works for drug molecules that are absorbed via passive diffusion.

This general trend that favors lipophilicity contradicts the fact that higher lipophilicity favors better absorption, as pH partition theory would have suggested. As an explanation, during transcellular absorption in the enterocytes, drug molecules must first enter through apical membrane, travel through the cytosolic domain, and then exit the basolateral membrane. If a compound binds too tightly to the cell membrane as the result of its extremely high lipophilicity, the compound would be unable to enter the aqueous cytosolic domain or exit from the lipophilic basolateral membrane into the aqueous lamina propria. As mature enterocytes require about 10 days to develop and function for about 4 days after maturation, drugs attached to cell membranes (apical or basolateral) would eventually slough off when the mature cells perish as the result of their natural life cycle. According to Lipinski's Rule of Five, the partition coefficient should be positive but less than 100,000 to 1 (or log PC = 5).[150,151] In another statistical study, the log PC was seen to be the best at log PC < 3.[152]

11.7.2 Size

Passive absorption in the GI tract is severely limited by the size of the penetrating drug molecule probably because of the well-organized and packed structure of the lipid bilayer. When a molecule is excessively large, the potential energy resulting from concentration difference is not sufficiently large to generate the high energy required to markedly disturb the bilayer, which is necessary for a large molecule to insert into it and then leave afterward. Therefore, the size (and perhaps the surface area) of a molecule are major factors limiting absorption via passive diffusion. According to Lipinski's Rule of Five, the optimal molecular weight is less than 500.[150,151] In a similar paper, that molecular weight was extended to 550.[152]At any rate, very few drug molecules with large molecular weights are absorbed to an appreciable extent (> 20%). Cyclosporin A is one of the exceptions; this drug exhibits good bioavailability to exert intended effects, and formulations with improved solubility demonstrate increased absorption.[153]

11.7.3 Charge

The effects of charge on the passive absorption of drugs are well recognized. In general, charged molecules are not as permeable as the corresponding uncharged species when the compound is absorbed via passive diffusion. However, the effect of charge on the absorption of drugs via carrier-mediated transport process is complex. Several transporters favor neutral substrates, whereas others prefer positively charged or negatively charged substrates.

11.7.4 Solubility

Solubility affects the absorption of drugs, as it affects the driving force of drug absorption—specifically, the concentration of drug molecules at the site of absorption. Other chapters in this book are devoted to this topic, so we will refrain from any major discussion of it here.

11.7.5 Dissolution

Dissolution affects the absorption of drugs because this property affects the driving force of drug absorption, as stated previously. However, the term describes the process of solubilization and is represented by the dissolution rate. Drug molecules must possess sufficient dissolution rates, as drug particles are scheduled to be in contact with the absorption area for only a finite length of time because of residence time constraints of the GI tract. Other chapters in this book discuss this property in greater detail.

11.7.6 Ionization (pK_a)

Numerous drugs are either weak acids or bases that exist in both ionized and unionized forms in vivo. The ionized part of the drugs cannot cross lipid membranes, whereas the unionized part of drugs can cross freely. The degree of ionization depends on the pK_a of the drug and the pH of the GI tract. The pK_a is the pH at which the drug is 50% ionized and 50% unionized. The ratio of two forms, which can be calculated by using the Henderson-Hasselbalch equation[154]

(as follows), at a particular site influences the rate of absorption.

For acidic drugs,

$$pK_a - pH = \log[AH/A^-] \quad (11.1)$$

If pH is lower than pK_a, more unionized species will be present.

For basic drugs,

$$pK_a - pH = \log[BH^+/B] \quad (11.2)$$

If pH is higher than pK_a, more unionized species will be present.

The unionized form of weak acids ($pK_a = 3-5$) and the ionized form of weak bases ($pK_a = 8-10$) predominate in the stomach (with a pH of 1). Hence, weak acids are more readily absorbed from the stomach than weak bases. Acidic drugs are present in ionized form in the intestines (with a pH of 7) and are thus less absorbed. However, given the small surface area of the stomach and the contrasting very large surface area of the intestine, even acidic drugs are often more absorbed from the upper part of the intestine. Basic drugs are present in unionized form in the intestines and are absorbed at a considerably more rapid rate. However, the effects of solubility in the intestines must be accounted for, as discussed in the following sections.

11.8 BIOLOGICAL FACTORS AFFECTING DRUG ABSORPTION

The oral route of administration is the most common and popular route of drug delivery. The oral absorption process of a drug from a pharmaceutical dosage form is complex. In general, absorption involves four phenomena: (1) dissolution of the drug from its dosage form; (2) solubility of the drug as a function of its physicochemical characteristics; (3) effective permeability of the drug to the intestinal mucosa; and (4) presystemic metabolism of the drug.[149] Moreover, the oral dosage form must be designed to account for extreme pH ranges, the presence or absence of food, degradative enzymes, varying drug permeability in the different regions of the intestine, and motility of the GI tract. A drug may encounter several barriers to absorption when released from its dosage form and upon dissolution into the GI fluids. The drug must remain in solution and not become bound to food or other materials within the GI tract. The drug must be chemically stable so as to withstand the pH of the GI tract, and it must be resistant to enzymatic degradation in the lumen.

For most drugs, the optimum site for drug absorption after oral administration is the upper portion of the small intestine or duodenum region. The unique anatomy of the small intestine or duodenum provides an immense surface area for drug absorption. The large surface area of the intestine is due to the presence of valvelike folds in the mucous membrane, which contain small projections known as *villi*. These villi contain even smaller projections known as *microvilli*, which form the brush border of epithelium. The duodenal region is also highly perfused with a network of capillaries, which helps maintain a concentration gradient from the intestinal lumen and plasma circulation. Overall, the GI absorption of orally administered drug is determined by the permeability of the GI mucosa, the surface area, the concentration gradient, and the transit rate in the GI tract.

Gastric emptying, especially that of food, the pH of the GI, and luminal enzymes are important factors affecting the plasma concentration profile of orally administered drugs. In addition, the intestinal transit rate also exerts a significant influence on drug absorption, as the rate determines the residence time of the drug in the absorption site.[150] In this chapter, the importance of GI biological factors in determining the absorption kinetics and bioavailability of orally administered drugs is discussed.

11.8.1 Transit time

Once a drug is administered orally, the exact location and environment of the drug product within the GI tract are difficult to determine. GI motility tends to move the drug through the alimentary canal, so that the drug does not stay at the absorption site. The transit time of the drug in the GI tract depends on the physiochemical and pharmacologic properties of the drug, the type of dosage form, and various physiologic factors.[151]

Intestinal propulsive movements determine the intestinal transit rate and, as a consequence, the residence time of a drug in the intestine. Evidently, greater intestinal motility results in a shorter residence time and less time for the drug to be absorbed at the site. Peristaltic activity increases after a meal as a result of the GI reflex, which is initiated by distension of the stomach and results in increased motility and secretion.

GI mixing movements are a result of contractions dividing a given region of the intestine into segments, thereby producing an appearance that is similar to a chain of sausages. These mixing motions tend to improve drug absorption since (1) mixing movements can increase dissolution rates and influence absorption and (2) the mixing process can increase contact between a drug and membrane. Transit through the

small intestine appears to deviate in a variety of ways from movement through the stomach. Once emptied from the stomach, the drug (such as pellets and tablets) moves along the small intestine and reaches the ileocecal valve within approximately 2–4 hours. Transit in the intestine appears to be less dependent on the physical nature of the drug, such as liquid versus solid, and size of solids in comparison with that in the stomach. Furthermore, food appears not to influence intestinal transit as it does gastric emptying. While no gender-related differences appear in intestinal transit time, vegetarians appear to have longer intestinal transit times in comparison with nonvegetarians.[152]

The colonic transit of pharmaceuticals is long, variable, and depends on the dosage form, diet, eating pattern, and disease. Contractile activity in the colon can be divided into two main types: (1) propulsive contractions or mass movements, which are associated with the aboral (ie, away from mouth) movement of contents and (2) segmental or haustral contractions, which serve to mix the luminal content and result in small aboral movements. Segmental contractions are brought about by contraction of the circular muscle and predominate intestinal transit, whereas propulsive contractions, which are due to contractions of the longitudinal muscle, occur only three to four times daily in normal individuals. Colonic transit is thus characterized by short bursts of activity followed by long periods of stasis. Movement is mainly aboral (ie, toward the anus). Colonic transit can vary from 2 to 48 hours. In most individuals, mouth-to-anus transit times are longer than 24 hours.[150]

11.8.2 pH

The pH of GI fluids varies considerably along the length of the GI tract. Gastric fluid is highly acidic, normally exhibiting a pH within the range 1–3.5 in healthy people in the fasted state. Following ingestion of a meal, gastric juice is buffered to a less acidic pH, which depends on meal composition. Typical gastric pH values following a meal are in the range of 3–7. Depending on meal size, the gastric pH returns to lower fasted-state values within 2–3 hours. Thus, only a dosage form ingested with or soon after a meal will encounter these higher pH values, which may affect the chemical stability of a drug or its dissolution, absorption, or a combination thereof.[150]

The pH of GI may influence the absorption of drugs in a variety of ways. If the drug is a weak electrolyte, the pH may influence its chemical stability in the lumen, as well as its dissolution or absorption. Chemical degradation due to pH-dependent hydrolysis can occur in the GI tract. The result of this instability is lower bioavailability, as only a fraction of the administered dose reaches the systemic circulation in the form of intact drug.[150] Despite of this possible change, long-term and sustained change of GI pH to improve the absorption of drugs has never been approved by the FDA.

11.8.3 Food

The presence of food in the GI tract can affect the bioavailability of the drug from an oral drug product. Digested foods contain amino acids, fatty acids, and numerous nutrients that may affect intestinal pH and the solubility of drugs. Several effects of food on the bioavailability of a drug product may include (1) delay in gastric emptying; (2) stimulation of bile flow; (3) a change in the pH of the GI tract; (4) an increase in splanchnic blood flow; (5) a change luminal metabolism of the drug substance; and (6) physical or chemical interaction of the meal with the drug product or drug substance.[153]

Besides the general information given here, interactions between food and drugs other than dilution, binding, precipitation, absorption, chelation, changes in gastric, and urinary pH, among others, must be considered. For instance, grapefruit juice may considerably increase the peroral bioavailability of numerous *CYP3A4* substrates by inhibiting intestinal phase I metabolism by up to 300%; drugs that exert these effects include felodipine, nifedipine, nisoldpine, and nitrendipine. Numerous drugs are transported back from the enterocyte into the GI lumen by the P-gp efflux transporter system. However, grapefruit juice also possesses a higher affinity for P-gp than other drugs. Therefore, efflux may be inhibited and bioavailability increases, for drugs such as cyclosporine, vinca alkaloids, digoxin, and fexofenadine. Grapefruit juice also exhibits affinity for OATP, which would inhibit the influx of drugs transported by this system from enterocytes to the plasma, thus decreasing their bioavailability.[154]

11.8.4 Luminal enzymes

Pepsin is the primary enzyme found in gastric juice. Lipases, amylases, and proteases are secreted from the pancreas into the small intestine in response to food ingestion. These enzymes are responsible for most nutrient digestion. Pepsins and proteases are responsible for the degradation of protein and peptide drugs in the lumen. Other drugs that resemble nutrients, such as nucleotides and fatty acids, may also be susceptible to enzymatic degradation. Lipases may affect the

release of drugs from fat/oil-containing dosage forms. Drugs that are composed of esters can be susceptible to hydrolysis in the lumen. Bacteria, which are mainly localized within the colonic region of the GI tract, secrete enzymes that have been utilized when designing drugs or dosage forms to target the colon.[150]

In summary, this chapter presented a general description of all barriers to the oral bioavailability of drugs. In this chapter, we showed that barriers to oral bioavailability present several layers, including solubility and dissolution rate, absorption, metabolism, efflux, and excretion. We have not discussed the transport of drugs to target organs, which may also serve as an important barrier for drugs to become bioavailable in the CNS, tumor cells, and difficult-to-access organs. Our understanding of the solubility and dissolution behaviors of solids has not changed considerably over the last 20 years in that we still cannot accurately predict solubility in vivo. However, we have made great progress in the last 15 years on research into the in vivo transport of drugs. However, more than 90 human transporters with unknown functions and substrates exist. Therefore, our prediction of drug absorption remains inadequate. The use of Caco-2 in the discovery process is helpful in addressing this bottleneck. The metabolism and excretion of drugs has received considerable attention from regulatory agencies because of drug-interaction issues and the difficulties associated with the prediction of issues, especially when enzymes and transporters may work together to enable complex functions. We are optimistic that we will make significant progress in this area in the coming decade by undertaking systematic biological and other multidisciplinary approaches.

12.1 INTRODUCTION

The most convenient route of drug administration for systemic actions is oral. The most important question during drug development for an oral-dosage form is how much of a drug will be bioavailable after its oral administration, and how quickly that happens. Successful design and development of orally bioavailable drugs requires that the drug molecules (1) be reasonably stable to chemical and enzymatic degradation (eg, within the intestinal lumen, intestinal wall, liver, and circulation); (2) be able to traverse the intestinal epithelial barrier to the portal circulation; and (3) can pass through the liver and enter the systemic circulation intact at a sufficient concentration to elicit the appropriate pharmacologic response. Therefore, good oral bioavailability generally facilitates formulation design and development, reduces intrasubject variability, and enhances dosing flexibility. Oral bioavailability (F) can be mathematically represented by

$$F = f_a \times f_g \times f_h \tag{12.1}$$

where, f_a is the fraction of drug absorbed, f_g is the fraction that escapes metabolism in the gastrointestinal (GI) tract, and f_h is the fraction that escapes the first-pass hepatic metabolism. Each individual value of f_a, f_g, or f_h ranges from 0 (completely unabsorbed or metabolized) to 1 (fully absorbed or unmetabolized). Therefore, oral drug absorption is one of the main factors governing drug bioavailability.

Oral drug absorption is the movement of the drug from its site of administration, the GI tract, into the bloodstream. The oral absorption of the drug in the solid dosage form from the GI tract is largely controlled by (1) dissolution rate and solubility, which determine how fast a drug reaches maximum concentration in the GI fluid; and (2) intestinal permeability, which relates to the rate at which a dissolved drug crosses the intestinal wall to reach the portal blood circulation. The determination of the dissolution, solubility, and permeability properties of drugs can thus provide information about drug absorption. This chapter will focus on these properties. It begins with the GI physiology. It then discusses the biopharmaceutical classification system (BCS). Further, it proceeds to introduce in vitro, in silico, and in vivo methods to evaluate intestinal permeability or to predict oral drug absorption. The chapter concludes by discussing future trends in oral drug absorption evaluation and prediction.

12.2 ANATOMY AND PHYSIOLOGY OF THE GI TRACT

The GI tract begins at the mouth, includes the esophagus, stomach, small intestine, large intestine (also known as the colon), and rectum, and ends at the anus. The entire system is about 9 m long in the average human being, according to the American Society of Gastrointestinal Endoscopy[1] and the entire GI tract is lined with mucous membrane, through which drugs may be readily transferred into the systemic circulation, and is highly perfused by a capillary network, which makes drug absorption possible. The human GI system absorbs nutrients and fluids in parallel with its

Developing Solid Oral Dosage Forms
DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00012-1

function as an efficient barrier against potentially hazardous bacteria and ingested and locally formed toxins. After a drug is given orally, GI transit and environments with respect to the surface area and membrane, pH, property of the GI fluids, enzymes, or intestinal transporters interact with drug molecules and influence drug absorption.

Small intestine (duodenum, jejunum, and upper region of ileum), the major and most efficient site for drug absorption of most drugs, has certain specific features: (1) an overall large surface area (0.33 m^2); (2) folds that result in a threefold increase in surface area (1 m^2); (3) fingerlike projections called *villi*, which increase the surface area by 30 times (10 m^2); (4) microvilli, which increase the surface area by 600 times (200 m^2)[2]; (5) a pH range of 5–7, which is favorable for most drugs to remain unionized; (6) a rich capillary network; and (7) transit time (3–4 hours).

The large intestine has specific features: (1) the presence of microbial flora localized in the colon, and the amount of bacteria varies depending on diet and use of antibiotics but can make up more than half the weight of fecal solids[3]; (2) a near-neutral pH; (3) reduced digestive enzymatic activity; (4) a much greater responsiveness to absorption enhancers; and (5) a much longer transit time (35–65 hours).[4]

Gastric residence time is variable, depending on many physiological, pathological, and pharmaceutical factors. For example, body posture, age, gender, osmolality, pH, and food are capable of influencing the gastric emptying. Fasted state gastric motility is influenced by the Interdigestive migrating motor complex (MMC).[5] There are four phases associated with the MMC. Phase I is approximately 45–60 minutes long and showcases minimal activity with the slowest corresponding gastric emptying. Phase II is 15–45 minutes long and consists of intermittent and erratic contractions. Phase III is the shortest phase, consisting of intense, short bursts of behavior lasting 5–10 minutes. Phase IV is a transition period from phase III back to phase I, lasting approximately 15–30 minutes.

The reported pH values of fasted gastric, duodenal, and jejunal fluids could range from 1.7 to 3.3 (median of 2.5) in stomach, 5.6–7.0 (median of 6.3) in duodenum, and 6.5–7.8 (median of 6.9) in jejunum.[6] The GI pH under the fed state will largely be governed by the administered meal itself, and the pH of the intestinal fluids is not affected to the same extent as gastric fluids because of the pretreatment in the stomach.[6] Under fed conditions, the duodenal pH is reported to be 5.4–6.5 (median of 6.0),[6] which is overlapping the fasted duodenal pH. Under fed conditions, the jejunal pH is reported to be 6.1.[6]

About 8–10 L of GI fluids are secreted into the GI tract daily. Gastric fluid is a complex and dynamic mixture consisting of saliva, gastric secretions, food, liquid intake, and refluxed liquid from duodenum. A literature review of parameters that characterize some attributes of gastric fluid and its subsequent intestinal presence is detailed in Tables 12.1 and 12.2 (reproduced from Mudie et al.[7]). Magnetic resonance imaging clinical studies have observed the formation and existence of small, discrete fluid pockets in the small intestine.[8] This fluid is also not distributed homogenously (as shown in Figs. 12.1 and 12.2). This method has been utilized to quantify GI fluid volume and transit after ingestion of 240 mL of water in fasted volunteers (as shown in Fig. 12.3).[9]

12.3 BIOPHARMACEUTICS CLASSIFICATION SYSTEM

The BCS is a scientific framework for classifying a drug substance based on its aqueous solubility and intestinal permeability.[10] According to this system, drug substances can be classified into four groups: (I) high solubility–high permeability, (II) low solubility–high permeability, (III) high solubility–low permeability, and (IV) low solubility–low permeability (Table 12.3). When combined with the in vitro dissolution characteristics of the drug product, the BCS considers three major factors: solubility, dissolution rate, and intestinal permeability, all of which govern the rate and extent of oral absorption from immediate release (IR) solid oral-dosage forms. Since the introduction of the BCS, its validity and applicability have been the subject of extensive research and discussion. The BCS framework has implications in the selection of candidate drugs for full development, prediction, and elucidation of food interaction, choice of formulation principle, including suitability for oral extended-release administration,[11] and the possibility of in vitro/in vivo correlation in the dissolution testing of solid formulations.[12] The regulatory applications of BCS are demonstrated by the U.S. Food and Drug Administration (FDA)[13,14] and a 2015 updated draft guidance for industry on waiver of in vivo bioavailability (BA) and bioequivalence (BE) studies for BCS class I/class III drugs in rapid dissolution IR solid oral-dosage forms.[15]

12.3.1 FDA guidance on biowaivers

The 2015 updated guidance[15] provides recommendations for sponsors of investigational new drug (IND) applications, new drug applications (NDAs), abbreviated new drug applications (ANDAs), and supplements to these applications that may request biowaivers

TABLE 12.1 Literature Values for Concentrations of Some Major Components of Fluid in the Fasted and Fed Stomach and Small Intestine

Fluid component			Stomach	Duodenum	Jejunum	Ileum
Bicarbonate (mEg/L^{-1})	Fasted	Mean	7.3	2.7, 6.7, 15	17, 30, 30, 8.2 ± 5 mM	40, 50, 70, 74, 75, 30 ± 11 mM
		Range	9–20		2–20, 5–10, 6–20	
	Fed	Mean		10	2.7, 2.6	
Bile Salts (mM)	Fasted	Median	0.1			
		Mean	0.08 ± 0.03, 0.3, 0.1	6.4 ± 1.3, 4.3 ± 1.2, 5.9 ± 1.8	2 ± 0.2	
		Range		1–5.3, 0.6–5.1, 0.3–9.6	0.8–5.5, 0.1–13.3, 5–6, 0–17	2–10
	Fed	Median		3.6, 5.2, 8.3, 11.9, 11.2, 5.2		1, 0.5
		Mean	0.06	14.5, 5.2, 16 ± 2, 10 ± 1, 9	8, 15, 8 ± 0.1, 6.5 ± 0.9	
		Range		1.6–6.2, 3.2–6.8, 6.7–13.4	0.5–40, 3–34	0.5–30, 0.2–1.3
Lipids (mg/mL)	Fasted	Median		0.5		
		Mean	0.56	0.6	0.1 ± 0.01 mM	
		Range		0–1.8		
	Fed	Median		1.8, 2.6		
		Mean			22 ± 1 mM	
		Range	50, 150	0.5–4.6, 1.1–3.6, 55–100		
Phospholipids (mM)	Fasted	Median		0.6		
		Mean			0.2 ± 0.07	
		Range		0.1–1.5, 0.03–0.06		
	Fed	Median		1.8, 1.2		
		Mean			3 ± 0.3	
		Range		1.3–2.4, 0.8–1.6		
Pepsin	Fasted	Median	0.1, 0.2			
		Mean	0.9			
		Range	0.8–1.3			
	Fed	Median				
		Mean	1.3, 1.7			
		Range	0.3–0.6, 0.6–1.7			
Lipase	Fasted	Mean	About 0.1 mg/mL			
	Fed	Range	11.4–43.9 U/mL			
Potassium (mM)	Fasted	Mean	13.4 ± 3		5.4 ± 2.1, 4.8 ± 0.5	4.9 ± 1.5
Sodium (mM)	Fasted	Mean	68 ± 29		142 ± 13, 142 ± 7	140 ± 6
	Fed	Mean			106 ± 15, 101 ± 17	139 ± 11, 133 ± 8
Chloride (mM)	Fasted	Mean	102 ± 28		126 ± 19, 135 ± 8	125 ± 12
Calcium (mM)	Fasted	Mean	0.6 ± 0.2		0.5 ± 0.3	

Unless indicated next to the value, units are noted next to the name of the component.

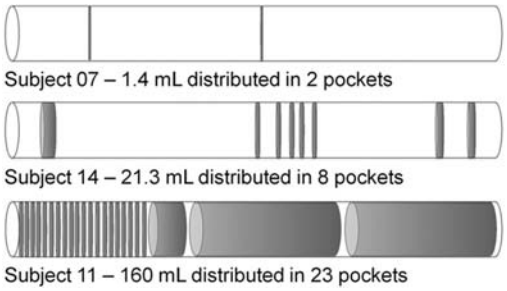

FIGURE 12.1 Graphical representation of the number and volume of small bowel water pockets for three subjects. The small intestine is represented as a cylinder. Shaded areas represent liquid pockets. The minimum (1.4 mL, Subject 14), near-median (21.3 mL, Subject 07), and maximum (160.1 mL, Subject 11) small bowel water volumes at the fasting baseline (before administration of the study dose of water) are shown to illustrate schematically high interindividual variability. *This figure reproduced with the permission of American Chemical Society (Mudie DM, Murray K, Hoad CL, Pritchard SE, Garnett MC, Amidon GL, et al. Quantification of gastrointestinal liquid volumes and distribution following a 240 mL dose of water in the fasted state.* Mol Pharm *2014;**11**:3039–47, http://pubs.acs.org/doi/abs/10.1021/mp500210c).*

for in vivo bioavailability/bioequivalence studies for highly soluble and highly permeable drug substances (class I) with rapid in vitro dissolution, or highly soluble and low-permeable drug substances (class III) with very rapid in vitro dissolution in IR solid oral-dosage forms, provided that the following conditions are met: (1) the drug must be stable in the GI; (2) excipients used in the IR solid oral-dosage forms have no significant effect on the rate and extent of oral drug absorption; (3) the drug must not have a narrow therapeutic index; and (4) the product is designed not to be absorbed in the oral cavity. The guidance also outlines methods for the determination of solubility, dissolution, and permeability.

12.3.1.1 Determination of drug solubility

According to the updated 2015 FDA draft guidance,[15] the pH-solubility profile of the test drug substance should be established at 37 ± 1°C in aqueous media with a pH in the range of 1–6.8; the pH conditions for drug solubility determination should be determined at pH = pK_a, pH = pK_a + 1, pH = pK_a–1, and at pH = 1 and 6.8, with a minimum of three replicate determinations of solubility in each pH condition. Standard buffer solutions used for solubility studies are described in the United States Pharmacopeia and the National Formulary (USP–NF). If these buffers are not suitable for physical or chemical reasons, other buffer solutions can be used. It is necessary to verify the solution pH after addition of the drug substance to a buffer. Methods include the traditional shake-flask method and acid or base titration methods. A validated

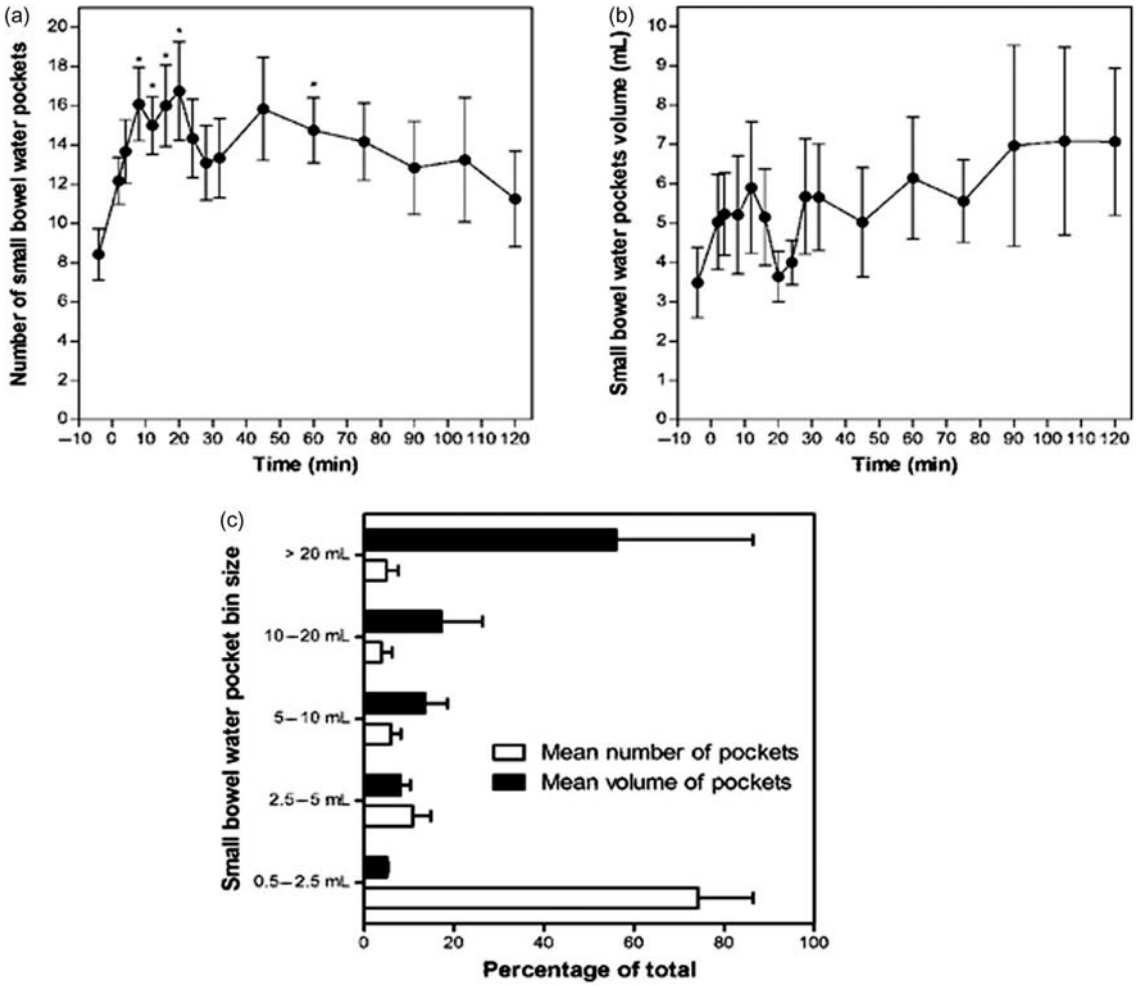

FIGURE 12.2 Small bowel water pockets before and after ingestion of a 240-mL water dose administered at $t = 0$ min (excluding all pockets in the smallest range < 0.5 mL). (a) Mean total number of small bowel water pockets. (b) Mean volume of small bowel water pockets. (c) Comparison between the percentage of the total number of pockets and the percentage of the total volume of each pocket in each volume range at the fasting baseline (before administration of the study drink of water). $n = 12$ healthy volunteers. Error bars represent ±SEM. Dunn's multiple comparison test versus baseline value $^*P < 0.05$. *This figure reproduced with the permission of American Chemical Society (Mudie DM, Murray K, Hoad CL, Pritchard SE, Garnett MC, Amidon GL, et al. Quantification of gastrointestinal liquid volumes and distribution following a 240 mL dose of water in the fasted state.* Mol Pharm *2014;**11**:3039–47, http://pubs.acs.org/doi/abs/10.1021/mp500210c).*

stability-indicating assay should be used to determine the concentration of the drug substance in selected buffers. A drug substance is considered highly soluble when the highest dose strength is soluble in 250 mL or less of aqueous media over the pH range of 1–6.8; otherwise, the drug substance is considered poorly soluble. The volume estimate of 250 mL is derived from typical bioequivalence study protocols that prescribe administration of a drug product to fasting human volunteers with a glass (about 8 oz) of water.

12.3.1.2 Determination of drug substance permeability

The permeability classification can be determined in human subjects using mass balance or absolute bioavailability, which are the preferred methods, or intestinal perfusion approaches. The FDA draft guidance[15] cites the use of human pharmacokinetic studies and intestinal permeability methods as acceptable ways to determine permeability classification. In many cases, a single method may be sufficient. When a single method fails to conclusively demonstrate a permeability classification, two different methods may be advisable. In the absence of evidence suggesting instability in the GI, a drug substance is considered by the guidance to be highly permeable when the extent of absorption in humans is determined to be 85% or more of an administered dose based on a mass balance determination or in comparison to an intravenous reference dose.[15] Otherwise, the drug substance is considered to be poorly permeable.

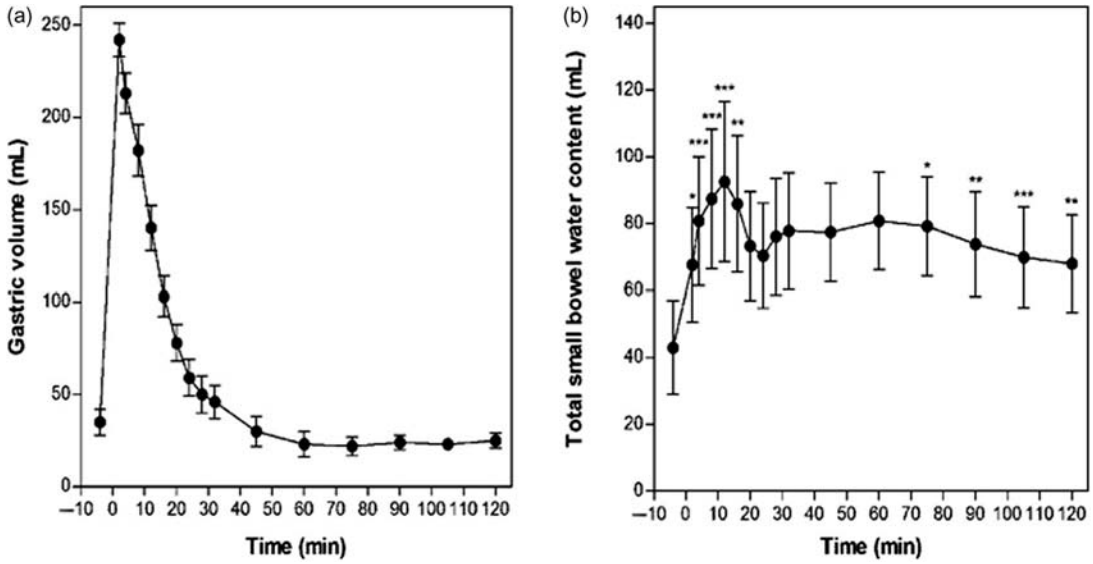

FIGURE 12.3 (a) Mean gastric volume and (b) mean total small bowel water content before and after ingestion of a 240-mL dose of water given at $t = 0$ min. $n = 12$ healthy volunteers. Error bars represent $\pm$SEM. Dunn's multiple comparison test versus baseline value $^{*}P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$. *This figure reproduced with the permission of American Chemical Society (Mudie DM, Murray K, Hoad CL, Pritchard SE, Garnett MC, Amidon GL, et al. Quantification of gastrointestinal liquid volumes and distribution following a 240 mL dose of water in the fasted state.* Mol Pharm *2014;**11**:3039–47, http://pubs.acs.org/doi/abs/10.1021/mp500210c).*

12.3.1.2.1 Mass balance and absolute bioavailability studies

In mass balance studies, unlabeled stable isotopes or radiolabeled drug substances are used to determine the extent of absorption of a drug. A sufficient number of subjects should be enrolled to provide a reliable estimate of the extent of absorption. Oral bioavailability determination can be performed using intravenous administration as a reference. The obtained extent of absorption in humans based on mass balance studies using total radioactivity in urine does not take into consideration the extent of degradation of a drug in the GI fluid prior to intestinal membrane permeation. Therefore, a drug's stability in the GI tract needs to be investigated unless more than 85% of unchanged drug is excreted via the urine. Experimentally, drug solutions in simulated fluids such as gastric and intestinal fluid USP should be incubated at 37°C for a period that is representative of in vivo drug contact with these fluids (eg, 1 hour in gastric fluid and 3 hours in intestinal fluid). Over 5% degradation of a drug in this study could suggest potential instability.

12.3.1.2.2 Intestinal permeability

The 2015 draft guidance[15] recommends that the following methods be considered appropriate to determine the permeability of a drug substance from the GI: (1) in vivo human intestinal perfusion; (2) in vivo or in situ animal intestinal perfusion; (3) in vitro permeation studies using excised human or animal intestinal tissues; or (4) in vitro permeation across a monolayer of cultured epithelial cells. The advantages and disadvantages of each method in determination of intestinal permeability will be discussed later in this chapter. An apparent passive transport mechanism can be assumed when one of the following conditions is satisfied:

1. A linear pharmacokinetic relationship between the drug dose and its area under the concentration-time curve (AUC) is demonstrated in humans.
2. Independence of the measured in vivo or in situ permeability on initial drug concentration in the perfusion fluid is demonstrated in an animal model.
3. Independence of the measured in vitro permeability on initial drug concentration in donor fluid or on transport direction using a suitable in vitro cell culture method is demonstrated.

To demonstrate the suitability of a method intended for BCS-based permeability determination, a rank-order relationship between experimental permeability values and the extent of drug absorption data in human subjects should be established using a sufficient number of model drugs (Table 12.4).[15] The model drugs should represent a range of low (eg, <50%), moderate (eg, 50%–84%), and high (≥85%) absorption and should have available information on the mechanism of absorption and reliable estimates of the extent of drug absorption in humans.[15] For in vivo intestinal perfusion

TABLE 12.3 Biopharmaceutics Classification System

Biopharmaceutics class	Solubility	Permeability
I	High	High
II	Low	High
III	High	Low
IV	Low	Low

TABLE 12.4 The Model Drugs Suggested for Use in Establishing the Suitability of a Permeability Method

Model drugs in establishing suitability of a permeability method		
High permeability	**Moderate permeability**	**Low permeability**
($f_a \geq 0.85$)	**($0.50 \leq f_a \leq 0.84$)**	**($f_a < 0.50$)**
Antipyrine	Amiloride	Acyclovir
Caffeine	Atenolol	Chlorothiazide
Carbamazepine	Chlorpheniramine	Enalaprilat
Disopyramide	Creatinine	Famotidine
Ketoprofen	Enalapril	Foscarnet
Metoprolol	Furosemide	Lisinopril
Minoxidil	Hydrochlorothiazide	Mannitol
Naproxen	Metformin	Nadolol
Phenytoin	Ranitidine	Polyethylene glycol (400)
Propranolol	Terbutaline	Sulpiride
Theophylline		

studies in humans, six model drugs are recommended. For in vivo or in situ intestinal perfusion studies in animals and for in vitro cell culture methods, 20 model drugs are recommended.

After demonstrating the suitability of a method and maintaining the same study protocol, it is not necessary to retest all selected model drugs for subsequent studies intended to classify a drug substance. Instead, two internal standards of a low- and a high-permeability model drug, in addition to the fluid volume marker (or a zero-permeability compound such as PEG-4000), should be included in permeability studies. The permeability values of the two internal standards should not differ significantly between different tests, including those conducted to demonstrate suitability of the method. At the end of an in situ or in vitro test, the amount of drug in the membrane should be determined to assist in the calculation of mass balance.

12.3.1.3 *Comparison of dissolution profile*

In the BCS draft guidance,[15] an IR drug product is considered rapidly dissolving when over 85% of the labeled amount of the drug substance dissolves within 30 minutes, using USP Apparatus I at 100 rpm or Apparatus II at 50 rpm (or at 75 rpm when appropriately justified) in a volume of 500 mL or less in each of the following media: (1) 0.1 N of HCl or simulated gastric fluid without enzymes; (2) a pH 4.5 buffer; and (3) a pH 6.8 buffer or simulated intestinal fluid without enzymes. In addition, very rapid dissolution is defined to be over 85% of the labeled amount of the drug substance dissolved within 15 minutes using the abovementioned conditions.

According to the draft guidance,[15] observed in vivo differences in the rate and extent of drug absorption from two pharmaceutically equivalent solid oral products may be due to differences in in vivo drug dissolution. If the in vivo dissolution is rapid or very rapid in relation to gastric emptying, oral drug absorption is likely to be independent of drug dissolution. Thus, for BCS class I (high solubility/high permeability) or BCS class III (high solubility/low permeability) drug substances, so long as the inactive ingredients in the dosage form do not significantly affect the absorption of active ingredients, demonstration of in vivo bioavailability or bioequivalence may not be necessary for drug products containing class I or III drug substances.

12.3.2 Scientific basis for BCS

The key parameters controlling drug absorption are three dimensionless numbers: dose number, dissolution number, and absorption number, representing the fundamental processes of dose, drug dissolution, and membrane permeation, respectively.

The dose number (D_0) is characterized by the volume required for solubilizing the maximum dose strength of the drug[16]:

$$D_0 = \frac{M/V_0}{C_s} \tag{12.2}$$

where, C_s is the drug solubility, M is the dose, and V_0 is the volume of water taken with the dose, which is generally set to 250 mL.

The dissolution number (D_n) is characterized by the time required for drug dissolution, which is the ratio of the intestinal residence time (t_{res}) and the dissolution time (t_{diss})[16]:

$$D_n = \frac{t_{res}}{t_{diss}} = \frac{3DC_s}{r^2\rho} \times t_{res} \tag{12.3}$$

where D is diffusivity, ρ is density, and r is the initial particle radius.

The absorption number (A_n) is characterized by the time required for absorption of the dose administered, which is a ratio of residence time and absorptive time (t_{abs})[16]:

$$A_n = \frac{t_{res}}{t_{abs}} = \frac{P_{eff}}{R} \times t_{res} \tag{12.4}$$

where P_{eff} is the permeability and R is the gut radius.

Drugs with complete absorption show $D_0 < 1$, while D_n and $A_n > 1$. This approach is used to set up a theoretical basis for correlating in vitro drug product dissolution with in vivo absorption. To follow the movement of a dosage form through the GI, the entire process needs to be broken down into several component parts in order to see it mechanistically. The fundamental starting point is to apply Fick's first law to the absorption across the intestinal membrane:

$$J_w = P_w \times C_w \tag{12.5}$$

where J_w (x, y, z, t) is the drug flux (mass/area/time) through the intestinal wall at any position and time, P_w (x, y, z, t) is the permeability of intestinal membrane, and C_w (x, y, z, t) is the drug concentration at the intestinal membrane surface. This equation is a local law pertaining to each point along the intestinal membrane. It is assumed that sink conditions (ie, drug concentration equals zero) exist and that P_w is an effective permeability. The plasma may be assumed to be the physiological sink since concentrations in the plasma are generally several orders of magnitude lower than that in the intestinal lumen in humans. The drug absorption rate (ie, the rate of loss of drug from the intestinal lumen), assuming no luminal reactions, at any time t is

$$\text{Absorption rate} = \frac{dm}{dt} = \iint_A P_w C_w dA \tag{12.6}$$

where the double integral is over the entire GI surface.

The total mass, M, of drug absorbed at time t is

$$M_{(t)} = \int_0^t \iint_A P_w C_w dA dt \tag{12.7}$$

These mass balance relations are very general since the surface can be of arbitrary shape and the concentration at the membrane wall and permeability can have any dependence on position and time. For full generality, the permeability P_w must be considered to be position dependent as well as time dependent.

Based on Eqs. 12.2–12.7, the following principle for bioequivalence may be stated: if two drug products containing the same drug have the same concentration-time profile at the intestinal membrane surface, then they will have the same rate and extent of absorption. Furthermore, this statement may imply that if two drug products have the same in vivo dissolution profile under all luminal conditions, they will have the same rate and extent of drug absorption. These general principles assume that there are no other components in the formulation that affect the membrane permeability, intestinal transit, or both. Accordingly, the fraction absorbed (f_a) of a solution follows an exponential function, and can be calculated as follows:

$$f_a = 1 - e^{-2An} \tag{12.8}$$

As to the establishment of in vitro-in vivo correlation (IVIVC), several factors need to be considered. These in vitro dissolution tests can only model the release and dissolution rates of the drug, and it is only when these processes are rate limiting in the overall absorption that IVIVC can be established. For class I drugs, the complete dose will be dissolved already in the stomach and, provided that the absorption in the stomach is negligible, the gastric emptying will be rate-limiting and therefore IVIVC is not expected. Thus, in vitro dissolution testing can be expected to be overdiscriminating for those drugs, since tablets showing different in vitro dissolution profiles may provide the same rate and extent of bioavailability. Class II drugs are expected to have a dissolution-limited absorption and an IVIVC can be established using a well-designed in vitro dissolution test.[16] But the IVIVC will not be likely for class II drugs if absorption is limited by the saturation solubility in the GI tract rather than by the dissolution rate. In this situation, the drug concentration in the GI tract will be close to the saturation solubility and changes in the dissolution rate will not affect the plasma concentration profile or the in vivo bioavailability. The absorption of class III drugs is limited by their intestinal permeability and no IVIVC should be expected.[16] However, when the drug dissolution becomes slower than the gastric emptying, a reduction of the extent of bioavailability will be found at slower dissolution rates, since the time during which the drug is available for transport across the small intestinal barrier will then be reduced. The class IV drugs present significant problems for effective oral delivery. Very limited or no IVIVC is expected.

12.4 INTESTINAL PERMEABILITY EVALUATION: CULTURED CELLS

The term *permeability* is defined as the rate (cm/second) at which a solute is transported across the intestinal membrane, irrespective of transport mechanism. Various methodologies can be used for evaluation of intestinal permeability and drug absorption; each has its advantages and disadvantages. Numerous in vitro methods have been used in the drug selection process for

assessing the intestinal absorption of potential drug candidates with distinct advantages and drawbacks. Compared to in vivo drug absorption studies, evaluation of intestinal permeability in vitro requires less compound; is relatively easier and, in the case of regional absorption studies, avoids complicated surgery and maintenance of surgically prepared animals; is more rapid and has the potential to reduce animal usage since a number of variables can be examined in each experiment; provides insights into the mechanisms (eg, carrier-mediated vs passive), routes (eg, transcellular vs paracellular), and regional differences (eg, small vs large intestine) involved in transepithelial transport; and is analytically more simple because compounds are being analyzed in an aqueous buffer solution as opposed to whole blood or plasma. However, one universal limitation with all the in vitro systems is that the effects of physiological factors such as gastric-emptying rate, GI transit rate, and GI pH cannot be incorporated into the data interpretation.

The successful application of in vitro models to predict drug absorption across the intestinal mucosa depends on how closely the in vitro model mimics the characteristics of the in vivo intestinal epithelium. Although it is very difficult to develop a single in vitro system that can simulate all the conditions existing in the human intestine, combinational in vitro systems are used as decision-making tools in drug discovery and development. Various cell models that mimic in vivo intestinal epithelium in humans have been developed and widely used. The cell lines are now routinely cultivated as monolayers for studies of the transepithelial transport of drugs. The examples of some selected cell culture models are summarized in Table 12.5.

TABLE 12.5 Cultured Cells Commonly Used for Permeability Assessment

Cell type	Species or origin	Special characteristics
Caco-2	Human colon adenocarcinoma	Most well-established and frequently used cell model
		Differentiates and expresses some relevant efflux transporters
		Expression of influx transporters is variable (laboratory to laboratory
MDCK	Madin Darby canine kidney epithelial cells	Polarized cells with low intrinsic expression of ATP-binding cassette (ABC) transporters
		Ideal for transfections
LLC-PK1	Pig kidney epithelial cells	Polarized cells with low intrinsic transporter expression
		Ideal for transfections
2/4/A1	Rat fetal intestinal epithelia cell	Temperature-sensitive
		Ideal for paracellularly absorbed compounds (leakier pores)
TC-7	Caco-2 subclone	Similar to Caco-2
HT-29	Human colon	Contains mucus-producing goblet cells
IEC-18	Rat small intestine cell line	Provides a size-selective barrier for paracellularly transported compounds

12.4.1 Caco-2 cells

The Caco-2 cell line was first isolated in the 1970s from a human colon adenocarcinoma. During growth, Caco-2 cells go through processes of proliferation, confluency, and differentiation.[17] When grown under standard conditions on semipermeable membranes, fully differentiated Caco-2 cells are very similar to normal enterocytes with regards to their morphological characteristics. Primarily, they have functional tight junctions and they develop apical and basolateral domains and brush border cytoskeleton. Because the permeation characteristics of drugs across Caco-2 cell monolayers correlate with their human intestinal mucosa permeation characteristics, it has been suggested that Caco-2 cells can be used to predict the oral absorption of drugs in humans. In the past two decades, there has been a dramatic increase in the use of Caco-2 cells as a rapid in vitro screening tool in support of drug discovery within the pharmaceutical industry, as well as in advanced mechanistic studies, including intestinal absorption, transport, and metabolism[18,19]; utilization of absorption modifying excipient in the drug formulation[20]; and oral toxicity.[21]

The Caco-2 cells are usually grown in culture T-flasks (75 cm^2 or 175 cm^2) in a CO_2-incubator at 37°C with 5% CO_2. The culture medium is Dulbecco's Modified Eagle Medium (DMEM) supplemented with 0.1 mM of nonessential amino acids, 100 U/mL of penicillin, 0.1 g/mL of streptomycin, 10 mM of sodium bicarbonate, and 10% fetal bovine serum (FBS). At a confluency of 70%–80%, the cells are split at a ratio of 1:3–1:5. For use in the transport experiments, the cells are harvested with trypsin-EDTA and seeded on polycarbonate filters (0.4 μm pore size, 1.13 cm^2 growth area for 12-well plate, 0.33 cm^2 growth area for 24-well plate) inside Transwell cell culture chambers at a density of approximately 75,000 cells/cm^2 (Fig. 12.4). The culture medium is refreshed every 24–48 hours. Transport studies are usually done after 18–21 days in culture, when expression of transporters (eg, P-glycoprotein (P-gp)) reaches its maximum.

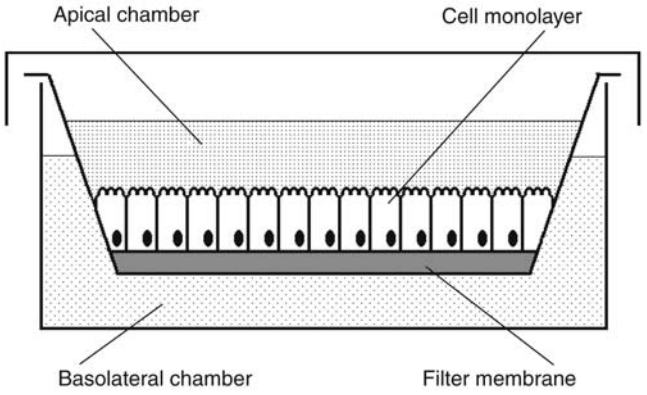

FIGURE 12.4 Typical experimental setup of a Caco-2 system used to study the transport of molecules across a monolayer.

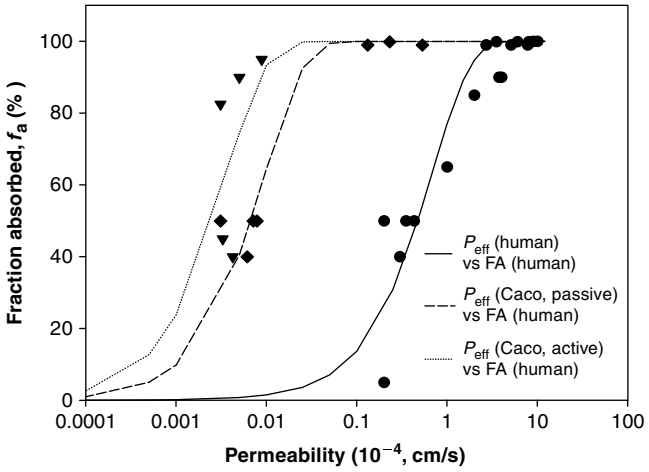

FIGURE 12.5 The relationship between human jejunal effective permeability, Caco-2 monolayer permeability, and the fraction dose absorbed in humans.

To ensure the integrity of the monolayer during the course of the experiment, quality control is done by measuring the transepithelial electrical resistance (TEER) values and the permeability of mannitol (low cellular permeability). Caco-2 inserts with TEER values greater than $250\,\Omega \times cm^2$ (24 wells) can be used in the study. The permeability of ^{14}C- or ^{3}H-mannitol should be lower than 0.5×10^{-6} cm/second. In each experiment, certain reference compounds (mannitol and propranolol with high cellular permeability) should be included. The apparent permeability (P_{app}) coefficient (expressed in cm/second) is calculated as follows:

$$P_{app} = \frac{V_R}{A \times C_0} \times \frac{dC}{dt} \tag{12.9}$$

where, V_R is the volume in the receiver chamber (mL), A is the filter surface area (cm^2), C_0 is the initial donor concentration of the drug (μg/mL), and dC/dt is the initial slope of the cumulative concentration (μg/mL) in the receiver chamber with time (second). If the P_{app} values in the apical-to-basolateral direction are not equal to those in the basolateral-to-apical direction, or if the P_{app} values decrease with increasing test compound concentration, this suggests the involvement of transporter pathways. Additional incubations may then be carried out to probe for the involvement of specific transporter or efflux systems. Completely absorbed drugs are found to have a high permeability coefficient ($P_{app} > 1 \times 10^{-6}$ cm/second), whereas incompletely absorbed drugs generally have a low permeability coefficient ($P_{app} < 1 \times 10^{-7}$ cm/second) in Caco-2 cells. Caco-2 cells have been demonstrated as an excellent model of the passive transcellular pathway,[22] or model comparison with parallel artificial membrane permeation assay (PAMPA).[23] Certain studies suggest that Caco-2 cells rank the permeability of drugs in the same order as more complex absorption models such as in situ perfusion models. These correlation studies are mainly performed with passively transported drugs (Fig. 12.5).

12.4.2 Limitations of Caco-2 cell model

There are a few important factors that limit the use of cultured cell models. The lack of correlation for paracellularly transported compounds is one limitation.[22] Caco-2 has been shown to have a significantly lower number of paracellular pores than the human intestine.[22] Low-molecular-weight hydrophilic compounds (eg, ranitidine, atenolol, furosemide, hydrochlorothiazide) displayed low permeability in the Caco-2 cell model despite the extent of absorption in humans is greater than 50%. In other words, this cell model can only serve as a one-way screen such that compounds with high permeability in this model are typically well absorbed in vivo; however, compounds with low permeability cannot be certainly classified as poorly absorbed compounds in vivo.

Another limitation is that the carrier-mediated drug intestinal absorption is poorly predicted with the Caco-2 cell model.[22] The Caco-2 cell model primarily measures passive drug transport (both transcellular and paracellular). Caco-2 cells can express some transporters (eg, peptide transporters, organic cation transporters (OCTs), and organic anion transporters (OAT)), but most intestinal transporters are quantitatively underexpressed when compared to those in vivo.[22,24] Thus, this model is likely to generate false negatives with actively transported drug candidates.

In addition, the correlation of the permeability of slowly and incompletely absorbed drugs in the Caco-2 cells and human jejunum seems qualitative rather than quantitative. These drugs (eg, lamivudine)[24] are

transported at a 30- to 80-fold slower rate in the Caco-2 cells than in the human jejunum. It is also very difficult to compare the absolute permeability coefficient value of individual compounds reported in the literature, particularly with compounds that are primarily permeate via the paracellular route. The variability may be attributed to differences in culture conditions and composition of cell subpopulation.

Additionally, there is the lack of metabolic enzymes in cell models. An ideal cell-based intestinal permeability tool would be one that simulates the human GI enterocytes not only in lipid bilayer characteristics, but also in metabolic enzyme activity. Although Caco-2 cell models are known to express adequate amounts of hydrolase, esterase, and brush-border enzymes, they fail to simulate the complete in vivo intestinal environment because they do not express appreciable quantities of cytochrome P450 (CYP) 3A4, the principal CYP present in human enterocytes.

Moreover, the use of appreciable amount of organic cosolvent is limited. The integrity of tight junctions is easily compromised by commonly used organic solvents (eg, methanol, ethanol, PG, PEG) even at a small concentration (more than 1%–2% v/v). Therefore, a significant percentage of new drug candidates with poor aqueous solubility cannot be evaluated in this model. Furthermore, cultured cell systems cannot be used to adequately evaluate those compounds that can nonspecifically bind to plastic devices.

In most cases, the preparation of fully functional cell monolayers generally requires a 3-week cell culture period with 8–9 instances of laborious cell feeding. However, the preparation time can be substantially reduced by modifying both the coating material and growth media. A shorter cell-culturing period to generate functional monolayers not only increases the overall productivity, but also reduces the chance of bacterial/fungal contamination so as to minimize downtime.

12.4.3 MDCK cells

The Madin-Darby canine kidney (MDCK) line, established in the 1950s, is another of the most frequently used cell lines for permeability assessment. MDCK cells are grown in the culture medium Modified Eagle Medium (MEM) supplemented with 2% sodium bicarbonate, 1% glutamine, and 5% FBS. Like Caco-2 cells, MDCK cells have been shown to differentiate into columnar epithelia and to form tight junctions when cultured on semipermeable membranes. Given the fact that Caco-2 cells are derived from human colon carcinoma cells, whereas MDCK cells are derived from dog kidney cells, the major difference between Caco-2 and MDCK cells is the absence or presence of active transporters and drug metabolizing enzymes. The use of MDCK cells has been demonstrated as a tool for assessing the membrane permeability properties of early drug discovery compounds.[25,26]

For passively transported compounds, MDCK cells can be used as an alternative for Caco-2 cells.[26–28] Although a high rank correlation coefficient of 0.93 for MDCK to Caco-2 P_{app} has been observed, the relationship between the permeability in cells and the absorption in humans is less strongly correlated in MDCK. Permeability values tend to be lower in MDCK cells than in Caco-2 cells. While for actively transported compounds, the discrepancy is more significant between these two cell models. One major advantage of MDCK cells over Caco-2 cells is the shorter cultivation period (3 days vs 3 weeks). A shorter cell culture time becomes a significant advantage considering reduced labor and reduced downtime in case of cell contamination. However, species differences should also be considered before using MDCK cells as a primary screening tool for permeability in early drug discovery.

12.4.4 Other cells

TC-7 is one of the subclones isolated from Caco-2 cells with very similar cell morphology, concerning apical brush border, microvilli, tight junctions, and polarization of the cell line. The dipeptide transporter is underexpressed in both cell lines. The TC-7 clone, however, appears more homogenous in terms of cell size. Both cell lines achieve similar monolayer integrity toward mannitol and PEG-4000. A comparison in apparent drug permeability has been made between TC-7 cell and its parental Caco-2 cells.[29] When using cyclosporine A as a P-glycoprotein substrate, active efflux is shown to be lower in the TC-7 clone than in the parental Caco-2 cells. The correlation curves obtained with both cell types are almost completely superimposable, based on the permeability result from 20 test compounds exhibiting large differences in chemical structure, molecular weight, transport mechanisms, and percentage of absorption in humans.

Lewis lung carcinoma-porcine kidney 1 (LLC-PK1) cells have also been explored as an alternative to Caco-2 cells for assessing the permeability of test compounds.[30] Several investigators have reported the utility of porcine cell line for characterizing the passive absorption discovery compounds.[31]

The cell model of 2/4/A1, which originates from fetal rat intestine, is found to be able to better

mimic the permeability of the human small intestine, particularly with regard to passive transcellular and paracellular permeability.[32,33] This immortalized cell line forms viable differentiated monolayers with tight junctions, brush-border membrane enzymes, and transporter proteins. The paracellular pore radius of 2/4/A1 cell has been determined to be 9.0 ± 0.2 Å, which is similar to the pores in the human small intestine, whereas the pore size in Caco-2 is much smaller (about 3.7 ± 0.1 Å). Therefore, 2/4/1A cells have been proposed as a better model to study passively transported compounds via the paracellular route than Caco-2 cells. The transport rate of poorly permeable compounds (eg, mannitol and creatinine) in 2/4/1A monolayers is comparable with that in the human jejunum and is up to 300 times faster than that in the Caco-2 monolayers, suggesting that the 2/4/1A cell line will be more predictive for compounds that are absorbed via paracellular route.

12.5 INTESTINAL PERMEABILITY EVALUATION: EX VIVO

12.5.1 The everted gut sac technique

The everted sac approach introduced in 1954 by Wilson and Wiseman,[34] has been widely used to study intestinal drug transport. Everted sacs are prepared from rat intestine by quickly removing the intestine from the decapitated animal, flushing with a saline solution, everting it over a glass rod (diameter 3 mm), filling it with fresh oxygenated culture medium, and dividing it into sacs approximately 2–4 cm in length with silk suture (Fig. 12.6). Sacs (with the mucosal side outside) are then submerged in a culture medium containing the drug of interest, and accumulation in the inner compartment is measured. Under optimal conditions, sacs remain viable for up to 120 minutes. To check sac viability and integrity, glucose concentration can be monitored inside and outside the everted sac during the experiments. It is a two-compartment system permitting the calculation of the kinetics of uptake into the epithelial tissue by assaying material in the cells, and transferring across the entire epithelial layer by measuring material that is found inside the sac at the end of the incubation period. The system has been used to study the uptake of liposomes and proteins, bioadhesive lectins, and synthetic, nondegradable polymers.[35]

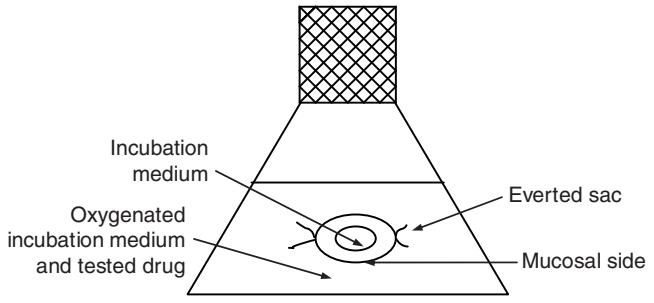

FIGURE 12.6 Everted sac: the sac is incubated by shaking in the oxygenate tissue culture medium. Each sac is removed at the required time point and drug is analyzed in the serosal space and tissue.

The everted sac technique is a useful tool to study the mechanisms of uptake of molecules. Test compounds are incubated with the sac at various concentrations and for different time periods to obtain the kinetics of uptake. At the end of the incubation, the compounds are analyzed in the tissue and the serosal space, and as tissue protein is measured, the uptake is expressed per unit protein for normalization. In the case of passive membrane diffusion, the compound is detected in both tissue and serosal space, and uptake will be concentration dependent. For carrier-mediated transports, uptake will be saturable and subject to competition by other substances transported by the carriers. Test compounds should be detected in both tissue and serosal space. In the case of active mechanisms, there will be inhibition by the metabolic inhibitors added to the system. Endocytosis is slow and may or may not be saturable, depending on whether it is receptor mediated, and inhibited by both metabolic inhibitors and inhibitors of microtubule assembly like colchicine. The compound will be detected in the tissue, and in very small amounts in the serosal space. If it is transported by the paracellular route, there will be no test compound in the tissue, only in the serosal space, and translocation should be concentration dependent. In addition, disruption of the tight junctions with the Ca^{2+} chelators ethylene diamine tetraacetic acid (EDTA) or ethyleneglycol tetraacetic acid (EGTA) should increase the uptake of molecules by the paracellular route.

Given the presence of P-gp activity along the rat intestine, the everted gut sac model can also be useful to study the action of intestinal P-gp on intestinal drug absorption. By comparing the transport kinetics of a substrate in the absence or the presence of potential P-gp inhibitors, the method can be used to evaluate the role of P-gp in the intestinal drug absorption and to screen for putative P-gp inhibitors. An understanding of the site specificity of absorption is most important to optimizing oral drug delivery, particularly in developing controlled released formulations.

The everted sac system affords a simple technique to investigate differences in drug absorption along the GI tract. The everted sac system is also a useful tool for screening absorption enhancers. The transport mechanism, which is modified by the enhancers, can be verified by using specific model compounds to measure the absorption in the presence and absence of enhancers. For example, quinine or digoxin for membrane diffusion, amino acids, or dipeptides for carrier transport, as well as mannitol for the paracellular route, can be used for this purpose. The everted gut sac has the potential for studying the metabolism of drugs by the intestinal mucosa. If drugs are metabolized by cell surface enzymes in the intestine, then the metabolic products will be detected in the medium following incubation. If the drug is absorbed into the cells, then it may be susceptible to first-pass metabolism within the enterocytes. The products of this metabolism may themselves be transported, in which case they would be detected in the serosal space, or they may be confined to the interior of the cells.

Thus, the everted gut sac system has a number of advantages. It is simple, quick, very reproducible, and inexpensive. The regional differences in drug absorption can be studied and differentiated with this system. It can provide information on the mechanism of drug absorption and be used to test the effects of enhancers and formulations on absorption. The system also has some disadvantages. The major disadvantage is that it is an animal model, and the absorption results obtained with this model may not always reflect the real absorption profile in humans. In addition, the test compounds have to across all the layers (including muscle) of the small intestine, instead of just the intestinal mucosa. Furthermore, the sink condition cannot be established due to the small volume inside the sac.

12.5.2 Ussing chamber

The Ussing chamber technique resulted from the pioneering work of Ussing and coworkers, who in the late 1940s and early 1950s published a series of papers describing the transepithelial ion fluxes. This technique has subsequently been modified by Grass and Sweetana to study drug transport. This technique utilizes small intestinal sheets that are mounted between two compartments. The mucosal and serosal compartments are usually supplied with Krebs-Ringer bicarbonate buffer (KRB), which is continuously gassed with a mixture of O_2:CO_2 (95:5). The test compound is added to either the mucosal or serosal side of the tissue to study transport in the absorptive or secretory direction, respectively. Apparent permeability coefficients (P_{app}) are calculated as for Caco-2 transport experiments from the appearance rate of the compound in the receiver compartment.

The applications of the Ussing chamber system include studying the transepithelial drug transport in combination with intestinal metabolism and investigating the regional differences in intestinal absorption.[36] Advantages of the technique are that the amount of drug needed to perform a study is relatively small, and the collected samples are analytically clean. Unlike in vitro cultured cell model, the presence of the apical mucus layer makes the system more relevant to in vivo condition. A novel factor called the *permeability ratio (PR)*, which is the value of in vitro intestinal permeability obtained from the Ussing chamber, further corrected by the permeability of lucifer yellow, a paracellular permeability marker, was recently proposed for reliable in vitro permeability.[37] By using this approach, the correlation with human in vivo intestinal permeability of 12 tested model drugs representing different BCS classes is high.[37] More important, the new method perfectly classifies all 12 model drugs.

In addition, the model offers the possibility to study bidirectional drug transport and concentration dependency of transport and the effect of specific transport inhibitors. The Ussing chamber model has been used to demonstrate transport polarity of compounds that are substrates of P-gp or the multidrug resistance (MDR)−associated protein.[38] Furthermore, species differences with respect to intestinal absorption characteristics can be determined, which can be useful during the selection of a suitable animal model for drug bioavailability studies. It should be noted that during preparation of the Ussing chamber system, dissection of the epithelial tissue is rather difficult to perform and the serosal muscle layers can be only partially removed, which may result in an underestimation of transport, which appears to be an issue, especially for lipophilic drugs.

12.5.3 In situ intestinal perfusion in rat

Among the various preclinical models that are used to study drug absorption, the in situ method is the nearest to the in vivo system. Intestinal segments of the anesthetized animals are cannulated and perfused by a solution of the drug and the amount of the drug that is taken up from the perfusate can be calculated (Fig. 12.7). Input of the drug compound can be closely controlled in terms of concentration, pH, osmolality,

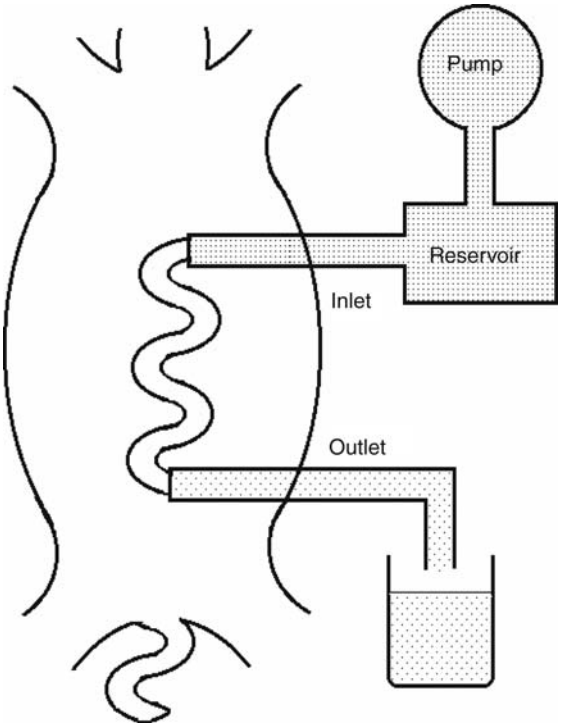

FIGURE 12.7 The in situ study of drug uptake by the single-pass perfusion technique. A rat is anesthetized, and an intestinal segment is cannulated and perfused with the solution containing the compound of interest. The amount of the compound taken up from the solution can be calculated from the difference between the inlet and the outlet concentration of the compound.

intestinal region, and flow rate. The advantages of in situ method include:

1. The barriers that a compound has to cross to reach the portal blood circulation are identical in the in situ and in vivo situations.
2. This method provides a unique possibility for studying the intestinal events under isolated status without the complication of biliary excretion and enterohepatic circulation.
3. It is good for producing some kinetic data, particularly as the blood supply, innervation, and clearance capabilities of the animal remain intact.
4. Like the Ussing chamber technique, the in situ method can also be used for the regional absorption studies, and observing the gross effects of enhancer. Thus, the method has been widely used for the selection of drug candidates. And in situ intestinal perfusion in rat jejunum in the predictive accuracy of uptake and efflux transport seems superior to Caco-2 cell model.[24]

The prediction of the extent of absorption in humans from rat intestinal perfusion data has been demonstrated for a series of compounds with variable absorption (5%−100%) in humans. A high correlation between effective permeability values determined in rat and human jejunum has been demonstrated. Therefore, in situ perfusion of rat jejunum is considered to be a useful tool to classify compounds according to BCS,[39,40] provided that appropriate reference compounds are included to account for interlaboratory variations in passively and actively transported drugs.

The basic experimental procedure is as follows. Rats are fasted for at least 12 hours and anesthetized, and then an intestinal segment (10−20 cm) is isolated and cannulated. This segment is rinsed with an isotonic solution before being constantly perfused with the solution containing the compound of interest. The perfusate is then collected in determined intervals. Complete recovery of PEG-4000 (a nonabsorbable marker), stable water flux, and the effective permeability coefficient (P_{eff}), with time for compounds transported both passively (antipyrine) and by a carrier-mediated mechanism (glucose), indicate that viability of the intestinal tissue is maintained during the experiment. The P_{eff} of antipyrine can also be used as an indication of extensive change of the mesenteric blood flow. P_{eff} is calculated as follows:

$$P_{eff} = \frac{-Q_{in} \times \ln(C_{out}/C_{in})}{2\pi rL} \qquad (12.10)$$

where C_{in} and C_{out} are the inlet and outlet concentration of the compound in the perfusate, Q_{in} is the flow rate of perfusion medium entering in the intestinal segment, and $2\pi rL$ is the mass transfer surface area within the intestinal segment, which is assumed to be the area of a cylinder with length L and radius r. The accessibility of the luminal compartment enables an estimation of intestinal metabolism to be made. However, perfusion systems give no information about events at the cellular or membrane level. The measurement of the rate of decrease of the drug concentration in the perfusate does not always represent the rate of absorption of the drug into the systemic circulation, particularly if presystemic or intracellular intestinal metabolism occurs. This problem can be overcome if this technique is applied in combination with measurements of the concentration of the drug in the portal vein. The method is also limited because of its cost factor, as it requires a large number of animals to give statistically significant absorption data. Relatively high amounts of test compounds are also required to perform studies, which is not feasible in early drug discovery.

Also, surgical manipulation of the intestine combined with anesthesia can cause a significant change in the blood flow to the intestine and may have a remarkable effect on absorption rate. More often, the method uses perfused intestinal flow rates higher than those in vivo; and as a consequence, the in situ intestine is fully distended and the luminal hydrostatic pressure increases. This distension may affect the intestinal permeability or absorptive clearance.

12.5.4 Intestinal perfusion in humans

Intestinal perfusion techniques have been first used in humans with the aim of studying the absorption and secretion mechanisms or the role of gastric emptying in drug absorption, while the techniques are too complex to be used for mass or routine screening studies. The basic principle of these techniques is to infuse a solution of the test compound and a nonabsorbable marker such as PEG-4000 into an intestinal segment and to collect perfusate samples after the perfusion has passed through the segment. The difference between the inlet and the outlet concentration of the compound in the solution is assumed to have been absorbed.

Three main single-pass perfusion approaches have been employed in the small intestine:

- Open system—A triple lumen tube including a mixing segment
- Semiopen system—A multilumen tube with a proximal occluding balloon
- Closed system—A multilumen tube with two balloons occluding a 10 cm long intestinal segment (Fig. 12.8).[41]

In the open system method, entering perfusion solution and GI fluids are mixed in a "mixing segment," and at the distal end of the mixing segment, a sample is taken that is considered to be the inlet concentration of the test segment. The absorption is then calculated from a second outlet sample taken at the end of the test segment, which usually is 20−30 cm distal to the mixing segment. A major disadvantage of this method is that the composition of the perfusate will change along both mixing and test segments, which makes it difficult to define the absorption conditions and therefore to determine reference drug permeability at well-controlled luminal conditions. Perfusate can flow in either direction, and it is difficult to estimate the actual segment length in this open system. The semiopen system, which has been introduced by Ewe and Summerskill, overcomes the problem of proximal contamination by using an occluding balloon proximal to the test segment. This method decreases proximal leakage, and therefore, the luminal composition will be maintained at equilibrium and drug permeability can be determined under well-controlled conditions. However, both the open and semiopen methods generally use rather high perfusion flow rates (typically between 5 and 20 mL/minute), which are significantly higher than physiological flow rates of 1−3 mL/minute. The recovery of liquid is low and variable with the length of the intestinal segment studied unknown. Lennernas et al. refined the technique by developing a new intestinal perfusion instrument, which consists of a multichannel sterile tube with two inflatable balloons, creating a 10-cm-long segment and allowing segmental intestinal perfusion (Fig. 12.8).[42] The tube is introduced orally after local anesthesia, and when the tube has been positioned, the balloons are inflated, creating a closed intestinal segment. The segment is rinsed, perfused with a drug-free perfusate and then perfused with the perfusion solution containing the test compound. The absorption rate is calculated from the disappearance rate of the compound from the perfused segment. The absorption rate can be calculated in different ways, but the intestinal P_{eff} most likely provides the best description of the transport process across the intestinal barrier. The P_{eff} is calculated as shown in Eq. 12.10. There is a good correlation between the measured effective permeability values and the extent of absorption of drug in humans determined by pharmacokinetics studies (Fig. 12.9).

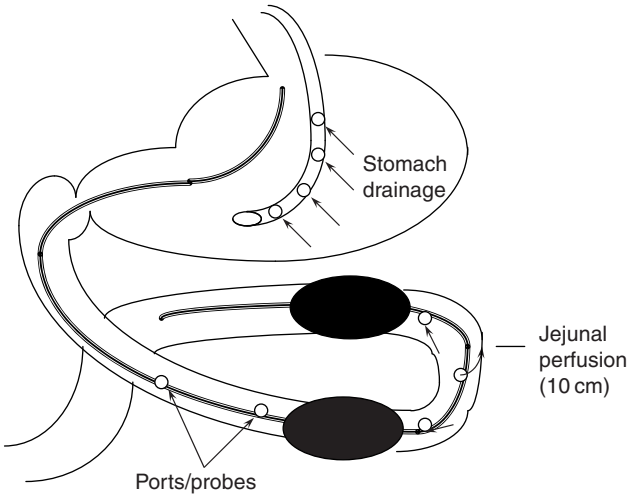

FIGURE 12.8 The multichannel tube system with double balloons enabling segmental perfusion in humans. The difference between the inlet and the outlet concentration of the compound in the solution is assumed to have been absorbed.

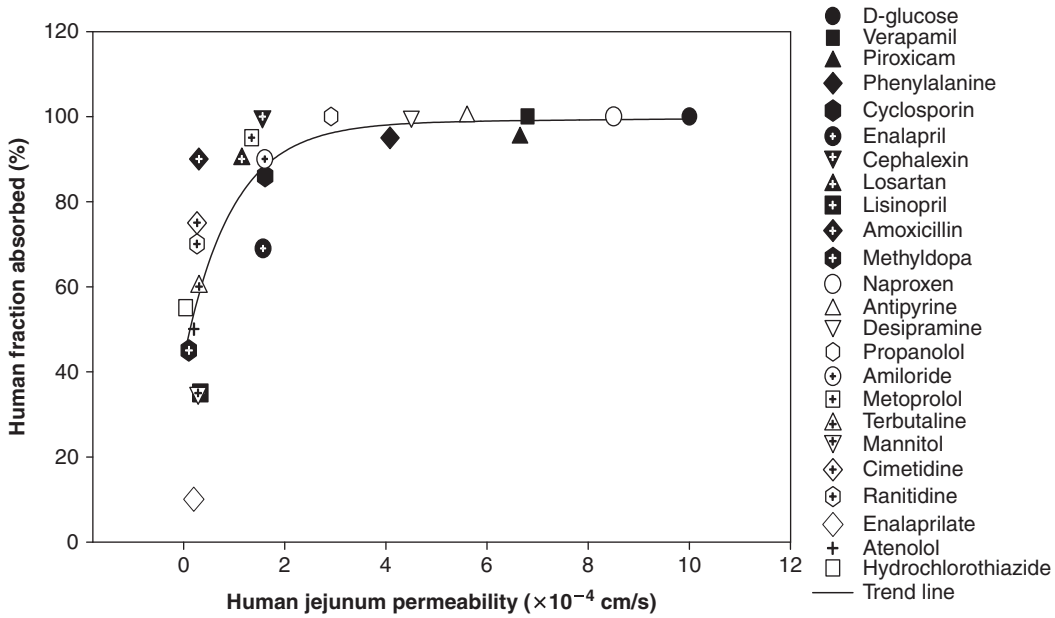

FIGURE 12.9 The relationship between human jejunal effective permeability and fraction dose absorbed.

12.6 IN SILICO METHODS

Computational screening has received much attention in the last few years. In silico models that can accurately predict the membrane permeability of test drugs based on lipophilicity, H bonding capacity, molecular size, polar surface area (PSA), and quantum properties has the potential to specifically direct the chemical synthesis and therefore revolutionize the drug discovery process. Lipinski's Rules of Five predict lower developability for compounds with more than 5 H bond donors, 10 H bond acceptors, molecular weight greater than 500, or *c* log *P* greater than 5.[43] Using this empirical model, useful predictions were achieved for closely related analog series of compounds. Additionally, approaches of the quantitative structure-activity relationship (QSAR) model and quantitative structure-property relationship (QSPR) model, and physiologically based pharmacokinetic (PBPK) modeling such as the compartmental absorption and transit (CAT) model have been developed for predicting oral drug absorption and bioavailability in humans.

12.6.1 QSAR

In last decade, significant progress has been made in the utilization of the QSAR approach in the early stages of drug discovery or development. The quantitative structure–human effective intestinal membrane permeability (P_{eff}) relationship was constructed based on seven structural parameters.[44] The predicted P_{eff} values had a good correlation with the experimental human absorbed fraction (F_a). This model was also used to perform high/low P_{eff} classification for 57 drugs that have been classified according to the BCS, and 72% of drugs could be classified correctly.

Several studies provided comparative QSAR analysis on PAMPA/modified PAMPA permeability.[45–47] One study predicted the PAMPA permeability with in silico descriptors, such as lipophilic partition coefficients (Log *P*), pK(a), and PSA.[45] The PAMPA prediction equation obtained in both studies could be applied for the prediction of both Caco-2 cell permeability and human intestinal absorption of mainly passively transported drugs.[45,46]

Prediction and mechanistic interpretation of human oral drug intestinal absorption using QSAR analysis in the stage of drug discovery and lead optimization has also been reported.[47–49] The important descriptors in oral absorption include log *P*, hydrogen bonding, and structural symmetry.[49] The final validated models are consistent and robust for the consensus prediction of oral drug intestinal absorption and are suitable for virtual screening applications.[47]

12.6.2 QSPR

Significant progress has been made in the utilization of this approach in the early stage of drug discovery. One study presented new linear and nonlinear predictive QSPR models to predict the human intestinal absorption rate.[50] The structure-property relationships so obtained involve only four molecular descriptors

and display an excellent ratio of number of cases to number of descriptors. The QSPR model has been reported for estimating both $\log P_{app}$ and the human intestinal absorption.[51] The results showed that the multivariate-statistics approach performs the best for estimating P_{app}, while a single variable like PSA describes the human intestinal absorption process satisfactorily.

12.6.3 PBPK modeling

Again, significant enhancement in the ability of PBPK models to successfully predict oral drug absorption and advance their role in preclinical and clinical development, as well as for regulatory applications, has been observed.[52,53] Predictive absorption models are used to determine the rate and extent of oral drug absorption, facilitate lead drug candidate selection, establish formulation development strategy, and support the development of regulatory policies.[54] The compartmental models mainly include the CAT model; advanced compartmental absorption and transit (ACAT) model; and advanced dissolution, absorption, and metabolism (ADAM) model.[54] The initial CAT model is a dynamic, mechanistic model that simulates and predicts the rate and extent of drug absorption from the human small intestinal tract. The CAT model has been modified and extended to be the ACAT model, which laid foundation for the commercial software, GastroPlus™.[55] More recently, the ADAM model was also developed based on the CAT model to include drug dissolution, GI fluid transit, drug degradation, gut wall permeation, intestinal metabolism, and active transport.[55] The Simcyp® software employs the ADAM model. Details of the prediction of oral drug absorption by PBPK modeling and simulation approach are described in chapter "Predictive Biopharmaceutics and Pharmacokinetics: Modeling and Simulation" of this book.

12.7 IN VIVO METHODS TO DETERMINE ORAL DRUG ABSORPTION

12.7.1 Mass balance study to determine drug absorption

Mass balance using radiolabeled drugs can be useful to estimate the fraction of dose absorbed. ^{14}C is the most frequently used radioisotope to label a drug, in nearly half of all studies, while 20% of studies are performed with ^{3}H. Mass balance studies to determine drug oral absorption have been available for certain drugs in animals[56] or humans.[57,58] Mass balance is determined based on the comparison of the radioactivity in the original dose to the amount of radioactivity in the excreta. Radioactivity measurements are independent of chemical structure, so total radioactivity measurements are the summation from the parent drug and its metabolites. The major advantage of mass balance study using radiolabeled drugs is that the total concentration of the parent drug and its metabolites can be quantified rather easily in various biological samples by determining the total radioactivity. Otherwise, the respective reference compound for each single metabolite will be needed. For animals, urine, feces, and bile samples dosed with the radiolabeled drug in question are collected over time, and the total radioactivity (of the drug and its metabolites) in the urine and bile sample reflects the actual amount of the drug absorbed into the GI enterocytes. For humans, normally, only urine and feces are collected; radioactivity in the urine suggests that the bioavailability is at least equal to the fraction of drug appearing in the urine; the amount of drug in the feces is a mixture of the unabsorbed drug (assuming oral administration), drug excreted in the GI tract, and drug excreted in the bile.

12.7.2 Rate of oral drug absorption into systemic circulation

After oral administration, the rate of the change in the drug amount in the body depends on the difference between the rate of drug absorption (rate of drug input) and the rate of drug elimination (rate of drug output):

$$\frac{dD_B}{dt} = \frac{dD_{GI}}{dt} - \frac{dD_E}{dt} \tag{12.11}$$

where D_B is the drug amount in the body, D_{GI} is the drug amount in the GI tract, and D_E is the drug amount eliminated. This equation is independent of the zero-order or first-order rate. Plasma drug concentrations over time in in vivo studies are usually measured.

The obtained plasma concentration-time curve for a drug following oral administration often presents several phases, including the absorption phase, time to reach peak concentration, postabsorption phase, and the terminal elimination phase (Fig. 12.10). During the absorption phase of a drug plasma concentration-time curve, the rate of drug input is greater than the rate of drug output; then, at the moment of drug peak plasma concentration, the rate of drug input equals the rate of drug output. Further, during the postabsorption phase of a drug plasma concentration-time curve, the rate of drug input is less than the rate of drug output; eventually, during the elimination phase when the drug at the absorption site becomes depleted, the rate

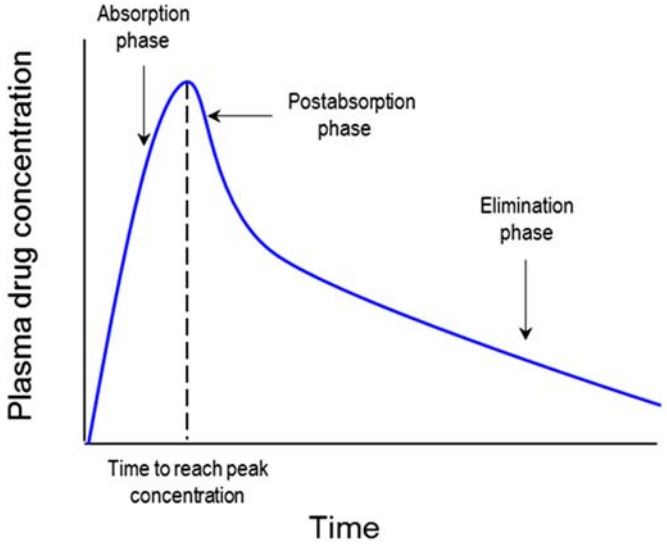

FIGURE 12.10 A typical plasma concentration-time curve for a drug after oral administration.

of drug input approaches 0, the rate of the change in the drug amount in the body represents only drug elimination from the body.

In pharmacokinetics, the overall rate of drug absorption could be described as either a first-order, or zero-order, or a mixed-input process. The drug absorption rate represents the net result of processes of drug dissolution, GI motility, blood flow, and drug transport across the membrane and into systemic circulation. Knowledge of drug absorption and drug elimination allows the prediction of steady-state drug concentration profiles. Analysis of drug absorption with the information of in vivo peak drug concentrations or time to achieve peak concentrations is also useful for the evaluation of the bioequivalence of generic drugs.

12.7.2.1 *First-order drug absorption*

Most pharmacokinetic models assume first-order kinetics for oral absorption. First-order drug absorption applies mostly to the oral absorption of drugs in solution or rapidly dissolving drug dosage forms in tablets or capsules (IR). Only drug in solution is absorbed into the body. The rate of drug input or the rate of drug disappearance from the GI is described by

$$\frac{dD_{GI}}{dt} = K_a D_{GI} F \tag{12.12}$$

where K_a is the first-order drug absorption rate constant from the GI, D_{GI} is the drug amount in solution in GI at a given time t, and F is the bioavailability. There are a few methods to calculate K_a based on in vivo data—namely, the method of residuals, mass balance methods (Wagner-Nelson method, Loo-Riegelman method), and the deconvolution method.[59]

12.7.2.2 *Zero-order drug absorption*

Zero-order drug absorption can also occur with oral drug absorption by a saturable process or a controlled release drug delivery system. Following oral drug administration, by zero-order drug absorption, drug in the GI is absorbed systemically at a constant rate of K_{ao}. The rate of drug input is simply K_{ao}:

$$\frac{dD_{GI}}{dt} = K_{ao} \tag{12.13}$$

where K_{ao} is the rate of drug absorption, which is a constant. In this case, the time for complete drug absorption to occur is equal to Dose of the drug/K_{ao}.

12.8 FOOD EFFECTS ON DRUG INTESTINAL ABSORPTION

Food-drug interactions in the GI have been widely associated with alterations of pharmacokinetic and pharmacodynamic parameters and proven to have significant clinical implications. Ideally, it is most advantageous if an oral drug administration can be provided independent of meal considerations. In the early stages of drug development, the food-drug interaction model would be beneficial when preclinical predictions could be of particular use and service to the industry. Although various in vitro and in vivo models can be found, no standard system currently exists to predict drug absorption and the effect of food.

12.8.1 GI physiological changes under fed state

Food effects on bioavailability are generally greatest when the drug product is administered shortly after a meal is ingested. The role of food in oral drug absorption may be attributed to a myriad of variables, ranging from the drug's physicochemical properties to the postprandial environmental changes in the GI. The environment of the GI varies markedly following meal ingestion. Food can alter a drug's transit time, luminal dissolution, drug permeability, and systemic availability by various means, including:

1. Increased gastric secretion and changed properties of gastric fluids (Tables 12.1 and 12.2); during digestion, gastric juice is secreted by the stomach wall into the lumen in order to provide various functions, including protein and lipid digestion, preparation of micronutrients for absorption in duodenum, protection against microbial overgrowth, dilution of chyme, and, relatedly, the

regulation of gastric emptying. The daily production of gastric juice ranges from 2−3 L with differences between the unstimulated and stimulated state. The gastric juice production under stimulation can be 10−50 mL/min, versus the unstimulated secretion of 1 mL/minute.[60]
2. Changed GI pH and viscosity; the nature of the gastric content is the mixed result of salivary flow, gastric secretions, and food properties.
3. Delayed gastric emptying and motility; generally, after a meal, the stomach is able to gather considerably more than 1 L of gastric content, whereas this maximum capacity depending on food volume and individual physiology often results in the gastric volume being large enough to exceed the gastric emptying. Due to long gastric transit times, the postprandial stomach plays an essential role in drug release and the appearance of food effects.
4. Stimulated bile flow; the levels of phospholipids and bile salts in the gut may increase fourfold to fivefold following a meal.[61]
5. Increased splanchnic blood flow.
6. Changed luminal metabolism (presystemic metabolism) of a drug substance; it has been well recognized that intake of grapefruit juice can markedly augment oral drug bioavailability (ie, dihydropyridines, terfenadine, saquinavir, cyclosporin, midazolam, triazolam, and verapamil and may also occur with lovastatin, cisapride, and astemizole), predominantly by inhibition of CYP3A4, and presumably additional inhibition of P-glycoprotein in the intestinal wall.[62] Since the duration of inhibitory effect of grapefruit juice can last 24 hours, repeated juice consumption can result in a cumulative increase in drug exposure.[63]
7. Physical or chemical interaction with a dosage form or a drug substance; in general, meals that are high in total calories and fat are more likely to affect the GI tract physiology, thereby resulting in a larger effect on the bioavailability of a drug substance or drug product. Therefore, the use of high-calorie, high-fat meals is recommended during food-effect bioavailability and fed bioequivalence studies.[64]

12.8.2 FDA guidance on food-effect bioavailability and bioequivalence studies

Food can change the bioavailability of a drug and can influence the bioequivalence between test and reference products. The influence of concomitant food intake on a drug prompted the FDA to issue a guidance for the industry on food-effect bioavailability and fed bioequivalence studies.[64]

In practice, it is difficult to determine the exact mechanism by which food changes the bioavailability of a drug product without performing specific mechanistic studies.[64] In terms of BCS class I drugs (high solubility/high permeability), important food effects on bioavailability are least likely to occur with many rapidly dissolving, IR drug products because absorption of the BCS class I drugs is usually pH- and site-independent and thus insensitive to differences in dissolution. However, for BCS class I drugs, food can still influence the bioavailability when there is a high first-pass effect, extensive adsorption, complexation, or instability of the drug substance in the GI; or, in some cases, excipients or interactions between excipients and food-induced changes in gut physiology can contribute to these food effects and influence the demonstration of bioequivalence; or, for rapidly dissolving formulations of BCS class I drug substances, food can affect drug peak concentration and the time to reach peak concentration by delaying gastric emptying and prolonging intestinal transit time. However, we expect the food effects on these measures to be similar for test and reference products in fed bioequivalence studies.

In terms of IR drug products for BCS class II, III, and IV drugs and for all modified-release drug products, food effects are most likely to result from a more complex combination of factors that influence the in vivo dissolution of the drug product, the absorption of the drug substance, or both. In these cases, the relative direction and magnitude of food effects on formulation bioavailability and the effects on the demonstration of bioequivalence are difficult, if not impossible, to predict without conducting a fed bioequivalence study.

Therefore, food effects have been investigated on BCS class II, III, and IV drugs. In general, positive food effects occur for BCS class II drugs when a higher systemic exposure is observed under fed conditions compared with the fasted state.[65,66] This is because food may improve absorption by enhancing the drug solubility in the intestinal lumen and inhibiting the efflux transporters in the intestine. Conversely, food can delay gastric emptying and prolong intestinal transit time, resulting in a delay in peak concentration of the drug product. In addition, in the presence of a meal, compounds of BCS class II weak bases are susceptible to variable dissolution and intestinal precipitation due to changes in GI pH and stimulated secretion of bile salts, while negative food effects are usually observed for most BCS class III compounds, showing decreased bioavailability after food intake.[66,67] For BCS class IV compounds, it is challenging to anticipate the direction of food effects because food effects can be formulation- and dose-dependent, as both solubility and permeability can be the rate-limiting steps for absorption.[66]

Based on the FDA guidance,[64] there are some recommendations for food-effect bioavailability and fed bioequivalence studies. For IR drug products, a food-effect bioavailability study should be conducted for all new chemical entities as part of IND applications and NDAs. Bioequivalence studies under fed conditions may be conducted as part of ANDAs for some IR drug products. Food-effect bioavailability and fed bioequivalence studies should be performed for all modified-release dosage forms.

12.9 REGIONAL DRUG ABSORPTION ALONG GI

It is well known that the transepithelial permeability of the small and large intestine varies with the intestinal site for drugs transported by passive diffusion, carrier-mediated mechanisms, or both. Understanding the regional differences in luminal conditions, GI transit and permeability is a fundamental requirement for establishing the subject-by-formulation interaction concept (which takes intersubject variations into consideration in relation to dosage form performance). Also, the permeability of each specific part of the intestine has to be taken into account in a more physiological manner in order to rationally design and develop advanced modified-release drug products. The information on regional drug absorption has been used to support and guide formulation development for drugs such as acipimox[68] and MK-0869.[69] Information of regional intestinal permeability in drug absorption along the GI have direct implications on the development of modified-release drug dosage forms.

12.9.1 Drug absorption from the stomach

Generally, absorption from the stomach is minor compared to from the intestine because of the gastric epithelial barrier preventing diffusion, the relatively small available surface area, and the negligible expression of nutrient (uptake) transport proteins. For a compound to be absorbed in the stomach, it needs to have high acidic solubility and rapid dissolution. Generally, the absorption of uncharged dissolved acidic drugs from the stomach is more ready than the absorption of basic drugs. Gastric acid secretion is one of the main parameters affecting the dissolution profile of solid dosage forms, particularly for drugs with pH-dependent solubility. The acidic secretion is controlled by various hormones and neurotransmitters, such as histamine, gastrin, acetylcholine, or somatostatin. Basal acid output amounts to 2–4 mmol/hour, but in a stimulated state, rates of up to 20–30 mmol/hour have been reported.[60] The gastric acid produced by the parietal cells has a maximum concentration of 160 mmol/L (pH 0.8). Under fasted conditions, the gastric pH value of healthy adults is reported to be within a pH range of 1–3. Under such acidic conditions, the dissolution of weak acids with higher pK_a values than the pH value of the gastric milieu (ie, ibuprofen, diclofenac, furosemide, and valproic acid) is hampered because they are primarily nonionized. In contrast, the dissolution of weak bases (ie, ketoconazole and dipyridamole) is enhanced because they are highly ionized. In addition, meal intake raises the pH values of the gastric content. Depending on meal composition and volume, values of up to pH 7 are reported in the literature, and the return to baseline pH values takes several hours, particularly for high-calorie meals.

12.9.2 Drug absorption from the small intestine

Small intestine is the primary site of absorption for most orally administered drugs. In addition, the proximal small intestine (P-SI) is more permeable than the more distal intestine (D-SI) and ascending colon. The effective permeation (P_{eff}) of drugs through the intestine often depends on the combined outcomes of passive diffusion and multiple parallel transport processes.[70] The human in vivo P_{eff} database from the jejunum is well established.[71] Single-pass perfusion studies have been used to calculate the P_{eff} of different substances from sites in the jejunum and ileum.[70] There is an in vivo human jejunal P_{eff} cutoff point at approximately 1.5×10^{-4} cm/second ($t_{1/2,abs}$ of about 42 minutes), which marks the difference between drugs that are rapidly absorbed (high P_{eff}) and those that are slowly and incompletely absorbed (low P_{eff}) from solution.[41] The cutoff point for the absorption rate based on in vivo jejunal perfusion data is in agreement with the simulated pharmacokinetic data.

Both intestinal metabolic enzymes and drug transporters determine the bioavailability of orally administrated drugs. One function of the small intestine in oral drug absorption can be attributed to its first-pass intestinal metabolism. The significant capability of the small intestinal mucosa to metabolize drugs has been reported, and the expression of metabolic enzymes (cytochrome P450s (1A1, 1B1, 2C9, 2C19, 2D6, 2E1, 2J2, 2S1, 3A4/5), UDP-glucuronosyltransferases, sulfotransferases, N-acetyltransferase) in human small intestine has been reported.[72] Intestinal metabolism mainly mediated by CYP can serve as a barrier to the systemic uptake of xenobiotics (including drugs) by facilitating excretion to the lumen of the intestine or by bioactivation of the xenobiotics, with consequent binding to enterocyte macromolecules. Another function of the small intestine in oral drug absorption can be attributed to drug

transport. The expression of a variety of influx (absorptive) transporters (intestinal oligopeptide transporter, dipeptide/tripeptide transporter (PepT1)) for amino acids, peptides, hexose, organic anions, organic cations, nucleosides, and other nutrients in human small intestine has been reported.[73,74]

In addition to influx transporters, adenosine triphosphate (ATP)−dependent efflux transporters such as MDR protein 1 (MDR 1 or P-glycoprotein 1), MDR-associated protein 2 (MRP2 or ABCC2), and breast cancer resistance protein (BCRP or ABCG2) are also expressed on the apical membrane of intestinal epithelia in humans and rodents.[73,74] P-gp is present at high levels in the villus enterocytes.[74] Also, the expression and activity of P-gp along the small intestine seems regional. In humans, the expression of P-gp is higher in the lower part of the intestine. P-gp has an affinity to a wide range of substrates to excrete various drugs into the lumen. It is an important factor that decreases the bioavailability of oral drugs, such as lumefantrine[75] or digoxin.[76] Notably, P-gp and CYP3A share a large number of substrates and inhibitors and are induced by many of the same compounds, including dexamethasone and rifampin.[77] Inhibitors of P-gp such as cyclosporine and verapamil have been shown to increase the drug absorptive transport.[78]

12.9.3 Drug absorption from colon

The colonic absorption of drugs can differ significantly from absorption in the small intestine as a consequence of several physiological, physicochemical, and biopharmaceutical factors. The permeability through passive transport is thought to be lower in colonic than in other intestinal tissue because of the smaller surface area and tighter junctions in the epithelial cell layer. There is a shortage of P_{eff} data from ileum and colon in the human intestinal tract.[71] There have not been any direct measurements of in vivo colonic P_{eff} for drugs in humans to date. In addition, the expression of efflux and uptake transporters such as P-gp and the human dipeptide/tripeptide transporter (hPepT1) appears to increase and decrease in the colon, which may limit the permeability, dissolution rate, and absorption. It has been reported that BCS class I drugs were generally well absorbed in the colon (with relative bioavailability in the colon greater than 70%) in a comparison of the plasma exposure of the drug following oral and colonic administration.[79] The low-P_{eff} drugs (BCS class III/IV) were less well absorbed in the colon (with relative bioavailability in the colon less than 50%). It has been reported that atenolol and metoprolol could function as P_{eff} markers for low- and high-colonic absorption, respectively.[79]

Interest has developed in directing drugs and dosage forms to effect primary drug release to the colon. Targeted distribution of an orally administered drug at the large intestine confers therapeutic advantages on the treatment of colonic diseases, peptide and protein therapy,[80] and chronotherapy.[81] To achieve such distribution control in the GI tract, the adoption of the prodrug concept gives birth to a colon-specific prodrug. Upon design of a colon-specific prodrug, one should take into consideration not only the delivery of a drug to the target site, but also its therapeutic effectiveness once it is there. The intestinal microbiota can be considered as a metabolically adaptable and rapidly renewable organ of the body. In addition, as knowledge will increase about the microbial bioconversion of polyphenolic compounds into bioactive metabolites in the colon, as well as whether food-based strategies can augment such bioconversion into more potent compounds with antioxidant and anti-inflammatory activity, new areas of research will be discovered. Furthermore, a colon-specific drug delivery system should prevent drug release in the stomach, as well as the small intestine. As the release of drugs from these polysaccharide-based systems is independent of pH and gastric-emptying time, these polysaccharide-based systems are considered the most effective and preferable means for colonic drug delivery in terms of target specificity.[82]

12.9.4 Advance in estimation of human in vivo regional intestinal permeability

The most recent study from the OrBiTo project (http://www.orbitoproject.eu/) presented the results for the indirect estimation of site-specific in vivo intestinal effective permeability (P_{eff}) in humans, and for the first time, it directly compared regional permeability along the human GI tract.[83] A good correlation was established between these indirect jejunal P_{eff} estimates and jejunal P_{eff} measurements determined directly using the single-pass perfusion double balloon technique. On average, P_{eff} estimates from the distal small intestine and large intestine were 90% and 40% of those from the proximal small intestine, respectively.

In this study, using deconvolution, the site specific P_{eff} can be calculated by

$$P_{eff} = \frac{CL_{abs}}{\text{absorptive surface area}} \tag{12.14}$$

where CL_{abs} is the intestinal absorption clearance rate.

Alternatively, P_{eff} can be expressed in a more straightforward way, assuming instantaneous and homogeneous distribution of active pharmaceutical

ingredients (APIs) in the total volume of the dose and subsequent flushes at all times:

$$P_{\text{eff}} = \frac{\text{absorption rate} \times \text{radius}}{\text{API remaining in lumen} \times 2} \quad (12.15)$$

12.10 FUTURE TRENDS

Significant advances have been made in the prediction of intestinal permeability using in silico techniques over the last decade. However, what is most needed now are more and better data to form the foundation of computational models that are capable of integrating the existing knowledge of intestinal permeability and permitting us to see relationships only hinted at in existing experiments. More and better data should also permit the application of nonlinear models to fit the observed curvilinear relationships between physicochemical properties/descriptors and permeability more accurately.

On the other hand, the effective use of cell culture techniques has dramatically improved the efficiency of permeability screening in the industry. Most biological screening assays are performed in miniaturized models such as 384- or 1536-well plates for ultrahigh-throughput screening.[84] Automation of cell-based drug absorption assays, including Caco-2 and MDCK, in 96-well format using permeable support systems has been reported.[85] Robotic systems coupled with the miniaturization devices can be extremely valuable because of the precision and high-speed handling of repetitive tasks and will definitely lead the way to an era of high-tech laboratories that operate smoothly, with minimal human intervention. Furthermore, some of the technological innovations can be made to reduce the time for cell growth. An automated 96-well plate Caco-2 permeation model with reduced growth time has been developed.[86] The efforts of improvements in culturing media, adjustments of seeding density, and use of modified transwell plates have already been made to shorten the cell growth time.[86] Further improvement in this area, with respect to cell culture techniques, will certainly be the focus of development efforts in the near future.

12.11 CONCLUSIONS

Optimizing bioavailability of orally administrated drug for systemic actions is one of the most important aims for the pharmaceutical industry. In order to achieve this goal, however, high-throughput, cost-effective, highly discriminating, and predictive models for the absorption of drug molecules in humans will be required. The current in silico approaches (physicochemical and certain in silico methods) seem to hold the promise of fulfilling this need, particularly as primary screening, with larger and more chemically diverse data sets ready before these models will be reliable enough to accurately predict the intestinal absorption.

Secondary screening can be achieved using automated, high-throughput in vitro systems (cell culture–based or animal tissue–based) for selecting and optimizing the chemical leads to identify potential drug candidates.

Finally, traditional approaches for the evaluation of drug absorption, such as in situ rat intestinal perfusion technique and in vivo animal or human studies, as well as PBPK models, should also be utilized simultaneously to prevent false positives and false negatives in the later stages of development.

Dissolution Testing of Solid Products

Y. Chen[1], *Z. Gao*[2] *and J.Z. Duan*[2]

[1]Novast Laboratories, Ltd., Nantong, China [2]U.S. Food and Drug Administration, Silver Spring, MD, United States

13.1 INTRODUCTION

A dissolution test is a comparative tool for measuring the in vitro performance of solid oral dosage forms. Dissolution of a solid product can be affected by the compositions and the properties of the powder, including particle size, polymorphism of the active pharmaceutical ingredients (APIs), excipients in the formulated product, the manufacturing process, and factors of the method and environment for dissolution testing. With proper selection of the test method in a well-controlled environment, a dissolution test can be sensitive to changes in composition, material property, and the manufacturing process. Therefore, dissolution testing is commonly used to design and select formulations and as a comparative tool for quality control for batch-to-batch consistency in routine manufacturing of solid pharmaceutical products.

When the human pharmacokinetic (PK) data are available from a sufficient number of versions of a product with different dissolution profiles, a properly developed dissolution test may lead to the development of in vitro–in vivo correlation (IVIVC)[1–3] for the drug products. In these cases, the dissolution test may be used as a surrogate for the in vivo performance test. With a clear correlation of in vitro dissolution with in vivo performance, a dissolution test can be used for a waiver of bioequivalence (BE) study in humans for registration of certain type of rapidly releasing biopharmaceutics classification system (BCS) Class 1 or 3 products,[4] and for significant changes in scale-up and postapproval changes (SUPACs)[5,6] via the use of the established IVIVC. Thus, such a dissolution test could decrease the regulatory agency review time and the pharmaceutical industry cost by reducing the development time and costs for the in vivo BE studies.

Dissolution testing has been applied as compendial test for solid oral products in the United States Pharmacopoeia (USP) since the late 1960s. Multiple chapters related to dissolution testing, such as Chapters <711>, <724>, <1088>, <1090>, and <1092>, are included in the current version of USP. In addition, dissolution assays have been adopted by regulatory agencies in different countries[2,7–11] as one of the quality requirements for approval of new products of solid oral dosage forms either by new drug applications (NDAs) or by abbreviated new drug applications (ANDAs) for generic drugs. Currently, all solid oral dosage forms are required to have a dissolution test, except for some cases in which disintegration may be more appropriate than dissolution as a performance test.

A dissolution test can be used to guide product development and for quality control of products. When an effective IVIVC can be established, the in vitro dissolution test is a valid measure for the in vivo quality/performance of the product. By contrast, a dissolution test is not a valid measure of in vivo performance when IVIVC has not been established. Furthermore, the same dissolution results for multisource products do not guarantee that the products will have the same in vivo performance. In the absence of IVIVC, the use of dissolution data is ambiguous for comparing different products.

Unlike other product quality attributes, which can be reproduced by different test methods, product dissolution is highly method dependent. Significantly different dissolution data can be generated for the same product using different dissolution methods, with all of the different results being true for the same product. Without IVIVC, the decision on the selection of test procedures and setting of dissolution specification

DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00013-3

becomes the preference of the people involved. In addition, there are different views and interpretations of dissolution test data by the regulatory agencies from different countries. Thus, the requirement of a dissolution test for drug products varies from country to country.

As indicated previously, dissolution data from a drug product can be affected by many factors of the dissolution test method, including the compositions of the test medium, test apparatus, mixing speed, aeration of the medium, and the physical environment for the test. Therefore, the contributions and influence of these factors must be carefully measured to achieve the proper interpretation and application of dissolution tests.

This chapter will begin with a brief review of the theory of dissolution, followed by an in-depth discussion on the current technologies for dissolution testing and suggestions for regulatory requirements of the test for products. The development and application of IVIVC will be discussed in chapter "In Vitro/In Vivo Correlations: Fundamentals, Development Considerations, and Applications," so it will not be discussed here.

Compendial requirements and Food and Drug Administration (FDA) guidance are referenced extensively, but not comprehensively, in this chapter. The authors acknowledge that different countries have different requirements. In fact, readers are encouraged to compare the differences between countries to ensure that the appropriate regulatory expectations are met based on the intended use and markets, and to promote the science and the proper use of dissolution tests.

13.2 THEORY OF DISSOLUTION TEST FOR SOLID DRUG PRODUCTS

13.2.1 Dissolution and drug absorption

After oral administration of any solid oral dosage forms (eg, immediate release (IR) or modified release (MR) tablets or capsules), the APIs in the dosage forms must dissolve into the gastrointestinal (GI) fluid (solution) before the APIs can become therapeutically effective (eg, locally in the GI tract or after being absorbed into the bloodstream to reach the site of action), as shown in Fig. 13.1.

The dissolution rate from the dosage form into the GI fluid may affect the drug absorption rate, hence the therapeutic effect of the dosage forms. Dokoumetzidis and Macheras[12] in their review of the history of dissolution testing credited Edwards[13] with publishing the first studies describing the relationship

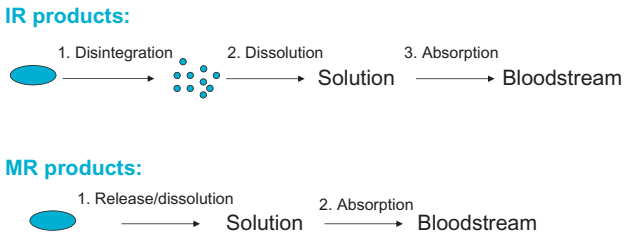

FIGURE 13.1 Schematic of the absorption steps of solid oral dosage forms.

between rates of dissolution and absorption. Initially, dissolution testing was included in the USP with an intention of measuring the physiological availability of the product in the GI fluid. However, direct verification of the dissolution in the GI fluid is difficult. Notably, the GI fluid is not the final destination for drugs that are entering the systemic circulation. After a drug dissolves into the physiological fluid in the GI tract, the drug will pass through the GI membrane and be transported into the bloodstream to reach the site of action and exert a pharmacological effect. Assuming that the absorption mechanism is the same for different lots of the same product or the same product made by different manufacturers (generics), the dissolution in the GI tract can be inferred by measuring the bioavailability (BA) of the product after oral administration. *Bioavailability* is defined as the rate and extent to which the drug is absorbed from a drug product and becomes available at the site of action [21 CFR 320.1(a)]. The concept of relating in vitro dissolution to in vivo BA was officially incorporated in USP19.

Over the past 50 years, the interest in developing in vitro tools to describe and attempt to predict in vivo performance, or the bioperformance, has been a central focus of biopharmaceutical research. In a number of studies, Amidon and his coworkers have developed comprehensive models to describe the transit of drug suspensions through the GI tract using chemical engineering concepts coupling mass transfer and fluid dynamics.[14,15] These models established the basic relationships between drug solubility, dissolution rate, and GI membrane permeability. New dimensionless parameters were introduced, including the dose number (which relates the dose applied to the ability to solubilize the ingested dose) and the absorption number (which relates the drug permeability to the residence time). These models were the basis for establishment of the BCS[16] that has provided a framework for interpretation of dissolution studies in the regulatory approval process, particularly in biowaivers for approval of new drug products and for justification of significant changes made to existing products via the

established IVIVC.[4–6] Over the last half-century, numerous methods have been tested in the quest to establish predictive methods for drug absorption from solid oral products. While there has been some successful examples, IVIVC is still not yet been established for many products due to the complexity of the in vivo dissolution and absorption processes. The dissolution process in the GI tract is not yet fully understood. An established IVIVC for one product is not necessarily applicable to a second product, not even for multisource products. Therefore, more study is required to understand the differences between the in vitro and in vivo dissolution processes. Once the differences are defined, the in vitro dissolution methods may predict the bioperformance of solid drug products, and to increase the regulatory flexibility for certain formulation and process changes.[4–6]

13.2.2 Dissolution tests for quality control

From the history of dissolution testing for oral solid products, it is known that product dissolution profiles can be affected by the quantitative and qualitative drug composition differences, manufacturing processes, the physical properties of the active and inactive ingredients and the various parameters of dissolution test methods. Thus, a change in compositions may lead to a change in product dissolution profiles. The responses of product dissolution to other changes in manufacturing of a product with fixed quantitative compositions increase the possibility that a dissolution test could become a useful tool for product quality control if the dissolution method is established to have sufficient robustness for monitoring the changes. For example, the change in the powder properties of a given formulation, such as the particle size distributions of API/excipients/granules,[17–19] polymorphism of API,[17,20,21] density of granules, viscosity grade of polymers, and source of excipients,[22] could lead to significant changes in dissolution profiles. The difference in manufacturing processes, such as direct compression and wet granulation, granulation conditions/parameters, lubrication time,[23] compression force,[18] and coating process parameters,[24] may also lead to different dissolution profiles. Some of the changes in dissolution may lead to changes in their bioperformance of the products, while others may not. That is, IVIVC could not be established for all products with all the changes. However, the sensitivity and versatile capability of dissolution testing to detect the material and process changes can be utilized as a tool for quality control by monitor the consistency in material and process, which may be advantageous over other existing analytical techniques.

The following aspects should be considered when using a dissolution test as a tool for quality control in the absence of a valid IVIVC:

1. The value of dissolution data does not have the same clear-cut implications for quality as the results of other types of tests such as potency or purity, in that the dissolution data is method dependent, while the other tests are not. For example, different dissolution methods/conditions may result in significantly different dissolution data for a same product, but the assay of a product can be the same using different test methods.
2. Dissolution tests can be meaningful for postmarketing quality control by vertically comparing with the specifications set based on the dissolution data of the BE/BA batches of the same product, but not for lateral comparison with different products in most cases except for products that are qualified for biowaiver. Other quality attributes, such as assay and impurities, can be used to compare laterally for different products in addition to the vertical comparison for the history of the same product.
3. If the method is not developed properly, dissolution results can be sensitive to test conditions, as well as to the manufacturing process for drug products. Therefore, the changes in dissolution data may be due to the lack of robustness of the method itself rather than the true significant changes in the manufacturing or in the bioperformance of the product.
4. While it is desirable to have discriminating power to detect significant changes that could lead to bioinequivalence of a product, dissolution testing should be robust to tolerate the normal variability in routine manufacturing to prevent unnecessary rejection of products. The need of discriminating power for quality control and the robustness for daily operation should be balanced during method development for each product.

13.2.3 Mechanism of dissolution

More than a century ago, Noyes and Whitney developed a basic equation indicating that when surface area is constant, the dissolution rate of a solid is proportional to the difference between the solubility and concentration in the bulk solution.[25] Later, Nernst and Brunner proposed a diffusion layer theory to correlate dissolution rate with the diffusion coefficient, surface area, solubility, and the thickness of the diffusion layer.[26,27] The Noyes–Whitney and the Nernst–Brunner equations formed the fundamental diffusion layer theory for studying particle dissolution. There

are also diffusion-convective models using various mathematical equations for dissolution process under different assumptions. Details on these models are discussed in chapter "Fundamental of Diffusion and Dissolution."

Hypothetically, the dissolution process for a solid may include three steps: (1) detachment of drug molecules from the solid, (2) solvation of the detached drug molecules by solvent (medium) molecules in a stagnant layer on the surface of the solid, and (3) transporting the solvated drug molecules from the stagnant layer into the bulk solution. The rates of the hypothetical steps 1 and 2 are governed by the thermodynamic properties of the solid, including the enthalpy and entropy of melting, and that of molecular interaction between the solute and the solvent. The correlation between the thermodynamic properties with solubility (hence the dissolution rate) has been well studied.[28] For the transport process in step 3, the thermodynamic properties for molecular interaction continue to be the governing factor for the diffusion process. However, pure diffusion is a very slow process that is not suitable for routine testing. In modern dissolution tests when mixing is used, the transport mechanism becomes a mixed type of diffusion and convection, in which convection may be the dominant mechanism for the transport. In other words, mixing rate (hence the hydrodynamic of the medium) is the key factor responsible for stripping the solvated drug molecules from the solid surface and transporting the drug molecules into the bulk solution in dissolution test. Therefore, dissolution rate is affected by mixing speed. See chapter "Fundamental of Diffusion and Dissolution" for different mathematical expressions relating dissolution rates to the hydrodynamic parameters under varied assumptions and conditions.

13.3 CURRENT TECHNOLOGY AND INSTRUMENTATION FOR DISSOLUTION TESTING

13.3.1 Current USP dissolution apparatus for oral dosage forms

There are seven apparatuses defined in USP general Chapter <711>. This chapter was recently harmonized with the European Pharmacopeia (Ph.Eur.) and Japanese Pharmacopeia (JP) to create common definitions and operating parameters for all drug release monitoring. Of the seven apparatuses, Apparatus V (paddle over disk) and Apparatus VI (rotating cylinder) are not used for oral drug products and will not be discussed here.

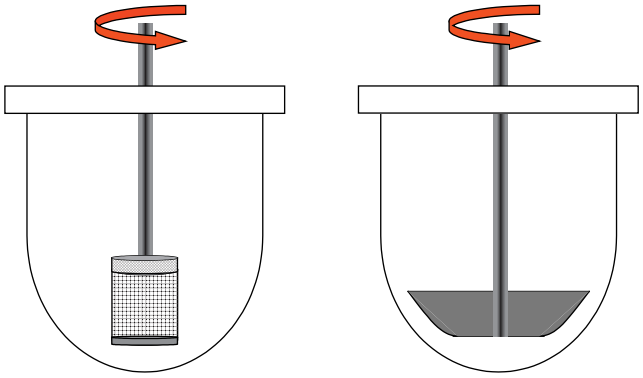

FIGURE 13.2 Schematic illustration of dissolution Apparatus I (basket) and II (paddle).

The widely used apparatuses for dissolution testing of solid oral dosage forms are Apparatus I and Apparatus II (Fig. 13.2). Both apparatuses employ a single hemispherical bottom vessel containing the dissolution medium with a centered spindle. The temperature of the vessel is controlled within narrow limits (±0.5°C) by immersion in constant temperature water bath or by other suitable technology. For Apparatus I, the dosage form is placed in a basket affixed to the end of the spindle. Agitation is achieved by rotating the basket; a rotational speed of 100 rpm is most commonly used. For Apparatus II, the dosage form is dropped directly into the vessel, and a paddle is used to induce agitation with typical rotation speeds of 50–75 rpm. In the cases where the dosage form may float (eg, capsule formulations), Apparatus I may be more appropriate. Alternatively, when using Apparatus II, the dosage form, either tablet or capsule, may be placed in a sinker designed to enclose the dosage form. There are various sinker designs (Fig. 13.3), and the most common sinker, as described by USP Chapters <711> and <1092>, consists of "a few turns of a wire helix." Soltero et al.[29] demonstrated that sinker design could affect dissolution results by entrapping material or altering the hydrodynamics and slowing dissolution. In addition to inhibiting flotation, the sinker may be useful for assuring consistent placement of the dosage form in the center of the vessel bottom. The hydrodynamic environment in the Apparatus II vessel is highly heterogeneous,[30,31] and it has been demonstrated that the position of the dosage form (eg, side vs center of the vessel or height of the dosage form) can alter the rate of dissolution.[32,33] For both Apparatuses I and II, the typical medium volume are 500 and 900 mL. Smaller and larger vessels are available to accommodate either low-dose or poorly soluble compounds, respectively. The medium type and agitation speed are selected as part of the method development process to whatever dissolution medium

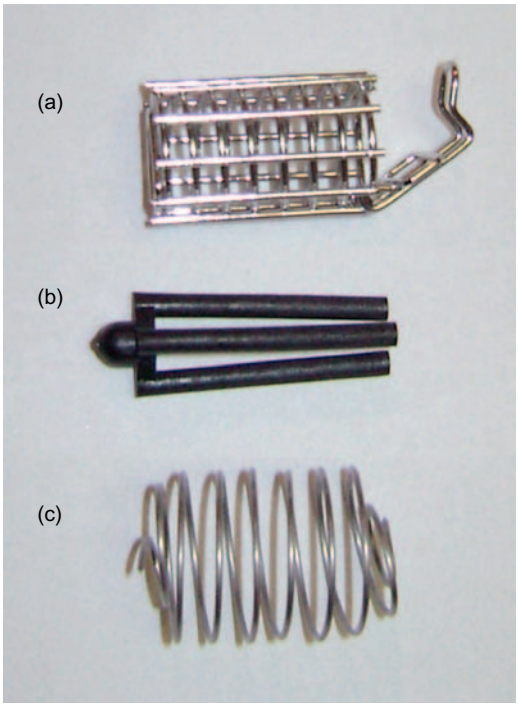

FIGURE 13.3 Example sinker designs. (a) Basket sinker, (b) three-pronged sinker, and (c) spiral sinker.

and agitation speed can be justified as providing an appropriate measure of product performance.

Sampling from Apparatuses I and II can be conducted either manually or automatically with filtration to eliminate undissolved drug particles and insoluble ingredients. The sampling time is recorded as the point of initiation of sampling. Manual sampling is conducted using syringes equipped with cannulas of a prescribed length to ensure sampling within the USP sampling zone, defined vertically as midway between the medium surface and the top of the paddle blade or basket, and radially as not less than 1 cm from the vessel wall. Dissolution vessels are typically fitted with covers containing sampling ports to facilitate reproducible sampling. These covers also minimize evaporation of the test medium during extended trials.[34] Automatic sampling devices employ sampling manifolds that either deliver the sample to a fraction collector or pass the aliquot through an online detector. Filtration can occur at the sampling port or inline. Whether manual or automatic methods are used, sampling can be conducted with or without replacement of the withdrawn media. With online detectors, the sampled aliquot can be returned to the vessel. In other cases, an equivalent volume of prewarmed media is delivered carefully to the vessel to prevent unacceptable alteration of the vessel hydrodynamics. Calculation of the amount of drug released versus time must be corrected for the volume changes that occur when the medium is not replaced.

Less commonly used equipment for measuring drug release from solid oral products includes Apparatuses III, IV, and VII. Apparatus III uses a reciprocating cylinder to induce agitation and to transport the dosage form through a series of vessels. This design allows monitoring release through a series of media at different pH to simulate the pH gradient of the GI tract. The reciprocating action may also be a better model of the pulsatile hydrodynamics of the GI tract than the hydrodynamic environments of Apparatus I or II.[35] Apparatus VII is a similar design, providing the capability of using smaller vessel volume (approximately 10 mL, as opposed to 250 mL for Apparatus III) and a shorter stroke length. Apparatus VII is used for extended release (ER) products where the amount of drug released is low and the smaller vessel volume improves the ability to quantify reliably the amount of drug released. Apparatus IV is a flow-through system designed to have improved control over the hydrodynamics of the medium. The flow has a pulsatile motion to mimic intestinal flow. This design also allows for continuous changes in the medium, such as inducing a pH gradient.

13.3.2 Possible variables during dissolution testing

Dissolution testing is widely used as an analytical technique for evaluating the drug release characteristics and consistency of a pharmaceutical product. A dissolution method for any particular product, including apparatuses, speeds, and media, is developed based on the characteristics of the product. However, dissolution results from the same product using the same method can still be affected by test variables. Thus, minimizing the variance due to the system used and the operator performing the work to obtain results that distinguish changes between different dosage forms or the same dosage form from different lots is necessary. Dissolution testing involves many variables, which can be grouped into four main categories: (1) analyst, (2) dissolution apparatus, (3) testing environment, and (4) sample.[36] The variables in the second category include vessel geometric irregularities, alignment of the instrument, and agitation speed. Variables of the testing environment include deaeration of dissolution media, media temperature, media pH, and vibration. To obtain reliable dissolution results, the variables from the first three categories must be minimized.

Gauge repeatability and reproducibility (gauge R&R) is a powerful tool that has been used to analyze

variability for USP Apparatus II dissolution measurement systems. The studies were designed to assess the variability due to apparatus, operator, and sample tablet. Evaluation of dissolution test results at 30 minute using 10-mg prednisone tablets (FDA/DPA NCDA#2) indicates that in the main contribution to the total variance, approximately 70% is due to the sample tablets, approximately 25% is from the apparatus, and approximately 5% is due to the operators. The results demonstrate that, following the American Society for Testing and Materials (ASTM)[37] procedure for mechanical calibration, the variation (gauge) due to a measurement system is small relative to the variation in the samples.

For some products, dissolved gases in the dissolution medium affect dissolution results. Thus, as the FDA Guidance for Industry states, these products require degassing of the medium prior to use for reproducible results. The solubility of nitrogen and oxygen, the main components of air, in water decreases with increasing temperature. This change in solubility causes a net flux of gas out of the water if the temperature is raised. If using a medium that has not been sufficiently degassed, bubbles can be seen forming around a tablet or capsule, which has been introduced to the dissolution vessel. For some products, these bubbles can affect dissolution results. A study conducted by the FDA suggested that measurement of total gases and not just oxygen in the medium was necessary to assess adequacy for dissolution testing.[38] The results indicate that the percent saturation of the total dissolved gases at room temperature must be well below 100% to prevent outgassing once the medium is brought to the dissolution test method temperature (typically 37°C). A general guidance for sufficient degassing is shown in Fig. 13.4. If the measured percent saturation of total dissolved gases at a given degassing temperature is below the solid line, outgassing will not occur when the temperature of the dissolution media is brought to 37°C.

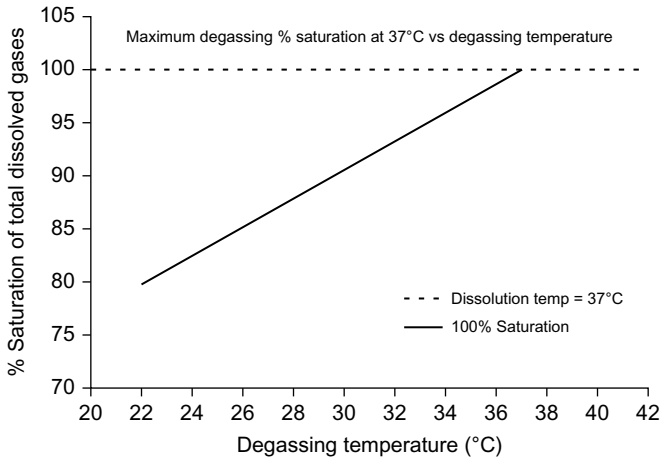

FIGURE 13.4 Maximum percent saturation of total dissolved gases allowed to avoid outgassing at 37°C.

The USP specifications in general Chapter <711> for a dissolution vessel currently specify the inner diameter of the cylindrical part and the height of vessel and assume that the inner surface of cylinder and hemisphere of the vessel are uniform.

The FDA conducted a study to explore the effect of the inner shape of standard 1-L dissolution vessels on drug dissolution results.[39] The geometric dimensions and irregularities of commercially available vessels (obtained from four different manufacturers) were examined using a three-dimensional video-based measuring machine. The definitions of geometric dimension and irregularity are included in Table 13.1.

The results showed that geometric characteristics varied within and among the sets of vessels, but the overall averages and standard deviations (SDs) of dissolution results (six vessels) showed no statistical significant differences among the vessel sets. The similarity of dissolution results indicates that when the dissolution apparatus is set up correctly and mechanically calibrated following the ASTM procedure, the variability can be minimized. However, some dissolution differences were noted when comparing individual vessels. With these types of comparisons, the vessel concentricity, sphericity, and radius of sphere were found to possibly influence the amount of drug dissolved, but flatness of vessel flange, cylindricity, and circularity showed no effect on dissolution results.

On the question regarding vibration effects on the dissolution experiment, the USP simply states that "no part of the (dissolution) assembly, including the environment in which the assembly is placed, contributes significant motion, agitation, or vibration." A vibration is a periodic motion, or one that repeats itself after a certain interval of time. Vibration may be generated by motors, mechanical motions, construction work, or vehicle traffic and can be transmitted through walls, floors, lab benches, and apparatuses. The vibration encountered during dissolution measurement includes system and environmental vibration. For a mechanically calibrated and well maintained dissolution apparatus, system vibration can be minimized. However, environmental vibration induced by laboratory equipment, building construction, or even by the analysts themselves is one of the more complicated factors affecting dissolution testing. The studies suggest that vibration affects the disintegrating and dissolving processes of drug products through different mechanisms. The results with 10-mg prednisone tablets indicate that applied vibration can lead to either an increase or a decrease in dissolution results, depending upon when that vibration occurs and the magnitude of the

TABLE 13.1 Definitions of Geometric Dimensions and Irregularities

Terms		Definitions
Geometric dimensions	Sphere radius	The measured value of the radius of the hemispheric region.
	Vessel height	The measured value from the base of the vessel to the top of the flange.
	Angle of cylinder to flange	The angle measured between the flange plane (horizontal) and the axis (vertical) of the cylinder.
	Diameter of cylinder	The measured value of the perpendicular cross-section diameter across the cylinder.
Geometric irregularities	Sphericity	All points on a three-dimensional (3D) surface share a common center point. The value will be zero for perfect shape.
	Circularity	The condition on a two-dimensional (2D) surface such as a sphere, cone, or cylinder where all the points along that surface are of equal distance to the center point of that feature. In the case of a circle, the points would be of equal distance to the center of the circle. For the perfect shape, the value will be zero.
	Cylindricity	All points on a surface are of equal distance from a common axis.
	Concentricity of two features (sphere part and cylinder part for dissolution vessel)	Both features share a common axis or center point. The measured sphere and cylinder share a common axis.
	The perpendicularity of the cylinder to the flange	The condition of the center axis of the cylinder as related to the 90-degree axis of the plane formed by the flange. For the perfect shape, the value will be zero.
	The flatness of the flange	All points measured are in the same plane. The plane is formed by all points measured on the flange surface. The flatness measurement is the sum of two distances from the plane. Distance 1 is the distance from the plane to the point farthest away from the plane in a positive direction. Distance 2 is the distance from the plane to the point farthest away from the plane in a negative direction. For the perfect shape, the value will be zero.

vibration during the dissolution test. These are particularly problematic because they may be beyond the analyst's control and typically cannot be predicted. The vibration measurement system described in the literature enables vibration changes occurring during dissolution testing to be monitored.[40–42]

Understanding how operational variables affect dissolution results will help drug development and product quality control by ensuring that the variables are properly controlled. For example, if a formulation is intended for IR, sample centering may need to be considered when using the USP paddle method. By contrast, if the formulation is an ER drug, in addition to all the other mechanical parameters, environmental vibration may need to be controlled during the dissolution testing.

Several variables, including dissolved gases in the dissolution medium, off-center placement of the test tablet, environmental vibration and various agitation speeds have been modeled. Mathematical models including Higuchi, Korsmeyer–Peppas, Weibull, and the Noyes–Whitney equation were employed to study the dissolution profile of 10-mg prednisone tablets (NCDA #2) using the USP paddle method. The results showed that dissolution variables affected dissolution rate constants differently, depending on whether the tablets disintegrated or dissolved. The detailed studies indicated that different dissolution variables affect drug release mechanisms differently. Placing a sample off-center caused a hydrodynamic change and mainly affected drug release during the disintegration process. Dissolved gases in the dissolution medium showed a complicated effect on the dissolution profiles, which may depend on the degree of gas saturation and the speed of bubble formation during dissolution testing, as well as interactions between the drug substance and the bubble surface. Environmental vibrations changed the dissolution rate by changing the aggregate condition of the disintegrated particles. Compared with the agitation in the medium, induced vibrations could produce a "secondary movement," which was relatively small and did not change the disintegration rate significantly, but did affect drug release rate by diffusion.

13.3.3 Calibration of dissolution apparatus

Currently, the qualification process for ensuring that a paddle or basket apparatus is suitable for its intended use is a highly debated and controversial

topic. Different instrument qualification and suitability methods have been proposed by various pharmacopeias and regulatory bodies.[43] The USP includes mechanical calibration specifications and the use of performance verification testing (PVT) to establish instrument suitability.[44] The process by which a test apparatus is determined to meet the compendial dimensional and operational specifications has been termed *mechanical calibration*, while the use of reference standard tablets is given the designation *chemical calibration*.[45] According to USP, the suitability of the dissolution paddle or basket assembly is determined by conformance to the dimensions and tolerances stated in its Chapter <711>. Chemical calibration allows a final and summative confirmation of the suitable operation of the integrated dissolution assembly, beyond the evaluation of its separate component attributes (eg, stirring element dimensions, control of rotation speed, dissolution medium volume). USP thinks that neither mechanical nor chemical calibration alone is sufficient to adequately furnish a robust demonstration of system suitability.

Originally, calibrator tablets were adopted to detect the influence on dissolution results due to improper alignment of the instrument, vibration in the instrument, failures in the drive chains and belts, and deaeration.[46] Thus, the calibrator tablet became an important check on operating procedures, especially in terms of consistency between laboratories on an international basis. For Apparatuses I and II, disintegrating a prednisone reference standard tablet is used to establish system suitability. USP provides a calibrator tablet of prednisone to be used to demonstrate that the bath configuration and operator practices meet specified standards. The acceptance criteria are established for each lot of calibrator tablets through collaborative studies with various laboratories around the world. Each laboratory measures the release under a defined protocol, and the results are compiled to provide the average ranges to be used as the acceptance criteria. However, the prednisone calibrator tablets have some stability issues, and the acceptance criteria for a given lot may be revised during their specified shelf life. One survey revealed that while calibrators were routinely being used to meet regulatory expectations, there were concerns that the results did not necessarily ensure accurate performance of the apparatus. Variability of the calibrator lots and the numbers of required calibrator tests were the primary concerns. Physical and mechanical performance checks have been suggested to be more important.[47]

The FDA has issued a guidance for industry, "The Use of Mechanical Calibration of Dissolution Apparatus 1 and 2—Current Good Manufacturing Practice (CGMP)," which recommends that a properly executed rigorous mechanical calibration will satisfy CGMP requirements for dissolution apparatus calibration in lieu of performance verification with specified tablets.[48] Using either Apparatus I or II, results are sensitive to the configuration of the various components such as the depth between the bottom of basket/paddle to the bottom of the vessel, centering and verticality of the shaft, leveling of the bath, and imperfections in the vessels. Bath standardization is typically monitored on a semiannual basis or after major repairs, equipment or location changes.

The ASTM, a voluntary consensus standard-setting organization, created a standard for mechanical calibration of basket and paddle dissolution apparatus building on these recommendations.[49] ASTM Standard E2503-07 provides guidance for basket and paddle dissolution apparatus setup and calibration to ensure reproducibility of results without specifying how to perform dissolution testing. This standard takes a more detailed approach to instrument setup than is currently outlined in the harmonized pharmacopeia chapters by providing quantitative criteria for shaft wobble. Shaft and vessel verticality are new parameters not currently addressed in the pharmacopoeia chapters. The ASTM standard also has tighter criteria for shaft/vessel centering (vessel offset), rotational speed, and basket wobble than that given in the Pharmacopoeia Discussion Group (PDG) harmonized dissolution testing. This change in calibration methodology, from the reliance on less stringent methodology and use of tablets to rigorous mechanical calibration, may reduce the bias and variation in measurement systems.

The Ph.Eur. recommends mechanical calibration for instrument qualification and suggests that the performance of the dissolution test instrument may be monitored by testing of an appropriate reference product.[50] The JP states that the fundamental system suitability of the dissolution apparatus must include conformance stated in its chapter of <Dissolution Test>, but specific requirements on performance verification of the apparatus are not given.[51] Hence, the International Conference on Harmonization (ICH) Topic Q4B on the harmonization of pharmacopoeial methods, in Annex 7, Dissolution Test General Chapter, notes that the harmonized dissolution test apparatus should be calibrated to ensure compliance with regional good manufacturing practice (GMP) requirements.[52]

The International Pharmaceutical Federation (FIP) recommends that the qualification of a dissolution test instrument should be performed following the calibration requirements as indicated in the FDA guidance. If additional system performance information is desired, PVT using a USP reference standard tablet or an established in-house reference product can be conducted.

13.3.4 Automation

Dissolution testing has become more valuable in development and regulation of pharmaceutical products. Obtaining the required data for the formulation screening, as well as quality control of postmarket drug products can lead to many dissolution tests in different media over long periods of time. Data in the literature showed that in the past 7 years, the total number of dissolution tests in laboratories more than doubled, from just over 2500 to more than 5800 dissolution tests.[53] A single formulation scientist can prepare enough formulations to keep two analysts busy for weeks testing the dissolution profiles. Even on short runs, the analyst must conduct many routine procedure, such as preparing dissolution media, filling the vessels, measuring the temperature of the media, dropping the testing samples, pulling aliquots of sample solution for test at specified times, and, at the end of the test, discarding the used media and cleaning the vessels for the next run. An efficient analyst in the dissolution laboratory can perform a maximum of two to four manual dissolution tests per day, depending on the run time and availability of dissolution apparatus and analytical instrument.

Automation in the pharmaceutical development laboratory offers great potential for increased efficiency and reduced laboratory errors.[54] The fully automated system consists of a dissolution tester, automated dissolution components for vessel cleaning, medium filling, tablet drops, a robotic system capable of attaching and removing USP Apparatus I baskets, a media switching valve (capable of delivering four types of media to the dissolution bath), an auto-sampler, a sample collection device, and an online UV/vis or high-performance liquid chromatography, all managed by advanced software with video recording. Fully automated dissolution tests can free the dissolution scientist from about 90% of the protocol steps in the laboratory, and has showed many other advantages. First, the automated cleaning of the bath vessels can eliminate costly analyst time and vessel breakage (safety) and also provide a more consistent cleaning. Second, except for the initial run setup, the overall automated testing can be performed without an analyst being present. Also, automated systems have capabilities to drop the tablets or capsules, record the media temperature prior to and after the test, degas and dispense the media, sample the vessels at preprogrammed times, and filter the sample solutions. The automated system reduces analyst-to-analyst variability, as well as the issues that can arise from different sampling positions, times, and tablet drops. The automated dissolution system dispenses the medium gravimetrically, which introduces less error and is done consistently from vessel to vessel and run to run. This is also important when replacing media that has been removed from sampling.

Manual dissolution bath still has an advantage for labs where the analyst does not routinely run the dissolution test or where the test methodology varies. Changes and modifications for each individual test will be easy to adapt manually.

Although fully automatic dissolution systems show advantages in terms of analyst time and reduced variability, there are several disadvantages that may need attention. The first of these is that the fully automated system is complex, with many capabilities. The problem is that the more features you have, the more errors that can be generated. The second disadvantage is the very steep learning curve for the software, which is further exacerbated if the analyst does not use the software on a regular basis. The third may be improper line cleaning. The time to troubleshoot broken seals or pumps that lost their prime and bring them back to operational status from dried-out lines, could take days. A further disadvantage is that the fully automated systems are not standardized with regard to automation when compared to different manufacturers. Operational steps that are not part of the compendial procedure should be validated. The method development and validation could be complicated and time consuming when carryover studies, line flush studies, vessel wash studies, filter studies, and sample evaporation studies all may be necessary to ensure the integrity and equivalency of the fully automatic system.

The USP proposed revision of <l092> "The Dissolution Procedure: Development and Validation" includes new sections on automation and the acceptance criteria and their interpretation.[55] This general chapter provides a comprehensive approach covering items to consider for developing and validating dissolution procedures and the accompanying analytical procedures. It addresses the use of automation throughout the test and provides guidance and criteria for validation.

13.3.5 Noncompendial dissolution methods

According to USP Chapter <1092>, a noncompendial apparatus may have some utility with proper justification, qualification, and documentation of superiority over the standard equipment. For example, a small-volume apparatus with miniature paddles and baskets may be considered for low-dosage strength products. A rotating bottle or dialysis tubes may have utility for microspheres and implants. Peak vessels and modified flow-through cells may be used for special dosage forms such as powders and stents. The

noncompendial dissolution methods have been summarized in several early publications.[56,57] Currently, conventional compendial dissolution testing remains a cornerstone of the drug development process and quality control testing. However, more studies have been done with respect to in vitro technology developments that provide the potential for formulation and analytical scientists to exceed the capabilities of the conventional dissolution test to achieve a more biorelevant testing regime.

Many current noncompendial dissolution methods have been developed based on multicompartmental models. Some of these methods not only mimic the hydrodynamics and composition of media, but also incorporate mechanical processing, digestion of real food, and gastric emptying. Examples of these systems are the TNO TIM−1 system[58] and the dynamic gastric model (DGM).[59] The TNO intestinal model (TIM) (TNO Pharma, Zeist, the Netherlands) is a computer-controlled model that simulates in vivo fluids at more realistic volumes, with more realistic fluid dynamics relative to the human stomach and small intestine. This also incorporates enzymatic activity, bile salts, and pancreatic juices.[60] DGM (Plant Bioscience Ltd, Institute of Food Research, Norwich, United Kingdom) is based on current biochemical and mechanical knowledge from the in situ stomach, including motility and shear.[61] DGM incorporates inhomogeneous mixing behavior with more realistic emptying into a model duodenum.[62] However, because of the complexity of these systems, some limitations such as result reproducibility and repeatability, cost of each test, ease of use of the method and the need of high throughput may prevent the wide use of these systems.

Some less complex systems have also been developed to simulate the physiological factors such as pH, fluid composition, and hydrodynamics to provide scientists a way of assessing product performance under more physiologically relevant conditions. These systems are typically configured to allow the transport of drug contents from a gastric compartment to a second intestinal compartment. One of the systems is the combined dissolution-absorption (permeation) model. Other studies developed a continuous dissolution-permeation system with the use of a two-compartment model consisting of two chambers (dissolution and receiver compartment) separated by a Caco-2 monolayer.[63−65] The similar design based on modification of USP apparatuses using artificial membranes instead of Caco-2 monolayers has also been reported.[66] Drug dissolution and permeation could be simultaneously determined with this model. Another example is the FloVitro dissolution system provided by the Dow Chemical company.[67] This system comprises gastric and small intestinal chambers with an additional third compartment connected to the intestinal chamber, which is intended to function as an absorptive compartment. The FloVitro approach, which integrates a tunable transfer system with deconvoluted in vivo dissolution data inputs, has the potential to combine a dynamic biorelevant dissolution test with biomodeling.

Other than multicompartmental models, dissolution apparatus with simulated GI physical forces was developed.[68,69] The novel stress test apparatus is capable of mimicking the pattern of irregular movement inside the GI tract and the physical forces applied on dosage forms during gastric emptying and intestinal transit. The system appears to have the utility for assessing the mechanical robustness of MR oral dosage formulations and their ability to withstand gastric forces and passage through the pylorus or ileocecal junction.

For these noncompendial dissolution methods, some in vitro parameters (media and hydrodynamics, physical forces, etc.) have been tested to simulate the in vivo conditions in hopes of finding successful predictions of the in vivo performance and IVIVC for oral formulations. However, despite decades of research into the area, there is not enough knowledge about these techniques, and there are very limited data available to validate the widespread use of these techniques at present. More studies are required to search for an accurate in vitro surrogate of the GI tract.

13.4 REGULATORY CONSIDERATIONS

13.4.1 The role of dissolution in product quality control

Over the past four decades, considerable scientific attention has been given to understand the mechanisms of drug dissolution and the factors (eg, formulation, manufacturing process, and physiologic factors) affecting drug dissolution, and to establish standardized methodologies for dissolution testing. The current scientific understanding and knowledge regarding drug dissolution has been predominantly based on studies of oral drug delivery systems. The FDA has published guidance documents covering the relevant topics, such as drug dissolution specifications from solid oral dosage forms and establishment of IVIVC,[2,7] demonstration of drug dissolution/release similarity when formulation and manufacturing changes are made,[5,6] and the waiver of in vivo BE studies.[4] Furthermore, the ICH Q6A guideline on establishing specifications has been developed.[70]

Because the release characteristics may have significant influence on drug BA, dissolution is an essential step in delivering drug molecules to their sites of action. Therefore, drug dissolution is a critical quality

characteristic that needs to be controlled throughout the life cycle of a product. When the hydrodynamics and media are appropriately chosen to have sufficient ruggedness and reproducibility without being over discriminating, dissolution testing can be used to ensure the batch-to-batch consistency and to detect any significant changes that could affect the in vivo performance of the product.

If IVIVC can be established and validated, then the in vitro dissolution can be a surrogate for the in vivo performance, which may be controlled in a range so that all lots with dissolution within the range are bioequivalent. Less optimal but still desirable, lots exhibiting dissolution profiles at the upper and lower dissolution limits should be bioequivalent to the clinical/BA lots or to an appropriate reference standard. In this way, the product quality is controlled with a concept of ensuring the consistency of the in vivo behavior of the product by comparing product dissolution to ensure that the product manufactured (each batch and every batch) is bioequivalent to the reference product, which in turn assures the efficacy and safety of the product. This concept leads to the basic abilities of dissolution testing: the ability to discriminate the products with quality differences, which reflect the differences of their in vivo performance and the ability to reject the batch that is not bioequivalent to the reference batch. In this chapter, the considerations for enhancing these abilities are discussed in the following sections.

Due to the in vivo implication of dissolution testing, there are significant opportunities to build upon the current regulatory decision system and to further improve its effectiveness and efficiency. These opportunities are further enhanced by the possibilities in regulatory decisions to utilize pharmaceutical development information (eg, ICH Q8[71]) and the availability of new technologies for more effective control of formulation and manufacturing variables that can affect drug dissolution when combined with a comprehensive system approach for regulatory quality assessment. The development of regulatory decision criteria based on scientific principles for quality assurance and control of drug dissolution or release rate is an important step for 21st-century pharmaceutical quality control.

Another important role of dissolution testing is in the evaluation of waiver of in vivo BA/BE studies (biowaivers), such as for preapproval and postapproval changes.[5,6,72] Provisions of biowaivers under certain conditions are provided in the Code of Federal Regulations. The regulatory basis for granting a waiver of the requirement for the submission of in vivo BA/BE data is derived from 21CFR320, where it states that either an in vitro test that has been correlated with and is predictive of human in vivo BA [320.24(b)(1)(ii)] or a currently available in vitro test that ensures adequate human in vivo BA [320.24(b)(5)] is acceptable for the evaluation of BA/BE.[73] Biowaivers based on comparative in vitro testing (eg, dissolution for solid dosage form) for different strengths of IR products can be granted under 21CFR320.22(d)(2). Recommendations on dissolution-based biowaivers for product strength equivalence for MR products is provided in the draft FDA guidance for BA and BE studies submitted in NDAs or investigational new drugs.[74] The topic of biowaivers is discussed further later in this chapter.

In the absence of IVIVC, dissolution tests can be used for product quality control to ensure that the dissolution results of the routine manufacturing batches are similar to that of the pivotal batches or BE batches. Dissolution data can be sensitive to the physical properties of ingredients, product compositions, and the manufacturing process for products; hence, dissolution tests may be able to detect batches that show significant differences in dissolution data that could lead to a significant difference in the in vivo performance of the products. Notably, the criterion of similar dissolution for quality control is limited to the same product created by the same manufacturing process. Application of the criteria to multisource products is difficult and not necessary except for some rapid-release IR products of BCS Class I and III compounds. With proper justification, different dissolution methods and specifications are acceptable for multisource products, especially for ER products. However, once the method and specifications are established for a product based on the batches that have demonstrated acceptable BA or BE, future batches of the product must meet the same specifications for dissolution.

13.4.2 Dissolution method development: regulatory considerations

Guidelines for development and validation of dissolution methods can be found in the FDA guidance and the current USP Chapter <1092>, and so they will not be discussed in detail in this chapter. To support and justify the selection of the proposed dissolution method, a report for method development should be included in the regulatory submission. The development reports generally include the information that follows in this section.

Solubility data for the drug substance over the physiologic pH range are important for dissolution method development because these data provide the basis for selection of an appropriate medium and determine whether a surfactant is needed.

A detailed description of the dissolution method being proposed for the evaluation of the product should be provided. The developmental parameters (ie, selection of the equipment/apparatus, in vitro

dissolution/release media, agitation/rotation speed, media pH, assay, sink conditions, use of sinker, and enzyme, if applicable) used to select the proposed dissolution method as the optimal test for the product are very helpful for evaluation of the dissolution method. If a surfactant is used, data should be included to support the selection of the type and amount/concentration of the surfactant. The conditions used for each test should be clearly specified. The dissolution profile should be complete and cover at least 85% of drug release of the label amount or whenever a plateau (ie, no increase over three consecutive time-points) is reached. A systematic approach for selection of the dissolution conditions is to use design of experiments (DOEs), which considers various factors simultaneously, not only for the main effects of the individual factors, but also for the interactions among the factors. For example, in Fig.13.5, the results of dissolution at 15 minutes of a model product are shown for an example DOE by varying media (pH 1, 4.5, 6.8, and water), surfactant [cetyl triethylammonium bromide (CTAB), lauryl dimethylamine-oxide (LDAO), and benzalkonium chloride (BenzChlor)], concentration of surfactant (0.5% and 1%) and paddle rotation speed (50 and 75 rpm). Here, because the complete dissolution was not obtained, the media at pH 4.5 or 6.8 and water were not appropriate. Based on the physicochemical properties of the compound, through data analysis and further experiment, pH 1 media at paddle rotation speed of 50 rpm with surfactant CTAB at concentrations of 0.5% were selected.

In addition to the factors listed here, ionic strength in the medium may play a role (Fig. 13.6, where phosphate buffer is used). Although the pHs for all three profiles generated are at 7.5, the ionic strengths of potassium phosphate are different (0.05, 0.1, and 0.2 M, respectively), which make differences in the dissolution of the model product.

For comparison, at least twelve samples per test are recommended. In general, the following sampling time points are selected: 10, 15, 20, 30, 45, 60, 90, and 120 minutes for IR formulations, and 1, 2, 4, 8, 12, and 24 hours for ER formulations.

Complete dissolution profile data should be provided, including individual, mean, and SD (or %CV) at each time point, as well as profiles for the product. The dissolution data at each time point are usually reported as the cumulative percentage of drug dissolved (the percentage is based on the product's label claim).

Data to support the discriminating ability of the selected dissolution method are critical for evaluation. In general, the testing conducted to demonstrate the discriminating ability of the selected dissolution method should compare the dissolution profiles of the reference (target) product and the test products that are intentionally manufactured with meaningful variations for the most relevant critical manufacturing variables (ie, ±10−20% change to the specification-ranges of these variables) including critical material attributes (CMAs) and critical process parameters (CPPs). Fig. 13.7 shows the dissolution profiles for two batches

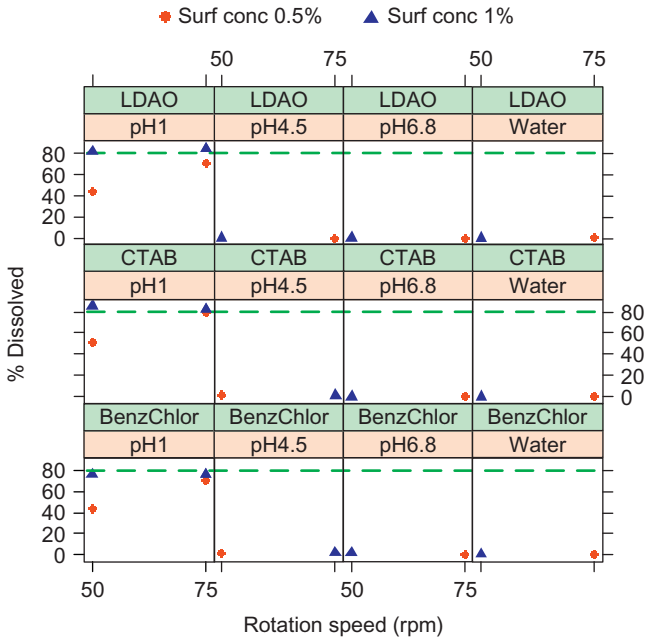

FIGURE 13.5 Example DOE for effects of media pH, surfactant type and concentration, and rotation speed upon dissolution.

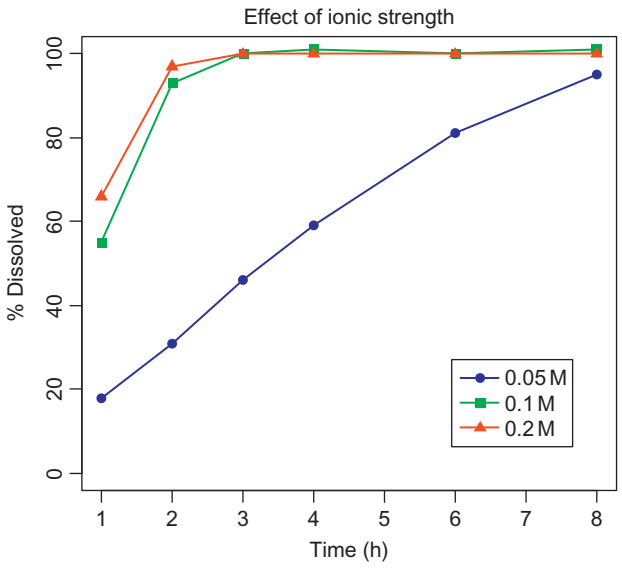

FIGURE 13.6 Effects of ionic strength on the dissolution of a model product.

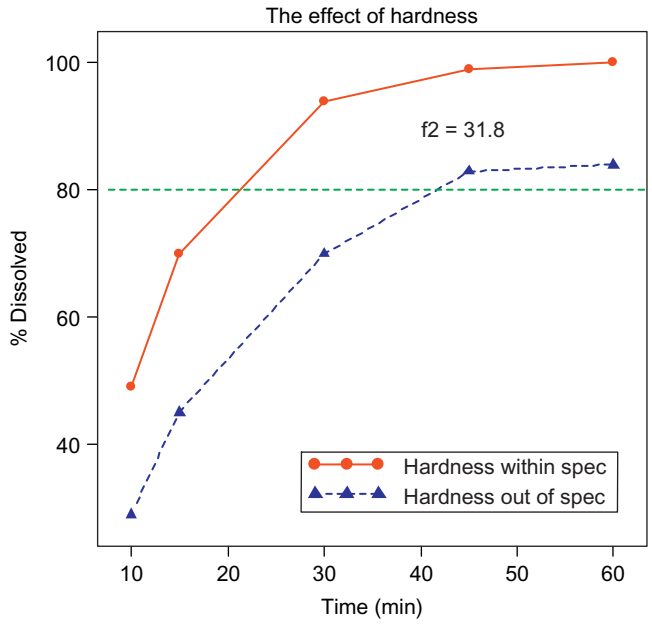

FIGURE 13.7 Effect of tablet hardness on dissolution.

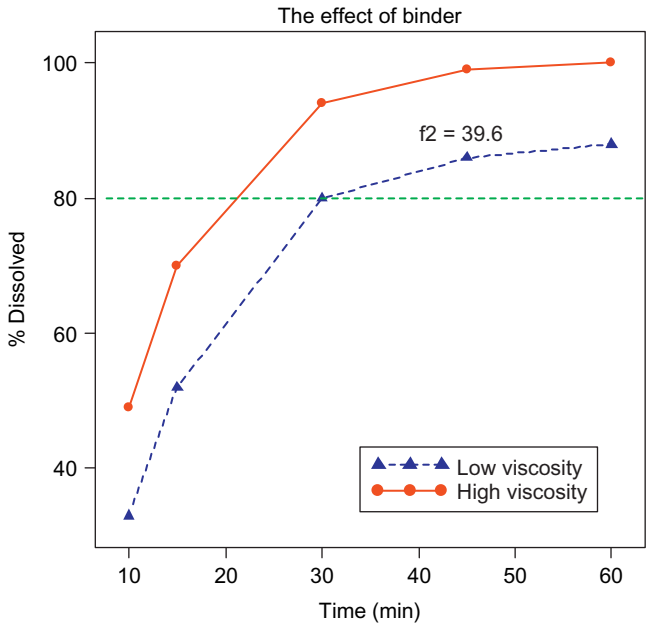

FIGURE 13.8 Effect of binder viscosity on the product dissolution.

of tablets with different hardness (by varying compression force, a CPP). As shown, the release of the batch represented by the line with up triangles is much slower, compared to the batch represented by the line with solid circles, and the former represents an incomplete dissolution although the assay results show the comparable potency between the two batches. This demonstrates that the dissolution method is able to distinguish these two batches with an f2 (similarity factor used to compare two dissolution profiles) value of 31.8, which is much less than 50, indicating that the significant difference between the two batches is detected by the dissolution method. Fig. 13.8 shows the dissolution profile comparison between a batch with the viscosity of the binder, a CMA, within the specification and a batch with the viscosity out of specifications. The dissolution method is able to distinguish these two batches with an f2 value of 39.6 indicating significant difference between the two batches. These two sets of data support the discriminating ability of the dissolution methodology selected.

Further, providing data that show the selected dissolution method is able to reject batches that are not bioequivalent to the reference batches is helpful. Fig. 13.9 shows the dissolution profiles for two batches A and B. A is the batch used in the pivotal clinical studies, which has demonstrated efficacy and safety. B is a batch with manufacturing changes and has been shown not bioequivalent to A. As seen, the dissolution is able to pick up the differences in this case. When setting appropriate acceptance criterion, these two

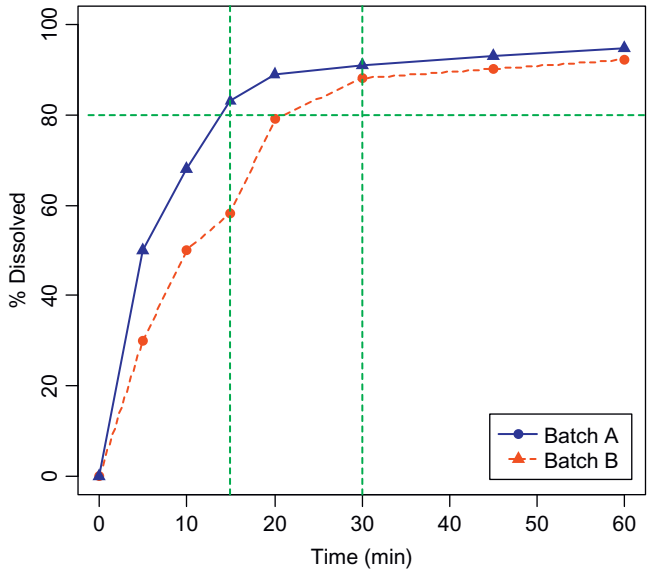

FIGURE 13.9 Dissolution profiles of two batches (A and B), which are not bioequivalent.

products can be distinguished and the product with poor quality (not bioequivalent to the clinical batch) can be rejected. Another example is shown in Fig. 13.10, where the dissolution shows distinctions of profile shapes, indicating the differences in clinical performance. The line with red empty circle has an initial burst, which is higher than the blue line with solid circle, followed by a slowdown and an increase at a much later time compared to the profile with solid

circle. The slowdown of the release may be responsible for the ineffectiveness of the product.

On the other hand, dissolution methods may sometimes overdiscriminate the formulations as indicated in Fig. 13.11, which shows the in vitro and in vivo profiles for the target formulation and three variants. Although the in vitro dissolution profiles show significant differences among target formulation and variants, all the in vivo profiles are bioequivalent. To make an appropriate judgment using all available information, knowledge management plays a critical role.

In addition, the validation data for the dissolution method (eg, system suitability test, method robustness, deaeration if necessary, and validation between manual and automated procedures) and analytical method (ie, specificity, precision, accuracy, linearity, stability, etc.) are needed to support the proposed method.

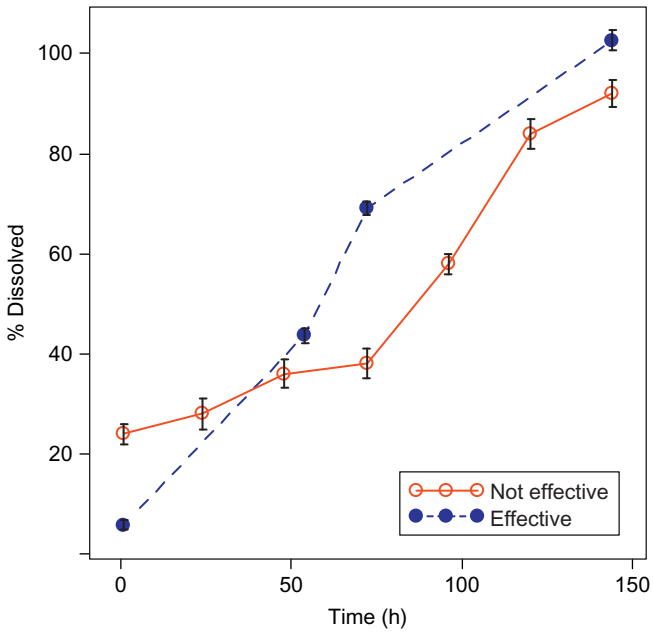

FIGURE 13.10 Dissolution profiles with different shapes have clinical efficacy differences.

13.4.3 Setting regulatory acceptance criteria for dissolution testing

When setting the dissolution acceptance criteria, the clinical performance of the product is the first and most important consideration. Thus, the data of the dissolution profile (eg, 10, 15, 20, 30, 45, 60, 90, and 120 minutes for IR products; 0.5, 1, 2, 4, 8, 12, and 24 hours for ER products; $n = 12$) from the pivotal clinical batches should be used for setting the dissolution acceptance criteria of the product (ie, specification-sampling time point and specification value). The manufacturing information of those batches (number, date, site, and size of the batch made) should also be provided. Since the pivotal clinical studies may last for a period of time due to patient enrollment and other factors, clinical supplies may not always be the freshest batches. In this case, the stability of the batches may be considered when setting the acceptance criteria.

Because the batches participating in pivotal clinical trials are limited, the dissolution range, within which the products will be bioequivalent to the reference

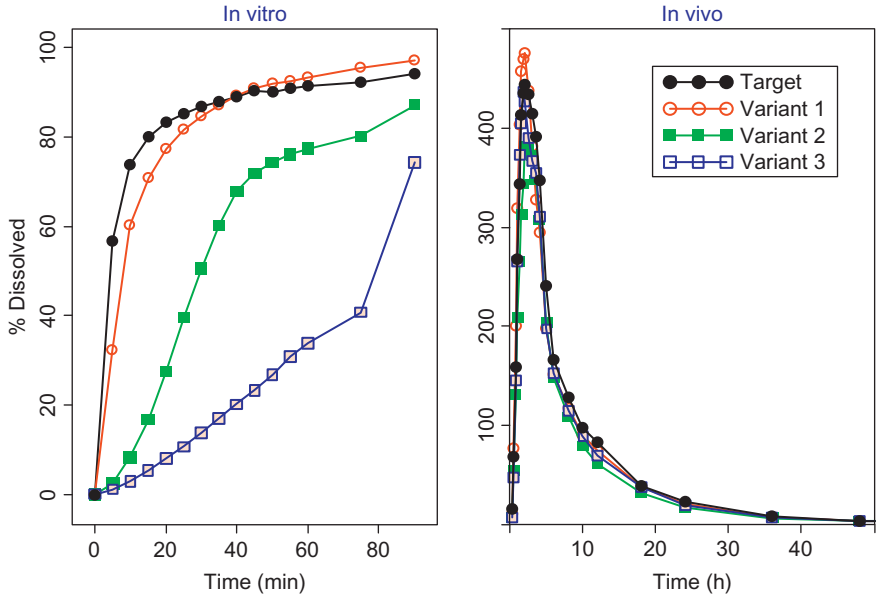

FIGURE 13.11 Overdiscriminating dissolution method.

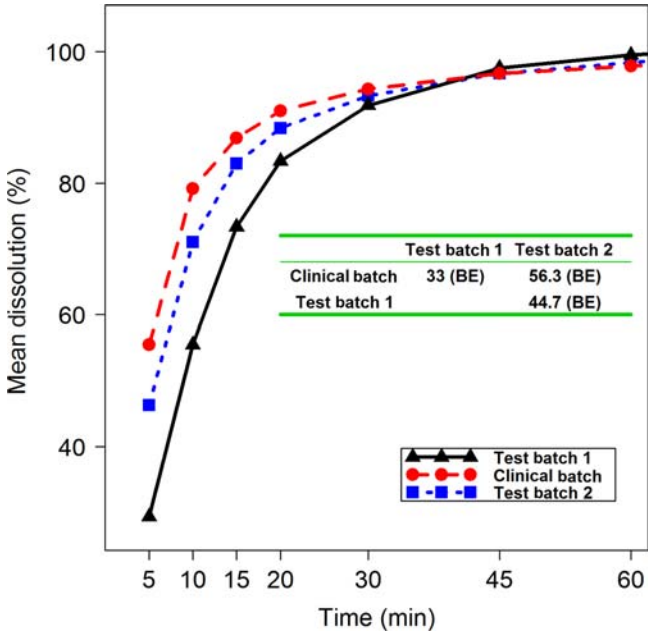

FIGURE 13.12 The dissolution profiles of three bioequivalent batches of formulations.

batch, can be difficult to identify. Further, the limited batches may not represent the real variability of the product caused by many factors, including the materials and the processes. In these ways, taking the batches involved in all the relevant clinical studies into consideration would be very helpful. The batches, which are bioequivalent to the reference batch, could be used for defining the range of the acceptance criteria. In the example shown in Fig. 13.12, the dissolution of the clinical batch (the dashed line with solid circles) is the highest compared to the other two batches: Test Batch 1 (solid line with up triangles) and Test Batch 2 (dotted line with solid squares). The dissolution profiles are similar between the clinical batch and Test 2 (f2: 56.3), but comparisons between the clinical batch and Test 1 (f2: 33) and between Test 1 and Test 2 (f2: 44.7) do not show similarity. On the other hand, however, a clinical study showed BE among the three formulations, with Test Batch 1 barely passing the BE criteria compared with the clinical batch. Therefore, the dissolution of Test Batch 1 could serve as the lower limit when setting the dissolution criterion. Another example is shown in Fig. 13.9 in the last section, when the acceptance criterion is set as $Q = 80\%$ at 30 minutes, both batches A and B would pass although they are not bioequivalent. Therefore, the criterion should be set as $Q = 80\%$ at 15 minutes, which would be able to differentiate these two batches and reject the one that is not bioequivalent to the clinical batch.

The in vitro dissolution profile should encompass the timeframe over which at least 85% of the drug is dissolved. If incomplete dissolution is occurring, the profile should reach the plateau (ie, no significant change in three consecutive time points).

For IR products, the selection of the specification time point should be where $Q = 80\%$ dissolution occurs. However, for a slowly dissolving product or a poorly water-soluble drug, specifications at two time points may be adequate. The first time point should include a dissolution range (eg, 40–60% dissolution), and the second time point should be where $Q = 80\%$ dissolution occurs.

For ER products, the establishment of at least three specification time-points covering the initial, middle, and terminal phases of the complete dissolution profile should be set. The specification ranges should be based on the overall dissolution data generated at these time points. If the maximum amount released is less than 80%, the last time point should be the time when the plateau of the release profile has been reached. In general, the selection of the dissolution specification ranges is based on mean target value $\pm 10\%$ and not less than (NLT) 80% for the last specification time-point. Wider specification ranges may be acceptable if they are supported by a validated IVIVC model.

Delayed release (enteric coated) products should have the following specifications established in both the acid stage and buffer stage per USP:

- Acid stage: No individual tablet exceeds 10% dissolved at 2 hours.
- Buffer stage: The selection of the specification time point should be where $Q = 80\%$ dissolution/release occurs. If it is a delayed release (DR)/ER product, at least three specification time-points covering the initial, middle, and terminal phases of the complete dissolution profile should be set at the buffer stage based on the ER product listed.

The acceptance criteria is recommended to be set based on the average in vitro dissolution data equivalent to USP Stage 2 testing ($n = 12$) for each lot under study for a tighter control. To illustrate this and provide the quantitative basis to set the dissolution acceptance criterion for an IR solid oral drug product, a simulation study of the dissolution profiles was conducted on a batch of a solid oral dosage form with 1 million units (tablets). The desired acceptance criterion was $Q = 80\%$ of label claim at 30 minutes. A total of 110 scenarios were examined, which include various combinations of two determinants: batch mean and SD values of dissolution at 30 minutes. The mean of the dissolution of the 1 million tablets varied from 79% to 89% of the label claim with 1% increment (11 levels) and the SD varied from 1% to 10% of the label claim with 1% increment (10 levels). For each of the 110 scenarios, 10,000 replicates were simulated. Based on USP

Chapter <711>, three stages of dissolution testing were conducted. The failure index at each stage for each scenario was calculated as the percentage of failed replicates in the 10,000 trials. The simulation was implemented by a function written in R software (version 2.15.3, R foundation for statistical computing). A contour plot was generated for each stage to demonstrate the relationship between the failure index and the two determinants (dissolution mean and SD).

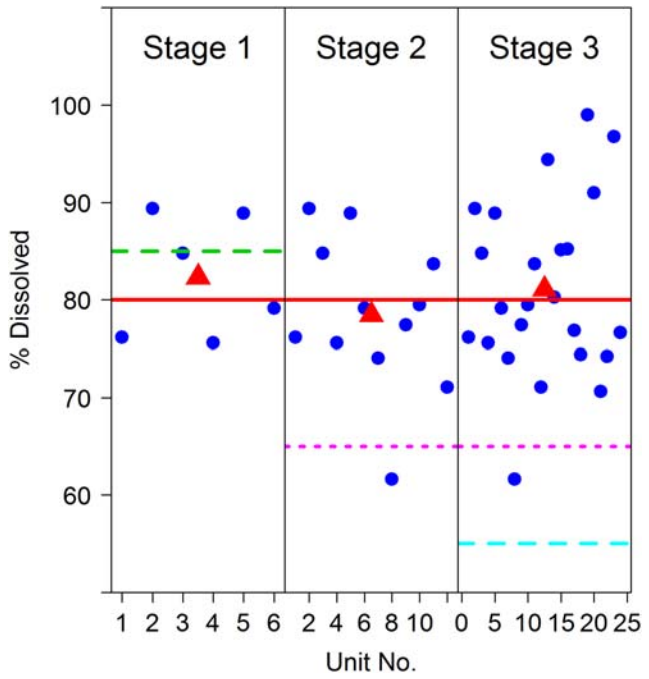

FIGURE 13.13 A typical case of three-stage dissolution for a time point at which the desired acceptance criterion is $Q = 80\%$ for an IR oral solid dosage form. The solid circle represents the dissolution value for individual unit, and the solid triangle is the sample mean. This batch does not pass Stage 1, which requires every unit ≥85% (the horizontal dashed line shown in Stage 1). The batch does not pass Stage 2 because the sample mean <80% (the solid horizontal line), and there is a unit less than 65% (the dotted horizontal line). It passes Stage 3 since the mean is above 80%, not more than two units less than 65% (only one less than 65%) and no one unit is less than 55% (the dashed horizontal line shown in Stage 3).

A typical case of three stages of dissolution testing at a given combination of mean and SD is shown in Fig. 13.13. The solid circles represent the individual dissolution values and the solid triangles are the mean values.

The failure index for each stage is dependent on the mean and SD values, as shown in Fig. 13.14. The contour lines represent the failure index at a given combination of the mean and SD values. As shown, in order for a batch to have 80% chance to pass Stage 1, the mean dissolution value of this batch must be at least 87% with very low SD of less than 1%. If the SD increases to 2%, the mean value must be at least 89%.

On the other hand, simulations indicate that if the mean dissolution value is 81%, the drug product's batch would have 80% chance to pass Stage 2 when the SD is less than 2.5%. Even when the SD increases to 8% (10% CV), the batch would have 80% chance to pass Stage 2 if the dissolution mean value is >84.5%. These observations by simulation indicate significant differences of passing the specification between Stage 1 and Stage 2 (or 3). Due to this difference, the acceptance criterion would be very permissive for Stage 2 and 3, if the setting of the criterion is based on Stage 1 dissolution data. Therefore, this suggests setting of the dissolution acceptance criterion be based on Stage 2 dissolution data is advisable. The 20% failure index contour line for Stage 2 (middle panel in Fig. 13.14) provides a quantitative estimate based on the observed mean and SD data and could serve as the guideline for the setting of the acceptance criterion for the dissolution test of IR solid oral dosage forms.

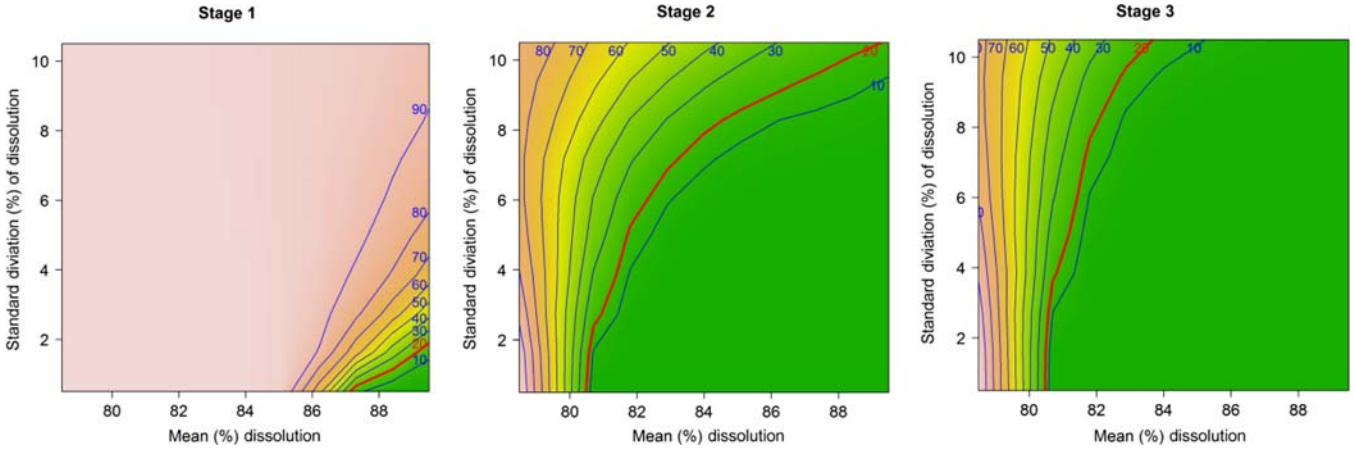

FIGURE 13.14 The influences of mean and variability of dissolution data on the failure rates for three stages of dissolution testing of IR formulation by simulation.

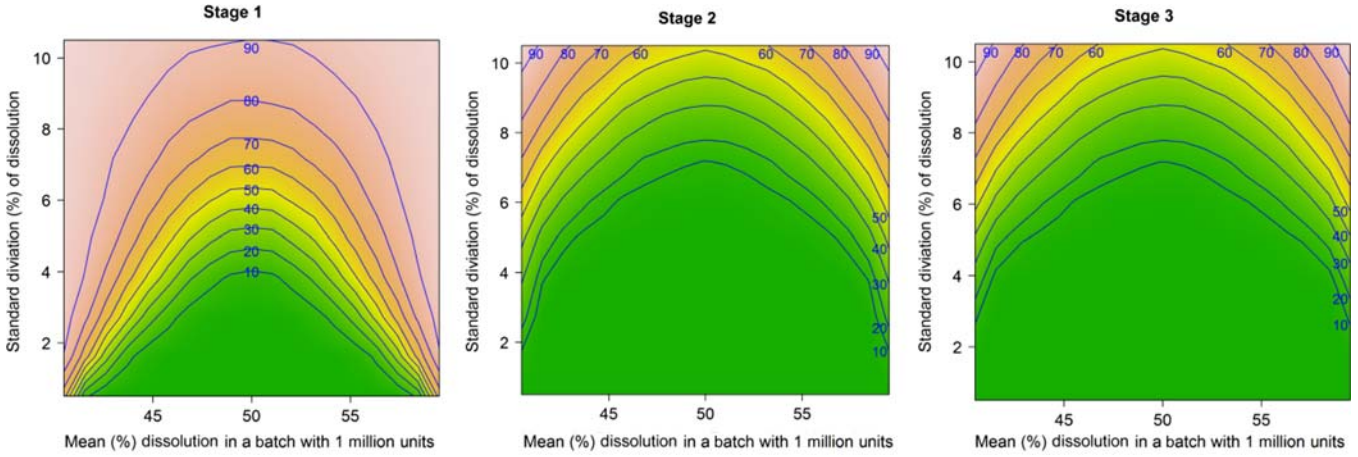

FIGURE 13.15 The influences of mean and variability of dissolution data on failure rates for three stages of dissolution testing of ER formulations by simulation.

This study provides scientific support for the current FDA's practice/recommendations on using Stage 2 data for the setting of the dissolution acceptance criterion. In addition, the study provides an example of a quantitative way to select the acceptance criterion's sampling time point based on the mean and SD of the dissolution data according to Stage 2 contour line with a 20% failure index in Fig. 13.14.

A similar simulation study was conducted to estimate the three stages of the dissolution for ER formulation, as shown in Fig. 13.15, and similar conclusions can be made, although the distinction between Stage 1 and Stage 2 (or 3) for ER formulation is not as dramatic as that for IR formulation.

Notably, the 80% success rate or the 20% failure rate discussed here for the simulation is for illustration purposes, to indicate the statistical power. One could argue that a failure rate of 20% is too high in manufacturing and should not be used as the objective to set the specifications for dissolution. However, the information from the simulation is valuable to assist setting a proper specification based on the clinical performance of the clinical batches using a quality-by-design approach to ensure the consistent performance of product by controlling the lot-to-lot variation, and to prevent the release of any lots with dissolution profiles that have been shown not bioequivalent in clinical study.

As discussed earlier, if a valid IVIVC model has been established, the model should be used to set the specifications for dissolution. Specifications should be set for the product with the fastest and slowest release rates to result in a maximal difference of 20% in the predicted C_{max} and area under the curve (AUC).

If there is no IVIVC/IVIVR established, the following steps may be considered to set up the dissolution acceptance criteria. The procedure fixes the Q value at 80% for IR products and presents a typical case for ER products using clinical batches as the bases for consideration.

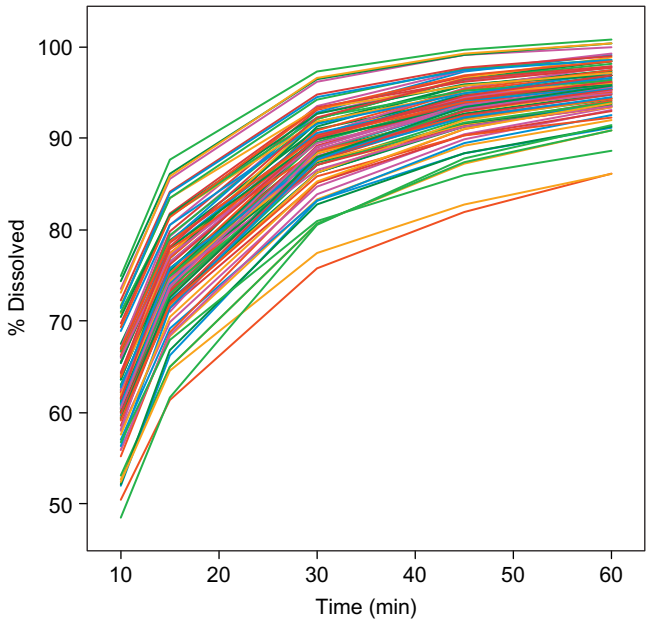

FIGURE 13.16 A plot of the dissolution profiles of all available batches for an IR product.

Step 1: Plot the available dissolution profiles to appreciate the variability and select the potential specification time points. Find the root causes if the variability is too high (>10% CV). Resolve the quality problems in manufacturing, assay, or both.

For IR formulation, the time point can be chosen where $Q = 80\%$ dissolution occurs. For ER formulation, three time points should be selected at initial, middle, and terminal phases of the complete dissolution profile. As shown in Fig. 13.16, in the current example, a

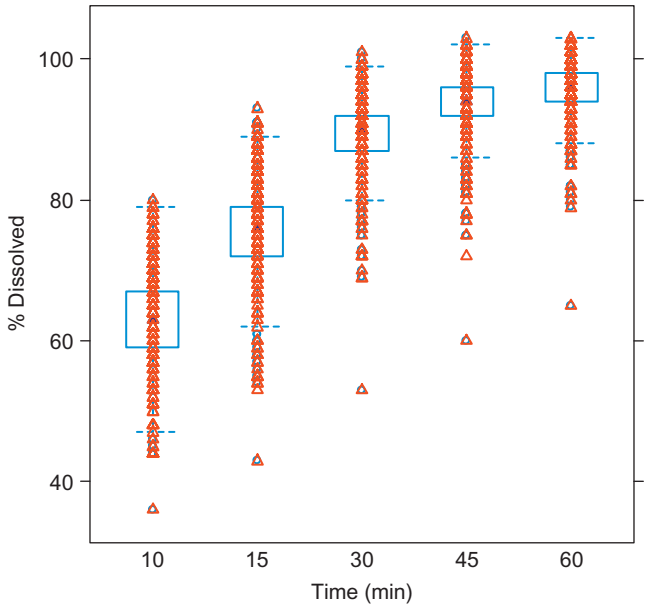

FIGURE 13.17 Box plots for the dissolution data at each time point. The mean, 25%, and 75% quartiles are identified for the distribution for an IR product.

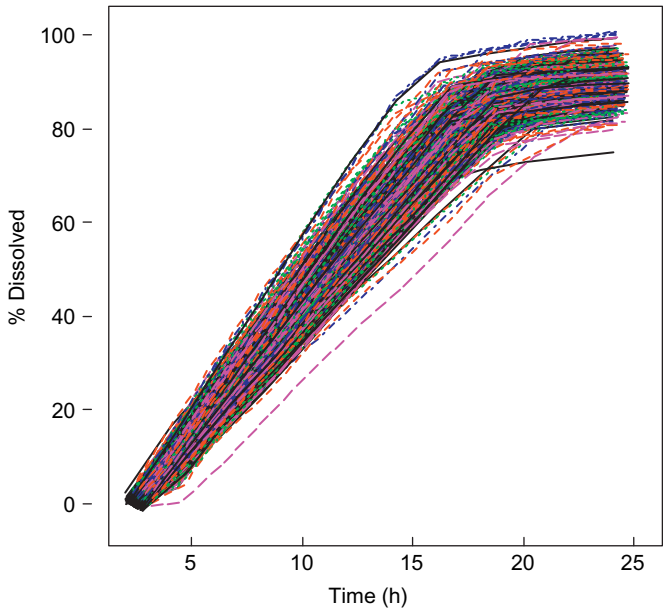

FIGURE 13.18 A plot of the dissolution profiles of all available batches for an ER product.

total of 90 profiles available for an IR product are plotted to get an insight regarding the general shape of the dissolution profile and the variability. Pay attention to the outliers and special features, such as strength-dependent behavior. To further appreciate the variability, Fig. 13.17 uses box plots for about 1000 individual units to identify the mean, the 25th, and the 75th quartiles of the distribution at each time point. From the plot, two observations can be made for this product. First, the variability is relatively large, which could raise a concern regarding the product quality, and second, the 30-minute time point could be a potential specification sampling time for this IR product. If the large variability is caused by product quality, the sponsor should make every effort to control the CMAs and CPPs. If the root cause for variability is assay, improvements of analytical procedure are needed. Before setting the appropriate dissolution specification, the variability should be reduced to a reasonable level (CV $<$ 10%).

For ER products, the same procedure can be followed. As shown in Figs. 13.18 and 13.19, the dissolution profiles and the distribution of all individual units at each time point are plotted. From these observations, potential specification time points at 6, 10, and 18 hours are selected.

Step 2: Plot the clinical batch dissolution data at the potential specification time point.

As mentioned previously, the dissolution of the clinical batches, which have shown the acceptable efficacy and safety, are the standards for setting dissolution

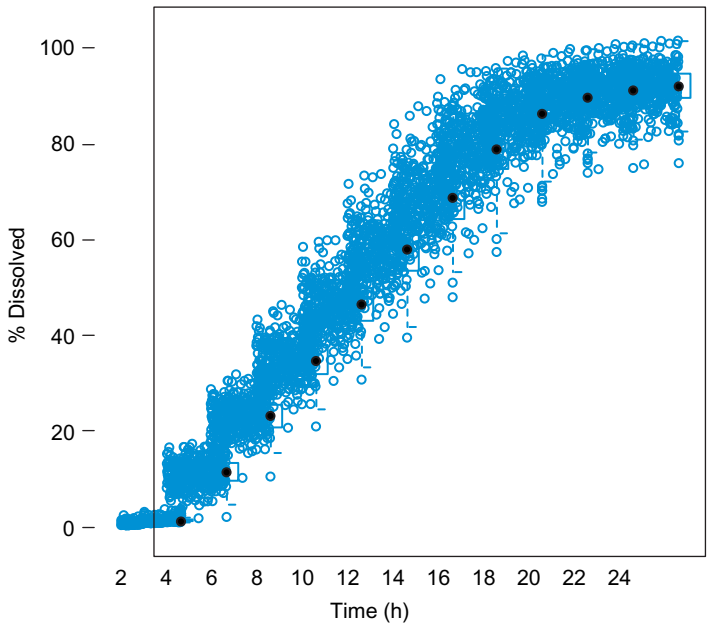

FIGURE 13.19 Box plots for the dissolution data at each time point. The mean, 25%, and 75% quartiles are identified for the distribution for an ER product.

acceptance criteria. As shown in Fig. 13.20, the dissolution of individual unit at 30 minutes for 26 batches used in pivotal clinical trials (showed acceptable efficacy and safety), are examined with an intention to set the acceptance criterion as $Q = 80\%$ at 30 minutes. As seen, although some batches could not pass Stage 1 due to individual unit values less than

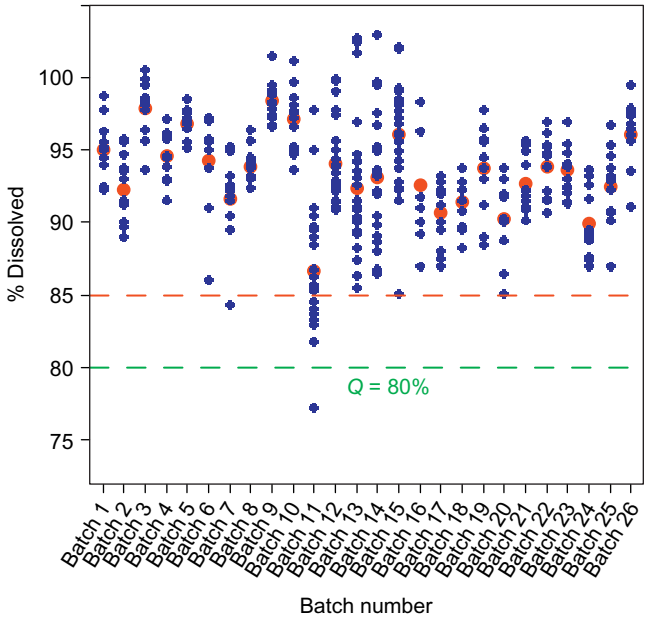

FIGURE 13.20 An example case of dissolution performance of 26 clinical batches of an IR formulation at the selected potential specification time point.

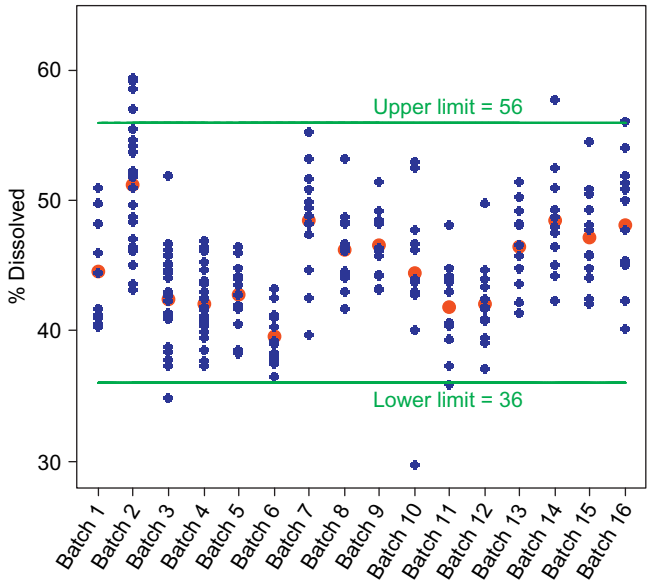

FIGURE 13.21 An example case of dissolution performance of 16 clinical batches of an ER formulation at one of the potential specification time points.

85% (Stage 1 requires all units to be $\geq Q + 5\%$), all batches will pass Stage 2 (the mean, represented by the bigger red dots (black in print versions) are above 80% and no single units below 65%). Therefore, the potential specification time point (30 minutes in this example) seems adequate.

Similarly, Fig. 13.21 shows an example of one of the specification time points (at 10 hours) for an ER product. As seen, the acceptance criteria 36–56% are based on the totality of dissolution data for 16 batches used in the pivotal clinical studies, considering both the mean (larger red dots (black in print versions)) and individual values (blue dots (gray in print versions)). Although some batches would not pass Stage 1, which requires all units to be within the specified range, all batches will pass Stage 2 since the batch means are within the specified range and no single unit out of the range by more than 10%.

Step 3: Confirm the selected specification time points by inspection of available dissolution data, including stability data.

When confirming the selection of the specification time point and the acceptance criteria, the simulation results shown in Figs. 13.14 and 13.15 should be considered to see if the specification will allow the product to pass the acceptance criteria with high power based on the middle panel in each graph. Generally, a bootstrap analysis for the clinical batches may be performed to get the mean and SD values, which can then be used to check against the contour line for the failure index.

Obviously, one should check the dissolution specification using the dissolution performance of the product employed in the relevant clinical studies, successful or not, which may provide further understanding of the product performance and its clinical relevance.

As mentioned previously, stability data on dissolution are important and should be taken into account when setting dissolution specifications. While significant changes in dissolution over the course of a stability study are not acceptable, minor changes in dissolution of an aged product may occur. In addition, the dissolution performance during stability for hard and soft gelatin capsules and gelatin-coated tablets due to crosslinking should be noted.[75]

If any issue arises during confirmation, go back to Step 2. This iteration would provide an optimal selection for dissolution specifications.

If the dissolution is not a sensitive indicator for the product quality compared to disintegration testing, it may be substituted by disintegration, as indicated by ICH Q6A.[70]

Note that the final determination on the acceptability of the dissolution acceptance criteria is made by regulatory review. The adequacy of the proposed dissolution acceptance criterion for the product is made during the NDA review based on the totality of dissolution data provided in the application.

The general approach used in setting dissolution specifications for NDAs are summarized in Fig. 13.22.

A dissolution test is commonly used as a quality control tool for ANDAs in the generic industry. For

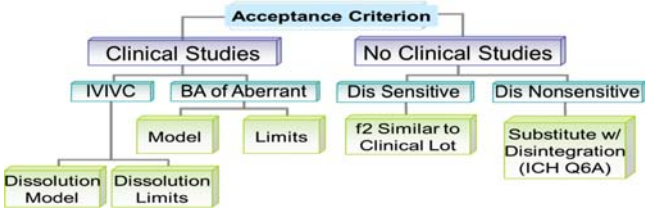

FIGURE 13.22 General scheme for determining the dissolution acceptance criteria for NDAs.

this purpose, the dissolution method and accompanying specifications are established based on the dissolution performance of the pivotal BE batch that has been demonstrated to be bioequivalent to the referenced listed drug (RLD) and the stability batches of the same formulation. Except for some rapidly dissolving BCS Class 1 or 3 drug products, for which waiver of in vivo BE studies may be granted under certain conditions (as discussed in the next section), IVIVC is very limited for ANDAs at present. In addition, the total number of batches of acceptable product available for setting dissolution specification for an ANDA is less than that of an NDA. Therefore, the applicability of the steps outlined here for NDAs may be limited for ANDAs. However, the concept is still valid for consideration in setting the specifications for ANDAs to ensure that the dissolution test has both ruggedness and repeatability for routine operation and, ideally, to have sufficient sensitivity to identify the differences that could potentially lead to a significant change in the in vivo performance of the products.

In many cases, the dissolution methods listed in the FDA's dissolution database[76] and in the USP are used for new ANDAs. Due to the lack of valid IVIVCs for multisource products and the fact that the dissolution of a given drug product can be affected by many factors, including formulation, manufacturing process, and powder characteristics such as particle size distribution and polymorphism of APIs and excipients for the product, the methods in the FDA database or USP may or may not be suitable for new ANDA products that have been shown to be bioequivalent to the RLDs. Therefore, ANDA sponsors may develop new dissolution methods/specifications if the existing methods in the FDA database or USP are not adequate for a new generic product. The FDA perspective and decision trees for selection of dissolution test and the suggestions for submission of dissolution data for ANDAs of both IR and ER products can be found in the literature.[77] Similarly, USP may include multiple dissolution tests or drug release tests in a same monograph for multisourced products that have different in vitro dissolution behavior but yet are bioequivalent to the RLD, which is common for ER products. However, it should be noted that, in some cases, only some the products meeting the different requirements stated in a same monograph are bioequivalent to the RLD. Some of the pharmacopoeial monographs may cover products with different therapeutic equivalence (TE) codes or for different uses, such as for twice-a-day or for once-a-day dosing; hence, those products are not expected to be bioequivalent. Product TE codes can be found in the FDA Orange Book at http://www.accessdata.fda.gov/scripts/cder/ob/default.cfm.

13.4.4 Biowaiver considerations and comparison of dissolution profiles

Waiver of BE studies in human (biowaivers) may be possible for (1) certain types of generic drug applications (ANDAs), (2) approval of lower strengths (or higher strengths in some cases) of products based on the successful BE of the designated strength of the product, and (3) postapproval changes to NDAs or ANDAs.

For ANDAs, biowaivers may be possible based on the BCS and the formulation and dissolution of products.[4] According to the FDA draft guidance,[5,6] biowaivers can be justified for rapidly releasing IR products containing BCS Class 1 drug substances (highly soluble and highly permeable), as well as BCS Class 3 drug substances (highly soluble and low-permeable). Rapid dissolution is defined as not less than 85% of the label amount of the drug substance dissolves within 30 minutes using USP Apparatus I at 100 rpm, or USP Apparatus II at 50 rpm (or 75 rpm with justifications), in a volume of 500 mL or less of each of the following media: (1) 0.1 N HCl or simulated gastric fluid USP without enzymes, (2) a pH 4.5 buffer, and (3) a pH 6.8 buffer or simulated intestinal fluid USP without enzymes. Dissolution profiles of the generic drug products under these test conditions should also be similar to that of the RLDs. Class 1 drug products should not contain any excipients that will affect the rate or extent of absorption of the drug. For Class 3 drug products, additional requirements are imposed for biowaivers, which includes (1) the drug product (test and reference) is very rapidly dissolving (NLT 85% dissolves within 15 minutes) in each of the recommended media and (2) the test product formulation is qualitatively the same and quantitatively very similar (eg, falls within SUPAC IR level 1 and 2 changes in composition) to the RLD.

Waivers of in vivo BE studies may be possible for the approval of lower or higher strengths of a product based on the acceptable BA/bioequivalency of the designated BE strengths of the product with the additional

requirement that (1) the formulations of the designated BE strengths of the test and the RLD products are proportional to their corresponding strengths of products and (2) dissolution testing of all strengths is acceptable (similar).[78]

Changes in SUPAC for IR and MR solid oral dosage forms in different classes, such as components, manufacturing site, scales, equipment, and process, can be classified into three levels.[5,6] Among the changes, Level 2 and Level 3 are the cases where additional dissolution test is needed to justify the changes and to ensure that the product quality and performance of the product remain similar upon the SUPAC changes, and to reduce the burden for the regulatory agency and the industry. One of the common criteria used for comparison of dissolution profiles is the use of similarity factor f2 (defined in Eq. (13.1)) for justification of the similarity of dissolution performance of the test (or postchange) and the reference (or prechange) batches. When f2>50, it can be considered that dissolution is similar for the prechange and postchange batches. Dissolution profile comparisons play an important role under these conditions. According to the SUPAC guidance,[5,6] an in vivo BE study is needed when the changes are likely to have significant impact on the product quality and efficacy. The BE study may be waived if IVIVC has been established for the product. The development of IVIVC is discussed in chapter "In Vitro/In Vivo Correlations: Fundamentals, Development Considerations, and Applications."

As discussed previously, the comparison of in vitro dissolution profiles is immensely important for justification of biowaivers and for SUPACs. The mathematical approaches for quantitative comparison of dissolution profiles are described in the literature. One of these approaches was published by Moore and Flanner.[79] They described a "similarity factor," also known as the *f2 index*, which is a logarithmic transformation of the average of the squared vertical distances between the test and reference mean dissolution values at each dissolution time point, as shown in Eq. (13.1):

$$f2 = 50 \times \mathrm{Log}\left\{\left[1+\frac{1}{n}\sum_{t=1}^{n}(R_t-T_t)^2\right]^{-0.5}\times 100\right\} \tag{13.1}$$

where Log = logarithm to base 10, n = number of sampling time points, $\sum$ = summation over all time points, and R_t and T_t = the reference and test dissolution values (mean of at least 12 dosage units) at time point t.

The value of f2 is 100 when the test and reference mean profiles are identical. The maximum distance between mean dissolution profiles at any time point cannot exceed 100%, in which case the value of f2 will be close to zero. An average difference of 10% at all measured time points results in a f2 value of about 50. Therefore, the values of f2 between 50 and 100 reflect less than 10% overall difference between the profiles suggesting similarity of the two dissolution profiles and thus, the release performance of the two products.[2,4–7]

The f2 index is used frequently by the pharmaceutical industry to compare mean dissolution profiles. Different FDA guidance documents suggest the use of the f2 index.[2,4–7] The f2 index provides an easily calculated single number to describe the comparison of dissolution profiles. However, the index has certain disadvantages.[80–83] For example, Eq. (13.1) does not take into account the variability or correlation structure or direction of the data. Also, the values of f2 are sensitive to the number of dissolution time points. Finally, the basis for the criteria to determine the similarity between dissolution profiles is somewhat ambiguous.

There are some restrictions for the f2 index, including the fact that the variability of the dissolution data should be less than 20% at early time points and less than 10% at other time points, and that only one time point with more than 85% dissolution should be used in the calculation. However, these restrictions were sometimes violated.

An important issue in the dissolution profile comparison using f2 is the practical significance of differences between mean dissolution profiles. That is, how large can the difference between mean dissolution profiles be before the differences are likely to affect in vivo performance?

Knowing how consistent f2 similarity is with the criteria for BE is important for assuring similarity in product performance. For this purpose, addressing the following two questions is necessary: (1) how likely the two products determined to be similar in vitro are not bioequivalent in vivo (false positive) and (2) how likely the two products determined to be dissimilar in vitro are bioequivalent in vivo (false negative).

A study was conducted to investigate the consistency between the in vitro dissolution profile comparisons using an f2 matrix and in vivo BE using the 80–125% criteria for an ER formulation.[84] The study utilized a simulation approach to examine several potential scenarios to get a general picture about this issue. Fig. 13.23 exemplifies a set of simulated dissolution profiles.

In the figure, the red (gray in print versions) solid lines in each panel are the dissolution profiles for the reference product, while the blue (black in print versions) lines are those for the test product. As can be seen, when the parameters of the test and reference used for simulation are the same, the profiles of the reference and the test are exactly overlapped (panel 25 with f2 = 100). However, as the parameters of the test

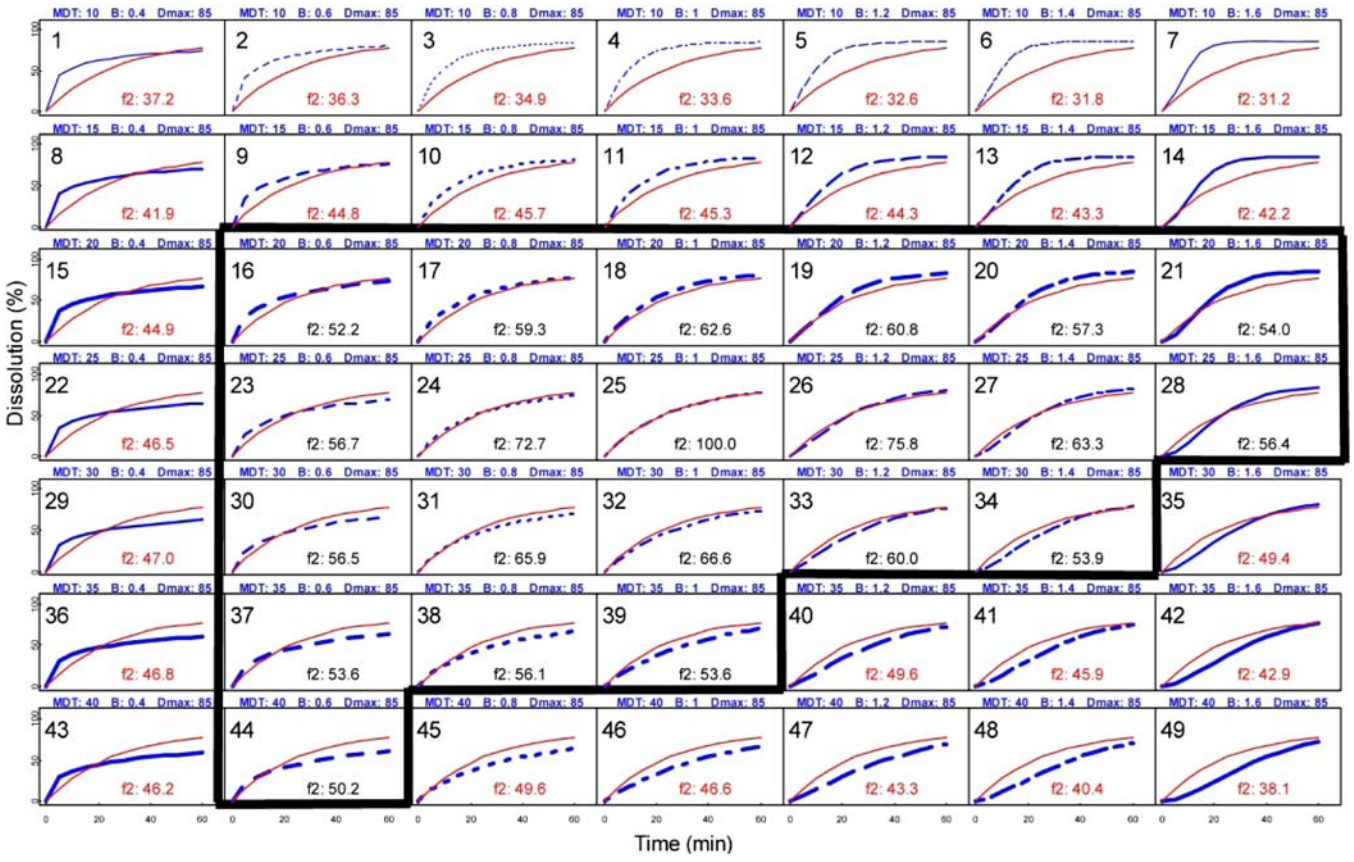

FIGURE 13.23 Simulated dissolution profiles. The parameters used for simulation are labeled at the top of each panel. The f2 similarity value is noted in each panel. f2 values ≥50 are colored black, while f2 values <50 are colored red (gray in print versions). The solid black border around the panels outlines the profiles that are similar.

product deviate from those of the reference, the profiles of the test product may be higher (top panels, such as panel 4), or lower than the reference (bottom panels, such as panel 46). In some other instances, the early parts of the test profile are higher, while the later parts are lower than the reference profile (the panels on the left, such as panel 22) or vice versa (the panels on the right, such as panel 28). The f2 values are labeled in each panel, which are smaller when the parameters deviate further. Those values that are less than 50 are colored red (gray in print versions), and thick black lines are drawn to separate the similar and dissimilar profiles.

For each dissolution profile, the in vivo concentration profile is predicted using an IVIVC model. The corresponding in vivo profiles for the dissolution profiles shown here are presented in Fig. 13.24. In each panel of this figure, the ratios of AUC and C_{max} (and the T_{max} difference) between the test and the reference are labeled, with those outside the BE range (0.8−1.25) colored red (gray in print versions). Thick black lines are drawn to separate the bioequivalent from biononequivalent profiles.

This study demonstrated the general consistency between in vitro dissolution comparison using the f2 factor and in vivo BE results. The results also indicate that dissolution profiles that are judged to be similar using the f2 factor may not always be bioequivalent when tested in vivo. On the other hand, in vitro dissolution profiles judged to be dissimilar by the f2 factor may sometimes generate in vivo bioequivalent profiles. As shown in Fig. 13.25, the Weibull parameter range used for generating the dissolution profiles, which are determined to be similar to the reference profile by f2 factor, is called the *f2 similarity region* (enclosed by thick, dashed blue (dark gray in print versions) lines), while the parameter range generating in vivo profiles that are bioequivalent to reference profiles is called the *bioequivalence region* (enclosed by red (light gray in print versions) solid lines for AUC, and black dotted lines for C_{max}). It can be seen that the f2 similarity region and the BE region are close, although they do not exactly match.

This study emphasized the importance of evaluating the shape and the completeness of in vitro dissolution curves when f2 is used to determine the similarity

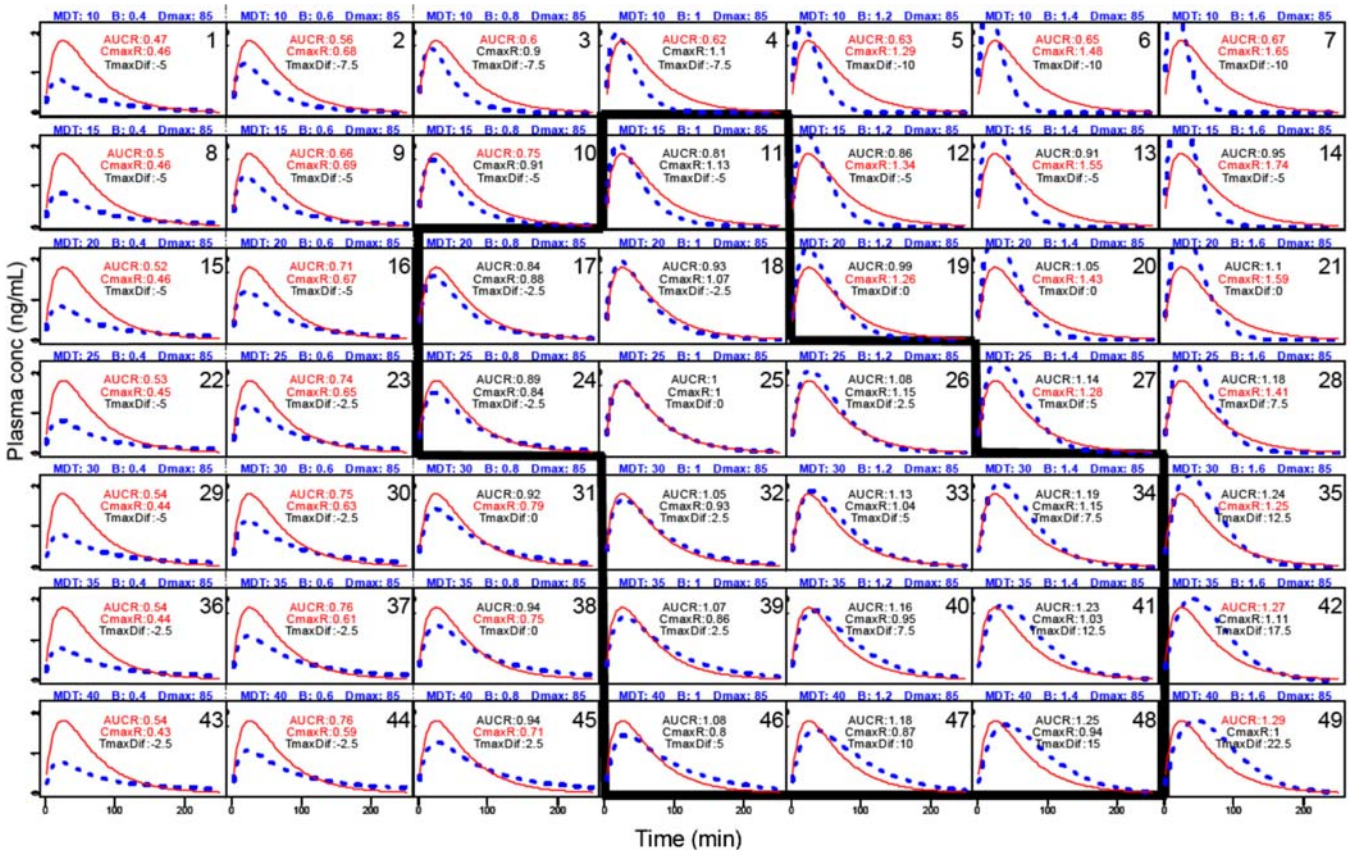

FIGURE 13.24 The in vivo profiles corresponding to the in vitro profiles in Fig. 13.22 based on the IVIVC model. At the top of each panel are the model parameters used for simulating the in vitro dissolution from which the in vivo profile were obtained. The red (gray in print versions) solid line denotes the reference profile, and the dotted line denotes the simulated profile. The AUC ratio, C_{max} ratio, and T_{max} difference are noted in each panel. The solid black border around the panels outlines the profiles that are bioequivalent.

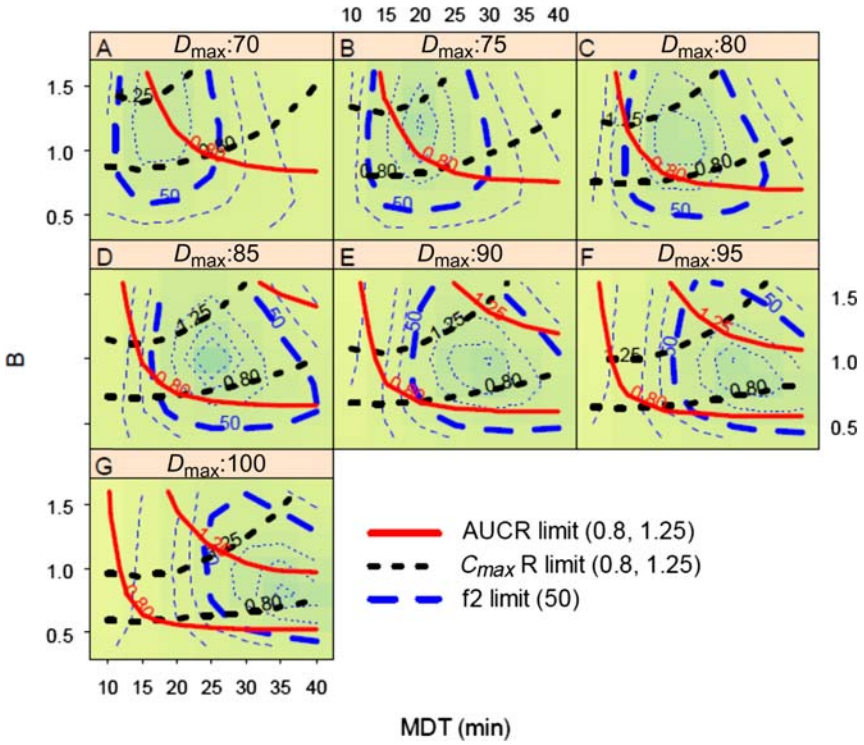

FIGURE 13.25 Effect of Weibull parameters (MDT, B, and D_{max}) used in the simulation of dissolution profiles on the AUC ratios, C_{max} ratios, and f2 comparisons. When the MDT and B take the values enclosed by the two thick red (light gray in print versions) lines (for AUCR) and the two black thick dotted lines labeled (for $C_{max}R$), the simulated in vivo concentration-time profiles are bioequivalent to the reference (BE region). The blue (dark gray in print versions) thick lines enclose a region in which the combinations of MDT, B, and D_{max} produce dissolution profiles similar to the reference profile (f2 similarity region).

between different formulations. This evaluation is important because the completeness of dissolution relates to the extent of drug absorption in vivo and the shape of a dissolution curve is translated to the rate of drug absorption in vivo. In particular, when there is a difference of more than 10% in the plateau levels between dissolution profiles of the test and reference product, or when the two dissolution profiles cross, there is a greater likelihood for the test product not to be bioequivalent to the reference product, although f2 similarity has been demonstrated. Under these circumstances, caution must be exercised when drawing conclusions.

13.5 SUMMARY

In this chapter, in vitro dissolution methods are developed to evaluate the in vivo bioperformance of solid oral dosage forms via IVIVCs, and as quality control tests to ensure the consistency of product manufacturing and the bioperformance of the resulting products. Valid IVIVCs are useful for biowaiver, for quality control, or both. Much research has been done since the middle of the 20th century, with successful IVIVCs being developed for some products. However, IVIVCs are still not yet established for many products, particularly for many ANDAs, either due to the fact that the complexity of drug dissolution and absorption along the GI tract is not yet fully understood, or the in vitro conditions could not mimic that of the GI system. Meaningful results and interpretation of dissolution data can be achieved only when the responses of the biological system to the physical properties of drug products are well understood, and test methods are properly established through thorough studies during the formulation and manufacturing process design and clinical development.

To provide meaningful dissolution data, numerous dissolution devices and methods (either compendial or not) have been studied for a variety of products, which will continue into the future with an attempt to provide biorelevant dissolution data. For any given apparatus, dissolution results can still be affected by various elements for the dissolution tests, such as setting and calibration of the apparatus, mixing speed, medium (volume, pH, ionic strength, surfactant, cosolvent, aeration), temperature, positions of dosage forms in the medium, sampling locations and time control, and interference by the environment. The effects of these elements and factors must be evaluated during the development of dissolution methods for each product.

The use of dissolution tests for quality control should also be directed toward guarding the bioperformance of products. For quality control purposes, the test methods should have sufficient discriminating ability to identify the changes in products and manufacturing processes that may lead to significant difference in the BA/equivalency than that of the pivotal batches or the BE batches. For this purpose, the effects of formulation and process parameters on product dissolution should be characterized so that discriminating methods can be developed to relate the dissolution behavior to changes in either formulation or process. However, the discriminating power of the methods should be evaluated for relevance to product bioperformance in order to make the methods and results meaningful. In the meantime, dissolution methods should be robust to allow normal variability in routine manufacturing and testing, and to avoid overdiscriminating, which may lead to unnecessary rejection of products.

Importantly, product dissolution could be highly method-dependent as well as product dependent. Some of the dissolution data may be correlated to the bioperformance of the product, while others may not. In the absence of IVIVCs, the quality meaning of dissolution data or similarity factor f2 cannot be defined for the bioperformance of the products. In fact, simulation studies for a product with valid IVIVCs have shown that not all batches of the product with $f2 > 50$ could be bioequivalent, and on the other hand, not all the batches with $f2 < 50$ fail to be bioequivalent. Therefore, unless the compositions and manufacturing processes are exactly the same, or unless IVIVCs have been established, the requirement in some countries for multisource products to have a similar dissolution before BE study is neither meaningful nor necessary, except for some rapid-release IR products of BCS class I and III drug substances, for which biowaivers may be possible if justified properly.

Specifications of product dissolution are always part of the dissolution tests. For NDAs, dissolution specifications are set based on the dissolution data of all clinical batches that have produced acceptable PK or clinical results. For ANDAs, specifications are set based on the dissolution data of the BE batches. Careful evaluation of the dissolution data of all the clinical/BE batches can provide an overall picture of the product behavior to facilitate the setting of specifications. ICH and FDA have provided guidance for setting dissolution specifications for different types of dosage forms, with or without IVIVCs. For products without IVIVCs, FDA guidance recommends setting the acceptable dissolution ranges as being $\pm 10\%$ of the clinical or bio-batches for all time points. When valid IVIVCs are available, a wider dissolution ranges can be set such that, via the IVIVC, the predicted C_{max} and AUC are in the range of $\pm 20\%$ of the target. For a

tighter control, the acceptance criteria is recommended to be set based on the average in vitro dissolution data equivalent to USP Stage 2 testing ($n = 12$) for each lot under study. Simulation is a useful tool to demonstrate the effects of mean and variability on the failure rate to pass different stages of dissolution test with desired power, which can also be used to examine if the proposed dissolution specifications are set properly.

CHAPTER

14

Bioavailability and Bioequivalence*

H. Zhu, B.V. Li, R.S. Uppoor, M. Mehta and L.X. Yu

U.S. Food and Drug Administration, Silver Spring, MD, United States

14.1 GENERAL BACKGROUND

Bioavailability (BA) assessment is essential in oral dosage form development.[1] BA studies, which characterize overall rate and extent of drug absorption, are commonly conducted to support new drug applications (NDAs). Different types of BA studies are carried out for various reasons:

- A relative BA study may be required to assess the exposure similarity between a new oral dosage form and an approved product (ie, reference list drug) in a development program for a 505 b(2) product. The exposure difference between the two products is useful to select doses in a subsequent clinical trial aimed to obtain efficacy and safety information about the new product.
- Demonstration of sufficient systemic absorption is essential to justify the necessity of formulating a new compound, such as a new chemical entity, into an oral dosage form. A dedicated BA study may be necessary by comparing systemic exposure of the new oral dosage form to that of a reference formulation, such as an intravenous formulation. BA information can also be obtained indirectly through multiple early phase clinical trials, such as a single ascending dose study, a multiple ascending dose study, or a mass balance study.
- Sometimes BA can be altered due to food intake or concomitant medications. The effect of food on absorption is typically investigated in a dedicated study in order to provide dosing instructions.[2]
- Likewise, for a drug product whose dissolution is significantly affected by pH (eg, over the pH range from 1 to 6.5), a drug–drug interaction study with a pH altering agent, such as a proton pump inhibitor, may be appropriate to evaluate the potential changes on BA.[3]

Bioequivalence (BE) studies focus on demonstration of absence of difference in the rate and extent of two products.[1,4] In other words, two bioequivalent products are anticipated to be similar in BA. BE studies can be used to support approvals of NDAs, abbreviated NDAs (ANDAs), and postapproval changes, illustrated as following:

- BE studies can be applied to support NDA submissions under several situations. One common situation is that data from a BE study can be applied to bridge a clinical trial formulation and a to-be-marketed formulation whose features are improved in parallel with the clinical development. In another situation, a new product, which is developed as a new oral dosage form or uses a new salt form of an approved active moiety, can gain marketing access relying on the agency's efficacy and safety findings of an approved product if BE between the new product and the existing product can be established.

*__Disclaimer__: The chapter reflects the views of the authors and should not be construed to represent the views or policies of the Food and Drug Administration (FDA). No official endorsement by the FDA is intended or should be inferred.

DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00014-5

- Generic substitutes, which are therapeutically equivalent and often less expensive to brand name products, are approved under ANDAs. BE must be demonstrated to support approvals of ANDAs.
- BE studies may also be required during postapproval period of NDAs or ANDAs in certain situations, for example when a major change in formulation, or manufacturing process, or manufacturing site occurs.

The concept of BA and BE has been evolving over years. In the 1970s, it was reported that patients receiving digoxin showed large variation in clinical responses. Subsequent investigations indicated that different clinical outcomes were associated with variation in BA of products manufactured by different firms or by the same firm but from different lots.[5,6] In 1974, one committee organized by the FDA Office of Technology Assessment (OTA) concluded that "current standards and regulatory practices do not assure bioequivalence."[7,8] In 1977, the Food and Drug Administration (FDA) started to request in vivo assessment in its published regulation on BE.[9] In 1984, the US Congress passed the Hatch-Waxman Act (also known as "Drug Price Competition and Patent Term Restoration Act"), which provides a legal basis to allow a BE study as a surrogate for clinical efficacy and safety trials. Since then, FDA published BE guidances for various specific products in addition to its general BA/BE guidance. BA/BE studies have become standard assessment in clinical development programs and support drug product approvals.[10] In recent years, BA/BE assessment has been expanded to address drug products with unique complexities, such as for drugs with narrow therapeutic indexes (NTIs), products with multimodal release mechanisms, and products acting locally.

The information included in this chapter will provide readers with an overview of the general concept of BA and BE. Details on typical BA/BE study designs and data analyses will be discussed, with a primary focus on the orally administered drugs. Special topics on BE for NTI drugs and highly variable (HV) drugs, together with application of partial area under the curves (pAUCs) for BE testing will also be presented.

14.2 DEFINITIONS AND KEY CONCEPTS

Different oral formulations may be associated with different absorption rate and extent. An immediate release formulation is designed to allow rapid release of an active moiety. An extended release formulation, on the other hand, controls drug release rate to ensure active moiety is available over a prolonged time interval. In recent years, a more complicated formulation is designed to include both an immediate-release component and an extended-release component. Different formulations intended for different BA features usually yield different plasma concentration time profiles.

BA/BE assessment is established on the basis of pharmacokinetics (PK), which characterizes plasma drug concentration versus time profiles. PK provides information on ADME process (ie, absorption, distribution, metabolism, and excretion) and describes the fate of an administered drug. Key PK parameters such as C_{max}, T_{max}, and area under the curve (AUC) can be obtained through concentration−time profiles. C_{max} represents the maximum concentration of the curve. The time to reach C_{max} is known as T_{max}. If adequately frequent plasma samples are taken in an appropriately designed study, C_{max} and T_{max} can be directly observed. AUC is the area under the concentration-time curve for the time interval of interest and is calculated by applying a numerical integration formula such as the trapezoidal rule. AUC_{0-t} represents the AUC over the time interval from zero to the last observation, while $AUC_{0-\infty}$ represents the AUC over the time interval from zero to infinity. $AUC_{0-\tau}$ is the AUC over a dosing interval (ie, τ). In the following section, the key concepts of BA and BE and the assessment of BA and BE using the major PK parameters are provided.[11]

14.2.1 Bioavailability

As defined in the Code of Federal Regulations, Title 21, Section 320, Part1 (§ 320.1), BA is known as "the rate and extent to which the active ingredient or active moiety is absorbed from a drug product and becomes available at the site of action."[12] Most drugs administered orally are not intended to be used locally in the gastrointestinal (GI) tract; instead, pharmacological effects can manifest only after the drug is absorbed and an adequate amount becomes available at the intended receptors of the target tissue through systemic circulation. Direct assessment of drug concentration at the target tissue is technically challenging. In addition, drug concentration at the local action site is thought to be in equilibrium with the drug concentration in systemic circulation. Therefore, in practice, the drug concentration in systemic circulation is used as a surrogate to that of the drug presented at the target tissue.

For an oral product, BA is mainly affected by three factors: physicochemical characteristics of a drug, dosage factors, and physiological factors (eg, pH in the GI tract).[13,14] Different studies can be conducted to evaluate changes in BA, which is commonly described by a ratio of C_{max} or AUC, due to these factors.

A BA study of an oral product estimates the relative fraction of the administered dose that is absorbed into systemic circulation when compared to that of a reference formulation. Ideally, a reference formulation is an optimally available formulation, which can be an intravenous formulation, an oral solution, or an oral suspension. Sometimes a different oral dosage form (eg, a different oral tablet) can be used too. Absolute BA is used to describe the relative fraction of systemic exposure for an oral dosage form when an intravenous dosage form (100% bioavailable) is used as the reference formulation, whereas the term *relative BA* is used when the reference is another nonintravenous formulation.[1]

PK parameter ratios, such as AUC ratios, between two formulations are commonly used to compare BA difference between two formulations. $AUC_{0-\infty}$ (or AUC_{0-t}) is generally applied for a single-dose BA study, whereas $AUC_{0-\tau}$ is for a multiple-dose study. Eq. (14.1) is used to calculate absolute BA, where D_{iv} and D_{po} are the intravenous and oral doses administered, respectively; and AUC_{iv} and AUC_{po} are the AUC estimates for the intravenous and oral routes, respectively.[1]

$$F = \frac{D_{iv}}{D_{po}} \cdot \frac{AUC_{po}}{AUC_{iv}} \tag{14.1}$$

Relative BA can be calculated by using Eq. (14.2), where D_A and D_B are the doses administered for drug formulation A and B, respectively; and AUC_A and AUC_B are the AUC estimates for the A and B formulations, respectively. Formulation A is the reference formulation:

$$F_{rel} = \frac{D_A}{D_B} \cdot \frac{AUC_B}{AUC_A} \tag{14.2}$$

14.2.2 Bioequivalence

According to § 320.1 (21CFR320.1), BE is defined as "the absence of a significant difference in the rate and extent to which the active ingredient or active moiety in pharmaceutical equivalents or pharmaceutical alternatives becomes available at the site of drug action when administered at the same molar dose under similar conditions in an appropriately designed study."[12] Similar to BA assessment, BE assessment for oral dosage forms can be performed based on drug concentration in systemic circulation, which is considered as a surrogate for concentration available at the site of action. Drug concentration in systemic circulation is determined by the ADME process, in which only absorption is thought to be affected by a formulation. Similar concentration levels are anticipated in the same subject receiving different oral dosage forms that show similar absorption rate and extent.

C_{max} and AUC, which are applied for BA evaluation, are the two major PK parameters used for BE assessment.[1] C_{max} bears the information on absorption rate, where an increased absorption rate is associated with an elevated C_{max}. The similarity in C_{max} of two formulations is suggestive for similar maximum effects or similar risks of the safety events. Like BA evaluation, $AUC_{0-\infty}$ (or AUC_{0-t}) and $AUC_{0-\tau}$are used to describe overall exposure for a single-dose BE study and a multiple-dose BE study, respectively. Generally, AUC represents the extent of absorption and is independent of the absorption rate. For drugs requiring chronic treatment, such as antidepressants, AUC is correlated with effectiveness and long-term safety events. Two products yielding similar AUCs are thought to have similar efficacy and long-term safety profiles. Other PK parameters, such as pAUC and T_{max}, are also used for BE assessment.

Pharmacodynamic, clinical, or in vitro assessment may also be performed in BE assessment.[4,15,16] Under situations where systemic absorption is not directly indicative of drug available at its site of action, a pharmacodynamic, clinical, or in vitro assessment may be used. This approach is commonly seen in small molecule products for local actions, such as topical products, nasal and inhalation products, locally acting GI products, and dental products. It is rarely seen in oral dosage forms intended for systemic indications.

14.2.3 Pharmaceutical equivalents, pharmaceutical alternatives, and therapeutic equivalents

Drug products are considered to be pharmaceutical equivalents if they contain the same active ingredient, in the same amount, with identical dosage forms and routes of administration. Pharmaceutical alternatives are drug products containing the same therapeutic moiety, but are different salts, esters, or complexes of that moiety, or are different dosage forms or strengths. Furthermore, drug products are considered to be therapeutically equivalent only if they are pharmaceutical equivalents (as described previously) that are expected to produce the same clinical effects and have similar safety profiles when they are administered to patients under the same conditions as specified in the product labeling information. In general, therapeutic equivalence may be reasonably inferred if two pharmaceutical equivalent products are shown to be bioequivalent. Therapeutic equivalence is thus an ultimate measure of the interchangeability of two distinct drug products or formulations.[10]

14.3 GENERAL COMPONENTS OF BA AND BE STUDIES

In clinical development, demonstration of BE and assessment of BA for oral dosage forms intended for systemic indications generally require dedicated phase 1 clinical trials using PK parameters as the endpoints. The focus for BA or BE studies is to evaluate absorption rate and extent, even though the study objectives differ. Therefore, design features are similar between the two types of clinical trials. In the following sections, the design features of a BE study will be discussed, as an example, in detail.

14.3.1 Study population

Standard BE studies are conducted in adults at least 18 years old and capable of giving informed consent. For most drugs, the PK processes are affected by demographic characteristics of patients. Thus, demographic characteristics of subjects enrolled in a BE study should represent the patient population, taking into account age, sex, and race. For example, if an oral dosage form is intended for both male and female patients, a BE study should be conducted in subjects with both sexes.[1,4]

Healthy volunteers are generally preferred in a BE study over patients for several reasons. BE assessment focuses on a comparison of drug absorption rate and extent of two formulations, not the therapeutic effectiveness of a formulation. The physical processes of drug absorption for solid oral dosage forms are usually the same in patients as they are in healthy subjects. Therefore, healthy subjects can adequately identify the differences in formulations, which fulfills the BE study purpose. On the other hand, patients may have different severity levels of the diseases, and some may require concomitant medication treatment, all these factors may potentially confound the BE study outcome. Practically, healthy volunteers are easy to enroll with simple inclusion and exclusion criteria and less chance of using concomitant medications. In addition, intensive PK samples are usually better tolerated in healthy volunteers than patients.

Sometimes patients are needed for a BE study. Safety and tolerability risks associated with the drug product are the general reasons that preclude healthy volunteers being enrolled in a BE study. For example, clozapine is approved for treatment-resistant schizophrenia. Clozapine has been shown to cause several potentially fatal adverse events, including agranulocytosis, syncope, seizures, myocarditis, and cardiomyopathy.[17] Because of these safety risks, FDA guidance recommends that the BE studies be conducted in stable patients.[18]

14.3.2 Study design

One typical BE study design is a single-dose, two-way crossover study design.[1,4,19] As illustrated in Table 14.1, subjects enrolled in the study are randomized into two sequence groups (Groups TR and RT) with balanced baseline and demographic characteristics. After the trial is initiated, subjects in the two groups receive test products and reference products, respectively. A reference product is usually the product whose efficacy and safety profile has been established, whereas a test product is the new product. If the drug is well tolerated, a subject is usually given a single unit of the oral dosage form with the highest strength. Blood samples are collected in subjects from both groups at various time points for PK characterization. Usually, the PK sampling should continue for at least three half-lives of the drug. To minimize potential carryover effect, time for wash-out accounting for at least five half-lives of the drug is recommended before the second period of dosing is initiated. In the second period, the treatment is switched. Subjects receiving the test product in period 1 are given the reference product in period 2, and vice versa. Blood samples are collected in the same manner as in period 1.

One feature of a crossover study is the same individual receives both the test product and the reference product, and the formulation effect can be compared at an individual level. It has been shown that the ADME process varies among subjects and may affect the variability of C_{max} and AUC estimates. The same subject provides a relatively homogenous environment to assess the formulation effect. Statistically, this approach is powerful and requires small sample size.

For a product with long half-life, a parallel study is practically more appealing than a crossover study.[1,4,19] Subjects enrolled in a parallel study are generally randomized into two groups with test product and reference product administered to one of the groups, respectively. Blood samples are collected for PK assessment over the time interval of at least three half-lives of the drug. In general, a parallel study requires less time than a crossover study because a subject receives treatment once and no washout is necessary. However, a large sample size is needed in a parallel

TABLE 14.1 Diagram of a Typical Two-Treatment, Two-Way Crossover BE Study

2	R	T

Note: T, test product; R, reference product.

study to identify the formulation effect because the difference in ADME process across different individuals may increase the variability of the estimated C_{max} and AUC.

Through simulations and clinical trials, it has been shown that a single-dose BE study is generally more sensitive than a multiple-dose study. For drugs with a high accumulation factor, a smaller confidence interval was shown at steady state than that following a single dose. Therefore, there is a better chance to claim BE based on results from a steady-state study than from a single-dose study. This is unfavorable from the regulatory standpoint of view.[20] However, for practicality reasons, a steady-state BE study may still be required. Usually, a steady-state BE study is conducted in patients stabilized with the treatment. It is not feasible to discontinue the current treatment or to completely wash out the patients. Take clozapine, for example. Per the FDA guidance, the BE study should be conducted in patients receiving multiples of 100 mg of an approved clozapine twice daily. Once entered the study (ie, in period 1), the patients should be dosed either with the test product or the reference product twice daily for 10 days before blood sample collection. Then the patients switch the treatment for another 10 days in the second period.[18]

Sometimes a replicated crossover study may be conducted to assess intrasubject (within-subject) variability allowing a scaled BE approach.[1,4,19] A typical replicate BE study is illustrated in Table 14.2, where subjects enrolled in the study may receive the same treatment more than once. As shown in Table 14.2a, subjects in group 1 receive the test product twice and subjects in group 2 receive the reference product twice. This study is known as *partial replication*. A partial replicate design with two treatments on reference product is commonly used in BE studies for HV drugs. Table 14.2b shows that subjects in two treatment groups receive both the test product and the reference product twice but with different order. This study is known as *full replication*. A full replicate design is preferred in a BE study for an NTI drug.

14.3.3 Biofluid matrices

PK endpoints used in BA/BE studies are commonly derived from concentration levels in peripheral blood (eg, plasma, serum, or whole blood). Blood samples are usually collected at defined time points to fully characterize a PK profile. Blood plasma, which contains extracellular fluid and protein, is the pale-yellow liquid after the collected blood samples are mixed with anticoagulant and blood cells are removed through centrifugation. Serum is the yellowish liquid after the whole blood is clotted. The content in serum is similar to plasma, except serum contains no clotting factors. Because most clotting factors do not specifically bind drugs, serum concentration and plasma concentration are usually similar. Drug concentration in whole blood includes drug concentration from both plasma and blood cells. Some drugs specifically bind to red blood cells. So the drug concentration in whole blood can be substantially different from that in serum or plasma.

Urine samples are sometimes taken for BA assessment. Urine samples can be useful if the drug is mainly eliminated through urine as the parent compound and the amount of drug excreted can be collected in a reasonably short period and measured as accurately as possible. It is uncommon to use other biofluids, such as saliva, cerebral spinal fluid, and lymphatic fluid in a BA/BE study.

14.3.4 Bioanalytical methods

In general, samples collected in a BA/BE study are quantified using a validated chromatography or a ligand binding assay.

High-performance liquid chromatography (HPLC) is the most commonly used chromatography assay to analyze PK samples. Usually, PK samples collected at defined time points are purified first. The objective for sample purification is to remove proteins, lipids, fatty acids, and other endogenous components that may affect sample separation and detection.[21] Proteins in the collected samples are precipitated by mixing with miscible organic solvents (eg, methanol or acetonitrile), often adjusted by different buffer, acid, or base, and removed through centrifugation. If needed, samples are further purified through liquid−liquid extraction (LLE)[21] and solid phase extraction (SPE).[22] For LLE,

immiscible organic solvents (eg, diethyl ether, MTBE) are mixed with the biological samples. The analyte of interest, usually transferred into the organic layer, is cleaned up for assay. For SPE, analyte is absorbed onto a solid phase column and then extracted by a diluent. Even with all cleanup procedures, the samples are still mixtures of various compounds. Second, the prepared samples are injected into chromatography instrument. Chromatography is a technique that the compound of interest is separated from interfering components, such as impurities, metabolites, and endogenous components remaining in the samples. The separation occurs from the interaction between the analyte and the analytical matrix (ie, a stationary phase and a mobile phase). In general, the separation relies on differences of hydrophobicity (reverse phase), molecular charge (ion exchange), and size (size exclusion) of the analyte and interfering components. Scientists may select appropriate solid phase and adjust mobile phase to ensure an optimal separation of the analyte and other components.[23] Third, the analyte is detected and quantified through a detection system. Various detection systems can be used in combination with a HPLC, where mass spectrometry is probably the mostly commonly used. Analytes obtained through a chromatography system are ionized first and then detected based on mass-to-charge ratio (m/z). Eventually, the concentration of the analyte can be obtained from chromatographic measurement.

A ligand assay relies on immunological reaction between an analyte and its specific antibody. In most cases, a ligand assay is applied to obtain concentrations of macromolecules, such as enzymes, peptides, and monoclonal antibodies.[24] Enzyme-linked immunosorbent assay (ELISA) is a good example. For a noncompetitive ELISA, the surface of a microplate is coated by a capture antibody to block all nonspecific binding sites. When the PK samples are applied, the analyte of interest is immobilized onto the plate in a concentration-dependent manner. The rest of the sample is then removed and the plate is washed. A secondary antibody containing an enzyme is added to the plate and binds to the analyte of interest, and then a specific enzyme substrate is added. The concentration of the analyte can thus be detected through the formation of the product of the enzyme and substrate interaction. The detection mechanism for a competitive ELISA is similar to that for a noncompetitive ELISA. The main difference is that a specific antigen is immobilized onto a microplate first. When an antibody is added, both antigens presented onto the plate and in the sample (ie, analyte of interest) compete for the limited binding sites of the antibody. Then, an antibody-analyte conjugate is washed away. Thus, a high concentration of analyte (antigen presented in the sample/solution) yield low antibodies immobilized onto the plate. The analyte concentration can thus be calculated.

Bioanalytical methods used in BA and BE studies, no matter a chromatography assay, a ligand assay, or other assays, are expected be accurate, precise, selective, sensitive, reproducible, and stability-indicating.[25]

Accuracy describes the closeness of the test results to the true concentration of the analyte. Accuracy is determined by replicated analysis of samples with known amount of the analyte using a specific analytical method. In general, a minimum of five determinations per concentration is recommended.

Precision describes the closeness of the test results upon multiple measurements with the same concentration level. There are two types of precision. One is known as within-run precision, which is an assessment of the precision during a single analytical run. The other one is known as *between-run precision*, which is a measurement of the precision with time, and may involve different analysts, equipment, reagents and laboratories. In general, the determined precision should not exceed 15% of the coefficient of variation (CV). At the lower limit of quantification, precision should not exceed 20% of the CV.

Selectivity is defined as the ability of an analytical method to differentiate and quantify an analyte in the presence of other components in the sample. Other compounds presented in the biological samples, including endogenous moieties, impurities, metabolites, and degraded products, may interfere with the analyte of interest. A validated method should demonstrate its ability to selectively quantify only the analyte of interest.

The stability of the chemical in certain matrix under specific conditions and in a specific time interval should also be assessed.

In 2013, FDA revised its guidance on bioanalytical method validation for bioanalytical methods mainly used in clinical pharmacology, BA, and BE studies. In this guidance document, the recommended validation information is discussed in detail.[25]

14.3.5 Compounds for bioassay

Concentrations of a parent compound (active ingredient or its active moiety in the dosage form) and its metabolites can be obtained through a validated bioassay.[1,4] The FDA recommends both the parent compound and, if possible, its active metabolites be measured in a BA study with the objective to assess the release of drug substance from a dosage form, and presystemic/systemic actions on the released drug substance. Concentration of a parent compound is

more preferable than metabolites in a BE study because changes in concentrations of a parent compound directly reflect the release rate and release extent of a dosage form. However, metabolite concentration may be preferred when the parent compound (eg, a prodrug) concentration is too low or measurable concentration lasts for too short a time. Sometimes both the metabolite and the parent compound concentrations are measured in a BE study when (1) the metabolite is shown to be formed in the GI tract or presystemically, and (2) both the parent compound and the metabolite contribute meaningfully to the overall efficacy or safety.

Concentrations of individual enantiomers can be obtained through a chiral assay. In general, FDA recommends that enantiomers be measured in a BA study.[26] BE assessment is usually performed based on racemate.[1] Sometimes enantiomers are measured if they exhibit different PK or pharmacodynamics characteristics, especially if the primary efficacy and safety reside in a minor enantiomer or nonlinear absorption is shown in one of the enantiomers.[1,27]

14.4 DATA ANALYSIS FOR BA AND BE STUDIES

14.4.1 Variables for BA/BE assessment

C_{max} and AUC are the most commonly used PK variables for in vivo BA/BE assessment.[1] As discussed in Section 14.2, C_{max} represents the rate of absorption and AUC represents the extent of absorption. Sometimes T_{max} and the shape of the PK profiles are also compared in a BA or BE assessment through visual inspection.

Quantitative analyses for the PK variables, such as C_{max} and AUC, are generally based on logarithmic transformation, which provides several advantages.[19] First, a direct subtraction of a logarithmic-transformed PK variable obtained from a test product and a reference product can be easily converted to the ratio of the same variable under normal scale. Usually, the ratio of the PK variable provides the most clinically relevant information. Second, PK variables can be expressed in a multiplicative fashion. Let's take $AUC_{0-\infty}$ as an example. It can be described by using Eq. (14.3), where D is the dose given to the subject. F and CL are the bioavailability and clearance for this individual, respectively:

$$AUC_{0-\infty} = \frac{F \cdot D}{CL} \tag{14.3}$$

The multiplicative terms (ie, F and CL) can thus be considered as a function of the subject. In the statistical analysis models for BE testing, all factors (eg, treatment, subjects, and sequence) that contribute to the variation in PK measurements are considered to be additive effects. Logarithmic transformation of AUC yields an additive equation (Eq. (14.4)):

$$\log AUC_{0-\infty} = \log D + \log F - \log CL \tag{14.4}$$

which is therefore preferable in BE analyses. Similar arguments can also be applied to C_{max} or other PK variables. Third, the observed AUC (or C_{max}) values in BA or BE studies under normal scale are often skewed and the variances between the test and reference groups may differ. The statistical models for BE testing are established based on two major assumptions: the normality and homoscedasticity of the variance. Log-transformation of the PK variables, however, makes the distribution appear more symmetric, closer to the normal distribution, and achieves a relatively homogeneous variance. The underlying assumptions for statistical testing can be better satisfied. Thus, log-transformations of PK variables in BA/BE evaluation is recommended by major regulatory bodies world-wide. It should be noted that log-transformation compares the geometric means of the PK variables from different treatment groups instead of arithmetic means.

Variability for the major PK parameters (eg, log AUC and log C_{max}) may provide useful information for BA and BE evaluation. There are different sources of variability for major PK parameters. Between-subject variability (ie, intersubject variability) is to describe the variability for the same product administered to different individuals. If the same product is given to the same individual multiple times (eg, in a replicate BE study), within-subject variability (intra-subject variability) can be calculated. A subject-by-formulation variability is used to describe the exposure change for the same individual upon product switching. Different types of variability provide information on product and patient characteristics; hence, the values should be assessed when needed.

In addition to major PK parameters, such as C_{max} and AUC, T_{max} is an important PK parameter obtained in a BA/BE study. T_{max} has relatively high between-subject variability and does not appear to follow common distributions, such as normal or log-normal distributions. No formal statistical testing has been recommended on the basis of T_{max}. However, T_{max} values can be important for drugs with quick treatment onset. Therefore, comparison of medians (and ranges) of T_{max} among different treatment groups are considered. There are cases where products are not deemed bioequivalent in which the median T_{max} are substantially different between the test product and the reference product, even if C_{max} and AUC satisfy the BE standard.

14.4.2 Statistical analysis for BE studies

14.4.2.1 Average BE

Average BE testing is the most commonly used, which is established to ensure that the true mean (ie, population average) difference of the major PK parameters between the test product and reference product is within a predefined range.[19] The test product is considered bioequivalent to the reference product only when the true means for all the major PK parameters (eg, AUC and C_{max}) of the test product is neither superior nor inferior to that of the reference product.

For most drugs with a reasonable therapeutic window, an approximately 20% change in mean major PK parameters (eg, AUC and C_{max}) is not anticipated to yield clinically meaningful changes in both efficacy and safety. Thus, for these products, the upper and lower thresholds (ie, δ_L and δ_U) are defined as ± 0.22 in log scale or ranging from 80% to 125% under normal scale. However, BE limits are not fixed for all products. For HV products (Section 14.5.2) and NTI drugs (Section 14.5.3), BE limits may be readjusted accordingly.

Average BE assessment is set up differently from a conventional statistical test aimed to demonstrate treatment difference between two groups. The null hypothesis for a conventional statistical test is the true means from the test product and the reference product are the same (ie, $\mu_T - \mu_R = 0$). The null hypothesis is rejected and alternative hypothesis is taken (ie, $\mu_T - \mu_R \neq 0$) when the calculated *P*-value based on the established statistic test is smaller than a predefined value (eg, 0.05). This predefined *P*-value is used to control type I error rate. For the sake of discussion, only in this paragraph, we call two products with equal true means of the PK parameters the "bioequivalent" products. Under the conventional statistic test, the type I error is to falsely claim "inequivalence" for two bioequivalent products. But this is not the focus of BE testing. Instead, BE testing should focus on falsely claiming BE for two inequivalent products. Therefore, different approaches are taken for average BE evaluation.

One approach is known as confidence interval approach. The confidence interval approach is to ensure the true mean difference of a major PK parameter between the test product and the reference product is likely to be sufficiently small. In this approach, the point estimate and 90% confidence interval of the mean difference of a specific PK parameter (eg, log AUC or log C_{max}) between the test product and the reference product can be calculated based on data. BE can be established if all estimated 90% confidence intervals of the major PK parameters are within the BE limits (eg, ± 0.22 in log scale or ranging from 80% to 125% under normal scale). As just discussed, the error that needs to be controlled in BE evaluation is falsely claiming BE for two inequivalent products, which is the Type II error for a conventional statistical hypothesis test. A Type II error cannot be directly controlled in a conventional hypothesis test. However, the Type II error can be reflected in confidence interval approach as the probability of not including an alternative value (ie, upper and lower BE limit). Therefore, BE can be concluded with an error rate not greater than 10% if the 90% confidence interval falls within the predefined BE limits.

The second approach is two one-sided tests (TOST). TOST ensures that the true mean difference of a PK parameter between a test product and a reference product is unlikely to be either too large or too small. TOST is performed with two sets of null and alternative hypotheses:

Test 1: Null hypothesis: $\mu_T - \mu_R \geq \delta_U$; alternative hypothesis: $\mu_T - \mu_R < \delta_U$

Test 2: Null hypothesis: $\mu_T - \mu_R \leq \delta_L$; alternative hypothesis: $\mu_T - \mu_R > \delta_L$

where μ_T and μ_R are the true means for the test and reference products, respectively; and δ_L and δ_U are the predefined regulatory upper and lower limits. Each test can be performed independently. If both null hypotheses are rejected, alternative hypotheses can be accepted and so can its intersection (ie, $\delta_L < \mu_{T-}\mu_R < \delta_U$). The null hypothesis for each of the tests is rejected from one side at a *P*-value of 0.05 level ($\alpha = 0.05$). Thus, the TOST approach is equivalent to the approach using 90% confidence interval.

14.4.2.2 Population BE and individual BE

In addition to the average BE test, two other statistical tests are recommended by the FDA's BE guidance—population BE test and individual BE test.[19] The focus for average BE assessment is to compare true mean difference between different treatment groups, whereas population BE and individual BE consider both the true mean difference and the variance difference.

Population BE is constructed to ensure prescribability. A physician may choose to prescribe to a new patient either a brand name product (innovator's product) or a generic product shown to satisfy population BE criteria. The general efficacy and safety profiles for the two products should be anticipated to be similar. To ensure prescribability, an equation is constructed to compare the expected squared difference between a test product (T) and a reference product (R) administered to two different patients (the *j*th and *j'*th patient) with the same reference product (R) given to these two

patients (Eq. (14.5)). In Eq. (14.5), μ_T and μ_R are the true means of the test product and reference product, respectively. σ^2_{TT} is the total variance for the test product, and σ^2_{TR} is the total variance for the reference product. The final test formula is shown in Eq. (14.6). It is important to ensure the calculated value is smaller than a predefined threshold in order to conclude BE of the test product.

$$\frac{E(T_j - R_{j'})^2}{E(R_j - R_{j'})^2} = \frac{(\mu_T - \mu_R)^2 + (\sigma^2_{TT} + \sigma^2_{TR})}{2 \cdot \sigma^2_{TR}} \tag{14.5}$$

$$\Theta_p = \frac{(\mu_T - \mu_R)^2 + (\sigma^2_{TT} + \sigma^2_{TR})}{\sigma^2_{TR}} \tag{14.6}$$

The point of the individual BE is to ensure switchability, which allows switching from a brand name product to a generic product without compromising the efficacy and safety in the patient. The comparison is between the expected squared difference of the mean PK variable for the same subject (the *j*th subject) receiving the test product (T) and the reference product (R), and that from the same individual receiving reference products (R) multiple times (Eq. (14.7)). As shown in Eq. (14.7), μ_T and μ_R are the true means of the test product and reference product, respectively. In addition, σ^2_{WT} and σ^2_{WR} are the within-subject variability (ie, intrasubject variability) for patients receiving the test product and reference product alone, respectively, and σ^2_D is a term known as subject-by-formulation variance, which describes the PK variable change for the same individual upon product switching. The final test formula for individual BE is shown in Eq. (14.8). The test statistics must be smaller than a predefined limit in order to claim individual BE. To allow full assessment of individual BE, a replicate BE study is necessary.

$$E = \frac{E(T_j - R_j)^2}{E(R_j - R'_j)^2} = \frac{(\mu_T - \mu_R)^2 + \sigma^2_D(\sigma^2_{WT} + \sigma^2_{WR})}{2 \cdot \sigma^2_{WR}} \tag{14.7}$$

$$\Theta_I = \frac{(\mu_T - \mu_R)^2 + \sigma^2_D(\sigma^2_{WT} + \sigma^2_{WR})}{\sigma^2_{WR}} \tag{14.8}$$

14.4.3 Data analysis for BA studies

PK data obtained from BA studies are generally summarized by descriptive statistics. In general, no formal statistical test is required for data obtained from BA studies. However, the mean ratio and the 90% confidence interval of a major PK parameter should still be reported.

14.5 SPECIAL TOPICS FOR BA AND BE ASSESSMENT

BA/BE assessment has been widely applied in various product development programs. In recent years, certain areas have been expanded with the evolving science. In the following sections, BE studies requiring pAUCs, BE studies for HV drugs, and BE studies for NTI drugs are discussed in detail.

14.5.1 BE studies requiring pAUCs

For some products, pAUC has been used as an additional PK variable in BA or BE assessment.[1] It is known as the area under the concentration time curve over a time interval of interest.[28] Eq. (14.9) defines the pAUC between t_1 and t_2 (ie, $pAUC_{t1-t2}$). For example, if there is a need to quantify drug exposure between 8 and 12 hours postdose, $pAUC_{8-12}$ should be obtained. In reality, a pAUC can be calculated based on trapezoidal rule. The area between two adjacent observed time points can be calculated from the area of trapezoid. Then the pAUC can be obtained by summing up all the segments within a time interval of interest. It can be shown that a pAUC represents the average concentration over the time interval of interest. Multiple pAUCs contain the information of the shape of the PK profile. For instance, the PK profile following the administration of a single dose of Ambien CR, a Zolpidem extended release tablet indicated for the treatment of insomnia, under fasting conditions, can be divided into two portions. In this case, $pAUC0_{1.5}$ and $pAUC1.5_t$ can be calculated separately: $pAUC0_{1.5}$ represents the early exposure and $pAUC1.5_t$ represents the late exposure. $AUC0_\infty$ represents the total zolpidem exposure. Overall, the two pAUCs define the shape of the underlying PK profile:

$$pAUC_{t1-t2} = \int_{t1}^{t2} C_t \cdot dt \tag{14.9}$$

The initial concept of pAUC was introduced back in the early 1990s. By then, scientists actively searched for an alternative PK variable to describe the rate of absorption. As we know, C_{max} is related to drug absorption rate and is used in BA and BE assessment. Unfortunately, C_{max} can be driven by other factors, such as the extent of drug absorption, distribution, and elimination. Chen et al. recommended using pAUC in BA and BE evaluation.[31] Tozer et al. interpreted pAUC as a measurement of early exposure.[32] In recent years, pAUCs have been recommended by the FDA to assess BA and BE for several products.

Also, pAUCs may serve several different roles in products with different release mechanisms. Some products follow the same release mechanism (monomodal release mechanism). For example, an immediate release tablet always releases the drug following zero-order or first-order kinetics. There is no release pattern change over time. Through simulations, it can be shown that pAUC, defined as the AUC between the time of dosing to the time of reaching the maximal concentration, is more sensitive than C_{max} in detecting difference in drug release for an immediate-release product. This pAUC may be correlated to clinical responses for some immediate-release products.[33] In some cases, conclusions of BE-based C_{max} and total AUC between the test product, and the reference product may be insufficient to demonstrate that there is no difference in safety or efficacy if the systemic concentration time profiles of the test product and the reference product are different (eg, time to reach peak drug concentration (T_{max}) is different). For example, differences in the shape of the systemic concentration profile between the test and reference products could imply that the test product may not produce the same clinical response as the reference product. The FDA's guidance recommends that pAUC be included as a measurement for BA/BE assessment.[1] In 2009, a workshop was sponsored by the American Association of Pharmaceutical Scientists (AAPS) in Baltimore, MD.[34] It was concluded by the experts from academia, industry, and regulatory bodies that "the current regulatory approaches criteria for BE evaluation were considered adequate for the assessment of therapeutic equivalence and interchangeability of conventional monophasic extended-release formulations." The current regulatory approaches refer to general C_{max} and AUC.

It has been found that pAUC is extremely useful for products containing both an immediate-release component and an extended-release component (multimodal release mechanism). In recent years, various products with multimodal release mechanisms were developed to ensure unique clinical needs, which are usually characterized as rapid onset, maintained pharmacological duration, and rapid offset. Multiple release characteristics can be altered to generate various PK profiles. For example, the drug release rate (Ka), and extent (F) for both immediate-release and extended-release components may be altered. In addition, the proportion of the immediate component and the delay time (T_{lag}) for the drug released from the extended-release component can be changed through formulation techniques. Hence, it is possible to generate different shapes of PK profiles with identical C_{max} and AUC, and pAUCs are critical to characterize BA and ensure BE.

A good example of this comes from the sleeping aid products mentioned previously. The Ambien CR tablet label indicates that Ambien CR (zolpidem tartrate) is an extended-release formulation of zolpidem with a bimodal release profile. Each Ambien CR tablet is comprised of an immediate-release component and an extended-release component, providing a rapid increase of zolpidem plasma concentration followed by a sustained plasma concentration level of zolpidem over the typical time interval for sleep.[35]

Thus, Ambien CR is a multiphasic modified-release formulation designed to meet the specific clinical needs for treating insomnia. According to the FDA-approved package insert, clinical studies showed statistically significant improvement of sleep induction in patients receiving Ambien CR over placebo. In addition, Ambien CR decreased wake time after sleep onset for the first 7 hours during the first 2 nights and for the first 5 hours after 2 weeks of treatment. As this multiphasic modified-release dosage form is designed to achieve both rapid onset of activity and sustained activity with sufficient duration, FDA suggests that additional BE metrics may be appropriate to ensure that a generic (test) version is therapeutically equivalent to the corresponding reference product. Thus, for Ambien CR, the pAUC metrics are proposed in addition to the traditional ($AUC_{0-\infty}$ and C_{max}) metrics.[36]

For certain locally acting drugs, pAUCs can also be important in establishing equivalence at the site for drug action. Take mesalamine, for example. The drug has been approved for the treatment of ulcerative colitis,[37] an inflammatory disease localized in the colon and presenting with open sores or ulcers. Pharmacologically, mesalamine is thought to act locally in the colon in order to control the inflammation, even though the drug by itself can be systemically absorbed. An effective treatment is on the basis of adequate delivery of mesalamine into the inflammation site in the colon. Based on the mechanism of action, a product with a delayed-release feature should be more efficacious than a product without delayed release, even though both products may yield the same C_{max} and AUC. In this case, pAUC is recommended to be used in the BE study to ensure that the delayed-release feature of an effective product is carried to its generic version, and further, to distinguish the mesalamine release exclusively in the colon versus mesalamine released partially outside the colon.[38]

14.5.2 BE evaluation for HV drugs

Sample size can be an issue for a BE study for a drug that is HV. HV drugs are drugs that exhibit at least 30% of the within-subject variability (intrasubject variability)

in one of the PK variables (eg, AUC or C_{max}).[39–41] There are data suggesting that more than 20% of generic products requesting for marketing approval in the United States between 2003 and 2005 are considered HV drugs.[40] The main concern for a HV drug is that a BE study requires a large sample size. For example, the general BE limits are 80% and 125%. Let us assume the underlying (ie, true) geometric mean ratio between the test product and reference product is 1. If the within-subject variability is 15%, only 10 subjects are needed in a two-way crossover study in order to ensure 80% of power to determine BE. The required sample size is tripled when the within-subject variability is 30%. Moreover, the sample size should be as large as 108 if the within-subject variability is 60%. If the underlying geometric mean ratio is not equal to 1, the required sample size should be further increased. For instance, if the underlying geometric mean ratio between the test product and reference product is 1.1 and the within-subject variability is 60%, the required sample size is 236 in a two-way crossover study with 80% power to demonstrate BE.[41]

Questions have been raised on the necessity of including large sample size in a BE study for a HV drug when the BE limits are set as 80% and 125%. Even though the cause of the high within-subject variability (ie, interoccasion variability) is unclear, some researchers believe that this variability is due to the drug rather than the formulation. Large presystemic metabolism, low BA, and acid liability appear to contribute to the large variability.[40,42] In addition, this large variability is also likely seen in the reference product from which the efficacy and safety information is derived. The large variability, if deemed to be clinically critical, is likely to yield efficacy and safety signals unfavorable to support regulatory approval of the reference product. In other words, the approval of the reference product implies clinical acceptance of the large within-subject PK variability and the product should have a wide therapeutic range.[43] Furthermore, the reference product may fail the BE testing with itself if the sample size is not large enough. Hence, it does not appear to be rational to enroll an unreasonably large sample size in a study with the objective to meet a fixed BE limit ranging from 80% to 125%.

The FDA has taken various actions to identify alternative BE assessment approaches for HV products. An advisory committee meeting was held in 2004. At the meeting, the committee recommended that FDA may expand the BE limits. One concept taken from individual BE testing was to allow reference scaling. The committee requested FDA to explore the feasibility of applying this approach to BE studies with drugs that are HV. In response to this request, the agency conducted several simulations, which show that reference scaling is a feasible approach for BE testing and the type I error can be well controlled.[44] The FDA's findings were presented to a second advisory committee meeting held in 2006.[45] Since 2006, FDA has formally adopted the reference-scaled average BE approach for drugs that are HV.[46]

The limits for a regular average BE testing are constant. In a regular average BE testing, the difference of the log-transformed true PK parameters ($\mu_T - \mu_R$) are supposed to be within a defined range (δ_L and δ_U) for a BE claim. Eq. (14.10) demonstrates this relationship. This relationship can be transformed into Eq. (14.11) because the upper and lower limits are symmetric around zero. The test product is considered bioequivalent to a reference product only when the 90% confidence interval of each PK variable of interest (eg, AUC and C_{max}) falls into the BE limit between 80% and 125%.[41]

$$\ln(0.8) = \delta_L \le (\mu_T - \mu_R) \le \delta_U = \ln(1.25) \tag{14.10}$$

$$(\mu_T - \mu_R)^2 \le \delta_U^2 = \ln(1.25)^2 \tag{14.11}$$

The key feature for a reference-scaled average BE assessment is to allow readjustment of the BE limits based on the within-subject variability of the reference product. Eq. (14.12) demonstrates the concept of a reference-scaled BE testing for a HV drug, in which σ_{WR}^2 is the variance term for within-subject variability of the reference product, and θ_s is the BE limit. The new BE limit, θ_s, is defined in Eq. (14.13), where the value of σ_{W0}^2 is a constant defined by the regulatory agency. Eq. (14.12) applies only when the within-subject variability of the reference product is greater than the predefined threshold value of variance, σ_{W0}^2. Eq. (14.14) is formed by combining Eqs. (14.12) and (14.13). For products whose within-subject variability of the reference product (σ_{WR}^2) is larger than the defined regulatory threshold for variance (σ_{W0}^2), the ratio of $\sigma_{WR}^2/\sigma_{W0}^2$ is always greater than 1. It means that the allowable limit is greater than ln(1.25). The larger the value of σ_{WR}^2, the greater the ratio ($\sigma_{WR}^2/\sigma_{W0}^2$). Hence, the allowed limits can be further expanded:

$$\frac{(\mu_T - \mu_R)^2}{\sigma_{WR}^2} \le \theta_s \tag{14.12}$$

$$\theta_s = \frac{[\ln(1.25)]^2}{\sigma_{W0}^2} = \frac{U_L^2}{\sigma_{W0}^2} \tag{14.13}$$

$$(\mu_T - \mu_R)^2 \le \frac{[\ln(1.25)]^2 \cdot \sigma_{WR}^2}{\sigma_{W0}^2} \tag{14.14}$$

For drugs whose within-subject variability (σ_{WR}) is less than or equal to σ_{W0}^2, BE testing is established on the basis of Eq. (14.15). In other words, BE testing uses

a constant average BE limit (ie, $\theta_s < \ln(1.25)^2/\sigma^2_{W0}$ for the mean difference of log-transformed PK parameters). Because σ^2_{W0} is a constant, the final BE testing can be shown in Eq. (14.16), which is the general form for average BE testing:

$$\frac{(\mu_T-\mu_R)^2}{\sigma^2_{W0}} \le \theta_s \frac{U^2_L}{\sigma^2_{W0}} = \frac{[\ln(1.25)]^2}{\sigma^2_{W0}} \tag{14.15}$$

$$(\mu_T-\mu_R)^2 \le U^2_L = [\ln(1.25)]^2 \tag{14.16}$$

Depending on the within-subject variability of the reference product, a different variance term (σ^2_{W0} or σ^2_{WR}) may be used in the test formula. As a result, the final BE limits may be expanded only when the within-subject variability of the reference product is large. Hence, this approach is also known as the *mixed-scaling approach*.[41]

To apply the mixed-scaling approach for a BE testing, within-subject variability of the reference product should be assessed. Thus, the study must be a replicate BE study (ie, a full or partial replicate design) where the reference product is administered to the same individual twice.[47,48] One key element in using mixed-scaling approach is to determine the cutoff value of the within-subject variability of the reference product, above which a reference-scaling is required. As defined by the FDA guidance, the practical cutoff value of the estimate of within-subject variability (σ_{WR}) is 0.294, even though the theoretical σ_{W0} is set as 0.25. Only when the estimate of within-subject variability for reference product is larger than 0.294 is a reference-scaling approach allowed. That is, the 90% confidence interval of the ratio for the PK parameter of interest should be within an increased BE range derived on the basis of the within-subject variability of the reference product. In addition, FDA guidance recommends that the point estimate of geometric mean ratio for a PK parameter should be within the regular BE limits of 80−125% as a secondary constraint.[46]

The mixed-scaling approach has been successfully applied to support approvals of multiple products. A good example is the postapproval formulation change for a mesalamine delayed-release tablet. Mesalamine has a high within-subject variability (>30%). The major PK parameters were calculated through noncompartmental analysis with data obtained from a single-dose full-replicate BE study. A reference-scaling approach was used and product passed the expanded BE limits, which led to the final approval of the product.[49]

14.5.3 BE evaluation for NTI drugs

In NTI drugs, relatively small changes in doses or exposures may yield serious treatment failure or severe adverse events. According to the Code of Federal Regulations (CFR 320.33), a narrow therapeutic ratio drug may be determined based on the following criteria:

1. There is less than a twofold difference in median lethal dose (LD_{50}) and median effective dose (ED_{50}) values.
2. There is less than a twofold difference in the minimum toxic concentration (MTC) and minimum effective concentration (MEC) in the blood.
3. Safety and effective use of the drug products requires careful titration and patient monitoring.[50]

In practice, some of the pharmacodynamics parameters, such as LD_{50}, ED_{50}, MTC, and MEC, are essentially unavailable from clinical trials or clinical practice.

The definition of an NTI drug was further discussed at the 2011 Advisory Committee (AC) meeting for Pharmaceutical Science and Clinical Pharmacology. Based on the AC recommendations and the description in the CFR, NTI drugs was defined as where small differences in dose or blood concentration may lead to serious therapeutic failures and/or adverse drug reactions that are life-threatening or result in persistent or significant disability or incapacity, such as warfarin.[51] Furthermore, it was considered that NTI drugs generally have the following characteristics:

- There is little separation between therapeutic and toxic doses (or the associated blood/plasma concentrations).
- Subtherapeutic concentrations may lead to serious therapeutic failure.
- They are subject to therapeutic monitoring based on PK or pharmacodynamic measures.
- They possess low-to-moderate (ie, no more than 30%) within-subject variability
- In clinical practice, doses are often adjusted in very small increments (less than 20%).

Two major approaches have been followed to establish BE for NTI drugs worldwide. The first approach is to tighten the BE limits[52] and the second approach is scaled-BE based on within-subject variability of the reference product. FDA uses the reference-scaled average BE approach for NTI drugs.[53,54]

FDA is recommending a full-replicate, crossover BE study for an NTI drug. In this study, the same subject receives both the reference product and the test product twice. This study design allows simultaneous comparisons of mean PK and within-subject variability between the reference product and the test product.

The comparison of means between a reference product and a test product is based on a reference-scaling approach similar to, but different from, what has been discussed in BE evaluation for HV drugs

(Section 14.5.2). A test product is considered bioequivalent to a reference product when the relationship shown in Eq. (14.17) is achieved. As discussed previously, μ_T and μ_R are the means of the log-transformed PK variables for the test product and the reference product, respectively. σ^2_{WR} is the within-subject variability of the reference product. θ^2_L is the upper BE limit for an NTI drug, which is narrowed down to ln(1.11). σ^{2*}_{WR} is the regulatory threshold. For an NTI drug,

$$\frac{(\mu_T-\mu_R)^2}{\sigma^2_{WR}} \le \frac{\theta^2_L}{\theta^{2*}_{W0}} = \frac{[\ln(1.11)]^2}{\theta^2_{W0}} \tag{14.17}$$

$$(\mu_T-\mu_R)^2 \le \frac{[\ln(1.11)]^2}{\theta^{2*}_{W0}} \cdot \sigma^2_{WR} \tag{14.18}$$

Eq. (14.18) is derived from Eq. (14.17) by multiplying σ^2_{WR} from both sides. In Eq. (14.18), the value of σ^{2*}_{W0} is 0.10 as defined by the regulatory agency. If a drug's within-subject variability (σ^2_{WR}) is also 0.10, $\sigma^2_{WR}/\sigma^{2*}_{W0}$ may cancel out. So, $(\mu_T-\mu_R)^2 \le [\ln(1.11)]^2$, which means the 90% confidence interval of the ratio of the major pharmacokinetic parameter between the test product and the reference product must be between 90% and 111%. The smaller the within-subject variability of the reference product, the narrower the BE range is. Likewise, if the within-subject variability of the reference product (σ_{WR}) is larger than 0.10, the allowable BE range can be greater than 90−111%. Under this situation, FDA requires that all PK parameters for BE testing must be within the regular BE range of 80−125% by using an unscaled average BE assessment.[55,56]

In addition to compare means of the PK parameters, the within-subject variability between the test product and reference product are compared in a BE testing. The main objective is to ensure the test product will not yield meaningfully larger within-subject variability than the reference product. The null hypothesis and alternative hypothesis are shown here[55]:

$$\text{Null hypothesis: } \frac{\sigma_{WT}}{\sigma_{WR}} > \delta$$

$$\text{Alternative hypothesis: } \frac{\sigma_{WT}}{\sigma_{WR}} \le \delta \tag{14.19}$$

The test statistics are used to compare the within-subject variability between the test product and reference product. Here, δ is the regulatory threshold, which can be considered as the nonsuperiority margin. If the confidence interval approach is taken, the 90% confidence interval of $\frac{\sigma_{WT}}{\sigma_{WR}}$ can be obtained through an F distribution. The upper value of the 90% confidence interval can be calculated by using Eq. (14.20), where S_{WT} and S_{WR} are the estimate of σ_{WT} and σ_{WR}, respectively; and ν_1 and ν_2 are the degrees of freedom for the F-test, where ν_1 is for the test product and ν_2 is for the reference product. The α value is set as 0.1. As shown in the FDA guidance on warfarin, to support a BE claim, the upper 90% confidence interval should be less than 2.5[55,56]:

$$\text{Upper 90\% confidence interval: } \frac{S_{WT}/S_{WR}}{\sqrt{F_{1-\alpha/2}(\nu_1,\nu_1)}} \tag{14.20}$$

Several product-specific BE guidances have been developed to guide the BE study design and data analysis for NTI drugs. For example, in 2012, the FDA published a BE guidance for warfarin. The guidance indicated that a full-replicate BE study is recommended and a detailed data analysis procedure has been provided.[56] The revised BE guidance for tacrolimus became available in 2012. The guidance also recommends a full-replicate BE study under both fast and fed conditions. In addition, the guidance requests the applicant to consider a scaled BE approach for data analysis.[57] These guidance documents laid out a pathway for companies to develop a generic product of an NTI drug.

14.6 BIOWAIVER AND BCS

In vivo studies are essential for BA and BE evaluation. However, as per FDA guidance, in the following three situations, the requirement for an in vivo study can be waived (ie, biowaiver):

- BA and BE for certain products are self-evident.
- In vitro data are sufficient to support BA and BE claims.
- Biowaiver may be granted based on BCS.

The details are discussed in the following sections.

14.6.1 BA and BE are self-evident

Biowaivers may be granted when the product is in solution because BA and BE are self-evident. A solution for parental, otic, or ophthalmic use does not require additional in vivo BA or BE evaluation if the active and inactive ingredients has the same concentration as another approved product. In addition, no in vivo BA/BE assessment for nasal solution, solution for aerosolization, nebulization, and skin use, or oral solution is necessary if the active ingredient is presented as the same concentration in the same dosage form as another approved drug product.[58] However, it is also critical to ensure that the inactive ingredient is not expected to alter the local or systemic absorption of the active drug.

14.6.2 BA and BE claim based on in vitro data

Sometimes in vitro data are sufficient to support biowaivers.[58] Biowaivers can be given to different strengths of the same solid dosage form based on information of formulation and in vitro dissolution test, provided that the following three conditions are met: (1) BE has been established on one of the strengths of the product; (2) the formulation of the to-be-waived strength product is proportionally similar to that of the other strength of product used in the BE study; (3) there is comparable dissolution of these two strengths of the products.

In vitro dissolution testing allows the direct comparison of the dissolution profiles of the test and reference products. Generally, a model-independent approach is recommended by the guidance. For example, similarity factor (f_2) can be calculated by using Eq. (14.21):

$$f_2 = 50 \cdot \log\left[100 \cdot \frac{1}{\sqrt[2]{1 + (1/n) \cdot \sum_{t=1}^{n} (R_t - T_t)^2}}\right] \quad (14.21)$$

In this equation, n is the total number of sampling time points. R_t and T_t are the cumulative percentage dissolved at the each of the selected time points from the reference product and the test product. The f_2 value between 50 and 100 is suggestive of similar dissolution profiles.[59]

In addition, biowaiver can be granted if in vivo and in vitro correlation has been established.

14.6.3 Biowaivers and BCS

Sometimes biowaivers may be granted by relying on BCS,[60] a scientific framework to categorize a drug substance based on its solubility and permeability (Table 14.3).

A BCS I product should show high solubility, rapid dissolution, and high permeability. In general, in vivo BE studies may not be required for a BCS class I product with a wide therapeutic index.[61] *High solubility* means that the drug in the highest strength is able to dissolve in no more than 250 mL of aqueous solution over the pH range of 1−6.8 at 37 °C ± 1 °C. The ionization characteristics of the test drug can be used to determine the number of pH conditions that should be studied. An immediate-release product with rapid dissolution is anticipated to release 85% of the labeled drug within 30 minutes, using US Pharmacopeia (USP) Apparatus I at 100 rpm or Apparatus II at 50 rpm in a volume of 500 mL or less in each of the following media: (1) 0.1 N HCl or simulated gastric fluid USP without enzymes; (2) a pH 4.5 buffer; and (3) a pH 6.8 buffer or simulated intestinal fluid USP without enzymes. An IR product is considered very rapidly dissolving when 85% or more of the labeled amount of the drug substance dissolves within 15 minutes using the abovementioned conditions. A highly permeable drug is determined as at least 85% of the administered dose can be absorbed, given that there is no instability issue of the drug in the GI tract.[61]

TABLE 14.3 Biopharmaceutical Classification System

BCS class	Solubility	Permeability
I	High	High
II	Low	High
III	High	Low
IV	Low	High

Multiple approaches can be followed to determine the permeability of a drug. PK data from human studies can be used to determine if a compound is highly permeable. For example, if absolute BA is reliably estimated (with adequate sample size and reliable study design and conduct) as 85% or above, the data by itself is sufficient to support that a compound is highly permeable. Mass balance study results based on isotope-labeled drugs can be used to estimate the extent of drug absorption. However, a mass balance study usually has large variability. The results alone might not be reliable. Intestinal permeability studies can be used to determine the permeability of a drug. These studies include in vivo human intestinal perfusion studies, in vivo or in situ intestinal perfusion studies in animals, in vitro permeation studies using excised human or animal intestinal tissues, or in vitro permeation studies across a monolayer of cultured epithelial cells.[61]

It should be noted that existence of efflux transporters may complicate the interpretation of the in vitro permeation study, and in vivo or in situ animal model results. The in vitro and in vivo or in situ animal model studies are suitable for passively transported drugs. If the cell or animal models do not reflect the transporter level in human, the classification for permeability may be misleading. To avoid this situation, the FDA guidance recommends that limiting the use of nonhuman permeability test methods for drug substances that are transported by passive mechanisms only. For instance, lack of dose/exposure-dependent change in BA in human studies may be suggestive that passive transport is the main mechanism for drug absorption.[61]

Stability in the GI tract is another factor should be taken into consideration when the permeability data is taken from total radioactivity from a mass balance study or from the loss of drug from an in vivo or in situ animal permeation study. In vitro stability test is

recommended to be conducted at 37°C over the time period that represents the appropriate contact time in the relevant fluids in body. For instance, stability study can be conducted over 1 hour in gastric fluid or 3 hours in intestinal fluid. A greater than 5% loss of the drug amount is indicative of instability of the drug.[61]

Biowaivers may be granted for a BCS III product. EMA[62] and Health Canada[63] both allow biowaivers for a BCS III product. In the latest draft FDA guidance published in 2015, a BCS III product may be considered for biowaivers.[61] This draft guidance is currently available for public comments.

BCS-based biowaivers provide a convenient way to avoid unnecessary in vivo BA and BE evaluation. It has been widely used to support NDA and ANDA submissions for various oral dosage forms.

14.7 SUMMARY AND FUTURE PERSPECTIVES

BA/BE evaluations are routinely performed in product development programs. BA/BE studies provide critical information to support product approval.

BA/BE assessment is typically based on a well-designed phase I clinical trial with PK samples collected at various time points from healthy volunteers or patients. The parent compound, and its metabolites when necessary, can be assessed through a valid bioassay. PK parameters, such as C_{max} and AUC, can be obtained through concentration-time profiles obtained from each individual. For special products with complicated release mechanisms, pAUC can be calculated over the time intervals of interest. Log-transformed major PK parameters between a test product and a reference product are compared. Average BE testing is the most common approach. It is designed to ensure the true mean difference between the log-transformed PK parameters between the test product and the reference product falls within a predefined range (ie, ln(0.8) to ln(1.25)). Two products are considered bioequivalent if the 90% confidence intervals of the ratios for all PK parameters of interest between the test product and the reference product are within the defined BE limits. However, the BE limits are not always fixed. For a HV product, the BE limits can be expanded based on the within-subject variability of the reference product. The approach is known as a reference-scaling approach. For an NTI product, the BE limits are defined by within-subject variability of the reference product together with unscaled BE approach.

In vivo BA/BE studies might not be necessary when the product can meet certain criteria. For example, in vivo BE studies for a BCS class I product (ie, high solubility, high permeability, and rapid dissolution) with wide therapeutic index may not be required. In addition, biowaiver can be given to the solution products when the BA is self-evident, as well as to different strengths of the same solid dosage form based on appropriate information on formulation and in vitro dissolution test.

The concept of BA/BE is still evolving. For example, long-acting injections, which can be given once every 2 weeks,[64] monthly,[65] or even longer,[66] are developed to provide convenient ways to administer drugs and improve compliance. These products usually employ relatively complicated release mechanisms. As a matter of fact, the extended dosing intervals require prolonged durations for BE studies, which can raise potential dropout issues and further complicate the interpretations of the results. In recent years, some novel concepts have been discussed to assess BA/BE for long-acting injections. For instance, Gehring and Martinez indicated that pAUC can be extended in the assessment of BA/BE for long-acting injections.[67] All these activities reflect the continuous efforts from the scientific and regulatory community to improve BA/BE assessment and hence protect public health.

Predictive Biopharmaceutics and Pharmacokinetics: Modeling and Simulation*

Y. Yang, Y. Zhao, J.Z. Duan, P. Zhao, L. Zhao and X. Zhang

U.S. Food and Drug Administration, Silver Spring, MD, United States

15.1 INTRODUCTION

Biopharmaceutics is the study of the physical and chemical properties of a drug, and its dosage form, as related to the onset, duration, and intensity of drug action. It bridges in vitro characteristics with in vivo performance. The term *biopharmaceutical performance* refers to the influence of pharmaceutical formulation variables on in vivo performance.[1] In vivo performance can be assessed by pharmacokinetics (PK), pharmacodynamics (PD), or clinical end points, among which PK is the most frequently assessed in vivo performance. Predicting biopharmaceutical performance is a common interest of scientists working on drug product development and regulation because such predictions may reduce drug development cost and timelines. Scientists have been developing qualitative models (such as the biopharmaceutics classification system (BCS) and the biopharmaceutical drug disposition and classification system (BDDCS)), and quantitative models (such as a number of models that will be discussed in this chapter) to predict in vivo performance for various drug products.

Predicting oral absorption is difficult due to the complicated process involved. Briefly, when a solid dosage form is administered orally, it will disintegrate, dissolve, transport into enterocytes, be metabolized, and travel along the gastrointestinal (GI) tract. This process can be affected by formulation properties, drug substance properties, and GI physiology. The qualitative models, such as BCS and BDDCS, are classification systems based on a drug substance's solubility and permeability, and the extent of drug metabolism to predict drug absorption, disposition, and potential drug–drug interactions (DDIs) in the intestine and liver.[2] Details on BCS can be found in chapter "Oral Drug Absorption: Evaluation and Prediction" of this book.

The BDDCS is a modification of the BCS. In the BDDCS, a drug substance can be categorized in terms of solubility and the extent of metabolism: class I (high solubility, extensive metabolism), class II (low solubility, extensive metabolism), class III (high solubility, poor metabolism), and class IV (low solubility, poor metabolism). In addition, in the BDDCS concept, both uptake and efflux transporters in the intestine and liver are important in determining drug disposition by controlling absorption and bioavailability.[2] The qualitative models give a quick assessment of a drug's in vivo performance during development. In many cases, qualitative prediction is not adequate to address drug development and regulatory issues. Therefore, quantitative models are developed.

The objective of this chapter is to introduce quantitative models that can be used to predict biopharmaceutical PK performance for orally administered drug products. The outline of this chapter includes the following: (1) a general introduction to the conventional- and

Developing Solid Oral Dosage Forms
DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00015-7

mechanism-based PK models, (2) detailed discussions about quantitative predictions of absorption, distribution, metabolism, and excretion (ADME) using biopharmaceutics and PK modeling and simulation and its application in both drug product development and in regulatory assessment, and (3) challenges, opportunities, and future research directions.

15.2 MODELING AND SIMULATION APPROACHES FOR BIOPHARMACEUTICS AND PK

This section summarizes the most commonly adopted modeling and simulation methodologies for the prediction of the in vivo performance of solid oral dosage forms. These modeling strategies include the following: conventional compartment PK modeling, including population pharmacokinetic (popPK) modeling; and physiologically based pharmacokinetic (PBPK) modeling to predict drug ADME to support drug product development and various regulatory activities. Conventional PK and popPK models are used to estimate PK parameters and their variability using observed data sets. Sometimes it is difficult to interpret the results obtained from the conventional popPK model due to the lack of physiological framework. PBPK models take advantage of the physicochemical properties of drug substances, formulation properties of drug products, and physiological variability for certain human populations to predict PK performance of the drug product. The PBPK model can be developed with little or no human PK data, and, the predictions may be very valuable for further drug development.

15.2.1 Conventional compartment PK modeling and population PK modeling

Simplified conventional compartment PK models were developed to describe PK and ADME. Most widely used conventional compartment PK models are one-, two-, and three-compartment models with zero- or first-order absorption and linear or nonlinear elimination. The absorption is generally described by one or more absorption rate constants (k_a). The actual drug absorption process in a model may be described as first order, zero order, or a combination. The selection of either first-order or zero-order absorption is driven by observed data. Systemic drug absorption after oral administration of a solid dosage form is usually assumed to follow a first-order process. Distribution can be described by volume of distribution (V_d), and elimination can be described by clearance (CL).

The population PK approach is tightly connected with the conventional PK modeling in a way that both approaches are empirical and data driven, which is often referred as a *top-down* approach. The term *population PK* was coined by Lewis B. Sheiner and his longstanding statistician friend and coworker, Stuart Beal.[3] For the purpose of population PK modeling, nonlinear mixed-effects modeling is the most frequently referred approach.[4] Nonlinear mixed effects modeling during drug development is at the heart of a "Learn and Confirm" paradigm advocated by Sheiner.[5] The importance of variability is highlighted in population PK analysis than in traditional PK analysis. One main premise in population PK is that each individual is characterized by his or her own PK parameters; thus, inferences about the population of PK parameters is analogous to the population of patients and identifies covariates (eg, age, body weight, laboratory values, concomitant medications, other diseases, etc.) that correlate with PK variability.

Computing software tools of NONMEM (ICON), Pharsight Phoenix NLME (Pharsight), Kinetica (Adept Scientific), and Monolix are available for nonlinear mixed effects modeling.[4] Both the US Food and Drug Administration (FDA)[6] and the European Medicines Agency (EMA)[7] issued a specific, detailed Guidance on Population PK for Industry for the purpose of planning, analyzing, and reporting the data in a submission package. Decisions in drug development are increasingly being made on model-based population analyses.

15.2.2 Physiologically based PK modeling

Scientists intended to build a physiologically based model to describe PK many years ago, prior to the development of today's conventional PK models, but they did not make much progress due to the limitations of computational tools at that time. Physiologically based models to describe PK became feasible more recently with the development of computational tools. PBPK modeling is an approach in which the interactions of a drug with all components of the body are integrated, with the primary aims of permitting mechanistic insights into the global behavior of the system to be gained and of making meaningful extrapolations.[8] Prediction of human PK or ADME in early drug development using PBPK modeling may facilitate the selection and risk assessment of drug candidates before they are used in humans. PBPK models[9] also allow the full time-course of systemic drug and metabolite exposure to be evaluated realistically under all the

TABLE 15.1 Summarization of the Major Components in Physiologically Based Pharmacokinetic Modeling and Simulation

Structures	Human physiological or PK parameters	Drug substance and formulation parameters
Physiological compartment	Human body weight	Molecular weight (MW)
Anatomy	GI transit time	Logarithm of partition coefficient between *n*-octanol and water (log*P*)
Experimental design	Aqueous volume in each organ	Logarithm of the acid dissociation constant (pK_a)
Full model	Blood flow in each organ	Dose
Minimal model	Hepatic extraction ratio (ER)	Solubility
	Blood:plasma partition ratio	Precipitation time
	Protein binding	Particle density
	pH in GI lumen	Permeability
	GI fluid components	Particle size distribution

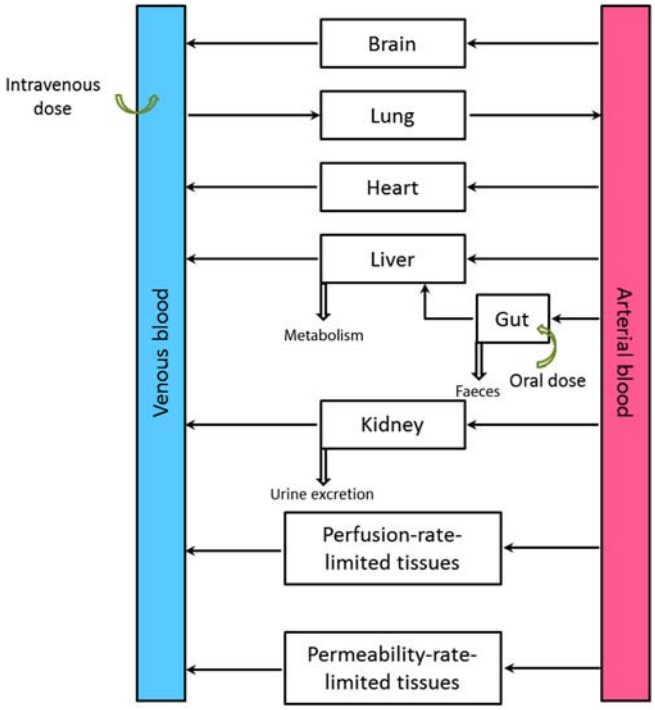

FIGURE 15.1 Schematic description of physiologically based pharmacokinetic modeling.

conditions and situations that are likely to be encountered during clinical development and beyond.

The concept of the PBPK model is to describe the concentration profile of a drug in various tissues, as well as in the blood over time, based on the drug characteristics, site and means of administration, and the physiological processes to which the drug is subjected. It comprises three major components: structural model, system-specific properties, and drug properties (listed in Table 15.1).[9] Structural model comprises the anatomical arrangement of the tissues and organs of the body, linked by perfusing blood. System-specific properties include organ mass or volume, blood flow, and tissue composition. Drug properties often include tissue affinity, plasma-protein-binding affinity, membrane permeability, enzymatic stability, and transporter activities. PBPK models are composed of many compartments corresponding to the different tissues of the body, connected by the circulating blood system (venous and arterial). A schematic of a PBPK model is shown in Fig. 15.1. A tissue can be described as either perfusion-rate-limited or permeability-rate-limited. Perfusion-rate-limited kinetics applies when the blood flow transporting the drug is often the limiting factor to distribution in the various cells of the body, while the tissue membranes present no barrier to diffusion.[10] A well-stirred tank has been the predominant flow-limited tissue compartment model in PBPK modeling.[11] Permeability rate-limited kinetics occurs where the permeability across the cell membrane becomes the limiting process.[10] When developing this kind of model, the mass-balance differential equations used in the model should describe both eliminating and noneliminating tissues.

The mass balance equation for the rates of change in drug concentration in a perfused noneliminating tissue is generally expressed as follows[12]:

$$V_t \frac{dC_t}{dt} = Q_t \times C_{art} - Q_t \times C_{vt} \tag{15.1}$$

where C_t is the total concentration in the tissue, V_t is tissue volume, Q_t is tissue blood flow, C_{art} is the drug concentration in the arterial blood reaching the tissue, and C_{vt} is the drug concentration in the venous blood leaving the tissue.

Accordingly, for a perfused eliminating tissue, the mass balance equation for the tissue can be expressed as follows[12]:

$$V_t \frac{dC_t}{dt} = Q_t \times C_{art} - Q_t \times C_{vt} - \text{in vivo } CL_{int,u} \times C_{vt,u} \tag{15.2}$$

where $CL_{int,u}$ is in vivo unbound intrinsic CL and $C_{vt,u}$ is the unbound venous tissue concentration.

Permeability rate-limited kinetics occurs where the permeability across the cell membrane becomes the limiting process.[10] Tissues possessing a permeability

barrier are modeled with permeability-limited equations that require consideration of two tissue subcompartments of vascular and extravascular spaces of noneliminating organs[13,14]:

$$\frac{dC_1}{dt} = \frac{Q_t}{V_1} * (C_{art} - C_1) - \frac{PS}{V_1} * \left(C_1 - \frac{C_2}{K_p}\right) \quad (15.3)$$

$$\frac{dC_2}{dt} = \frac{PS}{V_2} * \left(C_1 - \frac{C_2}{K_p}\right) \quad (15.4)$$

where C_1 and V_1 are the drug concentration and volume in the vascular subcompartment, C_2 and V_2 are the drug concentration and volume in the extravascular subcompartment, PS is the permeability surface area coefficient, and K_p is tissue:plasma distribution coefficient of the drug.

When selecting physiological compartments used in the model, specific considerations may be needed for a specific drug. Usually, liver can be considered as a separate compartment since drug metabolism occurs in the liver. For a lipophilic drug, fat can be considered as a separate compartment, given that the drug may have extensive partition into the fat. For a volatile drug, the blood compartment may be replaced by a blood−lung compartment.

During drug development, as more and more data become available, PBPK modeling can be used to predict the complexities of oral drug absorption, the likely intersubject PK variability. For small molecules, PBPK models have successfully been used to predict human exposure and to design the proposed dose regimens in phase I studies.[12] Intravenous and oral PK of 21 diverse compounds have been simulated.[15] With the use of Monte Carlo methods, a particular strength of PBPK modeling is the capability to predict variability in PK beyond observed limits and to anticipate individuals whose attributes combine to give extreme PK risk.[8,16,17]

Computing software tools such as GastroPlus (Simulations Plus Inc.), Simcyp Simulator (Simcyp Ltd), PK-Sim (Bayer Technology Services), MATLAB (MathWorks Inc.), and STELLA (isee systems) are available for PBPK modeling; note that the FDA does not endorse any computational software product or company. All these programs now strive to account for all relevant processes of the GI absorption of drugs, including release from the dosage form; decomposition/complexation in the GI tract; and the various mechanisms of drug uptake, efflux, and first-pass metabolism in either gut wall or liver; and to describe the interplay of these factors in determining the rate and extent of drug absorption from the GI tract.[18] The FDA has issued a guidance about using model-based strategy to evaluate and predict DDIs.[19] Recently, the EMA issued the specific detailed guideline on qualification and reporting of PBPK modeling and analyses.[20]

15.2.2.1 Absorption

Oral drug absorption is affected by drug substance properties (eg, dose, lipophilicity, pK_a, solubility, permeability, partition coefficient, and chemical stability), formulation factors (eg, particle size, release kinetics, and dissolution kinetics), and the physiology of the GI tract (eg, intestinal pH; transit time; GI motility; luminal and hepatic metabolism; blood flow; endogenous substances, such as bile salts; transporters; and exogenous substances such as nutrients). Permeability, solubility, and dissolution are the three primary drug- and formulation-specific factors that influence drug absorption.[21] Many details about GI physiology, drug permeability, solubility, and dissolution are described in chapter "Oral Drug Absorption: Evaluation and Prediction" of this book. Permeability reflects the physiological properties of membrane to the solutes. Solubility is one of the physiochemical properties of a drug substance that affects the absorption for a solid oral drug. Dissolution is the dosage form variable that determines the rate and extent of a drug dissolved in solution.

Passive permeability (P) of drug molecules across a cell membrane can be expressed as follows[22]:

$$P_{passive} = \frac{J}{\Delta C} = \frac{D \times K}{h} \quad (15.5)$$

where J is the flux (amount of material flowing through a unit cross section), ΔC is the drug concentration difference between the donor and receiver compartment, D is the diffusion coefficient, K is the partition coefficient, and h is the thickness of the cell membrane. The diffusion coefficient (D) depends on the drug molecular weight or size, and K is a measure of the solubility of the drug molecules in lipids. Therefore, passive permeability is related to membrane properties and drug properties. For a specific drug substance, passive membrane permeability should be a constant (P_m) that is independent of drug concentration.

The permeability for active transport can be presented similarly[22]:

$$P_{active} = \frac{J}{C} = \frac{J_{max} \times C}{K_m + C} \times \frac{1}{C} = \frac{J_{max}}{K_m + C} \quad (15.6)$$

where J_{max} is the maximum drug flux, K_m is the drug affinity to the carrier, and C is the concentration in the donor compartment. Obviously, active permeability depends on drug concentration.

Therefore, the total effective permeability depends on the concentration of drugs that are absorbed

through both passive diffusion and active transport, and it can be expressed as follows:

$$P_{\text{eff}} = P_{\text{passive}} + P_{\text{active}} = P_{\text{m}} + \frac{J_{\max}}{K_{\text{m}} + C} \tag{15.7}$$

When at very low drug concentrations (ie, $C \ll K_{\text{m}}$), drug permeability is independent of drug concentration. On the other hand, at high drug concentrations (ie, $C \gg K_{\text{m}}$), drug permeability depends on drug concentration.

Factors such as solubility, permeability, pK_{a}, and luminal pH behave interactively, affecting oral drug absorption. Ionization and pH plays an important role in the balance of solubility and permeability. The ionized form is usually more soluble in aqueous conditions than the neutral form, but the neutral form penetrates the enterocyte layer more easily by passive diffusion than the ionized form does.

Drug dissolution must take place with a solid drug dosage form in the GI tract before it can be absorbed. Factors that affect dissolution also have an impact on the fraction absorbed. The Noyes–Whitney equation can be used to describe the dissolution rate as follows[23]:

$$\frac{d_m}{d_t} = A \times \frac{D}{h} \times (C_{\text{s}} - C) \tag{15.8}$$

where d_m/d_t is the rate of the dissolution of a solid drug, A is the surface area of the interface between the dissolving substance and the solvent, D is the diffusion coefficient, h is the thickness of unstirred boundary layer, and C_{s} and C represent the solubility concentration of the drug substance and the concentration of the dissolved substance at a given time t, respectively.

As per the official definition (CFR title 21, section 320.1), bioavailability (F) means the rate and extent to which the active ingredient or active moiety is absorbed from a drug product and becomes available at the site of action. For orally administered drug products intended for systemic action, F is determined by a number of processes:

$$F = f_{\text{a}} \times f_{\text{g}} \times f_{\text{h}} \tag{15.9}$$

where f_{a} is the fraction of drug dose absorbed across the apical cell membrane into the cellular space of the enterocyte, f_{g} is the fraction of drug dose escaped from intestinal first-pass metabolism, and f_{h} is the fraction of the drug dose escaped from hepatic first-pass metabolism.

15.2.2.1.1 Compartmental absorption and transit model

PBPK modeling to predict oral drug absorption of solid drug dosage formulation has wide applications. Initially, a compartmental absorption and transit (CAT) model that divides the GI tract into seven compartments was developed.[24] The CAT model was developed by considering gastric emptying, small intestinal transit, in vivo dissolution, and first-order absorption.[24] It is a dynamic, mechanistic model that simulates and predicts the rate and extent of drug absorption from the human GI tract. The drug solution transfers from one compartment to the next in a first-order fashion. The colon is considered only as a reservoir. The CAT model is developed based on the following assumptions: (1) absorption from the stomach and colon is insignificant compared with that from the small intestine; (2) transport across the small intestinal membrane is passive; (3) dissolution is instantaneous; and (4) drug substance moving along the small intestine can be viewed as a process of flowing through a series of segments.[24] The basic equation for the CAT model is described as follows[25]:

$$\frac{dD_n}{dt} = k_{\text{t}} \times D_{n-1} - k_{\text{t}} \times D_n - k_{\text{a}} \times D_n \tag{15.10}$$

where D_n is the percent of dose in the nth GI compartment, n is the number of total compartments, k_{t} is the first-order transit rate constant, and k_{a} is the first-order absorption rate constant. Therefore, in the CAT model, the fraction of dose absorbed, f_{a}, can be estimated by[24]

$$f_{\text{a}} = 1 - \left(1 + \frac{k_{\text{a}}}{k_{\text{t}}}\right)^{-7} = 1 - (1 + 0.54 P_{\text{eff}})^{-7} \tag{15.11}$$

where P_{eff} is the human effective permeability, expressed in cm/hour.

The value of $P_{\text{eff, human}}$ can be obtained by the in situ intestinal perfusion method.[26] The model of this method was described in great detail in chapter "Oral Drug Absorption: Evaluation and Prediction." Briefly, the drug concentration is measured at the inlet and outlet of the perfusion tube. The drug permeability ($P_{\text{eff, human}}$) is calculated with the following equation[27]:

$$P_{\text{eff,human}} = \frac{Q \times \frac{C_{\text{in}} - C_{\text{out}}}{C_{\text{out}}}}{2\pi r L} \tag{15.12}$$

where Q is perfusion flow rate, C_{in} is inlet drug concentration of the perfusion tube, C_{out} is outlet drug concentration of the perfusion tube, and $2\pi rL$ is the mass transfer surface area within the intestinal segment, which is assumed to be the area of a cylinder with length L and radius r.

15.2.2.1.2 Advanced compartmental absorption and transit model

The advanced compartmental absorption and transit (ACAT) model was developed based on the

CAT model to include additional functions, including gut metabolism and modeling of modified-release drug products. This model is featured with first-order transport from one compartment to the next, and nonlinear metabolism/transport kinetics, nine GI compartments (stomach, duodenum, jejunum 1, jejunum 2, ileum 1, ileum 2, ileum 3, ileum 4, and colon), and six states of drug component (unreleased, undissolved, dissolved, degraded, metabolized, and absorbed), and three states of excreted material (unreleased, undissolved, and dissolved).[25] The ACAT model in predicting oral drug absorption considers drug physicochemical factors (pK_a, solubility, and permeability), dosage formulation factors (dose, particle size, and density), and physiological factors (gastric emptying, intestinal transit rate, first-pass metabolism, luminal transport, GI blood flow, and food effects). The GastroPlus software was developed based on the ACAT model. It is recommended that experimental data (human P_{eff}, solubility, etc.) be included to increase the reliability of GastroPlus. Since the determination of human P_{eff} is complex and expensive, in situ permeability values of rat or dog intestine are used instead. The human P_{eff} is estimated based on the measured permeability in rat or dog using a built-in correlation.[24] The data from epithelial cell culture models such as Caco-2 and MDCK can also be used for the purpose of prediction.[28]

15.2.2.1.3 Advanced dissolution, absorption, and metabolism model

Further, the advanced dissolution, absorption, and metabolism (ADAM) model was also developed based on the CAT model to include drug dissolution, GI fluid transit, drug degradation, gut wall permeation, intestinal metabolism, and active transport. The ADAM model consists of seven compartments (duodenum, jejunum I, jejunum II, ileum I, ileum II, ileum III, and ileum IV) for the small intestine. In each segment of the small intestine, ordinary differential equations are used to describe the dynamics of the amount of solid drug mass available for dissolution, the amount of solid mass trapped in the formulation and not available for dissolution, the amount of dissolved drug, and the drug concentration in the enterocyte.[29] The ADAM model considers drug factors (solubility and dissolution, drug stability, and permeability), dosage formulation factors (drug release and particle size), and physiological factors (gastric emptying, intestinal transit time, GI fluid pH and dynamics, first-pass metabolism, luminal transport, GI blood flow, and food effects).[29] The Simcyp software employs the ADAM model.

15.2.2.2 Distribution

The volume of distribution of a drug is a parameter that relates the amount of the drug in the body to the concentration of the drug at the site of measurement. For example, the volume of distribution at steady state (V_{ss}) in plasma corresponds to the equivalent plasma volume in which a drug is apparently distributed into the body at given doses. Physiologically, the volume of distribution at steady state is determined by[30]

$$V_{ss} = V_p + \sum t\left(V_t \times K_{t:p}\right) + V_e \times \left(e{:}p\right) \qquad (15.13)$$

where V_p, V_t, and V_e are the volume of plasma (about 4 L in humans), tissue, and erythrocyte, respectively; $K_{t:p}$ is the tissue-to-plasma partition coefficient; and $e{:}p$ is the erythrocyte-to-plasma ratio. The tissue-to-plasma partition coefficient ($K_{t:p}$)[12] can be calculated by the Poulin–Theil method using tissue composition-based equations[31] with the correction[32] or by the Rodgers–Rowland method using mechanistically derived equations.[33,34]

In addition, the PBPK modeling approach is used to predict local exposure to the brain of central nervous system–targeted drugs in humans from preclinical data. In one study,[35] acetaminophen was used as a test compound, as it is not subjected to active transport processes. The regional brain PK of acetaminophen was described by developing a physiologically based model.

Physiological volumes in humans involve plasma water (about 4 L), extracellular fluid (about 15 L), and total body water (about 40 L). Drugs bind to plasma and tissue protein. The binding of drugs to plasma proteins and tissue macromolecules exerts an important influence on the pattern of drug distribution. Plasma protein binding tends to restrict drug in the plasma, and tissue binding tends to accumulate drug in the tissue. Drug concentrations vary from tissue to tissue and is the highest where binding is most extensive. Overall, drug distribution is driven primarily by the passive diffusion of a drug along the concentration gradient created by the unbound drug in the plasma and tissues. Uptake and efflux transporters may also be involved and may either promote or limit a drug's distribution beyond that predicted by passive diffusion alone. Albumin, α1-acid glycoprotein, and lipoproteins are the plasma proteins principally involved in the binding of drugs. Albumin is the most abundant and has a concentration of about 40 g/L. Many drugs bind to albumin, particularly weak acids and neutral drugs. Drug binding to plasma or tissue proteins is a capacity-limited process that is governed by the law of mass action. Several factors decide drug protein

binding, including affinity of the drug for the protein, drug concentration if saturation is possible, and level of binding protein.

15.2.2.3 First-pass intestinal metabolism

In the human intestine, various metabolic enzymes (in particular, cytochrome P450s (CYPs) and uridine 5′-diphosphate-glucoronosyltranferase (UGT)) are expressed intensively[36] in epithelial cells, which could largely affect the bioavailability of orally administrated drugs. For example, CYP3A accounts for 80% of total intestinal P450s[37] and CYP3A substrates (eg, cyclosporine, nifedipine, midazolam, and verapamil) have their bioavailability reduced due to the first-pass metabolism in the gut wall.[36,38] Approximately one-third of the marketed drugs are metabolized to a substantial extent by CYP3A.[39] The impact of intestinal metabolism and intestinal bioavailability merits investigation for orally administrated drugs.

For the purpose of estimating the fraction of dose escaped intestinal first-pass metabolism (f_g), an approach named the "Q_{gut} model" has been developed.[40] This model treats the entire small intestine as a single homogenous organ following the form of the well-stirred liver model. It includes a flow term (Q_{gut}), which accounts for both permeability through the enterocyte membrane and the villous blood flow. Modeling equations of "Q_{gut} model" include[40]

$$f_g = \frac{Q_{gut}}{Q_{gut} + (fu_{gut} \times CL_{int,gut})} \tag{15.14}$$

$$Q_{gut} = \frac{CL_{perm} \times Q_{ent}}{CL_{perm} + Q_{ent}} \tag{15.15}$$

where fu_{gut} is the unbound fraction of drug in the enterocytes, $CL_{int,\ gut}$ is unbound intrinsic gut CL, CL_{perm} is permeability CL through the enterocytes, and Q_{ent} is mucosal blood flow (18 L/hour in an average human being). The value of $CL_{int,\ gut}$ is calculated by the product of the in vitro intrinsic CL and a correction factor taking into account enzyme content involved in substrate transformation. The value of CL_{perm} can be determined by the measured Caco-2 permeability at pH 7.4 and an estimate of the human small intestinal surface area.[41]

The predictive power of the Q_{gut} model has been further assessed in a study of 25 CYP3A substrates ranging over the full range of f_g values (0.07−0.94).[42] By using the Q_{gut} model, good agreement between predicted and in vivo f_g was noted for drugs with low to medium intestinal extraction when in vivo f_g is $\geq$0.5, but a lower predictive performance is observed when f_g is $\leq$0.5.[43]

15.2.2.4 Hepatic and renal CL

For solid oral drug formulation, after entering the systemic circulation, both hepatic metabolism in liver and renal excretion through the kidney can be involved in the drug's CL, hence determining the exposure levels of drugs and metabolites. A drug's total CL in the entire body equals the sum of the CLs of various organs[44]:

$$CL_{total} = CL_m + CL_r + CL_{others} \tag{15.16}$$

where CL_m is metabolic CL in liver, CL_r is renal CL, and CL_{others} is drug CL in other organs.

A drug's CL is the irreversible removal of it from certain organs, and is defined as[44]

$$CL = Q \times ER \tag{15.17}$$

where Q is organ blood flow and ER is the extraction ratio of the drug in the organ.

ER is an index of how efficiently the organ extracts drug from the blood that goes through it, and it ranges from 0 to 1. ER across an organ depends on the fraction of unbound drug in the blood (f_u) and intrinsic CL of the organ (CL_{int}, the inherent ability to remove the drug by the organ in the absence of any limitations) and is calculated by the following equation[44]:

$$ER = \frac{f_u \times CL_{int}}{(Q + f_u \times CL_{int})} \tag{15.18}$$

Drugs with low ER ($ER < 0.3$) show a capacity-limited CL ($CL = f_u \times CL_{int}$), where the CL is primarily determined by the unbound fraction of the drug and the intrinsic CL. Drugs with high ER ($ER > 0.7$) show organ blood flow-limited CL ($CL = Q$), where CL is directly affected by changes in blood flow.

15.2.2.4.1 Drug hepatic CL

The liver is a major site of drug elimination. Quantitatively, the liver normally accounts for the metabolism and the CL of a majority of drugs. Drug-metabolizing enzymes mainly localized to cellular endoplasmic reticulum catalyze the biotransformation of drugs to often pharmacologically inactive or sometimes active metabolites (eg, codeine (prodrug) conversion to morphine (active) and morphine conversion to morphine-6-glucuronide (active)) in humans. NADPH-cytochrome P450 reductase (P450R)/cytochrome P450s (P450s, namely CYP1A2, CYP2A6, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4/5) are enzymes that mediate phase I oxidative reactions, whereas the uridine 5′-diphosphate-glucoronosyltranferase (UGTs, namely UGT1A1, UGT1A4, UGT2B4, and UGT2B7), sulfotransferases (SULTs, namely SULT1A1, SULT1A2, SULT2A, and SULT2B), glutathione *S*-transferases, and *N*-acetyltransferases are enzymes that mediate the

phase II conjugative reactions of most drugs.[44] For most drugs on the market, hepatic CL determines the drug exposure after the drug is absorbed.

Many mathematical models have been developed to describe in vivo hepatic drug CL. The most commonly used hepatic CL models are the venous equilibrium (well-stirred) model, the undistributed sinusoidal (parallel-tube) model, and the dispersion models.[45] The well-stirred model considers the homogenous drug concentration throughout the liver, and it assumes bulk flow, with the model equation as follows[45]:

$$CL_h = Q_h \times \frac{f_u \times CL_{int}}{(Q_h + f_u \times CL_{int})} \tag{15.19}$$

where Q_h is hepatic blood flow and CL_{int} is the intrinsic CL in the liver (see Eqs. (15.17) and (15.18)).

The parallel-tube model, which considers the liver to be a tube, assumes an exponential decline in drug concentration through the liver under the assumption of plug flow, with the following model equation[45]:

$$CL_h = Q_h \times (1 - e^{-(f_u \times CL_{int})/Q_h}) \tag{15.20}$$

The dispersion model is an intermediate of the previous two models.

For model building, it is necessary to investigate each determinant of the drug CL in vitro. The drug in vivo intrinsic CL (unit: L/minute or L/hour) can be extrapolated based on its in vitro intrinsic CLs based on the in vitro hepatocyte, liver microsome, or expressed enzyme experiments (unit: μL/minute per functional unit of the system).[46] In vitro experiments for CL prediction contain three elements: a general setup, a biological component, and a compound to be tested. The setup involves an incubation vessel and a suitable solution, but these nonbiological components may have a considerable effect on biological components and on the compound and its movement and fate through the system. The biological component involves the biological material, such as the enzyme sources (eg, liver slices, cultured hepatocytes, subcellular fractions (liver microsomes and homogenates), and recombinant expressed enzymes), and in vitro kinetics (eg, metabolic/elimination rate and competence, binding, and uptake/efflux factors (passive diffusion versus transporters)). For the compound, one should be able to measure its concentration in various compartments of the system and its biotransformation. In essence, meaningful information can be extracted from an in vitro system for in vitro–in vivo extrapolation.

Enzyme kinetics generally considers that 1 mol of drug interacts with 1 mol of enzyme to form an enzyme–drug intermediate. This rate process can usually be described by the Michaelis–Menton equation, which assumes that the rate of enzymatic reaction depends on the concentration of both enzyme and drug and that an enzyme–drug intermediate is initially formed, followed by the formation of the product and then the regeneration of the enzyme. The velocity of metabolism is described by the Michaelis–Menton equation:

$$v = \frac{V_{max} \times S}{S + K_m} \tag{15.21}$$

where v is the velocity of the reaction, V_{max} is the maximum velocity, S is the drug/substrate concentration, and K_m is the Michaelis constant, which is the substrate concentration when the velocity of the reaction is equal to 50% of the maximum velocity. The two parameters V_{max} and K_m determine the profile of a simple enzyme reaction rate at various drug concentrations. The relationship of the rate of metabolism to the drug concentration is nonlinear, which can be represented by a hyperbolic profile.

Scaling factors include the number of hepatocytes, liver microsomal content, expressed enzyme amount per gram of liver, liver weight, and body weight. A body of information on the prediction of CL by the metabolic enzymes other than CYP and UGT, particularly involving conjugation reactions mediated by amidases and sulfatases, is currently lacking.

15.2.2.4.2 Drug renal CL

The renal CL of a drug includes the combination of glomerular filtration, secretion, and reabsorption through proximal tubules. Using a noncompartmental approach, renal CL can be expressed as[44]

$$CL_r = \frac{A_u}{AUC_0^\infty} \tag{15.22}$$

where A_u is the drug amount ultimately excreted unchanged in urine and AUC_0^∞ is the area under the plasma concentration time curve.

Physiologically, renal CL of a drug equals

$$CL_r = \frac{\text{excretion rate}}{\text{plasma concentration}} = \frac{\text{filtration rate} + \text{secretion rate} - \text{reabsorption rate}}{\text{plasma concentration}} \tag{15.23}$$

When the drug is not actively secreted and the reabsorption is negligible, the renal CL of a drug is often related to the renal glomerular filtration rate. Drugs are usually filtered through the glomerulus in a nonselective process if they are in a free, nonprotein-bound form.

15.3 APPLICATION OF BIOPHARMACEUTICS AND PK MODELING AND SIMULATION IN DRUG DEVELOPMENT

In the previous section, we have discussed theoretical models that have been developed to predict the ADME of drug products. Numerous research articles have been published on PBPK modeling. A quick search using "physiologically based pharmacokinetics" as the keyword would find 1895 articles as of May 2015. Table 15.2 includes some representative case examples where mechanism-based models have been used in the

TABLE 15.2 Examples of Published Absorption PBPK Modeling Used in the Development of Solid Oral Dosage Formulation Within the Last 10 Years (2006–15)

Modeling purpose	Drug	Human BCS classification	Program used for modeling	References
Absolute oral BA	164 drugs	I–IV	CAT	47
PK prediction	Multiple compounds		Simcyp & ADAM, Gastroplus, PK-Sim, and MATLAB	48–52
Food effects	Novartis compounds	I, II, IV	GastroPlus & CAT	53–55
Interplay of food, drug, and CYP3A enzymes	Nifedipine	II	PK-Sim, Simcyp & ADAM	56,57
Oral absorption & food effects	Aprepitant	IV	STELLA	58
Food effects on drug absorption	Merck compound A	IV	STELLA	59
Food effects on absorption	Celecoxib	II	STELLA	60
Predicting PK for a buffered sublingual formulation	Propranolol	I	Gastroplus & ACAT	61
Impact of nonsink intestinal permeation on BA for poorly soluble compounds	1,3-dicyclohexyl urea	–	GastroPlus	62,63
Identify biorelevant solubility	Abbott compound	–	GastroPlus	64
Salts selection	Phenytoin	II	GastroPlus	65
Formulation optimization by PBPK/PD modeling	Nifedipine	II	Simcyp	66
Formulation optimization	SNX-2112	–	MATLAB	67
Formulation impact on oral absorption and CYP3A4 mediated gut metabolism	Multiple compounds	I–III	Simcyp	68
Formulation assessment	Atazanavir	II/IV	STELLA	69
Formulation development, PK profiles for immediate release and modified release products	Furosemide	IV	STELLA	70
In vivo relevant dissolution	Diclofenac		STELLA	71
Pharmaceutical product development	Multiple compounds	I–III	GI-Sim	72
PK of immediate release and extended release formulations	Cimetidine	III	PK-Sim	73
Formulation optimization (particle size)	Cilostazol	II	PK-Sim	74
In vivo PK	Commercial and Pfizer compounds	I–II	PK express model	75
Predict PK of various dosage forms and formulation	Melatonin	II	MATLAB Simulink	76
Predict PK of various formulations in various population	Quetiapine	II	Simcyp	77
In vivo relevant dissolution	Diclofenac	II	STELLA	78
Human intestinal first-pass metabolism	Multiple compounds	I–II	MATLAB	41
Intestinal metabolism	Verapamil/ compound A	–	MATLAB	79

area of oral absorption or predicting biopharmaceutical performance for oral dosage forms within the last 10 years.

Scientists have been very creative in utilizing absorption PBPK models to address scientific questions during drug development. As shown in Table 15.2, the drug substances that have been modeled covered a wide range of physicochemical properties, including BCS I–IV drugs. Computational platforms that have been used for modeling included Gastroplus, GI-Sim, MATLAB, PK-Sim, Simcyp, and STELLA. A direct use of these model types is to predict oral bioavailability and PK profiles for various drug substance and formulations.[47–52,73,76,77] As a practical tool for drug product development, oral PBPK absorption models have been used extensively in pharmaceutical development.[72] For example, it was reported to be used in salt selection,[65] particle size optimization,[74] optimization for PK profiles,[70] and even PD profiles.[56] Absorption PBPK models have also been used to study the intestinal metabolism.[41,56,57,66,68,79] Recently, efforts have been made in the area of quantitative prediction of food drug interaction using oral absorption PBPK models.[53–56,58,60] Scientists have been working to develop in vivo relevant dissolution methodology for a long time. With the application of mechanistic absorption models, researchers were able to link in vitro dissolution with in vivo performance in a mechanistic framework.[59,60,64,78] More important, mechanistic oral absorption models have been used to test scientific hypotheses and address barriers encountered in drug development. For example, nonsink permeation in the small intestine was incorporated into an absorption PBPK model to explain the low bioavailability, which could not be explained by low solubility alone.[62,63] The simulation was verified in rat studies by perfusing the drug substance to reach high plasma concentrations to mimic the nonsink permeation conditions.[63]

15.4 APPLICATION OF BIOPHARMACEUTICS AND PK MODELING AND SIMULATION IN REGULATORY ACTIVITIES

15.4.1 In the new drug evaluation

There is no doubt that mechanistic-based PK models have had a great impact on drug discovery and development in many different areas (Table 15.2),[80] such as bioavailability prediction, food effect prediction, formulation optimization, impact of drug substance properties on bioavailability, in vivo dissolution, GI metabolism, in vivo CL, first-pass metabolism prediction, cross-species extrapolation, and DDIs. As a result, regulatory agencies started to receive more and more submissions containing PBPK modeling.

The PBPK modeling approach has especially facilitated clinical pharmacology-related decisions.[81] In Zhao et al., PBPK modeling cases submitted for investigational new drugs (INDs) and new drug applications (NDAs) between Jul. 2008 and Jun. 2010 were summarized, which have facilitated the following types of regulatory decision making: the need to conduct specific clinical pharmacology studies, specific study designs, and appropriate labeling language.[81] In that paper, all the PBPK models were applied to address metabolism-related questions, such as DDI prediction; prediction of PK in hepatic impairment populations in extensive, intermediate, or poor metabolizers; and in pediatric populations.

Among the areas that PBPK modeling has been submitted in new drug application and evaluation, DDI prediction has been the main area of interest (Table 15.3). There are also examples where PBPK models were applied to predict PK in different populations: the levonorgestrel-releasing intrauterine system, and simeprevir oral capsules, and for absorption-related process prediction, such as predicting the p-glycoprotein (p-gp) contribution to oral absorption (ceritinib) and predicting the impact of stomach pH on absorption (panobinostat). Similar trends have been observed by the EMA, where DDI prediction is the major area of PBPK modeling applications and then PK in special populations.[82]

In 2015, a series of articles were published that summarized the experiences and viewpoints of experts in industry, European regulatory agency, and the US FDA regarding the application of PBPK modeling in drug development as a regulatory review.[80,82,83] Overall, all the parties agreed that PBPK modeling is a tool with great potential to assess benefits and risks. There are some areas in which scientists have high confidence, such as PK prediction for CYP-cleared substrates, absorption prediction for BCS I drugs, and DDI prediction involving reversible CYP inhibition alone or CYP induction alone.[80] Confidence levels for many other areas are still low, such as CL and absorption involving active transport; DDI prediction involving combined reversible, time-dependent inhibition; induction of CYPs; and absorption for BCS III and IV drugs.[80]

15.4.2 In generic drug evaluation

Unlike with NDAs, where firms have started submitting PBPK modeling in their application packages, PBPK modeling in generic drug applications is rare. The Office of Generic Drugs of the US FDA had

TABLE 15.3 New Drug Applications That Involved Physiologically Based PK Modeling (2009–15)

Drug name	Approval year	Area
Sildenafil[84,85]	2009	DDI
Cabazitaxel[86]	2010	In vivo intrinsic clearance prediction
Rivaroxaban[87,88]	2011	DDI

Rilpivirine[90,91]	2014	DDI
Belinostat[117]	2014	DDI
Lenvatinib[118,119]	2015	DDI
Panobinostat[120,121]	2015	DDI, impact of stomach pH on absorption

internally started exploring this type of predictive tools to address various issues in bioequivalence (BE) guidance development, citizen petition responses, abbreviated new drug application (ANDA) review consultations, protocol development for regulatory research studies, and investigation of postapproval issues.[1] In terms of the distribution of the number of projects using PBPK modeling in each area, the majority of the modeling activity has been in the BE guidance development and consult response (ie, internal needs to address questions).[122] Specifically, the PBPK absorption models have helped answer a number of questions, such as whether the in vivo dissolution profile correlates with the in vitro dissolution profile; whether the partial AUCs are appropriate as BE metrics; whether there will be in vivo alcohol dose dumping for specific formulations based on in vitro alcohol dose dumping studies; whether the GI local concentration/exposure correlates with the plasma concentration/exposure; the sensitivity of PK parameters to the change of formulation parameters, such as particle size; and the formulation parameters that affect PK BE conclusions.[122]

The main difference between the generic product and the reference drug product is the formulation difference. Mechanistic-based absorption and PK models that capture the formulation characteristics would be used to identify critical quality attributes by parameter sensitivity analysis and potentially very useful in product development. The challenge is verification of the prediction and building confidence in using this type of modeling and simulation tools to aid generic drug development and review.

15.5 SUMMARY

In this chapter, we first briefly introduced two basic modeling and simulation approaches for biopharmaceutical and PK: population PK-pharmacodynamic modeling and physiologically based PK modeling. Then we focused on introducing the theories of using mechanisms based on PBPK models to predict ADME. A search in PubMed was conducted to summarize the published case examples and areas where mechanistic PBPK models have been applied (Table 15.2). Finally, cases were introduced where mechanistic PBPK modeling and simulation were used in the new drug evaluation (Table 15.3), as well as generic drug evaluation.

Overall, mechanistic PBPK modeling and simulation have great potential for drug development and evaluation. The confidence level differs depending on the parameters to be predicted. There are also many scientific challenges connected with the development of better predictive models.

In Vitro/In Vivo Correlations: Fundamentals, Development Considerations, and Applications

Y. Qiu[1] *and J.Z. Duan*[2]

[1]AbbVie, Inc., North Chicago, IL, United States [2]U.S. Food and Drug Administration, Silver Spring, MD, United States

16.1 INTRODUCTION

For decades, developing in vitro tests and models to assess or predict the in vivo performance of pharmaceutical products has been sought after as a means of screening, optimizing, and monitoring dosage forms. With solid oral dosage forms, it most frequently starts with an attempt to link the results of an in vitro release test to in vivo pharmacokinetic studies. Through exploring the association or relationship between in vitro dissolution/release and in vivo absorption data, an in vitro/in vivo relationship (IVIVR) may be identified for a drug product. Such a relationship is often qualitative or semiquantitative in nature (eg, rank order). When a predictive relationship or model is established and validated between in vitro dissolution and in vivo absorption profiles, it is designated as in vitro/in vivo correlation (IVIVC).

IVIVC of oral solid products have received considerable attention from the industry, regulatory agencies, and academia over the past two decades, particularly since the publication of Food and Drug Administration (FDA) guidance of dissolution testing of immediate-release (IR) and IVIVC of extended-release (ER) dosage forms in 1997[1,2] and subsequent guidelines issued by European regulatory authorities (EMA).[3–5] As a result, there has been increased confidence, effort, and success using in vitro tests to evaluate or predict in vivo performance of solid drug products, especially ER dosage forms, based on IVIVC.[6–13] With an established IVIVC, the dissolution data can be used not only as a quality control tool but also for guiding and optimizing product development, setting meaningful specifications, and serving as a surrogate for a bioavailability study. This chapter will discuss basic principles and methodology utilized to establish and evaluating IVIVC models, as well as applications of IVIVC in developing solid dosage forms with a primary focus on ER products. Additional topics include the importance of understanding drug substance, dosage form, their in vitro and in vivo behaviors, and in vitro test methods to explore and develop IVIVC.

16.1.1 In vitro/in vivo correlation

IVIVC is defined by United States Pharmacopeia (USP) and the FDA respectively as follows[2,14]:

> *USP:* the establishment of a relationship between a biological property, or a parameter derived from a biological property produced by a dosage form, and a physicochemical characteristic of the same dosage form.
> *FDA:* a predictive mathematical model describing the relationship between an in vitro property (usually the extent or rate of drug release) and a relevant in vivo response (eg, plasma concentration or amount of drug absorbed).

Evaluation of IVIVCs by different levels was first proposed for oral dosage forms in the USP's information chapter <1088>[15] and was later adopted globally. Presently, IVIVC is categorized by the FDA into levels A, B, C, and Multiple C depending upon the type of data used to establish the relationship and ability of the correlation to predict the complete plasma profile of a dosage form.[2]

DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00016-9

Level A: A predictive mathematical model for the relationship between the entire in vitro release time course and the entire in vivo response time course, for example, the time course of plasma drug concentration or amount of drug absorbed.
Level B: A predictive mathematical model for the relationship between summary parameters that characterize the in vitro and in vivo time courses, for example, models that relate the mean in vitro dissolution time to the mean in vivo dissolution time, or to mean residence time (MRT) in vivo.
Level C: A predictive mathematical model for the relationship between the amount dissolved in vitro at a particular time (eg, Q_{60}) or the time required for dissolution of a fixed amount (eg, $T_{50\%}$) and a summary parameter that characterizes the in vivo time course (eg, C_{max} or AUC).
Multiple Level C: Predictive mathematical models for the relationships between the amount dissolved at several time points of the product and one or several pharmacokinetic parameters of interest.

Level A is the most informative and most useful from both scientific and regulatory perspectives in that it represents a point-to-point relationship between in vitro release and in vivo release/absorption from the dosage form. It can be used to predict the entire in vivo time course from the in vitro data. Multiple Level C is also useful as it provides the in vitro release profile of a dosage form with biological meaning. Level C can be useful in early stages of product development or setting meaningful specifications, although it does not reflect the complete shape of the plasma concentration-time curve. Level B utilizes the principles of statistical moment analysis. However, it is the least useful for regulatory applications because different in vitro or in vivo profiles may produce similar mean time values.

16.1.2 IVIVC and product development

The value of IVIVC in product development has been recognized since the early 1960s. Exploring in vitro/in vivo association or correlation is very useful in guiding formulation and process development. A validated IVIVC can support formulation and process changes and scale-up, help develop meaningful dissolution specifications, and support the use of dissolution as a surrogate for an in vivo study, since IVIVC provides a biological meaning to the results of the in vitro test.[2] Thus, availability of a validated predictive IVIVC can result in a significant positive impact on product quality, development efficiency, and reduced regulatory burden.

The approaches and challenges of developing an IVIVC have undergone extensive discussion and debate since the 1980s.[16–25] In general, there is increased uncertainty associated with developing an IVIVC for IR oral dosage forms because the in vivo apparent drug absorption is often a function of a multitude of variables, many of which are difficult to isolate or mimic in vitro. For example, a correlation between the in vitro dissolution and the in vivo absorption for IR dosage forms of highly water soluble drugs (eg, Biopharmaceutical Classification System 1 and 3) is usually not possible because gastric emptying or membrane permeation is often the rate-limiting step. Absorptive and efflux transporters and/or gut metabolism can play a significant role in the apparent absorption of BCS 2–4 compounds[26–28] depending on the dose, physicochemical, biopharmaceutical properties, and dissolution rate, making correlating dissolution with absorption difficult.[29] Compared to IR products, an IVIVC is more suitable for ER dosage forms where drug release is, by design, rate limiting in the absorption process. In addition, because a patient is typically exposed to a specific range of plasma levels over an extended period of time (eg, up to 24 hours) following administration of a modified-release (MR) dosage form, an in vitro test method with a qualitative or quantitative relationship with in vivo data is desired to assure the consistent in vivo performance. Hence, the FDA has recommended investigation of the possibility of an IVIVC in the development of ER dosage forms.[2]

16.2 DEVELOPMENT AND ASSESSMENT OF AN IVIVC

The regulatory guidance on IVIVC of ER oral dosage forms issued by the FDA in 1997 provides a comprehensive scientific framework and regulatory guideline to IVIVC model development, evaluation, and applications. In general, establishing an IVIVC consists of (1) study design, (2) model building, and (3) model validation based on an appropriate statistical assessment.

16.2.1 Study design and general considerations

Development of an IVIVC requires in vitro and in vivo data of formulations with varying in vitro release rates and corresponding in vivo differences. These data may come from studies at the early or late stage of product development, such as bioavailability studies conducted in the formulation screening stage or an in vivo study specifically designed to explore IVIVC.[11,30,31] The in vitro release rates, as measured by percent dissolved for each formulation studied, should differ adequately (eg, by 10%).[2]

To obtain useful data for IVIVC, discriminating dissolution methodology is essential. Based on the FDA

guidance,[2] in vitro data are preferably generated in an aqueous medium using USP apparatus I (basket) or II (paddle), operating within an appropriate range of rotation speeds (eg, 50–100 rpm). In other cases, USP apparatus III (reciprocating cylinder) or IV (flow-through cell) may also be used. Generally, any in vitro test method may be used to obtain the dissolution characteristics of the dosage forms as long as it is shown to be predictive of the in vivo performance. The dissolution profiles of at least 12 individual dosage units should be determined for IVIVC purposes. The coefficient of variation (CV) for the mean dissolution profiles of a single batch should be less than 20% at early time points and less than 10% at other time points.

According to the FDA guidance,[2] bioavailability studies for IVIVC development should be performed in humans with enough subjects in order to adequately characterize the absorption profiles of the drug product. Although crossover studies are preferred, parallel studies or cross-study analyses are also acceptable. The latter may involve normalization with a common reference treatment. The reference product in developing an IVIVC may be an intravenous solution, an aqueous oral solution, or an immediate-release product of the drug. In addition, IVIVCs are usually developed in the fasted state. When a drug is not tolerated in the fasted state, studies may be conducted in the fed state.

16.2.2 IVIVC modeling

The principles and methodologies of IVIVC modeling and assessment have been extensively addressed and reviewed in the literature.[32–34] Developing an IVIVC model begins with understanding the following mathematical principles for characterizing in vivo drug release/absorption profiles or parameters associated with different types of IVIVC.

16.2.2.1 Convolution and deconvolution approaches used in Level A correlation

Convolution and deconvolution methods are essential tools for establishing Level A IVIVC. Convolution is a model-independent method based on linear system theory.

A linear system has the property that the response to a linear combination of inputs is the same linear combination of the individual responses (superposition). If the input is shifted in time by some amount, and the output is simply shifted by the same amount, such a system that is not sensitive to the time origin is known as a linear time-invariant (LTI) system.[35]

Once the impulse response function of a LTI system (ie, the way the system responds to a unit impulse) is measured, how the system will respond to any other possible inputs can be predicted in principle. This is because (1) the inputs to the system can be decomposed as a linear combination of some basic inputs, and (2) responses (or outputs) can be constructed as the same linear combination of the responses to each of the basic inputs in a wide variety of ways as illustrated in Fig. 16.1.

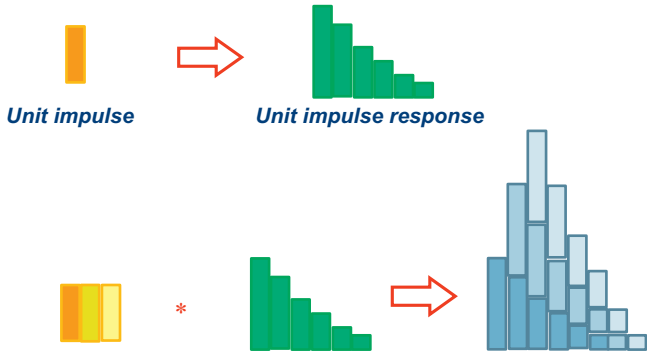

FIGURE 16.1 Illustration of input-response relationship of a LTI system (* denotes the convolution operation).

In pharmaceutical applications, drug disposition in the body is considered an LTI system. One of the measurable responses to the drug input (absorption) would be the plasma concentration-time profile. The response to an instantaneous (impulse) input would be the plasma concentration-time profile of following an intravenous bolus injection that is unique to individual drug molecules. Therefore, through applying the superposition principle of an LTI system in the study of the drug absorption process, a response, $C(t)$, to an arbitrary input, $f(t)$, of the system can be obtained using the following convolution integral[36]:

$$C(t) = f(t)^{*}C_{\delta}(t) = \int_{0}^{\infty} C_{\delta}(t-\tau)f(\tau)d\tau \qquad (16.1)$$

where $C_{\delta}(t)$ is the unit impulse response (UIR) that defines the characteristic of the system. It is the response of the system to an instantaneous unit input, usually attainable from an IV bolus or oral solution. By the same principle, $f(t)$ can be obtained by deconvolution, the inverse operation of convolution. Their applications in IVIVC are illustrated in Fig. 16.2, and representative systems are provided in Table 16.1. The definition of a system is flexible and is determined by the nature of the time functions involved.[37] Depending on the specific $C_{\delta}(t)$ and input responses used to define a system, $f(t)$ obtained by deconvolution in IVIVC may represent the dissolution process, absorption process, or the combined processes of the two.

In exploring IVIVC, Level A correlation is usually estimated by a two-stage procedure, that is, deconvolution

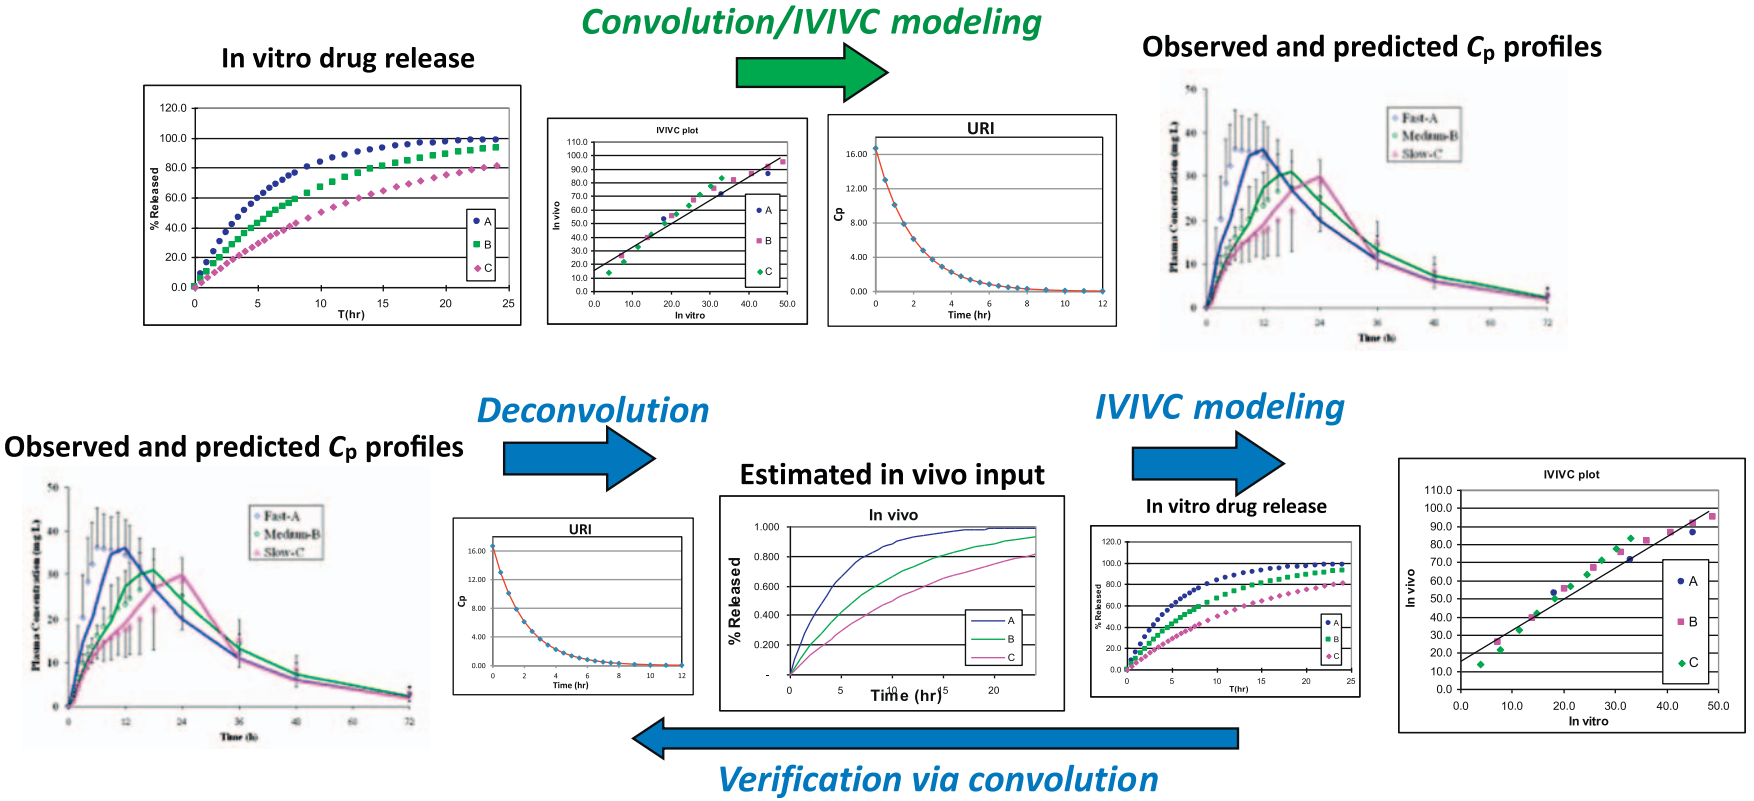

FIGURE 16.2 Illustration of convolution and deconvolution in IVIVC development.

TABLE 16.1 Illustration of System Definitions for Oral Administration

Case	Unit impulse response $C_\delta(t)$	Input response $C(t)$	Input function $f(t)$
I	Plasma level profile of IV bolus 	Plasma level profile of oral solution 	Absorption in the GIT II	Plasma level profile of IV bolus 	Plasma level profile of oral solid dosage form 	Dissolution and absorption in the GIT III	Plasma level profile of oral solution (or IR dosage form as an approximation) 	Plasma level profile of oral solid dosage form 	Dissolution in the GIT 
followed by correlating the fraction dissolved in vitro with the fraction released or absorbed in vivo. It may also be evaluated via a single-stage procedure, that is, a direct comparison of the observed with the predicted plasma concentration-time profiles obtained by convolution of the in vitro data and UIR. According to Eq. (16.1), the in vitro drug release and the in vivo input (release/absorption) estimated by deconvolution of the UIR with the observed plasma data are either directly superimposable or may be made to be superimposable by the use of a scaling factor when a 1:1 IVIVC exists. Similarly, the plasma concentration profile observed following oral administration should be in good agreement with that obtained by convolution of the UIR with the in vitro release data if there is a Level A IVIVC.

16.2.2.1.1 General solution

The exact solution of convolution or deconvolution can be obtained by operation of Laplace transform if each functional form is defined:

$$L\{C(t)\} = L\{(C_\delta {}^* f)(t)\} = L\{C_\delta(t)\}L\{f(t)\} \tag{16.2}$$

$$f(t) = L^{-1}\{\bar{f}(s)\} = L^{-1}\left\{\frac{\bar{c}(s)}{\bar{c}_\delta(s)}\right\} \tag{16.3}$$

where L and L^{-1} denote Laplace transform and inverse Laplace transform, respectively. Deconvolution methods include explicit (numerical point-area and midpoint methods, least squares curve fitting using polyexponential, polynomial, spline functions) and implicit methods (prescribed function or deconvolution via convolution).[38–50]

Since the disposition of most drugs can be described by polyexponentials,

$$C_\delta(t) = \sum_{i=1}^{n} A_i e^{-\alpha_i t} \tag{16.4}$$

the in vivo input function $f(t)$ can be obtained using Eq. (16.3). For example, in the case of single-exponential disposition ($n = 1$), $C_\delta(t) = A_1 e^{-\alpha_1 t}$, and hence, $f(t)$, the input rate, is given by [40]:

$$f(t) = \frac{[C'(t) + \alpha_1 C(t)]}{A_1} \tag{16.5}$$

The amount of drug absorbed from time 0 to t, $X_a(t)$, is then obtained by integration:

$$X_a(t) = \int_0^t f(t)dt = \frac{\left[C(t) + \alpha_1 \int_0^t C(t)dt\right]}{A_1} \qquad (16.6)$$

In cases where $C(t)$ or $f(t)$ cannot be fitted to an explicit function, numerical methods are used to deal with the raw data.

16.2.2.1.2 Numerical deconvolution

It is well recognized that classical linear compartmental kinetic models exhibit superposition linearity due to their origin in linear differential equations. Hence, linear systems analysis, especially in the form of numerical algorithms, is conceptually simple, and thus it is a useful tool for assessing absorption and IVIVC. Deconvolution using purely numerical algorithms has been used for evaluation of IVIVC since the 1960s.[51–53] The general process for deconvolution usually uses the basic principle of deconvolution through convolution (DTC) to determine the input function. The DTC method is an iterative procedure consisting of three steps. The input function is first defined by the selection of its initial parameter values followed by convolution with UIR function to calculate the response (drug concentrations). Subsequently, the agreement between the observed drug concentrations and the calculated according to preset objective function is evaluated quantitatively. The iteration continues until the objective function reaches the preset values. According to Eq. (16.1), the response, $C(t)$, can be obtained given the UIR, $C_\delta(t)$, and the input, $f(t)$. Since the UIR defines the characteristic of the system, a general assumption is that the UIR would be identical for different formulations of the same compound. Therefore, explicit UIR is not required to calculate the response for one formulation $[C(t)_1]$ when another formulation has input $[f(t)_2]$ and response $[C(t)_2]$ data available.

The general numerical algorithms for convolution and deconvolution are shown as:

Convolution $C(t) = f(t) * C_\delta(t)$

$$C(t)_1 = f(t)_1 * C_\delta(t)_1 * T$$
$$C(t)_2 = [f(t)_1 * C_\delta(t)_2 + f(t)_2 * C_\delta(t)_1] * T$$
$$C(t)_3 = [f(t)_1 * C_\delta(t)_3 + f(t)_2 * C_\delta(t)_2 + f(t)_3 * C_\delta(t)_1] * T$$
$$C(t)_n = [f(t)_1 * C_\delta(t)_n + f(t)_2 * C_\delta(t)_{n-1} + \cdots + f(t)_n * C_\delta(t)_1] * T$$

Deconvolution $f(t) = C(t) // C_\delta(t)$

$$f(t)_1 = (C(t)_1/T)/C_\delta(t)_1$$
$$f(t)_2 = (C(t)_2/T - f(t)_1 * C_\delta(t)_2)/C_\delta(t)_1$$
$$f(t)_3 = (C(t)_3/T - f(t)_1 * C_\delta(t)_3 - f(t)_2 * C_\delta(t)_2)/C_\delta(t)_1$$
$$f(t)_n = (C(t)_n/T - f(t)_1 * C_\delta(t)_n - f(t)_2 * C_\delta(t)_{n-1} - \cdots - f(t)_{n-1} * C_\delta(t)_2)/C_\delta(t)_1$$

Deconvolution $C_\delta(t) = C(t) // f(t)$

$$C_\delta(t)_1 = (C(t)_1/T)/f(t)_1$$
$$C_\delta(t)_2 = (C(t)_2/T - f(t)_2 * C_\delta(t)_1)/f(t)_1$$
$$C_\delta(t)_3 = (C(t)_3/T - f(t)_2 * C_\delta(t)_2 - f(t)_3 * C_\delta(t)_1)/f(t)_1$$
$$C_\delta(t)_n = (C(t)_n/T - f(t)_2 * C_\delta(t)_{n-1} - f(t)_3 * C_\delta(t)_{n-2} - \cdots - f(t)_n * C_\delta(t)_1)/f(t)_1$$

The algorithms use piecewise integration to decompose Eq. (16.1). For example, the top block (convolution) uses pieces of the input and UIR functions, which are in reversed positions in the interval $0 \ldots t$ by assuming that both functions, input and UIR, are known as staircase functions, and both are given with a regular and common time interval, T, which requires all raw data points to be consistent. If this condition is not met, interpolations/extrapolations are needed to make the data consistent with T. The top block algorithm is most convenient for numerical calculations, especially when the inverse equations are employed in deconvolution, as shown in the midblock and the bottom block. Only for extremely small time intervals, all function values may be used just as points of the relevant time function. Otherwise it is essential to interpret them consistently as either "point" or "areas" representative for each time interval. Langenbucher presented an example dataset, which was used by several authors[44,46,54] to illustrate the convolution/deconvolution algorithms.[39] It is reproduced in Table 16.2 for reference. The data include the UIR, input, and response where T is 0.5 or 1.0.

Based on the numerical algorithm, the data are used to illustrate the convolution and deconvolution calculations as shown in Table 16.3. The top block is the convolution calculation. The next two blocks are deconvolutions for calculating the inputs and UIR, respectively.

Although the numerical calculations are rather tedious, they are usually done by computer programs in actual applications. It is helpful to understand the underlying operations, especially when a customized program is needed. The commercial software commonly used to perform convolution and deconvolution calculations include IVIVC Toolkit for Phoenix, WinNonlin by Pharsight Corporation, and IVIVCPlus, an add-on module of GastroPlus by Simulations Plus, Inc. MS Excel has also been shown to be a useful tool for IVIVC applications.[55]

16.2.2.1.3 Model-dependent deconvolution

Two commonly used deconvolution methods for estimating the apparent in vivo drug absorption profiles following oral administration of a dosage form are Wagner–Nelson and Loo–Riegelman methods.[56] These are model-dependent approaches based on mass balance. The Wagner–Nelson equation is derived from

TABLE 16.2 An Example for the UIR, Input, and Response

Time (h)	UIR			Input				Response
	$C_\delta(t)$	$C_\delta(t)_{0.5}$	$C_\delta(t)_{1.0}$	$f(t)$	$f(t)_{0.5}$	$f(t)_{1.0}$	$\int f(t)dt$	$C(t)$

a one-compartment model and the mass balance, $X_a = X_t + X_e$, where X_a, X_t, and X_e are amounts of drug absorbed, in the body and eliminated at time t, respectively. By derivation, the amount of drug absorbed up to time T, $(X_a)_T$, is given by: $(Xa)_T = VC_T + kV\int_0^T Ctdt$, where V is the volume of central compartment, C_T is concentration of drug in the central compartment at time T, and k is the first-order elimination rate constant. In the study of IVIVC, this is often expressed in terms of fraction (F) of the dose (D) absorbed for comparison with fraction released in vitro:

$$F_a(T) = \frac{(Xa)_T}{(Xa)_\infty} = \frac{C + k\int_0^T Ctdt}{k\int_0^\infty Ctdt} \tag{16.7}$$

where $F_a(T)$ or FD is the fraction of the bioavailable drug absorbed at time T. It should be noted that Eq. (16.7) is identical to Eq. (16.6). Therefore, the Wagner–Nelson method represents a special case of deconvolution with a single-exponential disposition. When intravenous data are not available, the apparent in vivo fractional absorption profile can be obtained by using terminal phase elimination rate constant, k, and partial areas under the plasma concentration curve using Eq. (16.7). However, it should be pointed out that: (1) k value should be derived from the true elimination phase, which may be difficult for drugs with a prolonged absorption phase and/or long half-life; and (2) only apparent absorption is estimated using this method.

The approximate equation used in absorption analysis for the two-compartment model was first published by Loo and Riegelman in 1968.[57] Wagner published an Exact Loo–Riegelman method for a multicompartment model in 1983.[58] It is a general equation for the absorption analysis of one- to three-compartment models. It requires IV data for the calculation of absorption profiles. For biexponential disposition, mass balance leads to: $(X_a)_T = X_c + X_p + X_e$, where X_c and X_p are amounts of a drug in the central and peripheral compartments at time T, respectively. By derivation,[58] $(X_a)_T$ can be determined:

$$\frac{(Xa)_T}{Vc} = C_T + k_{12}e^{-k_{21}T}\int_0^T C_t e^{-k_{21}t}dt + k_{10}\int_0^T C_t dt \tag{16.8}$$

where k_{12}, k_{21}, and k_{10} are the microconstants that define the rates of transport between compartments. On the basis of mass balance, $(X_a)_T = X_c + Xp_1 + Xp_2 + X_e$, a similar equation can be derived for triexponential disposition. The corresponding Exact Loo–Riegelman equations are given as:

$$\frac{(Xa)_T}{Vc} = C_T + k_{12}e^{-k_{21}T}\int_0^T C_t e^{-k_{21}t}dt + k_{13}e^{-k_{31}T}\int_0^T C_t e^{-k_{31}t}dt + k_{10}\int_0^T C_t dt \tag{16.9}$$

It can be shown that the Loo–Riegelman method is also a special case of deconvolution where in vivo disposition is described by two or three exponentials.[50] The theoretical and practical aspects of absorption analysis using model-dependent approaches have been thoroughly discussed by Wagner.[56]

16.2.2.2 *Mean time parameters used in Level B correlation*

Level B correlation is based on correlating mean time parameters that characterize the in vitro and in vivo time courses, for example, the in vitro or in vivo mean dissolution time (MDT) and in vivo MRT. Mean time parameters have been commonly utilized in pharmacokinetic studies and used to describe in vitro release. They are useful in studying specific models as well as less differentiated, more general system models. Many important concepts, definitions, and computations on this subject have been thoroughly discussed by Veng-Pedersen[59] and Podczeck.[60]

16.2.2.2.1 In vivo parameters

By definition, MRT is the average total time a drug molecule spends in the introduced kinetic space. It depends on the site of input and the site of elimination. When the elimination of the molecule follows first-order kinetics, its MRT can be expressed by[59]:

$$\mathrm{MRT} = \frac{\int_0^\infty tCtdt}{\int_0^\infty Ctdt} = \frac{\mathrm{AUMC}}{\mathrm{AUC}} \tag{16.10}$$

where AUMC is area under the moment curve. Estimates for MRT can be calculated by fitting $C(t)$ to a polyexponential equation followed by integration or by using trapezoidal rules.

For noninstantaneous input into a kinetic space, such as oral absorption, the MRT estimated from extravascular data includes a contribution of the mean transit time for input, known as mean absorption time (MAT, or mean arrival time, or mean input time).[59]

The MAT of drug molecules represents the average time taken to arrive in that space, and it can be estimated as:

$$\mathrm{MAT} = \frac{\int_0^\infty t f_{\mathrm{in}}(t)dt}{\int_0^\infty f_{\mathrm{in}}(t)dt} = \frac{\mathrm{AUMC}}{\mathrm{AUC}} \tag{16.11}$$

where $f_{\mathrm{in}}(t)$ denotes an arbitrary rate of input into the kinetic space. For oral delivery, the MAT can be determined according to the equation:

$$\mathrm{MAT} = \mathrm{MRTpo} - \mathrm{MRTiv} \tag{16.12}$$

The term MAT thus obtained represents the mean transit time involved in apparent absorption process in the gastrointestinal (GI) tract. When the formulation contains a solid drug, the MAT includes in vivo dissolution as well as absorption. If data of the same drug given in a solution state are available, the in vivo MDT can be estimated by:

$$\mathrm{MDT}_{\mathrm{solid}} = \mathrm{MAT}_{\mathrm{solid}} - \mathrm{MAT}_{\mathrm{soln}} = \mathrm{MRT}_{\mathrm{solid}} - \mathrm{MRT}_{\mathrm{soln}} \tag{16.13}$$

16.2.2.2.2 In vitro parameters

The measured amount of a drug substance in a cumulative-release profile can be considered as a probability that describes the time of residence of the drug substance in the dosage form. Therefore, a dissolution profile may be regarded as the distribution function of the residence times of each drug molecule in the formulation.[49] By definition, the MDT is the arithmetic mean value of any dissolution profile. If the amount of the drug remaining in the formulation is plotted as a function of time, the arithmetic mean value of the residence profile is the MRT of the drug molecules in the dosage form.

The techniques that are used to calculate MDT or MRT can be divided into model-independent (pragmatic plane geometry and prospective area) and model-dependent methods (eg, polyexponential, Weibull, and overlapping parabolic integration).[49] In general, model-independent approaches are used when release kinetics are unknown. These methods are based on area calculations from the amount released at various times. The following simple method is often used to determine the MDT and MRT using trapezoidal rules[49]:

$$\mathrm{MDT} = \frac{\int_0^\infty (M_{\max} - M(t))dt}{M_{\max}} = \frac{\mathrm{ABC}}{M_{\max}} \tag{16.14}$$

$$\mathrm{MRT} = \frac{\int_0^\infty tA(t)dt}{\int_0^\infty A(t)dt} \tag{16.15}$$

where ABC is the area between the drug dissolution curve and its asymptote. $A(t)$ is the amount of drug remaining in the dosage form at time t. $M(t)$ and $M_{\max}$ are the amount of drug released at time t and the maximal amount released, respectively. The model-dependent methods are based on the derived parameters of functions that describe the release profiles. It should be noted that one important source of errors in calculations comes from the often incomplete release. The calculation of the moments in such case is based on the maximum drug release. For systems that have a complete drug release, the size of errors depends on the number of data points and the curve shape.[49]

16.2.2.3 Summary parameters used in Level C correlation

The extent and rate of drug release from a dosage form are often characterized by one or more of the single measurements (eg, Q_{60}, $T_{50\%}$, or $T_{85\%}$), particularly when there are not enough data points available to define the time functions of the profiles, or there are simply no suitable models that describe the dissolution curves. These parameters are most often obtained either directly from the dissolution measurements or by interpolation. Although they do not adequately characterize the whole dissolution process, they are utilized in quality control and in Level C correlation studies. The in vivo parameters used to correlate with the in vitro parameters are bioavailability parameters reflecting the rate and extent of absorption (eg, AUC and $C_{\max}$).

16.2.2.4 Establishment of a Level A IVIVC model

Establishing an IVIVC model requires in vitro data from formulations with different release rates (eg, fast, medium, and slow) and a discriminating in vitro test methodology. The corresponding in vivo response can be plasma concentrations or the amount of drug released and/or absorbed in vivo. The latter is obtained from the observed plasma concentration-time curve by deconvolution. There are advantages and disadvantages for either type of response variable. When plasma concentration is used as a response variable (single-stage approach), the link between the in vitro dissolution profile with the in vivo plasma concentration profile has clear clinical relevance because many pharmacokinetic parameters such as $C_{\max}$, $T_{\max}$, and

AUC are directly derived from the plasma concentration-time profile. Using the amount of drug released/absorbed as a response variable (two-stage approach) is intuitively straightforward because the in vitro and in vivo parameters are directly compared.

16.2.2.4.1 Two-stage approach

A deconvolution-based IVIVC model is established using a two-stage approach that involves an estimation of the in vivo release/absorption profile from the plasma concentration-time data using an appropriate deconvolution technique (eg, Wagner–Nelson, numerical deconvolution) for each formulation. Subsequently, the calculated in vivo percent absorbed or released is correlated with the percent released in vitro, as illustrated in Fig. 16.3 using a basic linear model with intercept (a) and slope (b):

$$(\%\ \text{absorbed})_{\text{in vivo}} = a + b(\%\ \text{released})_{\text{in vitro}} \qquad (16.16)$$

A slope closer to one indicates a 1:1 correlation, and a negative intercept implies that the in vivo process lags behind the in vitro dissolution. A positive intercept has no clear physiological meaning. It can be a result of relatively high variability or curvature at the early time points. When the in vitro data are not in the same time scale as the in vivo absorption, it is usually necessary to incorporate a scaling factor, such as time-shifting and time-scaling parameters, within the model. Nonlinear models, while uncommon, may also be appropriate.[13] The two-stage approach is the most frequently used in building IVIVC models.

For an IVIVC with a two-stage approach, an important aspect is to find the relationship between the in vitro dissolution and in vivo dissolution/absorption profiles. The general strategy is to use scaling and/or shifting or have the time scaled and shifted to match the in vitro and in vivo profiles. In the software commonly used, such as Winnonlin Phoenix, the following models are built in.

A. Fabs = Diss(Tvivo)
B. Fabs = AbsScale * Diss(Tscale * Tvivo)
C. Fabs = AbsScale * Diss(Tscale * Tvivo − Tshift)
D. Fabs = AbsScale * (Diss(Tscale * Tvivo − Tshift) − AbsBase)

Where Fabs is the in vivo absorption fraction; Diss() is a function for dissolution, dependent on the in vitro time in the parenthesis, which could be the same as in vivo time: Tvivo as in model A, the scaled in vivo time by Tscale as in B, or the in vivo time scaled by Tscale and shifted by Tshift as in C and D. In B, C, and D, to get the in vivo fraction (Fabs), the in vitro dissolution (Diss) has to be scaled by AbsScale. Before this scaling, in D, Diss would be corrected by baseline (AbsBase).

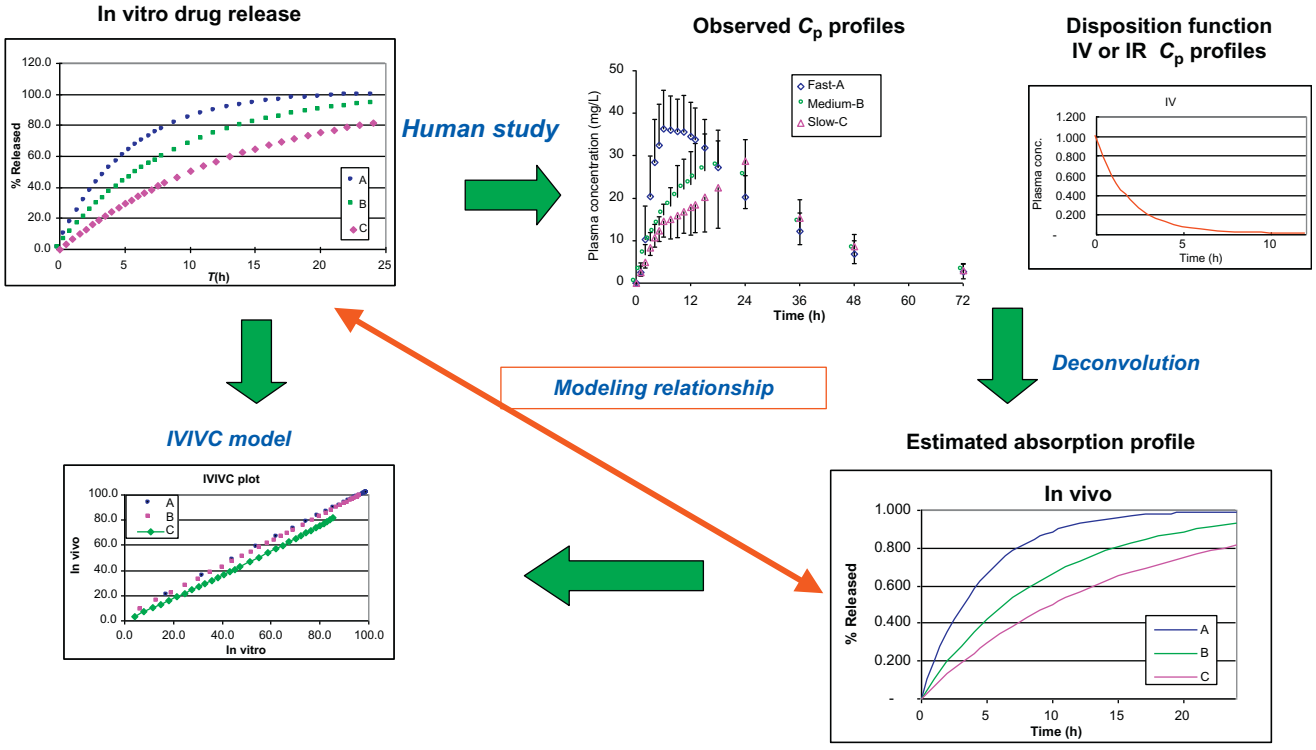

FIGURE 16.3 Illustration: building a Level A IVIVC model using the two-stage approach.

When all the scaling and shifting factors are included, it may be difficult to identify the appropriate model. To get an insight of the effect of these factors, a simulation study was performed in which the effects of three levels of each of the scaling (scale, AbsScale in B, C and D), baseline correction (shift, AbsBase in D), time scaling (Tscale), and time shifting (Tshift) were examined. The levels for the four parameters are provided below:

Level	Scale	Shift	Tscale	Tshift
1	0.3	−30	0.5	−5
2	1	0	1	0
3	1.5	30	2	5

There were a total of 81 possible combinations, and the results are shown in Fig. 16.4, where the values of the four factors are labeled in each panel.

Panel 41 shows case A, where the in vitro time is the same as in vivo time, resulting in a 1:1 relationship. The in vitro and in vivo profiles are superimposed. When the model is baseline corrected, the shape of the profiles does not change, and the profile just shifts up (or down), while scaling gets an n:1 relationship (n is dependent on the values of AbsScale). The time scaling and shifting lead to the inconsistent in vitro time and in vivo time and different shapes of the profiles. Time scaling and shifting are needed if the in vitro and in vivo profiles exhibit different rates and/or a difference in lag time.

In addition to these built-in models, the software usually allows the user to specify a customized model. As shown in Fig. 16.5, the relationship between the in vivo and in vitro profiles seems to follow a sigmoidal shape, and an E_{max} model could be used.

In summary, the patterns of in vitro and in vivo profiles may provide clues for an appropriate model. Plotting the in vitro and in vivo data at the same time points is helpful for recognition of the patterns in addition to the Levy plots.

16.2.2.4.2 Single-stage approach

An alternative modeling approach based on convolution can be utilized to directly predict the time course of plasma concentrations using Eq. (16.1) in a single step.[61] Based on the assumption of equal or similar release rates between in vitro and in vivo, the input rate, $f(t)$, is modeled as a function of the in vitro release data with or without time scaling to predict the in vivo plasma profiles by convolution with the dose-normalized plasma data from an IV or IR reference dose. The IVIVC is assessed and validated by statistically comparing the predicted with the observed plasma levels. This convolution-based modeling focuses on the ability to predict measured quantities rather than indirectly estimated in vivo fraction absorbed and/or released. Thus, the results are more readily evaluated in terms of the effect of in vitro release on in vivo performances, for example, AUC, $C_{max,}$ and duration above minimum effective concentrations. For instance, in using this approach to estimate the plasma concentrations from the in vitro data, a poly-exponential UIR with lag time could be used in the model as follows:

$$C_\delta(t) = \sum_{i=1}^{nex} A_i{}^* e^{-\alpha_{(i)}(t-t_{lag})} \tag{16.17}$$

where, nex is the number of exponential terms in the model, t_{lag} is the absorption lag time, and C_t is the plasma concentration at time t. The input rate may be modeled as a function of the in vitro cumulative amount dissolved. For example, Veng-Pedersen, et al. reported a scaled convolution-based IVIVC approach by which the dissolution rate curve was first obtained via differentiation of a monotonic quadratic spline fitted to the dissolution data. Using time and magnitude scaling, the dissolution curve was then mapped into a drug concentration curve via a convolution by a single exponential and the estimated UIR function. The model was tested by cross-validation and demonstrated to be predictive of the systemic drug concentration profiles from the in vitro release dissolution data using four different tablet formulations of carbamazepine.[62]

It should be noted that the single-stage approach is based on the assumption of an LTI relationship between the input (drug release) and the response (plasma concentrations). Multiple formulations with different release rates are usually used in establishing an IVIVC. If a significant fraction of the dose of the slow-releasing formulations is released beyond the site (s) of drug absorption (ie, truncated absorption), an overestimation of plasma concentrations can occur because Eq. 16.1 predicts the same dose-normalized AUC as the reference dose used to estimate $C_\delta(t)$.[62] To address the potential discrepancies between in vitro and in vivo release/absorption, Gillespie proposed an extended convolution-based IVIVC model using a function relating the cumulative amounts released or the release rate in vitro (x_{vitro}) to that in vivo (x_{vivo}), $x_{vivo} = f\ (x_{vitro})$. Thus, plasma concentrations of multiple ER formulations can be more accurately predicted by substituting $f(t)$ with x_{vivo} in Eq. (16.1) if there is an IVIVC. Selection of a specific functional form of x_{vivo} can be based on a mechanistically understanding of the in vitro/in vivo relationship or semiempirically based on the goodness of model fitting. Certain plausible relationships include linear, nonlinear, or

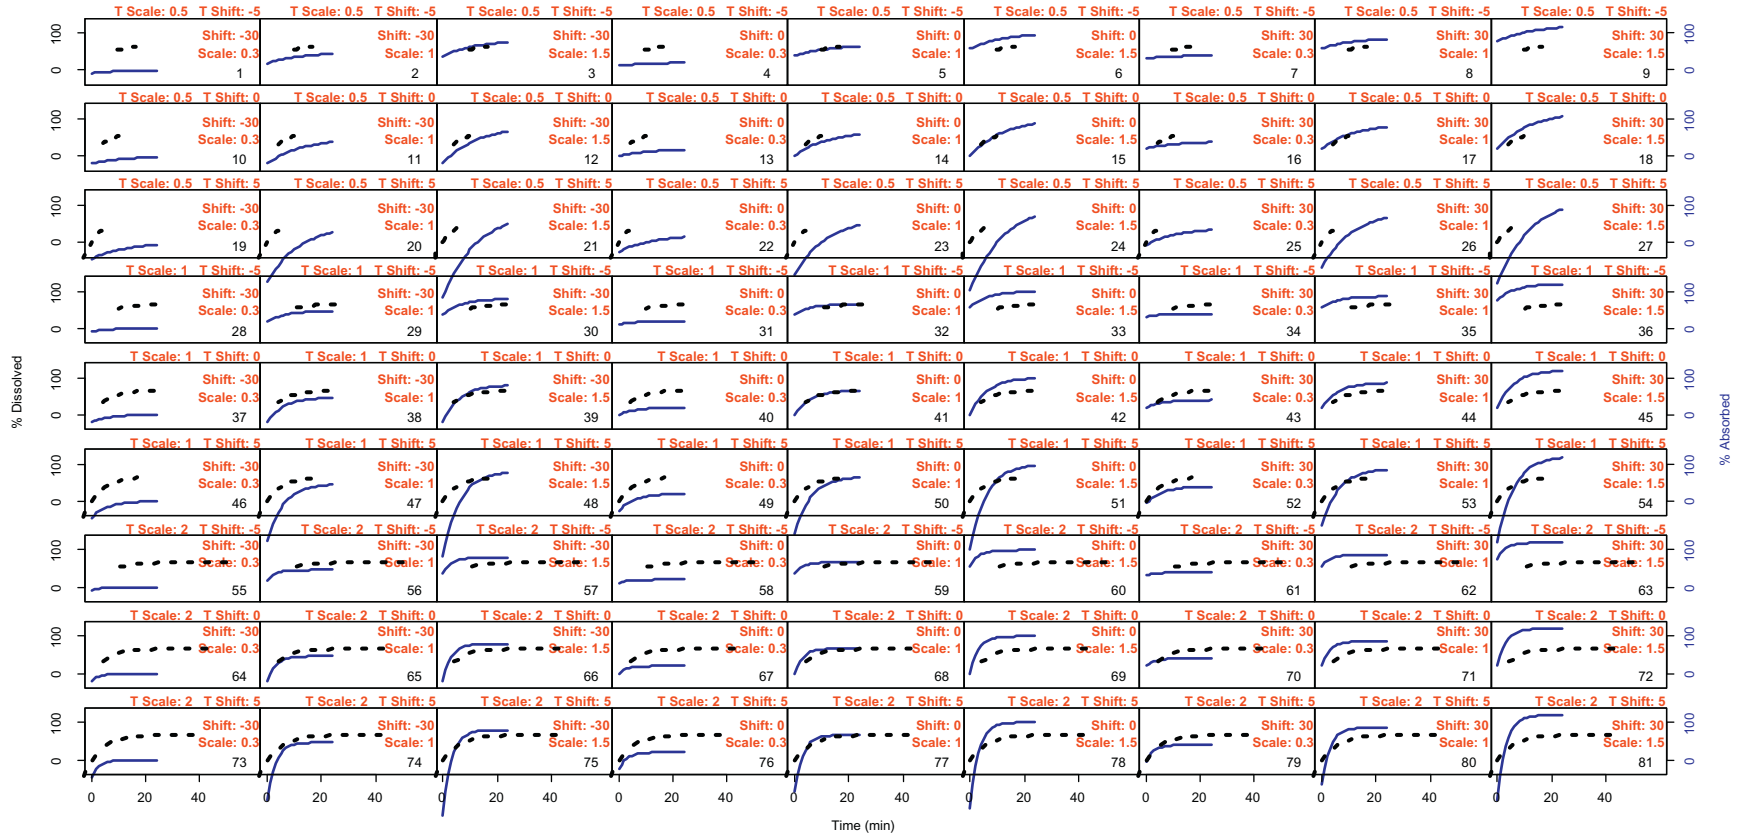

FIGURE 16.4 Simulated in vitro and in vivo profiles based on Model D Fabs = AbsScale * (Diss(Tscale *Tvivo − Tshift) − AbsBase) (dashed and solid lines are the in vitro dissolution and in vivo absorption profiles).

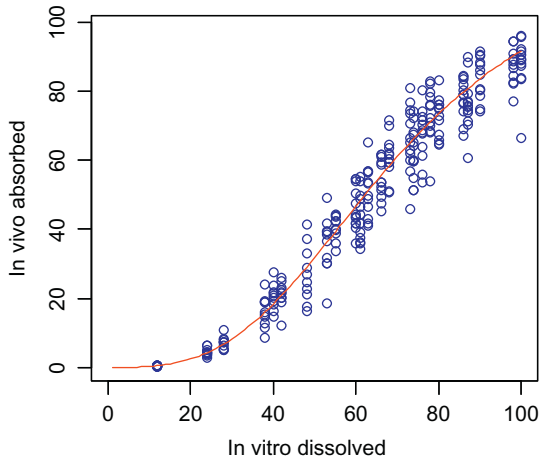

FIGURE 16.5 A nonlinear in vitro/in vivo relationship fit by E_{max} model.

time-variant functions; linear or nonlinear time-scaling for taking into account the effects of lag time; truncated absorption; or saturable presystemic metabolism.[62,63] For ER systems, the apparent absorption in vivo is limited by the drug release from the dosage form, of which the kinetics is determined by the system design. In many cases, the release kinetics can be described by one of the following models: zero-order, first-order, square root of time, or Peppas's exponent models.[64] Therefore, the parametric function, $C(t)$, describing the plasma concentrations of an ER dosage form can be defined via convolution of $C_\delta(t)$ with the input, $f(t)$, prescribed from the in vitro model according to Eq. (16.1). For instance, the functional form of $C(t)$ can first be obtained by convolution of a prescribed function of input (eg, first-order) with a known UIR. The unknown parameters remaining in the $C(t)$ equation are those from the prescribed input function, $f(t)$, which can then be solved by fitting the $C(t)$ equation to the observed plasma concentrations. The resulting $f(t)$ is compared with the observed in vitro data to evaluate IVIVC. This approach is also known as DTC, as discussed in the previous section.

In predicting $C(t)$ by convolution, data from an IV or oral solution is desirable because it provides an estimate of $C_\delta(t)$ independent of the ER data. However, such a reference dose is not always available, particularly for compounds having low aqueous solubility. Nevertheless, an estimation of $C(t)$ by convolution for evaluation of IVIVC is still possible using only data from ER formulations.[62] In such cases, the prescribed parametric functional forms of both $C_\delta(t)$ and $f(t)$ can be mechanistically or empirically selected and substituted into Eq. (16.1). The parameters of $C_\delta(t)$ are then estimated by fitting the overall convolution model to the plasma concentrations of ER formulations. Predictive performance of the IVIVC is evaluated by comparing the predicted and observed results. It should be pointed out that the ability of the model to predict changes of the in vivo plasma concentrations with varying release rates should be validated by separately or simultaneously fitting the data from multiple formulations. By doing so, a $C_\delta(t)$ function can be reliably defined. Thus, one of the most critical requirements of this approach is to use at least two ER formulations with different release rates in the assessment of IVIVC.[61]

While the use of the two-stage procedure is more widespread, the convolution approach has gained increased interest. O'Hara et al. compared odds and identity models that include a convolution step using the data sets of two different products and a nonlinear mixed-effects model fitting software to circumvent the unstable deconvolution problem of the two-stage approach.[65] Gaynor et al. used a simulation study to show the convolution modeling approach produces more accurate results in predicting the observed plasma concentration-time profile.[66] Jacobs et al. described an IVIVC model for an oral product consisting of IR and ER components of galantamine by combining the IR and ER pharmacokinetic profiles using a one-stage convolution-based method.[67] The average percentage prediction error (PE) indicated a good fit of the new model.

16.2.2.4.3 Compartmental and population approach

Both convolution- and deconvolution-based methods assume that the system being modeled is linear, but in practice, this is not always the case, as many drugs are eliminated by nonlinear (saturable) processes.[68–70] Therefore, a linear system approach can fail when the disposition of a drug substance falls within a nonlinear range. The extent of this failure depends on the magnitude of the nonlinearity observed.[71] To overcome problems resulting from nonlinear kinetics, the use of a method that can reliably accommodate the nonlinear characteristic is imperative. One of the effective methods to analyze nonlinear data is to use a compartmental approach. In a published study, the performance of a compartmental approach for nonlinear systems using the population approach for IVIVC modeling is evaluated.[72]

The population approach is to seek the sources and correlation of the variability in vivo, in vitro, and their relationship. The principles are similar to population pharmacokinetics (popPK), and understanding of the basic popPK concept will be greatly helpful. Fig. 16.6 introduces the concept of two types of variability considered by popPK. The solid circles are the data points for subject 1, from which a fit line is generated (dashed line). The open circles are the data points for all other

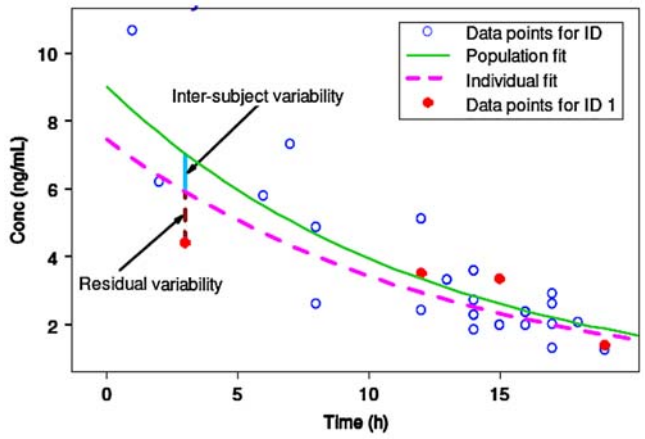

FIGURE 16.6 An illustration of popPK concept.

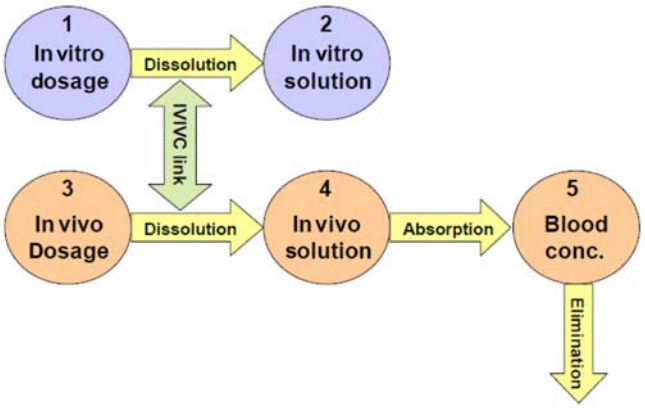

FIGURE 16.8 IVIVC based on a compartmental approach.

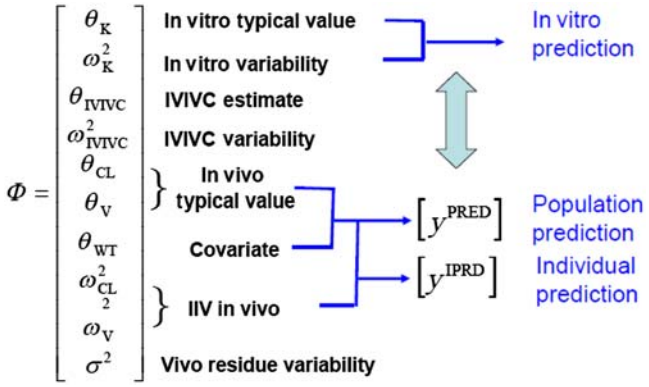

FIGURE 16.7 Various sources of variability considered in population IVIVC.

subjects. A population fit line (solid line) is generated from all the points (both solid and open circles). If one data point at a specific time (3.5 hours) for a specific subject (ID 1) is considered, conceptually, the PE is composed of two parts: one resulting from interindividual variability and another from residual variability.

For population IVIVC, not only the residue variability and the intersubject variability but also the in vitro variability and the variability of in vitro/in vivo correlation should be considered, as shown in Fig. 16.7. Clearance (CL) and volume distribution (V) are different from their typical values (θ_{CL} and θ_V) due to the fixed effects such as weight (θ_{WT}), age (θ_{AGE}), and gender (θ_{SEX}). They also can be affected by the intersubject variability (ω^2_{CL} and ω^2_V) and the residue variability (σ^2). In addition, the fixed effect (θ_K) and the random effect (ω^2_K) for in vitro (dissolution) performance and the fixed effect (θ_{IVIVC}) and the random effect (ω^2_{IVIVC}) for the correlation should be taken into consideration.

Fig. 16.8 shows how an IVIVC relating to in vitro and in vivo drug dissolution could be described in terms of compartments.[73] This technique retains most of the benefits of the convolution approach: in vitro fractions dissolved and in vivo plasma concentrations are modeled directly in a one-step process, and the IVIVC can be specified to incorporate random effects, time dependence, and scale factors as required by each particular set of data.

16.2.2.5 *Establishment of a Level C IVIVC model*

Building a Level C IVIVC model is rather straightforward. It involves correlating the amount dissolved at various time points with C_{max}, AUC, or other suitable bioavailability parameters. Data from at least three formulations of different dissolution rates are required for establishing a linear or nonlinear relationship between the in vitro and in vivo parameters because each data point of the correlation plot corresponds to only one formulation. A single-point Level C correlation may facilitate formulation development or allow a dissolution specification to be set at the specified time point. The information is generally insufficient for justifying a waiver of a bioequivalence study. A multiple-point Level C correlation may be useful to support a biowaiver if the correlation has been established over the entire dissolution profile with one or more bioavailability parameters of interest. A relationship should be demonstrated at each time point with the same parameter such that the effect on the in vivo performance of any change in dissolution can be assessed. When such a multiple Level C correlation is achievable, the development of a Level A correlation is often more likely. A multiple Level C correlation should be based on at least three dissolution time points covering the early, middle, and late stages of the dissolution profile.[2]

16.2.3 Evaluation of a correlation

To assure a useful and reliable Level A IVIVC, the FDA guidance requires that the model should be demonstrated consistently with two or more formulations with different release rates. Therefore, the first important step in evaluating the appropriateness of the model is to test whether a single correlation fits all tested formulations. One of the statistical assessment approaches is to compare the fit of a reduced model where all tested formulations are fitted to a single correlation line with that of a full model, where each formulation is fitted to a different correlation line.[33] If both models fit well, the IVIVC is considered validated. If the full model fits well, but the reduced model does not, or if the full model is statistically different from the reduced model at significance level of 0.05, the IVIVC becomes formulation dependent and, therefore, is invalid. It is noted that the time-scaling factor, if used, should also be the same for all formulations. Different time scales for each formulation indicate the absence of an IVIVC.[2]

Following the establishment of a Level A IVIVC model, it is necessary to demonstrate that prediction of the in vivo performance from the in vitro dissolution characteristics is accurate and consistent. The FDA guidance suggests evaluating the goodness of fit by measuring the prediction error (PE), that is, differences between the observed and the predicted values over a range of in vitro release rates. As illustrated in Fig. 16.9, determination of PE involves calculation of the in vivo absorption (input) profiles from the in vitro data using the established IVIVC model, followed by the prediction of the corresponding plasma concentration profiles via convolution. The guidance further elaborates approaches to validate the model internally and externally. Internal validation can be accomplished through measuring PE using data from the same study used to develop the IVIVC. The internal PE evaluates how well the model describes the data used to develop the IVIVC. It could be adopted for cases where the IVIVC was derived using two or more formulations with different release rates, providing the drug is not considered a narrow therapeutic index drug. The external validation approach requires a data set that was not used in the development of the IVIVC, such as formulations with a different release rate, formulations with minor manufacturing process changes, or a formulation from a different manufacturing batch obtained from a different study. It is desirable and affords greater confidence in the model.

The criteria used in the FDA guidance on IVIVC are as follows: For predicted C_{max} and AUC, the mean absolute percent prediction error (% PE) should not exceed 10%, and the PE for individual formulations should not exceed 15%. A PE of 10–20% indicates inconclusive predictability and illustrates the need for further study using additional data sets. For drugs

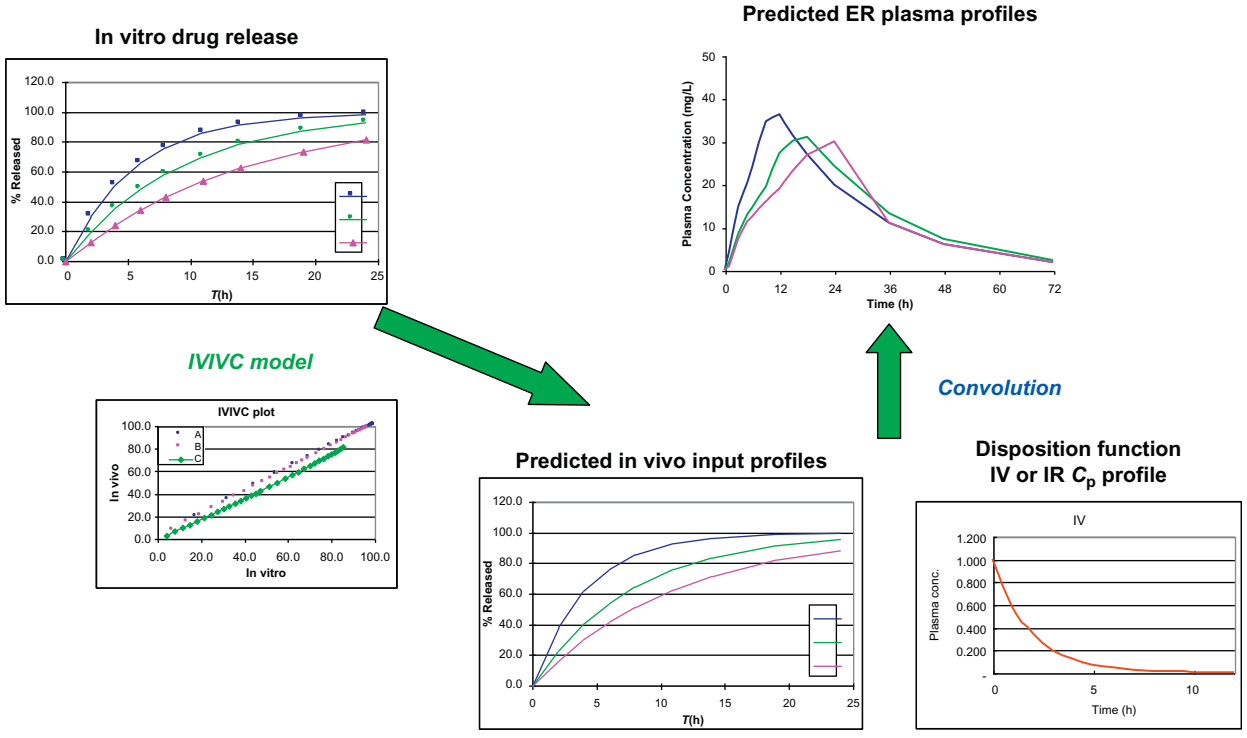

FIGURE 16.9 Illustration: prediction in IVIVC model validations and applications.

with a narrow therapeutic index, external validation is required despite acceptable internal validation, whereas internal validation is usually sufficient with nonnarrow therapeutic index drugs. In general, the less data available for the initial IVIVC development and evaluation of predictability, the more additional data may be needed to define completely the IVIVC's predictability. A combination of three or more formulations with different release rates is considered optimal.[2]

For Level C correlations, assessment of the predictability will depend on the type of application for which the correlation is to be used. The methods and criteria are the same as those for a Level A correlation. A recent example of the successful development and validation of a Level C IVIVC was reported by Kesisoglou et al. for suvorexant IR tablets based on amorphous solid dispersion.[74] Four different batches of tablets were manufactured using a hot-melt extrusion process and compressed at different tablet hardnesses to produce distinct dissolution profiles. These batches were evaluated in a relative bioavailability study in healthy volunteers followed by investigation of a relationship between dissolution and C_{max}. A validated multiple Level C IVIVC was developed between C_{max} and Q_{10}, Q_{15}, Q_{20}, Q_{30}, Q_{45} and the disintegration time, and it was used to set clinically relevant dissolution specification and in process control of tablet hardness.

16.3 CONSIDERATIONS IN IVIVC DEVELOPMENT

Defining a quantitative and reliable relationship between in vitro drug release and in vivo absorption is highly desired for the rational development, optimization, and evaluation of solid dosage forms and the manufacturing process. A validated IVIVC can significantly (1) increase the development efficiency by reducing the time and resources required for formulation and process development, scale-up, and optimization; (2) assure product quality by setting meaningful specifications; and (3) reduce regulatory burdens by using an in vitro test as a surrogate to in vivo bioavailability studies required for certain postapproval changes. Therefore, exploring and developing IVIVC where possible should be an important part of solid oral product development.

Since the early 1990s, extensive colloquiums and research publications have mainly focused on the basic principles, development methodology, modeling, evaluation, and applications of IVIVC and have laid a solid scientific foundation for regulatory guidance and decisions. Most of the relevant scientific discussions are based on the premise of availability of in vitro and in vivo information appropriate for establishing an IVIVC. However, it should be emphasized that modeling and statistical assessment is only one aspect of IVIVC development, and obtaining suitable in vitro and in vivo data is not a given. To achieve an IVIVC, at least two formulations that differ in the in vivo and in vitro performance should be available. In fact, many failed attempts in achieving an IVIVC for solid products can usually be attributed to a lack of a predictive in vitro test or an adequate in vivo difference between test formulations. Thus, it is crucial to understand how a drug's physicochemical and biopharmaceutical properties, delivery technology, and formulation design and their interplays with both the gastrointestinal tract (GIT) and the in vitro test methodology may impact in vitro and in vivo data.

16.3.1 In vivo absorption versus in vitro test considerations

In developing IVIVC, the in vitro parameter commonly utilized is drug release, which can be determined with precision under a controlled condition. It is a function of drug and dosage form characteristics and test methods and conditions. The in vivo response is usually the dissolution and absorption estimated from the availability of the drug in systemic circulation that typically has high variability. It is a function of a multitude of physicochemical, biopharmaceutical, and physiological variables, formulation, and their interactions. For test formulations that exhibit varying apparent in vivo absorption characteristics, the most critical element in establishing an IVIVC is the ability of in vitro tests to correlate quantitatively with the in vivo performance. To assess the challenges and the opportunities of developing a predictive and meaningful in vitro test, it is essential to first understand the absorption characteristics of the drug substance and the complexity of drug absorption from dosage forms in the GI tract.

16.3.1.1 Apparent drug absorption from the GI tract

The in vivo drug release and subsequent absorption from a solid product, particularly a modified-release dosage form, take place in one of the most complex environments where the interplays of the GI tract with the dosage forms as well as with intralumenally released drugs is highly dynamic. The process is known to be influenced by (1) drug property (solubility, ionization, stability, solid phase, lipophilicity, permeability, surface area, and wetting property); (2) dosage form design (dose, release mechanism, composition, type,

size and transit characteristics of the dose unit, sensitivity to shear force, and drug release location or duration); and (3) GI physiology and biology (motility, residence time, food, lumen contents, fluid volume, transport pathways and mechanism, enterohepatic recycling, effective permeability, surface area, metabolism, uptake and efflux transporters, and microflora). This type of information is highly valuable in anticipating and deciphering in vitro and in vivo data of the drug molecule and the dosage forms as related to the development of an IVIVC. For example, an apparently truncated absorption or a significantly decreased extent or rate observed with the slow-release formulations 4–5 hours post dosing may be related to one or more the following factors discussed in chapter "Rational Design of Oral Modified-Release Drug Delivery Systems" and literature[75–81]: lower apparent permeability in the large bowel due to inadequate lipophilicity or involvement of gut enzymes/transporters; high dose/solubility ratio; microbiotic degradation or decreased delivery rate of the formulations due to a change in lumenal environment. When assessing discrepancies between in vitro and in vivo data, delivery technology and formulation design, and release mechanism, in vitro test method and condition are important factors to consider. For instance, a dosage form generally experiences a low and well-controlled flow field and shear rate in a typical in vitro test, while it is known to be subjected to a myriad of physical forces in vivo, including pressure and shear stress from cyclic strain associated with villous motility and repetitive deformation engendered by peristaltic muscular contractions and relaxation of the intestinal wall.[82] As a result, it is not uncommon to observe differences between in vitro and in vivo behaviors for formulations that are sensitive to the release environment, particularly for hydrophilic matrix formulations containing a relatively high percentage of soluble components and/or a low percentage of low-viscosity-grade polymers. For example, an appreciably more rapid in vivo release and/or increased in vivo differentiation among formulations exhibiting different in vitro release rates can be attributed to a change of the release-control mechanisms from diffusion in vitro and erosion in vivo because a predominantly diffusion-controlled drug release in vitro is known to be less sensitive to variations in gel strength and matrix integrity.[11,12,83,84] On the other hand, decreased in vivo discrimination can be a result of a weaker and more environmentally sensitive gel, active pharmaceutical ingredient (API)–polymer interaction, or nonnegligible contribution of particle dissolution to the drug release in vivo due to a nonsink condition.[85] More detailed information on variables that may influence apparent absorption, including drug properties, biopharmaceutical factors, and product/process design, can be found in chapters "Oral Absorption Basics: Pathways and Physicochemical and Biological Factors Affecting Absorption," "Oral Drug Absorption: Evaluation and Prediction," "Predictive Biopharmaceutics and Pharmacokinetics: Modeling and Simulation," "Rational Design of Oral Modified-Release Drug Delivery Systems," and "Product and Process Development of Solid Oral Dosage Forms," respectively.

16.3.1.2 In vitro test method

Among various in vitro physicochemical tests, dissolution testing is one of the most important tools for product quality assessment, process control, and for assuring sameness after making formulation or process changes. While different dissolution tests have been applied to determine drug release, including the commonly used compendia methods (eg, basket, paddle, or reciprocating cylinder), the dissolution rate of a specific dosage form is, in many cases, an arbitrary parameter that often varies with the test methodology with respect to its relevance to the in vivo performance unless an IVIVC is demonstrated.[32,86] One of the main reasons is that none of the existing in vitro methods represents or mimics the highly dynamic and complex in vivo conditions and a wide range of variables involved in the drug absorption from solid dosage forms in the GI tract.

Over the years, the exploration and the development of various in vitro tests or models have been undertaken in an attempt to match or predict in vivo data and/or to simulate specific aspects of the GI condition.[87] These studies include designs ranging from simple and very complex setups and can be divided into three broad categories listed in Table 16.4. The common attempt made in these studies is to match in vivo data by adjusting the in vitro discrimination and release rate of different test formulations through altering test media, hydrodynamics, mixing, creating shear force, or dynamic flows. It should be noted that many tests are static and only capable of imitating very limited aspects of the complex in vivo conditions. For example, some test methods are focused on test medium, supersaturation/ precipitation, and/or apparatus variables. Other models based on multiple compartments or vessels are designed to integrate dissolution with digestion and absorption or simulate motility and successive dynamic processes occurring in the GI tract. The most complicated in vitro model is a multicompartment, dynamic, computer-controlled system designed to simulate the human stomach, small intestine (TIM-1), and large intestine (TIM-2), respectively.[88,89] The system is intended for gathering information about the effects of various simulated GI conditions on biopharmaceutical behavior of the API

TABLE 16.4 Types of In Vitro Drug Release Tests for Predicting In Vivo Performance

Type	Examples	Variables altered	References
Standard pharmacopoeial methods	USP I, II, III, or IV	Hydrodynamics; agitation; pH; ionic strength; surfactants; enzymes; additives (eg, bile salts, lecithin, fat, milk)	10,93–99
Modified pharmacopoeial methods	USP II + polystyrene beads	Hydrodynamics; shear stress; mechanical attrition; mixing; pH; test medium; release vs dissolution, etc.	100–112
	USP II + Stationary basket		
	USP II + two-phase		
	Milk/fat as test medium		
	FeSSIF/FaSSIF as test medium		
	Ex vivo intestinal fluid		
Complex models	Rotating dialysis cell	pH; food; mixing; motility; transit; digestion, secretion; microflora, permeation, etc.	8,86,113–119
	Flow-through cell drop method		
	Multicompartmental systems		

and dosage forms. However, setting up experiments and generating data are time consuming and extremely labor intensive. It is unsuitable for routine product quality control. In addition, literature reports of its utility and application in IVIVC development are still absent, although there are reports of its use in evaluating relative formulation performance.[90,91]

In summary, the most important aspect of IVIVC is to develop a predictive in vitro test. In practice, product quality and performance characterized by such a test is the drug release from the dosage forms. However, the state of the art has yet to allow the development of a universal predictive model independent of drug molecule and dosage form characteristics because physiological, physiochemical, and biological conditions of the GI tract and their interplays with the API and drug products in vivo are extremely complex[7,85,92] Nevertheless, it remains possible to develop tailored predictive tests for an individual API and/or product based on the understanding of the critical aspects of importance to in vivo absorption. For instance, when in vivo drug release is the dominant controlling factor in the rate of appearance of the drug in the blood, the focus on key API and formulation variables that affect the drug release and the corresponding in vitro test method is crucial in identification of a predictive test condition. Furthermore, continued pursuit of such a test not only can bring considerable benefit to product development and quality control, but it also will help advance scientific understanding and continued effort in developing new biopharmaceutical tools for improved prediction of in vivo drug absorption.

16.3.2 Drug and formulation considerations

The essential conditions for correlating in vitro dissolution with in vivo performance include (1) the apparent in vivo absorption is dissolution-rate limited; (2) in vitro drug release (dissolution and/or erosion) is the critical dosage form attributes; (3) test formulations exhibit different in vivo performances; (4) in vitro test is discriminating (IVIVR) and/or predictive (IVIVC) of in vivo performance. When these conditions are met, an IVIVC is deemed feasible. To develop an in vitro dissolution test that can be used to evaluate how changes in formulation and/or manufacturing processes may affect in vivo performance, integrated knowledge of drug properties, delivery technology, formulation, and biopharmaceutics is required to understand the specific challenges, choose the right biopharmaceutical tools, and design the appropriate studies.

16.3.2.1 Immediate-release dosage forms

It is generally accepted that an IVIVC is more difficult to achieve for IR dosage forms. With rapid drug release, the apparent drug absorption of the dosage form usually occurs in the upper small intestine where many factors other than dissolution are known to limit, affect, or contribute to the apparent absorption, as discussed previously. The short absorption phase, in most cases, is difficult to characterize, making Level A IVIVC modeling less likely than Level C or multiple Level C. Thus, the feasibility of an IVIVC is often drug and product dependent. For BCS class 2 drugs, of which dissolution is prolonged due to very low solubility and/or product and process characteristics, an

IVIVC is possible. One such example is the relatively slow-eroding polymer matrix of amorphous solid dispersions that contain a high level of carrier polymer(s) and are manufactured using a melt-extrusion process.[74,120] In the case of BCS class 1 drugs, an IVIVC is less likely unless the drug dissolution is significantly slowed due to formulation, processing, or the compound belongs to a borderline solubility classification. IVIVC is very rare for BCS class 3 drugs, of which gastric emptying, permeability, and transporters are typically involved in drug absorption. The opportunity for IVIVR or IVIVC may sometimes exist for BCS class 4 drugs, of which dissolution, permeability, and transporters can all influence the rate of in vivo absorption depending on the relative contributions of each factor and whether the low permeability classification is borderline or due to metabolism.[121] Challenges and various physicochemical, biopharmaceutical, and physiological factors that need to be considered in developing IVIVC and IVIVR of IR oral dosage forms have been reviewed extensively.[92,122] One of the major issues with assessing the feasibility of IVIVC using the BCS classification is that the boundaries for high solubility and permeability are set very conservatively.[92] As a result, each BCS class includes compounds with a broad range of properties and potentially different rate-limiting steps for absorption. For example, a low-solubility compound that narrowly misses the 90% fabs boundary would technically fall into BCS class 4, and yet it is very unlikely to have permeability-limited absorption. For such a compound, IVIVC remains possible. Similarly, certain BCS class 2 compounds are less likely to be candidates for developing an IVIVC.[92] Therefore, it is important to understand the specific characteristics of API and drug products, including the operating principles and manufacturing process. It should be noted that when a quantitative in vitro/in vivo relationship cannot be established or validated, an IVIVR that defines a dissolution range or space with demonstrated bioequivalence can also be useful in assuring acceptable in vivo performance via mapping in vitro and in vivo data of different formulations.[84,92,123]

16.3.2.2 *Extended-release (ER) dosage forms*

Compared to IR products, an IVIVC is, in general, more desirable and readily defined for ER solid dosage forms. In fact, it is often expected that an in vitro release test is predictive or has an in vivo rank order because drug input from the GI tract is by design controlled or modified by the drug release from the dosage form. With an ER dosage form, the apparent absorption takes place in the small intestine, ascending colon, and/or throughout the large intestine depending on the API properties and the product design.[124] A longer absorption phase over an extended period of time, in principle, renders it possible to develop Level A, B, C or Multiple Level C IVIVC. However, matching in vivo drug release remains challenging due to significant heterogeneity in permeability and lumenal environments (eg, pH, water, surface area and contents, transporters, and gut wall metabolism) in different segments of the digestive tract. Thus, the feasibility of an IVIVC remains dependent on the drug molecule, delivery technology, formulation design of the dosage forms, and their interactions with an in vitro test method and condition. Investigation of IVIVC for ER dosage forms should start with understanding drug properties, doses, and their relationship with the associated formulation technologies discussed in chapter "Rational Design of Oral Modified-Release Drug Delivery Systems." In general, the in vivo apparent absorption of ER products containing soluble compounds (eg, BCS class 1) is primarily limited by the drug release from a diffusion or osmotically controlled ER system with fewer significant confounding factors. Thus, an IVIVC is more likely. With BCS class 2 drugs, solubility-to-dose ratio, drug-release mechanism, release duration, and absorption pathways can significantly influence the in vitro and in vivo relationship. In addition, drug particle dissolution following its release (metering) from the dosage form may also play a significant role depending on the dose and solubility of the drug substance. A detailed discussion is provided in an example in the case study section of this chapter. IVIVC for a typical BCS class 3 or 4 drug is more difficult to obtain because of the various factors often involved in its apparent absorption from the GI tract, including low and variable membrane permeability, transporters, and regional dependency.[75,76,78,79,125] In fact, many of the drugs in BCS class 3 or 4 are either not feasible for ER development or exhibit very limited absorption windows,[76,78] such as ranitidine, atenolol, furosemide, erythromycin, cefazolin, amoxicillin, hydrochlorothiazide, methotrexate, acyclovir, and neomycin.

Dosage form behavior as related to IVIVC development depends on drug property, delivery technology, and formulation design. During the drug release from ER systems across different segments of the GI tract, the drug and dosage form are subject to a wide range of environments and conditions, such as varying surface area, absorption pathways, permeability, metabolism, mixing, secretion, lumen content, and amount of fluids. As a result, the in vivo absorption from ER may significantly vary with regions, making its estimation for IVIVC modeling unreliable due to deviations from the system definition of Case III in Table 16.1. In addition, in vitro and in vivo mechanisms may differ or change depending on the drug and formulation design. Increased variability of the

TABLE 16.5 Example of Extended-Release Systems and Food Effect on Bioavailability Parameters

Product	Dosage form	C_{max}	AUC	T_{max}
Theophylline	IR tablet	Decrease (30–50%)	No change	Increase

apparent absorption often observed with ER products may also be exacerbated by improper or less robust formulation designs. A review of literature indicates a wide range of in vivo performance and/or relationships with in vitro drug release for many drugs formulated using different or the same types of delivery technologies. For example, part of the in vivo behavior of a solid product can be inferred from the effect of food on its PK characteristics, that is, food effect. Food intake is known to directly and indirectly induce changes in the GI environment and conditions, including gastric emptying, intestinal motility, mixing, mechanical and shear stress, lumen content, pH, viscosity, ionic strength, osmolality, secretions (bile salts and digestive enzymes), and the activity or capacity of metabolic enzymes and transporters.[27] There is no general in vitro or animal model that is predictive of the effect of such changes on drug absorption. However, the potential impact of these changes on the in vivo performance may be used as an indirect gauge for evaluation of the robustness of an ER solid product in IVIVC development. A survey of food effect on AUC and C_{max} of 47 selected marketed ER products[126] shows that out of 32 soluble APIs, seven exhibit food effect on AUC and eight on C_{max}, while among 15 insoluble APIs, six exhibit food effect on AUC and 14 on C_{max}. Four out of seven osmotic pump products displayed food effect on AUC or C_{max}. Table 16.5 shows ER products of two well-known BCS class 1 drugs and their food effect.[127] It is evident that both ER technology and formulation play a significant role in how a product performs in the GI tract. Therefore, the opportunity and success of developing an IVIVC of ER dosage forms depends on individual APIs as well as the delivery systems and the formulation design.

TABLE 16.6 Common Extended-Release Systems and IVIVC

ER system	Characteristics
Matrix	• In vitro release sensitive to in vitro test conditions. • In vivo results depend on individual drugs and formulation design. • Hydrophilic matrix: Gel strength and system integrity also affect rate and mechanism of drug release in vivo. • Possible to alter in vitro test condition for obtaining IVIVC.
Reservoir	• In vitro release typically sensitive to in vitro test conditions. • In vivo results depend on individual drugs and formulation design. • Possible to adjust test condition for obtaining IVIVC.
Osmotic pump	• In vitro release generally insensitive to test conditions. • In vivo results depend on individual drugs. • Higher probability to obtain IVIVC. • Lack of flexibility to adjust test condition to match in vivo performance.

Table 16.6 is a comparison of three broad types of ER drug delivery systems discussed in chapter "Rational Design of Oral Modified-Release Drug Delivery Systems" with respect to the characteristics related to IVIVC. Among the three types of ER technologies, it is well known that the drug release from an osmotic system is generally insensitive to in vitro test conditions, thus offering a higher chance of matching the in vivo drug release. However, once the in vitro test fails to predict, it is much more difficult to achieve IVIVC via altering the in vitro drug release of an osmotic system. On the other hand, the drug release from the other

two types of systems (reservoir and matrix) is most often dependent on the drug property and in vitro test methodology and conditions, thus providing greater flexibility and opportunity of adjusting the test variables to match the in vitro data with the in vivo profiles. It should be pointed out that for matrix systems, the drug release rate and mechanism are affected by formulation as well as system strength and integrity. The latter is also a function of formulation design. As a result, different formulations of the same drug molecule may exhibit different sensitivity to the test variables, which, in turn, can influence their respective in vitro/in vivo relationships. Therefore, it is important to evaluate key formulation attributes and variables that influence the behavior of a specific dosage form.

16.4 IVIVC DEVELOPMENT APPROACH

The scientific values and significant patient and operational benefits of exploring and establishing an IVIVC in the development of solid dosage forms have been well recognized.

It is important to create an IVIVC strategy and define a rational and effective approach for integration into the product development lifecycle in the project planning stage prior to initiating any development activities.

16.4.1 General strategy and approach

Exploration of IVIVC may start in the early, mid, or late stage of product development depending on the objective and resources of a development program. For example, an IVIVC can be investigated through review and evaluation of the historical in vitro and in vivo data or initiation of an IVIVC study at a later stage of development. This type of retrospective development strategy is usually either driven by the regulatory expectation or due to a lack of awareness of IVIVC and its value in the rational development of a solid product. To fully realize its potential, IVIVC development should begin at the early stage and continue throughout the formulation development cycle if necessary. A prospective or concurrent development strategy requires an integrated evaluation of a drug substance, ER technology, in vitro test method, and IVIVC feasibility followed by incorporating an IVIVC investigation in the formulation screening and development. When the IVIVC is explored as a part of the first in vivo formulation screening studies or subsequent development studies, it can be used to aid in the development of a project timeline, planning of formulation/process studies, and scale-up activities. If an IVIVC exists, it is advantageous to establish the model and validate it if necessary at the early stage to facilitate and accelerate subsequent product development, thereby saving time and resources associated with certain necessary bioequivalence studies. It also helps set the development and regulatory strategy. If an IVIVC is unlikely, a different product development strategy will have to be defined, for example, by planning bioequivalence studies required to support process scale-up and/or certain formulation changes in the development of an ER dosage form.

In the first stage of developing an ER product, two or more prototype formulations with different in vitro release rates are usually tested in humans in order to identify a formulation with a predefined PK performance (see chapter: Rational Design of Oral Modified-Release Drug Delivery Systems). With properly designed formulations and an in vitro test, the study can offer the first opportunity to explore and develop an IVIVC concurrently. For example, to enhance the chance of success or gain insight into an IVIVR, it is essential to consider building similar robustness in the prototype formulations to ensure a consistent release-control mechanism in vivo. This can be achieved via formulation design and additional testing prior to the in vivo test in humans. The former can be accomplished by considering key formulation variables that are likely to affect in vivo performance such as type and level of the rate-controlling materials, properties and loading of the drug and fillers, operating principle, and size and shape of the delivery system in designing the prototypes. The latter may involve challenging the prototypes through testing the in vitro behaviors (integrity, rank order of drug release) under different conditions (apparatus, medium, type and intensity of mixing, physicochemical and mechanical stress) or studying in an appropriate animal model. To fully exploit the information and potential of such in vivo studies for IVIVC, it is also beneficial to select and remain focused on one type of delivery technology in dosage form development. As discussed in chapter "Rational Design of Oral Modified-Release Drug Delivery Systems," when testing prototype formulations with drug-release profiles that bracket the theoretical target absorption profile in vivo, different outcomes may be obtained depending on the API, formulation design, and in vitro test methodology. Fig. 16.10 illustrates four examples of possible in vitro/in vivo relationships of such a study. Unless a quantitative IVIVC is obtained in the first study (Example I), further investigation is required to pursue an IVIVC depending on the outcome. Generally, if little difference is found in the in vivo performance, the in vitro test is considered overdiscriminating (Example IV). It would still be useful to modify the

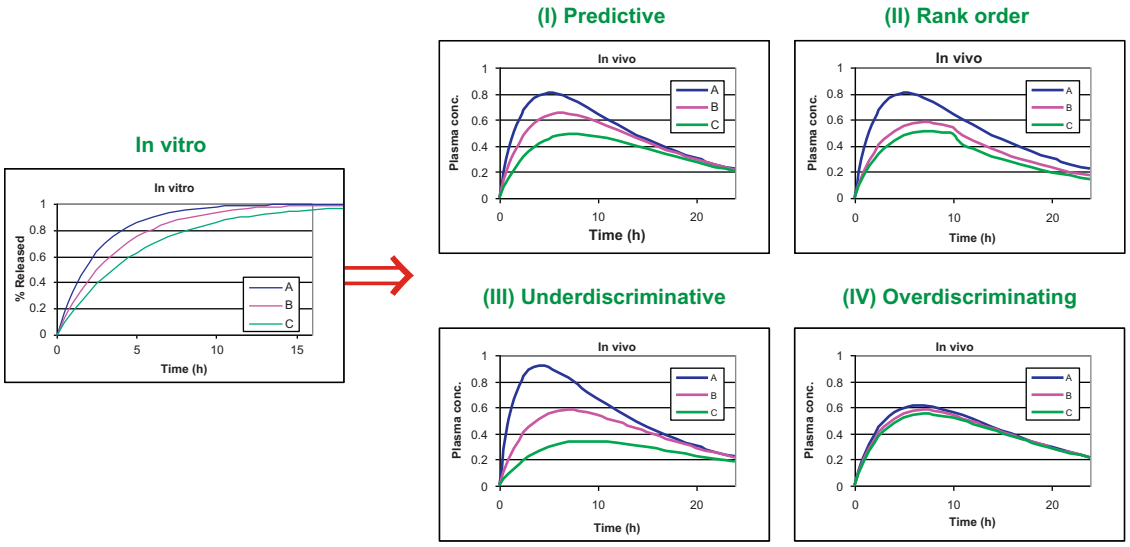

FIGURE 16.10 Examples illustrating possible outcome of the first bioavailability study of prototype ER formulations with varying in vitro release rates.

test conditions to achieve a similar in vitro performance for guiding formulation modifications in the subsequent in vivo studies. If the formulations show in vivo differences (rank order or underdiscriminating), the in vitro test conditions can be modified to correspond with the in vivo data for establishing an IVIVC. Adopting such an IVIVC strategy and making it a part of the dosage form development may take the following sequential steps:

1. Evaluate in vivo behaviors based on the understanding of drug's properties, dosage form, and their interplays with the GI tract.
2. Identify and investigate the mechanism/variables that likely influence or control both in vitro and apparent in vivo drug release.
3. Study test variables to identify condition(s) that:
   a. Differentiates between formulations with different in vivo behaviors.
   b. Deciphers the dosage form behavior and its relationship with the release-controlling variables (eg, critical formulation, processing parameters).
4. Design an in vitro test that matches in vivo performance (if feasible).
5. Establish, evaluate, and validate IVIVC.

It is evident that for formulations with varying PK profiles, developing an IVIVC relies heavily on the successful design of a discriminating in vitro test method.

16.4.2 Design of a predictive in vitro test

The first step in developing a predictive in vitro test is to ensure IVIVC feasibility, that is, that the drug release from the dosage form controls the drug input from the GI tract. While the in vitro data generated for an IVIVC are typically drug release, the estimated in vivo release or apparent absorption is the drug availability in vivo. As discussed previously, the latter is often a function of many other variables in addition to the drug release. Thus, the possibility of using an in vitro release test to predict the in vivo performance is drug and formulation dependent and should be explored on a case-by-case basis.

In the case of IR dosage form of which dissolution is limiting the rate of absorption (eg, certain BCS class 2 or 4 drugs), it is sometimes possible to develop dissolution tests for predicting differences in bioavailability among different formulations and dosing conditions. To achieve an a priori correlation, common approaches include altering the test apparatus or test conditions, some of which are described in Table 16.4. For example, to simulate the composition, volume, and hydrodynamics of the contents in the GI lumen, model compositions of the gastric and intestinal contents before and after meal intake were used as the dissolution media.[105] However, success as measured by meeting the rigorous IVIVC criteria for IR has been scarce, primarily because of the many confounding variables involved in apparent absorption in vivo.

In comparing in vivo with in vitro data of ER dosage forms, it is important to take into considerations a drug's properties, stability, and absorption pathways in relation to the effect of pH, transit time, location of drug release, food, ER technology utilized, and release-control mechanisms.[7] These types of integrated knowledge are essential in anticipating and evaluating the possible interplays of drug-GIT, formulation-GIT and

drug-formulation, and their impacts on the relationship between in vivo and in vivo data. While the results of an in vivo study are invariant, the evaluation of the API characteristics, delivery system, and formulation design can provide greater insight into the in vivo absorption behaviors to help assess IVIVC opportunity and develop a prognostic method.

In general, the observed difference between the in vivo apparent absorption or release mechanism and the in vitro data may be attributed to formulation factors (eg, robustness of the selected delivery technology or a particular composition), test method factors, and/or unique physicochemical and biopharmaceutical properties of the API (eg, low solubility, high dose, enterohepatic recycling, saturable metabolism, truncated absorption, effect of the absorbed drug or metabolite on the GI motility). Some of the drug-related factors can't be simulated by the in vitro test, but they can confound the deconvolution results or make the IR reference inappropriate as the UIR to estimate in vivo absorption if not taken into consideration.[33] For example, the in vivo absorption of the oxybutynin osmotic pump was found to be not only higher than that of the IR reference but also significantly longer (>24 hours) than the in vitro drug release (~15 hours) and the average GI residence time of solid dosage forms as well, resulting in a lack of IVIVC.[128] The former could be attributed to the reduced gut metabolism of the drug released in the lower bowel.[80] However, the latter observation was not understood because oxybutynin has neither known pharmacological effects on GI motility, such as opioid analgesics,[129] nor enterohepatic recycling. Wang et al. compared in vitro and in vivo data of a pulsatile release dosage form of methylphenidate (Ritalin LA). The double peaks were observed in plasma concentration-time profile results from two separate IR doses that were 4 hours apart.[130] This is likely a result of the favorable absorption properties combined with the low dose of methylphenidate. Slower absorption observed for the second phase can be attributed to the decreased in vivo dissolution rate of the second IR due to the changing drug-release environment in the lower bowel.

Sako et al.[131] investigated the effect of composition of a hydrophilic matrix on the in vivo release of acetaminophen. Three formulations containing different fillers showed similar in vitro dissolution profiles using different agitation intensity but had considerable different in vivo performances (Fig. 16.11). The observed discrepancy was believed to result from the different gel strengths of the matrix systems. In developing an in vitro test that differentiates the formulation behaviors, the test method was modified by subjecting the tablets to mechanical stress after 1 hour of dissolution (shaking with glass beads for 10 minutes), which resulted in drug-release profiles similar to those in vivo. It should be mentioned that in addition to creating artificial shear and attrition,[13,131] other techniques that are useful to characterize gel microstructure, formation, and strength of a hydrophilic matrix system include magnetic resonance imaging (MRI) microscopy, confocal microscopy, rheometry, texture analyzer, dynamic mechanical analyzer (DMA), and increasing the ionic strength in the dissolution medium.[132–138]

For high dose-to-solubility ratio drug substances that undergo drug dissolution upon delivery (metering) from the ER device, changing the regional dissolution and absorption environment (eg, surface area, amount of water, motility, enzymes, and transporters) may become a significant factor affecting the apparent in vivo absorption, thus IVIVC. For example, a discrepancy between the in vitro and in vivo data of the nifedipine osmotic pump was believed to be a result of the inability of conventional in vitro tests to separate release (metering) from dissolution due to large volume of test medium used throughout testing.[139] Generally, the in vitro test can become overdiscriminative or underdiscriminative of the in vivo results when particle dissolution upon release from an ER system plays a role in absorption, especially if a significant portion of the dose is delivered in the lower bowel.

An additional challenge in exploring a predictive in vitro test for an insoluble compound such as nifedipine is that its extent of absorption also depends on the particle size (or dissolution rate) of the drug upon its release from ER system,[140] which is difficult to reflect using a conventional test method. Furthermore, the potential influence of the solid phase of an insoluble drug substance on in vitro dissolution and in vivo absorption may also complicate the in vitro and in vivo relationship. For example, solid phase transition that occurs in situ or results from precipitation during drug release[141,142] may impact the in vitro and in vivo drug release in a different manner. It should be noted that these types of differences may affect the validity of using an IR reference as the UIR to estimate in vivo absorption.[33]

In investigating IVIVC for dosage forms with more complex release profiles or containing more than one drug substance (eg, bimodal, pulsatile release, and fixed-dose combination), it is essential to take into consideration both the properties of individual actives and their release characteristics. Depending on the release design feature, separate test methods may sometimes be required to match the in vivo absorption of the individual drugs or one part of the profile. It is also possible that a predictive test can only be developed for one of the actives or a portion of the dose and release profiles. For example, for a bimodal release profile consisting of an IR followed by an ER or an ER followed by an IR delivery (Fig. 16.12), it may be feasible to develop an IVIVC for only one (ER) or both portions of the curve. However, special attention is required when developing IVIVC models for more complex MR dosage forms. In a recent paper, Qiu et al. used three model drugs to illustrate the importance of understanding drug properties and product design in establishing and evaluating IVIVC of bimodal MR products.[143] Directly modeling in vitro and in vivo data without first considering drug properties, design characteristics, release mechanisms involved, and product behaviors may lead to a misleading, erroneous outcome or incorrect conclusions in the development of an IVIVC. For products containing more than one drug with synchronized or divergent-release profiles, various IVIVC outcomes are possible depending on a drug's BCS class, biological properties, dose, and IR-to-ER ratio. In any case, a predictive test method will always be useful whether it is for one or both drugs, a portion or the entire absorption profile in setting dissolution specifications and guiding or justifying changes to part of the formulation and process of interest.

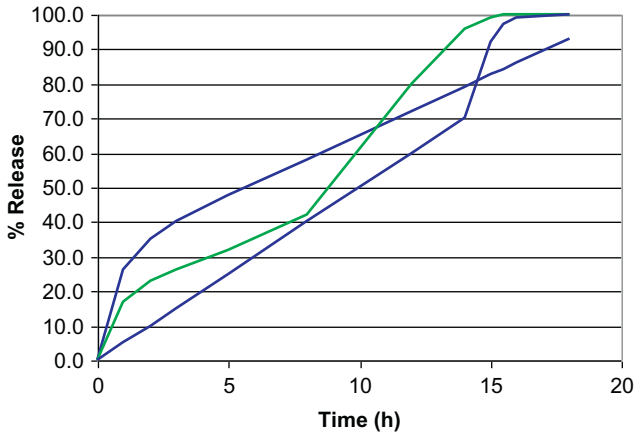

FIGURE 16.12 Illustration of bimodal drug release profiles.

In the method development process, the challenge frequently encountered is that the in vitro release not only differs from the in vivo release/absorption in rate and extent, but it may also exhibit a different release mechanism when a routine pharmacopoeial method is used (eg, USP II, 75 rpm, SIF). A general approach to developing an in vitro test for IVIVC requires identification of the mechanism that controls the in vivo drug release[7,144] For delivery systems that are sensitive to a release environment, the effects of test variables on release kinetics need to be investigated in order to understand how formulation variables and dosage form behaviors respond to environmental changes. In certain cases, formulations can be subject to more stressed conditions (eg, shear stress, high osmolality, ionic strength or agitation intensity, multiple apparatuses) to test robustness or to show difference. Subsequently, a qualitative or quantitative relationship between the drug release and key test variables may be established to guide the selection of a test condition that allows the in vitro data to match both the mechanism and the rates of in vivo release. To define this type of relationship, a well-planned experimental design based on understanding of the API, formulation, and their interplays with in vitro tests is more important than an attempt to simulate particular aspects of GI conditions without considering the specific issues associated with the formulation being studied. For example, switching to FaSSIF and/or FeSSIF media or a multicompartment dissolution system[118,145,146] is unlikely to resolve mismatch problems between in vitro and in vivo data related to a release mechanism change, gel strength, API-polymer interaction in vitro, impact of gut metabolism, or transporters or API on intestinal motility, as discussed previously.

Once an in vitro method that correlates with the in vivo absorption is established, its value as a quality control tool of a drug product is significantly enhanced. It serves as a tool to distinguish between acceptable and unacceptable drug products with respect to the in vivo performance. Lastly, it should be noted that a newly developed method cannot be

considered reliable and acceptable unless it has been validated and demonstrated to be predictive of different formulations with varying in vivo performance.

16.5 APPLICATIONS AND LIMITATIONS

The most important aspect of developing an IVIVC is to identify an in vitro test that can serve as an indicator of how a formulation will perform in vivo and how changes in formulation and/or processing may influence product performance. According to the FDA guidance on IVIVC for extended-release solid dosage forms,[2] a validated IVIVC can be used (1) for setting meaningful dissolution specifications to ensure product quality and in vivo performance and (2) for requesting a biowaiver so that the regulatory burdens, cost, and time associated with product development or postapproval changes can be significantly reduced.

16.5.1 Setting dissolution specifications

In vitro dissolution specifications are established to ensure batch-to-batch consistency and to differentiate between acceptable and unacceptable drug products, thus minimizing the possibility of releasing lots that might not have the desired in vivo performance. In general, dissolution behaviors of the clinical bioavailability batches are used to define the amount released at each time point.[1,2] Dissolution specification settings for IR products should be based on consideration of BCS classification and its ability discriminate with respect to changes in critical material, formulation, and process variables.[1,147] For ER products, challenges often arise in determining the acceptable variation around each time point for ER dosage forms. For new drug applications (NDAs) or abbreviated new drug applications (ANDAs), the specifications are based on the pivotal clinical batch or biobatch of a drug product. In the absence of an IVIVC, the range at any dissolution time point specification has to be within $\pm 10\%$ of the mean profile obtained from the biobatch. A deviation greater than 20% would be acceptable provided that the batches at the specification limits are bioequivalent.[1,2] For ER products, a minimum of three time points covering early, middle, and late stages of the profile are required, with dissolution of at least 80% at the last time point.

In setting dissolution specifications, a validated Level A IVIVC is most useful in ensuring that all lots within the specification limits are bioequivalent. In general, the convolution approach, as illustrated in Fig. 16.9, is preferred, and the specifications should be set on mean data using at least 12 dosage units. In determining the release limits, the dissolution curves defined by the upper and lower extremes established from the biobatch are convoluted to project the corresponding in vivo plasma concentration profiles. A maximum difference of 20% in the predicted C_{max} and AUC is allowed between lots with the fastest and slowest release rates.[2,148] Alternatively, an acceptable set of plasma profiles representing formulations with faster and slower release rates relative to the biobatch can be used to set dissolution specifications by deconvolution based on the principles illustrated in Fig. 16.3. These curves selected based on extremes of 20% difference in C_{max} and AUC are deconvoluted, and the resulting input curves are used to establish the upper and lower dissolution specification ranges at each time point via the IVIVC model.

In the case of Level C and Multiple Level C IVIVC, the specification ranges should be set at the correlation time point such that there is a maximum of 20% difference in the predicted AUC or C_{max}.[2] If the correlation involves more than one parameter, the one resulting in tighter limits should be used. In addition, drug release at the last time point should be at least 80%. Lake et al. reported an example of applying Level C IVIVC to set meaningful dissolution specifications using four carbamazepine IR tablets.[149] In cases where an IVIVC is absent or cannot pass validation criteria, it is still possible, though less optimally, to set a biorelevant specification using lots representing the upper and lower dissolution limits that have been shown to be bioequivalent to the clinical/bioavailability lots or to an appropriate reference standard. An example of establishing this type of biorelevant specification is provided in a case study of this chapter.

Although the general procedure and criteria for the establishment of dissolution specifications that ensure bioequivalence based on IVIVC have been proposed,[2,150,151] few discussions have centered on the detailed process and practical considerations in setting meaningful and realistic specification limits in product development. Elkoshi[152] described a procedure based on release rates that confines C_{max} and AUC values within any desired range to set the minimum range specifications for both zero-order and first-order release products. In reviewing the methods for setting dissolution specifications, Hayes et al.[153] evaluated the most commonly adopted deterministic interpretation approach; that is, those batches passing the in vitro specifications would be bioequivalent, and those failing the specifications would not be bioequivalent if tested in vivo. According to the authors, the deterministic interpretation may not be appropriate, and the conditional probability needs to be considered due to random variation. Through a computer simulation based on an IVIVC model, the conditional

probabilities are shown to depend on the choice of dissolution specifications. The authors further described a method for optimizing the dissolution specifications that take production into consideration. A practical procedure of using IVIVC to establish dissolution specification based on scientific, regulatory, and operation considerations is provided in the case study section of this chapter.

16.5.2 Supporting waiver of in vivo bioavailability study

In addition to serving as a quality control test, comparative dissolution tests have been used to waive bioequivalence or bioavailability studies required for both IR and MR solid dosage forms under certain circumstances. Regulatory requirement including scientific basis, approaches, and evaluation criteria associated with these biowaivers have been clearly laid out in various regulatory guidelines. According to the regulatory guidelines,[1,154–156] the biowaiver request for investigational new drugs (INDs), investigational medicinal product dossiers (IMPDs), NDAs, MAs, ANDAs, and postapproval changes of IR solid dosage forms should be based on the consideration of a drug's BCS class,[157] therapeutic index, and potential effect of excipients on bioavailability. The global regulations with respect to biowaivers for IR solid oral products in the USA, the EU, Japan and from the World Health Organization (WHO) were reviewed by Guptaa et al.[6] To stimulate discussion of biowaivers and methods, the focus group on BCS and biowaivers of the International Pharmaceutical Federation (FIP) to date have published scientific data and biowaiver justifications for a total of 45 BCS class 1-3 compounds in the Journal of Pharmaceutical Sciences,[158] although many of them have not been accepted by regulatory agencies. These drug substances include: acetaminophen, acetazolamide, acetylsalicylic acid, acyclovir, amitriptyline hydrochloride, amodiaquine, hydrochloride, atenolol, bisoprolol fumarate, chloroquine phosphate, chloroquine sulfate, chloroquine hydrochloride, cimetidine, ciprofloxacin hydrochloride, codeine phosphate, diclofenac potassium, diclofenac sodium, doxycycline hyclate, efavirenz, ethambutol dihydrochloride, fluconazole, furosemide, ibuprofen, isoniazid, ketoprofen, lamivudine, levetiracetam, levofloxacin, mefloquine hydrochloride, metoclopramide hydrochloride, metronidazole, nifedipine, piroxicam, prednisolone, prednisone, primaquine diphosphate, propranolol hydrochloride, pyrazinamide, quinidine sulfate, quinine sulfate, ranitidine hydrochloride, ribavirin, rifampicin, stavudine, verapamil hydrochloride, and zidovudine (azidothymidine).

For modified-release products, a dissolution test based on a validated IVIVC can be used for obtaining a waiver for demonstrating in vivo bioavailability often required for NDAs, ANDAs, scale-up, and postapproval changes.[2,159] The criteria for granting the biowaivers using IVIVC are (1) the difference in predicted means of C_{max} and AUC is no more than 20% from that of the reference product, (2) dissolution meets specifications. According to the FDA guidance, categories of biowaivers are also based on the therapeutic index of the drug, the extent of the validation performed on the developed IVIVC, and the dissolution characteristics of the formulation. For instance, for nonnarrow therapeutic index drugs, an IVIVC developed with two formulations can be used for a biowaiver in Level 3 manufacturing site changes and Level 3 nonrelease-controlling excipient changes defined in SUPAC Guidance for MR Solid Dosage Forms.[159] If an IVIVC is developed using three formulations, or two formulations with external validation, a biowaiver may include (1) Level 3 process changes, (2) complete removal or replacement of nonrelease-controlling excipients without affecting the release mechanism, (3) Level 3 changes in the release-controlling excipients, and (4) change of strength (lower than the highest strength).

16.5.3 Limitations and additional considerations

Limitations to the IVIVC methodology reside in the physicochemical, biological, and pharmacokinetic properties of the drug substance and the formulation design, as well as the methodology used to model, evaluate, and validate the IVIVC.

In the development of an IVIVC, the basic assumption of the linear system analysis is that the drug substance exhibits linear pharmacokinetic disposition. Thus, saturable absorption, absorption windows, rate-dependent absorption or rate-dependent presystemic metabolism, and enterohepatic recycling are important factors to consider when modeling and validating an IVIVC because they directly or indirectly result in deviation from the linear assumption.[12,160–163] In addition, an IVIVC should not be developed using plasma concentrations of racemate when there is stereoselective dissolution or absorption between the two enantiomers.[164] More importantly, the dissolution process should be the rate-limiting step in the absorption process, as discussed previously. In most cases, IVIVC models are being established using the average in vivo response, thus ignoring the intersubject and intrasubject variability. For drugs that have relatively high intersubject variability, it is important to take into account the intersubject and intrasubject variability in

constructing and evaluating the IVIVC model.[148,165,166] Cardot and Davit recently described some of the intricacies and possible traps related to the use of mean versus individual data, correction of formulations with different bioavailability, lag time and time scaling, the impact of intersubject and intrasubject variability, and the potential confounding effects of flip-flop kinetics. All of these factors must be considered to increase the chance of a successful IVIVC.[25] Lastly, the in vivo studies used for developing an IVIVC are conducted in healthy volunteers under a well-controlled environment. Factors that might affect the in vivo performance of the dosage form or physiology should also be considered,[167,168] such as food, disease state, age (pediatric and geriatric), and drug–drug or drug-GIT interactions, all of which can affect the GI motility and/or the GI transit time.
