The state-of-the-art is such that an IVIVC is typically only valid for one particular type of dosage form containing rate-controlling excipients with the same release mechanism. Even with the same type of solid dosage form, such as a tablet, different release mechanisms (eg, diffusion vs osmosis) often necessitate the development of a separate IVIVC for the same drug molecule. In IVIVC modeling, the absorption parameters obtained with the most widely used Wagner–Nelson method reflect only the rate and not the extent of absorption. Problems can arise from a correlation established using formulations that have different systemic bioavailability. For example, decreased or truncated absorption in the lower GI tract may occur with slow-releasing formulations due to less liquid available for dissolution, lower permeability and surface area, the presence of bacterial metabolism, or a short residence time. As a result, the IVIVC will be apparently formulation-dependent if not corrected. This is illustrated using a simulated example. Two formulations (I and II) were originally designed to release a drug over approximately 8 and 14 hours (Fig. 16.13a). Following oral administration, decreased bioavailability of Formulation II was observed because the window of absorption is found to be approximately 8 hours (Fig. 16.13b). The apparent in vivo absorption profiles of the two formulations obtained by the Wagner–Nelson method are also shown in Fig. 16.13a. A comparison between the in vitro release and the in vivo absorption indicates a good 1:1 relationship for Formulation I and a significant deviation from the relationship for Formulation II as a result of overestimation of the in vivo absorption. Therefore, in developing an IVIVC, reduced AUC needs to be accounted for, for instance, by using time-dependent function: $X_{\text{in vivo}} = g(t)\ X_{\text{in vitro}}$ where $g(t)$ is a step function for truncated or site-dependent absorption.

16.6 CASE STUDIES

16.6.1 Influence of API solubility on IVIVC

Nifedipine is practically insoluble. Its in vivo apparent absorption from the osmotic pump or matrix systems consists of sequential steps of release or metering of drug particles followed by particle dissolution and permeation across the intestinal membrane. This is indirectly supported by the known dependency of bioavailability on the drug particle size discussed previously. Conventional USP tests using a large volume of test medium containing a solubilizer to create sink conditions are incapable of separating the particle dissolution from the drug release. In investigating the IVIVC of Push-Pull osmotic pump of nifedipine, Grundy et al.[103] designed a two-phase test to measure the rate of drug transfer from an aqueous phase into an organic phase, that is, the processes of release of suspension from the device, particle dissolution, and

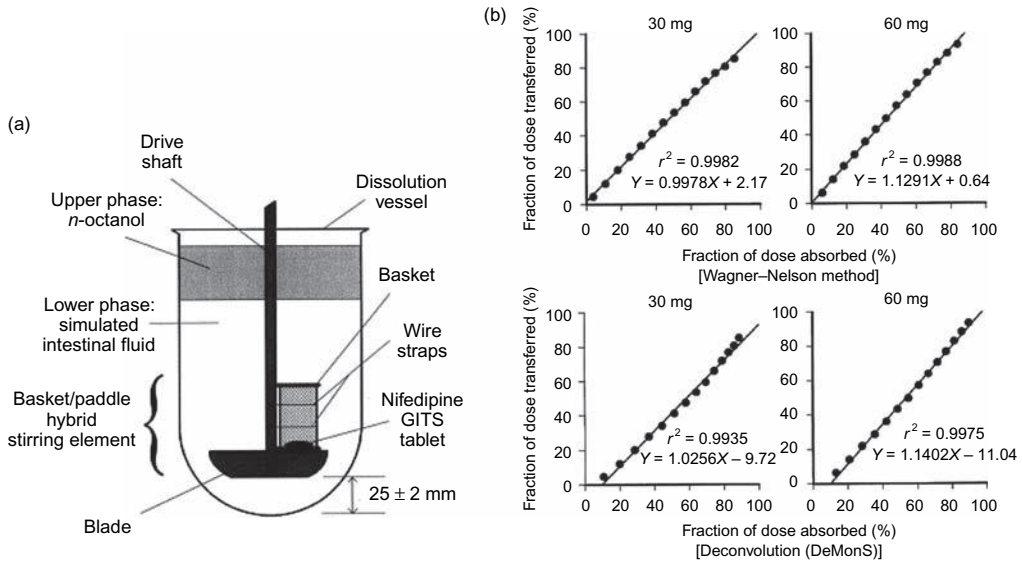

FIGURE 16.14 A Two-phase in vitro test system designed (a) for improving IVIVC of ER dosage form of an insoluble drug, nifedipine (b). *Reprint with permission: J Control Release 1997;48(1–8):9–17.*

subsequent partitioning into the organic phase (Fig. 16.14a). The authors demonstrated that a zero-order rate of drug transfer (0.96 mg/h) obtained from such a test system closely matched the estimated in vivo absorption rate of 1.03 mg/h (30-mg strength) as compared to a rate of 1.7 mg/h based on the conventional test. As a result, an improved 1:1 Level A IVIVC was obtained for all strengths ($R^2 > 0.99$). Similarly, the impact of the drug's solubility on IVIVR was also evaluated in studies comparing ER hydrophilic matrix formulations containing crystalline and amorphous compound with high dose-to-solubility ratio.[85,169] Three tablet formulations containing crystalline API and 10–30% hydroxypropyl methylcellulose (HPMC) exhibited different dissolution rates in a conventional USP method using 900 mL of test medium. However, the in vivo performance of the three formulations is similar, likely a result of a nonsink condition for the in vivo drug release. When the more soluble amorphous drug was used in the same type of ER matrices to improve the particle dissolution, a rank order relationship between the in vitro and in vivo data was observed in the same in vitro test.

16.6.2 Developing a predictive in vitro test[11,12,83]

Depakote ER tablet is a hydrophilic matrix-based, extended-release system with high drug loading. It provides approximately 20 hours of apparent zero-order in vivo absorption (Fig. 16.15). The active ingredient, divalproex sodium, is a stable and permeable compound with pH-dependent solubility. During early

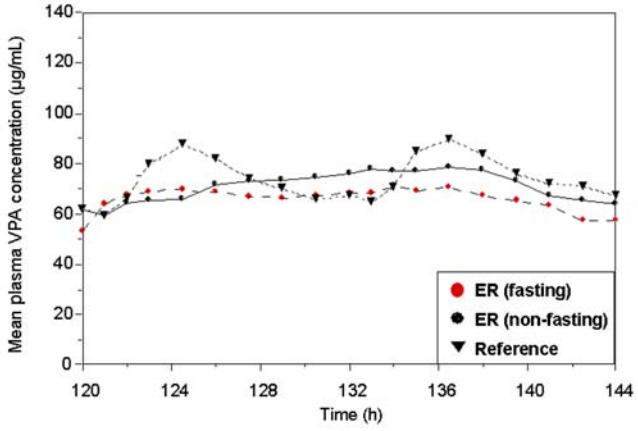

FIGURE 16.15 Mean steady-state plasma concentration profiles of once-daily Depakote ER tablet dosed under fasting and nonfasting conditions with twice-daily enteric Depakote tablet as reference.

formulation development, the in vitro drug release of three different formulations were all found to be slower and showed inadequate separation compared to in vivo absorption (underdiscriminating) when a conventional test was used (Fig. 16.16a). In addition, the mechanism of the in vitro release was diffusion controlled, whereas the apparent absorption profile obtained by deconvolution showed zero-order absorption, suggesting a predominantly erosion-controlled in vivo release (also supported by steady-state plasma concentration curves in Fig. 16.15).

In order to develop a new in vitro test that predicts in vivo absorption, statistically designed studies were carried out to investigate the effects of various in vitro testing variables on drug release. The variables

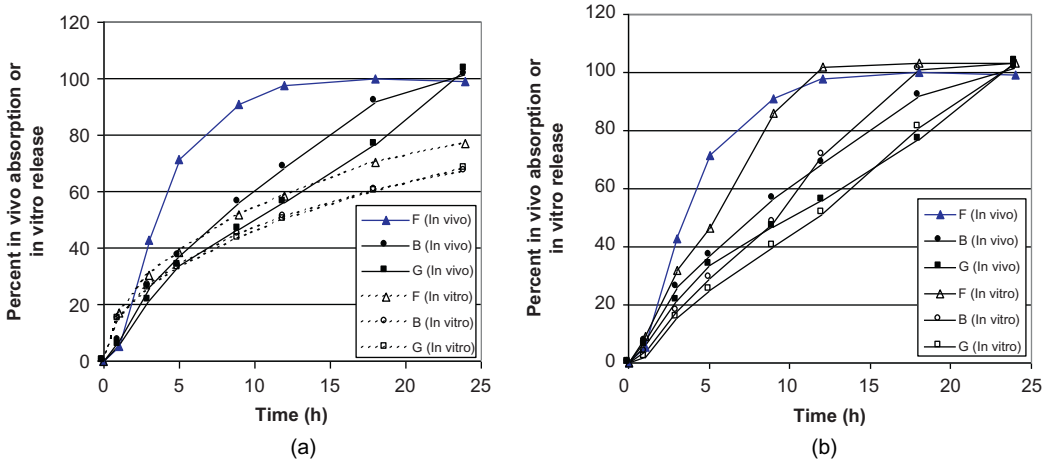

FIGURE 16.16 Mean in vivo absorption versus in vitro release profiles of three formulations using (a) conventional in vitro test method (USP II, 100 rpm, pH 7.5 phosphate buffer) and (b) a predictive test method (USP II, 100 rpm, 0.75 h 0.1 N HCl followed by 0.05 M phosphate buffer containing 75 mM SLS at pH 5.5).

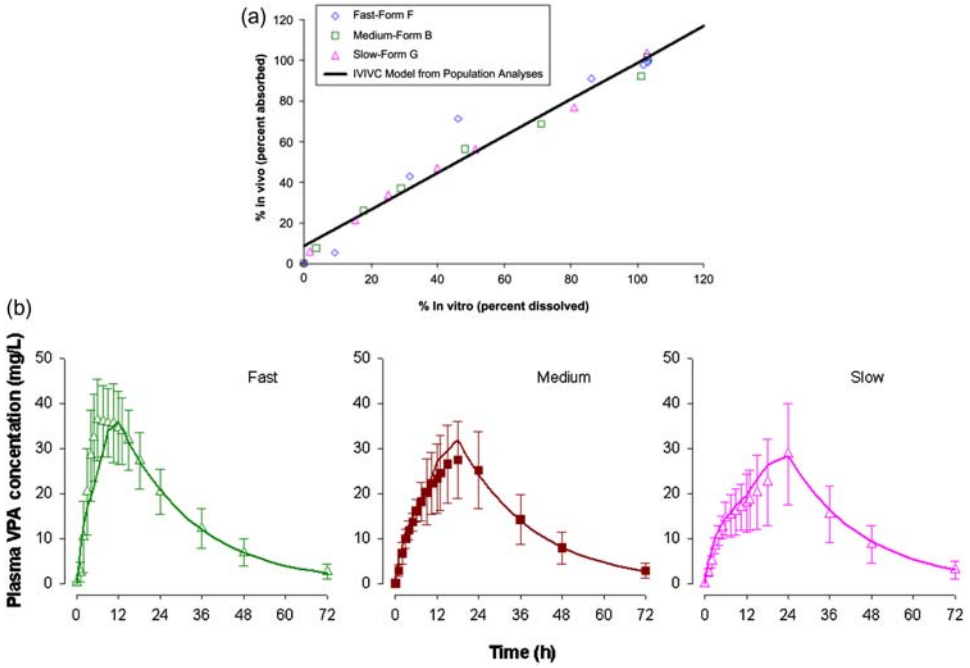

FIGURE 16.17 Results of in vivo/in vitro correlation studies of extended-release divalproex sodium tablets: (a) IVIVC plot and (b) mean predicted in vivo plasma profiles of three different formulations.

investigated included agitation intensity, apparatus, surfactant, pH, and ionic strength of the dissolution medium. Based on factorial studies and statistical analysis, a new set of test conditions was determined and demonstrated to correlate with the in vivo drug absorption for various ER formulations (Fig. 16.16b). Statistical evaluation of the in vitro method based on a hypothesis test indicated that the same IVIVC equation holds for the three different formulations (Fig. 16.17a). A mixed-effects model was used for data analysis in which the dependence among observations from the same subject in the human pharmacokinetic study was taken into account. Fig. 16.17b shows the agreement between the observed and the predicted plasma profiles of the tablets. The method has been successfully validated internally and externally on multiple occasions over a period of eight years. More importantly, it has been applied to (1) set meaningful drug-release specifications, (2) justify biowaivers for postapproval changes, and (3) assure product quality by timely

detecting significant dissolution changes during commercial production due to a change of the key rate-controlling polymer property that could not have been detected had the conventional dissolution test been used as a QC tool.[170]

This study illustrates a useful approach in identifying a predictive method for the development of an IVIVC, that is, adjusting the dissolution test conditions to correlate the in vitro data with the in vivo behaviors of the formulations.

16.6.3 Illustration of setting an optimal dissolution specification based on IVIVC using Monte Carlo simulation

The ability to establish a meaningful dissolution specification acceptable for commercial manufacturing has profound implications in ensuring consistent product performance and the routine production of the solid products. A specification based on product and process understanding assures both product quality and supply. If the specification range is unnecessarily narrow, the probability of failing a batch is increased due to the inherent variability of the raw materials, the product, and the manufacturing process. If a wide range is set for passing batches or solely based on the individual product and process capability, the in vivo performance may not always be ensured, especially in the absence of an IVIVC. One of the most significant advantages of establishing dissolution acceptance criteria using an IVIVC is that it offers greater flexibility for identifying a specification that maximize the probabilities of an assured product in vivo performance and a successful commercial production. More specifically, it allows for searching an optimal range in a multidimensional space defined by the needs of bioequivalence, quality control, manufacturability, and regulation.

One of major challenges in arriving at an optimal dissolution specification prior to regulatory filing is a lack of sufficient data to measure process capability at full production scale. To address this problem, Monte Carlo simulation can be used to evaluate acceptability of the proposed dissolution specifications with respect to manufacturability, bioequivalence, and regulatory requirement based on the inherent material, product, and process variability.[171–173] Monte Carlo simulation is a statistical tool for stochastic model calculations and analysis of propagation from uncertainties in model inputs into uncertainties in outputs (results).[174] It is commonly used to assess risk by making use of a pseudorandom drawing that simulates the real-life sampling to produce distributions of different outcome values. Its core idea is to use probability curves and random samples of inputs to explore the behavior of a complex stochastic system and determine/model the probability of different outcomes that cannot readily be predicted due to the intervention of random variables. Monte Carlo simulation generally includes four basic steps[175]: (1) define a domain of possible inputs, (2) generate inputs randomly from a probability distribution over the domain, (3) perform a deterministic computation on the inputs, and (4) aggregate the outputs for analysis. A number of statistical software, such as Minitab, Matlab, and MS Excel are often used to run Monte Carlo simulations.

This case study describes a useful approach to identify the dissolution specification limits that ensure product quality, performance, and robustness of commercial manufacturing. It is a data-driven approach that utilizes the available dissolution data, a validated IVIVC model, and Monte Carlo simulation, consisting of the following steps:

1. Based on the pivotal biobatch, generate multiple sets of specification ranges that meet bioequivalence criteria by confining differences in IVIVC model-predicted C_{max} and AUC values within 20%.
2. Review and gather all existing dissolution data, which often include individual values of hundreds or thousands of individual tablets generated from a pilot scale, a larger scale, and stability studies during product development, and perform statistical analysis to estimate the probability distribution and variability of dissolution data resulting from natural variations in raw materials, product, processing, and test method.
3. Perform Monte Carlo simulation to select an acceptable specification that accommodates the inherent system variability. Specifically, dissolution data are generated using Monte Carlo simulation based on the statistical distribution (mean and spread) of the existing representative data. The simulated data are tested against the proposed specification limits using dissolution stage testing criteria (L1, L2, and L3). The simulation is typically iterated tens of thousands of times to estimate the overall probability of failing different stage testing associated with each set of proposed specification. For example, 100,000 production lots can be simulated by randomly sampling 100,000 groups of six tablets for dissolution stage testing when assessing individual sets of specification. The simulation is repeated for every set of proposed specifications until a set of specification is identified with minimum risk of failing the dissolution stage testing while ensuring all batches within the lower and upper specification limits are bioequivalent to one another.

Table 16.7 shows an illustrative example of this approach. Monte Carlo simulations were conducted

TABLE 16.7 Monte Carlo Simulation Results for Assessing Four Sets of Dissolution Specifications of an Extended-Release Tablet Based on IVIVC and Manufacturing Consideration

Specification set	Q (2 h)	Q (8 h)	Q (12 h)	P[a] (Fail L3)	P (pass L1)	P (pass L2)	P (pass L3)
I	NML 20%	35–66%	NLT 80%	0.0%	89.3%	10.2%	0.5%
II	NML 18%	33–62%	NLT 80%	0.0%	78.2%	12.3%	0.5%
III	NML 18%	36–60%	NLT 80%	0.1%	75.4%	24.4%	0.1%
IV	NML 20%	38–58%	NLT 80%	0.2%	72.9%	26.1%	0.8%

[a]*P: Probability of passing or failing dissolution stage testing.*

using four sets of specifications that meet the in vivo bioequivalence criteria for an ER tablet product. Sets I and II are considered acceptable for commercial manufacturing because they show a minimum risk of batch failures. It is worth noting that the accuracy and the reliability of this approach depend on the quality and the representativeness of the database used to estimate the inherent variability. Data from the commercial production following product approval should be collected and used to verify the simulation results and further improve the model if necessary.

16.6.4 Setting clinically relevant specifications

In science-based pharmaceutical development, IVIVC is recognized as one of the most important biopharmaceutical tools for enhancing drug product and process understanding and for ensuring consistent efficacy and safety throughout the drug product's lifecycle because it allows for the establishment of clinically relevant product specifications. Clinically relevant product specifications may be defined as those that can ensure the delivery of the intended dose at a consistent rate to patients to guarantee safety and efficacy profiles for the marked product relative to those achieved by the clinical trial formulations. By linking product quality to the clinical performance in product development, manufacturing, and continual improvement, clinically relevant specifications or controls associated with product critical quality attributes (CQA), critical material attributes (CMA), and critical process parameters (CPP) are expected to assure high product quality with a consistent safety and efficacy profile desired throughout lifecycle of a drug product. As a bridge between in vitro testing and in vivo exposure, an IVIVC can be effectively employed for understanding the impact of the drug product CQAs on in vivo performance. Through IVIVC, product quality specifications can be established optimally with assured clinical outcomes, using in vitro dissolution testing as a surrogate. For example, Duan et al. reported the use of IVIVC in setting the clinical relevant specifications for an ER matrix tablet.[176] During the development, three CMAs were identified as high-risk factors: particle size distribution (PS) of the API, viscosity of a matrix forming agent (MFA), and the PS of a matrix forming enhancing agent (MEA). Their impact on dissolution was investigated using a design of experiments (DOE). The data were analyzed by partial least square regressions and validated by comparing the model predicted and the observed dissolution values, along with a "leave one out" cross validation. The validated model was first used to predict dissolution at different values of MFA viscosity, particle sizes of MEA, and the API. The corresponding effects on AUC and C_{max} were subsequently evaluated using a multiple Level C IVIVC. The predicted AUCs and C_{max}s were compared to those of the clinical batches with demonstrated efficacy and safety, and the ratios of AUC and C_{max} were calculated and plotted against the three CMAs. For instance, Fig. 16.18 shows the combined effect of MFA viscosity and MEA PS on AUC ratio predicted using dissolution data at 3 hours under four different values of API particle size, expressed as the ratios of larger to smaller particle size (3.2, 6.6, 12.1 and 14.4). The rectangular box encloses the acceptable spaces for setting appropriate specifications, since they fall well within the bioequivalence range (0.8–1.25).

16.6.5 Setting biorelevant dissolution specification

Methylphenidate (MPH) is an amphetamine-like central nervous system stimulant commonly prescribed to treat attention-deficit/hyperactivity disorder (ADHD) in children, adolescents, and adults, as well as narcolepsy. It is a weak base with a pK_a of 8.77 and a log$P$ of 3.19. Its hydrochloride salt is freely soluble in water (18.6 mg/mL), stable, and well absorbed from the intestinal tract with a short elimination half-life of 3–4 hours.[177] These favorable properties combined with a low dose make MPH an ideal candidate for oral MR delivery. As a result, products using different MR

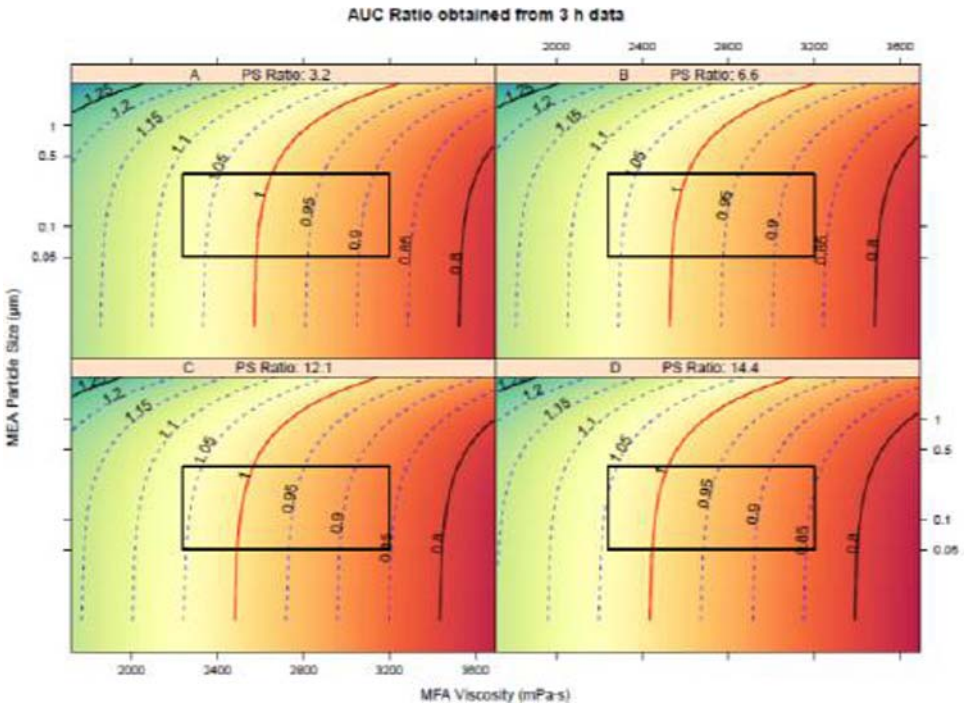

FIGURE 16.18 Effect of different combinations of three CMAs on AUC ratios predicted using the in vitro data at 3 h based on a Multiple Level C IVIVC.

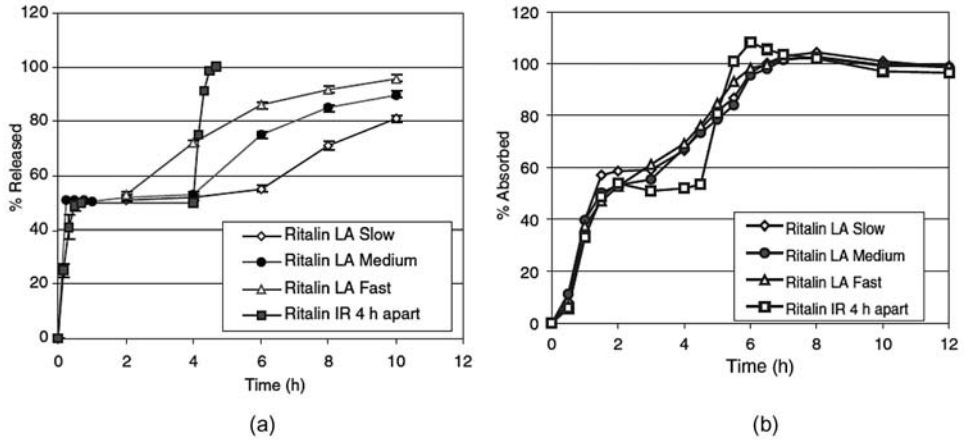

FIGURE 16.19 In vitro dissolution and in vivo absorption profiles of three Ritalin LA formulations and Ritalin IR tablet administered 4 hours apart.

design principles have been commercialized (see chapter: Product and Process Development of Solid Oral Dosage Forms). Wang et al. reported a study that evaluated the in vitro dissolution and in vivo absorption of MPH from a pulsatile release product (Ritalin LA capsule) using an IR formulation (Ritalin IR tablet) as a reference.[130] The Ritalin LA capsule consisting of 50% IR and 50% DR beads was designed to mimic PK performance of the IR product given 4 hours apart. In the study, three formulations, slow-, medium-, and fast-release, were prepared by varying the release rate of the DR portion by coating the IR beads to a different weight gain with an acrylates copolymer (Fig. 16.19a). The in vitro dissolution of the three MR formulations was determined using USP apparatus 1 (100 rpm) in 0.01N HCl for 2 hours followed by a pH 6.8 phosphate buffer. The three formulations were evaluated in 18 healthy volunteers under fasted conditions using a single-dose, randomized, four-way crossover design.

It was found that the three test formulations exhibited similar plasma concentration-time profiles with two peak concentrations and were bioequivalent

with respect to C_{max} and AUC and the corresponding values describing the first and second peaks, although the in vitro dissolutions were different.[130] Fig. 16.19b showed that the absorption of MPH was biphasic, with a rapid absorption phase between 0 and ~2 hours and a slightly slower second absorption between ~3 and 6 hours. The results of this study can be used to justify and establish the biorelevant dissolution specification by defining a dissolution space that ensures bioequivalence in the absence of an IVIVC. More specifically, a wide range of dissolution specifications can be set based on the in vitro profiles of the fast and slow formulations, as shown in Fig. 16.19a, because batches prepared within the limits have been shown to be bioequivalent.

16.7 SUMMARY

The general concepts, theory, modeling methodology, assessment, and applications of in vitro/in vivo correlation have been established and extensively investigated, though differences in scientific approaches remain in the details of model development and evaluation. The state of the art is such that there is no universal in vitro model that can mimic or reproduce the highly complex and dynamic GI environment or predict the in vivo performance of solid oral dosage forms. Therefore, development of an IVIVC must be carried out case by case based on the understanding of the API properties, product characteristics, and their interplay with in vitro test method/conditions.

IVIVC is generally more likely for ER dosage forms than IR products, since drug absorption is typically limited by the drug release. To increase the chance of success, it is crucial to evaluate IVIVC feasibility of in vitro and in vivo results by integrating knowledge of physicochemical and biopharmaceutical characteristics of drug substances, dosage form design, and their interplays with the GI environment and in vitro test conditions. It is also important to make IVIVC strategy an integral part of the dosage form development program.

Once an IVIVC is developed and validated, the predictive in vitro test can be used as a surrogate for in vivo studies, a guide for setting meaningful product specifications, and a reliable tool for quality control. Whenever feasible, an IVIVC-based in vitro test method should be implemented in the QC laboratories such that any potential or unexpected changes of in vivo performance of a product during production can be detected to ensure safety and efficacy of every commercial batch.

17.1 INTRODUCTION

Preclinical studies are designed to verify therapeutic targets and assess the efficacy and safety of new drug candidates in relevant in vitro and in vivo models. The goals of preclinical studies are to select the right drug candidates to test in humans and understand the translation from preclinical results to clinical outcomes.

Preclinical in vivo studies include pharmacokinetics (PK), efficacy, and safety studies. Early efficacy studies, including pharmacodynamics (PD), dose scheduling, and combination studies, are usually conducted in mice and rats. Safety evaluations, including maximum tolerated dose (MTD), dose range finding, and good laboratory practice (GLP) studies, are conducted in rodent and nonrodent species. Furthermore, telemetry studies and other in vivo assessments may be required to mitigate development risks at the preclinical stage.

Different routes of administration can be explored at the preclinical stage for hypothesis testing. Intravenous (IV) bolus, IV infusion, oral, subcutaneous and intraperitoneal administrations are commonly used at the early drug discovery stage to understand exposure and signal relationships. However, the same administration route as the intended route for the clinical and commercial drug products is typically required for efficacy and safety evaluations of drug candidates. Oral and IV infusion are the most common administration routes for preclinical safety evaluations.

A desired preclinical formulation should provide sufficient and robust exposure, have fit-for-purpose stability, and not cause adverse effects or interference of test signals in animal models. Achieving the appropriate exposure during the preclinical stage is important, as it allows evaluations of target engagement, PK/PD and efficacy relationships, and early safety liabilities. Suitable formulations are critical to ensure the achievement of the appropriate exposure for in vivo assessments. Rational preclinical formulation development can also facilitate candidate selection and guide clinical formulation development.

The common challenges of achieving optimal exposure and formulation development at the preclinical stage include: (1) early leads often have suboptimal physicochemical (eg, poor solubility, purity, stability and solid-state properties, batch-to-batch variation) and PK properties (eg, low permeability, high clearance); (2) lack of PK/PD information and a clear understanding of the optimal exposure or coverage; (3) limited compound availability and short timelines; and (4) lack of in vitro and in vivo relationship for formulation selection.

Preclinical formulation efforts are often focused on three areas: (1) enhance solubility and exposure for poorly soluble compounds, (2) reduce C_{max} and/or prolong exposure to improve the therapeutic index, and (3) increase exposure at the site of action by local delivery and targeting.

Developing Solid Oral Dosage Forms
DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00017-0

This chapter is centered on improving oral exposure through rational formulation design. There are six sections in this chapter:

1. Considerations in Designing Formulations for Preclinical Species
   Review formulation, study requirements, and considerations for safety evaluation.
2. Use of Active Pharmaceutical Ingredient (API) Properties to Guide Formulation Design
   Discuss key physicochemical properties and their impact on formulation design and performance.
3. Preclinical Formulation Development
   Detail preclinical formulation approaches with a focus on enabling technologies for poorly water-soluble compounds.
4. In Vitro Dissolution Method to Evaluate Formulations
   Describe current advancements in understanding of dissolution behaviors of enabling formulation and rational design of in vitro dissolution methods.
5. Preclinical Formulation Selection
   Discuss pros and cons of formulation approaches and rational formulation selection.
6. Case Study

Illustrate the formulation development process using a compound from real world.

17.2 CONSIDERATIONS IN DESIGNING FORMULATIONS FOR PRECLINICAL SPECIES

17.2.1 Type and requirements of nonclinical safety assessment studies

A nonclinical safety assessment usually begins in the drug discovery phase as part of the screening process that leads to the selection of a candidate for clinical development, and it reaches all the way into late-stage clinical development of a potential new drug. The main purpose of non-GLP studies during drug discovery is the identification of development-limiting toxicity. Studies are usually performed for the last 1–3 drug discovery lead compounds in a rodent and nonrodent species and aid in the selection of the final compound chosen to progress into development. Single-dose studies are typically performed at three-dose levels to gain information on the toxicokinetic profile and drug tolerability and to ultimately select a dose range for repeat-dose toxicology studies. Typical doses for these early single-dose studies are in the range of 30–300 mg/kg. Prior to the final selection of a drug candidate for development, a repeat-dose range-finding study is conducted for typically 7–14 days in a rodent (rat or mouse) and nonrodent (dog or monkey) species, with the route of administration usually being driven by the final intended route of administration in humans.

During the development phase, single and repeat-dose studies are designed to assess various toxicology areas such as carcinogenicity, immunotoxicity, phototoxicity, reproductive and developmental toxicity, genotoxicity, local tolerance, and abuse liability. The typical endpoints for repeat-dose toxicology studies are toxicokinetics, clinical signs, clinical pathology (hematology, serum chemistry, coagulation, urinalysis), gross pathology, histopathology, and safety pharmacology (cardiovascular, central nervous system, respiratory). Core safety pharmacology and genetic toxicology studies need to be conducted prior to a new drug candidate entering clinical studies in humans for the first time. Timing for reproductive studies depends on the human population to be exposed. Prior to the compound entering the first clinical studies, an investigational new drug-enabling GLP study is required in a nonrodent and a rodent species, which usually lasts for 4 weeks, and is needed to set clinical starting doses and dose-escalation paradigms. Safety studies in later development stages in general provide guidance to clinical investigators and maintain subject and patient safety in clinical studies and following registration. A stepwise process is utilized in the planning of clinical trials to assess the potential toxicity in advance of use in humans. For short clinical studies lasting for less than 6 months, the same duration of a preclinical study in a rodent and a nonrodent species is required. For long-term clinical studies lasting for more than 6 months, a 6-month rodent and a 9-month nonrodent study are performed. Carcinogenicity studies are usually conducted in mice and rats and last for 2 years, with tumorigenicity as the main endpoint. However, for products with a maximal clinical dosage duration of less than 6 months, or those intended for life-threatening oncology indications, carcinogenicity studies are generally not required.[1]

17.2.2 Complexities caused by high exposure requirement but minimal adverse effect

The timing of a nonclinical study (discovery or development), dose regimen (dose, frequency, and duration), test species, and route of administration all have a significant impact on the formulation development strategy. The ultimate goal is to maximize the exposure in the test species to identify the safety risks associated with the test compound. The desired target plasma concentrations of nonclinical toxicology studies

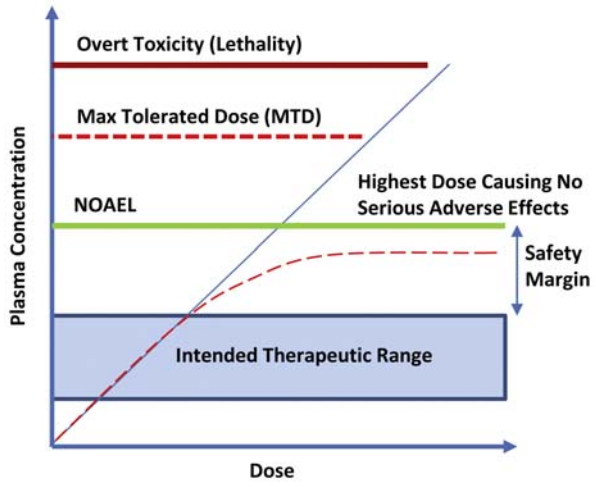

FIGURE 17.1 Interplay between dose and exposure level requirement in various studies. *MTD*, maximum tolerated dose; *NOAEL*, no observed adverse effect level.

usually far exceed the intended therapeutic range for a given drug, oftentimes 100-fold or more, depending on the therapeutic area for which the drug is developed. Especially in rodent species, extremely high doses are often explored to establish a no observed adverse effect level, the highest dose causing no serious adverse effect; an MTD; and an overt toxicity level (lethality). In order to enable the extremely high plasma concentrations desired in nonclinical studies, the formulator is challenged with the identification of formulation options that solubilize the drug substance and keep it from precipitating after administration to achieve a close-to-dose proportional increase in exposure over a very wide dose range. However, due to the limited solubility of most test compounds, a less-than-dose proportional increase in exposure and ultimately a plateau beyond which exposure does not increase further with increasing dose are often observed at the higher end of the dose range, as shown in Fig. 17.1.

17.2.3 Complexities in dosing preclinical species

At the same time, a formulator needs to be aware of the physiological differences between nonclinical test species, some of which are summarized in Table 17.1. Especially for oral administration, these physiological differences can have a profound effect on the performance of a formulation, since the oral absorption is, in many cases, limited by the test compound's solubility or dissolution rate, and, therefore, factors such as gastric residence time and gastrointestinal (GI) residence time

TABLE 17.1 Physiological Differences Between Nonclinical Test Species[2–12]

Parameters	Humans	Rats	Dogs	Monkeys
Fasted gastric pH	0.95–3.2	1.5–3.0	3.5–4.5	2.8–4.0
Fed gastric pH	4.3–5.4	3.8–5.0	3.5–5.5	
Basal gastric output (mEq/h)	2.0–5.0	0.8657 (mL/4 h/ 100 g)[13]	0.1	Similar to humans unless stressed
Peak output (fed state), (mEq/h)	18–23		39	Similar to humans unless stressed
Duodenum pH	5.0–7.0	6.5–7.0	5.5–7.5	5.6–6.0
Stomach capacity (L)	1–1.6		1.0	0.1
Gastric emptying time (min)	16–140	10–30	100	
Sm. intestine transit time (min)	240	90	60–120	
Total GI residence time (min)	2400	1200	770	1200

can greatly impact the exposure achieved from a given formulation in different species. In addition, since many test compounds are ionizable, the differences in the gastric and intestinal pH of the test species could cause significant differences in the ionization state and solubility of the test compound, leading to differences in the tendency or extend of precipitation from a solubilized formulation once it enters the gastric milieu after oral administration.

Differences in the stomach capacity of test species result in species-specific restrictions to the maximum volume that can be administered orally per dose. The administration of excessive dose volumes may produce pain, excitement, altered physiological parameters (eg, serum electrolyte imbalance, increased blood pressure, and increased respiration rate) and can cause abnormal test compound absorption. The ideal and maximum dose volume limits are usually defined by animal care and use committees in each organization that conducts animal studies. While these limits are typically aligned based on surveys amongst pharmaceutical companies, biotech companies, and contract research organizations and based on literature,[14] there might be differences in the limits used from organization to organization. Table 17.2 lists commonly used maximum dose volumes for different species that the authors have experience with, but these should not be interpreted as absolute guidelines.

TABLE 17.2 Dose Volume Guidance

Species	Average Weight (kg)	Dose Volume (mL/kg)	Average Max. Volume per Dose (mL)	Solution/ Suspension Conc. Required Using Example Dose of 20 mg/kg (mg/mL)
Mouse	0.025	10	0.25	2
Rat	0.25	10	2.5	2
Rabbit	4	10	40	2
Dog	10	5	50	4
Macaque (Cyno)	5	5	25	4
Marmoset	0.4	10	4	2

These dose volume restrictions have a significant impact on the solution or suspension concentration that is required to administer a defined dose. Therefore, the target concentration that a formulator has to aim for to administer a given dose can vary depending on what test species the formulation is developed for, as outlined in Table 17.2.

17.2.4 Complexities due to use-limit of excipients

An additional challenge for the formulation selection for nonclinical safety studies is the fact that the majority of newly selected drug candidates have poor aqueous solubility and low bioavailability (BA) from suspension formulations, and oftentimes the formulator needs to employ a combination of multiple cosolvents, surfactants, or other excipients to increase the solubility and the precipitation resistance of the test compound to achieve the desired in vivo exposures. However, it is important to consider the potential for undesirable effects of the selected excipients and to stay within the ranges that do not lead to toxicity findings caused by the vehicle itself, which could interfere with the intended readout of the safety study.[1,15,16] Excipients employed in formulations should ideally maximize exposure while having minimal impact on the pharmacology and toxicology readouts. The final dosing formulation will be selected based on the chemical and physical stability, the solubility, the required concentration (mg/mL), wettability, crystallinity, and the acceptability of the excipients in animals. Since many excipients have physiological effects (eg, GI permeability, transit time, mobility, efflux, and metabolism), their impact on the PK, efficacy, and toxicity should be taken into consideration. At times, the side effects observed after the administration of the vehicle alone may appear manageable, but these effects could exacerbate drug-related side effects, thereby complicating the interpretation of the study results.

The acceptable level of a specific excipient also depends on the dose frequency and duration of the study. For single-dose studies or repeat-dose studies that only span several days, a well-understood, low-level biological or toxic effect of the vehicle might be acceptable, allowing the formulator to use higher concentrations and doses of certain excipients. However, for long-term repeat-dose studies, such effects may not be tolerated, and the formulation has to be adjusted to lower levels of the excipient that causes the effect.

When selecting a vehicle, both the concentration and the total dose of the excipients should be taken into consideration. The sensitivity towards a specific excipient can be species-dependent. A common example of a vehicle-related effect is the laxative effect of the cosolvent polyethylene glycol (PEG) 400 or surfactants such as poloxamers, causing loose stool and emesis in dogs and primates, which can lead to variable and reduced exposure.[17–20] Rats and mice, on the other hand, usually show a much higher tolerance for such excipients and can, therefore, be safely dosed with higher levels. Surfactants such as poloxamers, Cremophor EL or vitamin E D-alpha tocopheryl polyethylene glycol 1000 succinate (TPGS) at high doses may inhibit the efflux transporters such as P-gp, and, therefore, have the potential to impact the PK profile of certain test compounds that are P-gp substrates. In addition, they may alter the extent of gut wall metabolism and change the exposure of metabolites.[17,21] The acceptability and potential side effects of a given excipient can also be related to the intended study duration. Corn oil, for example, is well suited for short-term studies, but when administered chronically in rats, it can cause altered body weight, survival rate, and tumor incidence.[1] Vehicle-related toxicities or changes in PK or metabolite profile of the test compound could complicate the interpretation of the study results, especially when there is no previous internal experience or published data. As with dose-volume restrictions mentioned earlier, many organizations have established their own internal guidance on the acceptable limits for each of the commonly used excipients depending on test species (and in some cases different strains of the same species), route of administration, and dose regiment (single or repeat-dose study).

Table 17.3 provides examples of such limits for typically used levels of certain excipients and commonly observed adverse effects associated with these excipients that are based on literature[1,15–17,22] and experience from the authors' organizations.

TABLE 17.3 Examples of Excipients Use Limits

		Single Dose								
		Mice		Rats		Dogs		Monkeys		
		Oral % w/w (g/kg)	IV % w/w (g/kg)	Oral % w/w (g/kg)	IV % w/w (g/kg)	Oral % w/w (g/kg)	IV % w/w (g/kg)	Oral % w/w (g/kg)	IV % w/w (g/kg)	Comments

17.3 USE OF API PROPERTIES TO GUIDE FORMULATION DESIGN

Understanding of API physicochemical properties is essential for developability assessment and formulation design. Oral BA can be impacted by many factors, including solubility, dissolution rate, stability, permeability, and metabolism. It is critical to understand the BA limiting factors and if exposure can be improved through formulation design. For example, if the oral exposure is limited by solubility/dissolution or stability, formulation can usually improve the exposure. However, if the oral exposure is limited by permeability or metabolism, then it is less likely to be improved through formulation.

In this section, we will discuss the impact of key API properties on oral absorption and formulation design.

17.3.1 Solubility and bioavailability

Solubility is one of the key attributes of a drug candidate, as it can significantly impact in vitro profiling, in vivo exposure, and formulation development and performance. Low solubility is one of the major challenges for drug discovery and development. Up to 75% of drug candidates in development are classified as low solubility.[23] It is believed that high-throughput screen (HTS)-based chemistry approaches and exploration of more challenging targets are leading to more hydrophobic and less soluble drug candidates.[23–25]

17.3.1.1 Factors that impact solubility

Aqueous solubility of a given molecule is the interplay of multiple factors, including solid-state properties (eg, crystal packing, lattice energy), ionization (pH, pK_a), and solute/solvate interactions. It is important to understand what limits solubility to guide the formulation effort.

17.3.1.2 Solid-state properties

The equilibrium solubility of a pharmaceutical solid is not only dependent on solvent and solute interactions but also on the intermolecular interactions in the solid state. The compound has to overcome crystal packing to dissolve in the solvent. Therefore, solid-state properties can impact API stability and solubility. Higher apparent solubility is typically observed from solids with a higher energy state (eg, metastable or amorphous solids). The most thermodynamically stable form has the lowest energy stage and the lowest solubility. The melting point and heat of fusion can be reasonable indicators for lattice energy at early development. Disruption of the tight crystal packing through the molecule design can be a viable approach to increase the solubility at the drug discovery stage. Recently, the solid-state perturbation tool has been adopted to predict solubility and suggest chemistry modifications to improve solubility based on the interaction energy calculated from a single crystal structure.[26] The rationale of this approach is to improve solubility by altering the crystal packing energy via designing in weaker intermolecular interactions without impacting the other key properties such as potency, selectivity, and lipophilicity.

17.3.1.3 pH and pK_a

The ionization state of a molecule can significantly impact its solubility. The solubility of an ionizable compound is strongly dependent on the pH of the media and the pK_a of the molecule. The solubility of an ionizable compound can be described by the pH-solubility relationship derived from the Henderson–Hasselbalch equation, where the solubility is a function of intrinsic solubility (S_0), pH of the medium, and pK_a of the molecule. Detailed solubility equations are listed in chapter "Solubility of Pharmaceutical Solids" (Eq. 1.42 for acidic compound and Eq. 1.45 for basic compound). Fig. 17.2 shows the solubility of acidic compounds as a function of pH, intrinsic solubility, and pK_a. It highlights the importance of selecting a compound with a higher intrinsic solubility. It also indicates the benefit of having a stronger pK_a in chemical structure for solubilization purpose.

However, it is well known that the ionization state not only impacts solubility but also affects permeability,

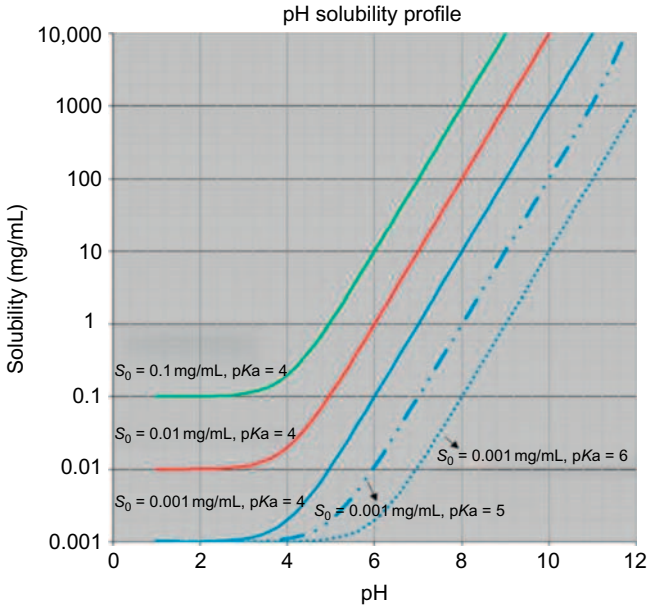

FIGURE 17.2 Illustration of how changes in intrinsic solubility S_0 and pK_a affect the pH-solubility profile of an acidic compound.

distribution, and other PK properties. The ionization state can also impact binding to transporters, enzymes, complexation (eg, with cyclodextrins),[27] and partition into organic solvents. Therefore, many properties need to be considered and balanced when it comes to the design or the selection of an optimal pK_a value for a drug candidate.

17.3.1.4 Lipophilicity

Lipophilicity plays a significant role in drug discovery and compound design. The lipophilicity of an organic compound can be described by a partition coefficient, log*P*, which can be defined as the ratio of the concentration of the unionized compound at equilibrium between organic and aqueous phases. For compounds with ionizable groups, the distribution of species is impacted by pH. The ionization state of a molecule can impact its lipophilicity. This leads to the definition of the distribution coefficient (log*D*) of a compound, which takes into account the dissociation of weak acids and bases. Generally speaking, more lipophilic compounds are less soluble in aqueous media. However, lipophilic compounds may have good solubility in oils and lipids; therefore, they can be good candidates for lipid-based formulations.

Lipophilicity not only impacts solubility but also influences permeability; potency; selectivity; absorption, distribution, metabolism, and excretion (ADME) properties; and toxicity. High lipophilicity (log$P > 5$) often contributes to high metabolic turnover, low solubility, and poor oral absorption. In addition, highly lipophilic compounds tend to bind to hydrophobic targets other than the desired target, and, therefore, there is an increased risk of promiscuity and toxicity.[28,29] Low lipophilicity can also negatively impact permeability and potency and thus results in low BA and efficacy. Leeson and St. Gallay conducted an analysis on patented compounds between 2000 and 2010 from 18 pharmaceutical companies, including Abbott, AstraZeneca, Bristol-Myers Squibb, Lilly, and Novartis. They found that the mean log*P* of these patented compounds range from 3.5 to 4.5. In addition, across the 18 companies, there was a trend of reduction in cLog*P* over time that was small but statistically significant.[30] It is generally considered that compounds with a log*P* greater than 1 or less than 4 are more likely to have optimal physicochemical and ADME properties for oral drugs.[31–33]

17.3.2 Solubility prediction and screen

17.3.2.1 Solubility prediction

Solubility prediction remains an area of interest for many researchers. Various prediction models have been reported in the literature. The models for intrinsic solubility prediction can be divided into several categories[34]: (1) fragment or group contribution-based models,[35–37] (2) log*P* and melting-based models,[38,39] and (3) statistically derived models based on 2-D or 3-D chemical descriptors.[40–42] However, the accurate prediction of solubility remains challenging. The majority of organizations still relies on experimental solubility results for compound prioritization and decision making.

17.3.2.2 Solubility screen and measurement methods

High-throughput (HT) solubility screening methods have been widely used to profile solubility during the early drug discovery stage. A large number of compounds to be profiled in various assays also requires standardized procedures in compound handling and distribution. In most cases, these are performed in 96-well or 384-well microtiter plates. For early HT solubility assays, the compounds are often dispensed by two methods. One method is to introduce the compounds as dimethyl sulfoxide (DMSO) stock solutions into aqueous media. The alternative method is to dispense the compounds as DMSO solutions, and then aqueous media are added after DMSO is removed from the plate. The final pH and solid form are typically not measured or characterized in either case. The HT solubility is determined by measuring the concentration of the saturated solutions using UV-Vis spectroscopy or liquid chromatography (UV or LC) after the solids are removed by filtration/centrifugation or by detecting precipitation formation using UV or nephelometric turbidity detector. These HT assays tend to overestimate the solubility due to the remaining organic solvent and/or formation of amorphous material during precipitation from DMSO stock solution. However, it is a very useful tool to rank the order of the compounds and flag the solubility risks at the early stage with only a small amount of compound required. In addition, the early solubility information also helps to interpret results from other in vitro assays.

During the lead optimization phase with a short list of compounds, it is recommended to conduct an equilibrium solubility study using crystalline solids with final pH and physical form measurements. This is because the pH and the physical form can significantly impact the solubility, as we previously discussed. In addition, the physical form can change during the course of solubility experiments. For examples, a free form can form a salt or a hydrate, or an amorphous material or metastable polymorph can convert to a more stable crystalline form. Therefore, it is important to understand the physical form of the initial and final solids. The most commonly used techniques to characterize the physical form of the

residual solids from solubility studies are polarized light microscopy (PLM) and powder X-ray diffraction (PXRD) (refer to chapter: Solid-State Characterization and Techniques, for techniques used for solid-state characterization).

During the drug development stage, the "shake-flask" method is typically considered as the standard method for determining the thermodynamic solubility. In the shake-flask method, a compound with known physical form (typically with most stable crystalline form) is added into a flask/vial with an excess amount to the medium, and the resulting suspension is agitated at a predetermined temperature and speed. Samples are collected at the predefined time point(s) typically at least 1–2 days. The residual solids are removed by filtration, the solubility of the compound is quantified by high-performance liquid chromatography (HPLC) or ultra-performance liquid chromatography (UPLC), the final pH is measured and recorded, and the physical form of the residual solids is characterized.

A detailed review of the solubility determination method is out of the scope of this chapter. There is a vast amount of information on this topic in literature for interested readers.[43,44]

17.3.2.3 Solubility screen in vehicles

The pH solubility measurements are typically performed during the early stage of development. Some organizations also incorporate solubility in biorelevant media in the early-stage HT screens to understand the developability risk as oral candidates. Solubility in different organic solvents is sometimes conducted to facilitate polymorph, salt selection, and process optimization. For poorly soluble compounds, additional solubility screening is typically performed with different solubilizing vehicles to guide the formulation design and developability risk assessment. Solubilizing vehicles include cosolvents, surfactants, complexation agents, and oils/lipids. The common screening excipients are listed in Table 17.4. In addition, different counterions also impact solubility due to different K_{sp} values. In situ salt screening with different counterions can provide useful information on solubility enhancement and formulation development. The theory and practical aspects of in situ salt formation to improve solubility have been discussed in the literature.[45,46]

With more technology advances such as solid dispensing, analytical and solid-state tools, there is an increasing trend to use prediction tools at early stage and incorporate HT capability in later-stage solubility measurement to increase efficiency and reduce the cost. At the same time, there is also an increasing desire to build in more focused screens with a more rational selection of excipients and conditions based on physicochemical properties of the compound.

TABLE 17.4 Typical Excipients and Vehicles Screened for Solubility During Early Stage of Development

Type of Vehicles	Examples
pH buffers	pH 1, pH 4, pH 6.5, pH 7.4, pH 9
Biorelevant media	SGF, FaSSIF, FeSSIF
Cosolvents	Polyethylene 400 (PEG 400), propylene glycol (PG), ethanol and dimethylacetamide (DMA)
Surfactants	Polysorbate 80 (Tween 80), Polyoxyl 15 Hydroxystearate (Solutol® HS 15/Kolliphor® HS 15), Pluronic® F-68, Polyoxyl-35 castor oil (Cremophor® EL/Kolliphor® EL), D-α-tocopheryl polyethylene glycol 1000 succinate (Vitamin E TPGS), caprylocaproyl polyoxyl-8 glycerides (Labrasol), sodium lauryl sulfate (SLS)
Complexation	Hydroxypropyl-β-cyclodextrin (HP-β-CD), sulfobutylether-β-cyclodextrin (SBE-β-CD/Captisol®)
Oils/Lipids	Medium-chain triglyceride (eg, Miglyol® 812), medium-chain monoglycerides & diglycerides (eg, Capmul® MCM), phospholipids (eg, Phosal® 53 MCT)
Counterions (for ionizable compounds)	Acidic compounds: NaOH, KOH, meglumine, lysine, arginine, etc. Basic compounds: HCl, methanesulfonic acid, phosphoric acid, etc.

17.3.3 Formulation design with solubility information

If exposure is limited by solubility or dissolution rate, it is critical to understand what factors limit solubility. For ionic compounds, pH adjustment and salt formulation are the most commonly used approaches to enhance solubility and dissolution. For compounds with a high melting point and tight crystal packing, a number of approaches, including cocrystal, salt, and amorphous formulations, can be explored to disrupt the crystal packing. For compounds with a strong tendency to precipitate from a solution or crystallize from an amorphous form, exicipients such as polymers or surfactants may be required to inhibit or delay precipitation or crystallization by reducing API–API interactions, molecule mobility, or supersaturation ratio. For highly lipophilic compounds, a lipid or oil-based formulation such as an emulsion or self-emulsified drug delivery systems (SEDDS) may be considered to improve solubility. In some cases, lipid or oil-based formulations may enhance permeability and promote lymphatic absorption. These solubility/dissolution enhancing approaches will be discussed in more details in the enabling technology section.

17.3.4 Stability

The physical and chemical stability of a compound is very important for developability assessment and

formulation design. The primary goal of the stability assessment at the preclinical stage is to (1) elucidate the development risk with respect to temperature, pH, light, humidity, and oxygen; (2) guide formulation design; and (3) define the storage condition and shelf life.

Liquid formulations are the most commonly used formulations for preclinical studies. The major routes of degradation are through hydrolysis, oxidation, or photochemical means. In addition, the presence of excipients such as cosolvents, complexing agents, and surfactants can also impact formulation stability. Understanding of stability and degradation mechanisms is important for selecting the dosage form, optimizing formulation variables, and defining storage conditions. During the candidate selection phase, accelerated stability studies of drug substances and formulations are typically performed in selected conditions.

17.3.4.1 Implication to formulation design

In order to mitigate the chemical stability risk via formulation design, it would be ideal to understand the rate, mechanisms, and pathways of degradation, although it may not be feasible at the early stage of drug discovery and development. Hydrolysis is affected by pH, temperature, buffer species, and ionic strength. The reactions are typically acid or base catalyzed; therefore, pH is one of the key factors influencing the stability of a compound. It is common to adjust the pH of a formulation to maximize or balance stability and solubility. Oxidation is another common degradation encountered. Autoxidation is the most common oxidative route, and its pathway can be described in three stages: initiation, propagation, and termination. In addition, hydroperoxides, common impurities in pharmaceutical excipients such as Tween 80, PEGs, and PVP, can catalyze oxidation.

Certain excipients (eg, antioxidants or complexing agents) can be used to improve chemical stability. For example, cyclodextrins have been reported to improve the photo and hydrolysis stability due to protection of functional groups that are sensitive to the degradation.[47,48] In addition to formulation pH and excipients, concentration range and storage conditions can be optimized to maximize stability. If the compound is extremely unstable in a solution, alternative formulations need to be considered. Suspensions, oil/lipid, or solid formulations may have a better chemical stability than solution formulations.

Physical instability such as precipitation of a solution, dissociation of a salt, or physical form conversion in a suspension or solid dosage forms can also negatively impact the formulation quality and in vivo exposure. Formulation approaches, composition (including concentration, pH, and excipients), and storage conditions can be explored to achieve the required stability for preclinical studies. For example, surfactant and polymeric excipients can inhibit or delay the physical form conversion in suspensions.

17.3.5 Evolution of solid forms and batch-to-batch variation

At an early stage, the synthesis route and the crystallization process are not fully developed or optimized. Batch-to-batch variation in the physical form and impurity profiles are common with early drug discovery batches. The physical form is often not optimized, and early batches tend to be amorphous or metastable forms. The impurity profiles can also change from batch to batch. The physical form can impact solubility, stability, and, therefore, BA of the drug candidate. For example, a suspension or a solution developed with a metastable form from an early batch can achieve good exposure. However, when a more stable crystalline form is produced with later batches, the suspension formulation may not provide sufficient exposure due to decreased solubility of the new, more stable crystalline form, or the compound may not be formulated in the same solution formulation developed with the early batch. The impurity profile can also impact the formulatability and chemical stability.

17.4 FORMULATIONS FOR BCS CLASS I/III COMPOUNDS

One of the biggest challenges for toxicology dosing formulation development is the high dose requirement to assess the toxicity of test compounds. Paired with species-specific restrictions on dose volume, these dose requirements often result in very high target concentrations for formulations. The biopharmaceutical classification system (BCS), introduced in 1995 by Amidon[49] and incorporated in 2000 by the Food and Drug Administration as a guidance for industry,[50] divides drug substances into four classes, depending on their solubility and permeability (Fig. 17.3). The distinction between high and low solubility compounds depends on the highest administered clinical or commercial dose of a given compound. If this dose is soluble in $\leq$250 mL of an aqueous media across the entire physiological pH range (pH 1 to 7.5), the compound is considered high solubility and is assigned to BCS Class I or III. If the highest dose is only soluble in $>$250 mL, the compound is assigned to BCS class II or IV.

Since doses required for a nonclinical safety assessment often exceed clinical/commercial doses by far, the BCS does not strictly apply to the formulation

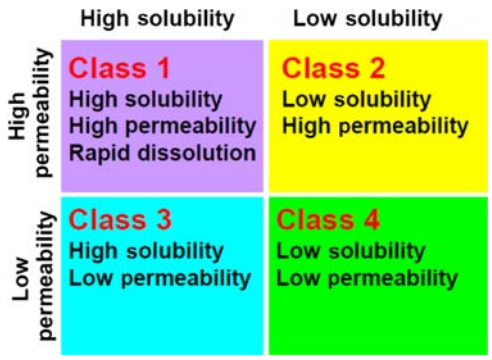

FIGURE 17.3 Biopharmaceutics classification system. *Source: Adapted based on Amidon GL, Lennernaes H, Shah VP, Crison JR. A theoretical basis for a biopharmaceutic drug classification: the correlation of in vitro drug product dissolution and in vivo bioavailability. Pharm Res 1995;12:413–20.*

development for nonclinical safety studies, since even BCS class I and III compounds do not necessarily dissolve completely in 250 mL at the highest doses administered during these studies. However, due to their high aqueous solubility, BCS class I and III compounds still represent the best chance to be formulated as simple solutions or suspensions without the need for more complicated formulation strategies involving solubility-enhancing excipients.

17.4.1 Aqueous solution formulations

The approach that oftentimes allows for the easiest formulation preparation and handling is a solution. Amongst solution formulations, purely or mostly aqueous systems are most preferred, since they eliminate the potential risk of an excipient-related toxic effect. Even if the solubility of the test compound is not sufficiently high across the entire physiological pH range, solution formulations at high concentrations might still be achievable in the case of ionizable drug substances. In addition to the reduced risk of excipient-related toxic effects, solution formulations have the advantage that solid-state properties of the drug substance, such as crystal form or particle size, are of no concern assuming the most stable form is used in producing the solution formulation. In most cases, they can be easily prepared by dissolving the drug substance at the right concentration with pH adjustment if necessary. Stirring or sonicating of the formulation for a period of time might be required to achieve full dissolution of the test compound. Stability studies that are required to support use-time recommendations for GLP studies need only be focused on the chemical stability of the test compound and potential light or temperature sensitivities thereof. It should, of course, be ensured that no precipitation out of solution occurs under the recommended storage conditions and durations.

Due to the often very high concentration requirements for safety studies mentioned earlier, only a few compounds allow for the use of fully aqueous solution formulations across the entire dose range of a toxicology study. Other approaches to increase the solubility of a test compound and allow for the use of solution formulations include the addition of cosolvents, surfactants, or complexing agents (these approaches will be covered in a separate section in this chapter); however, they introduce the risk of vehicle effects, and care needs to be taken to stay within the concentration and dose volume limits for each excipient depending on the test species.

17.4.2 Suspension formulations

In cases where the solubility of the test compound is not sufficient to dissolve the dose into a solution formulation, a suspension formulation is typically developed. For BCS class I and III compounds, dosing of a suspension might still result in a dose-proportional increase in the exposure across most of the dose range, since the compound might have enough solubility/dissolution rate in the aqueous environment of the GI tract to fully dissolve and get absorbed, even if the solubility is not high enough to dissolve the entire dose in the dose volume administered. The advantage of a suspension formulation is that it typically uses a simple, aqueous vehicle, often a Methocel (hydroxypropyl methylcellulose) solution with a low level of surfactant to aid in the wetting of the solid test compound, so that the risk of vehicle effects is minimal. The suspension usually can be prepared by the stepwise addition of small portions of the vehicle to the entire amount of test compound in a mortar and thorough trituration with a pestle after each addition of vehicle to ensure the complete wetting of all solid particles and the formation of a fully homogeneous suspension. In cases where this trituration method is not feasible due to the large scale of the suspension preparation, the suspending vehicle can be added directly to the test compound and followed by more vigorous mixing to obtain a homogeneous suspension. However, the use of a suspension formulation also adds certain challenges and complexities to the formulation preparation, handling, and storage that do not exist for solution formulations. If during the toxicology study the dose volume is subdivided from a bulk suspension for each dose, the homogeneity of the suspension needs to be ensured during the entire use-time period. In addition, an appropriate procedure for resuspension after storage, such as sonication,

stirring, or shaking, needs to be identified to ensure that a homogeneous suspension can be obtained prior to every dose after the formulation was stored for a period of time. In cases where the test compound settles and forms a solid cake during storage that is difficult to break up and resuspend, continuous stirring during the entire use-time period might have to be employed. Changes in particle size of the suspended test compound during the use-time period also need to be evaluated. Particle size reduction caused by sonication or stirring during each resuspending cycle or especially during continuous stirring on storage has to be avoided. At the same time, particle size growth (Ostwald ripening) during repeated refrigeration/warming cycles over the course of the use-time period might become an issue. Lot-to-lot particle size and morphology variations of the test compound can potentially lead to batch-to-batch differences in homogeneity of the dosing suspension or its tendency to settle and cake during storage. Of course, particle size differences in a suspension can also lead to differences in the dissolution rate after administration and with variations in exposure, especially for BCS class II and IV compounds with low solubility. Lastly, the potential for crystalline form changes of the drug substance in a suspension needs to be investigated. For suspensions of amorphous drug substances or solid dispersions, there is a risk of drug substance crystallization from suspension over time.

17.5 FORMULATIONS FOR BCS CLASS II/IV COMPOUNDS USING ENABLING TECHNOLOGIES

Low aqueous solubility is the common attribute that classifies the BCS Class II/IV drug molecules. Compounds in these two classes have a tendency to exhibit low BA due to solubility-limited absorption or dissolution rate-limited absorption. Poor dissolution can be caused either by large particle size/small surface area or low solubility. To emphasize the importance of solubility, the dissolution/solubility-limited case is referred to as solubility-limited absorption, while the dissolution/particle size-limited case is called dissolution-limited absorption.[51] If the absorption barrier is dissolution/particle size-limited, then particle size reduction is a potential path forward. If the absorption is solubility-limited, improving both the solubility and the dissolution rate may be necessary.

For BCS II/IV compounds, extra formulation effort is often required in order to garner sufficient API exposures in vivo. This makes the formulation design more complicated compared to that for BCS Class I/III compounds. Theoretically speaking, if not limited by time and API quantity, an iterative trial-and-error type of comprehensive formulation screen may eventually result in a workable formulation. However, an aggressive timeline and the high cost of an API at the preclinical phase preclude a massive formulation screen. We advocate an efficient and rational formulation development process starting from the understanding of the root cause for the low solubility and dissolution rate.

The dissolution rate has been long established to be directly correlated to solubility, a thermodynamic property. The dissolution process can be viewed as a pseudochemical reaction, which is governed by thermodynamics. The Gibbs free energy, ΔG, is the balance between enthalpy, ΔH, and entropy, ΔS, at a given temperature T ($\Delta G = \Delta H - T\Delta S$). When a solute is introduced into a solvent system, dissolution will take place and continue until equilibrium is established or ΔG becomes zero, at which point the solubility of the solute is reached.[52] Since dissolution produces more randomness of molecules in the entire system (including solid and solution states), the ΔS is generally positive. Thus, dissolution is more driven by the net enthalpy of solution, ΔH_s.

The dissolving of a solid involves two consecutive processes: (1) the melting of the solute where the solute molecules break free from the solute-solute molecular interactions, described by the heat of fusion (ΔH_f^T) at the dissolution temperature, T, and (2) the mixing of the melt solute molecules with surrounding solvent molecules, namely, the establishment of solute-solvent intermolecular interactions, resulting in the change in heat of mixing (ΔH_{mix}). This two-step process can be expressed by the following equation[53]:

$$\Delta H_s = \Delta H_f^T + \Delta H_{mix} \tag{17.1}$$

From Eq. (17.1), it can be realized that in order to overcome the ΔH_s barrier during dissolution, we can either reduce the term of ΔH_f^T or facilitate the term of ΔH_{mix}. As such, Eq. (17.1) is the basis behind a wide array of solubilization and dissolution rate-enhancing techniques currently used by many researchers. For example, if the low aqueous solubility of a compound is due to its high hydrophobicity, indicated by a high log$P$ value, then we can change the solution environment to promote more solute-solvent intermolecular interactions. This can be done by adjusting the pH, adding a cosolvent, introducing lipids or surfactants, mixing with a complexing agent, or using combinations of these tactics. If the high heat of fusion (ie, high melting point) is the major barrier for achieving aqueous solubility, then techniques to break down the lattice energy are expected to be more effective. These techniques either introduce high-energy solid

forms such as amorphous or metastable solid forms or change the parent compound into a salt, if the compound is an acid or base strong enough to produce salts. The compounds with both high log$P$/log$D$ and a high melting point are apparently more difficult to formulate, and sometimes modification to the chemical structure is necessary to improve these properties.

It is also well-known that the dissolution rate correlates with the surface area of drug particles (refer to Nerst and Brunner equation in chapter: The Fundamentals of Diffusion and Dissolution of this book). Reducing the particle size, thus increasing the surface area, is probably one of the earliest approaches pharmaceutical scientists have used to increase BA.[54] The surface area term in the Nerst and Brunner equation is often viewed as the total surface of the exposed solid, such as the flat surfaces or the surface area of spherical particles. The initial dissolution is actually more driven by the corner and edge effect[55]; molecules at corners, edges, and defect spots are bound together with smaller interaction energies and are inclined to dissolve first. Particle size reduction technology creates proportionately more corners, edges, and other defects when the particles are turned into smaller ones, which help increase the dissolution rate.

When crystals are made into nanoparticles, the dissolution rate can increase significantly. The dissolution rate constant of a small particle, k_S, versus the dissolution rate constant of a large particle, k_L, can be calculated by Eq. (17.2)[55]:

$$\frac{k_S}{k_L} = \frac{C_{sol,S}}{C_{sol,L}} \times \left(\frac{r_L}{r_S}\right)^2 \tag{17.2}$$

where $C_{sol,S}$ is the solubility of the small particle, $C_{sol,L}$ is the solubility of the large particle, r_L is the radius of a large particle, and r_S is the radius of a small particle. The solubility ratio of a small particle over a large one can be calculated by the Freundlich equation (Eq. 17.3)[56]:

$$\ln\frac{C_{sol,S}}{C_{sol,L}} = \frac{2\gamma V_m}{rRT} \tag{17.3}$$

where γ is the interfacial tension, r is the radius of the small size particle, V_m is the molar volume of the particle (the molecular weight divided by the density), R is the ideal gas constant, and T is the absolute temperature. Let's use acetaminophen as an example to calculate the dissolution rate increase after particle size reduction to nanoparticles. Assuming the large particle has a particle size of 50 μm (a commonly used particle size for APIs), and the small particle is 800 nm, which is a good average size achievable by nanotechnology. With acetaminophen's molecular weight of 151.16 g/mol with a density of 1.2 g/cm^3 and the interfacial free energy of 30 mJ/m^2 at 310K (37°C),[56] the solubility of an $r = 800$ nm crystal is calculated to be 1.0037 times the solubility of a macrocrystal using Eq. (17.3). This shows that reducing the size to 800 nm only very slightly increases the solubility. The gain in the dissolution rate is mainly coming from the surface area increase: the dissolution rate ratio, k_s/k_L, of a $r = 800$ nm crystal versus a 50 μm crystal is $1.0037 \times (50{,}000\ \text{nm}/800\ \text{nm})^2 = 3920$, according to Eq. (17.2). Putting this value in practical perspective, if the large 50 μm particles take 60 min to dissolve, the 800 nm nanocrystals will take 0.9 s to dissolve, assuming discrete particles are dispersed and wetted in aqueous solutions. This represents potentially a tremendous dissolution rate advantage with the nanotechnology. It should be pointed out, however, no matter how fast the dissolution rate is, the highest concentration the nanocrystals can obtain is the crystalline solubility or slightly above the crystalline solubility. This contributes, at least partially, to the observation that nanotechnology is more suitable for BCS Class II compounds when the absorption is limited by the dissolution rate. With BCS Class IV (poorly permeable), formulations that generate supersaturation (higher concentration than equilibrium crystalline solubility) are expected to work much better. This aspect will be detailed in the context of developing in vitro dissolution method.

The aforementioned tactics that manipulate either the ΔH_f^T term or ΔH_{mix} term or particle size reduction have been collectively referred to as enabling technologies because they have enabled the delivery of challenging poorly water-soluble pharmaceutical compounds that otherwise would have been discarded during the drug discovery phase. All these approaches have been or can be used in the toxicology applications. Fig. 17.4 provides a systematic categorization of these formulations. Solution-based approaches are aimed at changing the solvent environment, while solid-based approaches reach the purpose by changing the solid properties of the API. Fig. 17.4 also emphasizes the importance of crystallization inhibition in every approach, since fast crystallization from supersaturated systems can reduce or even negate the effectiveness of these formulations. Nanosuspension has not become a mainstream formulation strategy for routine toxicological studies due to the challenges in scale-up. However, it is an excellent formulation for PK studies and early-stage toxicological studies. Readers are referred to published articles on this technology.[54,57,58] Complexing agents, such as cyclodextrins, can be effective solubilizers, but there are concerns of causing toxicological signals at large doses.[59–61] The other frequently used techniques are detailed in the following text with regard to mechanisms, application and methods of design, characterization, and preparation.

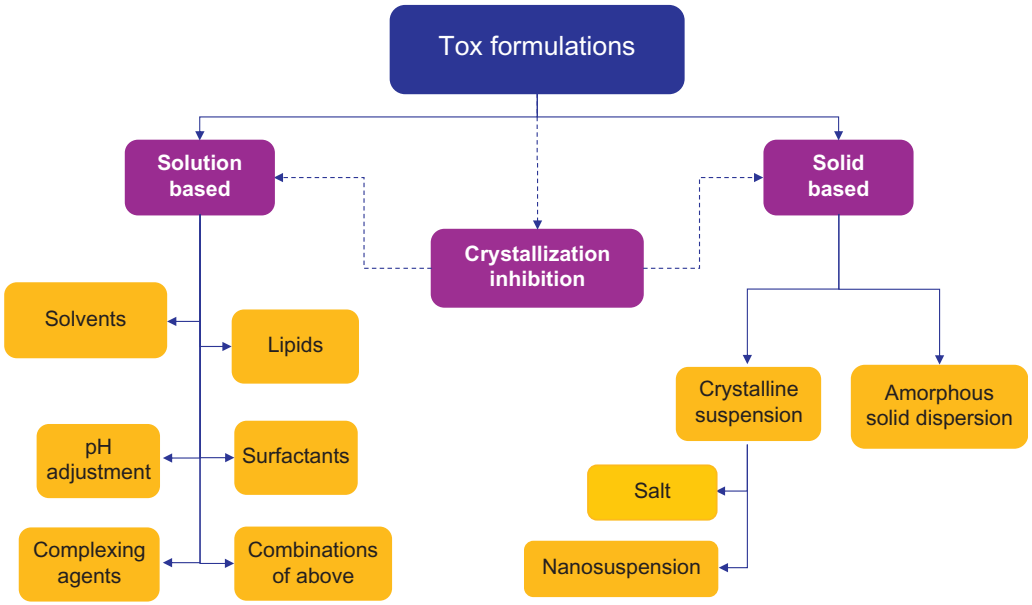

FIGURE 17.4 Categorization of enabling toxicology formulations for delivery of poorly water-soluble pharmaceutical compounds.

17.5.1 Solubilization by changing solution pH

As described in the previous section of factors that impact solubility, changing the pH is the most straightforward way to bring weakly basic or acidic pharmaceutical compounds into solution. The relationship between solubility and pH follows a set of defined models (equations) derived from Henderson–Hasselbalch ionization equations (reference to chapter: Solubility of Pharmaceutical Solids in this book). In other words, the solubility can be predicted if the intrinsic solubility and pK_a values of the compound are known.[62] Since pH is at log scale of [H^+], each pH unit change equals to a 10-fold [H^+] concentration change, and, therefore, one pH unit away from a pK_a will prompt a 10-fold solubility change (Illustrated in Fig. 17.2 and Eq. 17.4). For dibasic or diacidic compounds, the solubility will institute a 100-fold change with each pH unit change away from the second pK_a, and for tribasic or triacidic, a 1000-fold change. This makes pH adjustment a very powerful technique.

Using an acidic compound with a pK_a of 4.0 and an intrinsic solubility of 10 μg/mL as an example, based on one acidic pK_a—solubility model (Eq. 17.4), its total aqueous solubility (S_T) is 10 μg/mL at pH 2.0, 20 μg/mL at pH 4.0, 100 μg/mL at pH 5.0, 1000 μg/mL at pH 6.0, and 25,000 μg/mL at pH 7.4. If the goal is to make a 20 mg/mL solution, one can simply use a commonly available pH 7.4 phosphate buffer for this compound.

$$S_T = S_0\left(1 + 10^{\mathrm{pH}-\mathrm{p}K_a}\right) \tag{17.4}$$

In reality, oftentimes accurately measured intrinsic solubility and pK_a values are missing at the early stage. However, an estimation can be obtained from various sources, as described in previous section (Solubility Prediction and Screen). This information is used to assess the feasibility of the pH adjustment approach.

In practice, formulation starts with the targeted (or required) drug concentration, which is calculated based on the known targeted dose and the allowed dosing volume. For example, if the dose is 100 mg per kg of rat weight, then the target solution concentration is 10 mg/mL based on the commonly accepted dose volume of 10 mL/kg for an aqueous solution in a rat. To minimize API consumption in the prototype formulation screen, one could use the smallest possible volume, for example, by weighing about 1 mg and adding a final volume of 100 uL to make the final concentration of 10 mg/mL. To adjust the pH, the most commonly used base is NaOH and acid is HCl. They are added at a 1:1 molar ratio (API: pH modifier) or at an amount to reach a desired pH value. In the above case, if 10 mg/mL becomes a clear solution after pH adjustment, then the solubility target is successfully reached.

Although formulation preparation through pH adjustment is as simple as adding a counterion, many details still need to be taken into consideration and are listed in the following.

1. Chemical stability of the compound at extreme pH values. Chemical reactions such as hydrolysis are accelerated under extreme pH conditions.
   The degradant may exhibit increased solubility compared to the parent compound, which can be

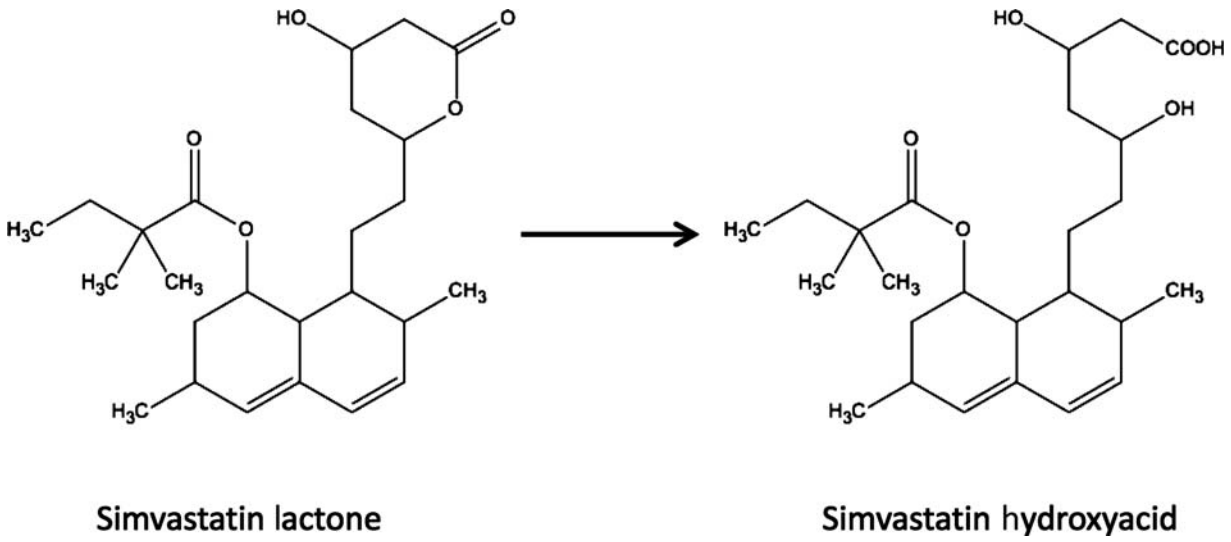

FIGURE 17.5 Under basic pH conditions, simvastatin lactone undergoes hydrolysis to simvastatin hydroxyacid, which becomes soluble at pH 13. *Source: Chemical Reaction adapted from Ungaro F, Giovino C, Catanzano O, Miro A, Mele A, Quaglia F, et al. Use of cyclodextrins as solubilizing agents for simvastatin: effect of hydroxypropyl-β-cyclodextrin on lactone/hydroxyacid aqueous equilibrium. Int J Pharm 2011;404:49–56.*

misleading if visual solubility is used to guide the direction of formulation development. One real life example is the solubility of simvastatin. The aqueous solubility of simvastatin was listed in the Merck Index[63] as 60 μg/mL at pH 1 and 70 mg/mL at pH 13, a greater than 1000-fold increase from pH 1 to pH 13. Simvastatin is a neutral compound, and its solubility at the pH 1−13 range should be a constant not a variant. It is impossible to observe the 1000-fold solubility difference across pH 1−13. What happened was that simvastatin is prone to hydrolysis at a basic pH, opening the ester bond in the six-membered lactone[64,65] to form hydroxyacid (Fig. 17.5). The degradant hydroxyacid is ionizable at a basic pH; thus it becomes much more soluble at pH 13, leading to an erroneous solubility assessment. Therefore, the chemical structure of the API should be carefully examined prior to pH adjustment, and stability should be particularly watched for when pH adjustment is to be attempted.

2. Solid form change during formulation preparation. At the early stage of discovery, compounds are purified by chromatographic separation and drying out the solvent. This often produces a metastable solid form (amorphous or higher-energy-state crystalline form), and conversion to a thermodynamically more stable form through solution-mediated transformation may occur at any time. This conversion process may be slow in neutral pH aqueous solutions due to low solubility. However, the pH adjustment creates a higher drug concentration that greatly increases the molecular collision rate to trigger nucleation and facilitate the solution-mediated phase transformation (SMPT) (refer to the section of transformation among solids in chapter: Crystalline and Amorphous Solids). Crystallization can occur through two ways: the transformation to a more stable crystalline form or to a salt with the added counterion. Either situation may lead to precipitation during the formulation preparation. If the precipitation occurs within several hours, one may still salvage the same formulation by preparing the formulation right before the dosing in a quick PK screen. For a long-term safety studies, reformulation will be necessary using a stable solid form.
3. Possible poor in vivo performance due to precipitation/crystallization as a result of pH gradient in GI tract. As described before, the solubility increases logarithmically with the pH decrease for basic compounds or with the pH increase for acidic compounds. Unfortunately, the solubility can also decrease with pH changes at the same dramatic level. This creates a large supersaturation to induce precipitation/crystallization. The solubility enhancement thus obtained may be lost in vivo due to pH gradient in the GI system. Using the same example acidic compound as illustrated before with a pK_a of 4.0 and an intrinsic solubility of 10 μg/mL, it can be formulated into a 20 mg/mL solution in a pH 7.4 buffer. When the solution formulation is dosed in rats (stomach pH of 4), up to 99.99% of the dose could potentially precipitate out in the stomach,

since the solubility at pH 4 is decreased to 20 μg/mL. Redissolving of the precipitates may not occur quickly enough to allow the dose to be absorbed, although the pH will gradually increase to 6.8 at which the solubility is higher. Similar phenomenon occurs to basic compounds, which dissolve better in the stomach, but then precipitate as the compound moves down the GI tract. It is important to know this precipitation tendency and profile before finalizing the formulation. An appropriate in vitro dual pH dilution test can be used for this purpose. Different additives such as crystallization inhibitors or solubilizers can be added to the formulation to maintain the supersaturation for a longer period of time or to reduce the severity of the precipitation. The effectiveness of the additives can be screened using the same in vitro dilution testing, which will be described in more details in the section Evaluating Formulation Performance by In Vitro Dissolution.

4. Safety concerns of extreme solution pH to animals. The safe pH range depends on the dosing volume, dosing duration (one dose versus repeated dose), and animal species. For example, a pH 2 solution is acceptable for one-time dosing but may cause irritation to the esophagus in long-term toxicological studies. The pH of Coca-Cola and Pepsi was reported as 2.5–2.6, which is probably at the lower end of a safe pH.
5. Limitation in dose loading. Every type of formulation approach has dose-loading limitations, although they are due to different reasons. The dose-loading limit by pH lies with the value of the intrinsic solubility and the acidity or basicity of the compound (pK_a). If the intrinsic solubility is in the ng/mL range, it is probably not possible to load the target high dose into a solution formulation, since changing the pH to 6 units away from the pK_a will only bring the solubility to the mg/mL range. On the plus side, dose loading through pH adjustment can be projected relatively easily, and the lengthy time to evaluate the feasibility can be avoided.

17.5.2 Formulation through suspension of salt

Salt formation is a well-established approach to overcome dissolution rate obstacles. In a solid dosage form for human use, salt is mixed with excipients, the blend of which is then tableted or encapsulated. This formulation approach is not usually adopted in preclinical studies. Solid dosage forms are not suitable for rodents, since they cannot swallow the big dose unit. For long-term studies in rodents, salt can be mixed into the food as a dosing route on the conditions that the taste is acceptable and adequate BA can be obtained. In reality, hardly any drug tastes good, especially when mixed into the food at high percentages. Gavage of freely flowing formulations (suspension) is usually the only dosing option for salt. Lager animals such as dogs can be trained to take pills; however, the tablets or capsules made for clinical studies are not able to deliver the large dose and/or lack the dose flexibility to meet the wide dose range that is often required in toxicological studies. These practical limitations determined why salt is usually dosed as suspensions in preclinical studies. This section, therefore, is focused on salt suspension formulations.

For salts of poorly water-soluble compounds, the major concern is the physical stability. Conversion back to the parent form can potentially occur when suspended into an aqueous medium. This is because the salt is a metastable solid form when the solution pH is away from the pH_{max}. An example of a pH-solubility profile of a weakly acidic drug, flurbiprofen,[66] is illustrated in Fig. 17.6, and used to explain the pH_{max} and its relevance to salt physical stability. Fig. 17.6 shows that when the solution pH is much less than the pK_a of flurbiprofen (ie, 2 pH units below the pK_a), the solubility of the drug is a constant, termed as intrinsic solubility (S_0). As the pH increases to $\geq pK_a$, the solubility continues to increase until the pH reaches the pH_{max} (at ~pH 7.3 for flurbiprofen) at which a salt is formed. At any pH above the pH_{max}, the solubility again becomes a constant, which equals to the solubility of the salt.

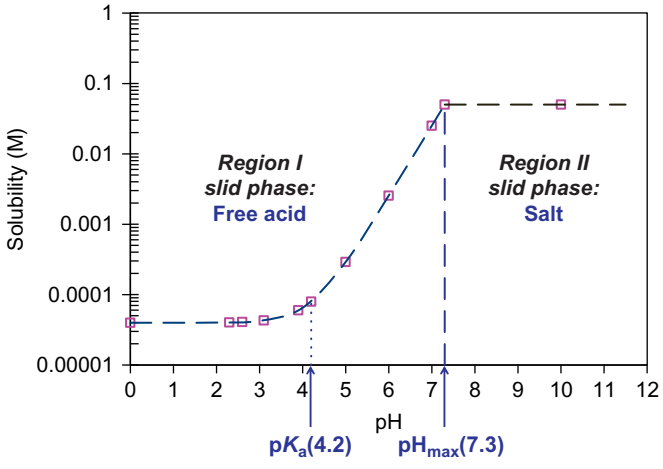

FIGURE 17.6 The pH-solubility profile of a weakly acidic drug, flurbiprofen, with a pK_a of 4.2. *Source: Adapted from Pudipeddi P, Serajuddin ATM, Grant DJW, Stahl PH. Solubility and dissolution of weak acids, bases, and salts. In: Stahl PH, Wermuth CG, editors. Handbook of pharmaceuitcal salts properties, selection, and use. New York, NY: Wiley-VCH; 2002. p. 19–41.*

Therefore, the pH-solubility profile is essentially a phase diagram. The pH_{max} divides the phase diagram in Fig. 17.6 into two regions: Region I is located below the pH_{max}, and Region II is located above the pH_{max}. In Region I, the free acid of flurbiprofen is the thermodynamically stable solid form, whereas in Region II, the salt of flurbiprofen is the thermodynamically stable form. At pH_{max}, the salt and the free form are at equilibrium with each other. In other words, the salt is a metastable form at any pH below its pH_{max}. If the salt particles of flurbiprofen are added to a solution with a $pH < 7.3$, the salt will eventually convert to the free acid of flurbiprofen. When equilibrium is reached, the solid recovered will be the free acid rather than the salt. This process is commonly known as disproportionation of a salt.[45,67] The same phenomenon exists for salts of basic compounds, where the pH-solubility relationship is a mirror image of that of an acid. The pH_{max} is located below the pK_a of the base, and the salt is metastable when placed in a solution with a pH greater than the pH_{max} and may convert back to the free base. The salt-to-parent conversion occurs through SMPT (refer to the section on transformation among solids in chapter: Crystalline and Amorphous Solids) where the salt dissolves first into the solution to reach a high enough supersaturation, which then triggers a nucleation of the crystal form of the free acid or free base.

To stabilize the salt in a suspension, we should consider both the thermodynamic and kinetic factors in the salt-to-parent form transformation process. Based on the pH_{max} theory illustrated in Fig. 17.6, if the suspension pH is below the pH_{max} of a salt of basic compounds, or above the pH_{max} of a salt of acidic compounds, the salt will be in a thermodynamically stable region and will never convert to less soluble parent form crystals. In reality, this is less likely to be achieved, as shown by Eq. (17.5) and Eq. (17.6). Eq. (17.5) is the Henderson–Hasselbalch equation of a monobasic drug. $[B]$ is the concentration of the unionized base, and $[B^+]$ is the concentration of the ionized base. Eq. (17.6) is written as the Henderson–Hasselbalch equation at the salt solubility equilibrium point,[68] where $[B]_s$ is the solubility of the unionized base, K_{sp} is the solubility product of the salt, and $\sqrt{K_{sp}}$ is the salt solubility, which can also be written as $[B^+]_s$. In a salt suspension, the maximum concentration of the salt is the salt solubility. Practically, before the salt solubility can be reached, the free form may have already crystallized if the nucleation of the free form is facile. For the sake of this discussion, let's assume the salt solubility can be reached quickly during the suspension preparation step. At the solubility of the salt, the solution pH will be at the pH_{max} of the salt, or the maximum pH of the salt suspension will be equal to pH_{max}. The pH is not able to go below the pH_{max} of the basic drug. Similarly, the pH of a salt suspension of an acidic drug will not reach above the pH_{max} of the salt.

$$pH = pK_a + \log\frac{[B]}{[B^+]} \tag{17.5}$$

$$pH_{max} = pK_a + \log\frac{[B]_s}{\sqrt{K_{sp}}} = pK_a + \log\frac{[B]_s}{[B^+]_s} \tag{17.6}$$

The discussion indicates that the salt suspension will not be thermodynamically stable, although being close to the pH_{max} does reduce the driving force for nucleation of the parent form crystals. In order to be within the thermodynamically stable region, an extra amount of counterion needs to be present, for example, adding NaOH to a sodium salt suspension until the pH reaches above pH_{max}. This is a viable approach, since a small pH increase above pH_{max} for basic compound salts or a small pH decrease to below pH_{max} for acidic compound salts will suffice to make the salts thermodynamically stable, as long as the final pH does not extend to extreme acidity or basicity to render safety concerns.

If the thermodynamic stability pH region cannot be reached due to safety concerns, the kinetics of the salt-to-parent form conversion in suspensions can be intervened using formulation and dosing techniques. Different methods can be tried to slow down the conversion process. The suspending agents, usually polymers used at 0.2–2%, result in a higher viscosity, which may slow down the conversion rate. Therefore, a prudent approach is to select a polymer or a combination of polymers that can act as both a good suspending agent and a strong crystallization inhibitor capable of preventing or significantly delaying the solid form transformation. In recent years, understanding of the mechanisms of crystallization inhibition by polymers has significantly improved from the studies of amorphous solid dispersion formulations.[69–76] The methodology in selecting the polymers will be discussed in more detail in the amorphous solid dispersion section. An alternate way was reported to dose salt particles suspended in an organic solvent.[77] It was thought that the lower solubility of the salt in the solvent would delay the conversion kinetics. The solvent-based dosing method introduces an unnecessary potential safety risk to animals and removes the benefit of the salt suspension as a benign aqueous formulation. Stabilizing the suspension through a polymer-based methodology is a more reasonable approach.

The length of physical stability required for the salt suspension depends on the nature of the study and the different dosing routines established in the different study units. It is desirable and sometimes necessary to obtain a suspension formulation with 1 week or

longer physical stability, since a weekly formulation preparation schedule is preferred for resource savings. In the worst-case scenario when week-long physical stability cannot be obtained, there is an option to prepare the salt suspension on daily basis or right before dosing.

Prior to making salt suspensions, the suspension density (weight percentage) is calculated based on the dose and the dosing volume. For example, if the dose is 300 mg/kg of rat at a dosing volume of 10 mL/kg, the minimal suspension density is 30 mg/mL (or 3%). The procedure for preparing a salt suspension is the same as that described previously (section Suspension Formulations) for BCS Class I/III compounds. It should be mindful, however, to use the initial higher solid-to-liquid ratio (higher surface area), which helps drive the salt to quickly reach salt solubility to avoid or minimize the salt-to-parent form conversion. The acceptable threshold of the suspension viscosity can be tested by pulling the suspensions into a syringe with the dosing gavage tube attached and expelling the suspension out of the syringe. If the loading and unloading of the suspension from the syringe is smooth and does not require excessive efforts, feasibility of dosing can be assumed. Essentially, the highest possible dose is limited by the suspension viscosity.

After the suspension is administered in vivo, the absorption is dependent on the dissolution rate from the salt particles. API particle size and distribution should be controlled for reproducible performance. The particle size control should consider not only the particle size of the dry API but also the actual API particle size in the suspension. An aggregation or glomeration of particles in a suspension due to wetting problems reduces the effective surface area. A wetting agent (eg, 0.1% Tween 80) is typically applied to overcome wetting issues; however, in this case, caution should be exercised for the potential of the wetting agents (ie, surfactants) to promote crystallization of the parent form.[78] Particle size distribution control also should consider minimizing the Ostwald ripening effect where particles grow at the expense of smaller and more soluble particles. Polymers find themselves yet another application here to inhibit or slow down the crystal growth.[79,80] Appropriate and smaller particle size also helps stabilize the suspension without fast sedimentation and pass the suspension through the narrow diameter of the gavage tube used in dosing small animals (rat or mouse).

It should be noted that salt selection is a prerequisite for a successful salt suspension formulation to use in preclinical studies. Salt selection is often a part of the solid form selection process, which is complex and involves multiple functional areas from discovery, process chemistry, and formulation development. Salt selection should consider the dissolution rate, stability, manufacturability, and formulatability of the salt. Physical stability is one of the important criteria. We often have a tendency to identify a salt with a higher solubility and dissolution rate; however, a salt with a higher solubility produces a pH_{max} more far away from the neutral biological pH, which leads to a higher risk of salt-to-free form conversion (physical instability) when the salt is placed in a neutral pH aqueous medium.[68] Selecting a physically more stable salt will greatly reduce the challenges in formulating and dosing the salt suspension for preclinical studies.

17.5.3 Solubilization through cosolvents

Cosolvent-based formulations are widely used due to relatively fast formulation development and the generally straightforward preparation for daily use. The useful solvents are those semipolar such as PEG 300, PEG 400, propylene glycol (PG), ethanol, DMA, and so forth. These solvents possess the ability to form hydrogen bonding with water molecules and induce a certain degree of polarity in nonpolar drug molecules, thus bringing about miscibility between nonpolar drug molecules and water.[81] For this reason, semipolar solvents are quite versatile. They can be added to aqueous solutions to produce a simple aqueous/solvent blend or an aqueous/multiple solvent blend, or they can be added to a lipid/surfactant to formulate more complex lipid-based formulations (to be separately described). Some of them can be used as a neat solvent under certain restrictions.

The solubility behavior of drug molecules in solvent-aqueous mixtures is complex. Fig. 17.7 schematically describes two types of solubility profiles. In solvent system A, the solubility of a drug molecule increases initially with an increasing percentage of a good solubilization solvent but plateaus at certain solvent percentage, after which the solubility goes downhill with further increase of the good solvent.[82] In solvent system B, however, the solubility keeps increasing with the addition of more good solvent, and the maximum solubility resides at the 100% good solvent composition.

The solubility increase with a good solvent follows a semilogarithmic relationship established by Yalkowsky et al. (refer to Eq. 1.58). When more than one solvent is used in the mixture, a similar relationship applies,[22] as described in Eq. (17.7). In Eq. (17.7), $[S_{tot}]$ represents the overall drug solubility, which is the sum of the intrinsic solubility, $[S_0]$ and the solubility created by each solvent. The magnitude of the solubility gain by a solvent is the product of the volume fraction of the solvent, f_i and the solubility power of the solvent, σ_i, which is a unique property of the solvent. Eq. (17.7)

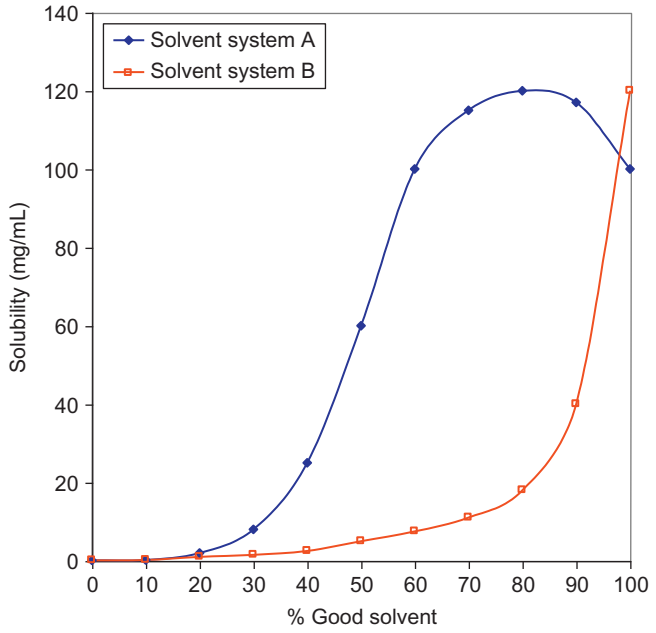

FIGURE 17.7 Schematic illustration of solubility profiles in mixtures of solvent and aqueous solutions.

provides a theoretical basis that multiple solvents can be used together, since the solubilization power is additive.

$$\log[S_{tot}] = \log[S_0] + \sum_{i=1}^{n} \sigma_i \cdot f_i \qquad (17.7)$$

The formulation using cosolvents starts with a solubility screen in various cosolvents. The goal is to identify the best solvent or solvent mixtures for further formulating into a blend with water or aqueous buffer. A solubility screen can also be done in predetermined blends of solvents and buffers that have been working for a certain group of compounds. For example, if a group of compounds historically dissolve well in PEG 400 and have a basic pK_a of ≥ 6, a formulation blend with PEG 400 and a slightly acidic buffer (ie, pH 4 buffer) serves a good starting point.

Cosolvents often provide an excellent solubility increase over the aqueous solubility. Unfortunately, cosolvents can be toxic, especially when used neat or at a high percentage (refer to Table 17.3). Another issue is that, if mixed with aqueous buffer in the final formulation, the solubility power decreases at a semilog scale, which threatens to achieve target drug loading. This dilemma can be mitigated to some degree using several modifications, for example, using a mixture of multiple solvents. With an appropriate blending ratio of various solvents, it is possible to increase the overall solvent content to maximize the solubility while maintaining or reducing the vehicle toxicity. This is based on the assumption that the toxicity enacted by each solvent is additive, which may not be true in every case. Additional consultation with toxicologists in the preclinical safety area is encouraged. Another approach is to add pH adjustment simultaneously. Li and Zhao[22] determined that the pH/cosolvent combination works synergistically to significantly increase the solubility. As previously described, the same caution on chemical stability and side effect at an extreme pH must be exerted. It should also be noted that pK_a values change in the presence of a solvent; a base will become a weaker base, and an acid will become a weaker acid. Therefore, the pH of the cosolvent solution may change to a more extreme pH when the same amount of counterion as used in the pure aqueous formulations is added. A final pH measurement is recommended before dosing in the animals. An alternative way is to mix the solvent with a buffer at a safe pH. To further increase the solubility, the aqueous phase can contain other solubilizers such as surfactants or cyclodextrins. Finally, all of the methods can be combined if necessary. For example, for an acidic compound (ie, pK_a of ~ 4) with a good solubility in PEG 400, ethanol, and a chemical structural element to potentially going into the cyclodextrin cavity, a mixture of 40% of PEG 400, 10% ethanol, and 50% of 30% beta-cyclodextrin in a pH 7.4 buffer may provide a desirable outcome. However, some solubilization mechanisms may not compatible with each. In such cases, it is wise not to combine these approaches.

Special attention should be paid when the formulation contains a high-solvent content. On one aspect, diluting a high-solvent-content formulation by aqueous medium tends to induce fast precipitation based on the steep portion of the solubility-phase diagram (Fig. 17.7). Dilution is an inevitable event when dosing in vivo. This risk should be evaluated by an appropriate in vitro dilution test, which should be an integral part of the formulation development. The rational design of an in vitro dilution test will be covered in the section of Evaluating Formulation Performance by In Vitro Dissolution. Another aspect comes from the safety perspective. The dosing volume of a high-solvent-content formulation may have to be reduced for safety reasons. The allowable dosing volume is often different among different preclinical species (see Table 17.2). Therefore, the safe dosing volume should be determined before rushing into the formulation effort in order to avoid the last minute surprise.

17.5.4 Lipid and surfactant-based formulations

Lipid and surfactant-based drug delivery systems are among the most versatile and effective formulation

approaches to enhance the BA of poorly water-soluble compounds. The number of commercial formulations, however, is limited mainly due to practical limitations in drug loading (thus a high pill burden), the concerns on API and excipients chemical stability, the requirement of compatibility with capsule shells, and a more complex manufacturing process. Most of these disadvantages will vanish in the preclinical setting where dosing volume can be large, much more flexible, long-term chemical stability is not required, and the capsule is not a component of the formulation. Therefore, this category of formulations is well suited for use in preclinical studies. However, lipid and surfactant-based formulations are often viewed as more mysterious. One reason is probably due to the difficulties in predicting the solubility in lipid excipients as opposed to other systems such as pH adjustment, cosolvent addition, or complexation. Another reason is because the performance of the formulations is less predictable by conventional in vitro dissolution or dilution testing. Adding more to the mystery is the large variety of lipid excipients; the numerous commercial names of lipids and surfactants alone may overwhelm a novice formulator. Therefore, the successful development of lipid and surfactant-based formulations will require the learning of rational selection of the excipients and the use of appropriate in vitro dissolution methods to determine the potential in vivo performance.

17.5.4.1 Commercially available excipients

The first and foremost step in learning lipid and surfactant-based formulation is to gain knowledge in the various excipients. The ability to formulate well is heavily dependent on the understanding of excipient properties and miscibility among the excipients. The list of commercial available excipients is shown in Table 17.5. This table separates the excipients into three categories: water-soluble, water-insoluble, and surfactants. Such a division is helpful for users to conveniently locate the needed excipients based on the class of lipid formulations to formulate. Phospholipids listed under the water-soluble group actually have limited solubility in water and can be moved to the water-insoluble category. The water-insoluble group is the most varied and diverse group, encompassing natural oils and fatty acids; semisynthetic monoglycerides, diglycerides, and triglycerides; semisynthetic PEG derivatives of glycerides and fatty acids; polyglyceryl fatty acid esters; cholesterol; and phospholipids. Each of these subcategories further branches out through varying fatty acid chain lengths, degrees of esterification (mono-, di-, or tri-), and compositions. Some of them are unique blends named as particular trade names such as Gelucire marketed by Gattefosse. To make it more complex, different vendors assign different trade names to their products; this gives rise to a similar blend being called different names. Fortunately, comprehensive summaries of the water-insoluble group have been written in a book chapter by L. Gibson.[83] Readers are encouraged to read the reference to gain more comprehensive knowledge.

17.5.4.2 Selection of excipients

Before selecting the excipients, it is beneficial to understand the structural constituents of lipid-based formulations. Pouton and Porter[85] divided lipid-based drug delivery systems into four types:

- Type I: Oils (triglycerides, diglycerides, and monoglycerides) only.
- Type II: Oils and less water-soluble surfactants.
- Type III: Oils, water-soluble surfactants, and cosolvents.
- Type IV: Water-soluble surfactants and cosolvents (no oils).

Compounds from modern drug discovery mostly do not solubilize well in pure oils, especially not in long-chain glycerides. Achieving a high drug load in Type I and in some instances in Type II is relatively difficult. On the other hand, these compounds tend to solubilize better in polar oils, phospholipids, surfactants, and cosolvents that are part of Type III/IV formulations. In addition, Type III and IV are SEDDS or self-microemulsifying drug delivery systems. They are easily dispersible in aqueous medium, leading to high supersaturation level, which is the major reason for the significant BA enhancement. These properties propelled the much more frequent use of Type III and Type IV than Type I and II in preclinical applications.

When the lipid-based formulation is diluted into an aqueous GI milieu, the drug molecules are protected from precipitation by remaining as a solution in lipid droplets, surfactant micelles, and/or other different lipid/surfactant aggregates. This indicates that the solubility in the excipients is an important factor not only for achieving high drug loading in the formulation but also for enhanced in vivo performance. Therefore, the logical selection of excipients starts with a solubility screen in the excipients. In general, the excipients that provide the highest solubility are the ones that should be considered. Water-miscible solvents such as PEG 400 and ethanol provide high drug loading owing to their unparalleled solubilization power and their ability to reduce the viscosity of the formulations for easier handling; therefore, they are indispensable in formulating Type III and IV formulations. As described before, pure solvent-based formulations often result in massive precipitation when diluted into aqueous

TABLE 17.5 List of Commercially Available Excipients

Water-Soluble	Water-Insoluble	Surfactants
Dimethylacetamide (DMA)	Beeswax	Polyoxyl 35 castor oil (Cremophor EL)
Dimethyl sulfoxide (DMSO)	Oleic acid	Polyoxyl 40 hydrogenated castor oil (Cremophor RH 40)
Ethanol	Soy fatty acids	Polyoxyl 60 hydrogenated castor oil (Cremophor RH 60)
Glycerin	D-alpha-tocopherol (vitamin E)	Polysorbate 20 (Tween 20)
N-methyl-2-pyrrolidone (NMP)	Corn oil monoglycerides, diglycerides, triglycerides	Polysorbate 80 (Tween 80)
PEG 300	Medium chain (C8/C10) mono- and diglycerides	D-alpha-tocopheryl polyethylene glycol 1000 succinate (TPGS)
PEG 400	Long-chain triglycerides	Solutol HS-15
Poloxamer 407	Castor oil	Sorbitan monooleate (Span 20)
Propylene glycol	Corn oil	PEG 300 caprylic/capric glycerides (Softigen 767)
Hydroxypropyl-β-cyclodextrin	Cottonseed oil	PEG 400 caprylic/capric glycerides (Labrasol)
Sulfobutylether-β-cyclodextrin (Captisol)	Olive oil	PEG 300 oleic glycerides (Labrafil M-1944CS)
Phospholipids	Peanut oil	PEG 300 linoleic glycerides (Labrafil M-2125CS)
Hydrogenated soy phosphatidylcholine (HSPC)	Peppermint oil	Polyoxyethylene 8 stearate (PEG 400 monostearate)
Distearoyl phosphatidylglycerol (DSPG)	Safflower oil	D-alpha-tocopheryl polyethylene glycol 1000 succinate (TPGS)
L-a-dimyristoylphosphatidyl choline (DMPC)	Sesame oil	Polyoxyl 40 stearate (PEG 1750 monostearate)
L-a-dimyristoylphosphatidyl glycerol (DMPG)	Soybean oil	Peppermint oil
	Hydrogenated soybean oil	
	Hydrogenated vegetable oils	
	Medium-chain triglycerides	
	Caprylic/capric triglycerides derived from coconut oil or palm see oil	

Adapted from literature Strickley RG. Solubilizing excipients in oral and injectable formulations. Pharm Res 2004;21:201–30.[84]

solutions. However, when combined with lipids and/or surfactants, the precipitation will be buffered by the lipids and surfactants. Ionic surfactants such as sodium dodecyl sulfate have limited solubility in lipids; therefore, nonionic surfactants, especially those with high hydrophile-lipophile balance values such as Cremophor EL, Cremophor RH40, Tween 20 and vitamin E TPGS, have been shown to be compatible with lipids. Surfactants play interesting roles in Type III and IV formulations. When in the formulation blend, surfactants sometimes are antisolvent, since they may not solubilize the API as effectively as lipids and cosolvents. When the formulation is diluted into an aqueous media, surfactants stimulate the formation of emulsion droplets and also form micelles to solubilize the API. Because of the dual roles, the selection of surfactants should consider the drug solubility in neat surfactants as well as in surfactant micelles in the presence of an aqueous medium. The former is related to drug loading in the formulation, and the latter is related to formulation performance in vivo.

As shown in Table 17.5, there exist large numbers of excipients, and screening all of them for solubility is apparently not feasible with limited API quantity and time. Several ways can be considered to narrow the screen funnel. One of them is to take into account the physicochemical properties of the API. For example, moderately lipophilic compounds (log*P* in the 2–4 range) are usually not very soluble in long-chain triglycerides. Polar compounds are more compatible with polar lipids such as phospholipids and oleic acid. Another is based on the fact that lipid excipients that do not rely on lipolysis as a prerequisite for drug release are preferred for rapid drug absorption.[86] This will eliminate the long-chain glycerides and put emphasis on the medium-chain monoglycerides, fatty acids, and monoesters of fatty acids. Last but not least is to examine the properties of

the lipids. Behind the façade of commercial names, the vast number of lipids is actually classified into smaller sets of substances as shown in Table 17.5; for example free fatty acids; short-chain monoglycerides, diglycerides, and triglycerides; medium-chain monoglycerides, diglycerides, and triglycerides; propylene glycol esters; and phospholipids. Choosing one lipid from each class will form a representative lipid panel. A visual solubility screen in this panel of lipids is conducted to generate a solubility profile based on which more focused screen can then be pursued in a smaller subset of lipids. Similar approaches can be applied to the screening of the surfactants and solvents. A solubility screen funnel provides an efficient way to quickly identify useful excipients.

17.5.4.3 Formulation development

After the promising excipients are identified from the solubility screen, which may include lipids, solvents, and nonionic surfactants, the next step is to formulate vehicles by combining these excipients at appropriate proportions.

The first question in every new formulator's mind is: What is the appropriate proportion to mix these excipients identified through the initial solubility screen? In other words, how to determine the percentage of a surfactant and/or a cosolvent to add to the oil (in Type III), or how much cosolvent should be added to a surfactant (in Type IV)? The answer to this complex question is surprisingly simple in concept. It depends on the miscibility (forming a one-phase or isotropic system) among those excipients. The determination of the miscibility is a straightforward experiment simply by mixing the excipients at different ratios and then recording whether or not a single-phase solution is obtained. However, it is tedious and time consuming. The amount of surfactant required can be determined by adding incrementally increased amounts of surfactant to each lipid, evaluating the stability of the emulsions formed upon dilution, and then selecting the best emulsified vehicle. This is also a tedious process. Since the API after being dissolved into the vehicle may change the phase diagram as well as the emulsification outcome, determining precisely the blank vehicle's miscibility and its ability to emulsify seems not a wise use of time. In a fast-paced preclinical setting where the formulation is needed right away, these tedious and time-draining experiments often could not be afforded. A useful shortcut is to roughly determine the miscibility by starting from a center percentage point, for example, at 50% lipid with 30–40% solvent and 10–20% surfactant. If the first blend is not quite successful, then a couple of adjustments at 10% incremental changes can be made while keeping the surfactant at the highest possible level to ensure the best self-emulsifying ability. This can quickly close into the miscible region and identify the initial prototype formulations for first PK study. Further optimization in the composition of the prototype formulations can be continued after receiving promising PK results. Clearly, prior knowledge in the miscibility of the selected excipients, either from publication or personal accounts, provides valuable information to pinpoint the miscible blends. The accumulation of the knowledge comes with diligence and attention to detail. Every time a clear vehicle is observed, record the composition, and save the information. These miscible blends can be further investigated with interest to identify potential trends within the excipients with similar physicochemical properties. This can quickly expand the miscibility database that has been gradually established with each formulation endeavor. In turn, the invaluable experiences will expedite the next formulation design and development.

The next step following the successful development of the prototype excipient blends is to measure the final solubility of the API in each of the blends, usually by using a visual solubility method. Although the solubility is often additive in nature from the individual excipient, the solubility needs to be confirmed in the final blend. Interaction among the excipients themselves is not uncommon, which may influence the API solubility in the vehicle blend. Due to the viscosity of the vehicle, the visual solubility is routinely measured under moderate heat (ie, 40°C). Hence, it should be cautious to make sure the solubility can be maintained when the formulation is cooled to room temperature in order to determine the drug loading more accurately.

The solubility in the selected blends and the allowed dosing volume are the first criterion to triage in different prototype formulations. Those with high enough solubility to deliver the target dose are preferred. As described in the solvent-based systems, safety is related to the dosing volume. Similar to the solvent selection discussed previously, the allowable dosing volume of lipids, surfactants, and solvents is often different among the different preclinical species. Reliable excipient safety data, usually available from manufacturers' GLP toxicological or in-house studies, should be consulted prior to making a decision. An adjustment in the formulation composition may be needed in order to meet the safety requirements.

17.5.4.4 Formulation characterization and selection

Before advancing the selected prototype formulations to animal PK and BA studies, in vitro characterization of the formulation should be carried out. First, the physical stability should be monitored. The high solution

concentration provides a high-driving force for polymorphic transformation. A more stable polymorph of the API crystal or a crystalline adduct with any of the excipients may materialize over time, either of which leads to the precipitation of the otherwise clear solution. Once the polymorphic transformation has taken place, the drug loading will have to be redetermined. Lipid excipient adduct is often more detrimental than API polymorphic transformation because the lipid as a dominating component in the formulation exists at high thermodynamic activity, greatly favoring the adduct formation and decreasing the solubility. These adduct-formed formulations are often discarded. In addition, the chemical stability of an API can be a challenge for formulation development. The stability required usually coincides with the formulation preparation intervals on the dosing site. If the formulation is to be prepared weekly, then week-long stability is required. If heat is used to solubilize the API, then its effect on the stability should be included in the stability study. The last and the most critical characterization of the lipid/surfactant-based formulations is the dissolution/dilution testing. When diluted into an aqueous medium, the formulation should quickly disperse and form fine droplets and should not precipitate massively as crystalline particles. Because of the high importance of the in vitro dissolution, a special section is dedicated to how to develop a suitable in vitro dissolution method for enabling formulations. Details can be learned following the section of Evaluating Formulation Performance by In Vitro Dissolution.

17.5.5 Amorphous solid dispersions

Amorphous solid dispersion (ASD) renders the API into amorphous material, which is dispersed into a matrix consisting of either 100% polymer (single or multiple polymers) or polymer mixed with other excipients such as surfactants and lipids.

ASD formulation comprises of two unique properties that have collectively contributed to the significantly increased BA for poorly water-soluble drugs. The first property comes from the amorphous API. As described before, by disrupting the crystal lattice of the crystalline drug substance, the resultant higher-energy amorphous form provides a higher apparent solubility having a potential for higher dissolution rate. Thermodynamically, the higher dissolution rate is given; however, kinetically, the potential of higher dissolution rate oftentimes cannot be fully realized within the GI residence time if the amorphous drug is not properly formulated. Dosing a neat amorphous solid, which is analogous to a 100% drug loading ASD, may give a mediocre performance even when there is no crystallization. Thus, the second ASD property attributed to the success is the formulation itself, which is equally if not more important than the first property. Appropriately selected excipients in ASD formulations can drive the amorphous API to quickly dissolve and reach amorphous solubility in a solution, along the way creating nanosized amorphous particles. Ideally, these excipients then maintain this amorphous solubility by preventing or minimizing crystallization within the time scale relevant to in vivo absorption. ASD formulations have been utilized to deliver many life-saving drugs commercially.[87,88] Numerous papers and recently two books have been directed to amorphous pharmaceuticals and ASDs.[89–92] The readers are referred to these references. The focus here is on preclinical application of ASDs.

In preclinical studies, ASDs are found to be more readily applicable than in commercial human use. One of the greatest challenges in human formulation is the attainment of high drug loading for fewer or smaller pills. When increasing the drug loading, the API dissolution rate from the ASDs is inevitably decreased in addition to a potentially worsened physical stability. In preclinical ASD formulations, it is much more flexible to incorporate a wider variety and a higher percentage of hydrophilic excipients (ie, large amount of surfactants) to improve the dissolution rate at high drug loads. These excipients used at high percentage in preclinical applications are often not allowed in human formulations either for safety concerns or for processing reasons during commercial dosage form manufacturing. In addition, extra excipients such as binders or lubricants necessary for tableting or encapsulation can be eliminated, which further contributes to higher drug loading.

Another major challenge for commercial ASD formulation is the maintenance of physical stability during the product shelf life. This again is less demanding for preclinical applications due to the shorter duration of these studies, and in cases when the physical and chemical stability is not adequate, storage of ASD under refrigerated conditions during the relatively short period can be done to circumvent the shortcoming. Further, ASDs are more acceptable than lipid/surfactant/solvent-based formulations in that they are less toxic due to the nature of essentially being an aqueous suspension. Therefore, ASDs have become increasingly popular in preclinical studies.

The formulation development process for preclinical ASDs follows a similar path to that for human ASD formulations. The difference is that some steps in the process can be bypassed to accommodate the tighter timeline imposed at the preclinical stage, which will be discussed.

The formulation development starts with the evaluation of the physicochemical properties of the API. It has been believed that the amorphous solubility advantage is the prerequisite to justify for the amorphous solid dispersion approach. The amorphous solubility advantage can be either calculated or measured. The calculation involves the approximation of the free energy difference (ΔG) between the amorphous and the crystalline forms using the Hoffman equation[93]:

$$\frac{\sigma_a}{\sigma_c} = e^{\frac{\Delta G}{RT}} = e^{\frac{\left(\frac{\Delta H_f \cdot \Delta T}{T_m}\right)\left(\frac{T}{T_m}\right)}{RT}} \tag{17.8}$$

where $\frac{\sigma_a}{\sigma_c}$ is the ratio of amorphous-to-crystalline solubility, ΔH_f is the molar heat of fusion of the API crystal, R is the ideal gas constant, T is the temperature at which the solubility is concerned, T_m is the melting point, and ΔT is the temperature difference between the melting point and the solubility temperature. To improve the accuracy of the estimation, the solubility ratio should be further corrected, as described by Bogner and coworkers,[94] for the extent of ionization of the amorphous form versus the crystalline form at the pH of interest and for the amount of water the amorphous form absorbs, which reduces the thermodynamic activity of the amorphous solid. This correction requires the pK_a value of the API and the moisture sorption profile of the amorphous form.

The solubility difference can also be directly obtained through the solubility measurement if both crystalline and amorphous forms are available and the amorphous form is physically stable in aqueous media during solubility measurement. Either the calculation or the experimental measurement requires a reasonably pure and crystalline API, which is often lacking at the start of preclinical studies in addition to the time that entails.

In reality, accurate information on the amorphous advantage is nice to have but not essential when making a decision to proceed with an ASD. The reasons are: (1) in most cases, the amorphous form is more soluble than the crystalline counterpart; (2) as described, another attribute to determine the success of an ASD lies in the formulation. The hydrophilic matrix has been shown to enable liquid–liquid phase separation (LLPS) or nanoparticle formation during dissolution.[71,95–98] The extent of the dissolution rate increase by LLPS particles may well exceed the dissolution rate gained from the amorphous solubility advantage. The notion that only drugs with a high melting point can benefit from ASD formulation is not universally true; and (3) at the preclinical formulation stage, an ASD is not a first-line approach. It is pursued when other simpler approaches (such as a simple solvent formulation or pH adjustment) have failed. ASDs are often evaluated in parallel with lipid-based formulations. In other words, an ASD is competing with the lipid formulation approach, not with a crystalline form formulation. Therefore, the time and effort used to obtain an accurate amorphous advantage (ratio of amorphous solubility over crystalline solubility) can be saved for the moment until approaching the clinical formulation development stage.

A much more useful property to determine at this stage is the crystallization tendency of the API, which sheds light on the formulation strategy and design. Crystallization tendency is holistically a function of configurational entropy and molecular mobility.[99,100] Configurational entropy is intrinsic to the molecular structure. Simpler chemical structure and smaller molecular weight are attributed to lower configurational entropy. Lower configurational entropy means a higher probability to assume the proper orientation and conformation for crystal nucleation. Higher molecular mobility is related to smaller molecular size and volume and also is influenced by environmental conditions (viscosity and temperature). Qualitatively, crystallization tendency can be ranked by the timing of crystallization when a supersatured solution is created, when heating/cooling the melt in a differential scanning calorimetry (DSC),[101] or by stress testing of an amorphous solid made from solvent evaporation.[102] The DSC method[101] classifies drug molecules into three categories: Class I is a faster crystallizer (crystallization occurs when the melt is cooled to an ambient temperature), Class II is a medium-fast crystallizer (crystallization occurs when the cooled melt is reheated), and Class III is a slow crystallizer (no crystallization occurs when the cooled melt is reheated). Different formulation strategies should be adopted for compounds with different crystallization tendencies.

17.5.5.1 *Formulation for fast crystallizers*

For fast crystallizers, stabilizing the amorphous form is evidently the major challenge. The key to success will be to select the right polymer to effectively inhibit crystallization. Polymers play an important role in preventing the amorphous material from recrystallization via crystallization inhibition mechanisms.[71,72,74,75,103] The requirement for the polymer is twofold. First, the identified polymer should be capable of inhibiting crystallization in a solid state for achieving an adequate shelf life. Second, the polymer should be able to inhibit crystallization during the dissolution (in solution state) to maintain supersaturation for a superior in vivo performance. In preclinical studies, the latter is shown to be decisively more important, since ASDs are dosed as aqueous suspensions. Commonly used polymers include hypromellose acetate succinate (HPMCAS), hydroxypropyl methylcellulose (HPMC), copovidone,

Soluplus, polyvinylpyrrolidone (PVP), hydroxypropyl cellulose (HPC), and Eudragit.

The selection of a polymer can be done through a screen process. The crystallization inhibition in a solution should be the first to be addressed, as it is the most challenging to success. Based on a recent molecular dynamics simulation study, hydrophobic and van der Waals interactions are the dominating forces in establishing the drug-polymer interaction in aqueous solutions.[104] This indicates that polymers capable of forming strong hydrophobic interactions are more effective in inhibiting the crystallization of poorly water-soluble and hydrophobic drugs in an aqueous media (such as GI fluid). Polymers with both hydrophobic and hydrophilic moieties in the structure, such as HMPC or HPMCAS, are found as better choices.[105]

In solution-state polymer screen experiments, different polymers are predissolved into aqueous solutions (pH 1 and pH 6.8 buffers or SSIFs) at concentrations achievable in vivo. Supersaturation in these aqueous solutions is created by adding a high drug concentration stock solution made in an organic solvent such as methanol or by adding a high drug concentration solution made at extreme pH values. The extent and duration of supersaturation as well as the rate of crystallization from the solution are then monitored by a suitable analytical technique or multiple techniques depending on needs. For example, the drug concentration can be assayed by UV/Vis or HPLC. The crystallization can be detected by PLM, PXRD, or Raman spectroscopy. The polymer that maintains the highest supersaturation without crystallization is preferred. This screen scheme can also be used to investigate the combinations of polymers that may provide stronger effect than a singular polymer. For example, a polymeric blend of copovidone and HPMC was found to have a superadditive effect to prolong the supersaturation.[106] Some researchers have applied a more sophisticated HTS to execute the polymer screen in solutions.[107] This allows for more quickly mapping out the useful formulation space by evaluating more polymers and more supersaturation levels in a shorter time.

The second step in the polymer selection is to screen the polymers that can maintain amorphous stability in a solid state. Different from the solution state where crystallization inhibition is mainly mediated through hydrophobic and van der Waals interactions, solid-state-specific interactions such as H-bonding[108] or ionic interaction[109] can play a significant role. Polymers with a high H-bond donor or acceptor propensity are the candidates for consideration if the API structure has the matching H-bond acceptors or donors. However, it should be noted that water is ubiquitous. The hydrophilic polymers used in ASDs will retain or pick up water during formulation preparation and storage. For example, griseofulvin-PVP K30 solid dispersion crystalized upon exposure to moisture during storage due to PVP losing its inhibition capacity.[110] Whenever there exist water and hydrophobic molecules, there will be hydrophobic interactions taking place. Therefore, the ability of the polymer to engage in hydrophobic interaction with the drug is still important in solid-state crystallization inhibition. The set of polymers selected based on crystallization inhibition in an aqueous solution is presumably also useful in preventing crystallization in the solid state when exposed to moisture.

The screen for polymers to work in the solid state is done differently than in the solution state. Small-scale ASDs with different polymers each at different API loadings are prepared, such as by casting films,[111,112] and subjected to accelerated thermal and/or moisture stress conditions with miscibility or lack of crystallization being monitored periodically. Miscibility usually refers to a kinetically stable state where the API exhibits the apparent solubility in the polymer[113] without phase separation. Drug-polymer miscibility can be measured experimentally using various techniques such as Raman spectroscopy,[114] solid-state nuclear magnetic resonance (NMR)[115], or a combination of atomic force microscopy-based infrared, thermal, and mechanical analysis.[116] If phase separation occurs, the drug-rich phase becomes supersaturated, which may lead to crystallization. The detection of crystallization can be made using PLM or PXRD, which in general is easier to do than determining miscibility. Through this process, polymers that achieve miscibility or lack of crystallization at the highest drug loading can be determined and rank-ordered. As stated previously, toxicological studies are usually shorter in duration. If the formulation does not crystallize under ambient temperature and humidity for several months, the physical stability is deemed acceptable. The ideal situation is to identify a polymer or a combination of polymers that can stabilize amorphous material in both solution and solid state. In some challenging cases, it is sometimes useful to use the right polymer to tailor an appropriate drug-release rate at which the degree of supersaturation during dissolution is controlled to minimize the driving force for nucleation.[117] Since some polymers perform better in crystallization inhibition and others do better in enhancing dissolution rate, sometimes a combination of more than one polymer can be used to optimize the formulation.[118–120]

Increasing drug loading for the fast-crystallization class is especially challenging. Achieving a higher drug loading above 30–50% is often questionable.

The use of a surfactant for improving the dissolution rate should proceed with caution, since surfactants may increase nucleation and crystal growth rate.[78] For extremely fast crystallizers, selecting a more soluble polymer is perhaps the only effective means to increase drug loading. This is because if the API portion is solubilized in the polymer, the ASD system is thermodynamically stable and will not crystallize. Although the Flory–Huggins interaction parameter-based solubility prediction method is widely reported,[121,122] experimentally measured solubility values are more accurate and reliable. Determining the thermodynamic solubility in polymers using melting point depression-based methods have been reported.[123–126] API and polymer mixtures with an increasing percentage of API were cryomilled, annealed at different temperatures, and analyzed by differential scanning calorimetry (DSC) until undissolved crystals remain, and thus the upper and lower bounds of the equilibrium solubility temperature were determined.[124] The procedure required many DSC runs, which may take days to complete. This method was shortened significantly by taking an empirical approach utilizing a combination of differential scanning calorimetry measurements and a reliable mathematical algorithm to construct the solubility curve of a drug in a polymer.[126] A polymer screen through this solubility measurement is lengthy and costly, but it may identify a niche to formulate the extremely fast crystallizer. Finally, lower the drug loading may be still possible to formulate extremely fast crystallizers in ASDs.

17.5.5.2 Formulation for slow crystallizers

Slow crystallizers are ideal compounds for ASD formulations. Since crystallization is a small risk, it opens up the possibility to formulate higher-drug-loading ASDs. Different from faster crystallizers, the major challenge is switched from how to stabilize the amorphous form to how to enhance the drug release. Therefore, a different formulation strategy is considered.

Slow crystallizers that are poorly water-soluble are often hydrophobic. In spite of incorporating hydrophilic polymers, at some threshold of increasing drug loading depending on the hydrophobicity of the API, the solid dispersion will become too hydrophobic to dissolve into the aqueous phase at a desirable rate. The improvement in the dissolution rate will rely on selecting the appropriate polymers and secondary excipients.

The formulation development also starts with the polymer screen, albeit with a different focus. The miscibility or solubility in the polymer is still important, since any phase-separated hydrophobic drug region will hinder the dissolution, while the molecularly dispersed hydrophobic drug molecules may dissolve together with the fast-dissolving carrier molecules. Like in the case of fast crystallizers, miscibility is depending on polymer types. For example, it was shown that the miscibility of telaprevir is increased from 10% in HPMC or copovidone to 30% in HPMCAS.[116] Thus, the polymer screen is based on the dissolution profiles of different polymers incorporated into different drug loading ASDs made at small scale. Polymers that meet the criteria of rendering a fast dissolution rate and stimulating nanosized particle formation should be ranked as top selections.

Problematic dissolution rates from high-drug-loading ASDs can also be rescued by adding extra highly water-soluble excipients. These secondary excipients consist of mainly surfactants and in some cases lipids. The surfactants listed in Table 17.5 can all be potentially utilized in preclinical ASDs. As mentioned previously, there is a freedom of intercalating the high percentage of these secondary excipients (ie, 10–30%) for preclinical amorphous solid dispersion formulations as long as the T_g is above the ambient temperature, and the excipient level is tolerable by the animals at the intended dose. Physically, the ASDs containing a large amount of the secondary excipients may exist in multiple phases rather than in a single phase. The coexisting of several phases seems not having any negative impact to either the physical stability or the reproducibility of in vivo performance, especially for the slow crystallizers. Rather it brings the benefit of achieving higher drug loading while attaining a fast drug dissolution rate. Increasing the drug loading greatly reduces the dosing volume and subsequently the animal dosing time every day. Therefore, effort should be made to formulate the drug loading as high as possible. In vitro dissolution is the appropriate tool to gauge whether or not the dissolution rate is fast enough, which will be discussed in the section of Evaluating Formulation Performance by In Vitro Dissolution.

Evidently, formulation strategy for medium-fast crystallizers will be between the fast and slow crystallizers.

17.5.5.3 Preparation of prototype amorphous solid dispersion formulations

After the polymers are identified from the screen experiments, the next step is to prepare the different prototype ASD formulations, which are then characterized to arrive at the final lead formulation. To recapitulate, for the fast crystallizers, these selected polymers should be promising to inhibit crystallization in the solid state as well as in the solution state to achieve the desirable drug-polymer miscibility or solubility, while for the slow crystallizers, the best polymers are those that can promote high drug loading and at the

same time obtain an acceptable drug dissolution rate. Practically, what determines the formulation composition of various prototype ASDs is the drug loading. The drug-loading evaluation has been built into part of the polymer and the secondary excipients screen as delineated.

There are different methods available to prepare ASD formulations.[127] In order to make small-scale prototype formulations, the most convenient method is solvent evaporation using a rotary evaporator. This technique is commonly used in chemical synthesis, and a rotary evaporator is readily available commercially. In cases where formulations consist of a high percentage of cellulose-type polymers (ie, HPMCAS or HPMC without surfactants), rotary evaporation is difficult to operate due to film formation, which causes difficulties to recover the solid. The hardship in the recovery of the solid in general is tolerable because of the small scale.

A key to successful solvent evaporation is to locate a suitable solvent that meets the following criteria: (1) sufficient solubility for the API. The higher the solubility, the less solvent to consume; (2) sufficient solubility for the polymer and other excipients in the formulation; (3) low boiling point so that it can be easily removed; and (4) meeting the residual solvent safety requirement per ICH guidelines.[128,129] Solvents are divided into three classes per International Council for Harmonisation (ICH) guidelines: Class 1 solvents contain known human carcinogens and should be avoided in all; Class 2 solvents can be used but should be limited to permitted daily dose (PDE) due to nongenotoxic animal carcinogens; Class 3 solvents are preferred since they are relatively safe with low toxic potential, and the PDE is 50 mg or more per day. The list of Class 3 and Class 2 solvents and their PDE values can be found from the ICH guidelines. The most preferable solvents include Class 3 solvents, such as acetone, ethanol, and ethyl acetate, and Class 2 solvents, such as methanol. A combination of solvents may present an advantage to increase the solubility for API and excipients and lower the boiling point (after forming azeotropes).

After the solvent is found, the API and the polymer at the ratio of designed drug loading are dissolved to form a clear solution, sometimes with the help of moderate heating. The clear solution is then dried under vacuum in a rotary evaporator, usually heated slightly below the boiling point of the solvent. A second drying is carried out in a vacuum oven to further reduce the solvent to the acceptable level. The dried mass is recovered and ground to fine particles. These amorphous solid dispersion powders should be stored away from light and moisture prior to characterization and use.

17.5.5.4 *Characterization of prototype amorphous solid dispersion formulations*

The studies designed to rank the initial prototype amorphous solid dispersions are summarized into four categories (Fig. 17.8). The first three are universal for characterizing amorphous formulation systems, while the last is unique to animal studies.

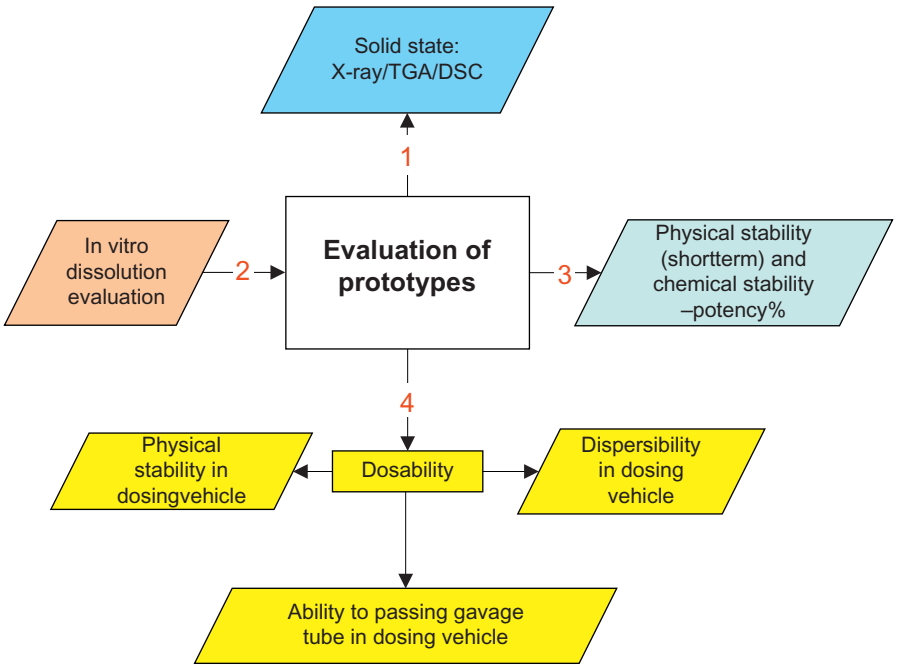

FIGURE 17.8 Characterization of initial prototype amorphous solid dispersion formulations.

The number one priority is to make sure the API is indeed turned into an amorphous state (tested by PXRD or PLM), the organic solvent level is meeting ICH criteria (determined by TGA or gas chromatography), and the glass transition temperature (tested by DSC) is preferably significantly higher than the ambient temperature. The second is to confirm that the formulation is doing what it is supposed to do: increasing the dissolution rate and maintaining supersaturation. It is very important to select the right dissolution method to assess this potential. This is so critical that a special section is dedicated to the in vitro dissolution method (see the section Evaluating Formulation Performance by In Vitro Dissolution). The third area of testing is to ensure the formulation is physically stable within a reasonable time frame. Since long-term physical stability is not required, stress testing at 40°C/75% RH or 65°C/25% RH is an overkill. Several months of stability in a closed container at ambient conditions is adequate. More extensive evaluation may be necessary for faster crystallizers. Thermal chemical stability against rotary evaporation temperature and secondary drying temperature, on the other hand, will be important in order to make it at a larger scale for long-term toxicological studies.

The fourth evaluation is specific to dosing in animals. The word dosability is created to describe the ability of any ASD formulation to be dosed smoothly. Similar to dosing the salt, gavage of freely flowing formulations (suspension) is usually the only option for administering an ASD to rodents and sometimes even for dogs when the dose cannot be carried within the limited numbers of capsules. The dosability as a suspension can be jeopardized in several situations: (1) if the amorphous form is quickly crystallized during the suspension preparation step, which basically obliterates the advantage of the amorphous solid dispersion; (2) if the powders do not disperse well into a smooth and uniform suspension or produce a suspension too viscous to load into syringes; (3) if foaming is substantial, which is a common problem when surfactants are part of the formulation; and (4) if the particles of the suspension are too large to pass through the narrow diameter gavage tube. Therefore, each of these four risks is to be rigorously evaluated prior to finalizing the formulation. Some of them are less challenging to resolve. An antifoam agent can be added to quench the foam. The particle size can be reduced by more aggressive milling. The growing of particle size in a suspension can be controlled using polymers. The viscosity can be reduced by selecting less swelling polymers.

However, the most intractable problem is the crystallization. In the presence of an abundance of water, the molecular mobility is as high as it can be, which potentially induces fast crystallization. The polymers contained in the formulation may lose the battle when against the strong headwind. Slowing down the drug release and/or finding a better suspending solution are possible ways to alter the kinetics of the crystallization. For example, when using an enteric polymer, such as HPMCAS or HPMCP as the polymeric carrier in ASD formulations, the amount of API (lopinavir) leaching out was shown to be below the amorphous solubility when the ASD is suspended in a lower pH buffer (pH 3 or 5).[130] This may help prolong the stability in some cases. A suspending solution containing different and more effective crystallization inhibitors (polymer or combination of polymer and surfactant) may also improve stability. A time window of several hours is needed from suspension preparation to dosing. If this dosing window cannot be met, an ASD is not a viable formulation approach.

Based on the results from the four areas of characterizations, the prototype formulations are compared, triaged, and narrowed down to the final or the final a few. The most promising formulations will be advanced to in vivo PK studies, often done in a dose-escalating fashion in comparison with other formulations such as lipid-based formulations. If the ASD formulation demonstrates advantages over the others, it will be declared as the final formulation for future studies. At this time, how to scale-up the ASD preparation will be the next discussion topic.

17.5.5.5 Scale-up the amorphous solid dispersion formulations

Larger scale ASD preparations can be done mainly through three technologies: rotary evaporation, spray drying,[131] and hot-melt extrusion.[132] Each technique has its unique pros and cons. The selection of the method is dictated by the polymers selected in the formulation, the availability of the technology, the know-how in-house, the thermal stability of the API, and the nature of the preclinical study. For example, if the formulation uses dominantly HPMC or HPMCAS-type polymers, spray drying is necessary. However, the fine and fluffy particles from spay drying create more work to prepare the suspensions. Hot-melt extrusion is solvent-free and produces high-density particles for easier suspension preparation, but it generally takes a longer time and more API to develop in addition to the need of specific equipment. The rotary evaporation is a more suitable technique for making an ASD supply for the preclinical studies for noncellulose polymers.

The principle for large-scale rotary evaporation is no different from a small scale. The API and formulation excipients are all dissolved into the solvent of

choice to form a solution, which is then heated under vacuum to remove the solvent. However, the same procedure is much more difficult to execute considering the scale. Assuming the solubility of the API is 50 mg/mL in the solvent, the calculated volume of the solvent required to turn 1 kg of API into ASD will be 20 L. It will take several batches to deliver the 1 kg API even using a large 10 L flask. Applying sufficient vacuum during the evaporation of 10–20 L of solvent will require a very powerful vacuum pump. The rate of solvent removal is a parameter to control in cases of faster crystallizers; a slow evaporation rate may cause crystallization. After finishing the evaporation, the massive amount of ASD cake is scraped out from the flask and milled into fine powders, which are then subjected to a second drying. The major challenge faced during the second drying process is the removal of the residual organic solvent. Much higher drying temperatures and longer drying times than the lab scale are often required to dry several kilograms of ASD powders to below the residual solvent specifications. The extensive heating may cause chemical degradation and crystallization. The drying temperature, if above the Tg of the formulation, may transform the ASD into a rubbery state and fuse the particles together. These risk factors should be evaluated in a small-scale experiment prior to the scale-up. For example, small ASD samples are heated in the anticipated drying temperature range over hours and days and periodically tested for chemical stability and particle morphology. The maximum drying temperature and time are then defined as control parameters during the scale-up. The final product is subjected to an analytical analysis in potency, crystallinity, and stability at GLP regulations if intended for GLP toxicology studies. The material is also tested for dissolution and dosability to ensure the larger scale product does not change these properties as compared with the small-scale prototype that was initially dosed in animals. These analyses define the formulation storage condition and shelf life for the intended toxicology studies.

17.6 EVALUATING FORMULATION PERFORMANCE BY IN VITRO DISSOLUTION

The theory of drug dissolution has been covered extensively in this book (refer to dissolution chapters in this book). This section will focus on evaluating the enabling formulations that create high supersaturation of the API in aqueous media, including pH adjusted, cosolvent, lipid and surfactant-based formulations (particularly Type III and IV), salts, and amorphous solid dispersions.

Since the mechanism of the enabling formulations is via creating supersaturation in the GI milieu, it is palpable that the performance of these formulations will count on the maintenance of the supersaturation. It quickly became clear that the standard dissolution test conducted under sink conditions is not able to evaluate these formulations because supersaturation is depleted under the sink conditions. Efforts have been, therefore, directed to imitate the nonsink conditions in vivo with the objective to predict in vivo performance. For example, the physiological conditions that can influence the supersaturation have been built into the design of an in vitro simple dual-pH dilution model for rats.[133] As illustrated in Fig. 17.9, the rat model mimicked how a formulation sample experiences the pH/medium change from a pH 4 buffer in stomach to a pH 6.5 FaSSIF in small intestine, the

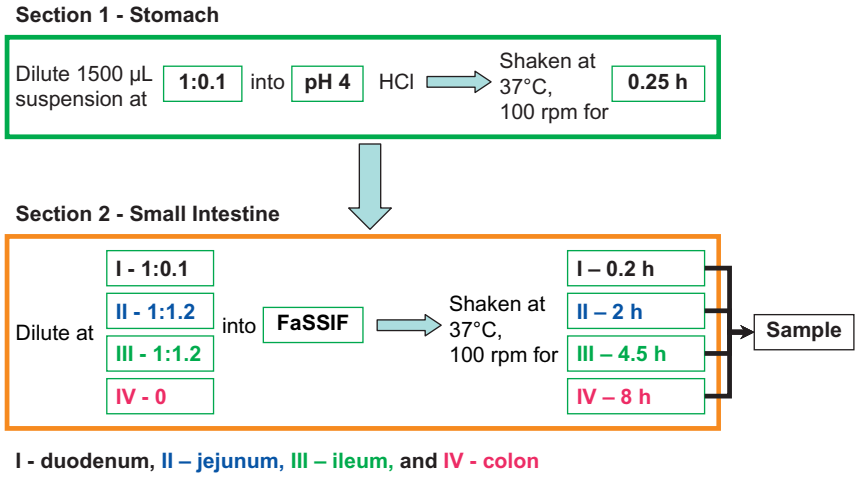

FIGURE 17.9 Schematic of a simple dual pH-dilution method to mimic dilution/dissolution in rats for evaluating enabling formulations.[133]

concentration change due to gradual dilutions along the GI tract, and different residence times at each section of the GI tract. Samples were taken from 0.2 to 8 h after the sample reached the intestine compartments and centrifuged to separate the supernatant from the solid phase. The solution phase was analyzed by HPLC assay to obtain the supersatuation concentrations. The formulation that resulted in the highest supersaturation was determined as the best formulation. This method was found to rank a series of formulations into a correct order in line with in vivo data for the model compound investigated.[133] This dissolution test can be conducted in a small beaker or vial in lieu of the standard US Pharmacopeial (USP) apparatus with ≥ 500 mL of dissolution medium. The simple dual-pH dilution is a straightforward experiment but requires hands-on manipulations to change the dissolution medium, add diluent, and take and analyze samples. Using the concept of dual pH and dilution was also reported in a microdissolution pH-shift test,[134] where the drug was introduced into a pH 2 solution for 20 min, followed by dilution into FaSSIF for another 180 min. The sample analysis was made automatic using commercially available μDISS Profiler (Pion Inc., Billerica, Massachusetts) fitted with UV-fiber optic probes for monitoring the drug concentration in situ. The UV dip probe offers an advantage of collecting the rich information of the drug concentration over a long period of time in a hands-free fashion, yet the interference from the background solution has to be removed or minimized before reliable data can be generated.

In spite of the effort to make the in vitro dissolution test more biorelevant, reasonable prediction of the formulation performance in vivo has been mostly elusive. Increasing the drug concentration by adding solubilizing agents such as cyclodextrin, surfactants, or solvents appeared to confer reduced permeability, as shown in rat jejunal permeability of several poorly water-soluble model compounds.[135–137] Some studies showed that monitoring the drug concentration in a water-immiscible 1-octanol layer added to the top of the aqueous dissolution medium (biphasic dissolution) may mimic the in vivo sink conditions and provide a better understanding of the supersaturation maintenance and absorption process.[138–140] The biphasic method started to link supersaturation with absorption but with limitations. The method simplified the permeation process for lacking a physical membrane barrier between the aqueous and 1-octanol layers and for treating the solubility in 1-octanol as the dominating factor for permeability.

To design a meaningful in vitro dissolution, it is essential to understand how the supersaturation is generated by the enabling formulations and what exactly the supersaturating system is undertaking to drive drug absorption. The former question has been made clear for a while: creating supersaturation by enabling formulation is analogues to launching a parachute into the sky.[141] However, the latter question was not clearly addressed. A further question was: When the parachute is launched toward the sky, how high can it go? These important unknown questions have been tackled in recent years by a series of publications.

In 2011, Alonzo et al.[93] reported that an felodipine amorphous solid dispersion at a low drug loading of 10% in a 90% HPMC polymer rapidly dissolved into a pH 6.8 buffer, forming a semitransparent and colloid suspension. The tiny droplets in the buffer were determined to be nanosized particles by dynamic light scattering, and the felodipine concentration in the colloid suspension was found to equate with its amorphous solubility. The colloidal species could also be generated by solvent switching and pH shifting. The transformation from an initially clear solution to a colloid phase was found to occur after a highly supersaturated solution was generated and can be attributed to a physical phenomenon called LLPS.[96] In 2013, Raina et al.[142] further confirmed that the LLPS threshold occurs at the amorphous solubility by studying several poorly water-soluble compounds. The data implied that the highest supersaturation any formulation can reach is the amorphous solubility above which the system separates into a two-phase system, wherein one phase is an initially nanodimensioned and drug-rich phase, and the other is a drug-lean continuous aqueous phase.

More interestingly, Raina et al. in the same paper[142] investigated the impact of LLPS formation on passive membrane permeability using a side-by-side diffusion cell. The flux, measured as a drug diffusional rate from the donor chamber to the receiver chamber in the diffusion cell, is theoretically correlated to the solute thermodynamic activity or free drug concentration. As shown in Fig. 17.10, when the drug supersaturation level was increased in the donor side, the flux of drug diffusion into the donor side increased linearly but abruptly stopped right at the LLPS threshold, above which the flux remained as constant. This indicates that the highest driving force for membrane permeation is when the solute activity is at amorphous solubility or the LLPS point. A higher concentration than LLPS is short lived, and the system quickly equilibrates to the LLPS level.

In a closely followed paper, Raina et al.[143] further demonstrated that the commonly used solubilizing agents, when added at excess to above the solubility of the solute, decreased the solute activity and consequently decreased the flux for membrane permeation. However, once more drug is added to reach

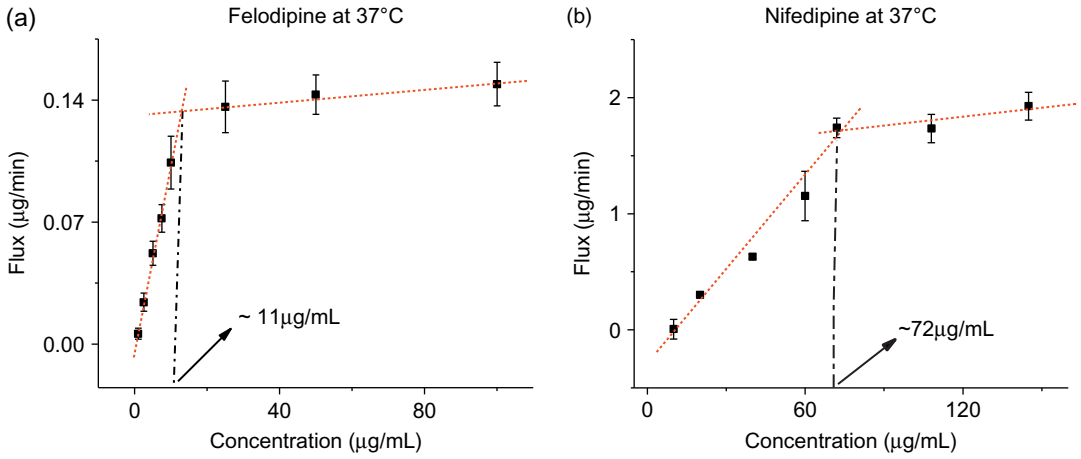

FIGURE 17.10 Diffusive flux versus concentration profiles for (a) felodipine and (b) nifedipine at 37°C. The flux of felodipine and nifedipine increases linearly with concentration up to the amorphous solubility (LLPS onset concentration). Further increases in concentration resulted in a plateau. *Source: Adapted from Raina SA, Zhang GGZ, Alonzo DE, Wu J, Zhu D, Catron ND, et al. Enhancements and limits in drug membrane transport using supersaturated solutions of poorly water-soluble drugs. J Pharm Sci 2014;103:2736–48.*

solubility, the flux is recovered to a normal level. This paper cleared the confusion about the role of solubilizing excipients and provided guidance on how to appropriately utilizing these excipients in enabling formulations.

These findings have had profound implications to formulation design as well as to in vitro dissolution method revamp. LLPS occurs at phase separation between the drug-rich phase and drug-lean phase (aqueous phase saturated with the drug). The numerous nanosized drug droplets are in equilibrium with the aqueous phase. Once the free drug molecules initially dissolved in the aqueous phase are absorbed, the nanosized drug-rich phase rapidly releases more drug to replenish the lost drug molecules in solution, thus maintaining the highest solute thermodynamic activity for absorption.[144] As long as LLPS can be maintained within the GI absorption window, the formulation is or is close to optimal. This new understanding in the role of supersaturation and LLPS is the foundation for designing an LLPS-based in vitro dissolution method that will effectively monitor the generation and maintenance of the highest solute (drug) thermodynamic activity.

Based on the core value of LLPS, a simple in vitro dissolution method can be designed to fit the purpose. Fig. 17.11 schematically describes the proposed LLPS-based in vitro dissolution method for evaluating the enabling formulation using a rat model in comparison with a human model. The scheme can be easily adapted to different animal models by replacing the in vivo parameters correspondingly.

As shown in Fig. 17.11, the LLPS concept-derived new dissolution method still takes into account the biorelevant conditions: (1) applying dual pH if the compound or excipients have pK_a value(s) within the physiological pH range of 1–7.4, (2) mimicking stomach and small intestine residence time and potential dilution along the GI tract, (3) using simulated small intestine fluid (FaSSIF or FeSSIF) as a dissolution medium, and (4) testing at in vivo temperature (37°C). However, the sample analysis is redesigned with the focus on determining whether or not the LLPS is generated and maintained. Nanosized droplets are manifested as a semitransparent or colloidal suspension, which can be monitored visually. A microscope (PLM) and/or nano particle size analyzer can be used to monitor the phase behavior and LLPS particles; the precipitates should be amorphous in nature and preferably in nano dimensions. The smaller the precipitated particles are, the better the formulation will be. Minimally, there should not be massive precipitation to crystalline form within several hours.

The free drug concentration determination in the sample analysis scheme presented in Fig. 17.11 requires interpretation. The drug concentration level measured to the solution phase of the samples should not be taken at face value, since part of the solution concentration can be due to the solubilizing agent, which is not free drug. An accurate measurement of free drug concentration can be accomplished using membrane diffusion-type experiments (ie, side-by-side diffusion cell[142]). It may not be feasible in the preclinical stage to engage sufficient time and resources in designing and conducting an appropriate membrane diffusion-based test. If the diffusion test is not affordable, the free drug concentration can be estimated by comparing the apparent concentration obtained from the dissolution samples with the measured amorphous solubility obtained under corresponding placebo conditions, as

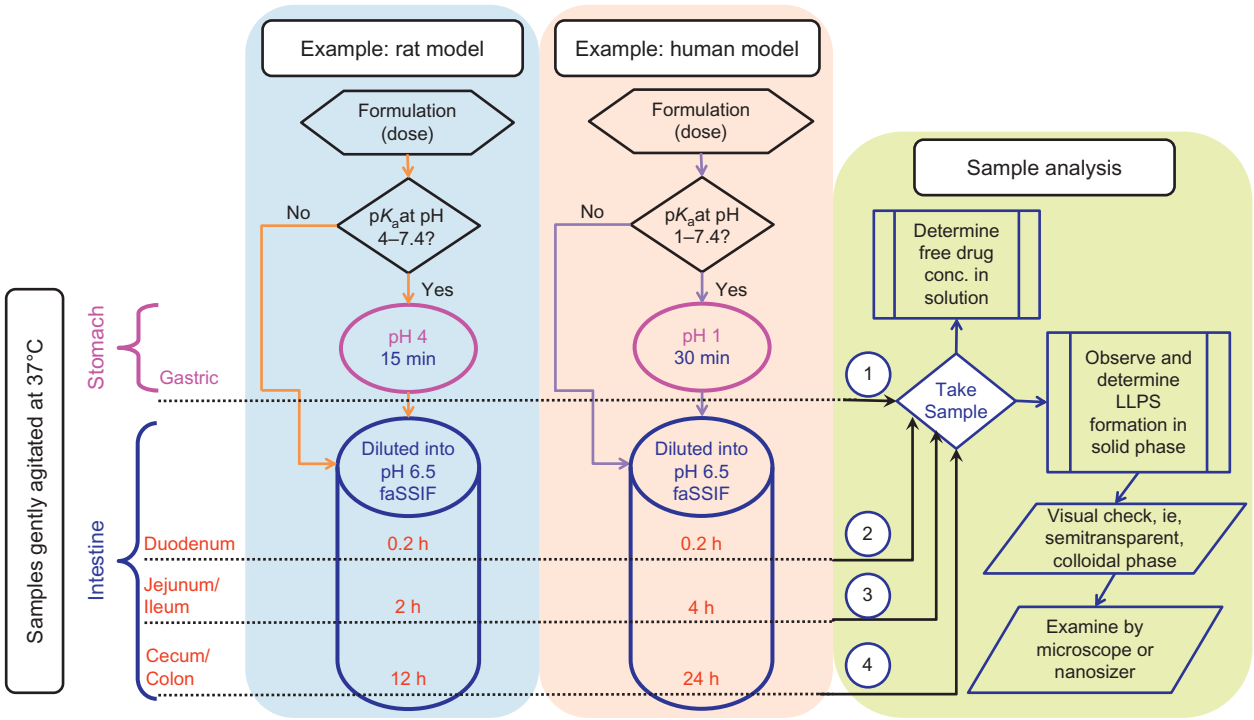

FIGURE 17.11 Schematic illustration of an LLPS-based in vitro dissolution method to evaluate enabling formulations.

illustrated in Table 17.6. If the solubility of the amorphous form in the placebo-containing aqueous medium is the same as that obtained from the dissolution samples, then the amorphous solubility (thus the highest free drug concentration) has been achieved during dissolution. In Table 17.6, the hypothetical formulations #1 and #2 have reached amorphous activity, but #3 did not, although the apparent solution concentration is much higher than those from #1 and #3. In case solubility measurement is also not affordable due to lack of either material or time, as a last resort, the free drug concentration can be inferred based on the residual solid properties. When the solid that is in equilibrium with the solution phase is determined to be amorphous, it can be assumed that the solution concentration is at amorphous solubility. Practically, as long as amorphous droplets or particles are observed, the solution concentration is at amorphous solubility, which is the highest possible supersaturation level. It is more important to know the length of the time the nano or submicron-sized amorphous drug is maintained.

The ranking of the formulation is based on the measurements from both solid-state samples (maintenance of amorphous nanoparticles) and solution-state samples (maintenance of amorphous solubility). For examples, #1 ranked: Nano to submicron-sized amorphous particles are maintained throughout, and the solution concentration reaches amorphous solubility; #2 ranked: Precipitates are in micron size but no crystallization, and the solution concentration reaches amorphous solubility; #3 ranked: Precipitates are initially amorphous but crystallized after 2−3 h into nano or submicron-size crystals, and the solution concentration gradually decreased but not significantly from amorphous solubility; #4 ranked: Massive crystallization into large parcels occurs within 2−3 h, and the solution concentration decreased to significantly below amorphous solubility or close to crystalline solubility.

The LLPS-based in vitro dissolution method is suitable not only for amorphous solid dispersions but also for any other formulations that possibly reach amorphous solubility during dissolution. These formulations include many enabling formulations such as cosolvent/pH adjustment-based formulations, salts, and lipid and surfactant-based formulations.

- Cosolvent/pH adjustment-based formulations. It is easily understandable that these formulations create an extremely high supersaturation when diluted into neutral pH aqueous solutions that can promote LLPS formation if crystallization can be prevented (ie, by adding crystallization inhibitors such polymers).
- Salts. The dissolution of salts has been reported to yield LLPS.[145] Considering that pH_{max} (at which the salts forms) is at least 2 pH units away from pK_a, the apparent solubility of the salt has to be 100-fold higher than the intrinsic solubility of the parent

TABLE 17.6 Author-Created Illustration of Estimating Free Drug Concentration or Solute Activity by Amorphous Solubility Measurement

#	Hypothetical Formulation Composition	Amount Used in Dissolution (mg of Drug)	Solubility Medium (mg of Placebo Dissolved in 5 mL FaSSIF)	Hypothetical Solubility Measured using amorphous form (mg/mL)	Hypothetical Apparent Concentration Measured in Dissolution Samples	Thermodynamic Solute Activity
1	Amorphous solid dispersion: Drug X: HPMCAS = 20: 80 (w/w)	20	80 mg HPMCAS	0.10	0.10	1.0
2	Amorphous solid dispersion: Drug X: HPMCAS: Tween 80 = 20: 65: 15 (w/w)	20	65 mg HPMCAS and 15 mg Tween 80	0.50	0.50	1.0
3	Surfactant formulation: Drug X: PEG400: Tween 20 = 10: 70: 20 (w/w)	20	40 mg Tween 20 and 140 mg PEG 400	2.0	1.0	0.5

This assumes that dissolution is done in 5 mL FaSSF.

crystalline form. The amorphous solubility advantage (solubility ratio of amorphous-to-crystalline form) usually does not exceed 100-fold of crystalline solubility. Thus, salt has a high potential to reach amorphous solubility during dissolution if without crystallization to the parent form. The polymer used as the suspending agent in the salt suspension may just as well act as a crystallization inhibitor to maintain the amorphous solubility.

- Lipid/surfactant-based formulations. The lipid/surfactant-based formulations, especially Type III and IV, contain a cosolvent, which upon dilution highly likely results in a higher supersaturation than the amorphous solubility. Therefore, the LLPS-based dissolution method is an appropriate avenue to evaluate any of these enabling formulations and aid formulation composition optimizations.

In addition, such an LLPS-based dissolution method is universally applicable to all APIs regardless of their permeability. It is a fact that the formulation effort usually does not change the drug permeability. This reality has been often interpreted as "little can be done through formulation if the absorption is limited by permeability," which is now a misnomer after understanding the LLPS and its relationship to drug activity and driving force for permeability. A more appropriate interpretation is that formulation can play a critical role in maximizing the permeability of BCS Class IV compounds in addition to enhancing the solubility and the dissolution rate. As stated repeatedly, the highest thermodynamic solute activity (or the highest free drug concentration), and thus the highest flux (or the highest driving force) for permeability, occurs at amorphous solubility. In the case of poor permeability due to transporters in the gut (ie, efflux), maintaining the highest free concentration (amorphous solubility) is the best way to saturate the enzymes and to enhance drug absorption.

As a conclusion, considerable advances have been made in last 5 years in understanding the dissolution behavior of the enabling formulations. We can expect this trend to continue into the foreseeable future. With new discoveries that never cease, the in vitro dissolution method will keep evolving to more perfection.

17.7 RATIONALE SELECTION OF FORMULATIONS SUITABLE FOR INTENDED STUDIES

The decision on which formulation strategy to choose often resembles a complicated multivariable analysis. This table summarizes the pros and cons of the different formulation approaches, which is helpful in facilitating the decision-making process (Table 17.7).

The timing of a nonclinical study (during discovery or development), dose regiment (single or repeat-dose study), duration of the study, test species, route of administration, and dose range all have a significant impact on the formulation development challenges that a formulator is presented with and can influence the choice of formulation and excipients. Often during the discovery stage, only very small quantities of a test compound are available for formulation development work, and only a very limited amount of time is available to identify an appropriate formulation for an upcoming study. The combination of extremely high doses desired for many safety studies, restrictions on acceptable dose volumes, and very limited drug substance availability oftentimes result in a scenario for a formulator where only a few milligrams of a drug

TABLE 17.7 Comparison Among Different Formulation Approaches.

Formulation Type	Advantages	Potential Issues
Solution (aqueous or aqueous with pH adjustment or cosolvent)	• Maximizes exposure. • Easy to prepare and dose. • Flexibility of combining pH, cosolvency, and complexation to further enhance solubility. • Eliminates exposure variability due to batch-to-batch variation in physical form and particle size.	• Difficult to develop for extremely poorly soluble compounds. • Tolerability issues from solubilization excipients. • Chemical stability issues.
Suspension (neutral solid form or salt)	• Good tolerability. • Supports high dose as not limited by solubility. • Better chemical stability than solution. • Better bridging to clinical solid dosage form (crystalline suspension).	• Exposure impacted by particle size and physical form. • Physical stability issues (form and particle size).
Nanosuspension	• Improved dissolution and enhanced exposure. • Supports high dose. • Good tolerability.	• Physical stability issues. • More complicated development path. • More complicated preparation and scale-up.
Lipid/surfactant-based formulations (forms either emulsion or microemulsion	• Applicable to many poorly soluble compounds. • Improved exposure due to solubilization and potential lymphatic absorption. • Easy to prepare and dose.	• Limited drug load. • Physical instability (adduct formation). • Lack of IVIVR for formulation selection and optimization. • Tolerability when high percentage of surfactants used.
Solid dispersion	• Good tolerability. • Improved exposure by enhancing dissolution and creating high supersaturation. • Broadly applicable with high success rate.	• Potential physical instability. • Limited drug load for compounds with fast crystallization tendency. • Need to develop a suitable suspension for animal dosing. • Scale-up requires development.

substance can be used to test the solubility in multiple test vehicles to achieve the concentration ranges of tens to hundreds of mg/mL. At the same time, the physical properties of the test compounds, such as particle size, crystallinity, and purity, which have a significant impact on the dissolution rate and the solubility in a given vehicle, might not be fully understood and optimized yet and are often not reproducible from batch to batch. Therefore, during the drug discovery stage, a formulator will most likely develop a fit for purpose formulation based on the physical properties of the drug substance at the time and the amount of material and time that are available. The resulting formulation might not be optimized for long-term stability of the drug substance in the formulation or acceptability of the used excipients for repeat dose or long-term studies, for example.

The quantity of the available drug substance and the knowledge and reproducibility of the physical properties increase as a project moves from discovery into development. Once a compound is identified as a candidate for development or even slightly before, a salt and polymorph screen is typically performed to identify a stable crystalline form. This often results in the selection of a crystal form that is different from the crystalline or amorphous phase that was used in the discovery phase, which can result in changed dissolution and solubility properties. As a result, the toxicology formulation may need to be further optimized for GLP safety studies. Depending on how different the crystal form (free base versus salt) or the formulation is, a bridging study might be necessary to evaluate the potential impact on in vivo exposure and the need to adjust the doses for the GLP study.

Other factors to consider during selecting the toxicology dosing formulation are the ease of formulation preparation and the chemical and physical stability of the formulation, which determines the use-time period. These factors are especially important for long-term studies where the dosing formulation has to be prepared many times and should, therefore, be easy to prepare.

There is usually a strong desire for the formulation to be stable for at least 1 week to reduce the frequency of preparation. Scale differences also need to be taken into consideration. A formulation preparation procedure might work well during formulation development on a small, milliliter scale under the employment of certain techniques such as sonication for solubilization or trituration by hand to achieve wetting, particle size reduction, or homogenization. However, it might be very difficult to be reproduced by a CRO (Contract Research Organization) or the drug safety department of the same organization on the larger scale of several liters during the actual toxicology study. Therefore, close communication and alignment between the formulator and the drug safety department/CRO are essential.

Overall, the strategy is to design and develop fit-for-purpose formulations based on the physicochemical properties of the drug candidate, study type, and requirement. The totality of the various important factors is considered to balance quality, speed, and cost when developing a suitable formulation strategy to enable the study.

17.8 CASE STUDY

Herein presented is an example illustrating the process of developing an oral formulation for safety studies.

17.8.1 Model compound properties

Compound X is a molecule with an extremely low aqueous solubility. The pharmaceutical properties are provided in the following table.

Properties	Data
Molecular weight	~500 g/mol
pK_a	8.5 (acidic)
Melting point of crystalline-free acid	~270°C (melt decomposition)
Log*D* at neutral pH	~3
Aqueous solubility	
In aqueous buffers at pH ≤ 8	<12 ng/mL (below detection limit of HPLC assay)
In faSSIF	~0.8 μg/mL
In feSSIF	~5 μg/mL
Chemical stability	Acceptable stability at pH 1–13
	Prone to degradation under peroxide
Permeability by Caco-2	Highly permeable

Based on these properties, Compound X is a BCS II compound. Its poor solubility is due to the combined effect of high lattice energy and hydrophobicity. Enabling technology will be required to deliver this compound. Three formulation approaches were evaluated: salt suspension, lipid/surfactant-based formulations, and amorphous solid dispersion formulations.

17.8.2 Crystallization tendency assessment

Since the three formulation approaches (salt suspension, lipid/surfactant-based formulations, and amorphous solid dispersion formulation) will create a supersaturation upon dosing, the success of these enabling technologies is hinged on how well the crystallization can be inhibited. The effectiveness of four polymers (copovidone, PVP, HPMC E5, and HPMC K3) in prohibiting crystallization was assessed by spiking the concentrated compound stock solution into a pH 6.8 buffer containing predissolved 10 μg/mL of each polymer. The compound concentration was monitored by an UV-dip probe at the ambient temperature. The concentration-time profiles are presented in Fig. 17.12.

The data in Fig. 17.12 indicate that Compound X has a high tendency to crystallize. The concentration in the absence of polymers drops immediately after supersaturation was created, although the concentration did not go all the way to <12 ng/mL (crystalline solubility at pH 6.8), which is attributed to the surface defect of the precipitates that manifest a higher apparent solubility. However, crystallization is significantly inhibited or reduced in the presence of polymers. Any of the four polymers studied was able to maintain

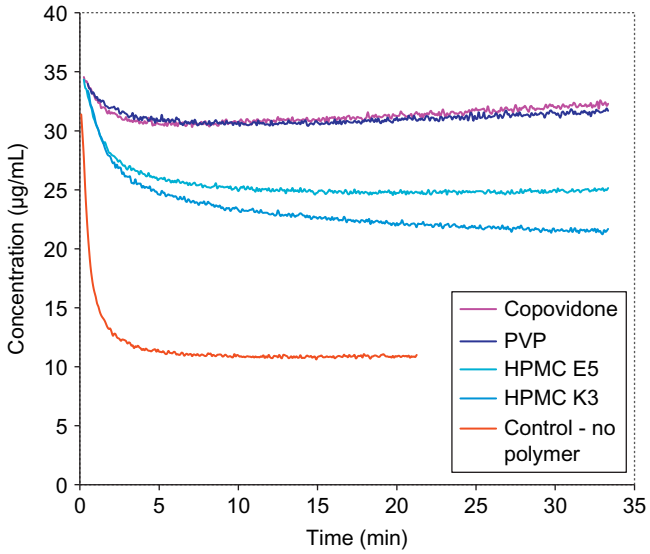

FIGURE 17.12 Polymer screen results in pH 6.8 buffer.

supersaturation. Copovidone and PVP appear to provide a somewhat higher concentration than the HPMC-type polymers, probably due to the nanoparticle effect on the UV-dip probe methodology. Nevertheless, the data suggest that the amorphous solubility in the pH 6.8 buffer is in the range of 22−32 μg/mL, which has been maintained over time by the polymers. Therefore, it is possible to use enabling formulations to deliver this compound.

17.8.3 Development of salt suspension

Taking advantage of the acidic pK_a at 8.5, a salt with acceptable pharmaceutical properties was made successfully. The feasibility of the salt suspension was studied by powder dissolutions in FaSSIF and in a suspending agent (0.2% HPMC in water) at 37°C, with samples filtered and analyzed by HPLC assay. A concentration range of 22−32 μg/mL was maintained for ~30 min in FaSSIF and for several hours in 0.2% HPMC. The 0.2% HPMC suspending agent provided the feasibility to dosing the salt as a suspension.

17.8.4 Development of lipid/surfactant-based formulations

The initial PK study was conducted in the standard PEG 400/DMSO (90/10) vehicle in which the solubility of Compound X was about 5 mg/mL. With the projected dose of ≥60 mg/kg, neat PEG 400 was not able to achieve the required solubility. To develop a viable formulation, the solubility screen was conducted in three groups of excipients: cosolvent, lipid, and surfactant, as shown in Table 17.8.

The solubility data in Table 17.8 pointed out potential ways to formulate a solution formulation: (1) using PEG 400 and pH adjustment, since the addition of NaOH (at 1:1 molar of NaOH:API) to ionize the compound increased the solubility by more than 30-fold in PEG 400; (2) using surfactants, since the aqueous solubility in the presence of 1% Tween or vitamin E TPGS was increased by more than 1000-fold. Vitamin E TPGS has a low miscibility with PEG 400, and it can be replaced by another surfactant, Cremophor RH40.

Based on the miscibility among PEG 400, Tween 20, and Cremophor RH40, two vehicles were prepared and tested for API solubility: (1) PEG 400 and Tween 20 at a 80:20 ratio and (2) PEG 400, Tween 20, and Cremophor RH40 at a 50:20:30 ratio. Adequate solubility of approximately 100 mg/mL was achieved to deliver the required dose. A dilution/dissolution test followed by a PK study in rat showed better in vivo data of PEG 400/Tween 20/Cremophor RH40 than PEG 400/Tween 20. This identified PEG 400/Tween 20/Cremophor RH40 as the lead formulation from the lipid/surfactant-based formulation category.

TABLE 17.8 Solubility Screen in Excipients to Develop Lipid/Surfactant-Based Formulations for Compound X

Excipient	Solubility of Crystalline Form of the Free Acid at Ambient Temperature (mg/mL if not Otherwise Noted)
Ethanol	1−2
PEG 400	~5
PEG 400 with NaOH (1:1 molar ratio with API)	>150
Propylene glycol	~3
A fatty acid	~70 μg/mL
A phospholipid	~8
A medium-chain monoglyceride and diglyceride	<4
1% Tween 20 in pH 6.8 buffer	~25 μg/mL
1% vitamin E TPGS in pH 6.8 buffer	~40 μg/mL
PEG 400/Tween 20 (80/20) with NaOH (1:1 molar ratio with API)	Close to 100 mg/mL
PEG 400/Tween 20/Cremophor RH40 (50/20/30) with NaOH (1:1 molar ratio with API)	~102 mg/mL

17.8.5 Development of amorphous solid dispersions

Fig. 17.12 indicates that polymers can effectively manage the physical stability of amorphous Compound X, which is otherwise a fast crystallizer. Table 17.8 shows that the surfactant can be beneficial in formulating Compound X into amorphous solid dispersions. Taking these two pieces of information together, a prototype formulation with the composition of 25% drug load in copovidone and vitamin E TPGS was designed. The organic solvent screen identified that ethanol, which under moderate heating, was able to dissolve the API as well as the polymer and vitamin E TPGS. The amorphous solid dispersion was made by solvent evaporation and characterized. The results have met all the requirements described in the amorphous characterization scheme in Fig. 17.8. In particular, the following positive results from the two critical attributes have been observed.

1. Physical stability of the ASD suspension. The ASD powders were suspended in a pH 6.8 buffer and gently stirred overnight at the ambient temperature.

The recovered solid remained amorphous, as shown by PXRD (Fig. 17.13).

2. Powder dissolution of ASD. The dissolution was conducted in a pH 6.8 buffer at 37°C with samples filtered and analyzed by HPLC assay. The measured concentration was kept at approximately amorphous solubility, as shown in Fig. 17.14. The concentration measured at 12 h remained at ~22 μg/mL on average.

The results demonstrate that the developed amorphous solid dispersion is suitable for dosing as a suspension in preclinical studies. It was, therefore, selected and advanced to in vivo characterization.

17.8.6 In vivo comparison of different formulations

The three developed enabling formulations (salt suspension, PEG 400/surfactants, and ASD suspension) were compared in several PK studies in rats and dogs at different doses. Fig. 17.15 shows the representative results that were generated in dogs at a 25 mg per dog dose. The three enabling formulations yielded a significantly higher BA than without the formulation effort (free acid suspension). Among them, the solution formulation (PEG 400/Tween 20/Cremophor RH40) is comparable to the amorphous solid dispersion, and, therefore, it was selected as the final formulation from

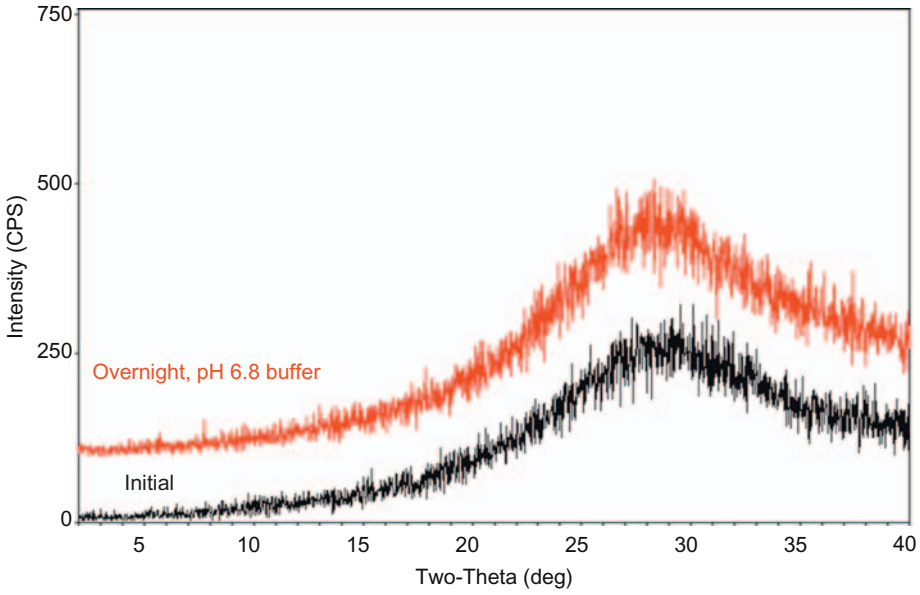

FIGURE 17.13 PXRD pattern of a prototype amorphous solid dispersion of Compound X after suspension in pH 6.8 buffer overnight at ambient temperature.

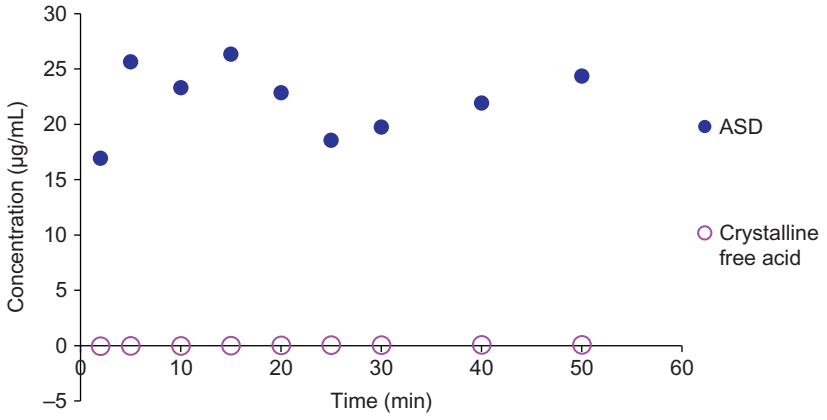

FIGURE 17.14 Powder dissolution of a prototype amorphous solid dispersion of Compound X in pH 6.8 buffer and 37°C. Dissolution profile of the crystalline-free acid was overlaid for comparison.

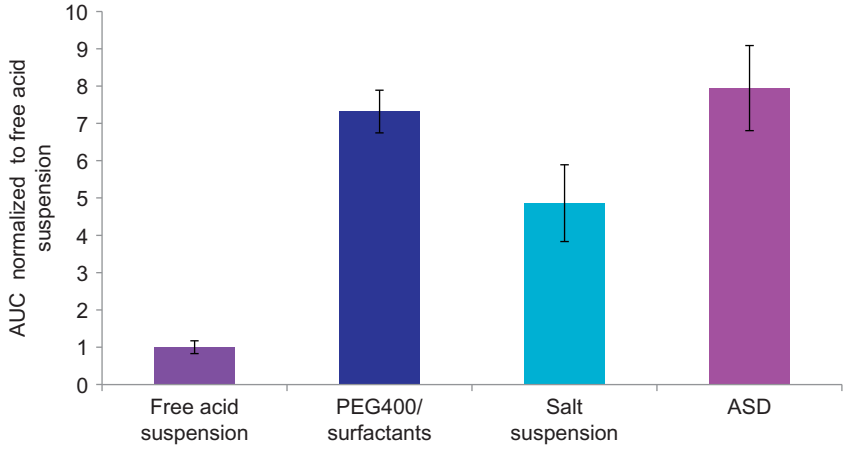

FIGURE 17.15 In vivo comparison among different formulations for Compound X with AUC normalized to that of free acid crystalline form suspension.

the perspective of easier formulation preparation than the ASD. The PEG 400/surfactants formulation was successfully used in long-term GLP studies to evaluate the safety of Compound X.

Acknowledgments

All authors wish to acknowledge the many colleagues and management in their respective companies for the support of their scientific research and publications. In particular, Yi Gao expresses gratitude to Geoff G.Z. Zhang, PhD, at AbbVie for insightful discussions and for sharing the graphic content in Fig. 17.7, and to John Lipari at AbbVie for discussing lipid-based formulations. Christoph Gesenberg would like to thank Kevin Trouba, PhD, DABT; Balvinder Vig, PhD; and Meagan McCallum at Bristol-Myers Squibb for their helpful contributions. Weijia Zheng would like to thank Robert Casella, PhD, at AstraZeneca for valuable discussions.

18

Rational Design for Amorphous Solid Dispersions

A. Newman

Seventh Street Development Group, Kure Beach, NC, United States

18.1 INTRODUCTION

Most active pharmaceutical ingredients (APIs) are crystalline materials that possess long-range order and well-defined structures. Many properties, such as solubility, stability, and bioavailability (BA) can be related back to the crystalline form.[1] In contrast, amorphous materials do not possess the long-range order of crystals, but will exhibit short-range order (Fig. 18.1).[2]

Amorphous solids are commonly used for improving dissolution and oral absorption of poorly soluble compounds because they exhibit higher apparent solubility values and faster dissolution rates compared with crystalline materials. However, they also have disadvantages, such as poor physical stability, which can result in crystallization, and poor chemical stability, which can lead to degradation. Since they are metastable forms, development of amorphous compounds involves a greater understanding of the handling, storage, and processing conditions needed to prevent crystallization and maintain the amorphous state.

Amorphous solid dispersions are defined as an amorphous API mixed with a polymer or mixtures of polymers and surfactants.[3,4] The polymer stabilizes the amorphous drug by lowering the chemical potential of the drug and increasing the activation energy needed for crystallization (Fig. 18.2),[5] which results in better physical and chemical stability, higher apparent solubility, and faster dissolution. Dispersions can also display extended supersaturation in solution due to crystallization inhibition by the polymers. By improving the stability and apparent solubility, amorphous solid dispersions can be more easily processed into common solid oral dosage forms. Due to the low equilibrium solubility of many APIs in the polymer,[6] and the amorphous nature of the API in the dispersion, these materials are generally in a metastable state and, therefore, may still exhibit poor physical and chemical stability.

This chapter introduces amorphous solid dispersions and their applications in designing solid oral dosage forms during drug development. It covers the key components in a dispersion, physical characterization techniques used to analyze the materials, as well as screening and selection methodology to help find a dispersion with the best properties, such as physical stability and solubility. It also includes a brief introduction of common processing technologies for manufacturing amorphous solid dispersions and examples of marketed products. More in-depth information on the fundamental principles, materials, formulation and process development, characterization, and regulatory considerations in developing amorphous solid dispersions are can be found in chapters "Crystalline and Amorphous Solids," "Solid State Characterization and Techniques," and "Oral Formulations for Preclinical Studies: Principle, Design and Development Considerations" of this book, recent books, and review articles focused on amorphous solid dispersions.

18.2 KEY COMPONENTS OF AMORPHOUS SOLID DISPERSIONS

The most important components of a stable and effective amorphous solid dispersion are carrier polymer(s) and surfactant(s). The choice and concentration of the polymer can greatly influence the stability and properties

Developing Solid Oral Dosage Forms
DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00018-2

of the dispersion. Early reports referred to solid dispersions as mixtures of polymer and crystalline drug.[7] The small particle size of the crystalline drug would help improve the dissolution for many systems. The term *amorphous solid dispersion* has been used to describe solid mixtures of polymer with amorphous drug. A number of other terms have been used to describe these systems, such as solid dispersion,[8] solid solution,[9] and molecular dispersions.[10] It is important to determine if the material being described in a study contains crystalline or amorphous API since the nomenclature has not been standardized in the literature.

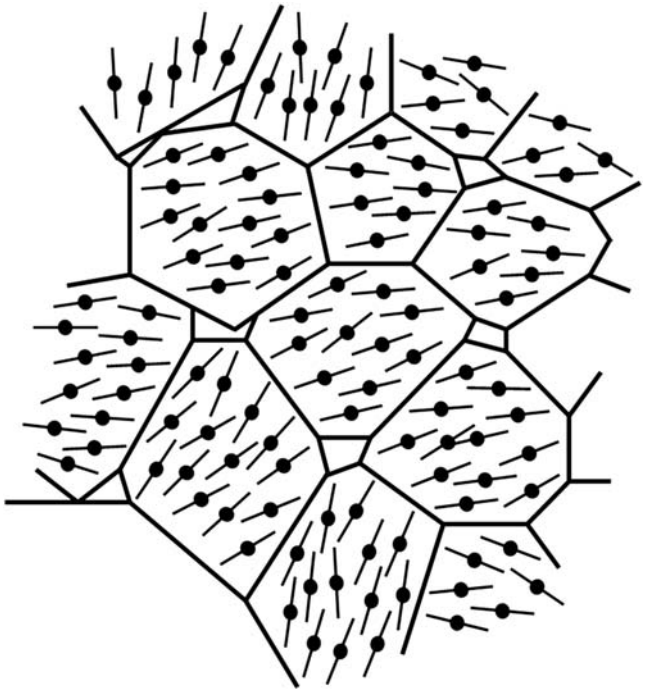

FIGURE 18.1 Short-range order in amorphous material. *Source: Reproduced with permission from Bates S, Zografi G, Engers D, Morris K, Crowley K, Newman A. Analysis of amorphous and nanocrystalline solids from their X-ray diffraction patterns.* Pharm Res *2006;23(10):2333–49.*

Polymers are the most common excipients incorporated into amorphous solid dispersions and a wide variety of polymers are available.[11] Other excipients, such as cyclodextrins[12] and phospholipids,[13] have been added to dispersion systems; it should be noted that both of these excipients provide a different solubilization mechanism than polymers (Fig. 18.3). Small molecules, such as citric acid[15] and amino acids,[16] have also been used to produce amorphous solid dispersions. The amorphous components in the dispersion should be miscible, meaning that the drug and polymer are composed of a single chemically homogeneous phase where all of the components are intimately mixed at the molecular level and the properties of the blend are different than the properties of the pure components. In contrast, a physical mixture of amorphous API and polymer would have the same properties as the pure components. Many miscible amorphous dispersions have improved physical stability,[17] but can become immiscible under certain conditions, such as elevated relative humidity where water is absorbed to produce a ternary system.[18] Partial miscibility is also observed and can be dependent on the concentrations used. For example, felodipine was found to be partially miscible with polyacrylic acid[19] and the dispersion was found to readily crystallize.[17] In contrast, felodipine was found to be miscible with polyvinylpyrrolidone (PVP) and this polymer proved to be an effective crystallization inhibitor.[20] Miscibility can be investigated using a variety of characterization techniques, such as differential scanning calorimetry (DSC) and spectroscopic methods.[21] Amorphous solid dispersions have been utilized at various points in the development process. For early animal studies, dispersions can provide improved apparent solubility resulting in a wide range of concentrations required for toxicology and BA work. Suspensions of amorphous dispersions have also been used for BA studies; it should be noted that the propensity of the dispersion

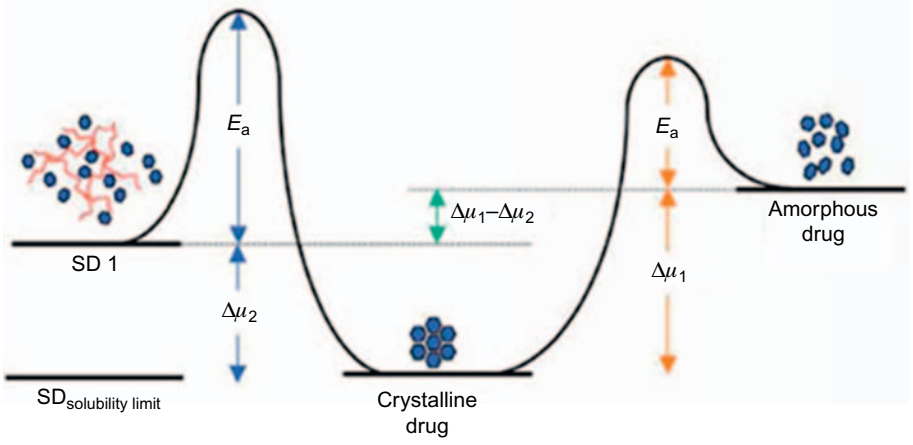

FIGURE 18.2 Hypothetical energy temperature diagram for amorphous, crystalline, and amorphous solid dispersions.[5]

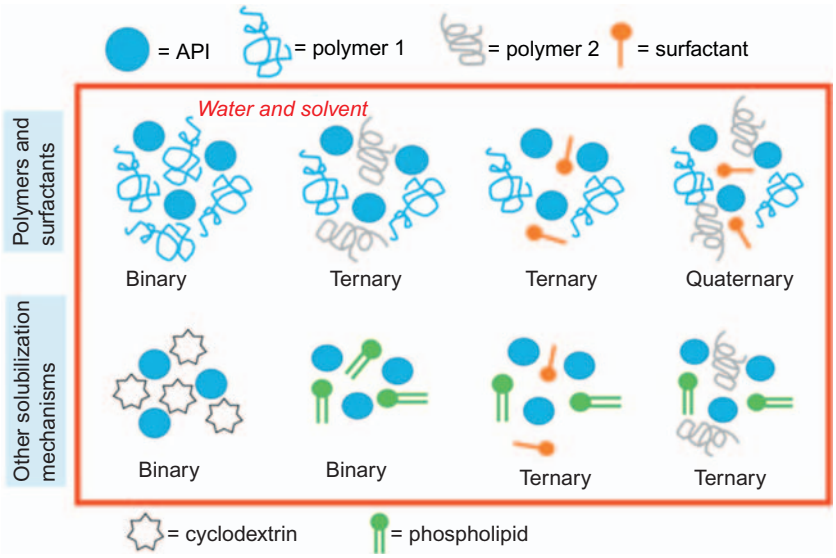

FIGURE 18.3 Graphic of different types of amorphous solid dispersions. The red (gray in print versions) box indicates that properties can change based on solvent and water content.[14]

to crystallize and the amount of API dissolved in the carrier should be understood for these preparations. If the dispersions provide the needed improvements in the preclinical studies, they can be moved into early clinical trials with simple formulations. Suspensions and neat dispersion in a capsule are formulations that have been used for early human trials. In some cases, excipients such as disintegrants or flow agents are added to provide a slightly more complex formulation with better properties than the dispersion alone. The amount of formulation development depends on the characteristics of the dispersion and the needs of the study. For some systems, the amorphous dispersion may have liabilities that do not allow the production of a marketed product. For these cases, a viable solid form is needed and additional work around a different form and/or formulation may be needed. There are a number of cases where amorphous solid dispersions have been used in late clinical trials and developed into marketed products, as shown in Table 18.1. Some dispersions may need special handling, such as using anhydrous excipients to keep water levels low, while others may be more robust, allowing for a variety of excipients and formulation processes.

18.3 CHARACTERIZATION OF AMORPHOUS DISPERSIONS

Many of the characterization methods used for solid form analysis can be used for amorphous solid dispersions. This section will cover common methods such as X-ray powder diffraction (XRPD), DSC, and spectroscopy infrared (IR), Raman, and solid-state nuclear magnetic resonance (SSNMR). Details on these methods can be found in chapter "Solid State Characterization and Techniques"; information provided here will be specific to amorphous solid dispersions. A number of emerging analytical methods have also been discussed.[22]

XRPD of amorphous dispersions should result in an amorphous halo if both the drug and polymer are amorphous. Crystalline peaks from the drug should not be evident in freshly prepared samples. XRPD can be used to monitor dispersion samples over time to determine conditions where the amorphous dispersion is stable (remains amorphous) or unstable (drug crystallizes). A 1:4 nifedipine:PVP amorphous solid dispersion compressed into tablets and stored at 60°C/75% relative humidity (RH) was analyzed by XRPD and dissolution over a period of 2 weeks.[23] Crystalline material was evident from XRPD after 1 week and was correlated with a significant slowdown in dissolution when compared with the initial amorphous dispersion.

The amorphous halo observed in the XRPD pattern can help determine miscibility. A physical mixture of the amorphous drug and polymer will be readily described by the individual components. When the components are miscible and interact with each other, the scattering pattern is different and will produce a different halo. Computational methods, such as pair distribution functions[19,24] and the pure curve resolution method,[25] can also be used with the XRPD data to help determine miscibility of a dispersion.

DSC and modulated DSC (mDSC) are commonly used for characterization of dispersions. Small amounts of crystalline material can be readily observed from a melt endotherm of the crystalline solid.[26] When the drug is fully amorphous, the DSC will show two glass transition

TABLE 18.1 Marketed Products Using Amorphous Solid Dispersions[14]

Product	API	Company	BCS class	Polymer	Dispersion process
Afeditab	Nifedipine	Elan/Watson	2	Poloxamer or PVP	Melt/absorb on carrier
Certican (non-US)	Everolimus	Novartis	3	HPMC	Melt or spray drying
Cesamet	Nabilone	Valeant Pharmaceuticals	2 or 4	PVP	Melt extrusion
Fenoglide	Fenofibrate	LifeCycle Pharma	2	PEG	Spray melt
Gris-PEG	Griseofulvin	Novartis/Pedinol	2	PEG	Melt extrusion
Ibuprofen	Ibuprofen	Soliqs	2	various	Melt extrusion
Incivek (US)	Telaprevir	Vertex Pharmaceuticals	2 or 4	HPMCAS	Spray drying
Incivo (Europe)	Telaprevir	Janssen Pharmaceuticals	2 or 4	HPMCAS	Spray drying
Intelence	Etravirine	Janssen Pharmaceuticals	4	HPMC	Spray drying
Isoptin SRE-240	Verapamil	AbbVie Inc	2	HPC/HPMC	Melt extrusion
Kalydeco	Ivacaftor	Vertex	2 or 4	HPMCAS	Spray drying
Kaletra	Lopinavir and ritonavir	AbbVie	2 and 4	PVP VA	Melt extrusion
LCP-Tacro	Tacrolimus	LifeCycle Pharma/Veloxis	2	HPMC	Melt granulation
Nimotop	Nimodipine	Bayer	2	PEG	Spray drying/fluid bed
Nivadil	Nilvadipine	Fujisawa Pharmaceutical	2	HPMC	
Norvir	Ritonavir	AbbVie	4	PVP VA	Melt extrusion
Noxafil	Posaconazole	Merck	2	HPMCAS	Melt extrusion
Onmel	Itraconazole	GlaxoSmithKline/Stiefel	2	PVP VA	Melt extrusion
Prograf	Tacrolimus	Astellas Pharma Inc	2	HPMC	Spray drying/fluid bed
Rezulin[a]	Troglitazone	Pfizer (Parke-Davis)	2	PVP	Melt extrusion
Sporonox	Itraconazole	Janssen Pharmaceuticals	2	HPMC	Spray layering (fluid granulation)
Torcetrapib[b]	Torcetrapib	Pfizer	2	HPMCAS	Spray drying
Zelboraf	Vemurafenib	Roche	4	HPMCAS	Antisolvent precipitation
Zortress (US)	Everolimus	Novartis Pharmaceuticals	3	HPMC	Melt or spray drying

temperatures (T_gs) for an immiscible system and one T_g for a miscible system.[21] The T_g of the miscible system will be altered depending on the API:polymer concentration and can be estimated using the Fox equation.[27] In some cases, such as the trehalose-dextran system, one T_g will be observed for an immiscible system due to the limitations of the DSC technique based on domain size.[24] Immiscibility was confirmed for the trehalose-dextran system using pair distribution functions[24] and SSNMR.[28]

It is important to note that water or solvent content can also change the T_g of a sample. A rule of thumb is that 1% water can lower a T_g value by approximately 10°C,[29] and the Fox equation can be used to estimate the T_g of a binary dispersion (API and polymer) containing water or solvent. Care should be taken to measure the water/solvent content of the sample before collecting DSC data so the T_g value can be correlated to the solvent content. Sample preparation is also key to getting reproducible T_g measurements. For a "wet" T_g (containing water or solvent), the sample should be placed in a hermetically sealed pan without a pinhole for the DSC scan; this preparation keeps the volatiles in the sample pan throughout the run.[30] For a "dry" T_g, temperature cycling is used to first remove the volatiles with subsequent T_g measurement for the solvent-free sample.[31]

IR and Raman spectroscopy are commonly used to probe intermolecular interactions between the components of a dispersion. The different selection rules for these techniques often result in the API having a stronger Raman response than the polymer, while polymers and drugs will typically both have strong IR absorption peaks that result in more signal overlap for some systems.

A number of studies have used IR spectroscopy to determine interactions and miscibility in dispersions.

This technique was used for an indomethacin-PVP system to show that dimers present in the crystalline drug were not present in the dispersion, but, were replaced by intermolecular bonding between the indomethacin and the polymer.[32] The hydrogen bonding observed in the dispersion helped inhibit crystallization of the drug by preventing indomethacin dimer formation. Other studies have utilized transmission IR spectroscopy of thin dispersion films of droperidol, ketoprofen, nifedipine, and pimozide with PVP, with all showing complete miscibility of the components.[33] Upon exposure to elevated relative humidity, it was found that the droperidol, nifedipine, and pimozide dispersions became immiscible forming drug-rich phases that eventually crystallized. Another study investigated the hydrogen bonding of felodipine with different polymers (PVP, hydroxypropyl cellulose (HPMC), and hydroxypropyl methylcellulose acetate succinate (HPMCAS)).[20] Based on the peak shifts, it was found that PVP formed the strongest hydrogen bonds with felodipine.

The use of Raman spectroscopy to analyze dispersion samples is also growing. As with IR spectroscopy, it is used to look at interactions between components in dispersions and determine miscibility. One report investigating diflunisal in dispersions containing PVP, HPMCAS, and HPC showed phase separation in the HPMCAS dispersions only.[34] Physical stability of dispersions has been investigated with Raman spectroscopy by quantifying the amount of crystalline material present. An example is an ibininabant:PVP dispersion formulated into a tablet with a 1% drug loading[35] where it was possible to detect the presence of 5% crystalline material (less than 0.05% of the total sample mass). While this result is not typical for many Raman methods, it does illustrate the possibilities when there is strong scattering of the drug and little overlap with the polymer. Raman microscopy has also differentiated amorphous and crystalline domains of a dispersion, as reported for a troglitazone:PVP system.[36]

Solid-state NMR has been used to investigate a variety of amorphous solid dispersion properties, such as miscibility,[28,37] intermolecular interactions,[38] molecular mobility,[39] domain size,[28] crystallization kinetics,[40] and ionization.[41] The technique has also been used to identify[28] and quantify crystalline material[42] in dispersion samples.

While ^{13}C SSNMR data are commonly collected for pharmaceutical compounds, a variety of other atoms can also be used to gain information on dispersions, such as ^{19}F[42] and ^{15}N.[41] ^{15}N atoms exhibit a low natural abundance, as does ^{13}C, so larger rotor sizes, more sample, and longer acquisition times are needed. ^{19}F atoms exhibit high sensitivity and high selectivity in fluorinated drugs and SS19F NMR analyses are becoming more common as the number of drugs containing fluorine continues to rise. One study used ^{19}F to investigate the mobility of flufenamic acid at a 20% drug loading in PVP or HPMC dispersions.[40] It was found that the molecular mobility of the flufenamic acid was higher in the HPMC dispersion and was related back to lower physical stability (enhanced crystallization) compared with the PVP dispersion. Another study discusses the quantitation of crystalline material in an AMG517:HPMCAS dispersion using ^{19}F SSNMR.[42] A detection limit of 3% crystalline material was measured for the dispersion at a variety of drug loadings.

Collecting the moisture sorption/desorption curves for amorphous solid dispersions provides useful information on hygroscopicity, handling conditions, and possible phase transformations. Data are commonly collected using an automated moisture sorption system or static humidity chambers that employ salt solutions.[43] The type of sorption/desorption obtained can then be used to probe the properties of the dispersion. In a study with various drugs and the hygroscopic polymer PVP, it was found that some miscible dispersions exposed to elevated relative humidity resulted in crystalline drug being produced (ketoprofen and indomethacin dispersions) while pimozide:PVP dispersion separated into a physical mixture of amorphous drug and amorphous polymer[33] A follow-up study with less hygroscopic polymers found that systems with strong drug-polymer interactions and a less hygroscopic polymer (such as HPMCAS) are less susceptible to moisture-induced phase separation, while more hydrophobic drugs are more susceptible even at low water contents.[44] In addition, crystallization kinetics have been determined using water uptake data.[45]

18.4 SCREENING AND SELECTION OF AMORPHOUS SOLID DISPERSIONS

Amorphous solid dispersion screens are used to find possible API and polymer combinations that provide the necessary properties for development. There are a number of steps in the screening and selection process, as outlined in Fig. 18.4. For an amorphous dispersion screen, collecting information on the API is the first step and data may include chemical structure, solid form, physical stability, chemical stability, hydrogen bond donors and acceptors, calculated solubility parameters, log P, and known solubilities of the solid in solvents and biorelevant media. All of this information may not be available for early development compounds and may be determined during the screen or later in development. Characterization of the API will provide a baseline for comparison when dispersions are found and can be used to help design experiments, such as the melting point of the API for melt

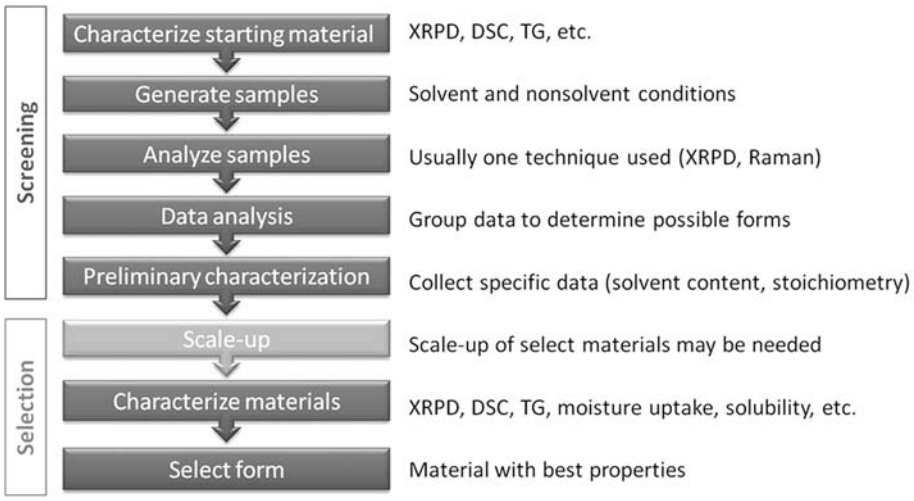

FIGURE 18.4 Outline of screening and selection activities.[46]

experiments and the temperature of desolvation or decomposition for heating studies. It is also useful to prepare the amorphous API for comparison with any dispersions that may be produced.

Designing the screening experiments will include a number of steps, such as choosing excipients, API: polymer ratios, and experimental conditions. Polymer properties to consider may include molecular weight, T_g, hydrophilic/hydrophobic properties, hydrogen bond donors/acceptors, calculated solubility parameter, pH-solubility profile, thermal stability, water uptake, and monomer levels. A variety of methods have been reported for choosing polymers to be included in a screen and some of these are summarized in Table 18.2. Some of these approaches can be easily incorporated into most screens and some will require more time and expertise. It is important to understand the API properties that need to be changed and try to include polymers that may improve that property. For example, if an API has a low T_g then a polymer with a significantly higher value would be used to help increase the T_g of the dispersion, or if the API is hygroscopic then a nonhygroscopic polymer would be targeted. For early development compounds, binary mixtures of API and polymer will be the easiest to investigate, but the option of adding multiple polymers or other components, such as surfactants, to make ternary systems can also be considered. Adding ternary systems to the screen will increase the number of samples and add complexity, but should be considered for difficult systems. The ratio of API:polymer also needs to be established and many studies use a range of 50–70% polymer, but it has been reported that even small amounts of polymer (such as 5%) can provide stabilization for up to 6 months and 30% polymer can provide stability for at least 2 years.[52] A range of compositions should be explored since it has been found that miscibility may change with API:excipient ratio.[53] The estimated drug loading should also be considered because the amount of polymer can significantly increase the size of the capsule or tablet to be produced.

Screening methods typically involve melt or solvent techniques, and many screening methods can be performed in 96-well plates.[54,55] To use melting methods, it needs to be established that the API will not thermally decompose at elevated temperature. Thermal screening methods include melt mixing,[56] DSC,[57] melt compression,[54] and small-scale extruders.[57] For solvent-based methods, it is important to find a solvent or solvent mixture where all components are soluble and chemically stable. When designing screening experiments, the goal is to remove the solvent as quickly as possible to produce the metastable amorphous dispersion. Methods include rotary evaporation,[47] freeze drying,[47] film preparation,[54] electrospinning,[58] and spray drying.[48] In many screens, a tiered approach is used and a combination of methods may be used to make different amounts of material throughout the screening and selection process. For example, a combination of DSC (5–10 mg), melt mixing (10 g), and small-scale extrusion (>10 g) was used to explore dispersions of PVP and five pharmaceutical compounds.[57]

Initial testing of the dispersions begins with XRPD to determine which samples are amorphous. From there a variety of properties can be evaluated, such as T_g, solvent content, solubility, hygroscopicity, dissolution, and stability. The amount of initial testing may be limited by the amount of material available, so it is important to understand the desired properties of the dispersion and prioritize these as the initial set of tests when possible. Based on these properties, a smaller set of amorphous solid dispersions will be moved to the next stage, involving scale-up and additional testing.

TABLE 18.2 Approaches for Choosing Polymers in a Dispersion Screen[14]

Method	Description	Comments	Reference
Empirical	Choose common polymers	Use a variety of polymers; melting point or solubility may be considered	47
Manufacturing	Choose polymers based on the desired large scale manufacturing (melt extrusion and spray drying)	Need low-melting polymers for melt extrusion, need solubility in solvent for spray drying	48,49
Solubility parameter	Choose polymers with a similar solubility parameter as the API	Similar solubility parameter maximizes mixing and promotes miscibility	a,b
Miscibility	Choose polymers that are miscible with API	Miscible systems may show better physical stability	c
Polymer properties	Choose polymer with high T_g	High T_g of polymer will increase T_g of the dispersion; want T_g around 70–80°C to be about 50°C above RT	21,47
	Choose polymer with low water sorption	Water will lower T_g and may decrease physical stability	47, d
	Review pH where polymer dissolves compared to pH of targeted absorption site in GI tract	Compare pH with that of API properties (acid vs base) and site of absorption (gastric vs intestinal)	50, e
DSC	Determine T_m/T_g ratio	Choose polymers with high T_g values to increase T_g of the dispersion compared to the amorphous API:high ratios may crystallize more easily	f
	Reduced crystallization temperature	Crystallization peak in DSC increases in temperature with increased interactions between API and polymer	a
	Determine width of T_g	Wide T_g may indicate partial miscibility	g
Interactions	Look at common H-bonding motifs, ion dipole interactions, or acid-base interactions between drug and polymer	Try to maximize interactions in dispersion disrupt bonding in crystalline materials (eg, PVP disrupts indomethacin dimers)	32, d,h,i
	Acid-base interactions	Ionic interactions produce strong interactions for stable amorphous solid dispersions	i,j
	Complex interactions	Use GEMANOVA analysis based on XRPD microscopy data	k
	Ab initio calculations	Rank order crystallization inhibitors	h
	Determine binding constants using affinity capillary electrophoresis	Drug-polymer binding constants based on changes in effective electrophoretic mobility of the drug upon binding to the polymer	l
Supersaturation	Determine polymers that improve supersaturation or stability in solution	Stable supersaturated solutions provide API:polymer ratios; spray drying used to produce dispersions	51, m,n
Drug solubility in polymer	Determine level of drug that will dissolve in polymer	Gives upper concentration for unsaturated dispersion	6, c,o

This additional testing may include BA studies depending on the development plan and timeline.

Dispersion selection is based on the characterization and property data collected for the dispersion samples. Early formulations may need certain properties that are essential in moving the molecule forward, such as improved solubility or BA, and these should be included in the selection criteria. A simple formulation with the necessary handling (such as temperature and low relative humidity) may be possible for small clinical supplies, but may not feasible for larger or longer clinical studies. Later in development, as the amount of clinical supplies increases and the formulation is modified, other processing, handling, and storage conditions would need to be considered. It is important to understand and include these development issues in the selection process.

Data obtained for the various dispersions can be reviewed in a number of ways. Two common methods are a decision tree[47] and a form matrix.[59] A decision tree narrows down the dispersion options based on a series of decision points. The dispersions that do not meet the criteria are removed from consideration and the rest are moved to the next decision point. Another option is a form matrix where the materials and properties are summarized in a table, acceptable properties are highlighted, and dispersions with the best properties are selected. For both approaches it is important to understand what is needed from an API property, formulation process, and development perspective. It should be noted that properties needed for early development may be different for a late-stage program and each selection should be assessed individually.

18.5 STABILITY CONSIDERATIONS

Amorphous materials are physically unstable and will have a tendency to crystallize to their more stable crystalline form (Fig. 18.2). One goal for amorphous solid dispersions is to maintain the amorphous API during drug product manufacturing and for the marketed drug's shelf life (physical stability). The second goal is to maintain a supersaturated solution of the API once the amorphous dispersion is dissolved in the gastrointestinal (GI) tract (solution stability); if the drug crystallizes upon contact with biological fluids or shortly after then the solubility advantage of the amorphous state is lost. This is illustrated in Fig. 18.5.[60]

Physical stability, or crystallization rate, in amorphous solid dispersions is dependent on a number of factors, such as the crystallization tendency of the drug alone,[61] miscibility,[17,33] storage temperature,[62] water content,[20] and the amount or type of polymer used.[20,63] Many of the polymers and excipients added

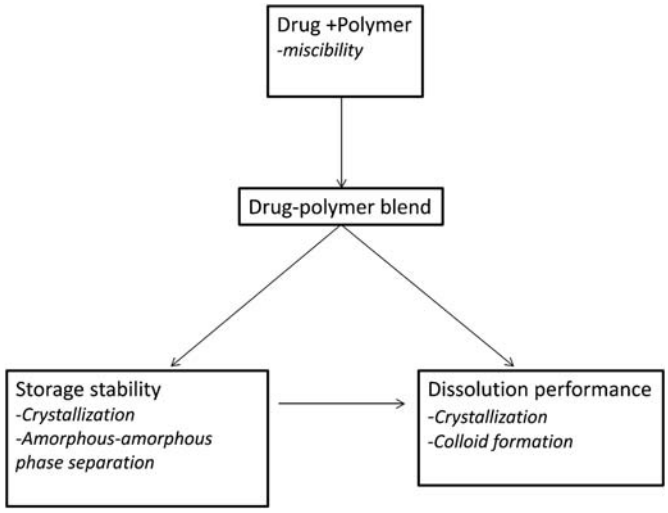

FIGURE 18.5 Schematic of factors important factors for the stability of amorphous solid dispersions. *Source: Reproduced with permission from Taylor LS. Chapter 5. Physical stability and crystallization inhibition. In:* Pharmaceutical amorphous solid dispersions. *A. Newman, editor. Hoboken, NJ: John Wiley and Sons; 2015.*

to amorphous solid dispersions can act as crystallization inhibitors and help maintain the amorphous nature of the drug in the solid phase. There are a number of possible stabilization mechanisms for polymers, including a decrease in molecular mobility related to T_g,[64,65] disruption of drug-drug interactions,[30] and formation of specific polymer-drug interactions related to miscibility.[32,66,67] It is likely that a combination of mechanisms contributes to the inhibition in most dispersion systems; however, these types of mechanisms can help guide polymer selection by comparing relevant API and polymer properties.

Assessing physical stability involves characterization methods (previously described) and presents a number of challenges. Physical stability testing is needed to determine which polymers best inhibit crystallization. This will involve different polymers, polymer grades, and concentrations, which can result in a large number of samples. Due to the small amount of API available in early development, these types of studies need to be carefully planned to obtain the most useful information. The low loading in amorphous dispersions also presents a challenge with many analytical techniques, and this aspect becomes more of an issue once the dispersion is formulated into a marketed product where the amount of active drug is further diluted. Determining crystallization rates as a function of temperature and water content can be difficult due to the lack of first principle models that accurately describe nucleation, growth, and overall crystallization kinetics in amorphous dispersions.[60] However, performing these studies may still provide a starting point for understanding the stability of a dispersion.

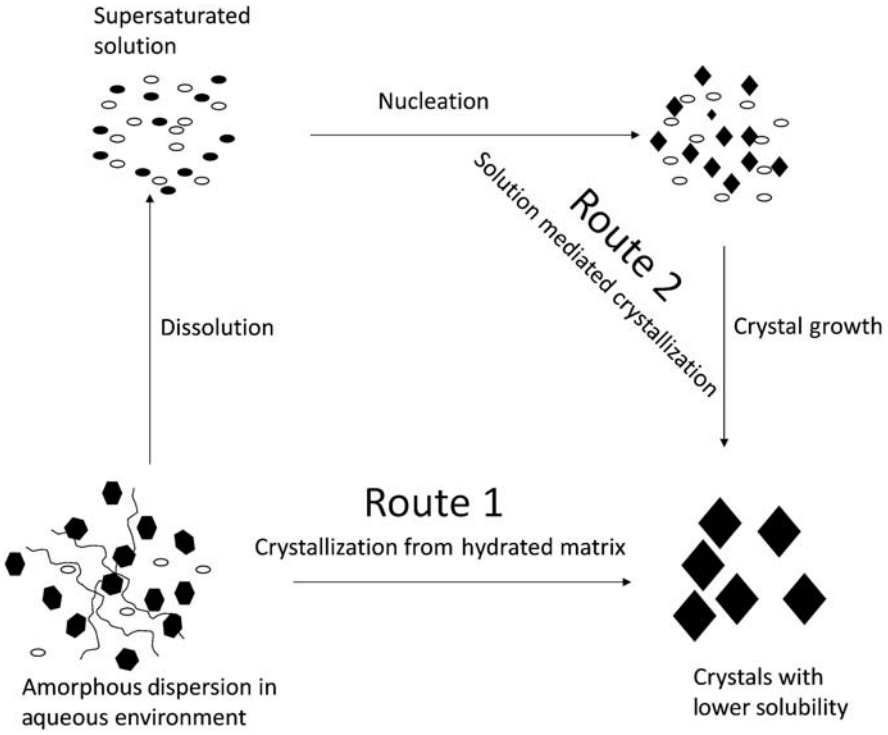

FIGURE 18.6 Schematic showing the possible routes of crystallization after adding an amorphous solid dispersion to an aqueous medium. Route 1 is matrix crystallization and Route 2 is solution crystallization. *Source: Reproduced with permission from Taylor LS. Chapter 5. Physical stability and crystallization inhibition. In:* Pharmaceutical amorphous solid dispersions. *A. Newman, editor. Hoboken, NJ: John Wiley and Sons; 2015.*

Crystallization from aqueous solutions, such as dissolution media or biological fluids in the GI tract, is another consideration. It is important that once the drug dissolves, the solution supersaturation is maintained to allow absorption of the drug. For dispersions with relatively high polymer content, the rate of release will likely be controlled by the polymer, not the API.[68] Fig. 18.6 shows two possible routes to crystallization when an amorphous solid dispersion is dissolved in an aqueous media: matrix crystallization (Route 1), where the dispersion may sorb water and the drug crystallizes in the matrix before dissolution, and solution crystallization (Route 2), where the drug is released into solution and then nucleates/crystallizes. For these types of studies, it is important to determine if crystalline or amorphous material is produced. If crystalline material is produced, the supersaturation of the solution will be lost, whereas if an amorphous material is produced, then supersaturation can be maintained.[69,70]

The ability of polymers or excipients to inhibit crystallization may influence precipitation (where turbidity is measured and it is not known whether crystalline or amorphous material is produced),[71] crystal nucleation,[72] or crystal growth.[73,74] In early development, studies can be performed to quickly assess the ability of various polymers to inhibit precipitation using turbidity[75] and can be performed in well plates.[76,77] A better understanding of the inhibition may be needed and more complex studies can be performed to obtain further information on the system as the drug progresses into development.

18.6 SOLUBILITY AND DISSOLUTION CONSIDERATIONS

Solubility and dissolution are important properties for amorphous solid dispersions because they have been linked to performance, such as BA. It has been shown that the flux across a membrane is enhanced for supersaturated solutions, but not for solubilized solutions;[78,79] therefore, using amorphous solid dispersions to create and maintain supersaturated solutions could lead to enhanced performance.

Solubilization depends on a number of drug properties, such as pKa, lipophilicity, and intermolecular forces in the solid state, as well as solvent properties, including pH, polarity, and solvent interactions. Solubility is a thermodynamic property and is defined by the concentration in solution in equilibrium with excess solid, therefore the value is based not only on the concentration in solution, but also by the solids present during the experiment. It is important to determine if equilibrium is established with an amorphous solid present during the measurement, with a crystalline material that has been produced during the solubility experiment, or colloidal drug aggregates.[80] The reference solubility is typically obtained with the most stable crystalline form. The solubility of other

TABLE 18.3 Method for Determining Solubility for Amorphous Solid Dispersions

Step	Comment
1. Ensure material has a uniform particle size to avoid multiple dissolution rates 75–150 μm is recommended	In early development this may difficult to obtain based on sample size: a range can be estimated using optical microscopy or SEM
2. Add a known excess of amorphous to medium (at least 10 × the crystalline solubility is recommended)	Amount of medium will depend on solubility and amount of sample available. Stirring (overhead or stir bar) can be limited by the volume of medium used
3. In order to improve powder dispersion, a paddle speed of at least 300 rpm is recommended	If wetting is not an issue, a lower speed, such as 100 rpm, is recommended
4. Draw sample at select time points and filter using an appropriate filter	Multiple time points are used to determine whether the profile levels off (equilibrium) or decreases (likely precipitation or crystallization)
5. Dilute samples immediately using organic solvent suitable for analysis method to prevent precipitation and/or crystallization	
6. Determine concentration in solution	
7. Pull an unfiltered sample at each time point and analyze for appearance of crystallinity	Wet sample analyzed by XRPD will provide information on the solid formed in solution; drying the sample may promote a form conversion and confuse the results
8. Determine the concentration versus time profile and note the first appearance of crystalline material	

Adapted from Murdande SB, Pikal MJ, Shanker RM, Bogner RH. Aqueous solubility of crystalline and amorphous drugs: challenges in measurement. Pharm Dev Technol *2011;16(3):187–200.*

metastable forms and supersaturation measurements reference that value.[81] In the case of an amorphous solid dispersion, the term *apparent solubility* is used to differentiate the amorphous value from the most stable crystalline form.[50,51,82] A suggested method for determining solubility is given in Table 18.3, which includes analysis of both the solution and the remaining solid.[83]

It is also important to decide which media will provide the most useful information. Solubility in water will provide a relatively straightforward comparison between the amorphous solid dispersion and a crystalline reference material This comparison can be used for initial assessment or for dispersion selection. However, it will not provide significant information on the solubility increase in biological media, which can be different based on pH and other factors. If absorption is expected in the intestine, then a corresponding media, such as simulated intestinal fluid, may be more appropriate. The transit time through the GI tract should also be considered when reviewing the time course of the experiment. If crystallization does not occur for 24 hours and the estimated residence time in the intestine is only a few hours, then the dispersion would be considered at low risk for crystallization.

Dissolution is different than solubility and applies to the kinetics rather than the thermodynamics of the process. Dissolution rate will increase with increasing surface area of the particles and drug solubility, and decrease with an increase in the thickness of the aqueous boundary and the concentration of drug already in solution. Dissolution will drive the initial solubilization of the dispersion and intestinal absorption will remove the solubilized drug, causing additional solubilization of the dispersion.

Typical dissolution methods based on United States Pharmacopeia (USP) criteria are used to determine similarity between lots for quality control purposes.[84] These methods are not usually applicable for evaluating in vivo performance. There are a number of parameters that need to be considered when developing a dissolution method for in vivo correlation, which are summarized in Table 18.4.[50] When developing dissolution methods for dispersions, the conditions chosen should mimic the GI tract, such as biorelevant media that matches the delivery route, pH, stirring rate, and volume. Most dissolution methods are run under sink conditions, however, nonsink conditions should be explored for poorly soluble drugs that may crystallize in the GI tract. Polymer properties also need to be considered and issues such as gelling, floating, or solids clinging to paddles, shafts, and glassware may be observed during method development. Crystallization propensity in the media over biologically relevant time frames should also be explored. For some dispersions, issues with wetting are overcome using surfactants.[26]

While Apparatus 1 (basket method) and Apparatus 2 (paddle method) are the most common USP methods used, it has been shown that Apparatus 3 (reciprocating cylinder) and Apparatus 4 (flow-through cell) offer advantages for low solubility compounds by allowing controlled pH and volume changes of the dissolution media throughout the analysis. A number of studies report the use of two-phase dissolution systems that attempt to mimic the GI tract (stomach and duodenum) and provide a better correlation with BA studies.[85–87] In one study, the crystallization of an amorphous form during dissolution was observed and

TABLE 18.4 Considerations for Amorphous Solid Dispersions[50]

Area	Considerations	Recommendations
Physical	Choice of polymer	Polymer characteristics (solubility, melting point, wettability, hygroscopicity, effect of pH, dissolution rate, etc.) and large-scale manufacturing process (spray drying, melt extrusion) need to be considered early in the development of the amorphous solid dispersion
	Polymer:API ratio	Optimize the amount of polymer required to provide the long-term physical stability desired in the solid state and crystallization inhibition in solution
	Miscibility	Determine if a one-phase miscible system has been produced
	Manufacturing processes	Consider that the amorphous solid dispersion produced at elevated temperatures may be miscible but may separate upon cooling to room temperature or under other conditions
	Hygroscopicity	Water uptake and the effect on T_g, physical stability, and crystallization need to be evaluated
Dissolution	Dissolution apparatus and media conditions	Dissolution method development should focus on conditions that mimic the GI tract (biorelevant media that match the delivery route, pH, stirring rate, volume); these conditions may not be applicable for routine dissolution testing to discriminate differences between lots
	Sink versus nonsink conditions	Both sink and nonsink conditions should be investigated and compared with data from the in vivo studies; for poorly soluble drugs nonsink conditions and the possibility of crystallization in the GI tract need to be evaluated
	Polymer controlled dissolution/wettability	Incorporate polymer properties into the dissolution method development (gel formation of the polymer, floating of particle/dispersion particles, solid clinging to paddles/shafts/glassware)
	Supersaturation in dissolution testing over hours	Test supersaturation over biologically relevant time frames in biorelevant media to determine if the API will stay in solution or crystallize out
Biological	Fasting versus Fed-pH effects	Food effects need to be evaluated; specifics on fasting times and post-dose feedings need to be detailed in reported studies
	Sink versus nonsink conditions	Dose-range dependent sink conditions along the GI tract (pH, volumes, residence times) need to be considered and investigated; these will be dependent on the solubility of the API and the amorphous solid dispersion
	Local effect of polymers on pH	pH effects of polymers, especially polymers used for enteric coatings, need to be evaluated throughout the entire GI tract
	Species differences	Investigate the use of alternative animal models, such as pigs and minipigs, that are a better model for non-primate studies
	Transporters and metabolism	Determine if APIs are substrates for human transporters and/or metabolizing isoforms and the affect this will have on absorption
	Gastrointestinal physiology	For highly lipophilic molecules, lymphatic absorption and not only blood absorption need to be determined in early studies; use extended GITA model to predict regions of optimal absorption; use feedback from in silico models to help refine formulations

dissolution results compared favorably with dog BA studies.[85] Fed versus fasted conditions can also be simulated with the media chosen for the dissolution method and this factor should be considered, and be similar to what will be used in the animal studies, when developing the method.

18.7 METHODS OF MANUFACTURING AMORPHOUS SOLID DISPERSIONS

A variety of methods are used to produce amorphous solid dispersions at small scales, but the most common methods to produce large amounts of material (hundreds of grams or kilogram quantities) are hot melt extrusion[88] and spray drying.[48] Another method that uses common formulation processing equipment to produce large-scale quantities of dispersions, fluid bed granulation, has also been used for certain drugs. All three methods have been used to produce marketed products, as summarized in Table 18.1.

Melt extrusion forms a dispersion by melting the API/polymer mixture followed by rapid cooling to solidify the components and prevent API crystallization (Fig. 18.7). A variety of polymers can be used for this process[49] and the most common polymers include

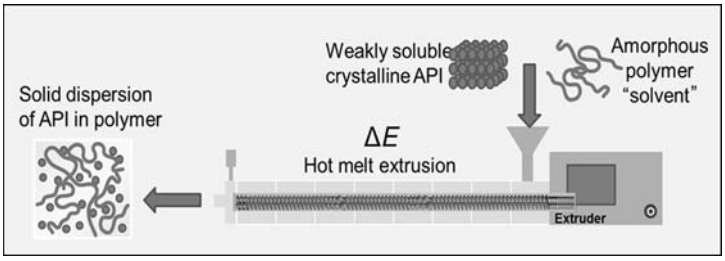

FIGURE 18.7 Hot melt extrusion process schematic. *Source: Reproduced with permission from Crowely K, Gryczke A. Chapter 10. Hot melt extrusion of amorphous solid dispersions. In:* Pharmaceutical amorphous solid dispersions. *A. Newman, editor. Hoboken, NJ: John Wiley and Sons; 2015.*

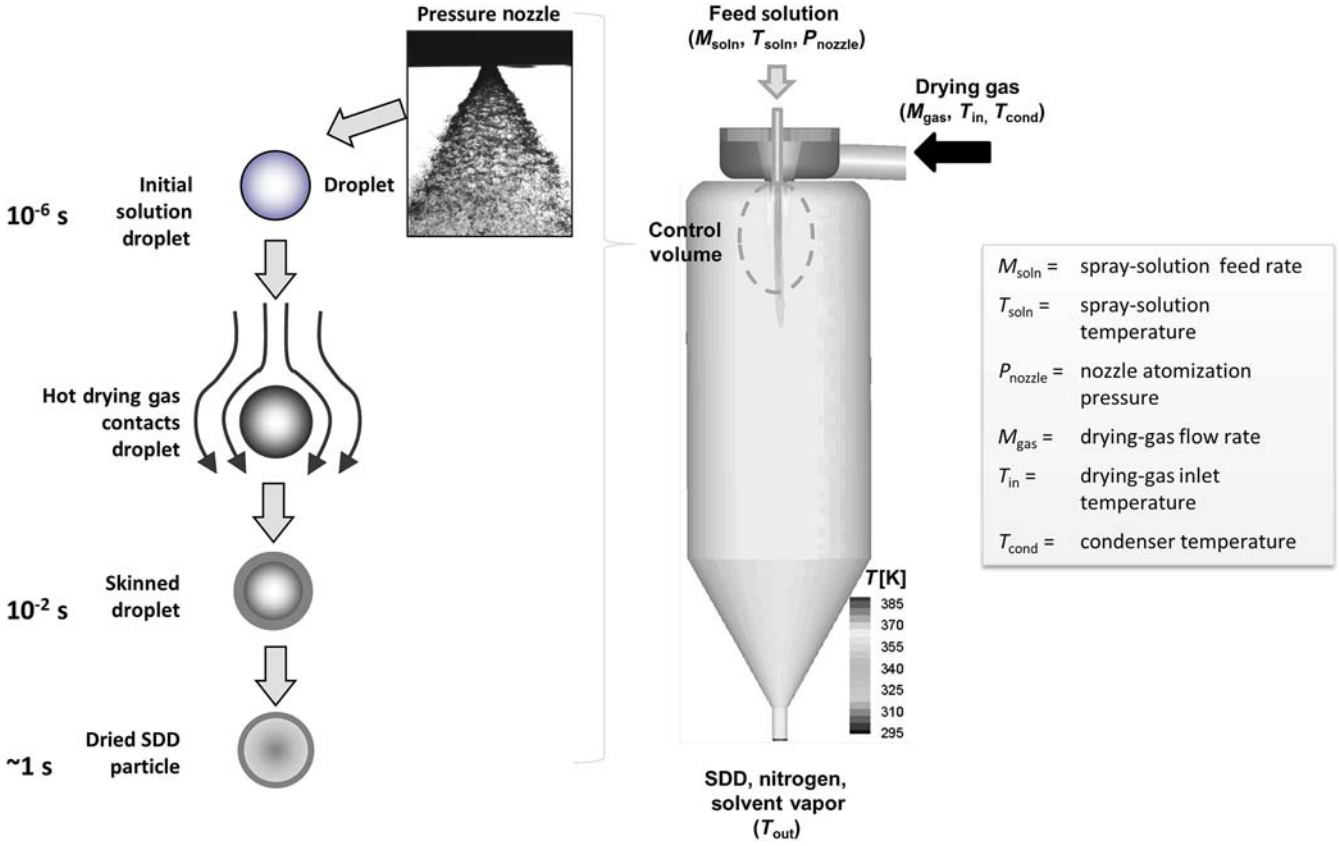

FIGURE 18.8 Spray-drying process schematic. *Source: Reproduced with permission from Dobry DE, Settell DM, Bauman JM. Chapter 9. Spray drying and scale-up. In:* Pharmaceutical amorphous solid dispersions. *A. Newman, editor. Hoboken, NJ: John Wiley and Sons; 2015.*

copovidone, povidone, HPMCAS, polyethylene oxide, polyethylene glycol (PEG), HPMC-E5, and methacrylates. The melting and T_g values of both drug and polymer are used to determine processing temperatures, usually 20−50K greater than the polymer T_g. Plasticizers, such as PEGs, poloxamers, and triethyl citrate, may be added to lower thermal transitions of the individual components or the extruded dispersion.[89] Additives to alter dissolution, such as surfactants, may be included to extend the duration of supersaturation or delay drug release. Extruders usually run in a continuous mode. Key process parameters include extruder screw design, feed rate, and temperature. It is critical that the API and excipients do not degrade at the processing temperature. The extrudate undergoes downstream processing to tailor the physical form for the final dosage form. Downstream processing can include pelletization or milling.

Spray drying is a solvent-based method commonly used to produce amorphous solid dispersions where droplets are produced and the solvent is removed within milliseconds (Fig. 18.8).[90] It is important to obtain solubility values of both the API and polymer in a solvent suitable for spray drying, such as dichloromethane, acetone, methanol, tetrahydrofuran, ethanol, ethyl acetate, water, and mixtures of these solvents. Both the API and polymer are dissolved in the solvent system. The spray-drying process consists of four stages: atomization of the liquid, mixing of the liquid with the drying gas, evaporation of the liquid, and

separation of the dried particles from the gas. By controlling various parameters, such as the atomization and drying parameters, dispersion particles can be engineered with specific properties, such as particle size and density. Secondary drying, using tray drying or vacuum drying, is added in many systems to remove residual solvent from the spray-dried dispersions. Small-scale spray dryers are available for milligram quantities of material, laboratory-scale equipment can produce gram-scale quantities, and production scale dryers produce metric ton batches. Spray drying has demonstrated scalability over these various batch sizes.[48,90]

Amorphous dispersions can also be produced using conventional manufacturing equipment, such as a fluid bed dryer/granulator or high-shear mixer, by spraying an API/polymer solution onto an inert substrate. The marketed product Sporonox is produced by a spray-layering process where a round core is initially sprayed with a coating film, followed by an amorphous dispersion layer containing HPMC and itraconazole, and then a seal-coating layer of PEG to prevent sticking of the beads.[91] These beads are then filled into capsules for the marketed product. Other methods have been used to produce dispersions at a scale for marketed products, such as melt onto a carrier (Afeditab) and antisolvent addition (Zelboraf). Detailed discussion of basic principles, process development, and scale-up of these manufacturing technologies can be found in relevant chapters in this book.

18.8 DOSAGE FORM DEVELOPMENT CONSIDERATIONS

Amorphous solid dispersions have been used in a variety of marketed products, as shown in Table 18.1. Once the amorphous solid dispersion has been chosen, it is important to understand how the large-scale production parameters may be related to the physical properties of the dispersion influencing dissolution, such as particle size and bulk density. Often, the manufacturing process will need to be examined and modified to produce large-scale batches with the desired properties.

Dispersion properties also need to be considered for the formulation process for a solid oral dosage form. Melt extruded dispersions have a tendency to be more dense, which may favor capsule formulations but may exhibit poor compression properties for tablets; therefore, a method to decrease the density may be needed. Spray-dried dispersions may consist of fine particles, exhibit poor flow and compression properties, and be poor candidates for capsule formulations. Methods to improve flow and compressibility of the spray-dried materials may be needed before tableting.

The physical stability of the dispersion will influence handling and storage conditions. For early formulations, the dispersion may be dispersed as a slurry in a liquid formulation vehicle. In correlating to BA, it is critical to determine how much API can be dissolved in the vehicle, as well as how long the solid remains amorphous in the liquid vehicle to determine a time frame for dosing after preparation. For dispersions that will be filled into capsules, the relative humidity of the room during encapsulation may need to be monitored and kept below a certain threshold to prevent crystallization. The amount of water in the capsules and possible migration to the solid amorphous dispersion placed in the capsule may need to be investigated.

The choice of excipients is a critical parameter to evaluate when using dispersions, especially in later development when the formulations become more complex. If the dispersion exhibits poor physical stability, especially around water, then anhydrous excipients should be considered. Some dispersions will show less issues with water. For Intelence, the package insert states that the tablet can be dispersed in water and taken immediately as a slurry.[92]

Formulation processes need to be considered because compression, heat, and exposure to moisture are commonly used to produce the final dosage form. Determining methods to measure physical stability (crystallization) and chemical stability (degradation) will be a key step in producing viable formulations. Analysis of the solid at different stages of the process will help narrow problem areas that would need remediation.

Stability testing of the drug product is needed to determine packaging, storage, and shelf life. The Food and Drug Administration has issued guidelines for stability conditions and time periods needed for long-term, intermediate, and extended stability studies on drug products.[93] Data must be examined to determine the conditions that affect the stability of the drug, and the process and packaging will need to be modified to ensure that the API remains amorphous.

18.9 CASE STUDIES

As discussed in this chapter, amorphous solid dispersions in early- and late-stage development will have different requirements, and the types of studies needed at each stage will be tailored as the product's launch approaches. In this section, case studies involving amorphous solid dispersions in early and late development, as well as in life cycle management, will be presented.

18.9.1 Early Development: Vemurafenib

Vemurafanib (Fig. 18.9) is a compound that is practically insoluble at pH 3 and 7 (<0.1 μg/mL), and an amorphous solid dispersion was used to improve its solubility. In the case of vemurafanib, a very high melting point and very low solubility in low-boiling solvents made conventional spray drying and melt extrusion methods unsuitable. The dispersions were prepared by a coprecipitation process shown in Fig. 18.10, which is an alternative preparation method that can be used when spray drying or melt extrusion are not feasible.[94] Dispersion samples prepared by the coprecipitation method were called microprecipitated bulk powders (MBP). Enteric polymers HPMCAS, hydroxypropyl methylcellulose phthalate (HPMCP), and Eudragit L 100-55 in a 40:60 or 30:70 w/w% drug: polymer ratio were used in the study. A solution of drug and stabilizing polymer in dimethylacetamide (DMA) is added to a dilute hydrochloric acid (HCl) solution maintained at 2–5°C; precipitation occurs

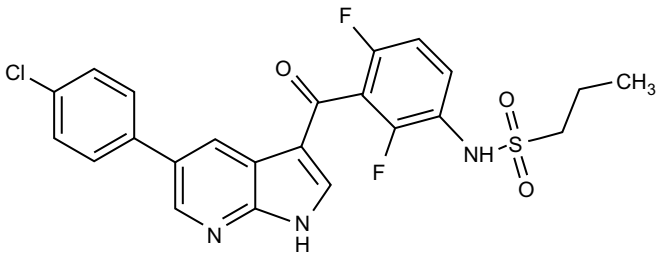

FIGURE 18.9 Structure of vemurafanib.

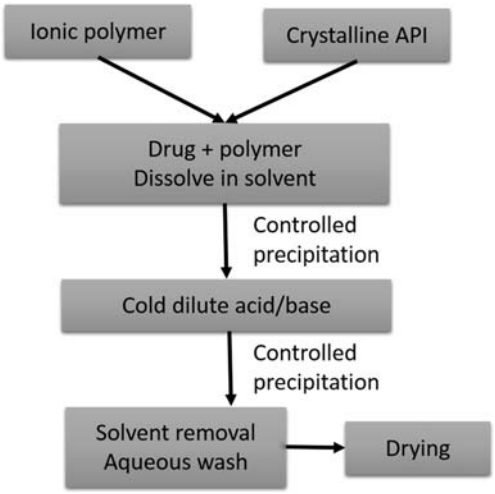

FIGURE 18.10 Schematic of the coprecipitation method used to produce MBP samples. *Source: Adapted from Shah N, Iyer RM, Mair H-J, Choi DS, Tian H, Diodone R, et al. Improved human bioavailability of vemurafenib, a practically insoluble drug, using an amorphous polymer-stabilized solid dispersion prepared by a solvent-controlled coprecipitate process.* J Pharm Sci *2013;102:967–81.*

based on the insolubility of the drug and polymer in acidic aqueous media, resulting in the API being dispersed in the polymer matrix.

Characterization of the samples showed that all three dispersions were amorphous. Upon storage at 40°C/75% RH in open containers for 4 weeks, the HPMCP dispersion exhibited signs of crystallization after 2 weeks while the other two polymers exhibited no crystallization after 4 weeks. Based on this, the HPMCP dispersion was not pursued further. One T_g value was measured for the remaining dispersions (102°C for the HPMCAS system and 111°C for the Eudragit system), suggesting a miscible system and good physical stability at room temperature (RT). Dissolution studies showed that HPMCAS was able to maintain a higher level of supersaturation (90%) than Eudragit (55%) over a 5-hour time frame. These values represent supersaturated concentrations levels of approximately 40 μg/mL (HPMCAS) and 22 μg/mL (Eudragit), which is almost a 100-fold increase for the HPMCAS dispersion over the crystalline drug. A pH solubility study ranging from pH 2 to 8 resulted in a two–threefold greater solubility in the enteric pH range of 6.8–8.0 for the HPMCAS material over the Eudragit L 100-55. Based on the higher supersaturation potential, the HPMCAS dispersion was chosen for further development.

Additional studies on the HPMCAS dispersion were performed. Scanning electron micrography (SEM) micrographs showed that the MBP particles have a relatively smooth and round surface, whereas the inner structure is a spongy network with pores in the range of 50–200 nm and larger bubbles in the range of 3–10 μm. Crystalline particles related to crystalline API were not detected in SEM images, indicating a homogenous dispersion of amorphous API and polymer, which agrees with the XRPD and DSC data. Dissolution studies using a flow-through cell showed that 100% of drug was released from the MBP after 120 minutes, compared with about 10% release from amorphous drug and a physical mixture of crystalline vemurafenib and HPMCAS. The particle size distribution of the MBP samples exhibited a d_{50} value of 60 μm and a d_{90} value of 220 μm. The dissolution rate of MBP samples of different particle sizes showed a decrease in dissolution with larger particles (125 μm) compared with smaller particles (48 μm), indicating that dissolution could be further enhanced by optimizing the particle size distribution.

HPMCAS MBP samples stressed at 40°C/100% RH showed a partial conversion to crystalline API (Fig. 18.11a) based on an XRPD quantitative method able to detect crystalline levels as low as 1.6%. Dissolution profiles of stressed and unstressed MBP samples (Fig. 18.11b) resulted in lower dissolution

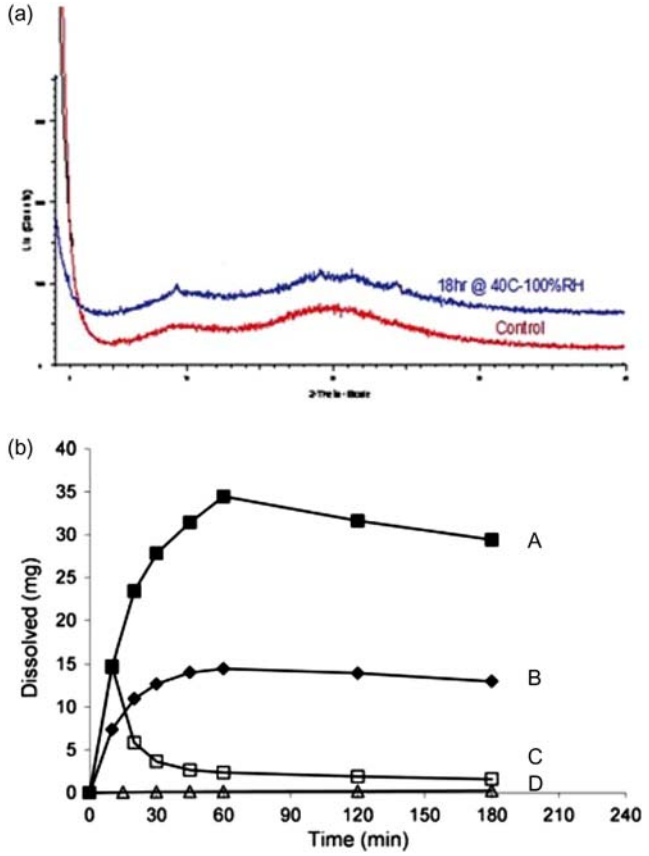

FIGURE 18.11 (a) XRPD profiles of control and stressed capsules of vemurafenib:HPMCAS MBP; (b) dissolution profiles of vemurafenib:HPMCAS MBP and crystalline vemurafenib: (A) unstressed vemurafenib:HPMCAS MBP, (B) stressed vemurafenib:HPMCAS MBP, (C) metastable crystalline vemurafenib, (D) stable crystalline vemurafenib. *Source: Reproduced with permission from Shah N, Iyer RM, Mair H-J, Choi DS, Tian H, Diodone R, et al. Improved human bioavailability of vemurafenib, a practically insoluble drug, using an amorphous polymer-stabilized solid dispersion prepared by a solvent-controlled coprecipitate process.* J Pharm Sci *2013;102:967–81.*

rates for the stressed samples due to the increased levels of crystalline material. A correlation plot of percent crystalline material and dissolution rate showed a good relationship between the two parameters (coefficient of correlation = 0.9753). Upon storage, the water content of MBP samples with different initial moisture contents (<1% vs approximately 2%) was found to be about the same, reaching a final water content of approximately 4% within 2 months of open storage at 30°C/75% RH and 40°C/75% RH. These data were used to determine handling and storage conditions of the MBP to maintain the amorphous nature of the solids.

The HPMCAS MBP was formulated into 40-mg strength capsules of vemurafenib, employing dry blending (MBP-1) and wet-mixing (MBP-2) processes. The effect of temperature and humidity on moisture content and percent crystallinity was evaluated after

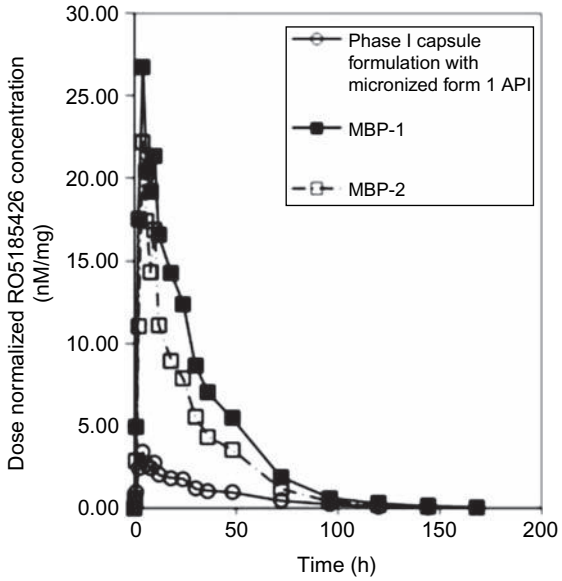

FIGURE 18.12 Comparison of dose-normalized exposure data among three capsule formulations: Phase I crystalline vemurafenib and two MBP amorphous vemurafenib formulations. *Source: Used with permission from Shah N, Iyer RM, Mair H-J, Choi DS, Tian H, Diodone R, et al. Improved human bioavailability of vemurafenib, a practically insoluble drug, using an amorphous polymer-stabilized solid dispersion prepared by a solvent-controlled coprecipitate process.* J Pharm Sci *2013;102:967–81.*

15 months using open and closed storage conditions (25°C/60% RH, 30°C/75% RH, and 40°C/75% RH). The open conditions resulted in water contents ranging from 3.5% to 4.5% and crystalline contents ranging from 2% to 24%. Closed conditions showed significantly less water (1.3–1.6%), and only 2% crystalline material under the most severe stress conditions. Based on these data, it was determined that protective packaging was essential to control moisture and maintain the amorphous nature of the HPMCAS dispersion.

A relative BA study in healthy volunteers was conducted using MBP-1, MBP-2, and a 100-mg Phase I crystalline drug capsule formulation containing 10% poloxamer F127. The study was conducted for 84 days with 18 healthy, male subjects ranging in age from 18 to 65 years old. Both MBP formulations had nearly identical exposures following a single 160-mg dose, with area under curve (AUC) values of 86 (MBP-1) and 80 μ Mh (MBP-2), compared with a value of 34 μ Mh for a single 300-mg dose of the Phase I crystalline formulation (Fig. 18.12). The relative BA for the MBP-1 and MBP-2 formulations was 4.4–4.7 times compared with the crystalline formulation. The maximum concentration (C_{max}) ratios were also found to be similar for both MBP formulations (3.6 and 3.1) when compared with the crystalline formulation. Based on these data, it was evident that the MBP formulations were superior to the Phase I crystalline formulations and

supported further development of the amorphous dispersion to improve the BA of vemurafenib.

This case study uses a bulk precipitation method that can be used when conventional spray drying and melt extrusion methods are not feasible. This preparation can be used at small or large scale, enabling relatively easy production of larger batches throughout the development process. A number of studies were needed on both the MBP and formulated product to understand the physical stability and effect of crystallization on dissolution, as well as to determine handling and packaging conditions. The result was an amorphous dispersion capsule formulation with improved BA at lower doses, which was a significant improvement over the Phase I crystalline formulation.

18.9.2 Late Development: Telaprevir

Telaprevir (Fig. 18.13) is small molecule that targets the hepatitis C virus. The molecule is an active site inhibitor and needs to be apolar in order to bind effectively, which then results in a very low aqueous solubility. Early development studies determined that an amorphous dispersion was needed to obtain the necessary properties for oral administration. An amorphous dispersion with HPMCAS was chosen for further development.[95]

After early development studies were completed, the amorphous solid dispersion needed to be formulated into clinical and commercial drug products. A spray-drying process was chosen for large-scale manufacturing of the dispersion based on the acceptable solubility of telaprevir in organic solvents and the ease of scaling up the process.[96] The overall formulation process would include secondary drying to remove excess residual solvent, blending with excipients, compressing the blend into tablets, and film coating the tablets. A quality by design (QbD) approach was used for late-stage development. The quality target product profile for the commercial drug product included (1) an immediate release tablet; (2) stable during 24 months of shelf storage; (3) orally administered; (4) bioavailable; (5) safe; (6) efficacious; and (7) easily distinguishable from other medications. From this profile, the critical quality attributes (CQAs) for the dispersion and the coated tablets were defined, and the possible impact on quality, safety, or efficacy were assessed (Table 18.5).

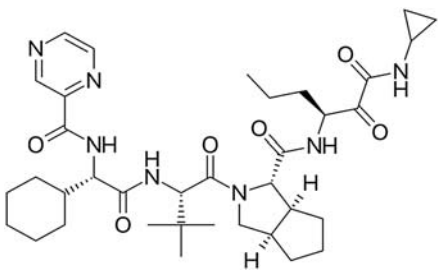

FIGURE 18.13 Structure of telaprevir.

The initial risk assessment suggested that the dispersion is a potential critical material due to its impact on dissolution. Each unit operation was studied to determine possible critical and key processing parameters using a design of experiment (DoE) approach. Table 18.6 lists dispersion manufacturing and tablet preparation steps that were identified to affect the dissolution. Based on this list, a set of experiments were identified to define the process design space for tablet CQA of dissolution. Dispersion attributes that needed to be controlled as part of the spray drying and secondary drying process were identified as particle size, bulk density, and wet solid form prior to secondary drying (must be amorphous). Thirteen factorial experimental designs were conducted, covering 148 runs, to evaluate factors that influenced the spray-drying process. An additional 14 runs were added from data obtained from the initial runs. The spray-drying process space was found to rely on (1) wet particle size, wet bulk density, and spray drying process parameters and (2) the change in particle size and bulk density after secondary drying. The acceptable ranges for particle size and bulk density were found to be $50-110\,\mu m$ and $0.33-0.52\,g/mL$, respectively, and spray drying conditions were found to consistently provide material with these specifications.

The spray-drying parameters were then used as inputs for a DoE on tablet compression (Fig. 18.14). A model was developed to estimate tablet dissolution based on the dispersion particle size, bulk density, and average tablet hardness. To produce the dissolution models, 241 tablet sublots were employed, and the mean cumulative release of drug from the tablet after 15 minutes (normalized to the 90 minutes point) was used to determine the factors affecting the dissolution. The early timepoint was found to be more sensitive to processing and dispersion particle size and bulk density. A value of $>80\%$ dissolution at 15 minutes was used to define the design space for compression and to ensure that the dissolution specification (Q at 45 minutes = 80%) was met. A mean average tablet hardness of 13 kP was assumed for the next stage, which was to reduce the model to a relationship between particle size and bulk density, representing the limiting design space to achieve acceptable dissolution.

The next phase was a QbD study on the physical and chemical stability of the drug product to determine shelf life. A temperature and relative humidity study was included to not only assess physical stability, but also to develop a chemical stability model that correlated the amount of epimer (the primary degradant of the API) with factors such as surface pH of excipient, moisture content of the tablet, storage temperature, and

TABLE 18.5 Summary of Critical Quality Attributes for Telaprevir[96]

Quality attributes	Spray-dried dispersion	Drug product	Potential impact on quality, safety, and/or efficacy
Identification	X	X	Ensures correct active ingredient
Appearance	X	X	Visual indicator of product quality
Assay	X	X	Ensures potency of subsequent tablet
Degradation products	X	X	Ensures that levels of impurities do not affect assay or safety (by exceeding the levels deemed safe in toxicology or clinical studies)
Residual solvents	X		Affects safety, potency, and physical stability of the product
Water content	X	X	Ensures that water content is not so high as to lower chemical stability or impact physical stability during the product's shelf life
Physical form	X[a]	X[a]	Ensures that telaprevir remains amorphous and, therefore, bioavailable
Particle size	X		Affects flowability and compactability of the powder during tableting which could lead to low potency or broken tablets (efficacy). Incorrect particle size affects downstream manufacturability through inability to meet content uniformity, tablet weight, and/or hardness. Particle size may impact dissolution
Powder bulk density	X		Affects flowability and compactability of the powder during tableting which could lead to low potency or broken tablets (efficacy). Incorrect bulk density affects downstream manufacturability through inability to meet content uniformity, tablet weight, hardness and/or appearance. These variations could have an impact on tablet dissolution
Tablet hardness		X	Ensures that the integrity of tablets is not compromised
Dose uniformity		X	Ensures dose is uniform across the batch
Dissolution		X	Impacts the rate of drug release
Microbial limits		X	Ensures safety of the drug product

[a]*Physical form should be amorphous for dispersion and tablet.*

TABLE 18.6 List of Parameters Identified to Affect Dissolution of Vemurafenib Drug Product[96]

	SDD process steps		Tablet process steps		
	Spray drying	**Secondary drying**	**Blending**	**Compression**	**Film coating**

storage time. Tablets were equilibrated at conditions ranging from 10% to 60% RH, and using tablet moisture contents ranging from 0.4% to 3.4%; the tablets were then sealed into foil pouches to maintain constant water content. The pouches were exposed to 25°C, 30°C, and 40°C for up to 12 months. A regression model was developed to predict the growth of epimer and was used to determine appropriate acceptance criteria for water content in the tablets and impurity content in an excipient. Good agreement was found with traditional stability data and the model was able to predict the amount of epimer formed.

Based on the epimer data, the maximum allowable tablet water content and maximum epimer value

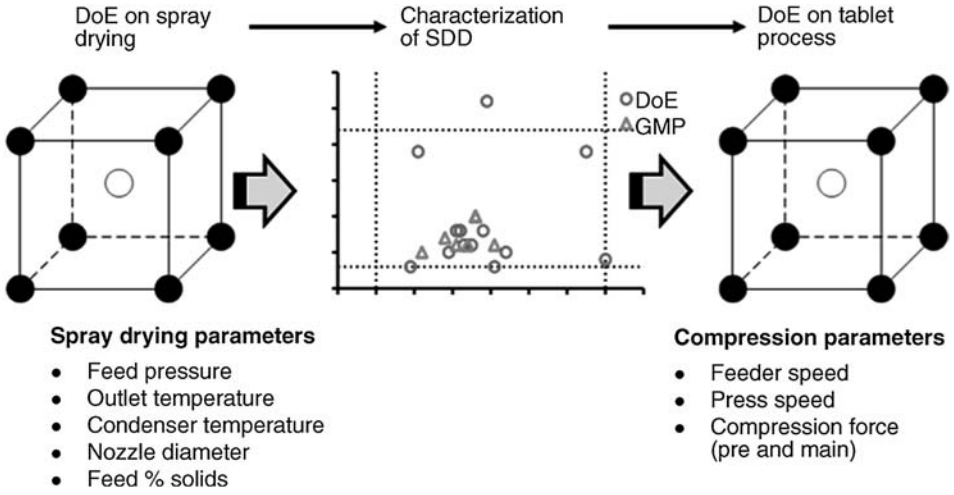

FIGURE 18.14 Interaction between outputs of spray drying and tablet compression. *Source: Reproduced with permission from Sanghvi T, Katstra J, Quinn BP, Thomas H, Hurter P. Chapter 11. Formulation development of amorphous dispersions. In Pharmaceutical amorphous solid dispersions. A. Newman, editor. Hoboken, NJ: John Wiley and Sons; 2015.*

(4.5%) during storage for 24 months at 25°C/60% RH was determined, and two packaging regimes were tested. The first, impermeable packaging, needed a maximum tablet water content of 2.4% to keep the epimer content less than 2% during a 24-month shelf life at 25°C/60% RH, and a tablet water content of 2.1% for storage at 30°C/60% RH for 12 months. Permeable packaging required a moisture vapor transmission rate (MVTR) less than 0.149 mg/day/tablet for a tablet containing 1.5% water and stored at 25°C/60% RH for 24 months and below 0.137 mg/day/tablet for storage at 30°C/60% RH for 12 months. These data showed that a maximum tablet water content of 1.5% at release and 2.5% on stability, along with the packaging having a maximum MVTR of 0.137 mg/day/tablet would give the necessary shelf life.

This case study illustrates the work needed during late development to produce a late-stage product that is suitable for market. A QbD approach was used to link spray-drying conditions, dispersion attributes, and tablet compression properties to dissolution performance. Understanding the interrelationships between all of these parameters was needed to produce a stable amorphous dispersion with acceptable properties. Once the optimal formulation was produced, additional work was performed to determine packaging that would maintain chemical stability over a 2-year shelf life.

18.9.3 Life Cycle Management

18.9.3.1 Kaletra

Kaletra is combination product containing ritonavir and liponavir, both biopharmaceutics classification system (BCS) 4 compounds, used to treat AIDS.

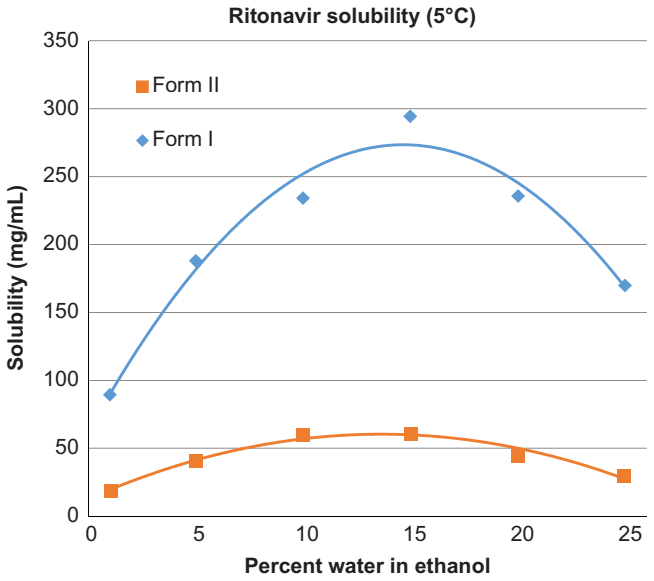

FIGURE 18.15 Ethanol:water solubility of ritanovir Forms I and II. *Source: Adapted from data in Bauer J, Spanton S, Henry R, Quick J, Dziki W, Porter W, et al. Ritonavir: an extraordinary example of conformational polymorphism.* Pharm Res *2001;18:859–66.*

Development started with ritonavir, which was discovered in 1992. It was not bioavailable from the solid state and not water soluble. The marketed product (Norvir) was available in 1996, with ritanovir dissolved in ethanol:water-based solutions to produce an oral liquid or a semisolid capsule formulation. Only one crystalline form was identified during development and in 1998, after 240 lots of capsules, a second form was identified in the capsules which was significantly less soluble in the ethanol:water system (Fig. 18.15).[97,98] The product was then reformulated with the new form.

Alternative methods to improve the solubility of ritonavir were explored, including amorphous solid dispersions.[99,100] Early studies investigated dispersions with PEG, and a significant increase in plasma concentration was observed for samples containing 10:90 ritonavir:PEG compared with crystalline material in dog studies. The 10% dispersion exhibited a 22-fold increase in AUC and a 13.7-fold increase in C_{max}. Lopinavir was a second HIV protease inhibitor under development and was found to be 10-fold more potent than ritonavir.[101] It was also found to be poorly soluble, and issues with low BA and fast elimination were observed when lopinavir was orally administered. It was found that coadministration with ritanovir dramatically improved the poor pharmacokinetic properties by preventing metabolism of liponavir. The combination of lopinavir and ritonavir produced a 77-fold increase compared with dosing with liponavir alone. Conventional solid tablet, capsule, and suspension formulations did not produce adequate plasma levels compared with soft-gel capsules,[102] and Kaletra soft-gel capsules were launched in 2000.

An amorphous solid dispersion of lopinavir and ritonvavir was investigated using melt extrusion technology, and a dispersion containing both drugs and copovidone was developed.[103–105] A number of processing parameters were investigated, such as mixing zone length (first, second, and overall), mixing zone angle, temperature, feed rate, and screw speed. Analytical results included amorphous nature, degradation products, and water content. A 200/50-mg lopinavir/ritonavir tablet formulation was developed that had a number of advantages over the soft gel formulation that was on the market. The soft gel was approved at a dose of 400/100-mg (three capsules) taken twice daily with food. Studies with the solid amorphous dispersion (200/50-mg lopinavir/ritonavir tablet formulation) resulted in more consistent lopinavir and ritonavir exposures, diminished food effect, and no refrigeration.[102] The plot for lopinavir and ritonavir BA under different fed/fasted conditions clearly showed no difference (Fig. 18.16).[106] Kaletra tablets were introduced in 2005.

This case study shows how changing the solid-state form from a crystalline material to an amorphous solid dispersion allowed development of a solid dosage form, which exhibited significant advantages over the initial soft-gel capsules. Melt extrusion was used to produce a dispersion that could be easily be formulated into a conventional tablet. A better product for patients was produced by decreasing the number of tablets, reducing food effects so it would not have to be taken with a meal, and storage at room temperature rather than refrigerated conditions.

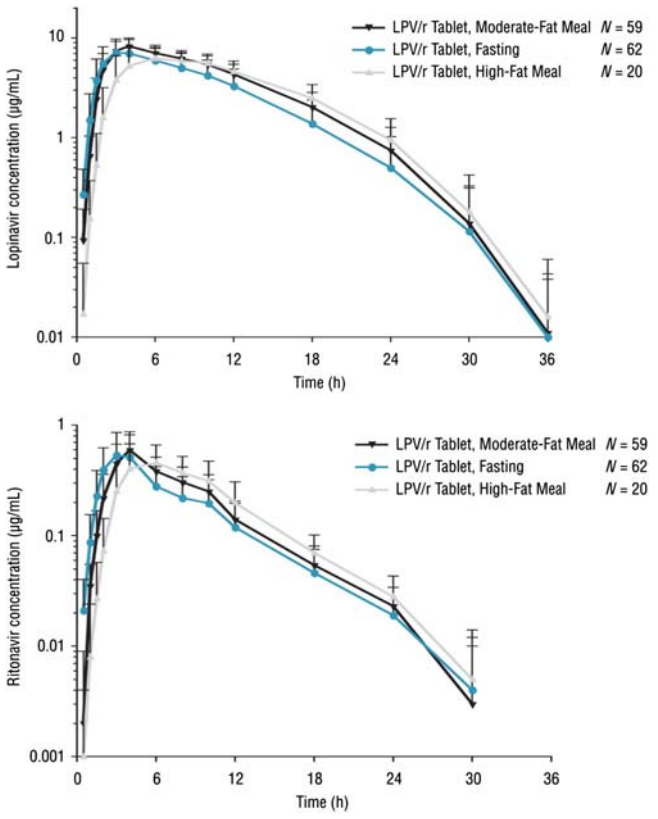

FIGURE 18.16 Plasma concentration of lopinavir (top) and ritonavir (bottom) after dosing Kaletra under different fed/fast conditions.[106]

18.10 CONCLUSIONS

Amorphous solid dispersions are one way to improve the properties of an API and they are typically used to help improve the solubility of poorly soluble compounds. They also have disadvantages, such as poor physical stability, which can result in crystallization, and poor chemical stability, which can lead to degradation. The screening and selection process needs to include knowledge of required dispersion properties as well as downstream processing to produce the formulated product. Since they are metastable forms, development of amorphous dispersions involves a greater understanding of the handling, storage, and processing conditions needed to prevent crystallization and to maintain a miscible dispersion. A number of marketed products containing amorphous solid dispersions show that this technology has been successful in developing poorly soluble compounds.

CHAPTER

19

Rational Design of Oral Modified-Release Drug Delivery Systems

Y. Qiu[1] *and P.I. Lee*[2]

[1]AbbVie Inc., North Chicago, IL, United States [2]University of Toronto, Toronto, ON, Canada

19.1 INTRODUCTION

Modified release (MR) drug delivery systems are developed to modulate the apparent absorption and/or alter the site of release of drugs to achieve specific clinical objectives that cannot be attained with the conventional immediate release (IR) dosage forms. Possible therapeutic benefits of a properly designed MR dosage form include improved efficacy and reduced adverse events, increased convenience and patient compliance, optimized clinical performance, a greater selectivity of activity, or new indications. A clinically successful MR product with enhanced medical benefits also offers commercial advantages, such as product differentiation and/or line extension, maximized drug potential and market expansion, and increased cost effectiveness.[1–3] As a result, MR product development has been an important tool of product line extension and an integral part of product life cycle management strategy.

Drug release modification is a technique or approach by which the delivery pattern of a therapeutic agent is altered via engineering of physical, chemical, and/or biological components into delivery systems for achieving desired/target plasma drug levels defined by clinical pharmacology. According to the US Food and Drug Administration (FDA), drug release characteristics of time, course and/or location of a MR system are chosen to accomplish therapeutic or convenience objectives not offered by conventional dosage forms.[4] More specifically, MR solid oral dosage forms include extended release (ER) and delayed release (DR) products. A DR dosage form releases a drug (or drugs) at a time other than immediately following oral administration. An ER dosage form is formulated to make the drug available over an extended period after ingestion, thus allowing a reduction in dosing frequency compared to a drug presented as a conventional dosage form (eg, a solution or an IR dosage form). For oral applications, the term "extended release" is usually interchangeable with "sustained release," "prolonged release," or "controlled release."

The design objective for modifying oral drug release is to alter the rate of drug input (dissolution/absorption) in the intestinal lumen to achieve a predetermined plasma profile. Common modes of oral MR delivery include (1) delayed release (eg, using an enteric coating); site-specific or timed release (eg, for colonic delivery); (2) extended release (eg, zero-order, first-order, biphasic release); and (3) programmed release (eg, pulsatile, delayed extended-release). Fig. 19.1 illustrates some examples of MR delivery profiles. Significant clinical and commercial advances have been made over the last two decades in delivering therapeutic agents via a nonmonotonic pattern at predetermined time intervals as a result of an improved understanding of the relationship between clinical pharmacology, on the one hand, and bodily physiology and biological conditions, on the other. For example, many body functions and diseases follow circadian rhythm (eg, daily fluctuations of hormones, gastric secretion and emptying, bronchial asthma, myocardial infarction, angina, rheumatic disease, ulcer, and hypertension). By timing the administration of a programmed release device, therapeutic plasma concentration can be obtained at an optimal

Developing Solid Oral Dosage Forms

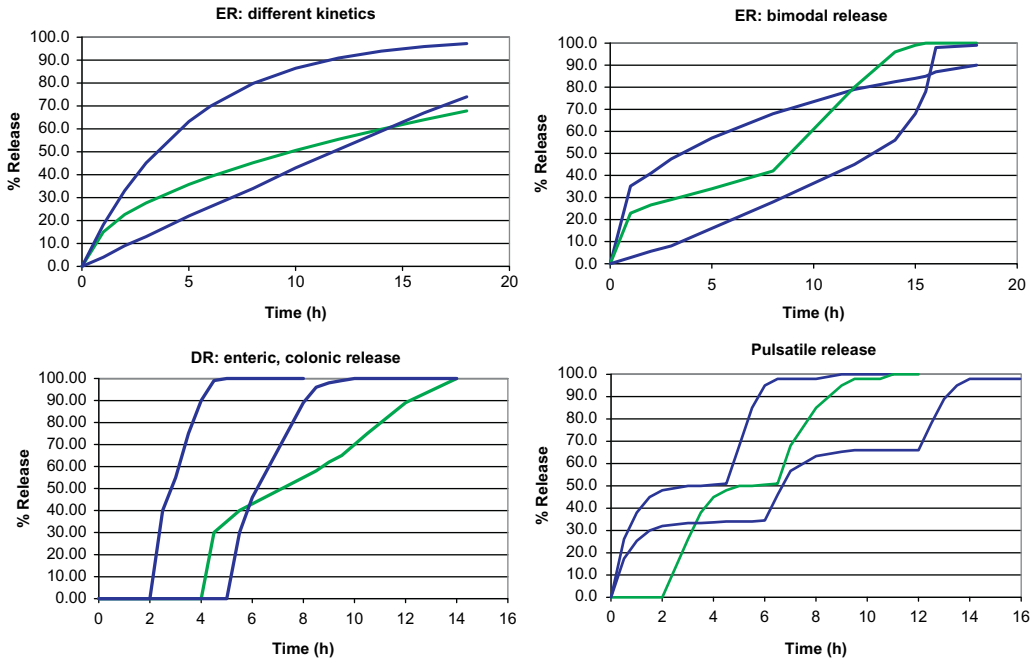

FIGURE 19.1 Examples of oral modified release profiles.

time to counter or utilizing the diurnal nature of certain diseases, such as angina, hypertension, asthmatic attacks or stiffness of arthritic patients during early morning hours, and heart attacks at night. Classic examples of utilizing MR delivery that have achieved significant clinical and commercial successes include MR products of Nifedipine, Methylphenidate, Mesalamine, Verapamil and Diltiazem, to name a few. For example, Procardia XL is a zero-order release tablet of Nifedipine that not only reduces dosing frequency from t.i.d. to once-daily but also drastically improves the efficacy-to-safety ratio. Controlling the input rate results in a gradual decrease in blood pressure without an increase in heart rate and syncope associated with t.i.d. administration. Methylphenidate is a compound indicated for attention deficit hyperactivity disorder (ADHD) without patent protection. Several new MR products of methylphenidate were introduced in the 1990s by different developers that offer clear clinical advantages over the products on the market at the time (eg, Ritalin, Ritalin SR). These products include a bimodal-extended release tablet (Concerta), a capsule (Metadate CD), and a pulsatile release capsule (Ritalin LA,). All of them were designed to produce fluctuation of blood levels over time to overcome acute tolerance associated with a constant rate of delivery, thus enabling dosing convenience of this controlled drug for school children. Asacol and Lialda are delayed release tablets designed to release mesalamine in the distal ileum and/or colon for ulcerative colitis treatment while Pentasa is an extended-release capsule that delivers the same active throughout the gastrointestinal (GI) tract. Hypertension and angina remain two of the most important risk factors for cardiovascular morbidity and mortality. MR products of cardiovascular drugs have been successfully developed to address the pharmacokinetic and circadian challenges to controlling blood pressure and angina by matching drug release to the natural circadian rhythms of the cardiovascular system; that is, chronotherapeutic drug delivery. Examples of such cardiovascular chronotherapeutics products include Adalat CC tablets that provides zero-order release followed by delayed IR of Nifedipine, as well as Covera-HS tablets and Verelan PM capsules, both of which utilize delayed extended release of verapamil. Following bedtime administration, these products provide a higher concentration of drug in the blood to protect against the early-morning increase in blood pressure and heart rate while maintaining effectual blood pressure reduction for 24 hours. Another classic example is Diltiazem hydrochloride, also a calcium antagonist for the treatment of hypertension. Three generations of dosage forms were developed with increasing clinical success and commercial competitiveness between the 1980s and 1990s. Annual revenues were approximately $260 million, $400 million, and $900 million for IR tablets (Cardizem) in 1988, twice-daily ER capsules (Cardizem SR) in 1991, and once-daily ER capsules (Cardizem CD) in 1996, respectively. Several years after patent expiry of the active ingredient, another new ER dosage form designed based on chronotherapy concept (Cardizem LA) was introduced to the market in 2003.

Many compounds are not suitable for MR delivery due to a variety of reasons, such as undesirable drug properties, large dose size, poor colonic permeability, lack of pharmacological rationale, or technical feasibility. Otherwise, solely for the purpose of convenience, one would expect very few marketed drug products with a dosing frequency of more than twice a day. Furthermore, despite many successes with developing oral MR products, as many or more failed attempts went unreported in the R&D laboratories of the pharmaceutical industry. Failures in the innovator companies can be partly attributed to the simple fact that the molecule of interest is not feasible for MR delivery. It can also be related to a lack of expertise in rational design and development of a robust MR product. For generic companies, unsuccessful attempts are mostly related to inadequate knowledge and skill in developing MR products and/or overcoming patent hurdles because the feasibility of the active has already been proven by the innovator's product. This chapter provides an overview of current MR technologies and rational approach to delivery system design. Case studies are used to illustrate how drug property and formulation influence the design and performance of oral MR delivery systems.

TABLE 19.1 Oral ER Systems Commonly Utilized in Commercial Products

	Matrix	Reservoir	Osmotic
Systems	Hydrophilic Matrix • Erosion/drug diffusion controlled • Swelling/erosion controlled Hydrophobic Matrix • Homogenous (dissolved drugs) • Heterogeneous (dispersed drugs)	Membrane Controlled Constant activity Nonconstant activity Membrane-matrix Combination	Elementary Osmotic Pump Microporous Osmotic Pump Layered Osmotic Pump (eg, Push-Pull, Push-Stick)
Common Dosage Forms	Monolithic tablet Multiparticulates (pellets orminitablets) Layered tablet Compression coated tablet	Multiparticulates (coated pellets, beads or minitablets) Monolithic tablet containing coated beads Monolithic coated tablet	Coated monolithic tablet Coated layered tablet Coated beads

19.2 ORAL MR TECHNOLOGIES AND DRUG DELIVERY SYSTEMS

Oral MR Drug delivery technology has been applied to new product development for more than 60 years. Over the past three decades, tremendous progress has been made in the advancement of theory, mathematical modeling, new rate-controlling materials, technology platforms as well as processing technologies. In particular, the emergence of high-performance polymers and aqueous based polymeric dispersion has made manufacturing of MR dosage forms more amenable to conventional means of processing. Today, oral MR technology has become more widely utilized for the in-house development of new products at both innovator and generic companies.

19.2.1 Common oral extended-release systems

Various physical and chemical approaches have been successfully applied to produce well-characterized delivery systems that extend drug release into the GI tract within the specifications of the desired release profile. Today, most proprietary and nonproprietary ER technologies are based on polymeric systems. The fundamental design principles, theoretical considerations and applications of these systems have been extensively addressed and reviewed.[1,5–8] A survey of commercial ER oral solid products indicates that most systems fall into one of three broad categories: matrix, reservoir (or membrane controlled) and osmotic systems (see Table 19.1). Drug release from these ER delivery systems generally involves one or a combination of the following mechanisms: drug diffusion (through pores of a barrier, through tortuous channels, through a viscous gel layer or through the interstitial space between polymer chains), system swelling (followed by diffusion and/or erosion and dissolution), or osmotic pressure-induced release (osmotic pressure buildup forced drug solution, suspension or wetted mass flowing out of the system). Each type of system has its advantages and shortcomings with respect to the performance, applicability, manufacture, control, development time and cost, among others.

19.2.1.1 Matrix systems

In a matrix system, the drug substance is homogeneously mixed with the rate-controlling material(s) and other inactive ingredients to form a monolithic crystalline, amorphous, or in rare cases, molecular dispersion matrix. Drug release occurs by drug

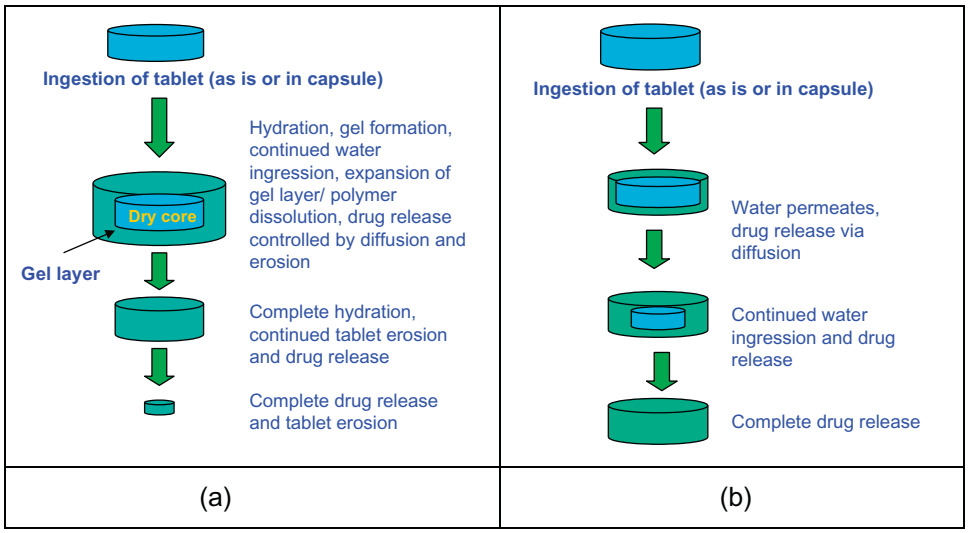

FIGURE 19.2 (a) Hydrophilic and (b) hydrophobic matrix systems and corresponding drug release process.

diffusion from and/or erosion of the matrix system. Based on the characteristics of the rate-controlling material, the matrix system can be divided into (a) hydrophilic and (b) hydrophobic systems, as shown in Fig. 19.2. For practical purposes, the former refers to a matrix system in which the rate-controlling materials are water-soluble and/or swellable, while the latter consists of a water-insoluble inert matrix with minimum swelling (ie, rigid matrix). Matrix systems consisting of a mixture of hydrophilic and hydrophobic rate-controlling materials belong to one or the other of the two systems depending on the dominant mechanism of drug release control. For instance, a matrix containing both types of polymers can be considered a hydrophilic matrix if the release control function and release kinetics (mechanism) remain essentially unchanged when the insoluble hydrophobic polymer is substituted with a conventional insoluble excipient (eg, dicalcium phosphate) that does not possess a rate-controlling property. However, at a high percentage, a nonswelling insoluble excipient may disrupt or destroy the ER properties of the matrix due to nonuniformity in the gel layer. The same holds true for a hydrophobic system if the hydrophilic polymer is substituted with a soluble excipient (eg, lactose). Additionally, the manufacturing method can also influence the primary release-control mechanism because the internal structure of a matrix can differ depending on whether the insoluble rate-controlling polymer(s) undergo solid phase transition (eg, dissolving, melting) during processing.

The matrix system has been most widely utilized to provide extended delivery of drug substances because of its effectiveness and capability of accommodating both low and high loading of drugs having a wide range of physical and chemical properties. From a product development point of view, it is cost-effective and easy to scale-up and manufacture. Additionally, this type of system is also suitable for in-house development since it is usually manufactured using conventional processes and equipment. However, the release characteristics of a matrix (eg, kinetics and pH-dependency) are usually determined by the properties of the drug substance and the rate-controlling polymer. To alter release profiles or to achieve unique release patterns (eg, biphasic or delayed ER), a more complex design and process, such as a layered or compression coated tablet or layered beads, would sometimes be required. Furthermore, a matrix system may lack flexibility in offering multiple strengths that are usually required for Phase 1–3 clinical studies in developing a new chemical entity because compositionally proportional dosage forms of different strengths may not provide the same proportional release rate in vitro and/or in vivo.[9] Thus, additional resources and development time are often required for new dosage strengths except for low dose drugs (eg, drug loading <5%).

19.2.1.1.1 Hydrophobic matrix systems

The hydrophobic matrix system was the earliest oral extended release platform for medicinal use. In fact, its prototypes can be traced back to the 2nd century BC and the 4th century AD, respectively, when animal fats and wax pills were used to prolong the medicinal effects of Chinese medicines.[10,11] For example, medical practitioners were instructed to "use wax pills for their resistance to dissolve thereby achieving the effect gradually and slowly."[12,13] In modern medicine, the matrix

technology has been successfully applied to commercial products for many decades. For example, Premarin tablets, one of the classic examples, has been on the market since 1942. In a hydrophobic inert matrix system, the drug is uniformly dissolved or dispersed throughout a matrix that involves an essentially negligible increase of the device surface area or change in dimension. For a homogeneous monolithic planar matrix system containing dispersed drug, the release behavior can be described by the Higuchi equation, which is a remarkably simple expression derived without solving the complex governing differential equations[14]:

$$M_t = [DC_s(2A - C_s)t]^{1/2} \tag{19.1}$$

M_t is the drug released per unit area at time t, A is the drug loading per unit volume, C_s is drug solubility, and D is the diffusion coefficient in the matrix phase. Eq. (19.1) was derived based on the assumptions that: (1) the initial drug loading in the matrix is greater than the drug solubility; (2) a pseudo-steady state exists (equivalent to the assumption of a linear drug concentration profile in the matrix); (3) the drug dissolution rate at the dispersed drug front is rapid; (4) a semiinfinite geometry applies and the area of the matrix is large that the edge effect can be neglected; (5) the diffusion coefficient is constant; (6) perfect sink conditions exist in the external media; (7) the distance between suspended drug particles is much smaller than the matrix thickness; and (8) no swelling or erosion but only the diffusion process occurs. In the case of $A \gg C_s$, Eq. (19.1) reduces to:

$$M_t = [2DAC_s t]^{1/2} \tag{19.2}$$

Thus, the amount of drug released is proportional to the square root of time, A, D, and C_s. Higuchi also extended this pseudo-steady state analysis to the release of suspended drug from a spherical matrix system.[15]

Drug release from a porous monolithic matrix system involves the simultaneous penetration of surrounding liquid, dissolution of the drug, and leaching out of the drug through interstitial channels or pores. The volume and length of the openings in the matrix must be accounted for in the diffusion equation, leading to a second form of the planar Higuchi equation[15]:

$$M_t = \left[\varepsilon C_s(2A - \varepsilon C_s)\frac{Da}{\tau}t\right]^{1/2} \tag{19.3}$$

where ε and τ are the porosity and tortuosity of the matrix, respectively, and D_a is the drug diffusion coefficient in the release medium. Tortuosity is introduced to account for an increase in diffusion path length due to branching and bending of the pores. Similarly, Eq. (19.9) can be derived based on pseudo-steady-state approximation ($A \gg C_s$):

$$M_t = \left[2D_a AC_s\frac{\varepsilon}{\tau}t\right]^{1/2} \tag{19.4}$$

The porosity, ε, in Eqs. (19.3) and (19.4), is the fraction of matrix that exists as pores or channels into which the surrounding liquid can ingress. It is the total porosity of the matrix after the drug has been extracted. The total porosity consists of the initial porosity, ε_a, due to air, or void space in the matrix before the leaching process begins, and the porosity created by extracting the drug, ε_d, and the water soluble excipients, ε_{ex}[16,17]:

$$\varepsilon = \varepsilon_a + \varepsilon_d + \varepsilon_{ex} = \varepsilon_a + \frac{A}{\rho} + \frac{A_{ex}}{\rho_{ex}} \tag{19.5}$$

ρ is the drug density, and ρ_{ex} and A_{ex} are the density and the concentration of water soluble excipient, respectively. When no water-soluble excipient is present in the matrix and initial porosity, ε_a, is smaller than the porosity, ε_d, Eq. (19.5) becomes:

$$\varepsilon \cong \varepsilon_d = \frac{A}{\rho} \tag{19.6}$$

Hence, Eq. (19.3) and (19.4) yield:

$$M_t = A\left[\left(2 - \frac{C_s}{\rho}\right)\frac{D_a C_s}{\tau\rho}t\right]^{1/2} \tag{19.7}$$

$$M_t = A\left[\frac{2D_a C_s}{\tau\rho}t\right]^{1/2} \tag{19.8}$$

Similar to Eqs. (19.1) and (19.2), a square-root-of-time release profile is expected with a porous monolith. In contrast to the homogeneous matrix system, the release from such system is proportional to drug loading, A.

It should be noted that (1) the Higuchi equation was originally derived for planar diffusion into a perfect sink; (2) the square-root-of-time relationship only fits data up to approximately 2/3 of the total release; and (3) the Higuchi equation is strictly valid only when the drug loading is in great excess of the drug solubility; that is, $A \gg C_s$. In fact, it can be shown that, at the limit of $A \to C_s$ which often occurs with drugs of high aqueous solubility, the Higuchi equation tends to fail giving an error of 11.38% as compared to the exact solution due to the failure of the pseudo-steady state assumption at this limit.[18] To provide a more practical and accurate equation that applies to all A/C_s values, Lee presented an approximate analytical solution to this moving boundary problem without making the

pseudo-steady state assumption which has been shown to be uniformly valid for all A/C_s values:[18,19]

$$M_t = \frac{1+H}{\sqrt{3H}}\left[C_s\sqrt{D\,t}\right] \tag{19.9}$$

where

$$H = 5\left(\frac{A}{C_s}\right) - 4 + \sqrt{\left(\frac{A}{C_s}\right)^2 - 1} \tag{19.10}$$

Similar to the Higuchi equation, Eq. (19.9) also predicts a square root of time dependence for the amount of drug release per unit area but with a different dependence on A and C_s (compare with Eqs. 19.1 and 19.2). As shown by Lee, when Eq. (19.9) is applied to the analysis of drug release from planar matrix systems, the deviations from the exact results are consistently one order of magnitude smaller than that of the Higuchi equation, particularly in the case of low A/C_s values or drug loading approaching the drug solubility ($A \rightarrow C_s$). Lee also provided an approximate analytical solution to the release of suspended drug from a spherical matrix system without making the pseudo-steady state assumption.[19] To extend to porous monolithic matrix systems, one can incorporate similar approaches of Eqs. (19.3)–(19.8) and modify the working equations (eg, Eq. 19.9) accordingly, as done by Foster and Parrott.[20] It should be emphasized that an initial deviation (or a delay) from the square root of time dependence may arise due to (1) the existence of a diffusion boundary layer at the matrix surface due to insufficient mixing; (2) the drug dissolution rate at the dispersed drug front becomes slow and rate limiting especially for low solubility drugs; (3) some limited swelling of the matrix occurs; or (4) a combination of the above.[18]

A simple semiempirical exponential relation was introduced by Ritger and Peppas in 1987 to describe the general release behavior from hydrophobic non-swellable matrices in the form of slabs, spheres, and cylinders.[21]

$$Q = \frac{M_t}{M_\infty} = kt^n \tag{19.11}$$

Q is the fractional release, M_t is the drug released per unit area at time t, M_∞ is the total drug release per unit area, k is a constant, and n is the diffusional exponent. In the case of pure Fickian diffusional release, the exponent n has a limiting value of 0.50 for thin slabs, 0.45 (range of 0.43–0.50 depending on the aspect ratio) for cylindrical samples, and 0.43 for spherical samples. For $n = 1$, zero-order drug release exists and for $1 > n > 0.5$, non-Fickian diffusion behavior is observed. In the 1990s, Wu and Zhou analyzed the same mathematical problem of dispersed drug release from matrix systems using the finite element method and showed the dependence of release kinetics on the initial solute loading, the external volume, and the boundary-layer thickness. Their models involved a moving boundary problem (or Stefan-type problem) and were solved numerically to describe the entire process of diffusional release for slabs, spheres, and cylinders without the need to make any pseudo steady-state assumption.[22–25] More recently, Yonezawa et al. published a model that can be used to describe the entire release process of a heterogeneous hydrophobic matrix system made from physical mixture of wax, soluble excipients, and the actives by compensating the deviation from the pseudo-steady-state approximation ($A \gg C_s$) at the later portion of the release profiles.[26–28] In general, hydrophobic matrix systems are not suitable for insoluble drugs because the concentration gradient is too low to allow complete drug release within a reasonable time frame; that is, GI transit time.

19.2.1.1.2 Hydrophilic matrix systems

Hydrophilic matrix systems are utilized in over 75% of the extended release products on the market today[29] because they are applicable across a broad range of oral products containing high and low loading of drugs with low, medium, or high solubility, and can be manufactured using conventional equipment and processing methods. Hydrophilic matrix systems are polymer based drug delivery systems designed to control the rate of drug release during the passage of the matrix through the GI tract.[30] During GI transit, the matrices are reduced in size through surface erosion and dissolution, which reduces the probability of expulsion of an exhausted "ghost" tablets usually seen with osmotic pump, hydrophobic matrices or reservoir system. Drug release from hydrophilic matrices involves two competing mechanisms: Fickian diffusional release and matrix erosional release. The primary rate-controlling materials are polymers that hydrate and swell rapidly in an aqueous medium and form a gel layer on the surface of the system. Diffusion across the viscous gel layer is not the only drug release pathway as the erosion of the matrix following polymer swelling also contributes to the overall release. The relative contribution of each component to total release is primarily dependent upon the properties of a given drug and matrix composition. For instance, the release of a sparingly soluble drug from hydrophilic matrices involves the simultaneous ingression of water and desorption of drug via a swelling-controlled diffusion mechanism. As water penetrates into a glassy matrix and lowers the polymer glass transition temperature, the polymer swells, forms a gel layer, slowly disentangles and eventually dissolves, releasing the undissolved drug. At the same time, the dissolved drug diffuses

through this swollen gel region into the external releasing medium. This type of diffusion with concurrent swelling and erosion generally does not follow a Fickian diffusion mechanism. The continuously changing variables that affect drug release (eg, diffusion pathlength, polymer swelling, viscosity, system dimension) make obtaining a precise mechanistic equation or model describing the release profile impossible. Over the past three decades, various models have been explored and developed toward fundamental understanding of drug release from hydrophilic matrices.[6,7,19,31–37] Among them, a semiempirical exponent equation that had its root in early studies of penetrant transport in homogeneous glassy polymers,[38] but was reintroduced in the pharmaceutical literature in the mid-1980s, has been widely used to describe drug release behavior from heterogeneous hydrophilic matrix tablet systems which has the same form as Eq. (19.11)[39,40]:

$$Q = \frac{M_t}{M_\infty} = kt^n \tag{19.11a}$$

where Q is the fraction of drug released in time t, M_t is the drug released per unit area at time t, M_∞ is the total drug release per unit area, k is the rate constant specific to the characteristics of the macromolecular network system and the drug, and n is the diffusional exponent.

This equation has been widely used in this field.[41–44] It has been shown that the value of n is indicative of the drug release mechanism. For $n = 0.5$, drug release follows a Fickian diffusion mechanism which is driven by a chemical potential gradient. For $n = 1$, drug release occurs via relaxational transport, which is controlled by the swelling phase-transition and erosion in hydrated polymers. For $1 > n > 0.5$, non-Fickian diffusion behavior is often observed as a result of contributions from both diffusion and polymer erosion. This is also termed "anomalous" release. Unfortunately, over the years, Eq. (19.11) has been misused, misinterpreted or misunderstood by many in the pharmaceutical field attempting to assign a controlling mechanism based on fitting the release data to this equation to identify an exponent, without gaining any insight into the underlying physical processes and controlling events of the systems involved.

To describe the polymer dissolution process in swellable polymers, Lee and Peppas were the first to investigate this phenomenon in the field of controlled release and, through the incorporation of a pseudo-steady state assumption; they showed that at the beginning of the dissolution process the gel layer thickness increases as a square root of time.[35,45] Lee and Peppas further extended this dissolution model to arrive at an equation of the following form describing the drug release from a polymer matrix undergoing dissolution[46]:

$$Q = k_1 t^{0.5} + k_2 t \tag{19.12}$$

where the first and second terms represents drug release due to diffusion and polymer erosion, respectively, and k_1 and k_2 are constants reflecting the relative contributions of these two processes which are functions of the polymer and drug volume fractions at the gel/drug core and gel/solution interfaces as well as the drug and solvent diffusion coefficients. This model has been adopted successfully for predicting drug release from pharmaceutical tablets during swelling and dissolution.[47,48]

A more general equation describing systems of different geometries with both diffusional and relaxational contributions to release was proposed by Peppas and Sahlin, who derived the following equation by introducing a second term into Eq. (19.11)[42]:

$$Q = k_1 t^n + k_2 t^{2n} \tag{19.13}$$

In the case of a flat geometry where surface area is fixed, the value of n would be equal to 0.5, resulting in Eq. (19.12).

Since the early 1990s, additional models have been investigated in an attempt to enhance the understanding of the matrix delivery systems.[49–52] One of the examples is the so-called "Spaghetti" model proposed to gain insight into the complex release process from hydrophilic matrix systems. This model treats polymer erosion as diffusion of polymer across an unstirred "diffusion layer" adjacent to the polymer gel layer. Thus, two competitive diffusional processes contribute to overall drug release; that is, diffusion of drug through the gel layer and diffusion of polymer across the diffusion layer. In addition to the solubility of the drug molecules that defines the diffusion component, polymer disentanglement concentration ($C_{p,dis}$) defined in Eq. (19.14) is used to gauges the contribution of polymer diffusion/dissolution for hydroxypropyl methylcellulose (HPMC)[53]:

$$(C_{p,dis})_{eq} = 0.05\left(\frac{MW_p X_p}{96000}\right)^{-0.8} \tag{19.14}$$

$$M_p \approx kt^1 \tag{19.15}$$

MW_p and X_p denote the molecular weight and weight fraction of polymer in the matrix, respectively, and M_p is polymer release at time t. Interestingly, the release profile of polymer (Eq. 19.15) resembles that for an erosion-controlled system of Eq. (19.11a). It should be noted that $C_{p,dis}$ is an intrinsic property of the polymer while $(C_{p,dis})_{eq}$ is an "equivalent" $C_{p,dis}$ of

polymer in a matrix. One may consider $C_{p,dis}$ as the equivalent "solubility" of polymer, as it defines the concentration at which a polymer detaches from a pure polymer system. Conceptually, the relative contribution of both mechanisms can be characterized by the solubility ratio of the drug, C_s to $(C_{p,dis})_{eq}$:

$$\text{If } \frac{C_s}{(C_{p,dis})_{eq}} >> 1, \quad \text{then } Q_t = kt^{0.5}$$

(Release is controlled by drug diffusion)

$$\text{If } \frac{C_s}{(C_{p,dis})_{eq}} << 1, \quad \text{then } Q_t = kt^{1}$$

(Release is controlled by polymer erosion)

Thus, drug release profiles from a hydrophilic matrix vary significantly with formulation design and solubility of the drug. For insoluble compounds, the zero-order release is readily attainable as C_s values are lower than $(C_{p,dis})_{eq}$. For soluble drugs, release kinetics typically follows the square-root-of-time relationship. To achieve zero-order release, one would need to increase $(C_{p,dis})_{eq}$ in the matrix to lower the ratio of C_s to $(C_{p,dis})_{eq}$, for example, by using polymers of low MW_p or decreasing X_p according to Eq. (19.4). However, the practical feasibility of this approach is dependent on the ratio, limited choice of polymer, and the minimum MW_p and/or X_p that is often required to form a robust matrix for extended release.

The drug release from hydrophilic polymer matrix systems involves (1) diffusion of dissolved drug through the gel layer; and (2) release of dissolved drug or drug particles through matrix erosion or dissolution of the polymer gel layer. As the aqueous medium penetrates a hydrophilic matrix tablet, the initial rate of hydration of the hydrophilic polymer such as HPMC would be rapid which immediately forms a gel layer around the matrix tablet and eliminates any pre-existing pores near the tablet surface. Additional uptake of the aqueous medium into the matrix system takes place by diffusion through the gel layer. Thus, the drug release from such hydrophilic matrix tablet occurs via diffusion through this expanding gel layer and is typically represented by a square root of time dependence in the cumulative drug release with some early deviations from linearity (or delays) due to the initial matrix hydration and swelling. The thickness of this swelling gel layer increases with time initially until the outer gel surface reaches a critical disentanglement concentration and erodes. Once this occurs, the drug release typically shows a positive deviation from linearity in the square root of time plot due to the contribution from polymer erosion.[33,39] Very often, the gel layer development may reach a steady state (or a constant gel thickness) as a result of synchronization of the moving solvent and erosion fronts; the gel thickness eventually decreases as the dry core disappears and the gel layer gradually depletes due to polymer dissolution as depicted in Fig. 19.3.[19,54]

Although the drug release profiles from hydrophilic matrix systems have often been associated with two limiting mechanisms as described above including purely diffusion controlled for soluble drugs (square-root-of-time kinetics) and purely polymer erosion controlled for insoluble drugs (zero-order release), this distinction appears to be overly simplified. First of all, for poorly soluble drugs where the drug dissolution rate is slower than the polymer erosion rate, it is reasonable that the polymer erosion rate will dictate the release of the drug particles, and the released drug particles will undergo further dissolution. On the other hand, while it is true that reasonably soluble drugs will be released mostly by diffusion across the gel layer because the low drug concentration at the eroding gel surface contributes very little to the total drug release, the polymer erosion process, however, does affect the gel thickness (the faster the polymer erosion, the smaller the gel layer thickness) and thereby directly influencing the diffusional path length for the release of the dissolved drug. As described by Eq. (19.14), higher molecular weight polymers have lower disentanglement concentrations while lower molecular weight polymers have higher disentanglement concentrations. In this case, reducing the molecular weight of the polymer makes the matrix erode faster (and the gel layer thinner) because of the increase of the disentanglement concentration.

As mentioned above the development of the gel layer thickness and the resulting drug release due to diffusion and polymer erosion was first investigated by Lee and Peppas[35,45,46] employing a pseudo-steady state assumption, however, it is important to note that their final working equations are only useful in dealing with systems containing dissolved drug since the

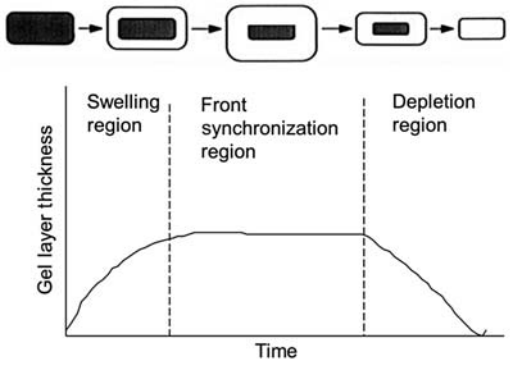

FIGURE 19.3 Dynamic gel thickness development in a hydrophilic matrix tablet.

dispersed drug situation was not analyzed. On the other hand, the problem of dispersed drug release from such a hydrophilic polymer matrix system is similar to the problem of dispersed drug release from an erodible polymer matrix investigated by Lee[19] without making the pseudo-steady state assumption. Although Lee's work does not explicitly deal with the initial swelling phase, the moving boundary problem investigated does include the release of dispersed drug due to both drug diffusion and polymer erosion, identical to the physical situation of the present hydrophilic polymer matrix system beyond the initial swelling phase. Therefore, Lee's approximate analytical solutions provide a reasonable physical picture of dispersed drug release from such a hydrophilic matrix system, in particular, they describe how the drug release is affected by the dispersed drug loading, drug solubility, polymer erosion rate constant, and drug diffusion coefficient.

More specifically, Lee's mathematical analysis[19] considers the competition between the diffusion and erosion processes in a matrix involving two moving boundaries as a function of two key parameters: drug loading to solubility ratio (A/C_s) and the relative magnitude of erosion versus diffusion (Ba/D), where a is the half thickness of the planar matrix, and B is the surface erosion rate constant. For the gel layer thickness development in a dispersed polymer matrix with $A/C_s = 5$, it can be shown in Fig. 19.4 that Lee's results predict that the faster the polymer erosion relative to diffusion (eg, $Ba/D = 10$ as compared with $Ba/D = 1$), the sooner it reaches a constant gel thickness due to front synchronization and the smaller the resulting gel thickness.

As to the effect of drug loading on the resulting drug release kinetics, Lee's results show that at a fixed relative polymer erosion to diffusion (eg, $Ba/D = 1$) the erosion characteristics (linear release region) becomes more dominant as the drug loading to solubility ratio (A/C_s) increases, whereas the early portion of the release profile remains dominated by the diffusion mechanism as illustrated in Fig. 19.5.

With respect to the effect of polymer erosion rate on drug release, Lee's results further illustrate that when the drug loading is much higher than the drug solubility (eg, $A/C_s = 5$), the polymer erosion characteristics dominate the drug release profile with increasing Ba/D as shown in Fig. 19.6. As expected, the erosion effect diminishes as the drug loading is at or below the drug solubility (ie, $A/C_s = 1$) (results not shown).

From Figs. 19.5 and 19.6, it is clear how the interplay of these parameters: drug loading to solubility ratio (A/C_s) and the relative magnitude of erosion versus diffusion (Ba/D) would affect the resulting drug release profiles. These are useful practical and

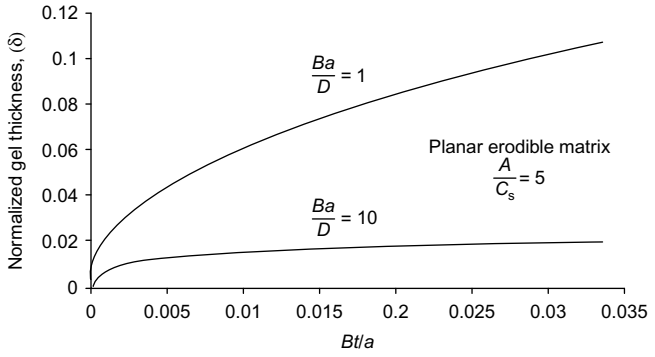

FIGURE 19.4 Effect of the magnitude of polymer erosion relative to diffusion on the gel thickness development in a dispersed erodible matrix system at $A/C_s = 5$.

phenomenological parameters which can be directly related to intrinsic variables such as the polymer disentanglement concentration, polymer *MW*, among others. as described in this chapter. It should be noted that although these results were obtained originally for the planar erodible matrix, the predicted general trends apply equally well to matrix tablets based on hydrophilic swellable and erodible polymers. More complex models describing the drug release from swellable and erodible matrix tablets (eg, HPMC-based) including the geometry effect have been investigated,[55] however those normally require numerical solutions every time a parameter is changed and therefore, is more cumbersome to use than approximate analytical solutions described above.

19.2.1.1.3 Modulation of drug release profile

Historically, constant-rate delivery has been one of the primary target profiles of extended-release systems for maximized coverage and minimized fluctuation in plasma concentrations, especially for drugs with a narrow therapeutic index. In a diffusion-controlled matrix system, the active agent has a progressively longer distance to travel and smaller releasing surface as the diffusion front moves inwardly, resulting in decreasing release rate over time; that is, nonlinear release characteristics. For hydrophilic matrices, the extent of drug release deviation from zero-order kinetics depends on the ratio of C_s to $(C_{p,dis})_{eq}$and A/Cs. Drugs with relatively high C_s typically exhibit a diffusion-controlled release profile. To overcome the inherently nonzero-order kinetics due to decreasing surface area and increasing diffusional path length associated with the diffusion-controlled matrix systems, considerable efforts have been and continue to be expended in modifying the delivery system. Over the past several decades, many creative designs have been reported that effectively alter the inherent nonlinear release behavior.[56–69] For example, nonuniform drug loading was used to offset the decrease in release rate by increasing the diffusional driving force over time. Geometry factors including cone shape, biconcave, donut shape, hemisphere with cavity, core-in-cup, among others, were utilized to compensate the decreasing release rate by increasing drug release surface over time. Control of matrix erosion, surface area and swelling, and matrix-membrane combinations have also been shown to be effective in providing zero-order or near zero-order release kinetics. However, many of these designs are more difficult to manufacture or impractical for commercialization.

With the growing need for optimizing clinical therapy and improved understanding of the pharmacokinetics-pharmacodynamics (PK-PD) relationship, additional delivery profiles other than zero-order kinetics are often desired, such as the profiles illustrated in Fig. 19.1. These targeted extended delivery patterns vary with drugs depending on their respective clinical pharmacology. To produce matrix systems having some of these unique drug release patterns or to overcome the inherent limitations such as pH-dependency of drug release, modifications to both hydrophilic and hydrophobic matrices have been investigated. Many of them have been successfully applied to commercial products. Among them are functionally coated matrix, layered tablet, compression coating, combined use of multiple polymers, functional excipients or geometry. For example, TIMERx and Geminex (bilayer) matrix systems utilize the synergistic interaction of xantham gum and locus bean gum in an aqueous environment to form a strong gel with a slowly-eroding core. Matrix systems containing both hydrophilic and hydrophobic rate-controlling materials also offer certain advantages.[70] Below are examples in specific areas in which significant progress has been made over the years in improving matrix delivery system. Many of the functional enhancements are achieved via utilization of interactions between polymer and drug, polymer and polymer, drug and excipients or polymer-excipients.

19.2.1.1.3.1 pH-independent drug release The rate of drug release of weakly basic or acidic drugs from matrix or reservoir systems usually differs with the environmental pH change due to the pH-dependent solubility (driving force) of the drugs and/or rate-controlling polymers. In principle, pH-independent release is desirable for a more consistent in vivo delivery because pH values in the GI tract vary with location and food intake. To achieve pH-independent drug release, pH modifying excipients are commonly incorporated in the formulation to provide constant local pH inside a dosage form.[71–75] However, the effectiveness of this approach is highly dependent on the quantity and properties of both API and the pH-modifiers, including pK_a, solubility, and molecular weight. For example, to ensure effectiveness and adequate duration of pH modulation for a weak base, an organic acid with lower pK_a and solubility is preferred because it provides increased acidity and longer residence time due to slower release. Use of highly soluble pH-modifiers can be less effective since these small molecules often leach out of the matrix system at a faster rate than that of the active, resulting in only transitory pH modification of the gel layer.[63] An example of such scenario would include an attempt to use a very soluble acid in an erosion-controlled hydrophilic matrix system or in a reservoir system requiring prolonged in vivo delivery (eg, 8–20 hours). Additionally, high concentration of the exceedingly soluble acid, such as citric or tartaric acid, in the matrix can create high local

osmotic pressure and/or ionic strength that would enhance initial water penetration, alter properties of the rate-controlling polymer, interfere with barrier properties of the gel layer and result in a change in hydration/gelling behaviors, release mechanism or overall drug release.[76–78] Some of the mechanisms involved include lowering of sol-gel transition temperature of the polymer, the suppression of water-polymer interaction that reduces polymer particle swelling and gel layer coalescence, hence disrupting the establishment of the diffusion barrier properties of the gel layer, and an increased water penetration. There was also some evidence for an increased gel layer fragility and susceptibility to erosion.[76] Furthermore, other properties of the pH-modifier that may influence processing and stability should also be taken into consideration. For instance, compression and blending of the matrix tablets may be affected by the bulk and compaction properties of the pH-modifier when a relatively high percentage is incorporated in the formulation. A significant change of dissolution on storage can occur as a result of gradually altered polymer properties including degradation, hydration/gelling behavior due to long-term exposure to acidic and/or highly osmotic and ionic microenvironment created by high hygroscopicity of the pH-modifier. For example, the viscosity of HPMC solution is known to be stable within pH of 3–11 but tends to decrease on storage under acidic or alkaline conditions.[79] Certain soluble acids, such as citric acid, can create an acidic environment with pH ≤ 2 at a concentration $\geq 2\%$, compromising HPMC performance. Wells et al. reported a drastic increase in dissolution rate of the original Wellbutrin SR tablets containing HPMC and cysteine hydrochloride, an acidic additive, at storage condition of 25°C/65%RH, resulting in significant reduction of product shelf-life to 9 months.[32,80] Through investigation, it was found that the accelerated dissolution could be primarily attributed to the slow acid hydrolysis of HPMC on storage. The problem was later resolved through product reformulation by increasing HPMC content to slow the initial dissolution and increase the ratio of HPMC to acidic additive.

To reduce or minimize the impact of these potential performances and processing issues, ionic polymers such as alginate, anionic polymers containing methacrylic acid or phthalate functional groups, cationic polymers with dimethylamino ethyl methacrylate, among others, in a matrix system have also been used and shown effective in maintaining a constant local pH environment.[74,81–83] Howard et al. and Zhang et al. showed the pH-independent zero-order release of a soluble basic drug (Verapamil HCL) using alginate/HPMC[84] and Alginate/HPMC/enteric polymer,[85] respectively. Rao et al. investigated combined HPMC/cationic polymer for pH-independent release of acidic molecules.[86] The advantages of using polymer as pH-modifiers include long residence time in the matrix, generally favorable processing characteristics, avoidance of extremely acidic, basic or highly osmotic and ionic microenvironment and contribution to the release rate control by certain polymers (eg, alginate). One possible limitation of using anionic polymers as pH modifiers includes its relatively higher pK_a (4–5). Depending on the pK_a, pH-solubility profiles and required dose/drug loading of the individual API, the effectiveness of polymeric pH-modifiers may be limited for certain formulations that require stronger buffering capacity. Lastly, it is important to understand whether a selected pH-modifier may interact with either the drug molecules or rate-controlling polymers. Such interactions may result in a undesired outcome in product performance and/or processing, such as compression, slow drug release or disruption of gel structure.[74,87] In some cases, excipient-polymer interactions may be utilized to adjust drug release behaviors for reduced sensitivity to environmental variations. For example, a so-called self-correcting hydrophilic matrix having strong gels was reported to be less sensitive to both pH and stirring condition.[88,89] This self-correcting system was based on the incorporation of a high concentration of electrolytes. However, its potential advantages over a conventional matrix system in vivo remain to be confirmed, and long-term stability information is unavailable in the public domain.

In summary, the use of buffering excipients in formulating pH-independent ER systems increases the complexity that can have consequences. Besides assessing drug release performance, the influence of the pH-modifier on the formulation, the API and processing need to be understood when designing such dosage forms.

19.2.1.1.3.2 Solubility enhancement Developing ER formulations of a poorly soluble drug can sometimes be challenging. Conceptually, certain insoluble drugs may exhibit a "natural" ER behavior when a right balance between particle size distribution and intrinsic dissolution rate is achieved such that the slow particle dissolution in vivo takes place within the drug particle's transit time through the absorption window in the GI tract. However, using formulation technology to control the release rate is more desirable for ensuring delivery control, consistency, and completion within GI residence time. Thus, incorporating more soluble or faster dissolving form of API in a matrix system is sometimes required for this purpose as well as for maximizing absorption of the drug released in the lower bowl where a limited amount of water is available for dissolution. Increased solubility and/or dissolution rate can be obtained through use of the

amorphous drug, a soluble salt, a complex or API nanoparticles. Rao et al. showed that both enhanced and pH-independent release of insoluble drugs were achieved using cyclodextrin as a complexation agent in an HPMC-based matrix.[86] Because of the slow eroding nature of the matrix system, complexation can take place in situ. Thus, it does not require a prior formation of the complex using a solution-mediated process. Tanaka et al. reported an eroding hydrophobic matrix system containing an amorphous solid dispersion of nilvadipine with HPMC.[90] Supersaturation was achieved without any recrystallization during dissolution, likely a result of crystallization inhibition by HPMC. In addition to that, the release rate was found to be independent of pH and agitation.

19.2.1.1.3.3 Modification of release kinetics One of the limitations in controlling the release rate of soluble drugs using a hydrophobic or hydrophilic matrix system is the inherently nonlinear release kinetics. In addition to the use of unique geometry or nonuniform drug loading mentioned above, commercially viable designs have been utilized to achieve zero-order drug release. For instance, multilayered matrix systems were shown to be effective through control of swelling and surface[91]. Hydrophobic matrices were press-coated with hydrophilic and/or hydrophobic barrier layer(s) to provide delayed drug release from the barrier surface to compensate for the decreasing release rate over time.[92] The same type of design can also be used to control effectively the release rate of highly soluble drugs that are difficult to slow down using monolithic hydrophilic or hydrophobic matrices.[93] Successful use of synergies of polymers for release control of soluble compounds was proven in vitro and in vivo with the TIMERx delivery matrix system. In studying a polymer complex between methylcellulose (MC) and carboxyvinylpolymer (CP) on the release characteristics of phenacetin (PHE), Ozeki et al. showed that the release profile of PHE from a 20% solid dispersion granules in MC−CP complex can be modulated via altering the MC/CP ratio and the molecular weight of MC. Contributions of diffusion and polymer erosion to PHE release increased as the molecular weight of the MC increased.[94] The synergistic effect of Starch 1500 in an HPMC-based matrix was claimed for a soluble drug molecule in vitro.[95] However, the underlying mechanism of this observation and in vivo performance require further investigation. While the desired outcome of release modification may be achieved by utilizing interactions between polymer and drug or excipients, it is always beneficial to investigate the underlying mechanism of the interactions based on both theoretical consideration and advanced analytical techniques in order to evaluate the practical utility, application, control and limitations.[96,97]

19.2.1.2 Reservoir polymeric systems

A typical reservoir system consists of a core containing a solid drug or highly concentrated drug solution surrounded by a film or membrane of a rate-controlling material. In this design, the only structure effectively limiting the release of the drug is the polymer layer surrounding the reservoir. Based on Fick's first law of diffusion, the governing one-dimensional release rate of a drug from a reservoir system at steady state is given by:

$$\frac{dM_t}{dt} = \frac{DSK}{L}\Delta C \tag{19.16}$$

M_t is the total amount of drug released at time t, D is the diffusion coefficient of the drug, S is the effective membrane or barrier surface area for drug diffusion, L is the diffusional pathlength (eg, thickness of the film), K is the partition coefficient of drug between the barrier membrane and external aqueous phases, and ΔC is the drug concentration gradient between the solubility, C_s in the reservoir and the drug concentration, C_e in the external aqueous medium. Since the membrane coating is essentially uniform in composition and thickness, for a given molecule and system composition, D, S, K, L, and ΔC are constant in Eq. (19.16) under sink conditions ($C_s \gg C_e$). Thus, the amount of drug released as a function of time can be obtained by integration:

$$M_t = \left[\frac{DSK\Delta C}{L}\right] t = kt \tag{19.17}$$

where k is the release rate constant. The driving force of such systems is the concentration gradient of active molecules between reservoir and sink. Thus, the drug release from this type of system follows apparent zero-order kinetics until ΔC is no longer constant due to complete dissolution of the solid drug in the core. Because the reservoir system relies on ΔC as the driving force for drug diffusion, applies to soluble drugs. For insoluble drugs, the values of C_s may be too low to render adequate driving force, resulting in over-attenuated and incomplete drug release.

In developing oral products based on ER reservoir technology, polymer film coated beads or tablets and microencapsulates (microparticles, pellets or minitablets) are common dosage form presentations. A polymer membrane that contains the drug also includes a hydrophilic and/or leachable additive (eg, a second polymer, surfactant or plasticizer) to give a porous device, offering a predetermined resistance to drug diffusion from the reservoir to the sink. The resistance provided is a function of film thickness and characteristics of both the film and the migrating species in a given environment. In the real-world products, the

mechanisms of drug release from the film-coated dosage forms can be categorized into (1) transport of the drug through a network of capillaries filled with dissolution media ($K = 1$); (2) transport of the drug through the homogeneous film barrier by diffusion; (3) transport of the drug through a hydrated swollen film; and (4) transport of the drug through flaws, cracks and imperfections within the coating matrix ($K = 1$).[98–100] The key factors affecting drug diffusion are polymers and pore former in the membrane coat, drug load, and solubility.[101] The preferred reservoir system normally consists of many coated units such as beads, pellets, and minitablets. In fact, most of the marketed products based on the reservoir system are multiunit dosage forms. Unlike a single-unit tablet, the number of particulates of a reservoir system is often sufficient to minimize or eliminate the impact of any coating defect associated with a limited number of units. An important feature of a multiunit system is that tailored drug release can be readily obtained by combining subunits with different release characteristics. The multiunit system is also adaptable to varying dose strengths without the need for a new formulation. This is highly desirable during clinical development program of the new drug candidates, where dose levels are frequently adjusted based on study outcome.

Similar to matrix systems, drug release from a reservoir system usually varies with pH unless the solubility of the active is pH-independent. To achieve pH-independent release for drugs with pH-dependent solubility, C_s in the core needs to remain unchanged. Success with incorporating buffering agents to maintain constant pH in the core has been reported. As with the pH-independent matrix system discussed previously, the effectiveness of this approach also depends on the loading, buffering capacity, relative quantity, solubility and molecular weight of the buffering agent relative to the drug. Finally, the osmotic pressure in the reservoir can become a significant factor in influencing release control depending on loading and solubility of both the active and certain soluble excipients. In some cases, the osmotic components may lead to the undesired coating rupture.

19.2.1.3 *Osmotic pump systems*

The osmotic pump system is similar in construction to a reservoir device but contains an osmotic agent that acts to imbibe water from the surrounding medium via a semipermeable membrane which is permeable to water but impermeable to drug. Such a device, called the elementary osmotic pump (EOP), was first described by Theeuwes and Higuchi (1975).[102] The delivery of the active agent from the device is controlled by water influx across the semipermeable membrane. The drug is forced out of an orifice in the device by the osmotic pressure generated by the device. The size of the orifice is designed to minimize solute diffusion, while preventing the build-up of a hydrostatic pressure head that has the effect of decreasing the osmotic pressure and changing the volume of the device.

In an osmotic system, the rate of water imbibition into the system in terms of volume can be expressed as:

$$\frac{dV}{dt} = \frac{Ak}{l}(\Delta\pi - \Delta P) \tag{19.18}$$

dV/dt is the rate of water flow, k is the hydraulic permeability, A is the membrane area, l is the thickness, $\Delta\pi$ is the osmotic pressure difference, and ΔP is the hydrostatic pressure difference. When the device is rigid, the volume of the device remains constant during operation. Thus, the amount of drug released at time t can be expressed by

$$\frac{dM}{dt} = \frac{dV}{dt}[S] \tag{19.19}$$

$[S]$ is the drug solubility. When the hydrostatic pressure difference is negligible and there is an excess of solid (saturated solution) in the device, Eq. (19.19) becomes

$$\frac{dM}{dt} = \frac{kA}{l}\Delta\pi[S] \tag{19.20}$$

Therefore, the drug release rate remains constant delivering a volume equal to the volume of osmotic water uptake.

In developing oral products, two types of osmotic pump systems have been commonly used, a one-chamber EOP system and a two-chamber system (eg, Push-Pull and Push-Stick). A comparison of different types of osmotic devices is provided in Table 19.2. In general, an EOP system is only feasible for molecules with a narrow range of solubility, for example, approximately 50–300 mg/mL, to achieve zero-order and complete release. To overcome such limitation, McClelland et al. investigated the conversion of release profiles from first-order to zero-order kinetics for highly soluble (>590 mg/mL) diltiazem hydrochloride that was released from controlled -porosity osmotic pump devices following first-order kinetics. By utilizing the common ion effect, the solubility was reduced in the presence of NaCl to 155 mg/mL. As a result, zero-order drug release was achieved over a 14–16-h period. To maintain an effective NaCl concentration within the drug compartment over the release duration, NaCl granules were coated with a microporous cellulose acetate butyrate 381-20 film.[103] In recent years, studies have shown more general application of controlled-porosity osmotic pump system to drugs

TABLE 19.2 Comparison of Selected Oral Osmotic Pump Systems

Osmotic system	Similarity	Difference
EOP	*Osmotic core* Semipermeable membrane controls water flow	*Single layer tablet* One small orifice Drug released as a solution
Push-Pull		*Bilayer tablet often latitudinally compressed* Osmotic agent in both layers one or more small orifices Drug released as a solution or suspension
Push-Stick		*Bilayer tablet longitudinally compressed* Osmotic agent in push layer One large orifice Drug released as a wet mass that requires subsequent disintegration and dissolution
EnSoTrol		*Single layer tablet* One or more small orifices Incorporation of wicking agent and solubility enhancer Drug released as a solution
Controlled Porosity and Single Composition Osmotic Tablet (SCOT)		*Single layer tablet* No predrilled orifice Drug released as a solution or wet mass through channels or cracks formed in situ
L-OROS		*Single softgel capsule* One small orifice Drug released as a liquid

with different properties.[104,105] For instance, Okimoto et al. described the successful application of a controlled-porosity osmotic pump tablet utilizing (SBE)7m-beta-cyclodextrin as both a solubilizer and an osmotic agent for drugs with varying physical properties, including five poorly soluble and two highly water-soluble drugs.[106] Sotthivirat et al. demonstrated that the incorporation of sulfobutylether-cyclodextrin results in the complete and sustained release of a sparingly water-soluble drug, prednisolone from a controlled porosity-osmotic pump pellet dosage form,[107] and further delineated the release mechanism from such controlled-porosity osmotic pump pellet system taking into consideration the viscosity effect due to changes in the cyclodextrin concentration.[108]

The two-chamber device was designed mainly to accommodate less soluble molecules and/or higher drug loading. It consists of a bilayer tablet compressed latitudinally or longitudinally with one push layer containing a highly swellable polymer and a drug layer (Fig. 19.7). In the GI tract, water is imbibed through the semipermeable membrane into both layers as a result of the osmotic activity gradient established across the membrane by the osmotic excipients. As both the drug and push layers hydrate, a drug suspension (eg, in Push-Pull) or semi-solid mass (eg, in Push-Stick) is formed in situ and the push layer begins to expand as a result of the hydration and swelling of the hydrophilic polymers. Delivery of the drug substance begins when the volumetric expansion of the osmotic push layer begins to "push" the active in the drug layer through the orifice, which is drilled through the semipermeable membrane on the drug layer side. Since rate control resides within the rate-controlling membrane, drug release is essentially insensitive to environmental effects, such as pH, agitation, and type of apparatus. However, this does not apply to the Push-Stick system, which contains a significantly larger orifice that is required for the delivery of the high payload. Since the 1990s, new single layer osmotic pump tablets have been designed and successfully applied to developing commercial products for poorly soluble drugs. The designs are based on the incorporation of solubility enhancement in the tablet core (eg, EnSoTrol) or in-situ creation of larger ports or channels for delivering less soluble compounds (eg, SCOT: Single Composition Osmotic Tablet).

In summary, classic osmotic pump systems offer zero-order release profile that are independent of the drug properties and release environment in most cases. However, fabrication of this type of system often requires specialized equipment and complex processes with a long cycle time. This is particularly true with the two-chamber systems, which often translates into higher cost, longer development time and larger numbers of formulation and processing variables to define and control. Additional drawbacks include (1) the solvent process required for semipermeable membrane coating, (2) sensitivity of the drug release to device dimension variation and membrane uniformity of individual units, and (3) delayed the onset of drug release.

19.2.1.4 Other extended-release systems

Additional systems that have been demonstrated to provide extended release are based on the formation of a less soluble complex or the use of ion-exchange resins,[109] among others. Polysalt flocculates were reported as an effective physicochemical approach to extending the release of aluminum sulfate through the formation of an insoluble complex with sodium

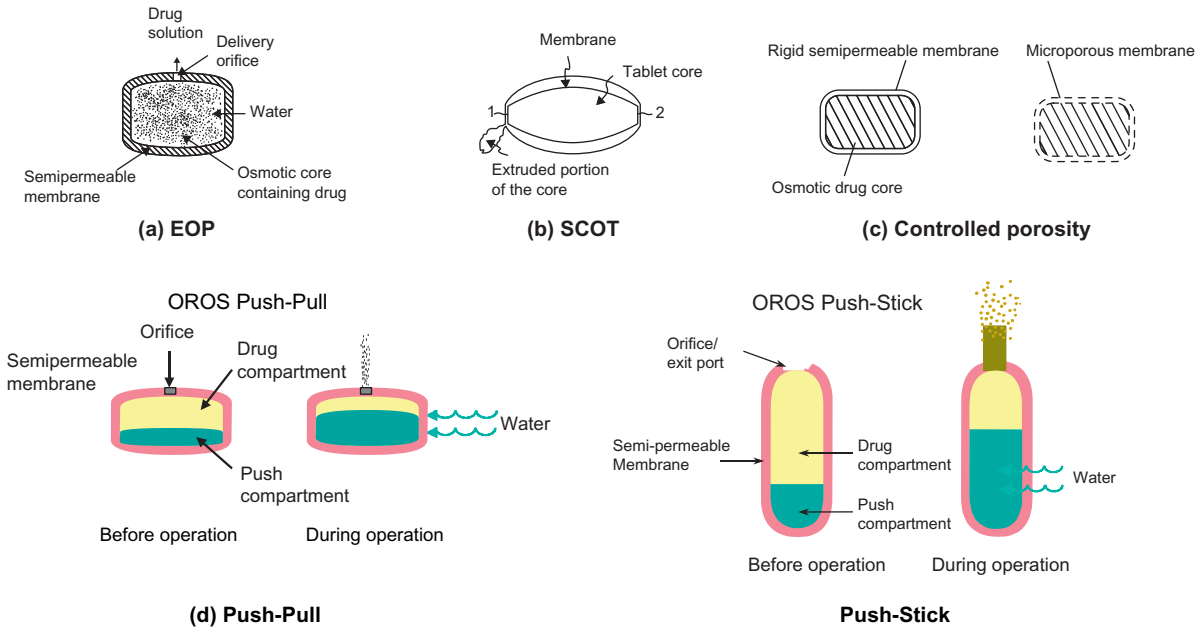

FIGURE 19.7 Schematic representation of different types of osmotic pump systems.

carboxymethylcellulose. Drug entrapment was effected by polymeric flocculation, induced by the addition of a physiologically inert electrolyte.[110] Utilization of a less soluble interaction product between diltiazem HCl and lambda carrageenan was investigated. Extended release of diltiazem from a compacted tablet was achieved via surface dissolution/erosion. The influence of complex particle size, compression force, pH of the dissolution medium, and compact dimensions on drug release was also evaluated.[111]

Synthetic polymer-based ion exchange resins were a result of advances in polymer chemistry in the middle of the 20th century. They were first developed for applications in wastewater purification and processing of fermentation products. Chaudhary and Saunders (1956) first suggested the utility of these materials for extended delivery of charged drugs.[112] Ion exchange resins are nonabsorptive polymeric insoluble particles containing basic or acidic groups in repeating positions on the polymer chain that can form ionic complexes with oppositely charged drugs.[113] The drug is bound to the resin and released by exchanging with appropriately charged ions in contact with the ion-exchange groups. The interactions are strongly governed by the pH of the medium or by the presence of competing ions. At a particular pH, one of the two entities may become neutralized depending on their respective pK_a values, thus eliminating the charge. The presence of high ionic strength buffers may reduce electrostatic interactions between the resin and drug due to a shielding/competitive binding effect. Thus, the resin may carry the drug and release the payload in a certain region of the GI tract due to a pH change or presence of competing ions. Abdekhodaie et al. developed and experimentally verified new mathematical models for drug release from ion-exchange microspheres.[114,115] The models were successfully applied to investigate the influence of important parameters pertinent to material properties and loading conditions on the kinetics, efficiency, and equilibrium of drug loading to aid the product design. Sriwongjanya and Bodmeier investigated the effect of ion exchange resins when incorporated as release modifiers into the HPMC-based hydrophilic matrix tablets.[116] Two model drugs, propranolol, and diclofenac, were studied. Drug release from matrix tablets containing drug-resin complexes was significantly slower than from the matrix tablets containing drug without resin. Pennkinetic technology developed by Pennwalt involves the use of ion exchange resins in combination with diffusion-controlling membranes to create extended-release liquid dosage forms. Examples of commercial products that utilize ion exchange resins include Tussionex Pennkinetic suspension containing hydrocodone and chlorpheniramine and Codeprex extended-release suspension of codeine polistirex/chlorpheniramine polistirex. Additional examples include Duromine containing the basic drug phentermine forming a complex with an anionic resin, and MS Contin suspension, which uses a polystyrene sulfonate resin. Medical-grade resins are available from a range of suppliers, including Rohm and Haas and Dow Chemicals. Duolite AP143 is an anionic resin, whereas Amberlite IRP64, Amberlite IRP69, and Amberlite IRP88 are cationic resins marketed by Rohm and Haas.

Drug delivery systems designed to be retained in the upper GI tract have been extensively explored and investigated for targeted and/or extended oral delivery since the 1970s. The primary objective of such systems, especially the gastroetentative devices, is to overcome regional dependency of drug absorption. For ER product, it is intended to prevent a loss of AUC due to truncated absorption of drugs with a limited window of absorption. A variety of experimental approaches that have been explored include utilizing floating (eg, low density for buoyancy) or settling mechanism (eg, high density), (2) bioadhesion, (3) altering motility with active or excipient, and (4) large size to limit gastric emptying, for example, via expansion by swelling or unfolding.[117,118] The proof of concept studies for some of these designs in humans have been reported using direct (eg, γ-scintigraphy) or indirect (PK) measures. However, none has been shown to function in a reliable and reproducible manner; that is, consistent performance under a fasting condition with acceptable intersubject and intrasubject variability of retention time. Additionally, most of the studies were carried out in a limited number of healthy subjects. For oral ER delivery, reproducibility of the gastric retention characteristics is most critical because it directly influences the bioavailability of a product. Therefore, presently none of the so-called gastroretentive technologies employed in the marketed products can be considered authentic and reliable despite the claims made by some drug delivery companies. However, it is noteworthy that an expandable system, Accordion Pill, using the design of a foldable sheet (eg, about 5 $\times$ 2.5 cm $\times$ 0.7 mm) has shown some promising in vivo results based on MRI, γ-scintigraphy, PK studies, and clinical trials. Its prolonged gastric retention with low-calorie meal has been shown in healthy volunteers.[119–121]

19.2.2 Other common oral modified-release systems

With the improved understanding of an active substance and its clinical pharmacology, various delivery profiles such as those illustrated in Fig. 19.1 are often required for enhanced or more rational and effective clinical therapy. Common examples of these nonmonotonic and multicargo delivery patterns include delayed drug delivery in the small or large intestines, pulsatile delivery, biphasic delivery (ie, IR followed ER or ER followed by IR), etc. These drug release profiles can be obtained by incorporating a range of immediate-release, delayed release, and extended release formulation approaches.

19.2.2.1 Enteric release

The enteric release is intended to delay the release of the drug (or drugs) until the dosage form has passed through the stomach.[4] The delayed liberation of orally administered drugs has been achieved through a range of formulation approaches, including single- or multiple-unit systems provided with coatings, capsule device, and osmotic pumps. The earliest physicochemical approach to delaying drug release is by applying an enteric coating to dosage forms as a barrier that controls the release location in the digestive system. Materials used for enteric coating prevent drug release in the stomach because they are typically acidic polymers that are stable/insoluble at acidic pH. The coatings dissolve rapidly at higher intestinal pH when the dosage forms reach the small intestine as shown in Fig. 19.8. Drugs such as aspirin, which have an irritant effect on the stomach, can be coated with an enteric film that will only dissolve in the small intestine. Enteric coating is also used to prevent the acidic environment of the stomach from degrading certain acid-labile medications, such as proton pump inhibitors. The common enteric dosage forms include coated tablet or capsule, coated multiparticulates in a capsule or compressed into a disintegrating tablet.

19.2.2.2 Colonic release

Targeting drug delivery to the colonic region of the GI tract has received considerable attention and is known to offer therapeutic advantages for certain drugs, such as more effective treatment of local disorders of the colon (eg, ulcerative colitis, Crohn's disease, irritable bowel syndrome and carcinoma) with reduced incidence of systemic side effects and lower dose. Colonic delivery systems are essentially delayed release dosage forms that are designed to provide either an immediate or sustained release in the large intestine. One of the better-known examples is the colonic delivery of mesalazine in the treatment of inflammatory bowel disease. More recently, scientific endeavors in this area have also been driven by the need of a portal for the systemic entry of the active substances including proteins and peptides that are unstable or poorly absorbed in the small intestine for a variety of reasons (eg, instability, metabolism). For drugs that are well absorbed throughout GI tract, sustained delivery in the colon has also been utilized in the treatment of nocturnal asthma or angina such as the previously mentioned cardiovascular chronotherapeutics products, Adalat CC and Verelan PM.

For optimal colonic delivery, the active needs to be protected from the environment of the upper GI tract before being released into the proximal colon. Based on the considerations of the unique features of the

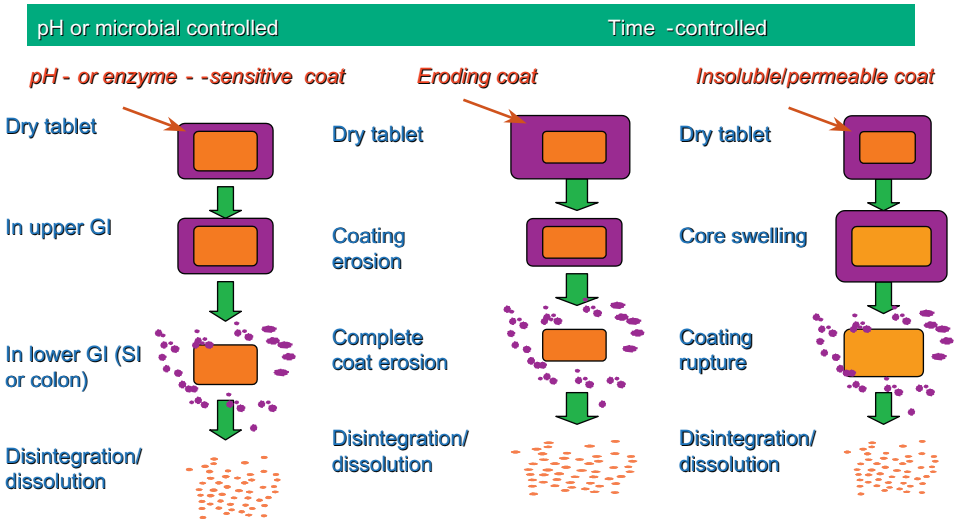

FIGURE 19.8 Examples of different types of delayed release systems and drug release process.

colonic environment: pH, transit time, pressure or microflora, various strategies and approaches have been investigated for colon-specific drug delivery. These include coated delivery systems using pH-sensitive or slow eroding polymers, swelling or controlled osmotic system for timed release and exploitation of carriers that are degraded specifically by colonic bacteria. Prodrugs have been designed to deliver 5-amino salicylic acid in the colon (eg, balsalazide, sulfasalazine, olsalazine). Certain plant polysaccharides (such as amylose, inulin, pectin and guar gum), pH-sensitive hydrogels and microbially degradable polymers especially azo cross-linked polymers have also been studied for targeting drugs to the colon. Among these approaches, coated systems that utilize the transit time and pH differential in the GI tract, as well as prodrugs that rely on colonic bacteria for release, have been utilized in commercial products.

A majority of the marketed colonic delivery products are timed release systems (see Fig. 19.8) that depend on the relatively constant transit time of 3–4 hours in the small intestine. Dosage forms such as beads or tablets are coated with enteric polymers that dissolve more slowly at intestinal pH (eg, Eudragit S). To ensure sufficiently delayed drug release of 3–4 hours following gastric emptying, the weight gain of film coating is significantly higher than that used in the enteric coating. Slowly eroding coating by compression or spraying has also been shown to be effective in timing drug release.[122] The concept of using pH alone as a trigger to release a drug in the colon is based on the pH variations along the GI tract. However, the reliability of this approach in vivo is questionable considering (1) the relative small pH difference between small and large intestines, (2) the high intersubject and intrasubject variability of intestinal pH, and (3) the impact of disease state on intestinal pH. The presence of azo reductase enzymes and glycosidase activity of the colonic microflora is the basis for designing prodrugs or polymers with a triggering mechanism for the release of drug in the colon. The release of drugs from azo bonded prodrugs or azo polymer coated dosage forms is supposed to take place after reduction and thus cleavage of the azo bonds by the azoreductase enzymes present in the colonic microflora. Similarly, natural polysaccharides that remain intact in the upper GI tract may degrade by polysaccharidases, providing site-specific drug release into the colon. To protect polysaccharides from swelling and dissolving in the stomach and small intestine, chemical cross-linking or use of a protective coat has been used. In principle, exploitation of the most distinctive property of the colon, abundant microflora, offers the most accurate site-specificity and delivery consistency in vivo compared with reliance on transit time or pH. However, applications of these modified polymers or prodrugs in commercial products have been limited primarily due to the additional resources, cost and time required for regulatory approval. Over the last two decades, the designs and evaluation of colonic drug delivery systems, as well as manufacturing considerations, have been extensively reviewed in the literature.[123–128]

19.2.2.3 *Pulsatile release*

Pulsatile delivery refers to the release of a portion of the total payload in a burst followed by periods of little/no release (lag phase) in a defined temporal pattern. In particular, oral pulsatile drug release pertains to the burst delivery of drugs following a programmed pattern from the time of oral administration. For example, Ritalin LA capsule is a pulsatile delivery system that provides IR of 50% of the total dose upon oral ingestion followed by a burst release of the remaining

drug after 4 hours. In the field of MR, these nonmonotonic and multicargo release profiles have been recognized and/or proven to offer clinical benefits in (1) optimizing chronotherapy, (2) mimicking natural patterns of endogenous secretion, and (3) providing optimal therapy for tolerance-inducing drugs where constant levels cause receptor down-regulation. Therefore, delivery systems with a pulsatile release pattern have received increasing interest in the product development.

A variety of pulsatile release systems have been investigated and successfully applied in commercial products. The fundamental system design is based on the combination of a range of formulation approaches, including single- or multiple-unit IR and delayed release systems discussed in Sections 1.2.2.1 and 1.2.2.2. The delayed release component in pulsatile delivery systems includes site-specific systems in which the drug is released at the desired site within the intestinal tract or time-controlled devices in which the drug is released after a well-defined time period. The literature reviews have provided detailed summaries of design rationale, the prominent design strategies and various single- and multiple-unit oral pulsatile delivery systems, including Pulsincap, Pulsys, and PORT Technologies.[129–134]

19.2.2.4 Bimodal release

Among nonmonotonic extended release patterns, bimodal (or biphasic) delivery profiles have been most commonly utilized to alter plasma level. The usual rationale for such designs include (1) providing rapid onset of action by adding an IR component to an extended release dosage form, (2) optimizing dosing schedules for chronotherapeutic drugs by incorporating a delayed release component in an extended release dosage form, (3) generating fluctuations of plasma levels to avoid or attenuate the development of acute tolerance due to constant exposure of drug at the receptor site, and (4) overcoming the problems associated with nonlinear pharmacokinetics, extensive first-pass metabolism, idiosyncratic pharmacokinetics or pharmacodynamics resulting in reduced bioavailability or altered drug/metabolite ratios.[135–138] Since the 1980s, many marketed products with biphasic drug release have been developed for various drugs, such as verapamil, diltiazem, nifedipine, methylphenidate, acetaminophen and zolpidem.

As with pulsatile delivery systems, biphasic release profiles are often achieved utilizing a range of formulation approaches, including single- or multiple-unit IR, delayed release and extended release systems based on the coating, matrix, and osmotic pump technologies or combinations thereof. Among common designs that have been applied are mixing systems with varying release rates, using layered tablets or multiwalled coatings, compression coated tablets with a slow eroding outer layer, combinations of delayed release coatings with osmotic pumps, among others. For example, Cardizem CD consisting of a rapid release bead and an extended release bead producing a unique "stair-step release profile."[111] Adalat CC is a compression-coated matrix tablet that provides zero-order sustained release followed by a delayed burst release. Lodotra also uses press-coated tablets (GeoClock) that provide rapid release of prednisone about 4 hours after administration at bedtime for a more effective treatment of the morning symptoms of rheumatoid arthritis.[139] Tylenol 8-hour is a bi-layer caplet designed to provide both fast and long-lasting pain relief. The first layer provides IR for fast relief and the second maintains the blood level of acetaminophen during the dosing interval. A similar design was discussed by Radebaugh et al.[140] Eichel described a delayed and sustained-release system comprising a multiwalled coated drug having an inner wall microencapsular enteric coating, a solid acid either incorporated in the enteric layer or layered over the enteric layer, and an outer microporous membrane wall for release rate control. The solid acid delays drug release by maintaining the enteric polymer in an impermeable state until the acid diffuses out of the drug or is neutralized. The multiwalled coated drug is admixed with an uncoated drug to provide biphasic release profile.[141]

19.2.3 Materials used for modifying drug release

Commonly used materials for modifying drug release from oral solid dosage forms can be categorized into long chain substituted or unsubstituted hydrocarbons and polymers. Natural or synthetic long chain hydrocarbons such as fatty acids, fatty acid esters, glyceryl esters, alcohol esters and waxes were among the earliest materials applied in modifying drug release from matrix systems. The use of waxes for prolonging the medicinal effect of herbal medicines can be traced back to the 4th century AD.[10,11] Polymers are sourced from natural products (eg, polysaccharides), chemically modified natural products (eg, cellulose ethers and esters) or synthetic in nature (eg, methacrylic ester copolymers). Today, polymers have become the dominating rate-controlling excipients in the MR arena due to their multitude of functionalities and relatively more consistent properties, especially those of synthetic or semisynthetic origin when compared with materials of natural origin. Some of the common materials that are approved for oral

administration are briefly discussed in this section based on their applications in different types of MR systems. The list is not intended to be exhaustive, but rather serves as a starting point for the interested reader.

19.2.3.1 Materials for matrix systems

The materials most widely used in preparing matrix systems include hydrophilic and hydrophobic polymers, as well as long chain hydrocarbons. Commonly available hydrophilic polymers include (1) nonionic soluble cellulose ethers available in a wide range of viscosity grades, such as HPMC (eg, Benecel K100LV, K250, K750, K1500, K4M, K15M, K35M, K100M and K200M, Methocel K100 LV, K4M, K15M, K100M; Metolose 100, 4000, 15,000, and 100,000 SR), hydroxypropyl cellulose (HPC, eg, Klucel GXF, MXF, HXF), hydroxyethyl cellulose (HEC, eg, Natrosol 250 HHX, HX, M, G) with varying degrees of substitutions and viscosity grades; (2) nonionic homopolymers of ethylene oxide, such as, poly(ethylene oxide), [H$(OCH_2CH_2)_n$OH] with a molecular weight range of 100,000 to 7,000,000 (eg, Polyox WSR N-12K, WSR N-60K, WSR-301, WSR-coagulant, WSR-303); (3) water-soluble natural gums of polysaccharides of natural origin, such as xantham gum, alginate and locus bean gum; (4) water swellable, but insoluble, high molecular weight homopolymers and copolymers of acrylic acid chemically cross-linked with polyalkenyl alcohols with varying degree of cross-linking or particle size (Carbopol 71G NF, 971P, and 974P); (5) cross-linked high amylose starch. In most cases these polymers can perform qualitatively similar functions, but possess different release-retarding capability and processing characteristics when used at the same level. They are usually available in micronized forms for facilitating the rapid formation of gelatinous barrier layer on the system surface.

Fatty acids, fatty acid esters, mono-, di-, and triglycerides of fatty acids, fatty alcohols, waxes of natural and synthetic origins with differing melting points as well as hydrophobic polymers are used in hydrophobic, nonswellable matrices. Examples include stearic acid, lauryl, cetyl or cetostearyl alcohol, glyceryl behenate, carnauba wax, beeswax, candelilla wax, microcrystalline wax and low molecular weight polyethylene, to name a few. Insoluble polymers include fine powders of ammoniomethacrylate copolymers (Eudragit RL100, PO, RS100, PO), polyvinyl acetate or its mixture with povidone (Kollidon SR), ethyl cellulose (Ethocel), cellulose acetate (CA-398-10), cellulose acetate butyrate (CAB-381-20), cellulose acetate propionate (CAP-482-20), and latex dispersions of the insoluble polymers (Eudragit NE-30D, RL-30D, RS-30D, Surelease). However, their applications as the sole rate-controlling material in the marketed matrix-based products are still limited.

19.2.3.2 Materials for reservoir systems

The common materials to form a drug release barrier surrounding a core tablet, drug particles, beads or pellets for diffusion-controlled reservoir systems include water-insoluble acrylic copolymers, ethylcellulose and polyvinylacetate. These film-coating polymers had historically been used in an organic solution prior to the 1980s. Today, they are applied as aqueous dispersions that form films by a process of coalescence of submicron polymer particles in most cases except where the solvent coating is required. Ammoniomethacrylate copolymers (Eudragit RL 30D, RS 30D) are water permeable and swellable film formers based on neutral methacrylic esters with a small proportion of trimethylammonioethyl methacrylate chloride. Methacrylic ester copolymers (Eudragit, NE30D) are neutral esters available as a 30% aqueous dispersion without the need of plasticizers unless increased film flexibility is desired. Ethylcellulose for film coating is available as an aqueous polymeric dispersion containing plasticizers under the brand name of Surelease and as pseudolatex dispersion, Aquacoat ECD, which requires an addition of plasticizers to facilitate film formation during coating. More recently, a polyvinylacetate aqueous dispersion (Kollicoat SR 30D) has been shown to offer similar functionality while providing improved resistance to an aqueous medium containing alcohol in dissolution test.

19.2.3.3 Materials for osmotic pump systems

Cellulose acetate is the most commonly used polymer that constitutes the semipermeable membrane of an osmotic pump device. Cellulose acetate containing a controlled percentage of acetyl content is often used together with other pH-dependent or pH-independent polymers to form films of varying water flux and permeability. Polymers used for such purpose include cellulose butyrate, polyurethane, ethylcellulose, poloxamer polyols, PEG, PVC, and PVA. Osmotic agents, such as sodium chloride, are another key ingredient of an osmotic system. In the more sophisticated two-chamber system, a hydrophilic polymer with a very high swelling ratio; that is, poly(ethylene oxide), is an essential component in the osmotic driving element, the push layer.

19.2.3.4 Materials for delayed release systems

Materials that have been applied to oral medication for enteric release primarily comprise of (1) shellac and zein of natural sources and (2) derivatives of cellulose and methacrylic acid copolymers containing carboxylic functional groups. Technology advances over

the past three decades have made synthetic and semi-synthetic polymers the most preferred system for enteric film coating of tablets or particles. At low pH in the stomach, the polymer is impermeable and insoluble, but in the higher pH environment present in the small intestine (eg, >5.5), the polymer dissolves and exposes the core tablet for the rapid or slow release of the actives. Examples of these pH-dependent anionic polymers include cellulose acetate phthalate (CAP), hydroxypropyl methylcellulose phthalate (HPMCP), methacrylic acid and methacrylic esters (Eudragit L 100, L 100-55, L12.5, L30D-55, S 100, S 12.5, FS 30D, Acryl-EZE), and polyvinyl acetate phthalate (Sureteric). Some of these polymers (eg, Eudragit) are often used to obtain predetermined lag times of the delayed release via pH and/or coating thickness control for colonic and pulsatile (later pulses) release. It should be noted that these ionic polymers have also been incorporated into the matrix, reservoir or osmotic pump systems to modify drug release profiles as discussed in this chapter. For delayed release system based on slow eroding mechanism, materials such as those utilized in matrix systems are used in compression-coated tablets that provide predetermined lag (eg, Adalat CC).

19.3 RATIONAL DESIGN OF MODIFIED RELEASE SYSTEMS

The majority of the systems for modifying apparent drug absorption are, in general, based on proprietary or nonproprietary polymeric delivery technologies. The ability to achieve the desirable in vitro and in vivo performance for a given drug substance is highly dependent upon several important factors that include the dose, physicochemical, biopharmaceutical, pharmacokinetic, and pharmacodynamic properties of the drug, as well as the proper selection of a formulation approach and formulation design. Each drug substance possesses inherent properties that require considerations specific to both the drug and the delivery system. Thus, successful dosage form development is, in fact, dictated by the properties of a compound in the context of physiological/biological constraints, rather than by the technology platform. This conclusion is supported by the fact that almost all MR products with the expired composition of matter patents have been unable to maintain market exclusivity solely based on delivery technology. There are numerous examples where the performance of the branded products has been matched by their generic counterparts based on similar or different ER technologies. Notable examples include Procardia XL, Cardizem CD, Concerta, Adalat CC, Wellbutrin XL, Ditropan XL, Glucotrol XL, Glucophage XR, Asacol, Toprol-XL, to name a few. Therefore, the first stage in designing an MR delivery system should be to conduct technical feasibility assessment by integrating a defined clinical rationale with the characteristics of the drug. The second stage is to select an appropriate MR technology based on the desired dosage form characteristics and other development considerations discussed in chapter "Product and Process Development of Solid Oral Dosage Forms" for in vitro and in vivo evaluation. More specifically, a rational design process should include the following steps:

1. Identify the clinical need and define target in vivo product performance
2. Conduct a study through experiments and detailed analysis to assess feasibility of intestinal absorption, challenges, and risk associated with MR delivery based on
   - Characterization of the molecule concerning its physicochemical and biopharmaceutical properties, dose, regional absorption, in vivo disposition and pharmacodynamics.
   - Pharmacokinetic simulation to calculate theoretical drug input rate and its range required to produce the desired plasma concentration-time profile based on in vivo disposition parameters and certain assumptions.
   - Determine whether physicochemical properties and absorption characteristics of the API in different segments of the GI tract allow for the required drug input within the residence time of the dosage forms (eg, solubility/dose ratio, apparent permeability, single unit versus multiparticulates)
3. If feasible, design and evaluate formulations with different release rates by selecting an appropriate MR technology, associated dosage form, manufacturing process and in vitro test methods.
   - Select prototype formulations with profiles that bracket the theoretical target absorption profile for testing bioavailability in vivo
   - Identify a formulation with acceptable in vivo performance or a direction to aid subsequent round of formulation refinement if iteration is required.
   - Explore an in vitro-in vivo relationship (IVIVR) or correlation (IVIVC) if different prototypes exhibit different in vivo performance.

In this section, the essential design elements and general considerations will be discussed in detail. Case studies are provided to illustrate how drug property, delivery technology and formulation approach influence the performance of oral MR delivery systems.

19.3.1 Identification of the clinical need and definition of the target in vivo product performance

The basic clinical rationale of developing a MR product is to achieve optimal drug treatment via programming the input profile such that the product offers one or more advantages in efficacy, safety, and patient compliance. According to the regulatory directive issued by European Medicines Agency (EMA),[142,143] development of MR products should be based on (1) a well-defined relationship between the pharmacological/toxicological response and the systemic exposure to the drug/metabolite(s) forms and (2) an integration of physiological, pharmacodynamic and pharmacokinetic considerations. In other words, modulating the rate, kinetics, timing and/or site of drug release in the GI tract requires an understanding of the time course of drug concentrations in the body (PK) and its relationship with the pharmacological effect including time course and intensity of therapeutic and adverse effects (PD). However, emphasis has been, in many cases, placed on reducing the dosing frequency or fluctuation of plasma concentrations associated with IR formulations than on understanding and ensuring improved pharmacological effect profile. As a result, it is not uncommon to see new drug delivery systems looking for a suitable drug candidate or projects being terminated due to a lack of feasibility of or the desired outcome. This can be attributed to the often assumed or overly simplified linear PK/PD relationship, and to the fact that the PK outcomes of drug delivery are easy to monitor and quantify. In reality, the relationship between systemic drug concentration (C) and intensity of effect (E) is very complex because of the vast array of pharmacological mechanisms and physiological processes that control drug responses. For instance, the common design objective of an ER dosage form is to maintain the plasma drug concentrations above the minimum effective concentration (MEC) and below the minimum toxic drug concentration (MTC) for drugs with defined therapeutic window. However, for antibiotics with known minimum inhibitory concentration (MIC), there are three types (or indices) of PK-PD relationship that define concentration needed for maximal bacterial killing: (I) concentration-dependent with prolonged persistent effect, (II) time-dependent with minimal persistent effect and (III) time-dependent killing with moderate to prolonged persistent effect.[144–146] The rate of killing is determined by either the length of time necessary to kill or the effect of increasing concentrations. Persistent effects include the Post-Antibiotic Effect (PAE) which is the persistent suppression of bacterial growth following antibiotic exposure. In designing MR dosage forms, the PK target profiles need to differ depending on the PK-PD indices[147] of different classes of antibiotics to maximize clinical efficacy and tolerability. For Type I antibiotics, achieving high AUC_{24h}/MIC and C_{max}/MIC ratios is more important for antibiotic efficacy. For example, a C_{max}/MIC ratio of at least 8–10 is needed to prevent resistance of aminoglycosides. For fluoroquinolones, $AUC_{24\,h}$ /MIC ratios of approximately 125 and 40 are optimal against gram negatives and positives, respectively.[144] For Type II antibiotics, the design of MR products should aim at maximizing the duration of exposure because the cumulative percentage of a 24-hour period that the concentration is above MIC ($T_{>MIC}$) is known to best correlate with efficacy. For beta-lactams and erythromycin, maximum killing is seen when the time above MIC is at least 70% of the dosing interval. Type III antibiotics exhibit time-dependent killing and moderate persistent effects.[144] Thus, the MR product design needs to strive for obtaining high $AUC_{24\,h}$ /MIC ratio with adequate $T_{>MIC}$.[148]

A variety of models based on the mechanisms of drug actions (reversible, irreversible and tolerance) have been developed to describe PK/PD, such as sigmoid E_{max}, biophase distribution, slow receptor-binding, turnover, indirect response, signal transduction and tolerance models.[149] For example, a sigmoidal E_{max} model or the full Hill equation is a four-parameter direct response model:

$$E = (E_{max}\, C^{\gamma})/(EC_{50}^{\gamma} + C^{\gamma}) \qquad (19.21)$$

E is the intensity of the effect, E_{max} is the maximum effect, C is the concentration, EC_{50} is a sensitivity parameter representing C producing 50% of E_{max}, and γ is the Hill or sigmoidicity coefficient that reflects the steepness of the E-C curve. Lower values (<1) will produce broad slopes, higher values (>4) are reflective of an all-or-none type of response. According to this equation, different fluctuations in pharmacological response (ΔE) may result from the same or similar concentration changes (ΔC) depending on the concentration ranges. Additionally, the slow and constant mode of drug input often provided by ER dosage forms may have varying therapeutic impacts depending upon drugs and their PK-PD relationships. Furthermore, the time course of drug effects can be fairly different from the time course of drug concentrations. A short elimination half-life does not necessarily indicate a short duration of action.

Fig. 19.9 shows the sequence of steps between drug administration and clinical response. The importance of efficacy and safety implications of the complex relationship between drug input and pharmacodynamics and research strategies for guiding the design of drug

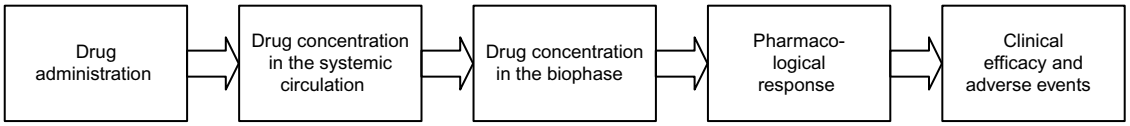

FIGURE 19.9 From drug administration to clinical response.

delivery mode have been discussed in details by Breimer and Hoffman.[150,151] For instance, the shape factor (γ), which determines the slope of the E-C curve of the E_{max} model, can have a significant impact on the design of an ER system. A relatively shallow E-C profile (small γ) may suggest a lack of pharmacodynamic rationale to develop an ER product because E is relatively insensitive to even a large change in concentration. When the concentration range required to elicit drug response is very small (large γ), such as for levodopa, the E-C profile represents an all-or-none phenomenon. Thus, as long as the drug concentrations remain above the MEC, the drug effect is essentially independent of the fluctuation in plasma levels. It is known that the nonsteady state E-C curves of certain drugs may exhibit clockwise or counter clockwise hysteresis due to desensitization or equilibrium delay or formation of an active metabolite.[1] In the former case, either pulsatile or constant rate input may be designed depending upon the desired pharmacological responses of the drugs (eg, gonadotropin-releasing hormone). On the other hand, a slow input rate may minimize the counter clockwise hysteresis and thus require lower C_{max} to achieve the desired response.

The impact of input rate on the efficacy and safety ratio is best illustrated by nifedipine. Comparative studies of slow versus rapid input have led to the realization and confirmation that the rate-of-increase of nifedipine concentration, rather than absolute concentration, is the determining factor for the observed hemodynamic effects; that is, a gradual decrease in blood pressure was observed without side effects (increase in heart rate) occurring with a slow regimen while the opposite was observed with a rapid regimen.[119] Methylphenidate represents another classical example where the delivery pattern can have a significant impact on the efficacy. To meet the clinical need for a more convenient dosing regimen of this controlled drug, several new MR products with different release modes were designed and clinically proven to be effective since the mid-1990s. The product designs include pulsatile release and biphasic extended release that provide fluctuations of plasma levels during drug release, thus overcoming the acutely acquired tolerance due to a constant level of drug exposure associated with Ritalin SR, the extended release version of Ritalin product lines that had been available for many years. These two examples show that a positive or negative clinical outcome may be rendered by constant PK profiles depending on the relationship between the kinetics of drug effects and the pattern and timing of drug input. Therefore, the design of release characteristics for an MR product should be based on the desired optimal drug concentration-time profile; that is, target product profile, defined by the quantitative information of the PK/PD relationship.

With increased research and understanding of biomarkers and surrogate endpoints that reflect the underlying mechanism of drug action, it is anticipated that understanding PK/PD relationships will play a more significant role in the establishment of clinical rationale, a definition of in vivo target product profiles and early decision in MR product development.

19.3.2 Feasibility study

In developing MR dosage forms, feasibility assessment is crucial to product design and development success. Once the delivery mode and in vivo target product profile are defined and disposition parameters are available, the corresponding theoretical drug input profile can be obtained by prospective PK simulation; for example, via adjusting input rate and kinetics to generate in vivo PK profiles, or by deconvolution of the target plasma profile. With a known therapeutic window or MEC, the required input or absorption duration and kinetics can be readily determined, for instance, by ensuring the plasma levels of the MR design constantly above the MEC over the dosing interval. When the quantitative PK-PD information is unavailable, the steady-state C_{min} of the clinically effective IR counterpart may be used as a conservative estimate of the MEC. For example, Fig. 19.10 shows a new ER dosage form was designed to maintain the average plasma concentration at or above the C_{min} (about 100 μg/mL) of a marketed IR dosage form throughout the dosing interval of 24 hours.

Following the completion of the theoretical MR design or paper exercise, the next step would be to do a "reality check"; that is, to evaluate the feasibility of the designed delivery in the GI tract because favorable and complete drug absorption throughout the GI tract is often an exception rather than a rule. For example, if a predefined plasma profile of a drug corresponds to 16 hours of zero-order drug input, it suggests that majority of the administered dose will have to be

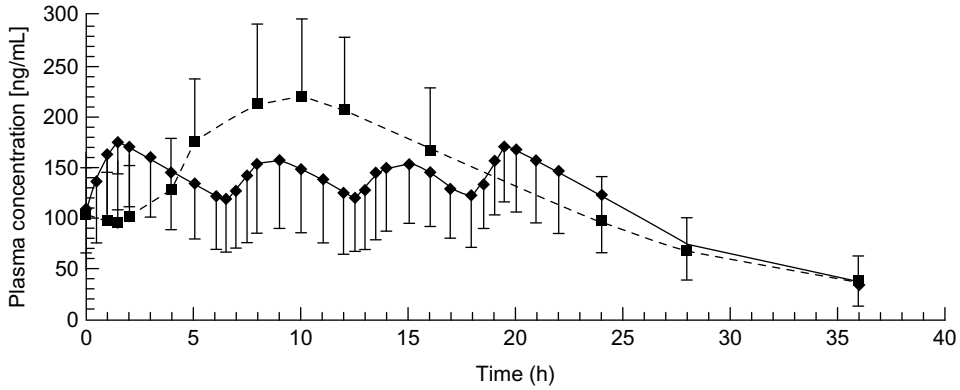

FIGURE 19.10 Mean (±SD) plasma concentration-time profiles of (+)− Tramadol after multiple-dose administration of an immediate release dosage form and a once-daily extended release dosage form in the fasting state (key: 50 mg IR (♦); 200 mg ER (■)). *Reprint with permission from Blackwell Publishing: Malonne, H. et al., Pharmacokinetic evaluation of a new oral sustained release dosage form of tramadol. Br J Clin Pharmacol 2004;57(3):270−278.*

absorbed in the large intestine under fasting condition because of the limited residence time of solid dosage forms in the small bowel. Thus, understanding absorption characteristics of the individual molecule of interest in the lower GI tract is crucial to the rational design of an MR dosage form. To assess technical feasibility and development challenges, it is essential to integrate the drug's physicochemical and biopharmaceutical properties in the context of the total dose, physiological/biological constraints and disposition kinetics. Among the key properties of a particular drug substance are solubility, lipophilicity, chemical stability, regional permeability, gut and hepatic first-pass metabolism, whether or not the drug is a substrate of gut enzymes and transporters and susceptibility of the drug to metabolism by gut microflora. To help better understand the suitability of a particular drug for MR delivery, some of the important factors and their impact on the product development are summarized in Table 19.3.

Orally administered drugs may be subject to acid or base hydrolysis and other chemical or enzymatic degradation that can influence bioavailability and design of the delivery system. For example, drugs that are unstable in the stomach require delayed onset of drug release until the dosage form enters the small intestine. This may result in shortened total GI residence time for extended absorption. On the other hand, drugs unstable in the lower GI tract due to metabolism by microflora would require complete drug delivery in the small intestine.

The regional absorption characteristics of a compound in the GI tract and residence time of dosage forms are the most important parameters in assessing the suitability of oral MR delivery.[1,153] With significant regional differences including surface area, permeability, secretion, enzymes, transporters, the volume of water, and so on, a drug substance often exhibits varying degrees of apparent absorption in different segments of the GI tract. In general, the transit time of most dosage forms before arrival at the colon, a less favorable site for drug absorption, is approximately 4−6 hours depending on the type of dosage forms, food intake, and composition. This may become a limiting factor for drugs requiring absorption beyond this time frame after dosing.[154] For certain drugs, favorable absorption in the large intestine can allow continued drug delivery for up to a total of 20−24 hours.[155,156] If drug release is not completed by the time the dosage form passes through the absorption region, a portion of the dose will not be delivered. Hence, it is very important to define the absorption regions or window of a specific compound in the GI tract before further development proceeds. MR dosage forms designed and tested in adults may not work the same with the young children because of the known differences in GI transit time of the delivery systems between adults and children younger than 3−4 years old. With shorter GI residence time in young children, truncation of drug absorption may occur depending on the characteristics of the drug substance and MR design, resulting in lower AUC and/or subtherapeutic plasma levels.[157]

Over the years, many techniques have been utilized to assess regional absorption potential or window of a compound, including in vitro or in-situ models and site-specific delivery in animal models and human subjects. Permeation characteristics of drugs in different GI segments can be evaluated through in vitro permeability of excised tissues or in situ perfusion studies in animal models (eg, rat or rabbit). Site-specific delivery via indwelling access ports in conscious animals (eg, dog and rat) offers a direct comparison of drug absorption in jejunum, ileum, and colon through

TABLE 19.3 Factors Affecting the Feasibility of Developing Oral Modified Release Systems

A. SOLUBILITY/DOSE
Low solubility combined with high dose may limit the suitability for developing an MR system that requires drug delivery in the lower bowel. Drug absorption is usually more variable or incomplete when the in vivo release occurs past the ileocecal junction where the amount of fluid available for dissolution is progressively limited, and the permeability and surface area are lower. In some cases, apparent absorption of poorly soluble drugs may be inherently prolonged due to the slow dissolution of the drug particles. However, achieving consistent drug release requires tight control of bulk powder properties of the API, including particle size distribution, morphology, surface properties and agglomeration, etc.
B. STABILITY
Drugs must be stable to pH, enzymes and flora throughout the entire intended delivery regions of the GI tract. For example, a drug subject to degradation by the colonic microflora is not a suitable candidate for MR delivery that requires an in vivo absorption beyond approximately 5–6 hours post dosing.
C. LIPOPHILICITY/PERMEABILITY
Absorption of BCS Class 3 or 4 drugs may be limited by permeability that also differs with regions of the GI tract due to difference in available surface area, uptake and/or efflux transporters involved.[152] Altering the release of such drug substances in the lower GI tract typically have little effects on the shape of PK profiles and usually result in truncated absorption when > 5–6 hours of in vivo absorption is required.
D. ELIMINATION $t_{½}$
The need for ER systems is often a result of short half-life. However, other variables (eg, MEC, a volume of distribution and dose) are also important in determining the ER feasibility. Hence, developing a twice-daily (or once-daily) system may be possible for one compound, but not feasible for another drug having similar half-lives.
E. THERAPEUTIC WINDOW
One of the common design objectives of oral ER drug delivery is to maintain plasma levels within the therapeutic window with reduced fluctuation. For drugs with relatively short half-lives, the lower the MEC and the higher the minimum toxic concentration (MTC), the more likely it is to achieve prolonged drug exposure above MEC using higher dose. However, this will result in a greater fluctuation in steady-state plasma levels that is often undesirable for narrow therapeutic index drugs.
F. FIRST-PASS METABOLISM
For drugs with saturable first-pass metabolism (hepatic or gut), bioavailability may be compromised due to slow input if drug absorption from IR dosage form is higher because of transient saturation. No significant impact is expected if drug absorption of both IR and ER is within linear range (ie, dose proportional).
G. PK-PD RELATIONSHIP
The relationship between drug concentration (C) and the pharmacological effect (E) plays a critical role in determining rationale and need for MR delivery as previously discussed.

concurrent monitoring of plasma levels. It can serve as a predictive model for human exposure depending on the drug's properties and absorption mechanism. In fact, a reasonably good correlation of regional absorption characteristics has been found between dog and human, particularly for passively transported compounds.[158] For small hydrophilic molecules for which the paracellular pathway also plays a role in permeation, the dog model usually overestimates the absorption in humans due to the "leakier" canine intestine, especially in the large intestine. To quantify colonic absorption for delivery potential, intubation studies have also been used via bolus and/or continuous infusion of a drug solution or suspension into the transverse colon in animal or healthy volunteers. Since the early 1990s, gamma scintigraphic studies have become one of the commonly used techniques for screening drug candidates for oral MR delivery.[159] For instance, regional differences in absorption can be determined by using noninvasive delivery devices, such as the Enterion capsule of Quotient Clinical[160] and the InteliSite capsule of Scintipharma, Inc. These radiolabeled capsules loaded with a drug solution or powder can be tracked via gamma scintigraphy and externally activated to release the drug when it reaches the desired location in the digestive tract following ingestion. Another effective method used by the two companies and Bio-Images Research Ltd. is to administer a radiolabelled MR dosage form followed by combined analysis of its GI transit characteristics along with location and timing of drug release.[161] Recently, Medimetrics developed a new system known as IntelliCap that combines the functions of drug delivery, measurement, and wireless communication.[162,163] It is an electronic drug delivery capsule that enables programmable dispensing of a drug while continually measuring and reporting pH and temperature as it travels through different segments of the GI tract. Based on the measured pH profile the capsule location is determined and individual GI transit times are obtained from each capsule. Hence, concurrent scintigraphic imaging is not required. Two product versions are available for controlled delivery of fluids, solids or powders: (1) IntelliCap CR is constructed for a fluid payload and dispenses drug in small increments under control of the microprocessor, allowing the creation of

a variety of delivery profiles; (2) IntelliCap FR is designed to deliver drug as a single fast-release event for flexible payload type including powder, particles, solid fluid. All of these studies are useful in evaluating absorption characteristics of the drug molecules in different segments of the intestinal tract with minimum confounding factor. However, the oral delivery feasibility of MR systems not only depends on regional absorption properties of the API but also variables associated with dosage form design, composition, and/or processing. Hence, an alternate approach that can often be efficient and effective is to incorporate feasibility assessment as part of the early product development. By applying interdisciplinary knowledge and integrating the drug's properties (physicochemical, biopharmaceutical and biological) with regional absorption information in animal models, a decision can often be made initially with regard to proceeding with formulation screening study in humans. The first screening study typically involves administering prototype formulations with varying in vitro release profiles that bracket the simulated target in vivo absorption profile by first assuming a wide window of absorption. If the study indicates decreasing bioavailability with slowing drug release, the absorption window can be inferred or approximated by deconvolution or examination of plasma profiles (eg, using a semilog plot). For example, the limit of drug release duration in vivo normally corresponds to where the observed truncation of apparent absorption occurred. The reliability of the information thus obtained usually depends on the number of the prototypes tested, the IVIVR, and understanding of certain potential confounding factors. This approach is appealing because (1) the time and cost required for a screening study are similar to that of a "cleaner" scintegraphic study and (2) with sufficient rationale, knowledge and experience invested in the design of prototypes and in vitro screening tools, there is a reasonable chance of identifying a target formulation in the same study or obtaining a rank order of in vivo performance which can often be used to guide formulation modification when necessary. The main drawback of this approach is its potential impact on making a "go/no go" decision when the study result is inconclusive with respect to the absorption window due to confounding factors.

The therapeutic window and MEC and their interplays with disposition characteristics of a drug also play a critical role in suitability evaluation for ER delivery. In theory, a lower MEC combined with slower elimination corresponds to a shorter required duration of drug input. Drugs with very short half-lives ($t_{1/2}$) and high volume of distribution undergo rapid clearance, which can make extended delivery challenging especially if the MEC is relatively high or therapeutic window is narrow. For instance, prolonged absorption is often required to achieve essentially flat plasma profiles for drugs with short half-lives and narrow therapeutic indices since fluctuation of the plasma profiles depends on the rates of elimination and input duration/kinetics. Therefore, a wide absorption window is often necessary to achieve extended release of this type of drugs. Lastly, it should be noted that a feasibility study is not required for developing generic MR products because it is already confirmed by the presence of branded products.

19.3.3 Selecting the MR system and testing system design

When oral MR delivery is feasible or shows promise, the logical subsequent step is to choose an appropriate MR technology that is capable of meeting a specific delivery need along with in vitro tests for evaluating prototype formulations with different release rates in vitro. This should be built on the understanding of drug properties, required dose and release/absorption kinetics, clinical and market needs including type and size of dosage form, number of strengths, among others. Additional practical considerations include development time and cost, and commercial production factors discussed in chapter "Product and Process Development of Solid Oral Dosage Forms" (eg, process, equipment, facility, manufacturability, robustness, cost, capacity, environment, and so on). In selecting an MR system that matches development needs, dose and solubility of the active are often the most important factors to consider because, within the size constraint of oral dosage forms, both variables impact the release mechanism and processing behaviors. Thus, there is no technology that is "one-size-fits-all." Nevertheless, it is not uncommon for a drug delivery company to tout a specific technology while downplaying the practicality and viability of technology transformation, such as system and process complexity, and many other factors discussed previously. Table 19.4 compares delivery capabilities and limitations of commonly utilized ER systems. From an enablement point of view, different MR systems can be equally effective in achieving the delivery objective when drug properties and dose are desirable. For example, similar MR performance of verapamil, theophylline and methylphenidate have been obtained using matrix, reservoir or osmotic pump technologies. Depending on dose and solubility, one type of delivery system may become more or less suitable for meeting a particular delivery need. Table 19.5 provides a high-level guide to the selection of ER systems on the basis of dose and solubility.

TABLE 19.4 Comparison of Commonly Used Oral Extended Release Technologies

System	Advantages	Disadvantages
Hydrophilic matrix	Suitable for compounds with a wide range of properties and low to high drug loading Generally robust formulation and process when rationally designed Use of conventional manufacturing equipment and process Cost effective: Shorter development time and lower cost Release kinetics and profiles can be tailored with modification Multiunits possible	Drug release often sensitive to test conditions Less flexibility to adjust dose strengths for single-unit system Increased formulation/process complexity to achieve tailored drug release (layered or compression coated system)
Hydrophobic matrix	Suitable for soluble compounds and low to high drug loading Use of conventional manufacturing equipment and process Release kinetics and profiles can be tailored with modification Multiunits possible	Not applicable to compounds with low solubility Nonzero-order release Propensity for incomplete drug release Drug release often sensitive to processing and test conditions Less flexibility to adjust dose strengths for single-unit system Increased formulation/process complexity for tailored drug release (layered or compression coated system)
Multiunit reservoir	Readily tailored release kinetics and profiles (eg, zero-order, pulsatile, biphasic, colonic) Minimized risk of dose dumping and local irritation Lower in vivo variability owing to favorable GI transit properties More consistent in vivo performance Easy dose adjustment: Single formulation amenable to multiple strengths Suitable for pediatric/geriatric use Use of conventional manufacturing equipment and process	Only applicable to compounds with relatively high solubility Drug release often sensitive to test conditions Limited drug loading Process development and scale-up more challenging
Osmotic pump	Applicable to compounds with a relatively wide range of properties Drug release generally independent of drug properties and test conditions Zero-order release	Limited drug loading Ghost tablets Delayed onset (1-2 h) and/or incomplete drug release Solvent-based process Lengthy, complex and inefficient manufacturing processes and control (eg, Layered tablet) Specialized equipment, facility Highest development and manufacturing cost and time

Once an MR system is chosen, in vitro characterization of its behavior and attributes is essential prior to testing in human. Factors that often affect the system performance such as, type and size of the dosage form, drug loading, excipient property, processing method, release mechanism, sensitivity to environmental changes, need to be considered when choosing appropriate in vitro test methods. For solid MR dosage forms, drug release test is the most important among various physical and chemical characterization methods. The USP drug release test (eg, using apparatus II or I) is commonly utilized for gauging the likely in vivo performance, thus guiding formulation screening despite its undefined relationship with in vivo performance at the early design stage. Depending on the drug properties and system design, test parameters including apparatus, agitation, pH, surfactants, additives, ionic strength, mechanical stress, among others, can be varied to better mimic certain specific GI conditions or to create shear stress on the structure for testing the performance robustness. A detailed discussion of development considerations related to meaningful in vitro release tests is provided in chapter "In Vitro/In Vivo Correlations: Fundamentals, Development Considerations, and Applications."

In designing and evaluating an MR dosage form, the initial objective is usually to prepare a formulation with an in vitro release profile similar to the theoretical in vivo absorption profile. Due to unknown IVIVR, additional formulations having in vitro profiles that bracket the target profile are useful for identifying a formulation with desired in vivo performance when they are tested in humans for the first time. In the event where an iterative study is required, the data from such a screening study provide not only a direction to formulation refinement but also an opportunity for early exploration of IVIVR or IVIVC. As discussed in chapter "In Vitro/In Vivo Correlations: Fundamentals, Development Considerations, and Applications," the earlier an IVIVC or IVIVR can be established, the more beneficial it is to the design and development of a MR product. A validated IVIVC offers a useful scientific and regulatory tool to aid formulation and process development and scale-up, justify specifications and make changes related to process, equipment and manufacturing site. Lastly, with any technology chosen, it is imperative to integrate the selection of formulation components and associated manufacturing process based on the multifaceted fundamental understandings discussed in chapter "Product and Process Development of Solid Oral Dosage Forms" in order to ensure consistent quality and a reproducible performance in vivo. For example, oral dosage forms are subjected to a range of shear forces such as peristalsis and also encounter a variety of pH and chemical environments during GI transit. In poorly formulated hydrophilic matrices, these mechanical and chemical challenges can potentially cause the matrix to lose its integrity prematurely and break up.[30] Thus, product design requires consideration of material properties, process operation and possible interactions that may influence the matrix integrity and consistent drug release. In particular, knowledge of the basic characteristics of the rate-controlling polymer and fundamental factors that affect drug release[30] is essential to design hydrophilic matrices with robust performance.

19.3.4 Case studies: impact of drug property and formulation design

The examples discussed in this section are intended to illustrate (1) the criticality of understanding drug characteristics and feasibility assessment and (2) there is no one-size-fits-all solution to designing an MR product (3) delivery technology is inconsequential for drug molecules with desirable properties for MR development.

19.3.4.1 Case study 1: methylphenidate HCl

Methylphenidate (MPH) is an amphetamine-like central nervous system stimulant commonly prescribed to treat ADHD in children, adolescents, and adults, as well as narcolepsy. It is a weak base with pK_a of 8.77 and a log$P$ of 3.19. Its hydrochloride salt is freely soluble in water (18.6 mg/mL), stable and well absorbed from the intestinal tract with a short elimination half-life of 3–4 hours.[164] These favorable properties combined with a low dose make MPH an ideal candidate for oral MR regardless of technologies applied.

The IR product (eg, Ritalin) that has been on the market since the 1950s is taken two or three times daily with rapid onset of action and demonstrated efficacy. In an attempt to offer more convenient administration and prolonged control of behavior, especially for school children for whom most prescriptions are written, several modified-release formulations have been developed with the objective of maintaining efficacy over the entire school day. This is of particular importance because it would eliminate the need for repeated administrations of methylphenidate, a Schedule II controlled substance while the patient is at school. An early MR product, for example, Ritalin SR, is a matrix tablet designed to maintain relatively flat plasma drug levels for the required treatment duration. However, the product did not provide equivalent efficacy to the multiple dosing of the IR product during the day due to the tolerance to the effects of the

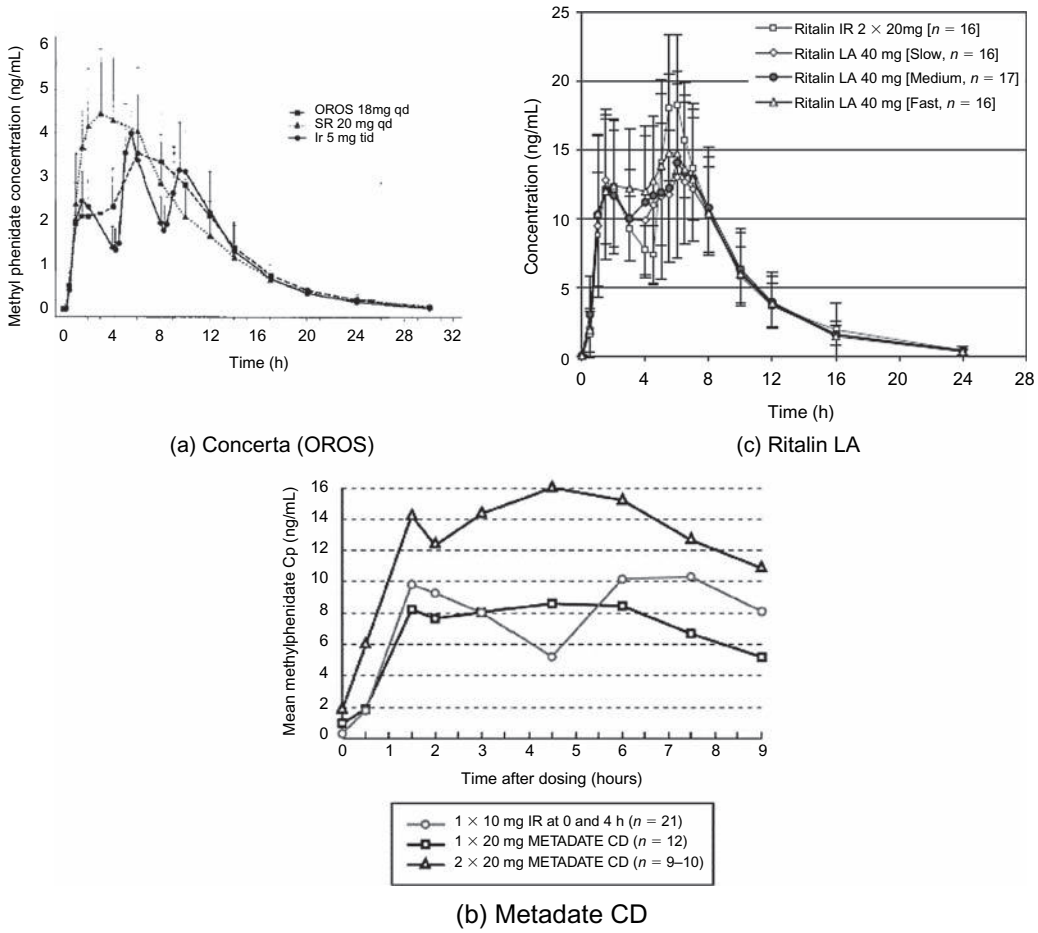

FIGURE 19.11 Plasma Concentration-time Profile of MPH after a Single Dose of MR and IR Formulations (All versus Ritalin SR tablet and/or IR tablet given 4 h apart). *Reprinted with permission: J Clin Pharmacol. 2000;40:379–388; Metadate® CD Package Insert, UCB, Inc.; Biopharm Drug Dispos 2004;25(2):91–8.*

drug discussed previously and a delayed onset of action.[165] Other similar ER matrix tablets include Metadate ER and Methylin ER. It was not until the 1990s when it was demonstrated that varying rate of drug input would be able to overcome the tolerance observed with the formulations that release the drug at nearly constant delivery rate. Subsequently, a new generation of once-daily MR products was developed that offer the equivalent efficacy of repeated administrations of IR MPH by altering the drug's input profile. The successful commercial products include (1) ER products generating biphasic release profiles for a rapid onset of action and a prolonged duration of action, such as Metadate CD capsules consisting of 30% IR and 70% coated ER beads and Concerta tablets consisting of an ER osmotic pump coated with IR component (Fig. 19.11a and b).[166,167] (2) Pulsatile release products that mimic PK performance of standard schedules of IR product, such as Ritalin LA capsules consisting of 50% IR and 50% DR beads that provide IR release 4 hours later (Fig. 19.11c).[168,169] This case study shows that all three types of ER technologies are equally effective in achieving a range of in vivo delivery performance when the molecule exhibits desirable characteristics suitable for MR design.

19.3.4.2 *Case study 2: clarithromycin*

The above example shows that favorable absorption characteristics combined with the rapid elimination of MPH make it possible to achieve the desired PK fluctuation using short pulsing intervals of drug input. To further evaluate the influence of drug's PK properties on the feasibility of oral pulsatile delivery, clarithromycin was selected based on its physicochemical and biopharmaceutics properties that are suitable for MR drug delivery.[170] It is a weak base with pK_a of 8.76 and solubility of 1.2 mg/mL at pH 6.8. It has a log$P$ of 2.69 and adequate stability in the intestinal tract. Its disposition parameters available from the literature indicate a terminal elimination rate constant of 0.115 hour^{-1}. PK simulation of the in vivo performance of the pulsatile release designs with varying pulsing intervals was performed by shifting the

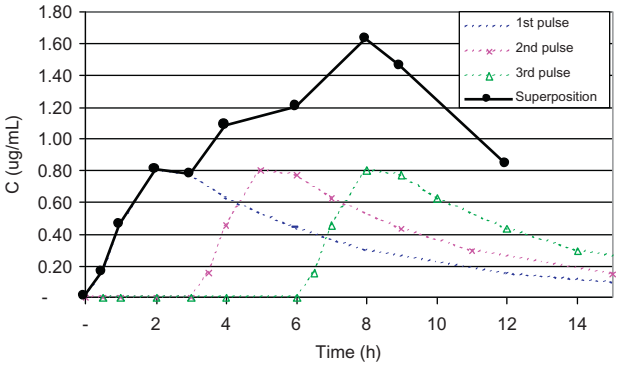

FIGURE 19.12 PK simulation of a pulsatile delivery design by superposition.

observed plasma profiles of a single dose study in humans using superposition principle. The basic assumptions for the simulation included (1) the formulation technology can deliver the exact pulses at predetermined time intervals and (2) the apparent absorption is uniform over the delivery duration with minimum impact of variable GI transit time, gut metabolism and release/absorption environment. An example illustrated in Fig. 19.12 shows that a design of three equally spaced pulses of equal doses over 6 hours hardly generated distinct peaks and troughs in plasma levels corresponding to the input variations. The fluctuations in plasma levels at steady state (not shown) were essentially nonexistent. Thus, the chance is very low for achieving multiple peaks/troughs at the biophase or site of drug action, which is the design objective.[171] It should be noted that this type of simulation represents the best-case scenario because the PK profile used for generating the profiles of the subsequent pulses resulted from absorption that occurs in the most favorable absorption environment in the upper intestinal tract. In reality, the second and third pulsing doses are expected to produce slower ascending plasma concentrations compared to the first pulse since they are absorbed in the distal ileum and/or large intestines. This case study illustrates that applying an in vitro MR design to obtaining a desired in vivo PK and clinical results requires the application of multidisciplinary knowledge and prospective evaluation of in vitro and in vivo outcomes before execution of the experiments. For pulsatile delivery, rapid clearance is essential to achieving distinct PK fluctuation resulting from pulses of shorter intervals. In addition to that, the influence of absorption window and inherently highly variable GI systems on performance of oral dosage forms should also be taken into consideration.

19.3.4.3 Case study 3: development compound A

A development compound in Phase III clinical trials is a neutral molecule with molecular weight of 236 and favorable log$P$ of 1.44.[2] It is stable and practically insoluble (170 μg/mL). The IR formulation requires a q.i.d. dosing regimen due to rapid elimination in humans ($t_{1/2} = 2.5$ hours). Based on the MEC of 1 μg/mL and a total daily dose of 2.4 g, PK simulation indicated that twice-daily administration would require an approximately 10 hours of in vivo input, suggesting at least 50% of the dose would be released/absorbed in the large intestine for a zero-order delivery system. However, regional absorption data were not available. To investigate technical feasibility of ER delivery, prototype hydrophilic matrix tablets and multiunit spherical hydrophobic matrix beads were designed as adult and pediatric dosage forms, respectively. Matrix systems were used because of the required high loading of an API with low solubility. In vitro studies showed apparent zero-order drug release from the matrix tablet due to the erosion-controlled mechanism. Drug release from the matrix beads more closely followed diffusion-controlled kinetics as a result of a combination of high surface area-to-volume ratio, short diffusion path-length and low driving force for drug release. Crossover PK studies of these formulations with varying release rates were conducted in healthy volunteers. The dosage forms were administered under a high-fat condition to increase gastric retention time. Evaluation of the plasma concentration-time profiles showed (1) decreasing release rates correspond to lower AUCs, (2) truncated absorption as indicated by the evident slope inflection of the semilog plot of the terminal phase occurred at approximately 5–6 hours post dosing. Interestingly, the average truncation time was delayed by about 1–2 hours for the matrix beads, suggesting a more favorable GI transit properties of multiparticulate dosage forms. Nevertheless, neither dosage form met the predetermined criteria of maintaining plasma levels above the MEC for approximately 12 hours. Concurrent evaluation of the metabolites showed that the absorption truncation was a result of degradation of the active compound by microflora present in the large intestine, which is consistent with the transit time of dosage forms in the upper GI tract. This case study shows that in vivo delivery window in the GI tract is determined by the inherent property of the drug molecule. Delivery technology is ineffective in overcoming feasibility obstacles when there is a large gap between the technology capability and required oral MR delivery need.

19.3.4.4 Case study 4: development compound B

A development compound in Phase II clinical trials is a polar molecule with molecular weight of 284, a pK_a of 8.3 and a log$D$ of −2.0 at pH 6.8. It is stable and highly soluble (> 0.8 g/mL) in the physiological pH range. Low permeability (Caco-2 $P_{app} = 0.27$ ×

10^{-6} cm/second) suggests it is likely a BCS class III compound. Phases I–II clinical studies used an IR formulation administered every 6 hours due to rapid clearance in humans ($t_{1/2} = 4$ hours). Based on the projected MEC of 10 μg/mL and a total dose of 6 mg, PK simulation indicated that twice-daily administration would require approximately 10 hours of in vivo input, suggesting a significant portion of the dose would be released and absorbed in the large intestine. A preliminary study for assessing the regional absorption in dogs via indwelling access ports to different regions of the intestinal tract showed that AUC values of ileum and colon delivery relative to that of jejunum were 0.94 and 0.67, respectively. In vitro drug release that follows square-root-of-time and near zero-order kinetics were obtained from matrix and ethylcellulose coated multiunit minitablets, respectively. However, a crossover single dose study of three ER formulations with decreasing release rate in healthy volunteers resulted in relative bioavailability values of 50%, 34%, and 29%, respectively. Truncated absorption was evident at approximately 4 hours post dosing under a fasting condition for all three ER formulations, indicating a lack of absorption in the lower bowel. The result of the dog regional absorption model was considered an outlier because an extensive database generated had demonstrated the predictive nature of the model. Combined analysis of drug properties, absorption mechanism and the physiological differences between human and the dog model suggests that the favorable absorption characteristics in the dog colon are likely a result of the leakier dog intestine that favors paracellular transport mechanism of a low dose, small polar molecule. This is consistent with the discussion of Section 1.3.2 and the results of a study that used the dog model for predicting colon permeability in humans. This study found that the relative bioavailability from administration to the colon of the dog correlated well with that of humans for model compounds of all four BCS classes except for atenolol, a hydrophilic small molecule. This case study illustrates the importance of understanding both the property and transport pathways of a compound in assessing in vivo absorption window for oral MR delivery.

19.3.4.5 Case study 5: oxybutynin HCl

Oxybutynin is an antispasmodic, anticholinergic agent indicated for the treatment of overactive bladder with symptoms of urge urinary incontinence, urgency, and frequency by relaxing bladder smooth muscle. It is a weak base with a pK_a of 9.87 and log$D$ of 1.83 at pH 7.3. Its hydrochloride salt is freely soluble in water (12 mg/mL), stable and well absorbed from the intestinal tract. These favorable properties combined with the low dose (5–15 mg/day) make it an ideal candidate for oral MR independent of technologies applied.

For over 20 years, use of IR dosage forms of oxybutynin has been limited by anticholinergic adverse events, such as dry mouth, difficulty in micturition, constipation, blurred vision, drowsiness, and dizziness. These side effects are dose-related and sometimes severe. Studies have indicated that oxybutynin metabolism mediated by the cytochrome P450 3A4 isozyme occurs primarily in the proximal GI tract and liver. Its primary active metabolite, *N*-desethyloxybutynin, is also responsible for much of the adverse effects. After administration of the IR formulation, *N*-desethyloxybutynin plasma levels may reach as much as six times that of the parent drug, substantially affecting the tolerability of the compound within the individual. For instance, in one population studied, after 6 months more than half of the patients had stopped taking the medication due to side effects. Another study estimate is that over 25% of patients who begin oxybutynin treatment may have to stop because of dry mouth.

Since the 1990s, ER products have been investigated and developed (eg, Ditropan XL, Cystrin CR tablets) to allow once-daily administration and prolonged control of symptoms. Clinical studies have shown that ER formulations not only consistently enhanced patient compliance and efficacy but also resulted in improved tolerability including significantly higher continuation rate due to marked reduction of moderate/severe dry mouth. The latter was attributed to substantially lower intestinal metabolism because a majority of the parent drug of the ER dosage form is delivered to the distal intestinal tract where metabolic enzyme activity in the gut wall is lower or absent. As a result, a substantial increase in bioavailability relative to the IR formulation was also imparted. More recently, to totally bypass presystemic metabolism, a 4-day transdermal patch (Oxytrol) was later successfully developed with tolerability profile similar to that of a placebo.[172–174] This example shows that understanding of a drug's disposition properties, biological and pharmacodynamic characteristics enable rational development of MR delivery strategy and design with maximized medical benefits.

19.3.4.6 Case study 6: phenylpropanolamine HCl in EOP

Phenylpropanolamine (PAA) is a sympathomimetic amine that shares structural similarities with amphetamine and ephedrine. The effects of PPA are largely the result of α-adrenergic agonist activity. Before its removal from the market after being around for almost 50 years, it was mainly sold in over-the-counter (OTC) preparations as decongestants or as appetite suppressants. Because of its association with increased risk of hemorrhagic stroke, FDA removed PPA from

OTC sales in 2005. Despite its current ban on human drug use, it is worthwhile to examine it from a historical perspective to illustrate the application of rational MR dosage form design principles to the development of the first osmotic oral dosage form containing PPA as an appetite suppressant in the early 1980s (Acutrim marketed by Ciba-Geigy). PPA is a weak base with a pK_a of 9.4 and a log$P$ of 0.67. Its hydrochloride salt is freely soluble in water and well-absorbed in the GI tract with over 60% bioavailability. It also exhibits linear pharmacokinetics in the dose range 25−100 mg with a plasma half-life of 2−3 hours. Because of its short half-life, an attempt was made to design a membrane-controlled drug delivery system to maintain a constant rate of drug delivery for once-a-day dosing rather than three times a day IR dosing to reduce the fluctuation of plasma levels. As reported by Good and Lee,[175] a desired steady-state plasma PPA concentration of 80 ng/mL was initially selected as the in vivo target (from the known minimum therapeutic plasma concentration range of 60−100 ng/mL) with the requirement that this steady-state level is attained as soon as possible after ingestion. Based on a one-compartment open model using the known pharmacokinetic parameters for PPA ($k_a = 1.58$, $k_e = 0.159$ & $V_D = 245.6$ L from oral solutions), a steady-state drug flux of 3.12 mg/hour from the delivery system was determined to be required to achieve this target steady-state plasma level, and an immediately available dose of 21.6 mg to be needed to quickly establish the desired steady-state level. An EOP for phenylpropanolamine-HCl was then designed to achieve these target levels taking into consideration of additional constraints that the total dose size is limited to 75 mg, and at least 90% of the total dose must be delivered within 24 hours. The final dosage form preserved most of the predicted properties except with some fine tuning, in which 20 mg of the drug is provided as an IR portion as a bolus coating on the EOP, the reservoir of 55 mg to be delivered through the orifice at a constant nominal rate of 3.5 mg/hour for 12.5 hours, and the remainder having a decreasing delivery rate as the excess solid drug in the core is being depleted. The in vitro dissolution profile for this EOP dosage form is compared with the predicted release profile in Fig. 19.13.

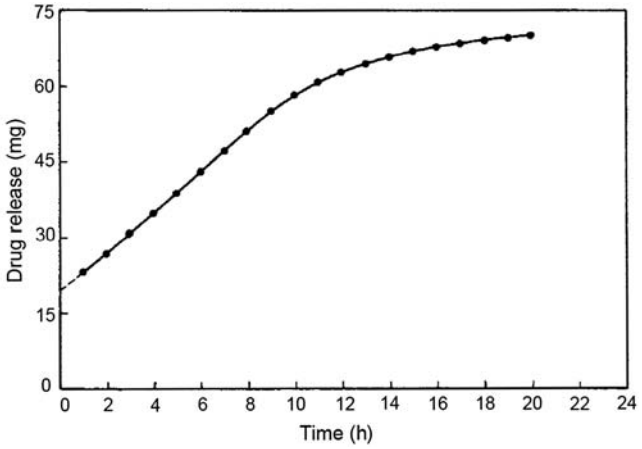

FIGURE 19.13 In vitro dissolution of PPA form EOP dosage containing a 20-mg bolus and 55-mg core. ●, experimental; −, predicted. *Figure adapted from W.R. Good and P.I. Lee. Membrane-controlled reservoir drug delivery systems. In: Langer RS, Wise DL, editors.* Medical applications of controlled release, *vol. I. Boca Raton, FL: CRC Press, Inc.; 1984. p. 1−39 (reproduced with permission from CRC Press, Inc. Copyright, 1984).*

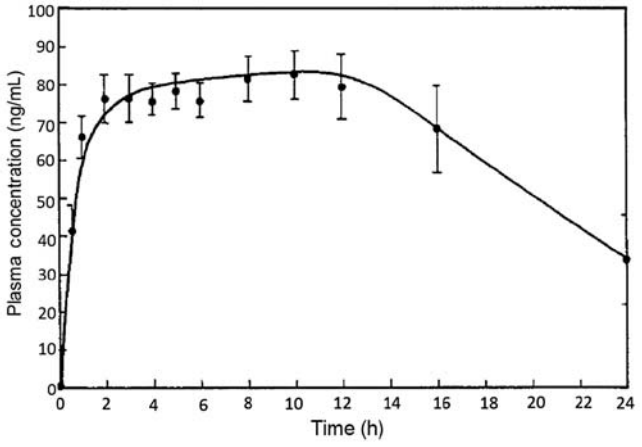

FIGURE 19.14 Comparison of plasma concentration profiles of unchanged PPA after a single dosing of an EOS dosage form containing a 20-mg bolus and 55-mg core ($n = 6$). ●, experimental; −, predicted. *Figure adapted from W.R. Good and P.I. Lee. Membrane-controlled reservoir drug delivery systems. In: Langer RS, Wise DL, editors.* Medical applications of controlled release, *vol. I. Boca Raton, FL: CRC Press, Inc.; 1984. p. 1−39 (reproduced with permission from CRC Press, Inc. Copyright, 1984).*

This EOP dosage form was subsequently tested in a pilot clinical study in six healthy subjects.[175] The resulting mean plasma concentration profile is shown in Fig. 19.14 together with that predicted from the known pharmacokinetic parameters. Additionally, the in vivo release profile deconvoluted from plasma data is compared with the in vitro dissolution profile in Fig. 19.15. It is clear from Figs. 19.14 and 19.15 that the agreement between the experimental data and that predicted from the pharmacokinetic analysis is excellent, particularly the indication of IVIVC in Fig. 19.15 further supports the usefulness of applying the rational design principles described here for a priori MR dosage form design.

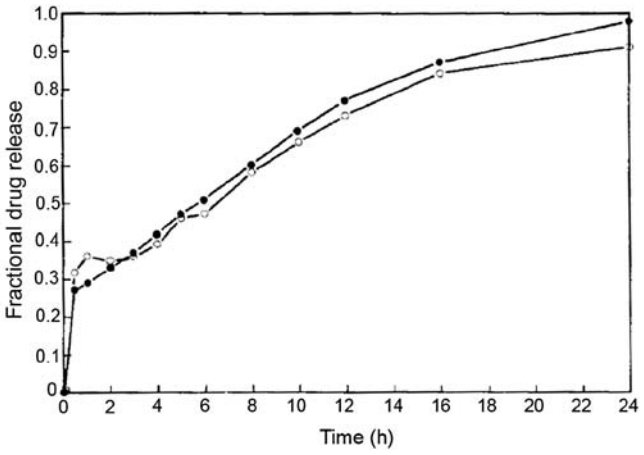

FIGURE 19.15 Comparison of in vitro release profile (○) deconvoluted from plasma data and in vitro dissolution profile (●) for an EOS dosage form containing a 20-mg bolus and 55-mg core. *Figure adapted from W.R. Good and P.I. Lee. Membrane-controlled reservoir drug delivery systems. In: Langer RS, Wise DL, editors.* Medical applications of controlled release*, vol. I. Boca Raton, FL: CRC Press, Inc.; 1984. p. 1–39 (reproduced with permission from CRC Press, Inc. Copyright, 1984).*

19.4 SUMMARY

The most important elements of utilizing MR drug delivery design to achieve desired clinical benefits include defining the clinical rationale and understanding the drug molecule. The success of designing a commercially viable MR dosage form depends on the physicochemical, biopharmaceutical, pharmacokinetic and biological properties of the drug candidate, rather than on a particular delivery technology. Today, almost all oral MR delivery needs can be addressed using at least one of the three broad types of well-established delivery technologies discussed in this chapter. However, there is no "one-size-fits-all" technology. It is more important to select a technology based on technical, practical, developmental, operational and commercial considerations because for many compounds with desirable properties, different "sizes" of technologies will fit "one" molecule.

20.1 INTRODUCTION

A pharmaceutical dosage form development program typically includes preformulation studies, analytical method development and validation, design, development, scale-up and optimization of formulation and manufacturing process, in vivo bioavailability and stability studies. This chapter focuses on transforming technology-based dosage form design into commercial drug products that meet patient requirements. The technology transformation process requires design and development of effective formulation and manufacturing process that assure consistent product quality and performance. In addition, it should also take into consideration regulatory requirements, manufacturability, process capability, robustness, efficiency and control, equipment, facility, capacity, development cost and time, environmental impact, and market dynamics, among others. For solid oral products, these considerations often have strong implications in developing a reliable dosage form and robust process to assure consistent product quality, manufacturability, and productivity, or in developing new formulation or manufacturing technologies for out-licensing.

A solid dosage form is a complex multicomponent heterogeneous solid system that is typically subject to mechanical stresses during its production. The majority of the components are organic compounds with a very wide range of physical, chemical, and mechanical properties, as opposed to the inorganic components, such as metals and solid solution alloys used in the high-tech and aerospace industries. Combining these different solid materials via pharmaceutical processing to form a product is usually accompanied by changes in density and volumes of coexisting solid phases, which can produce large stresses and strains, alter thermodynamic properties of the materials and affect mechanical and chemical equilibrium within and between solid phases and ultimately the structure of the material. As a result, product quality, performance, and/or processability usually depend on chemical, physical or mechanical properties, and compatibility of these materials. The complex interactions involved are difficult to understand as engineering and scientific models are unavailable to accurately determine or predict structures and processing behavior of physically combined solid powders containing multiple sources of stress, including thermal, mechanical, and gravitational. Moreover, the multistage batch process commonly used in pharmaceutical manufacturing makes it more difficult to determine the process controls and outputs due to the presence of a multitude of interacting material, formulation and process variables. For instance, the governing equations of the dynamic flow, stochastic mixing and bonding of solid particles with diverse morphology, and the density and surface properties in the presence or absence of a liquid are undefined or poorly understood in the context of high-shear wet granulation, drying, or blending, limiting the ability to reliably model these unit operations. Furthermore, a product's ultimate test is its intended clinical in vivo performance in patients. However, universal in vitro biopharmaceutics tools or models are unattainable for evaluating and predicting possible impact of dosage form attributes and process parameters on the bioavailability performance of various drug products due to complexity of

DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00020-0

biological systems. Hence, developing pharmaceutical products and ensuring consistent quality are both complex and challenging.

The present state of the art of linking product quality to the desired biological performance is to consider and test in vivo performance in the design and development phases of the drug product and process using rational approaches and predictive models where possible on a product-by-product basis. Therefore, for a product developed under a set of conditions, even a small incremental change/adjustment of the composition, processing steps or conditions, or equipment design, often requires an investment of extensive resource and time to generate experimental data to demonstrate that the product quality remains unchanged. This is partly caused by a lack of understanding of, and inability to predict, the possible impact of such change because of the complexity mentioned earlier of solid dosage forms. It is also affected by the conservative philosophy and policy adopted by both the sponsors and regulators since the pharmaceutical industry is one of the most regulated industries that generally requires very exacting quality standards. However, these challenges should not deter scientists and engineers from applying principles of multidisciplinary science and a systematic approach in developing solid dosage forms.

20.2 DEVELOPMENT OF SOLID DOSAGE FORMS

Because of the complexity of solid dosage forms and limitations and challenges in applying First-Principles approach in the pharmaceutical industry, the strategies, and approaches that have been, and continue to be, utilized in product and process development vary significantly from company to company, and even across project teams within the same organization. Some groups tend to rely more heavily on empirical studies and prior knowledge that can get the job done, albeit often inefficiently. Some work with past experiences or "gut feeling" that may or may not be valid or applicable. Others take a more rational approach by systematically applying applicable scientific and engineering principles to development. In general, these practices can be divided into three broad categories summarized in Table 20.1.

Today, it is widely recognized and accepted that adopting a rational development approach with increased level of scientific understanding can result in many benefits for patients, industry, and regulatory agencies. Advantages can include a higher level of assurance of product quality and performance, more robust manufacturing process and process control, increased cost savings and improved efficiency through minimized product rejects or recalls, reduced regulatory burden and enhanced opportunities for the first cycle product approval. It also helps to identify risks, contributes to the development of risk management strategy, streamlines postapproval changes, and offers opportunities for postapproval continuous improvement. In fact, this is the approach that the Food and Drug Administration (FDA) has been advocating as part of its ongoing quality initiative, "cGMPs for the 21st Century," first announced in 2002[1] to enhance and modernize pharmaceutical product quality and manufacturing. Over the past decade, the FDA has collaborated with the International Conference on Harmonization (ICH) and the industry in defining a shared vision, key concepts and general framework of the initiative. Among the critical concepts is pharmaceutical quality by design (QbD).[2] It is a systematic scientific approach to product and process design and development to ensure consistent product quality through understanding and controlling material, formulation, and manufacturing variables. In 2006, the principles of QbD were incorporated in the ICH Q8 (Pharmaceutical Development), Q9 (Quality Risk Management), and Q10 (Quality Risk Management)[3] guidance which has since been updated. In 2007, Office of Generic Drugs (OGD) of FDA officially started implementation of a question-based review (QbR) developed for its chemistry, manufacturing, and control (CMC) evaluation of the abbreviated new drug applications (ANDAs). The QbR is a science and risk-based quality assessment system that incorporates key concepts and elements of QbD. It requires applicants to use the common technical document (CTD) framework to address a series of prescriptive questions by applying QbD principles.[4]

In November 2014, the FDA issued a Manual of Policies and Procedures (MAPP 5015.10) that covers chemistry review of QbR submissions of drug and product applications (NDAs, ANDAs, and DMFs). More recently, FDA's quality initiative was further enhanced by forming a new office, the Office of Pharmaceutical Quality (OPQ) that streamlines processes of monitoring quality throughout the product lifecycle for both innovator and generic drug products. To assure consistent product quality and prevent quality failures that may potentially lead to drug recalls or shortages, product and process understanding is not only expected during the design and development stage but also in the postapproval improvements and commercial manufacturing stage. Specifically, the product and process should be designed to meet product critical quality attributes (CQAs) consistently. Product standards should be captured in scientifically sound and clinically relevant CQAs and specifications; the impact of starting materials and process parameters on product quality and manufacturing should

TABLE 20.1 Comparison of Approach to Solid Product Development

Approach	Characteristics	Likely outcome
Trial-and-error	Paying limited or inadequate attention to properties of raw materials and composition, and relevant scientific principles Trying out various experiments or hypotheses in various directions until a desired outcome is obtained through testing with certain degree of reliability Primarily relying on past experience and intuition: for example, copying "recipe" from one product to another; Using "shotgun" approach	Disconnect between results and underlying mechanism or principle Data generated can be overwhelming or sometimes misleading due to experiments with confounding variables Considerable demand for time and resources, resulting in poor efficiency Inconsistent or nonrobust product and process that can lead to quality failures during development and/or commercial manufacturing
Semiempirical	Using best guessed "trial-and-error" approach and/or observational studies based on prior knowledge and statistical principles with little or limited mechanistic understanding Combining experience with analysis of abundant data to identify trends or build empirical or semiempirical relationships	Results can be practically useful, but may be unreliable or misleading in certain cases due to improper design, limitations of experiments and/or lack of a thorough scrutiny of data and various formulation/process variables involved Higher demand for time and resources for data generation Lower level of assurance of consistent product quality and reliable process
Rational	Characterizing raw materials, formulation, process, and possible interactions Integrating formulation/process design and development by utilizing multidisciplinary scientific and engineering principles and applying a systematic approach Using knowledge-based, probabilistic, and best-guess approach appropriately through combining prior knowledge and data with basic understanding in experimental design	Enhanced understanding of how material properties, process variables, and product attributes relate to product performance, as well as the interplays between biological system and the drug substance or dosage form Increased efficiency and streamlined continual improvement Higher level of assurance for consistent quality of drug product and commercial manufacturing; minimized product rejects or recalls

be understood; critical sources of material and process variation should be identified and controlled; and the manufacturing should be continually monitored with quantitative quality metrics and updated to allow for consistent quality over time. To achieve these objectives, the adoption of the principles of rational product development is essential.

20.2.1 Rational development approach

Product realization process (ISO 9001:2008 Section 7) typically involves product identification, concept development, product, and process design and development including scale-up of the manufacturing process, and commercial production. Rational development of product and process requires integrated consideration of three essential areas: (1) preformulation studies, (2) formulation and process investigation, and (3) in vivo performance evaluation to develop a high quality dosage form with predefined quality attributes and drug delivery performance. The key to attaining a consistently high quality product and robust manufacturing process is to adopt proactively a systematic approach through applying multiple sciences and engineering principles, such as pharmaceutical sciences, chemistry, biological sciences, engineering, mathematics, and statistics as shown in Fig. 20.1.

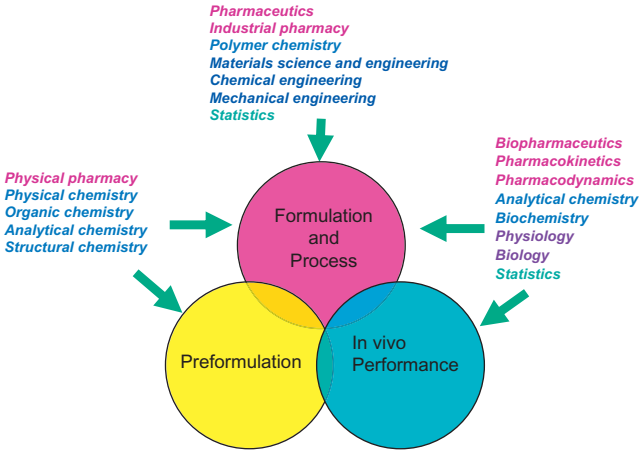

FIGURE 20.1 Multidisciplinary principles important to rational product development.

Development of a solid dosage form starts with defining a quality target product profile (QTPP) based on the clinical and patient needs. In addition to the desired in vivo performance, other important criteria include strength, type, size, drug loading, quality and performance attributes of the dosage form, as well as manufacturing and commercial requirements. The second step is to characterize properties of the active pharmaceutical ingredient (API) and excipients, including their physicochemical, biopharmaceutical,

mechanical properties, and compatibility, which has been discussed in detail in the relevant chapters of this book. Once the quality characteristics of the drug substance and excipients are determined, formulation and process feasibility and options should be evaluated. There are often more than one processing technologies that can be used to produce a solid dosage form with predefined product quality and performance attributes. The best possible manufacturing approach should be selected based on technical, economical, and practical considerations, including compatibility with the components, maturity of technologies, time-to-market, development cost, process complexity, scalability, manufacturability, robustness, commercial production efficiency, and cost along with available equipment, facility, capacity, and footprint. One of the most critical elements in developing a solid dosage form is to ensure a connection between the design of the formulation and manufacturing process. In addition to API, a formulation typically consists of essential excipients called for by a specific dosage form design, such as filler, binder, disintegrant, lubricant, release modifier, physical or chemical stabilizer, processing aid, etc. Selection of these components and a particular process train requires an integrated consideration of material properties, functionality and processing characteristics in connection with properties of a specific API, unit operations and the interactions between them. Such a concurrent development approach not only can result in quality products with consistent performance and robust process, but also help ensure optimum manufacturability and productivity, minimize or avoid potential material-related processing issues or process-related product quality or performance problems.

20.2.2 Integrated formulation and process design

The realization process of pharmaceutical products has undergone a number of significant changes over the last decade. Many of them are brought about, in large part, by the FDA's quality and patient-focused initiatives[1] and increased globalization. A successful dosage form development program requires specific knowledge at three critical stages: (1) designing product and process based on clearly defined requirements, (2) demonstrating a product design that meets product requirements, and (3) producing a reliable product reproducibly within established quality, cost, resource, and schedule targets. To create and efficiently manufacture reliable and consistent high-quality products, it is crucial to use an integrated concurrent approach in conceptualizing, designing, and developing products. This is done by incorporating a broad set of requirements, objectives, and constraints of the product life cycle, including patient needs, product quality, reliability, manufacturing, materials, cost, supply, environment, and safety aspects. In developing pharmaceutical products, drug properties, required dose, and mode of drug delivery typically dictate the choice of the dosage form and determine the overall approach to formulation and process design. Hence, understanding the characteristics and natural variability of formulation components, the process characteristics, and their interplay is the foundation for product development and commercial manufacturing. Specifically, knowledge of API physicochemical, mechanical, and biopharmaceutical properties is essential to the concurrent product and process design because it provides a basis for optimizing product quality and performance and ultimately maximizes the chances of developing stable, safe, effective, and commercially viable dosage forms of consistent quality. In parallel, understanding of the excipient properties and control are often equally important.

20.2.2.1 Material property consideration

For solid oral dosage forms, API properties often have a significant influence on the product's CQAs including purity, uniformity, drug release, and stability, as well as manufacturability. Therefore, it is important to take into account API material properties when designing a drug product and its manufacturing process. The basic concepts and techniques of physicochemical, biopharmaceutical, and mechanical characterization useful in the rational product development have been discussed in the relevant chapters of this book. In this section, we will discuss in details (1) how API physicochemical, powder/bulk, and biopharmaceutical properties can affect drug product quality and performance with a focus on dissolution/bioavailability, stability, and manufacturability and (2) what options are available to overcome challenges posed by such properties? In addition, we will also discuss how to practically integrate API material properties into the development of a fit-for-purpose formulation during various phases of clinical trials in order to balance risk, cost, speed, and quality of new drug development.

20.2.2.1.1 Physicochemical properties

API physicochemical properties can have a significant impact on stability, manufacturability, and in vivo performance of drug products. Therefore, designing formulation and manufacturing process should always start with understanding properties such as solubility, permeability, dissolution rate, ionization constant/pKa, melting point, polymorphism, and crystallinity.

The aqueous solubility of a drug molecule is one of the most critical factors that influence the rate of drug absorption after oral administration. The fundamental aspects of solubility can be found in chapter "Solubility of Pharmaceutical Solids." In general, high aqueous solubility is desired for maximizing the driving force in intestinal drug absorption. The majority of pharmaceutical compounds are absorbed via a passive diffusion process in the small intestine. For drugs that have high permeability, transport across the intestinal membrane is usually fast. However, low aqueous solubility or slow dissolution rate may limit the rate and extent of drug absorption. To enhance oral absorption of poorly soluble drugs, different formulation approaches have been developed and will be described in detail later. Permeability is another important factor that influences the rate and extent of drug absorption following oral administration. There are essentially three mechanisms by which a drug molecule may cross the intestinal membrane: passive diffusion, uptake transporter-mediated transport, and vesicular transport. These are discussed in details in chapter "Oral Absorption Basics: Pathways and Physicochemical and Biological Factors Affecting Absorption." Permeability is a composite of diffusion coefficient, partition coefficient, and membrane thickness. There are practically no formulation options available to effectively and consistently increase local permeability of poorly permeable drugs (such as BCS Class III/IV compounds) in the gastrointestinal (GI) tract. Certain excipients may alter membrane permeability in the in vitro setting, however, their use and effectiveness has not been proven in vivo mainly due to limited quantity present in a dosage form, need for synchronized transit with the API and effect of dilution in the dynamic environment of the intestinal tract. If a local enhancer is found to be effective, it will need first to address potential safety concerns before its regulatory clearance. Dissolution rate (see chapter: "Fundamental of Diffusion and Dissolution") is proportional to both solubility and surface area of API powder. Dissolution rate and free drug concentration in solution may be altered by formulation design to achieve the intended therapeutic exposure. For example, API particle size reduction, use of high energy solid phase, and/or selection of soluble excipients may be used to increase dissolution/solubility rate of less soluble drugs. In other applications, a modified release (MR) dosage form may be designed to reduce dosing frequency and/or achieve more prolonged and consistent exposure with the maintenance of the blood concentration within a specific range. These formulation technologies are described elsewhere in this book.

The majority of small molecules are either weak acids or bases. The ionization (or dissociation) constant pKa has a significant influence on solubility, permeability, dissolution rate, and stability. The total aqueous solubility of a weak acid or base drug is the sum of the concentrations of ionized and unionized species. Therefore, it is heavily influenced by both pKa and pH, which, in turn, could affect drug absorption in the GI tract, where the pH is known to be highly variable. For example, a weak acid with a pKa of 4 has low solubility in the stomach (pH 1−3), but the solubility dramatically increases as the drug enters small intestine where pH ranges from 5.5 to 7. Using a soluble salt helps rapid dissolution of the drug. However, one area of concern of using a soluble salt is that it may precipitate in vivo with abrupt pH changes. For instance, a soluble salt of a weak base with a pKa of 8 could rapidly dissolve in the stomach, but as the drug enters the small intestine, precipitation of the free base could occur. Another important physicochemical property is the melting point, which can be viewed as a measure of "energy" required to overcome attractive forces that "hold a crystal lattice" together.

Crystal lattices with greater molecular symmetry and the presence of hydrogen bonds significantly increase intermolecular interactions in the solid state, resulting in higher melting point. From a product development point of view, melting point is useful information because compounds with a higher melting point tend to have a lower solubility and hence slower dissolution rate. Melting point may also be used to assess and quantify the presence of impurities and the interconversion of solid forms.[5] From a manufacturing perspective, melting points below about 60°C are potentially problematic. Temperatures in conventional solid manufacturing such as fluid bed drying, tablet compression, and coating can exceed 50−60°C. During the milling process, hot spots in the milling chamber may have much higher temperatures. On the other hand, an API (or excipient) with a high melting temperature can be challenging for using melt processes to perform granulation or form molecular dispersion in polymers (eg, melt extrusion or congealing). Thus, the selection of manufacturing process should take into consideration the melting point of both API and excipients.

Polymorphism (see chapter: "Crystalline and Amorphous Solids") can have profound implications in formulation development because polymorphs may exhibit significantly different solubility, dissolution rate, compactibility, hygroscopicity, physical, and chemical stability. A metastable form often has higher solubility and dissolution rate, which may lead to higher oral bioavailability, such as chloramphenicol palmitate.[6] Although the use of a more soluble polymorph may provide higher bioavailability, it is important to keep in mind that a metastable polymorph (higher energy form) tends to convert to a

thermodynamically more stable form over time. The conversion between solid forms is affected by multiple factors, such as solvent, relative humidity, temperature and mechanical agitation. Conversion from a metastable form to a stable form could reduce dissolution rate and lead to inconsistent product quality. Therefore it is often preferred to select the thermodynamically most stable polymorph for development. It is also important to note that polymorph conversion may also occur during manufacturing processing (such as milling, wet or melt granulation, drying) even when a stable crystal form is chosen as a starting material for development.[7] Therefore, one should assess the risk of process induced transformation for any API with multiple solid forms.

Over the past decade, higher apparent solubility and faster dissolution rate of amorphous solids have increasingly been utilized to enhance delivery of insoluble APIs. The basic principles and formulation aspects of utilizing amorphous solids are discussed in details in chapters "Crystalline and Amorphous Solids", "Oral Formulations for Preclinical Studies: Principle, Design, and Development Considerations" and "Rational Design for Amorphous Solid Dispersions." For this type of product, crystallinity is a critical factor to consider during formulation and process development. The degree of crystallinity refers to the ratio of crystalline to amorphous content in a powder. Because the amorphous solid is thermodynamically unstable, it will eventually crystallize to a more stable, and potentially less soluble solid form when given sufficient time and under the right conditions. Generally, the rate of crystallization depends on many factors, such as temperature, relative humidity, processing history, and excipients, etc. To ensure consistent product quality and performance, it is essential to control batch to batch variation in amorphous content with no or minimized crystallinity. In practice, polymers are usually used in the formulation to inhibit crystallization within the desired product shelf-life. It is a rule of thumb that an amorphous solid dispersion (ASD) has reasonable physical stability when it is stored 50°C below its glass transition temperature. Hence, selection of the polymers, manufacturing process, packaging, and storage condition needs to be based on product and process understanding.

20.2.2.1.2 Powder and bulk properties

API powder properties can have an impact on bioavailability, stability, and processing of solid oral dosage forms. In particular, powder properties that include particle size distribution, particle shape, density, porosity, surface area, cohesiveness, and hygroscopicity may affect powder bulk handling properties such as compaction and flow characteristics which may, in turn, impact manufacturability of tablet dosage forms, particularly for formulation containing high percentage of API.[8] For example, to obtain consistent tablet weight and content uniformity during tablet compression on a high speed rotary tablet press, sufficient flow is necessary for discharging a formulation blend from the hopper to the feed frame and distributing it into a die cavity. In addition, an adequate compaction property of the powder blend is also required to form a strong and physically stable compact. Hence, understanding and controlling lot-to-lot variability of key API bulk properties are essential to ensure quality product can be produced consistently.

API particle size is known to affect drug dissolution of poorly soluble drugs. For a low dose (typically 10 mg dose strength or below) direct compression formulation, a small particle size is often needed to overcome manufacturing challenges related to achieving acceptable content uniformity of the API in the formulated blend.[9,10] Particle size, shape and surface properties of a solid also affect powder flow properties. APIs that are needle-like crystals often have poor filtration and flow properties causing issues with both the API isolation and drug product manufacture. Milling of long needles can enhance flow and improve content uniformity; however, excessively small particles tend to be cohesive, which can exacerbate flow problems, resulting in large tablet weight variation during compression for formulations with medium or high drug loading. For instance, the flow of small particles (eg, less than 10 μm) through an orifice is usually restricted because the cohesive forces between the particles are of the same magnitude as gravitational forces.[11] In addition, particle size may also influence compaction properties of pharmaceutical powders.[12] Furthermore, it should be noted that certain physical properties of starting materials can be significantly altered after processing. The bulk properties of a formulation blend at the end of the manufacturing process may be different from the additive properties of its constituents at the beginning of the process. Therefore, it is important to characterize API, excipients as well as formulation blends to gain a better understanding of how powder properties may affect content uniformity, dissolution, and manufacturability.

The density of a solid can affect flow, mixing, and compressibility. Since pharmaceutical particles are often of different sizes and typically have a morphology containing microscopic cracks, internal pores, and capillary spaces, three types of density are used to characterize pharmaceutical powders—true density, bulk density, and tapped density. True density is defined as the density of the material itself, exclusive of any voids or interparticle pores larger than molecular or atomic dimensions in the crystal lattice. Bulk density, which takes into account of macroscopic

interparticle space, is defined as powder mass divided by its bulk volume without any tapping. Tapped density is measured after a powder sample is subjected to mechanically tapping. True density is needed to calculate solid fraction of a compact, which is needed to analyze compactibility and compressibility of powder blends. Because many types of product processing equipment have a fixed volume, bulk density is often useful in calculating the batch size. Bulk density and tapped density can also be used to calculate compressibility index, an empirical tool to assess flow properties. A free flowing powder usually has a low compressibility index as its bulk density is close to the tapped density because the interparticle forces are not as significant as those of the poor flowing powder. As a general rule of thumb, a compressibility index greater than 30% indicates poor powder flow. Porosity not only affects compactability, but also density. It can be estimated from powder density and is an important attribute of pharmaceutical granules.

Granule porosity is typically determined by mercury porosimetry where mercury can fill inter- and intraparticle voids under pressure except the internal pores of the particles. Granules with a low porosity will be harder to compress than the same granules with a high porosity. Porosity may also affect product dissolution rate. It is believed that porous granules dissolve faster than dense granules since the pores allow water to penetrate granules more readily. Processing conditions can have a strong influence on the porosity of a powder. For example, fluid-bed granulation (FBG) is known to produce smaller and more porous granules than high shear wet granulation. Hence, this process is sometimes preferred for certain compounds/formulations that require enhanced dissolution or compressibility.

Hygroscopicity is a material's ability to adsorb and retain water molecules from the surrounding environment. Many drug substances and excipients, particularly water-soluble salts or amorphous API, readily adsorb atmospheric moisture, which can influence physical and chemical stability, flowability, and compatibility of drug products. For example, moisture facilitates conversion between anhydrous and hydrate forms, with potential adverse effects on the solubility and the physical stability of a solid. Some deliquescent materials can adsorb sufficient water to completely dissolve once a critical equilibrium atmospheric humidity (RHCE) is exceeded. As for chemical stability, there is a large body of evidence showing that the adsorbed water can facilitate solid-state reactions through increasing the molecular mobility of the reactants, or itself can participate in the hydrolysis as a reacting species.[13] For moisture sensitive compounds such as aspirin, hydrolysis can occur during the aqueous film coating process of tablets.[14] For moisture labile drugs, it is clearly important to control the amount of water/water activity to which API is exposed during manufacturing and storage.

In certain cases, moisture can have a positive impact on a drug product. For example, it may improve powder flow, and uniformity of the bulk density, as water helps dissipate powder's triboelectrostatic charge. Appropriate amounts of moisture may also facilitate compaction through increased bonding caused by enhanced plastic deformation.[15] Therefore, understanding hygroscopic properties of formulation components is essential in making rational decisions related to formulation, process, packaging, storage, shipping, and handling.

Understanding the mechanical and flow properties of APIs is important in the successful design of formulation and manufacturing process, especially for high drug load formulations where API properties dominate the bulk properties of the formulation. Mechanical properties of a material describe the relationship between applied force and the resulting deformation and are hence critical to understanding powder processing for tableting. In manufacturing tablet dosage forms, the compaction properties of a pharmaceutical powder are typically influenced by many factors, such as particle size, shape, crystal lattice arrangement, interparticle bonding, porosity, surface charge and moisture. A material can be characterized by its compressibility and compactibility. While compressibility is the ability of the powder to deform under pressure, compactibility is the ability to form mechanically strong compacts. Various methods have been used to evaluate the compaction properties with different advantages and limitations. The most common method is to produce a coherent compact by applying a compressive pressure (stress) to a powder, and analyze its tensile strength/hardness. Compaction characteristics of a material or blend including deformation mechanism, yield pressure, Young's modulus, tabletability, compactibility, and compressibility, etc., are usually obtained by varying the rate and extent of the applied stress (compression profile). Similar to compaction properties, flow properties are also influenced by many material properties including particle size and size distribution, particle shape, interparticle interaction, moisture, consolidation stress applied to powder. Characterization of API flow properties is essential in product and process development, as well as selection of solid handling equipment, to eliminate flow problems (eg, flow obstructions, segregation, irregular flow, and flooding) during processing. There are a variety of methods for characterizing flow properties: angle of repose, compressibility index, Hausner ratio, and flow through an orifice are often determined

to provide a rank-order estimation of powder flow properties. More sophisticated instruments, such as shear cells, can be used to characterize powder flow for quantitative performance predictions and engineering design calculations, such as estimation of the hopper angles required for mass flow. Details of powder compaction and flow characterization can be found in chapters "Particle, Powder, and Compact Characterization" and "Process Development, Optimization, and Scale-Up: Providing Reliable Powder Flow and Product Uniformity."

In developing solid drug products, understanding API powder and bulk properties, and the ability to control such properties, is critical for anticipating and preventing potential manufacturing issues, particularly for high and low drug load formulations. For drug substances with undesirable bulk properties, rational formulation and manufacturing process design, and/or API particle engineering can be utilized to overcome processing challenges. In the formulation design, suitable excipients can be selected to accommodate poor compaction and flow properties of the API. As a general rule of thumb, plastically deforming excipients with excellent compactibility should be used if the API is brittle or elastic. For example, microcrystalline cellulose is often used as a compression aid to accommodate poor API compaction properties. For API with poor flow properties, excipients such as glidant or direct compression grade fillers can be used to enhance flow properties of the formulation. Flow and compaction properties of a powder blend can also be improved by selecting an appropriate manufacturing process such as wet, melt, or dry granulation. Granulation technology may also be used to improve API content uniformity for low dose formulation (eg, the drug loading is $<5\%$ w/w). For API that has acceptable bulk properties, direct compression process may be preferred due to its simplicity and low cost. However, direct compression process is more susceptible to lot to lot variation of API and excipient material properties than the granulation processes. Selection of the manufacturing process also strongly depends on the type of dosage forms to be manufactured. For compounds that require enabling formulation technology (such as ASDs) to enhance oral bioavailability, a hot melt extrusion, or spray drying process may be required to generate amorphous API.

Finally, API powder properties may be modified by particle engineering technologies during the API isolation process because particle morphology, surface properties and bulk density are known to be dependent on crystallization process parameters such as crystallization solvents, cooling rate, particle properties of seeds, and seeding amount. In addition, API bulk properties may be further modified by altering the dryer design and drying process. As discussed previously, a needle-shape API can result in potential filtration, flow, and compaction challenges. Through API particle engineering it might be possible to design the API with suitable crystal morphology to enhance powder properties for downstream manufacturing by varying crystallization and API finishing conditions.

20.2.2.1.3 Biopharmaceutical properties

Biopharmaceutical properties of API can be characterized by two complementary well-known classification systems: the biopharmaceutics classification system (BCS) and the biopharmaceutics drug disposition classification system (BDDCS). BCS classifies drugs into four categories based on its solubility and permeability.[16] It provides a general framework to identify potential absorption barriers related to solubility and permeability and a useful guide for the rational design of immediate release (IR) dosage forms. BDDCS uses the same solubility criteria but differs in the criteria for permeability for different purposes.[17] It allows prediction of in vivo pharmacokinetic performance of drug products from measurements of permeability and solubility, including the effects of absorptive and efflux transporters and food on oral drug absorption. The importance of understanding biopharmaceutical properties of API in developing immediate-release solid products is discussed in the following sections based on drug's solubility and permeability. Considerations of biopharmaceutical properties in the design of MR dosage forms are discussed in chapter "Rational Design of Oral Modified-Release Drug Delivery Systems."

BCS class I and III compounds BCS class I compounds are expected to dissolve quickly in the GI fluid and readily cross the intestinal wall through the passive diffusion process due to high solubility and permeability. To achieve rapid and complete oral absorption, a conventional IR dosage form should be fit for purpose. Formulation and process development aspects of IR tablet and capsule formulations can be found in a series of reference books edited by Lieberman et al.[18] Although achieving fast dissolution of BCS class I drugs is usually less challenging, chemical stability, and/or manufacturing problems discussed in previous sections remain possible depending on the physicochemical and mechanical properties of the API involved and the required drug loading. Similarly, most of the potential challenges in developing IR oral dosage forms for BCS class III compounds are less likely to be related to dissolution due to its high solubility. Attempts to improve bioavailability through altering intestinal permeability using excipients at the amounts used in orally administered

formulations are ineffective due to the dynamic environment of the GI tract involving a very large surface area and effect of dilution or they are impractical because of safety concerns. Hence, the most effective way to improve oral absorption for BCS class III compounds is to increase membrane permeability through chemical modification of the API (eg, prodrugs) which is outside the scope of this chapter. Therefore, the objective of IR formulation design for this class of API is typical to make the drug available rapidly such that absorption is determined by the inherent biological properties of the API. It should be noted that certain excipients may negatively affect absorption of soluble drugs that exhibit site-dependent absorption characteristics due to their effects on GI motility and/or the transit time of drugs in the gut. For example, sorbitol has been shown to decrease ranitidine absorption. It was attributed to an increased GI fluid volume from the osmotic load of sorbitol, resulting in enhanced GI motility and reduced ranitidine transit time in the small intestine which is a primary absorption site for the drug.[19] Similar effects were observed with mannitol (an isomer of sorbitol) and polyethylene glycol (PEG) 400, All of these excipients are osmotically active at the amounts relevant to those used in pharmaceutical formulations.[20]

BCS class II and IV compounds The most common challenges posed by BCS class II and IV compounds are related to solubility or dissolution rate limited oral absorption when developing IR products. To overcome the dissolution problems, various approaches have been utilized and shown to be effective, including use of a more soluble salt, particle size reduction, improved wetting, ASD, complexation, and use of precipitation inhibitor. Forming a soluble salt is most commonly used since solubility, and dissolution rate of a salt can be many folds higher than that of the free acid or free base. Before selecting an appropriate salt for product development, solubility, dissolution rate, and other properties, such as physical and chemical stability, hygroscopicity, crystallinity, polymorphism, ease of synthesis, and toxicity, need to be thoroughly evaluated. However, it should be pointed out that use of a soluble salt for development has its limitations because it is not feasible for neutral compounds and it may be difficult to form stable salts of very weak bases or acids. For certain compounds, conversion from a salt to the less soluble free acid or free base can occur both in vitro and in vivo with pH changes. For example, a hydrochloride salt of a free base that rapidly dissolves at the low pH in the stomach may reach supersaturation on its total equilibrium solubility of ionized and unionized species. Upon emptying from the stomach, the free base may precipitate due to pH change, resulting in decreased bioavailability. In such cases, precipitation inhibitors may be used to prevent conversion from a salt to its free base, thereby, significantly improving the bioavailability of rapidly dissolving salts. Fundamental principles of this phenomenon and formulation approach to prevent precipitation can be found in chapter "Oral Formulations for Preclinical Studies: Principle, Design, and Development Considerations." Particle size reduction is also a common approach for enhancing the dissolution rate of poorly soluble drugs via increasing surface area. In most cases, API powders are micronized using cutter, hammer, roller, and fluid energy mills, which can reduce the particle size down to 1−100 μm.[21] Smaller particle size in the range of 200 nm to 1 μm may be achieved using a wet ball mill, with the milling chamber filled with grinding media and drug suspension. When particle sizes are decreased to nanometer size, the solubility may also be increased due to the Kelvin effect.[22] Therefore, use of nanoparticles can lead to an increase in both the dissolution rate and solubility for poorly soluble drugs. However, there are certain disadvantages associated with milling. Heat and mechanical impact generated during the milling process may cause physical and/or chemical instability. In addition, hydrophobic particles tend to agglomerate during size reduction, resulting in decreased effective surface area that can negate the benefit of size reduction. Excipients such as surfactants, sugars, polymers, or other excipients are often added to a formulation during processing to minimize agglomeration and improve wetting. Similar to salts, increasing dissolution in the stomach using a nanoparticle approach needs to be carefully considered to avoid the supersaturated state produced being susceptible to small changes in pH, which can cause rapid precipitation of the API. This can lead to unexpectedly low exposure with high inter- and intrasubject variability.

ASD have been successfully used to enhance oral bioavailability in an increasing number of development and commercial products of BCS Class II and IV drugs, such as, griseofulvin-PEG-dispersion marketed by Wander as Gris-PEG, Nabilone-PVP dispersion by Lilly as Cesamet, Ritonavir-copovidone dispersion by AbbVie as Norvir tablets, Vemurafanib-HPMCAS coprecipitation by Roche as Zelboraf tablets, Ivacaftor-HPMCAS dispersion by Vertex as Kalydecor tablets. Complexation using complexing agents (eg, cyclodextrin, CD) can also be used to solubilize drugs. The three-dimensional (3D) structure of the CD provides a hydrophobic cavity, which can take a drug molecule into the cavity to form an inclusion complex. The hydrophilic exterior of the CD allows the complex to interact favorably with aqueous environment. In order for the drug to be absorbed into systemic circulation, it

has to be dissociated from the drug–CD complex first. The kinetics of inclusion complex formation and dissociation between a CD and drug molecule is very rapid.[23] Dilution and competitive displacement are two major mechanisms that contribute to complex formation and dissociation process. CDs can be used to solubilize, stabilize, taste mask, and ameliorate the irritancy and toxicity of drug molecules in solid oral dosage forms.[24–26] Disadvantages associated with cyclodextrin include the potential safety concerns, high cost, and inability to accommodate high dose strength. Lipid-based drug delivery systems such as self-emulsifying drug delivery systems (SEDDS) that utilize the solubilization power of lipids and surfactants have also been used to improve oral bioavailability. It is evident that most of the formulation technologies for BCS class II and IV compounds aim to maximize the driving force for passive diffusion across the intestinal membrane through increasing drug concentration at the sites of absorption. In addition, enhanced oral absorption may also be partly a result of improved apparent permeability by saturating efflux transporters due to higher local drug concentration because most BCS Class IV drugs are substrates of efflux transporters.[17]

It should also be noted that precipitation in vivo may occur in certain cases if the drug concentration becomes supersaturated, leading to slower absorption.[27,28] The rate of drug precipitation/crystallization generally increases with supersaturation ratio (ie, the ratio of drug concentration to its solubility) and decreases with viscosity of the crystallization medium. Certain polymers such as hydroxypropyl methylcellulose (HPMC) and polyvinylporrolidone (PVP) are known to prolong the supersaturation of certain compounds. For example, PVP has been used to inhibit crystallization of sulfathiazole,[29] phenytoin,[30] oestratiol,[31] and hydrocortisone acetate.[32,33] Cellulose polymers such as HPMC have been used to stabilize the super-saturation of nifedipine,[34] albendazole,[35] hydrocortisone acetate,[36] and ibuprofen.[37] HPMC was also demonstrated to inhibit the precipitation of PNU-91325 from the supersaturable cosolvent (PEG 400 solution containing 20 mg/g HPMC) both in vitro and in vivo.[38] This had led to a fivefold increase in oral bioavailability of PNU-91325 compared to the neat PEG 400 formulation. It had been suggested that mechanisms of the crystallization inhibition might involve increased viscosity of crystallization medium, creating a steric barrier to drug molecules, adsorption to the crystals by the polymers, and/or through specific intermolecular interactions such as hydrogen bonding.[39–41] Recent studies have demonstrated that Van der Waals and hydrophobic interactions between the polymers and API play a major role in crystallization inhibition, which is discussed in more detail in chapter "Oral Formulations for Preclinical Studies: Principle, Design, and Development Considerations."

In summary, each of these approaches for improving solubility and dissolution has its pros and cons. For instance, particle agglomeration during or post size reduction can decrease effective surface area available for dissolution as discussed earlier. Physical instability is usually a major concern for ASD systems while achieving chemical stability in lipid systems can often be challenging. Complexation is incapable of providing supersaturation for increased driving force. Furthermore, in addition to solubility and permeability, many other factors are also known to influence oral absorption (see chapters: "Oral Absorption Basics: Pathways and Physicochemical and Biological Factors Affecting Absorption" and "Oral Drug Absorption: Evaluation and Prediction"). For example, chemical or enzymatic degradation in the lumen can reduce the bioavailability of certain compounds such as acid-labile compounds or proteins and peptides. Presystemic metabolism and active secretion by efflux mechanism can alter oral bioavailability, whereas uptake transporter-mediated transport may play a role in the absorption of poorly soluble or poorly permeable drugs. Many of these challenges are drug- and product-specific and thus should be evaluated based on the integrated understanding of the biopharmaceutical and physicochemical properties and required doses of individual drugs. No single formulation technology can be a solution for all.

20.2.2.2 *Consideration of drug properties in developing a "fit-for-purpose" formulation*

The approach of "fit-for-purpose" formulation development often differs for drug products of new chemical entity (NCE), generic and over-the-counter drugs. This section will focus on how one may integrate API properties into developing a fit-for-purpose formulation to support development of oral solid dosage forms containing NCEs. Development of NCEs is known to be complex, costly and time-consuming with low success rate. Many drug candidates fail to reach market due to safety, efficacy, and business reasons. In addition, the pharmaceutical industry is under increasing pressure to increase its efficiency and productivity. Therefore, it is important to design a fit-for-purpose formulation which fulfills its intended use in supporting various phases of clinical trials without requiring extensive development effort and resources. Table 20.2 summarizes objectives of clinical trials, formulation requirement, and material property consideration for developing a "fit-for-purpose" formulation.

TABLE 20.2 Development of a Fit-for-Purpose Dosage Form

Clinical trial	Objectives and characteristics	Formulation requirement	Material property consideration
Phase I	*Objectives:* To evaluate safety and tolerability. Identify a maximum tolerated dose *Characteristics:* Wide dose range Short duration (typically less than 1 month) Small number of subjects (20−100) Success rate: about 44%	Simple formulations offering a wide range of flexibility and adequate exposure to enable identification of maximum tolerated dose/establishment of sufficient safety coverage. When simple formulations cannot achieve adequate exposure, enabling technologies, such as amorphous solid dispersion or lipid-based formulations should be used to meet the primary objective of Phase I study Typically not requiring extensive stability or large scale manufacturability Speed to clinic with minimal development effort	API for reconstitution or API-in-capsule: Characterize pH-solubility profile, pKa, dissolution rate, precipitation tendency, target particle size (for dissolution rate purpose), solid form (if needed). API stability may be sufficient for shelf-life determination Tablet/capsule formulation: Additional considerations include particle size distribution needed for meeting content uniformity, solid form, minimum drug product stability needed to cover manufacturing, distribution, and duration of clinical trials
Phase II	*Objectives:* To evaluate safety and efficacy; Phase IIA: Proof of concept or mechanism Phase IIB: Identify optimal dose range for treatment *Characteristics:* 100−300 patients Duration: several months to 1−2 years Success rate: about 20%	Phase IIA: Formulations similar to Phase I or commercially viable dosage form Phase IIB: Commercially viable dosage form Sufficient stability and manufacturability required	Identify key challenges presented by API properties; Design formulation and process to overcome such challenges Understand impact of API, excipients, processing conditions, and their interactions on product quality attributes
Phase III clinical trials	*Objectives:* Pivotal studies to definitively assess efficacy and long-term safety of drug treatment compare to the current gold standard *Characteristics:* 300−3000 or more patients Duration: Several years Success rate: about 65%	Commercial dosage form and manufacturing process highly desired Stability with $\geq$2-year shelf life required Scalable and robust manufacturing process	Identify critical material attributes of API and excipients and establish control strategy. Justify formulation design based on knowledge of physicochemical, biopharmaceutical, powder properties of API and intended functionality of excipients. Identify critical process parameters and establish control strategy Understand interaction between formulation and processing conditions

Phase I clinical trials typically include a single rising dose (SRD) study, followed by a multiple rising dose (MRD) study in a small group of healthy volunteers. These trials usually encompass a very wide dose range, starting at a subtherapeutic dose, and gradually rising to a maximally tolerated dose. Therefore, formulations used in Phase I clinical trials not only need to have flexibility to cover a wide dose range but also need to achieve adequate exposure levels suitable for establishing a maximum tolerated dose. Phase I clinical trials usually are short in duration (typically $<$1 month) and involve a small batch size of clinical supply. Therefore, extensive stability data and scalable manufacturing process are not important for developing Phase I clinical trial formulations. In addition, many new drug development programs are terminated following Phase I clinical trials due to safety issues.[42] Hence, when feasible (eg, BCS class I and III compounds), a simple formulation such as API in bottle, powder in a bottle and API in a capsule can be used to enable speed to Phase I studies while conserving API and related development resources. One of the main challenges facing formulation development for Phase I studies is to achieve sufficiently high in vivo exposure, especially for drugs with limited solubility, since the higher dose in an SRD study can be many fold higher than the estimated therapeutic dose. Thus, it is crucial to understand how drug properties, such as solubility, dissolution rate and stability, may limit oral absorption. When simple or conventional formulation approaches are unlikely to provide sufficient exposure at significantly elevated dose (typically BCS II and IV

compounds), technologies for enhancing oral absorption discussed in previous sections are required, such as size reduction, lipid formulation, and ASDs. Selection of the formulation approach for a specific API needs to be based on consideration of physicochemical, mechanical, and biopharmaceutical properties of the API and their possible impact on bioavailability and manufacturing discussed previously.

Phase II clinical trials are typically designed to evaluate the short-term therapeutic effect of a new drug in patients and can often be divided into Phase IIA pilot studies and Phase IIB well-controlled studies. Phase IIA studies usually focus on proving the mechanism of action, often called "proof-of-concept" or "proof-of-mechanism" trials, whereas Phase IIB studies evaluate optimal dosage range for the treatment. Comparing to Phase I studies, Phase II trials are usually larger (including 100−300 patients) and last much longer (ranging from several months to 2 years) depending on the drug and intended indications. Therefore, formulations for a Phase II trial require a longer shelf-life and acceptable manufacturability. In most cases, Phase I formulations with adequate stability can still be used in Phase IIA studies to speed clinical trial start-up times considering the high attrition rate (about 80%) due to efficacy and/or safety issues.[42] Once proof of clinical concept is obtained, significant effort and resource are often required to develop a commercially viable dosage form for Phase IIB studies and beyond. Hence, the API properties need to be more extensively characterized for integration into designing and developing product and manufacturing process.

Phase III clinical trials are pivotal studies designed to demonstrate the potential advantages of the new therapy over other therapies already on the market. Safety and efficacy of the new therapy are studied over a longer period of time (eg, up to several years) and in more patients enrolled with less restrictive eligibility criteria (300−3000 or more depending upon the disease/medical condition studied). Phase III trial formulations and the corresponding manufacturing process need to be the same as those intended for commercial products because any formulation or manufacturing changes during or after Phase III clinical trials require justification that the product performance is unchanged, supported by appropriate in vitro testing, stability, and bioequivalence studies. In most cases, development of Phase III clinical trial formulations is a continuation of the abovementioned Phase IIB formulation. Systematic studies are usually carried out to enhance product and process understanding through identification and evaluation of critical material attributes (CMAs) of the key components including API and critical process parameters (CPPs) that are important to the development of a product and its manufacturing process. To ensure drug product quality can be met consistently during commercial production, a greater understanding of the possible impact of material and process variables and their interactions is needed to help define a control strategy of raw materials, formulation, manufacturing process, and container closure systems. The information and knowledge gained from these development studies and manufacturing experience provide scientific understanding to support the establishment of the design space, specifications, and manufacturing controls.

20.2.2.3 Product quality and performance considerations

The most important CQAs of oral solid dosage forms include drug release and stability. The former is the essential step rendering drug molecules available for absorption that would determine product safety and efficacy while the latter directly indicates whether a drug product can maintain its quality throughout shelf-life. Thus, understanding of the effects of formulation and process and their interplay on drug release and stability is the key to designing and developing a safe, effective, and stable dosage form. In developing both IR and MR oral products, formulation, and process design should be focused on (1) drug properties that influence drug release, stability, and/or processing behaviors (eg, chemical compatibility, flow, uniformity, and compaction) depending on the amount of the drug substance in each dosage unit (drug loading) and (2) potential impact of a particular process train on the physical and chemical characteristics of the drug substance that may affect product quality and performance. Specific delivery technology, formulation components, and product manufacturing processes are usually selected once a particular mode of drug release (eg, IR or MR) and type of dosage form (eg, tablet, capsule, or multiparticulates) are defined.

IR dosage forms are formulated to make drug molecules rapidly available for absorption following oral administration while MR counterparts are typically designed by altering drug-release characteristics in terms of time course and/or location to accomplish therapeutic or convenience objectives. Oral MR dosage forms include both delayed release (DR) and extended release (ER) drug products. For IR dosage forms containing soluble drugs, there are often multiple conventional formulation and process options available to meet the drug release need. The selection of the excipients and process can be made based on functional and practical considerations. However, use of excipients and process without adequate understanding can sometimes lead to issues associated with drug release

or manufacture. For example, tablet hardening on storage can lead to a change in disintegration and dissolution as a result of solid phase transition of the API or certain excipients induced by a particular processing operation (eg, milling or wetting or melting) as discussed in chapter "Crystalline and Amorphous Solids." In designing products containing insoluble drugs requiring enabling delivery technology, such as amorphous dispersions (addressed in chapter: "Rational Design for Amorphous Solid Dispersions"), an integrated formulation and process design is crucial because consistent solubility enhancement and physical stability is highly dependent not only on the API property and loading, but also on a proper combination of functional excipients and specific process technology. DR dosage forms are designed to release a drug at a later time during transit down the GI tract other than immediately following oral administration. The need for a DR delivery usually varies with the physicochemical and/or biopharmaceutical properties of drug molecules. For instance, certain drug molecules that are acid-labile require a delay of drug release in the acidic stomach to protect the drug until it reaches the small intestine. Some drugs intended for treating local conditions in the lower GI tract (eg, colitis) are also designed as a DR dosage form that requires more significant delay of drug release. In most cases, DR dosage forms are manufactured by coating single unit or multiparticulates using various enteric polymers which provide pH-dependent solubility behavior and control drug release in various parts of the GI tract. Depending on drug properties and the design objective (e.g., the extent of release delay), different polymers or amounts may be used. With regard to coating dosage forms, a pan coater is often chosen for single-unit tablets while Wurster coating in a fluidized bed is used for multiparticulates dosage forms. For ER products, different types of delivery technologies have been widely utilized over the years, such as reservoir systems, osmotic pumps, and hydrophilic matrix tablets. Each technology has its unique features, advantages and disadvantages. Drug properties and required dose usually play an important role in selecting appropriate ER technologies, their formulation composition and corresponding manufacturing process. In addition, assessing technical feasibility and designing an ER dosage form should be based on an understanding of permeability and solubility of the drug substance. These properties are particularly relevant for certain drugs for which the rate and extent of absorption differ in various regions of the GI tract, especially if absorption in the colon is relatively limited and slow. This can compromise delivery, as can reduced solubility of the drug substance further down the colon where fluid levels are low, and surface area is significantly decreased. More discussion related to rational design of ER dosage forms are available in detail in chapter "Rational Design of Oral Modified-Release Drug Delivery Systems."

Chemical stability is a critical product quality attribute that is directly linked to potency, purity, efficacy, and safety of a drug product throughout its shelf-life. Data required for assessing the stability of IR and MR solid products are usually similar to the design principles and manufacturing processes of both types of dosage forms are fundamentally the same. For most drug substances, the stability of the drug product depends not only on properties of the drug but also on formulation and process design. The first step in product design should be to understand the intrinsic stability of the drug molecule and its degradation mechanisms. Common drug degradation pathways include thermolytic (eg, hydrolysis), oxidative, and photolytic degradation.[8] Among them, photolytic degradation can usually be mitigated by reducing or eliminating light exposure using a coating or appropriate container closure systems. The most common drug degradation pathway is hydrolysis, followed by oxidation.[8] Fundamental aspects of drug degradation can be found in chapter "Drug Stability and Degradation Studies." Drug degradation is more complex in a formulated product, a multicomponent heterogeneous system. Some commonly used excipients are known to interact directly with certain drug molecules.[8] A well-known example is the Maillard reaction between a primary or sometimes secondary amine and a reducing sugar (eg, lactose/glucose). However, many interactions between drug molecules and excipients are nonspecific and not well understood, which may sometimes lead to significant stability problems in the formulation while the drug substance alone is stable. In such cases, the extent of degradation is often linked to drug loading rather than the absolute amount of drug. More significant degradation is usually associated with lower drug loading in the formulation due to a higher excipient-to-drug ratio. Drug degradation may also be enhanced due to the change of microenvironment pH created by the excipients present in the formulation. In addition, excipients can be a source of various impurities such as peroxide and metal ions which have been linked to increased drug oxidation. It is known that peroxides exist in a number of excipients such as povidone, crospovidone, PEG, polysorbates, and other modified excipients containing polyoxyethylene moieties.[43] To reduce or minimize the impact of excipients on product quality, it is necessary to assess excipient quality attributes and variability across different suppliers and different lots of the same vendor. On the other hand, certain excipient properties can also be utilized to improve product stability based on

the understanding of API's degradation pathways. For instance, bupropion hydrochloride, an antidepressant, was found to undergo extensive degradation in an alkaline environment based on a preformulation investigation. To develop an acceptable ER dosage form, weak acids or salts of strong acids were incorporated in the formulation (eg, ascorbic acid, malic acid, sodium metabisulfate, L-cystine hydrochloride, glycine hydrochloride).[44,45] These stabilizers serve to provide an acidic environment surrounding the active drug that minimizes its degradation. More recently, Oberegger et al. discovered a more stable bupropion composition for ER dosage forms through salt selection experiments.[46] However, use of highly acidic excipients may lead to degradation of the rate-controlling polymer, compromising product stability as discussed in Chapter 19, Rational Design of Oral Modified-Release Drug Delivery Systems. Thus, rational selection of formulation components based on the understanding of properties of drug and excipient as well as and their interaction is imperative.

Physical stability refers to changes in the physical characteristics of the formulation ingredients of a drug product such as phase transformation of the drug or excipients. Typical phase transformations include polymorphic conversion, hydration/dehydration, crystallization/amorphization, salt-to-free form conversion, and other mechanisms. Because the physical, chemical, and mechanical properties may differ significantly among various solid forms, these phase transformations can potentially alter the quality attributes and processing behaviors of a drug product. For example, partial or complete phase transformation may occur during processing operations[12] resulting in increased levels of crystal defects or formation of amorphous phase, which can be detrimental to chemical stability. Therefore, design of a manufacturing process should be based on the understanding of properties of drug substance and its interplay with each unit operation.

In practice, the degradation susceptibility of a drug molecule can often be predicted to a large extent from the knowledge of the drug, its molecular structure, past experience, and theoretical calculations. Thus, the formulation and process should be designed to resolve or control chemical or physical instability problems through understanding of the drug substance. For example, to minimize hydrolysis, control of moisture and microenvironment pH in the formulation, incorporation of desiccants in the container closure system, or selection of a dry manufacturing process may be considered during the product design. To mitigate oxidative degradation, an antioxidant and oxygen scavenger may be incorporated into a formulation or container closure system. To avoid or control process-induced phase transition that may affect product quality, proper selection of the unit operation or ingredient(s) that inhibit phase changes may be considered. Ideally, the solid form and appropriate excipients should be selected to reduce or minimize degradation such that no additional stability control strategies are needed in the formulation, processing, and packaging.

20.2.2.4 *Manufacturing considerations*

To ensure safe and effective products that are produced at a high level of quality, rational product and process design and commercial manufacturing all play an essential role. Despite significantly improved product quality and advances in the product development as a result of the quality-by-design initiatives over the past decade, quality issues in the pharmaceutical industry are unfortunate occurrences that have resulted in recalls, withdrawals, unprecedented drug shortages, or even risk to patients. Many of these problems have been related to manufacturing quality issues. In a recent report, the Government Accountability Office (GAO) found that approximately 40% of drug shortages resulted from quality concerns, with shortages continuing to rise in recent years.[47] Therefore, there is a clear need for enhanced understanding of the impact of manufacturing on product quality as well as the influence of product and process design for commercial production.

The production related quality or manufacturing problems encountered in the industry can sometimes be attributed to disconnects between the development and manufacturing organizations where consideration for the requirements of the next group is given a lower priority in an "over the wall" paradigm. For instance, a product development function may declare a product design "finished" once it meets the predetermined requirements for this part of an organization. Typically, these requirements focus on product quality attributes and delivery performance while neglecting other considerations, such as manufacturability, process reliability, and robustness, which can lead to inefficiency and quality issues in commercial production due to inadequate material and/or process controls or improper product and/or process design. In general, a problem encountered at the design or early development stage that is not understood and addressed will often cascade and become magnified through the subsequent development and production phases, resulting in increases in cost, timeline, and even degradations in product performance and quality. Hence, effective product development should go beyond the traditional steps of acquiring and implementing product and process design technology. It needs to consider and design patient requirements into the product while ensuring that both the manufacturing plant and the suppliers have the capability to effectively produce the product.

For a predefined QTPP, a product can be designed in different ways. A rational product development program should aim to optimize the product and process design with the production system by taking into consideration manufacturability, reliability, and robustness, manufacturing equipment, processes, capability, capacity, experience and expertise, material handling systems and supplies, among others.

The key to the success of such an integrated program hinges on the ability to obtain knowledge for making sound decisions to enable effective transition to the next phase. To avoid problems with serious ramifications later during scale-up or after product approval, it is important to adopt a knowledge-based approach by ensuring the right level of knowledge at each key decision point. To ensure that manufacturing considerations are taken into account earlier, when costs to anticipate and identify problems and make product and/or process design changes are significantly lower, it is crucial to start with the end in mind and to use concurrent scientific and engineering principles to capture design and manufacturing knowledge and conduct risk assessment with a proactive rather than a reactive focus. In particular, a key measure of manufacturability is whether the critical manufacturing processes and key properties of materials are in control and product reliability is achievable. This knowledge can facilitate informed decisions to develop a product by taking steps to ensure the product and process design is stabilized early so product performance and manufacturability can be demonstrated before production. For example, achieving consistent dissolution performance of a coated ER dosage form during scale-up or upon storage is often challenging. If product quality standard and process control are defined in the development phase without adequate understanding of formulation behavior, critical properties and variability of the rate-controlling polymers and critical process controls, there is a risk that products being transferred to production could only be made to work at the pilot scale by highly skilled technicians. But they could not be manufactured to meet quality specifications at commercial scale, or might need to rely on a "use test" for individual batches to pass dissolution specifications. In designing a tablet product made using direct compression process, basic studies of segregation tendency and compaction properties of various formulation blends are often carried out in the laboratory for the risk assessment associated with content uniformity and/or compression. However, it is more important to start formulation and process design by first understanding inherent properties of the API and available excipients, their interactions with one another and with the chosen unit operations and the anticipated effects of scale change. It is equally important to assess natural variations of critical material and process variables, how they may impact quality, manufacturability and the ability to control at the production scale. This type of knowledge not only can help guide formulation design, but also facilitate a sound decision to change the manufacturing process if the selected formulation and process design is found to be too sensitive to tolerate expected variations of critical variables of key components, process parameters, and/or equipment in the commercial production.

In the current patient-focused quality, manufacturing and regulatory environment, integrated product and process design for both functionality and manufacturability based on product and process understanding is critical to the development of high quality, highly functional products that can be effectively manufactured. A sound product and process design should balance product quality with design effort and ability to compensate for uncertainty in the raw materials, manufacturing, and testing. Process robustness and reliability activities should start at the earliest stages of product and process design and be integrated into the overall product development cycle. It should also continue throughout the life of the product. Although it may sometimes require additional effort early in the development process, the integration of product and process design through science and technology and improved business practices will result in a more reliable and manufacturable product to better meet patient needs, a quicker and smoother transition to manufacturing, a higher production efficiency and a lower total product life cycle cost.

20.2.2.5 Selection of dosage form and production method

Dosage form development involves design and development of a product with a predefined QTPP and manufacturing process. The most common solid dosage forms are single or multiunit tablets or capsules manufactured using various established processes and unit operations. The general aspects of these dosage forms, related technologies, process development, and in-process control (IPC) have been extensively addressed[18,48] and also discussed in details in the relevant chapters of this book. In general, processes for tablet manufacture include direct compression, wet granulation (high and low shear or twin-screw extrusion), dry granulation (eg, roller compaction, slugging), and melt granulation or thermoplastic pelletizing (eg, high shear, fluid bed, melt-extrusion, spray-congealing). Processes for producing round solid beads encompass extrusion-spheronization, drug layering of nonpareil seeds, spray-granulation, powder layering, spray-drying, and spray-congealing. Conventional compression processes are also utilized to prepare mini-tablets using either small conventional tooling or

multihead tooling (eg, ≤ 3 mm) depending on the tablet size and throughput considerations. Coating of tablets or beads is most often carried out in a pan coater or fluid-bed technology depending on the nature of the coating substrate (eg, size, tensile strength). Coating by compression (tablet-in-tablet) requires special compression machines. When a more sophisticated process is required for products of increased complexity, for example, multilayered tablets, compression coating, mixed beads, and/or mini-tablets, emphasis should be placed on the increased process and product understanding throughout development lifecycle to ensure successful development from small to commercial scale.

In the product design phase, often there is more than one delivery technology, formulation approach, or production method that is suitable for developing a viable product with predetermined quality and performance for a specific API. Rational selection of a dosage form and associated drug delivery technology, formulation, and manufacturing process needs to be based on a concurrent and integrated evaluation of a multitude of factors discussed in the previous sections, such as API characteristics, material properties, processing operations and their interaction, variations, process robustness, efficiency, and cost. Also, the use of conventional manufacturing processes and equipment is highly preferred whenever feasible.

20.2.3 Product and process understanding

A sound dosage form design provides manufacturers with a quality product and helps to ensure manufacturability and optimum productivity. Ideally, physicochemical and mechanical transformation processes of the raw materials that ultimately result in the desired product should be based on a mechanistic understanding of the materials and processing operations. However, the diversity and complexity of pharmaceutical ingredients, combined with the unit operation paradigm utilized in pharmaceutical manufacturing, usually make a thorough understanding difficult. In many cases, knowledge gained appears to be material- and equipment-specific (dependent on machine design, geometry, model, manufacturer, etc.), making it challenging to develop universal models for direct application to different scales, processes, and products. Nevertheless, it is both important and possible to overcome these obstacles and develop consistent, high-quality product and robust manufacturing process through the understanding of the API, formulation, process, sources of variability, and risks to product quality. The most important element in achieving a high level of product and process understanding is to utilize the scientific knowledge discussed in the previous sections and apply a systematic approach through a combination of design of experiments (DOEs), studies that lead to scientific understanding, engineering principles, empirical, semi-empirical, and mechanistic models where possible. Specifically, in the product development process, selection of an appropriate delivery technology, composition, and corresponding process option should be based on a comprehensive analysis of information of (1) target product characteristics (required dose, release mode, type of dosage form, etc.); (2) physicochemical, mechanical, and biopharmaceutical properties of the API; (3) formulation technology and level of complexity; (4) processing technology and associated operations, equipment, and sophistication of production; (5) raw material attributes, inherent variability, and potential interactions (eg, drug-excipient, excipient-excipient); and (6) interrelation between materials and unit operations. This type of information integration can be used to anticipate and evaluate the possible impact of formulation on processing or vice versa, including how product characteristics may dictate process choice or how processing operations may limit formulation selection. It is also required for assessing influence of formulation/processing on in vitro and in vivo performance. Examples have been provided in the previous sections to illustrate the importance of understanding API properties to achieve product performance and ensure quality. Many other examples of adopting a holistic approach to the development process can be found throughout this book. For instance, in manufacturing tablets, components present in high percentages (eg, drug or polymer) in the formulation often merit an increased level of scrutiny and quality control because they often influence or even dominate the processing behavior of an individual unit operation, such as fluidization, granulation, blending, or compaction. Assessment of compressibility of a tablet formulation requires characterization of the deformation and bonding properties of the major components and relationships with compression parameters (force, turret speed/dwell time, precompression), and moisture content for predominantly plastically deformed materials. In drug layering processes, low process efficiency resulting from drug–polymer interactions can be resolved more effectively by replacing the interacting excipient when compared with the attempt to increase efficiency via optimizing processing conditions.

In developing and manufacturing MR dosage forms, understanding and controlling critical properties and the natural lot-to-lot variability of rate-controlling materials within or outside the supplier's specifications are often necessary to minimize their potential impact on processing, drug release and/or in vivo performance. In recent years, the potential implication of solid phase change during processing is another area

that received increased attention.[7] For example, solid phase transition from the stable crystalline to the less stable amorphous drug caused by processing conditions can directly lead to chemical instability of the product.[49] Tablet hardening with age may adversely affect the disintegration and dissolution rate during storage.[50] Depending on the material properties and processing conditions, the change of tablet hardness may be attributed to recrystallization of a physically stable phase from a small portion of the metastable or amorphous form of either the drug substance or excipient (eg, mannitol) generated during processing. It should be noted that this type of phase transition is often a function of material characteristics, composition, type and processing condition of a specific unit operation. Its impact on dissolution may also depend on product design and associated dissolution mechanism. Through characterization of the materials and their interaction with the dosage form and process, the solid phase changes can be anticipated and avoided if they are undesirable. They may also be controlled and utilized to enhance product performance (eg, dissolution).[7]

In the process of applying a systematic approach to the concurrent design of products and processes, one of the most commonly employed tools is DOEs in addition to the use of prior knowledge. DOE is a structured, organized method for determining the relationship between factors (Xs) affecting a process and the output of the process (Y). For pharmaceutical processes with measurable inputs and outputs, it can be used to guide the optimal selection of inputs and analysis of results in parameter design, problem solving, and robustness study. Its basic concepts are available in the Experimental Design section of a free electronic textbook: StatSoft at http://www.statsoft.com/Textbook/Experimental-Design. The fundamental principles, techniques, and applications of DOE can be found in many books written on this subject.[51] In pharmaceutical development and manufacturing, appropriate application of DOE has proven valuable in maximizing information gained with minimum resources, identifying critical factors among a multitude of variables, solving problems in a complex system consisting of many confounding factors, defining, optimizing, and controlling product and process variables.[52–56] In fact, DOE is so widely applied in today's pharmaceutical research and development (R&D) and operations that there may be a perception that running experiments using DOE is equivalent to product and processing understanding. This, in part, is a result of the historical successes of DOE across multiple industries, and partly due to a lack of adequate understanding of the intricacies and pitfalls of designing and executing such experiments in the study of complex pharmaceutical systems and their performance in the multivariate environment and/or highly variable clinical settings. For example, understanding the measurement precisions of inputs versus those of outputs and the need for repeat observations, identifying confounding factors are not trivial, while putting together a DOE design table is a very simple task as all of the well-known classes of standard designs can be generated automatically by software once the number and nature of input variables and the responses are defined. It is important to point out that an incorrectly or improperly designed DOE not only can result in wasted resources and time but often generate data that are confusing or misleading. Some of the common problems associated with DOE experiments in dosage form development or investigation include (1) choosing the inappropriate design, variables and, in particular, their ranges; (2) running uncontrolled experiments due to obliviousness of confounding factors; (3) generating unreliable or inconclusive data resulting from inadequate repeat measurement, sample size, or lack of understanding of the signal-to-noise ratio (SNR). Therefore, it is imperative to gain a clear understanding of the study factors and responses, variability, possible confounding and interacting factors, analytical variation before selecting appropriate input and responses, the range of investigation, and experimental design. More specifically, when choosing and implementing an experimental design, it is vital to first acquire a basic knowledge of the studied system and utilize multidisciplinary principles and expertise (eg, pharmaceutics, chemistry, engineering, statistics, among others) for identifying test variables and defining levels. Moreover, knowledge of the difference between control and noise factors is also critical. In particular, it is very important to carefully select a small number of experiments under controlled conditions and take into account the following interrelated steps:

1. Define an objective to the investigation, for example, identify important variables or find an optimum.
2. Determine the design variables that will be controlled and their levels or ranges of variation, as well as variables that will be fixed.
3. Determine the response variables that will be measured to describe the outcome and examine their precision.
4. Among the available standard designs, choose the one that is compatible with the objective, number of design variables and precision of measurements.

It should be emphasized that DOE design is, in most cases, a strategy to gather empirical knowledge, that is, knowledge based on the analysis of

experimental data and not on theoretical models. Thus, it is mainly useful for investigating a phenomenon, not the underlying mechanistic cause of a problem. Thus, use of experimental design strategy in conjunction with the application of the scientific and engineering principles, techniques, and practices presented throughout this book is essential to the effective and efficient development of robust product and process from laboratory to production scales.

20.2.4 Process scale-up and optimization

Following the completion of formulation and process design, essential steps required for final product commercialization include process scale-up and optimization. Process scale-up is referred to as the process transfer from small scale (laboratory scale or pilot scale) to a larger scale (pilot scale and/or production scale).[57,58] Process scale-up requires careful planning and effective selection of equipment, process parameters, and a control strategy based on product and process understanding and experience gained during development. To warrant a robust manufacturing process that is capable of consistently producing safe and effective product in the commercial setting, the influence of equipment, material and process attributes as well as variability on CQAs should be understood thoroughly.[2,3,59,60]

Scale-up is often defined as increasing batch size.[57,58] Depending on the nature of the process, increasing batch size does not necessarily imply the enlargement of processing volume of each unit operation. Examples of increasing batch size without enlargement of process volume of the unit operation include combination of multiple small granulation batches and extending the compression time using the same tablet press. In these cases, the transition to larger batch size is relatively orderly and straightforward. However, when equipment changes are required to increase batch size, process scale-up could become more complex. This is due to the fact that scaling-up of many parameters of pharmaceutical batch processes is often nonlinear and lacks a reliable scale-up model. Thus, it is difficult to predict large-scale process performance or define process parameters based on data and experience with small-scale equipment without conducting process experiments at an intermediate or the intended full scale.[2,57,58,60]

Under the QbD paradigm, process scale-up and optimization should follow a systematic, scientific, and risk-based approach.[2,3,59,60] The typical scale-up and optimization process can be illustrated in Fig. 20.2.

The first essential step for a successful scale-up should be thoroughly evaluating critical manufacturing variables for each unit operation, including CMAs and CPPs identified from small or intermediate scale experiments.[2,3,59,60] Additionally, equipment evaluation between scales to understand and identify the capability and limitation should be performed. Potential scale-dependent process parameters should also be identified during this step.

Scale-up experiments can then be designed to (1) verify the small scale results and (2) establish design space and controls strategy at the large scale. Various sources of variability should be properly included in experimental design to better understand the process robustness. Ensuring product quality during scale-up, maintaining geometric, thermodynamic, or kinetic/dynamic similarity between scales are basic principles that should be employed.[57] When the dimensional analysis can be applied, dimensionless numbers developed based on these similarities are largely independent of scale.[57,61,62] It is believed that two processes can be considered similar when they take place in similar geometrical space and all dimensionless numbers describing the process have similar numerical value.[57,61,62] According to this theory, the scale-up procedure would be: (1) expressing the unit operation into set of dimensionless numbers, and (2) matching the numeric value of those dimensionless numbers among different scales. An example of often used dimensionless number is the Froude number, which has been applied to the scaling of granulation process.[63] Computer based modeling, such as Finite Element Model (FEM), Discrete Element Method (DEM), is also starting to gain interest for scaling processes. However, due to the complexity of pharmaceutical manufacturing processes, the development of quantitative, first-principle-based dimensionless numbers and models that accurately describe the system are often unavailable. Hence, empirical/semiempirical approaches have been utilized to determine the process set points and ranges. When process parameters are scale-dependent, two types of scale-up approaches have been used: parameter-based and attribute-based. In practice, a combination of both strategies is often utilized.[64] One example of empirical scale up is to match the tip speed among intermediate bulk containers (IBC) of different sizes for dry blending/mixing process of free flow materials. Such a scaling principle provides a simple and quick estimation of the process operating range. Prior knowledge could also play a significant role and should be utilized when designing the scale-up experiments. When conducting process scale-up trials, more frequent testing than would be typical during routine manufacturing is usually needed to understand all potential variabilities and their impact. Defining proper sampling plans and acceptance criteria are both

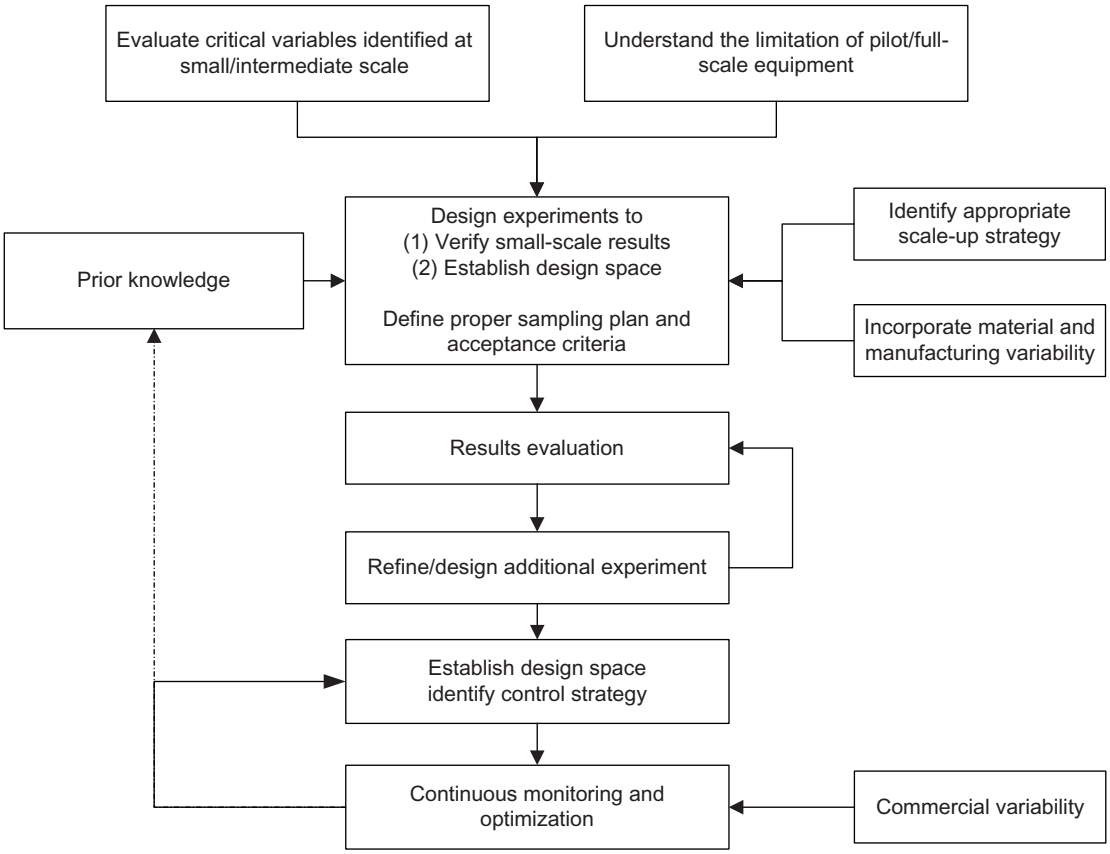

FIGURE 20.2 Typical road map of process scale-up and optimization.

critical and should be aligned with the identified CQAs and/or IPCs to ensure predetermined product quality and performance remain unchanged. On-line process measurement, if available and reliable, can provide real-time results without potential sampling bias and process disturbances.[2,65] As process scale-up is an inherent part of product process validation lifecycle, appropriate monitoring programs for quality attributes and process parameters should be established at this stage.[66,67] Those monitoring programs can serve as the basis for further process optimization.

Prior to commercial production, it is essential to build confidence in process consistency within the established process ranges with respect to performance indicators and product CQAs, However, in most cases a significant amount of data are usually unavailable at the development stage due to time, resource and material constraints. Thus, product and process understanding along with proper statistical tools are needed as a product moves through different stages of its lifecycle to gain increased understanding of manufacturability and process robustness. For example, process capability expressed as a process capability index (eg, Cpk) or process performance index (eg, Ppk), is a measurable statistical property of a process to the specification (see chapter: "Commercial Manufacturing and Product Quality" for definition). At the beginning of production, Cpks for all critical product measurements should be calculated to determine the general ability of the process to meet specifications. However, to obtain meaningful results, data should include the normal variation of production conditions, materials, and operators. In general, more than 25 subgroups of results are recommended.[68] Performing capability analysis with data or results of an inadequate number of batches could potentially lead to skewed analysis due to sampling variability and limited sample size. Throughout the lifecycle of the product, since a much wider range of variability will be encountered, process performance should be evaluated from time to time to enhance process understanding and identify optimization opportunity. After commercialization, an important part of process improvement activities is variability reduction through assessing process capability as well as material and process control. Although manufacturing efficiency, safety, and product yield are rarely considered critical to product quality attributes, they indirectly reflect a degree of process certainty and control, therefore, should be carefully

evaluated during scale-up and optimization. For example, inconsistent or lower than expected product yield indicates manufacturability issues. In such cases, process and control strategy should be reexamined and improved accordingly.

In summary, process scale-up and optimization is essential to pharmaceutical commercialization. It is an integral part of product process validation lifecycle. The experimental design for scale-up and optimization should be based on product and process understanding. An appropriately designed process scale-up and optimization will provide a high level of confidence in manufacturing robustness and consistent product quality. Detailed discussions of process scale-up can be found in individual chapters dedicated to various pharmaceutical processes in this book.

20.3 TECHNOLOGY TRANSFER

20.3.1 Technology transfer overview

In the pharmaceutical industry, "technology transfer" may broadly refer to the business processes required for successful progression from drug discovery to product development, clinical trials, and full-scale commercialization. For the development and transfer of knowledge and manufacturing technologies of finished solid dosage forms, it is usually defined as transferring the product out of the development laboratories and the process development pilot plant into full commercial-scale manufacturing facilities for new product launch. Technology transfer can also refer to transferring a commercial product from existing commercial sites to other commercial sites, also referred to as "site to site transfer." This section mainly covers the key points for the technology transfer related to new product launch. However, most of the principles described here can also be applied to site transfer.

Appropriate technology transfer includes the transfer of technical knowledge of the product and process, analytical test methods from a sending organization to a receiving organization, as well as the establishment of the related quality control system and documentation for the new product at the receiving organization. The sending organization is typically an R&D organization or a development partner that has developed the technology. The receiving organization is normally a commercial manufacturing site (for product/process transfer) or a quality control laboratory (for test method transfer). This process is important to ensure that product quality and performance developed during R&D remain unchanged in full-scale commercial product manufacturing and can be maintained during routine commercial manufacturing after launch.

Technology transfer is a complex process that typically involves multiple functional areas. The ultimate goal is to effectively transfer manufacturing process, specifications and controls, as well as analytical methods based on sound scientific and engineering principles, while striving for optimization of efficiency, flexibility, and capability of the process. Technology transfer should also be a continuous knowledge/experience transfer and information exchange between parties, rather than a one-time event. Problems often arise at interfaces when the transfer process is not properly planned, communicated, and executed, and can result in a high rate of batch rejections or even a delay in bringing new products to market. Thus, effective and efficient technology transfer has been, and will continue to be, critical to the success of the pharmaceutical industry. Technology transfer may include API process transfer, drug product process transfer, and analytical methods transfer. Analytical methods transfer is normally part of the API or drug product transfer to support the manufacturing site change. The API process transfer includes transfer of the API synthesis of intermediates and final products as well as test methods for raw materials, starting materials, reagents, catalysts, intermediate and final products. A lab run using reagents from the commercial site is normally the first step in the process transfer. A solvent run is then conducted at the commercial site using the same process train and operating conditions without the use of solids and other raw materials except solvent. It is intended to test the manufacturing procedure and equipment capabilities without consuming expensive and limited raw materials. Critical process control parameters such as temperature, solvent charge quantities, mixing and material transfer rates, can be studied using a solvent run. Following the solvent run, engineering run(s) are typically conducted to fine tune the process parameters. The experimental data together with the data generated in the R&D pilot plant and at lab scale can be used to justify the process ranges and IPC limits. After the process ranges are justified, IPC and final product specifications are established, and the API process can be qualified at the commercial sites. The International Society for Pharmaceutical Engineering (ISPE) provided a detailed guide on the requirements for API transfer.[69] This section will mainly focus on the drug product transfer.

20.3.2 Technology transfer of drug product

A technology transfer of drug product normally includes the transfer of the product/process as well as

the drug product test methods. Sometimes, the API test methods also need to be transferred to the DP manufacturing site since API release testing might need to be performed to ensure quality control of the incoming materials. Technology transfer of drug product is normally initiated when the compound reaches Phase IIb in drug development. This is often the time when planning of commercialization of the compound is initiated, and a commercial manufacturing site is selected. During initiation of the technology transfer, the overall project scope is defined, technology transfer lead, stakeholders and team members are identified, and high-level technology transfer milestones are established. A technology transfer team typically contains members from multiple functional areas, such as pharmaceutical and analytical R&D, operations (manufacturing and engineering), quality, regulatory affairs, supply chain, and program management. As with any multifunctional team, clearly defining roles and responsibilities of team members is the key to success. The technology transfer team lead plays a key role in the success of the transfers and is expected to be an individual with appropriate technical experience and knowledge from drug development and manufacturing, project management skills and experience, and excellent communication/negotiation skills. Stakeholders include the management from the key functional areas who are funding or affected by the technology transfer (eg, R&D, manufacturing site, quality, and regulatory and supply chain). The high-level technology transfer milestones normally include:

- Site readiness, especially when a new or modified facility or new equipment is introduced
- Completion of test method transfer to the receiving lab(s)
- Completion of process transfer to receiving site
- Phase III clinical supply readiness (if Phase III supply is manufactured from the commercial site)
- Completion of stability batch manufacturing at the receiving site (site specific stability batches)
- Completion of demonstration, or confirmation, batch at the receiving site
- Completion of process validation at the receiving site
- Regulatory filing submission

20.3.2.1 Technology transfer planning

After forming a technology transfer team and setting up technology transfer milestones, the technology transfer team needs to develop a detailed technology transfer strategy/plan which typically includes project scope, key deliverables and timeline, project resource requirements, transfer strategy, gap assessment, and acceptance criteria.

Project scope needs to define clearly what is in the scope of the specific transfer. For example, the transfer may or may not include transferring the final packaging operation or an alternate API source may or may not be in the scope of the transfer. Key deliverables for a technology transfer normally include timelines for the key milestones agreed upon. A full list of team members should be provided in the project resources section of the technology transfer plan.

The transfer strategy includes the master plans for the transfer of the product and process knowledge to the manufacturing site, test method transfer, stability and shipping, packaging, market and material sourcing, regulatory strategy and facility and equipment strategy. Planning of the product and process knowledge transfer includes detailed action plans and timelines to further develop the commercial process/formulation, scale up and transfer to the commercial site, manufacturing of registration, demonstration/confirmation and validation batches. API specifications, excipients specifications, and drug product specifications need to be established at the receiving site with the related knowledge transferred from the sending site. A site specific hold time study is recommended to be performed during the technology transfer to justify the process hold time of product at each stage of the process. Since the hold time study normally takes time to complete, proper planning at the early phase of transfer is recommended. Cleaning procedures and cleaning validation are typically site specific. The cleaning procedures from the sending site should be compared with the procedures at the receiving site to assess if the cleaning procedures at receiving site need to be modified to meet the requirement of the new compound. Packaging processes (including bulk packaging and finished product packaging process) should be considered as part of the process transfer as appropriate. Different packaging material might require different packaging conditions. When new packaging material is introduced, thorough packaging process development work could be helpful to establish the optimized packaging process parameters for the new material. Test method transfer strategy includes a list of methods that need to be transferred, the sending and receiving sites of each method, and transfer strategy for each method. Depending on the capability of the commercial site, some methods might need to be transferred to other third party labs. In many cases, the release lab is different from the labs that perform the stability study and testing. Therefore, test method transfer to stability labs should also be considered. The methods being transferred include API, excipients and drug product release methods, cleaning methods including testing for residual API

and detergent, as well as any required in-process testing methods. The testing sites to support formulation/process development, registration, clinical lot release and stability should also be planned and selected to ensure resources are properly allocated. Stability strategy contains the plan for primary stability, site stability, and any supportive stability studies (eg, in-use stability and bulk stability) required for a product launch. A matrix or bracketing approach may be used where appropriate. A shipping study justifies the temperature excursions during shipping and may include a simulated or real time shipping study to evaluate the physical integrity of the drug product during shipping. The packaging strategy includes the packaging configuration planned for bulk API, bulk DP, finished DP as well as the packaging site. Selection of packaging configurations needs to consider both chemical and physical stability of the drug substance and drug product. Market and material sourcing strategy includes the targeted markets for the DP and potential material vendors. Vendor qualification activities need to be planned for new vendors. Plan for alternative suppliers should also be addressed especially for critical excipients or supplier at higher risk. The regulatory strategy includes regulatory assessment of data requirements for filing in countries where the drug product will be marketed as well as planning to meet expectations during any anticipated GMP inspection or prior approval inspections. The regulatory strategy is closely linked to stability strategy since the stability requirements might be different from country to country. Some country-specific documentation may take time to prepare and should be listed in the regulatory strategy and planned accordingly. In a transfer where a new facility needs to be built, and new equipment needs to be purchased, the technology transfer planning should also include capital purchase and facility engineering planning. The environmental differences (eg, temperature and relative humidity control) from the receiving site and sending site also need to be considered to ensure product quality is not impacted during manufacturing. Capital items may include the cost of the facility, IT system investments, equipment installation and qualification expenses, lab equipment purchasing, certification, among others. Expense usually includes rearrangement of the current facility, demolition, engineering, certification, among others. The initial manufacture estimate (IME) often includes employee costs, general production support, disposal costs, process cost, among others. A gap analysis for technology transfer needs to be performed in the early phase of the transfer to capture all the identified gaps with a remediation plan. The gap assessment normally includes potential process/analytical equipment gaps, environmental control gaps, process/product knowledge gaps, etc. The final piece of the technology transfer plan is acceptance criteria. The metrics defined in Table 20.3 provide a baseline to measure technology transfer success.

TABLE 20.3 Metrics for Measuring Transfer Success

Metric	Description
Drug product facilities	DP site(s) have necessary equipment and procedures in place for manufacturing, testing, approving, cleaning, and packaging per project timeline
Analytical methods	Methods are transferred and ready for use per project timeline for API, excipients, drug product, and cleaning
Drug product development	The process operating space is defined and justified The process is properly scaled up to meet commercial-scale requirements Process validation requirements are incorporated in the product development to ensure successful process qualification and robust commercial manufacture Packaging requirements are established to ensure product stability
Regulatory strategy	The regulatory strategy is defined and incorporated into the tech transfer requirements and project timeline so the filing occurs on schedule
Launch readiness	Quality system and product-related manufacturing and testing documentation are in place and commercial supply chain is ready in time for DP approval from regulatory authority. Adequate supply of product is available for launch

The technology transfer plan is a living document and should, if necessary, be revisited and revised (with appropriate version control) periodically during execution of the transfer.

20.3.2.2 *Execution of technology transfer*

During the execution phase of the transfer, a detailed project timeline based on the technology transfer plan should be developed. Effective communication between all functional areas throughout the execution phase is crucial. Documentation during the execution phase is not only important to ensure a smooth transfer but also required by the regulators. Table 20.4 provides an example of the documents that need to be available at the receiving sites for the technology transfer.

Additional information for pharmaceutical technology transfer can be found in the guidelines published by World Health Organization in 2011[70] and by the

TABLE 20.4 Examples of Documents Needed at Receiving Sites

Category	Documents
API	API specification and any additional characterization that have potential impact on drug product
Formulation/process	Formulation development report (including formulation declaration, justifying function, type and amount of components, and API characteristics)
	Development report for Phase II DP manufacturing process including the following information:
	Process justification identifying and justifying the critical process parameters and critical quality attributes Batch summary of historical batches Equipment scale and its operating parameters and ranges Nonconformities and investigations API/excipients used and COAs Summary of batch release results and in-process testing results Special storage and product handling Special hold time requirement Yield of each step Manufacturing batch records (blank and executed) Site SOPs Cycle time of each step
Facility and equipment	Facility requirements: Containment Environmental Utilities Room temperature and humidity controls IQ/OQ documentation Equipment requirements Any modification to the commercial equipment/instruments and computer systems IQ/OQ/PQ documentation Equipment selection justification Material transfer equipment Capacity Controls Operating ranges Calibration/validation ranges PAT Cleaning procedures
Environmental health and safety	• Dust explosion data • Special emission controls • Waste streams (description, composition) • Toxicity information • Process hazards
Analytical	• Stability reports listing the current data and status of ongoing and completed stability studies • Validation or transfer documentation (eg, failure mode and effects analysis (FMEA), risk control strategy, gap assessments) necessary for method understanding • Analytical method development reports • Availability of samples for the test methods transfer • Hands on training and best practices prior to test method transfer • Analytical equipment setup • Specification and specification justification document (including drug product and excipients)
Cleaning	Cleaning method and cleaning validation report
Packaging	• Packaging selection/justification report • Type of packaging and specifications: • Primary packaging for the finished product • Bulk packaging • In-Process material packaging • Hold time studies • Vendors for packaging • Environmental controls during packaging and storage • Shipping study or simulated shipping study

ISPE in 2014, respectively.[69] These guidelines present a clear standardized process for transferring technology between two parties and recommend a minimum base of documentation in support of the transfer request. They define key terms with consistent interpretation that enables the capture and sharing of essential knowledge. These guidelines are useful from the earliest phase of a product's lifecycle to postapproval transfers, and provide guidance and insight into the essential activities and documentation required to move a product, process or method from one unit to another. The information is equally applicable to ethical and generic products, as well as technologies originating from any region around the world.

20.4 CASE STUDIES

20.4.1 Influence of material properties and processing conditions on tablet capping

Capping is one of the mechanical defects that can occur in the tableting process and it can cause catastrophic failure of the compact. Capping is defined as the separation of the top or bottom curvature part of the tablet from the tablet body either partially or completely. It can occur as the tablet ejects out of the die, or during subsequent handling or hardness testing. Tablet capping may be influenced by formulation material properties, process conditions and tooling shape. In recent work published by Akseli et al.,[71,72] the authors developed a nondestructive ultrasonic method to correlate material and process variables quantitatively to tablet capping tendency. They studied a variety of powder blends with a wide range of material properties. These blends consisted of different levels of two model drugs (acetaminophen (APAP) and ascorbic acid) with either brittle fillers (lactose monohydrate, or Tablettose 80) or plastically deforming fillers (microcrystalline cellulose, or Avicel PH 102). In addition, they also studied 10 commercial production blends for which there was extensive manufacturing knowledge of capping tendency. To compare the capping tendency between commercial products with the experimental blends made at lab scale, all blends were compacted under the same controlled conditions using Presster, a compaction emulator. The number of tablets that capped during ejection and hardness testing for each powder blend was counted and used to calculate the formulation capping tendency. A nondestructive ultrasonic tester was used to analyze the acoustic properties of pressure and shear waves in the tablets from which it was possible to derive elastic properties such as Young's modulus E (ie, describes the tendency of a material to deform along an axis when opposing forces are applied along that axis) and shear modulus G (ie, describes the tendency of a material to shear when acted upon by opposing forces). Tablets were tested along axial and radial directions and dimensionless ratio $EG^{E} = E_{axial}/E_{radial}$ and $EG^{G} = G_{axial}/G_{radial}$ were calculated and used to reflect how elastic properties vary along axial and radial directions of tablets. The key conclusion included that: when the ratios EG^{E} and EG^{G} (referred to as *EG* ratios later) approach unity the tablet is expected to be more homogeneous, and capping is less likely to occur: As the *EG* ratios deviate from unity, heterogeneities in the tablet are expected to be more pronounced, and capping is more likely to occur. Fig. 20.3 shows time of flight (TOF) for longitudinal (pressure) and transverse (shear) ultrasonic pulses in the tablet acquired for one of the test products (Product-9) in both axial and radial directions for a commercial product. The calculated *E* and *G* ratios of 0.98 and 0.95 indicate no risk of tablet capping with this commercial product.

Based on the study, a very good correlation between the *EG* ratios and tablet capping tendency could be obtained among 26 lab and commercial samples with widely ranging material properties. As shown in Fig. 20.4, no capping was observed either during ejection or hardness testing when EG ratios are greater than 0.65, which was defined as the green "acceptable region." When the *EG* ratios are between 0.45 and 0.65, capping was occasionally observed during hardness testing, which was in the yellow "moderate region." When the *EG* ratios are less than 0.45, tablet has high risk for capping, which was shown in the pink "poor" region.

Material properties usually have the most significant influence on the capping tendency of formulation blends. Take APAP blends, for example, it is well known in the literature that APAP containing formulations are prone to capping due to poor compression characteristics of APAP.[73] From Fig. 20.4 it can be seen that when APAP was blended with Tablettose 80, a commonly used filler which undergoes brittle fracture during compression, the resulting powder blend exhibited high tendency for capping when the APAP loading is as low as 5%. However, when APAP was blended with microcrystalline cellulose, another commonly used filler which undergoes plastic deformation during compression, the resultant blend did not show a tendency to cap even at a drug load of 20%. When a different model drug, ascorbic acid, was tested, binary blends with Tablettose 80 containing 1–10% API did not exhibit capping tendency. However, when drug loading was increased to 20%, high capping tendency was observed. Similar to the APAP example, use of plastically deforming filler

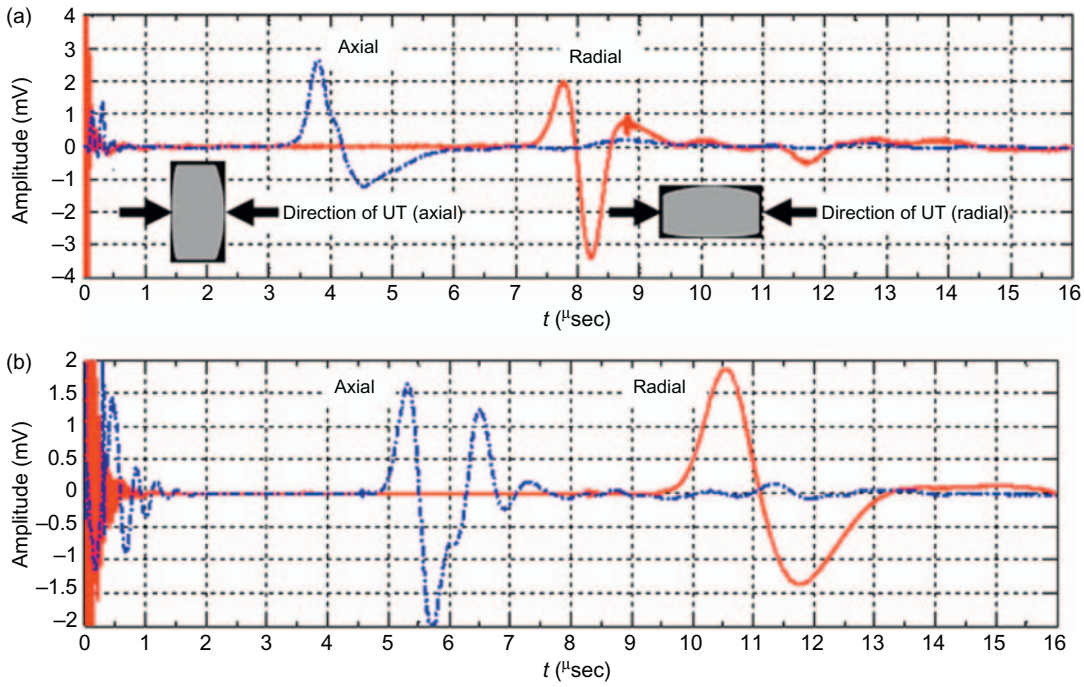

FIGURE 20.3 Comparison of the axial (blue dashed line) and radial (red solid line) TOF of longitudinal (pressure) (a) and transverse (shear) (b) ultrasonic pulses in the tablet acquired for Product-9. The capping rating of this product is 3 (acceptable).[71]

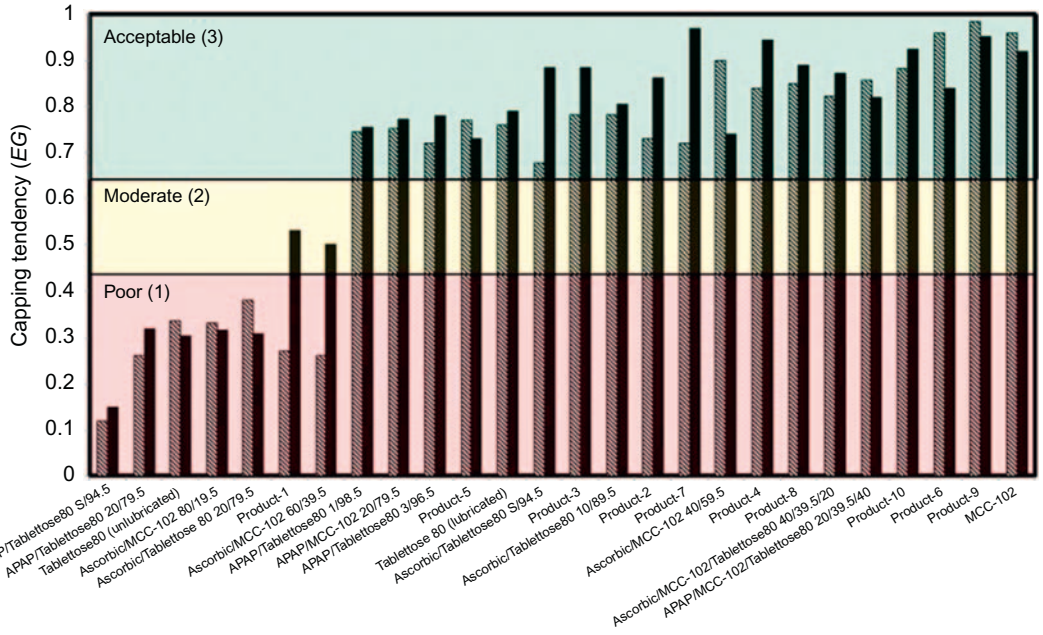

FIGURE 20.4 Nondestructive ultrasonic assessment of tablet capping tendency. Patterned and black colored bars are representing the $EG^{E} = E_{axial}/E_{radial}$ and $EG^{G} = G_{axial}/G_{radial}$, respectively.[71]

(MCC) can accommodate much higher drug load than brittle filler Tablettose 80. At 40% drug load, capping problems were absent with binary blends of ascorbic acid and MCC. At 60% drug load, a moderate capping issue was encountered. At 80% drug load, the risk for capping was significantly higher. These examples not only illustrate the need understand the impact of material properties on product manufacturability (ie, capping), but also the importance of selecting suitable excipients during formulation design to

accommodate undesirable material properties of a drug substance.

Besides material properties, processing variables can also significantly impact tablet capping tendency. In a subsequent study, Akseli et al. systematically investigated the effect of processing conditions on the same sample set. A DOEs (D-optimal surface response design) was used to study the effect of three factors on tablet capping tendency, that is, tooling shape (round, bevel edge, oval shape), compression force (5, 10, 15, 20, 25 KN), and compression speed (25, 40, 80 rpm). In this work, capping risk criteria were refined to indicate different regions of the *EG* ratio: poor/capping region: $EG < 0.4$, high-risk region: $0.4 < EG < 0.5$, low-risk region: $0.5 < EG < 0.6$, acceptable region: $EG > 0.6$. The impact of processing conditions can be illustrated using commercial products 1 and 2 in Figs. 20.5 and 20.6. As shown in the figures, Product 1 has moderate capping risk and Product 2 shows no capping tendency. The observations made during compression studies using a Pressuer in the lab are consistent with production experience of the commercial products. Because Product 1 has inherent tendency to cap, it is especially important to understand how the processing variables may affect risk of tablet capping. As shown in the Fig. 20.5, tooling shape has the most pronounced effect on tablet capping tendency with oval shaped tooling > bevel edged tooling > round tooling. Oval shaped tablets have moderate to high risk of capping under all conditions studied. The bevel edged tablets performed slightly better than the oval tablets in terms of capping risk. However, all tablets made using bevel edged tooling still show moderate to severe capping risk under all conditions. The round tablets offer the best opportunity for minimizing capping risk. Tablets made using round tooling have acceptable capping risk where compression force is very low. In contrast to Product 1, material properties of Product 2 are more desirable with acceptable capping risk. The risk for capping is low within a much larger processing space where the process parameters can be varied. Similar to Product 1, a pronounced impact of tablet tooling shape on capping tendency was observed with the same rank order: oval shape > bevel edge > round tooling. The safe process region is the widest for round tooling and the smallest for oval shape tooling. It should be noted that even though Product-2 has excellent material properties from a capping risk perspective, tablet capping may still occur under certain process conditions.

The general learnings from this case study indicate (1) both material properties and processing variables can have a significant impact on tablet quality and manufacturing. Therefore, it is essential to evaluate the potential influence of material properties, process variables, and their interplay on product quality and manufacturing during the design and development of product and process; (2) for formulations with material properties prone to have processing risks, options to minimize or eliminate the risk by varying process conditions are often limited. For formulations with improved material properties, process understanding is still crucial in developing a robust manufacturing process; (3) fast and material sparing predictive tools

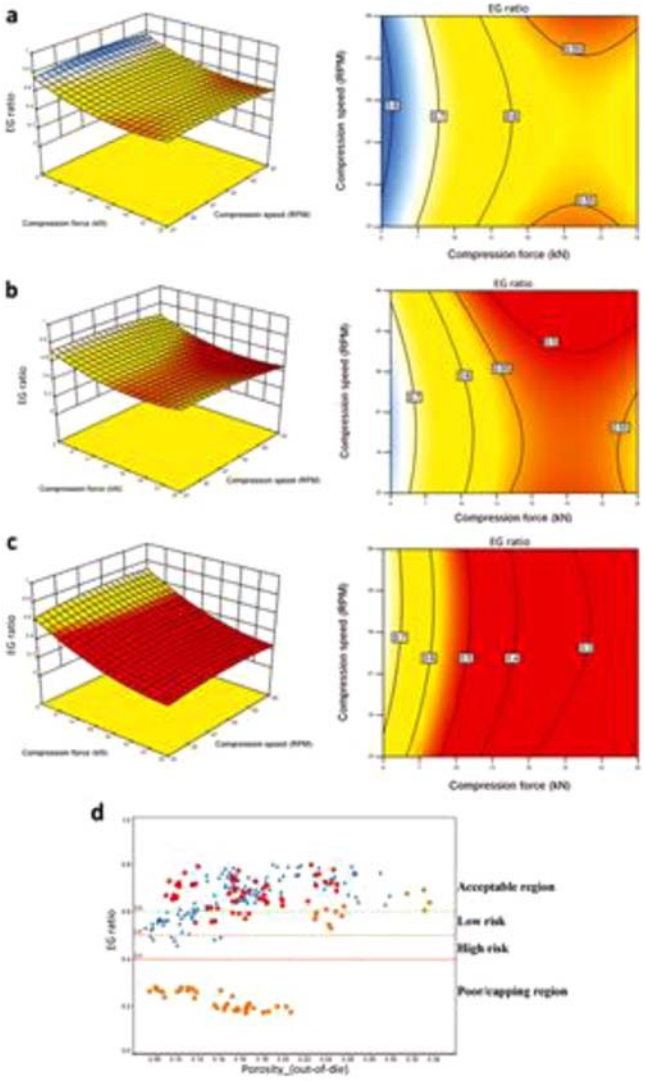

FIGURE 20.5 Three-dimensional surface plots and two-dimensional contours of *EG* ratio versus compression force versus compression speed for round (a), beveled edge (b), and oval shape tablets (c) manufactured using Product-1 blend. *EG* ratio as a function of tablet porosity for Product-1 (d) manufactured with round (circle), beveled edge (triangle), and oval shaped (square) toolings—poor/capping region: $EG < 0.4$, high-risk region: $0.4 < EG < 0.5$, low-risk region: $0.5 < EG < 0.6$, acceptable region: $EG > 0.6$.[72]

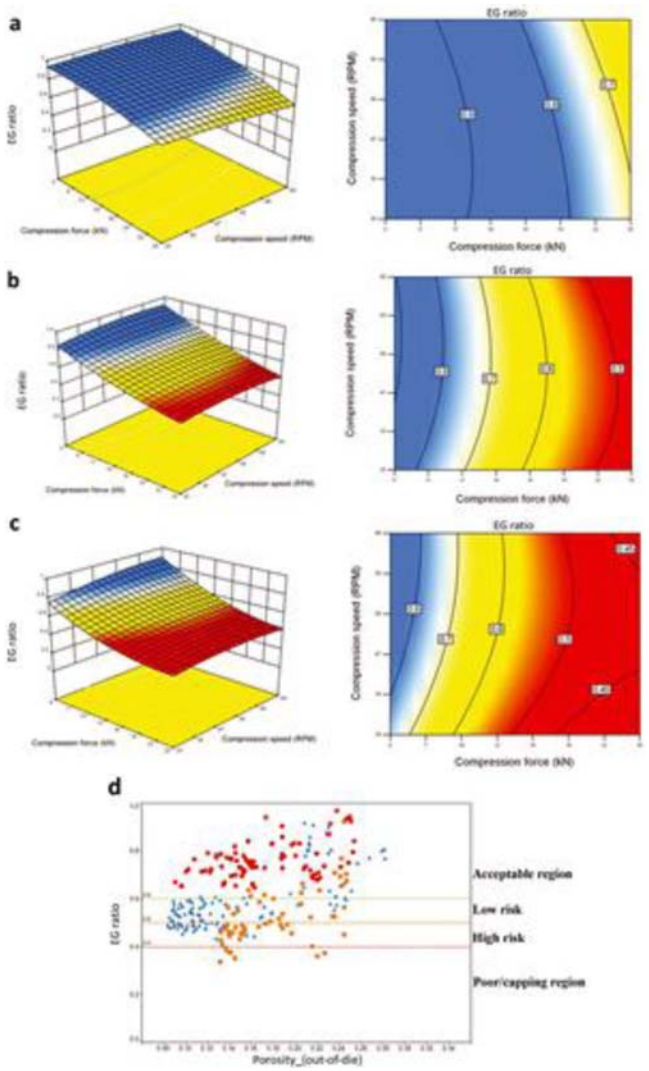

FIGURE 20.6 Three-dimensional surface plots and two-dimensional contours of *EG* ratio versus compression force versus compression speed for round (a), beveled edge (b), and oval shape tablets (c) manufactured using Product-1 blend. *EG* ratio as a function of tablet porosity for Product-2 (d) manufactured with round (circle), beveled edge (triangle), and oval shaped (square) tooling—poor/capping region: $EG < 0.4$, high-risk region: $0.4 < EG < 0.5$, low-risk region: $0.5 < EG < 0.6$, acceptable region: $EG > 0.6$.[72]

such as the ultrasonic capping test can be used to evaluate and anticipate risk early on, facilitate product and process development with enhanced understanding of CMAs and process parameters, and to develop a risk mitigation strategy.

20.4.2 Understanding formulation design of ER dosage forms of verapamil

Verapamil is an L-type calcium channel blocker used in the treatment of hypertension, angina pectoris, cardiac arrhythmia. Verapamil is a weak base with pKa of 8.8 and pH-dependent solubility (about 65 mg/mL at pH 1.2 and 4.5, about 13 mg/mL at pH 6.8). It is a BCS Class I compound with high permeability in upper and lower bowels.[74,75] The strengths of IR dosage forms range from 40 to 120 mg. The favorable dose, solubility, and permeability indicate that all three types of ER systems are suitable for this compound. This is reflected in the commercially available once-daily oral ER products which include a matrix (Isoptin SR and Calan SR tablets), reservoir (Verelan and Verelan PM capsules), and osmotic pump systems (Covera-HS tablets).

ER products of verapamil were first developed using hydrophilic matrix systems. Isoptin SR and Calan SR are matrix tablets based on sodium alginate, a pH-dependent, natural water-soluble linear unbranched polysaccharides consisting of different proportions of β-D-mannuronic acid (M) and α-L-guluronic acid (G) units.[76] At acidic pH below the pK_a of M (3.38) and G (3.65) monomers, sodium alginate is converted to insoluble and nonswellable alginic acid. In addition, solubility of the API increases with decreasing pH. Hence, drug release from the matrix tablets is dependent on pH as shown in Fig. 20.7a.[77] At pH 1.2, the in vitro release from matrix tablets is slow and mainly driven by diffusion because of high solubility of the API and the formation of the inert alginic acid. In addition, surface area available for drug release also changes over time due to tablet cracking and lamination at acidic pH.[78] At pH 4.5 and 6.8, sodium alginate hydrates and swells rapidly, forming a gel layer that controls the drug release rate. The data in Fig. 20.7a show that drug release at pH 4.5 was essentially governed by polymer erosion as indicated by the release kinetics in spite of high drug solubility. In addition, the drug release profile is essentially the same as that at pH 6.8 even though drug solubility is five fold lower at high pH. These observations can be attributed to the interaction between the protonated tertiary amine cation of verapamil and the carboxyl anion of sodium alginate, resulting in erosion-controlled drug release and a decrease in free drug concentration in the gel.

One of the shortcomings of both Isoptin SR and Calan SR tablets is that they need to be taken with food to maintain a narrow peak-to-trough ratio of the plasma profile. The significant food effect on oral absorption was believed to be, at least in part, associated with the effect of pH on drug release To overcome pH dependence of drug release, Howard and Timmins designed a new ER matrix system of verapamil by incorporating a pH-independent polymer in the alginate-containing formulation.[79] In an acidic environment (eg, stomach), the pH-independent polymer (eg, HPMC) hydrates to form a gel layer and serve to the

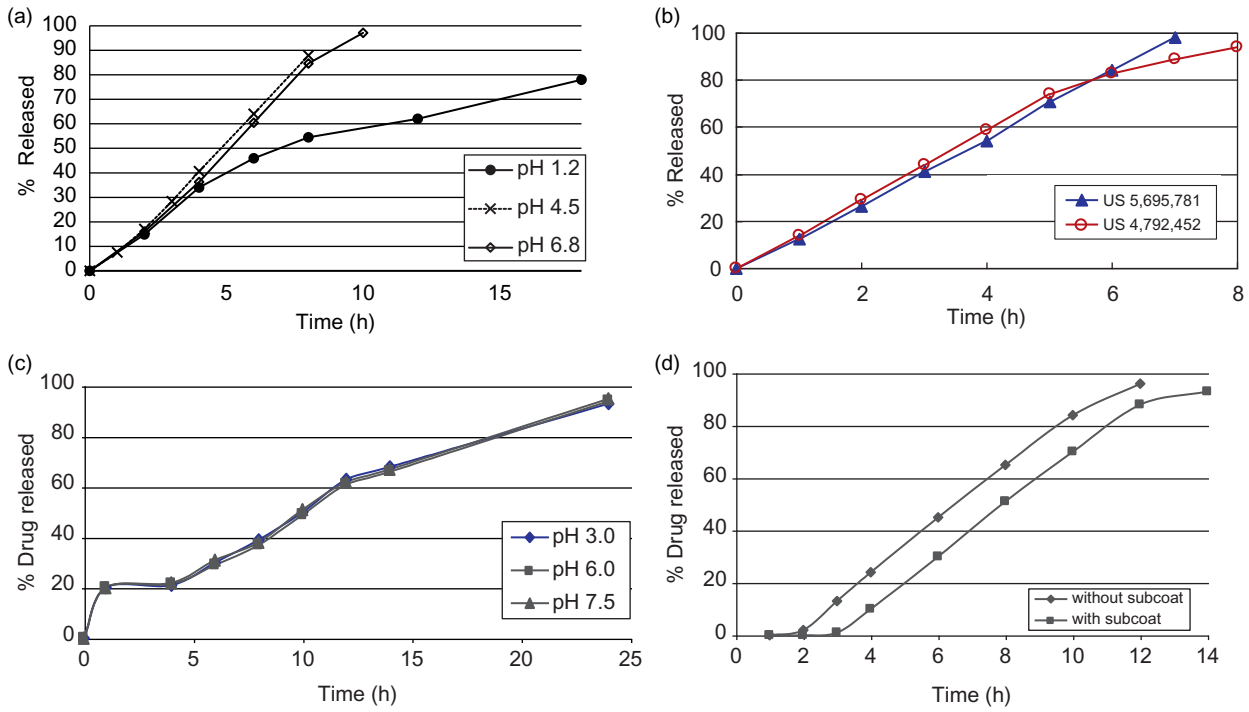

FIGURE 20.7 Drug release of verapamil from different ER systems: (a) pH-dependent matrix; (b) pH-independent matrices; (c) reservoir; and (d) osmotic pump.

control release rate of soluble API. As the pH increases with the passage of the tablets from the stomach to the intestinal tract, the alginate in the tablets starts to hydrate and form a gel layer that helps maintain lower pH in the matrix and contributes to modulation of the release rate. As a result, drug release from this system is independent of pH and follows zero-order kinetics for up to 80% of the dose as shown in Fig. 20.7b. To design a more robust pH-independent zero-order ER system, Zhang and Pinnamaraju incorporated an additional anionic polymer, a methacrylic acid copolymer, into the matrix system consisting of sodium alginate and a pH-independent polymer, HPMC.[80] Data in Fig. 20.7b showed that pH-independent zero-order release was obtained for up to nearly 100% of drug release. In both designs, the anionic methacrylate and/or alginate copolymers present in the HPMC-based matrix play a significant role in achieving pH-independent and zero-order release. The decreasing drug release rate over time from the matrix at higher pH due to decreasing solubility and surface area/diffusion path-length is compensated for by (1) maintaining lower gel layer pH and (2) interaction between the tertiary amine of the API and carboxyl group discussed previously.

ER capsule of verapamil hydrochloride, Verelan, is an ER reservoir system that contains a mixture of rapid and ER coated beads.[81] The formulation of the ER core consists of nonpareil seeds, API, a binder, talc, and a pH-modifier, malic acid with two pKas (3.4 and 5.1) to help achieve pH-independent release by providing low pH (high API solubility), hence more constant driving force for diffusion after being coated using the rate-controlling ethylcellulose film. The finished capsule dosage form contains 20% of the uncoated beads and 80% of the membrane-coated beads. Drug release profiles in Fig. 20.7c indicate that the drug release from this system is independent of pH. It should be noted that the original product was developed over two decades ago when the film coating polymers were applied in an organic solution. Significant advances have since been made in a polymer coating of solid dosage forms. Today, the majority of the membrane coating of a reservoir system is applied as aqueous dispersion that forms a film by a process of coalescence of submicron polymer particles. The film coating process is typically performed in a fluidized bed with Wurster insert. The properties of the resulting functional coating are influenced by coating formulations as well as processing variables. The details and in depth discussions of the coating process development are addressed in chapter "Development, Optimization, and Scale-Up of Process Parameters: Wurster Coating" of this book. To further improve the clinical outcome, the second generation reservoir ER system of verapamil, Verelan PM, was developed and approved in 1999. It was designed by applying chronotherapeutic principles to drug delivery,

or targeting drug release to the circadian rhythm of the disease state, to improve clinical responses.[82] Verelan PM is a bead-filled capsule that uses the CODAS (Chronotherapeutic Oral Drug Absorption System) ER technology designed for bedtime dosing by incorporating a 4- to 5-hour delay in drug delivery. The delay is controlled by the type, composition and level of release-modifying polymers applied to drug loaded beads. The drug release is essentially independent of pH, food intake, and GI motility.

Covera-HS tablet is also a chronotherapeutic ER dosage form of verapamil specifically designed to deliver the drug in higher concentrations during time of greatest need (eg, postawakening period) and in lesser concentrations at night when heart rate and blood pressure are lowest and cardiovascular events are least likely to occur. It is a two-chamber OROS Push-Pull osmotic system that consists of an active drug layer and an osmotic push layer. The device is designed to provide delayed onset of drug release by adding a coating layer between the tablet core and semipermeable outer membrane. Depending on the composition and level of the subcoat, the onset of drug release can be controlled. The ER drug delivery is independent of pH, GI motility, and food. This type of ER osmotic device is prepared with the following steps according to the issued US patents.[83–85]

(a) Composition and preparation of active drug layer:

Verapamil hydrochloride	600 g
Poly(ethylene oxide)	305 g
Sodium chloride	40 g
Polyvinylpyrrilidone	50 g
Magnesium stearate	5 g

All ingredients except magnesium stearate were granulated with anhydrous ethanol. The dried granules were lubricated with magnesium stearate. This procedure provides granules for the active drug layer.

(b) Composition and preparation of osmotic push layer:

Polyethylene oxide	735 g
Sodium chloride	200 g
Hydroxypropyl methylcellulose (Methocel E5)	50 g
Ferric oxide	10 g
Magnesium stearate	5 g

All ingredients except magnesium stearate were granulated with anhydrous ethanol. The dried granules were lubricated with magnesium stearate. This procedure provides granules for the osmotic push layer.

(c) Preparation of core tablet: A bilayer core tablet comprising an active layer and a push layer was compressed in a bilayer tablet press. A subcoat is applied on to the bilayer core tablets using enteric coating material.

It should be pointed out that manufacture of layered tablets often faces challenges as this type of tablets are prone to delaminate along the interface, causing layer separation during processing, scale-up or storage before coating, particularly when formulation and process are developed in isolation. Thus, to design a physically robust bilayer tablet with well-adhered layers, prospective assessment of delamination tendency of different layers of different compositions should be conducted through integrated evaluation of material properties, formulation, and process variables. Knowing the interaction, deformation and bonding properties between different materials during compaction is of vital importance to better understand the compaction behavior and possible failure mechanisms of bilayer tablets. For example, the deformation, relaxation, and bonding characteristics of a push layer primarily consisting of polyethylene oxide[86] should be evaluated if the active layer is predominantly deformed by brittle fracture. Significant mismatch of the physical and mechanical properties between the two layers often leads to difficulties in the development and manufacture of the layered tablets. Other parameters important to the development of layered tablets include level and extent of lubrication, granulation characteristics, tamping and compression forces, turret speed, and equipment.[87–89]

(d) Composition and preparation of semipermeable membrane:

Cellulose acetate	55%
Hydroxypropylcellulose	40%
Polyethylene glycol	5%

All ingredients in the formulation are dissolved in 80% acetone and 20% methanol. The bilayer tablets were coated in a pan coater. Two orifices were drilled on the side of the tablet containing the active drug. An optional color or clear coat may also be applied. It is noted that the most significant drawback of developing osmotic systems is the need for organic solvents in the manufacturing process. Others include tedious and complex processing operations that require extensive process studies and control.

Fig. 20.7d shows the in vitro drug release profiles of verapamil from the osmotic pump system. The dosage

form without and with an enteric subcoat exhibited a lag time of 1.5 and 3.0 hours in drug release, respectively, followed by zero-order release of verapamil.

20.4.3 Improving process robustness and capability through enhanced process understanding

FBG is a commonly employed unit operation in the pharmaceutical industry to improve flow properties and compressibility of fine powders by enlarging particle size.[90–93] The fluid-bed wet granulation process usually consists of three steps: dry mixing, spray agglomeration, and drying to the desired moisture level (as shown in Fig. 20.8).[90] Physical properties of granulations are dependent upon both formulation and operational variables that are associated with the process. For example, process humidity is known to be an important factor affecting granulation characteristics, thus, controlling the bed humidity is critical as it has a substantial impact on physical properties of the granules required for downstream processing including flow, packing efficiency, and compactibility.[90–93]

In order to improve process understanding and robustness of a legacy product, Lourenco et al. used in-line microwave resonance technology (MRT) to monitor granule moisture, temperature, and density of an industrial-scale FBG process with a batch size of 500 kg.[90] The commercial formulation used in the granulation study consisted of an API, a filler, and a binder which was applied as an aqueous solution. Through analysis of 192 batches using a combination of off-line particle size measurement and multivariate data analysis (MVDA), including multiway partial least squares (PLS), and principal component analysis (PCA), a significant seasonality effect on granule properties was observed. The multivariate batch control charts generated using the first principal component scores of the PLC model (Fig. 20.9a) show that process variability decreased over time during the mixing phase and eventually reached similar level for all production batches, indicating that the powder mixture reached homogeneity despite different initial state. However, for both the spraying and the drying phases (Fig. 20.9b and c), the batches produced from January to March (colder and drier months) are different from those made from April to July (warmer and wetter months). A much higher variability was noted at the end of spaying phase although the process parameters are controlled at the nominal conditions. This heterogeneity then led to the time profile shift in the drying phase, that is, longer drying time is generally required for the batches manufactured in warmer months when the humidity is higher. This seasonality effect was also confirmed by temperature and moisture profiles of the granules and the off-line particle size measurement (see Fig. 20.10). Compared to granules manufactured in the warmer months, the granules produced in the colder months had a lower moisture content, broader particle size distribution, and a higher portion of fines. Since all batches are manufactured with the same process parameters, observed high variability of this product was attributed to the influence of the inlet air relative humidity.

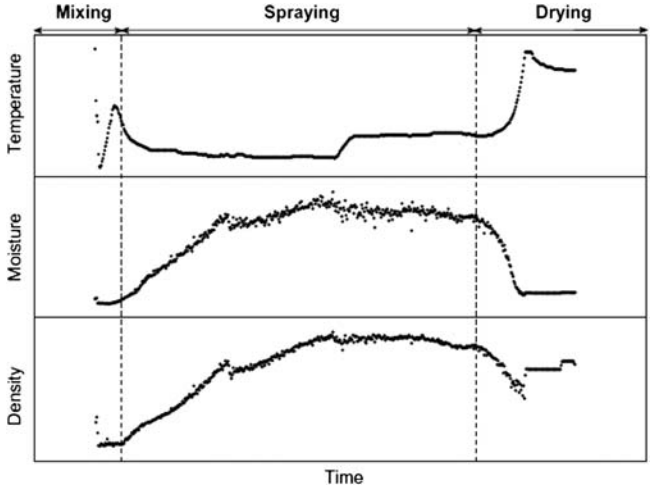

FIGURE 20.8 Typical time profiles of granule temperature, moisture, and density during fluid-bed granulation (FBG).[90]

Granules with highly variable property are undesirable because it can negatively impact the downstream process, resulting in poor process capability, manufacturing difficulty or even product failures. Low process capability due to high variability is not uncommon for many legacy products. This is because those legacy products are often manufactured under predetermined and fixed operating conditions defined without sufficient product and process understanding during development. Based on the understanding of the root cause for this product, one of the obvious approaches to reduce process variability would be to control inlet air humidity. However, it requires facility modification (such as an HAVC system) and equipment upgrades which are undesirable from a practical and economic standpoint. Thus, process optimization through enhanced process understanding was used as an alternative approach to decrease the intrinsic variability and improve process reproducibility. More specifically, the author conducted process re-development/optimization experiments by applying QbD approach.[91] All potential risks were identified and analyzed based on multidisciplinary risk assessment; three process parameters, including (1) inlet air temperature, (2) binder spray rate, and (2) air flowrate, were considered critical based on the relevant process

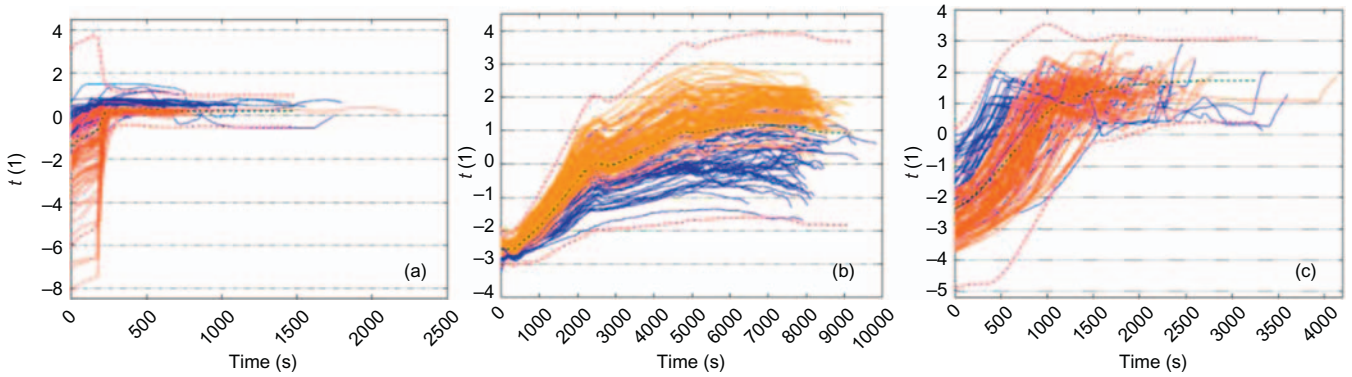

FIGURE 20.9 Multivariate batch control charts for (a) mixing phase, (b) spraying phase, and (c) drying phase. (Batches are colored according to production month (January–March: black, April–July: grey).)[90]

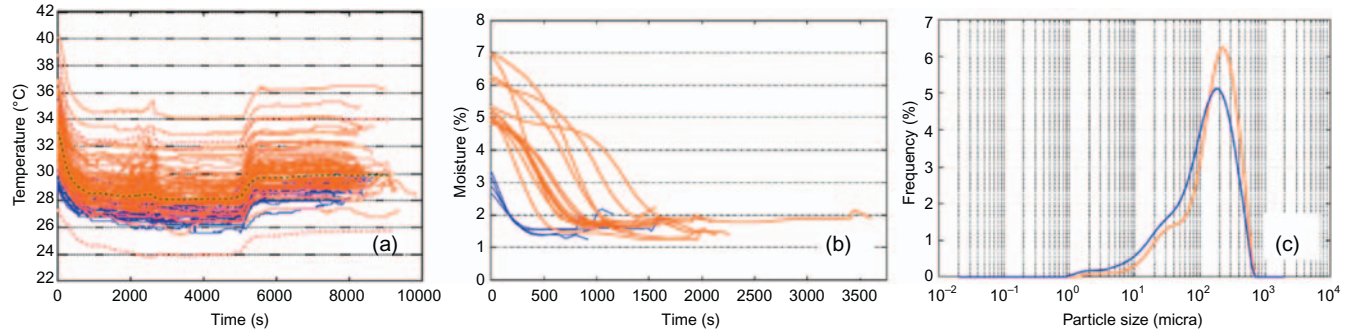

FIGURE 20.10 (a) Granule temperature profile during spraying phase, (b) granule moisture profiles during drying phase, and (c) average granule particle size distribution. (Batches are colored according to production month (January–March: black, April–July: grey).)[90]

knowledge (empirical and theoretical). Two sets of DOEs, a screening DOE and an optimization DOE, were executed on the pilot scale with a batch size of approximate 180 kg. In general, an optimization DOE should be performed within the same space as the screening DOE. However, results from the two DOEs were combined and analyzed simultaneously using PCA in this study because the binder spray rate was intentionally altered outside the range explored in the screening DOE (Fig. 20.11). The effect of CPPs on CQAs of the granules (ie, particle size distribution (PSD), bulk and tapped densities, flowability, and angle of repose) was investigated. The results demonstrated that the granule quality is strongly correlated with the moisture profile during the spraying phase. The granules manufactured under wetter conditions have improved flowability, narrower PSD, and less agglomerates (ie, smaller impact by drying phase conditions).

Taking into consideration the multivariate interactions, a design space was determined using a mathematical model between the CPPs and CQAs and shown in Fig. 20.12. In Fig. 20.12a, the desired dimensional space corresponds to the granules flowing through an orifice with values lower than 5.5 s/100 g as marked by a filled circle. The design space of the granule moisture time profile can be computed using the model as shown in Fig. 20.12b. Outside the design space, there is a risk of either a fluidization issue/bed collapse (above the upper limit) or decreased granule quality (below the lower limit). The corresponding design space for the inlet air temperature and binder spray rate in the spraying phase are shown in Fig. 20.12c, which excludes the lower right corner where granules flow through an orifice for which the value is equal or higher than 5.5. Density and flow properties of the pilot-scale granules manufactured within the design space showed lower variability compared to the historical commercial-scale granules (Fig. 20.13). A narrower PSD with a decrease in fine particles was also observed (Fig. 20.14). These granules were successfully compressed into tablets that meet all quality requirements.

To apply the study findings to the commercial-scale FBG process, acceptable limits of critical parameters were calculated using the scale-up approach of matching (1) solid density in FBG, (2) air flow Reynolds number, and (3) a process time constant related to spraying flux. A comparison between the newly proposed process ranges and the existing filed limits and

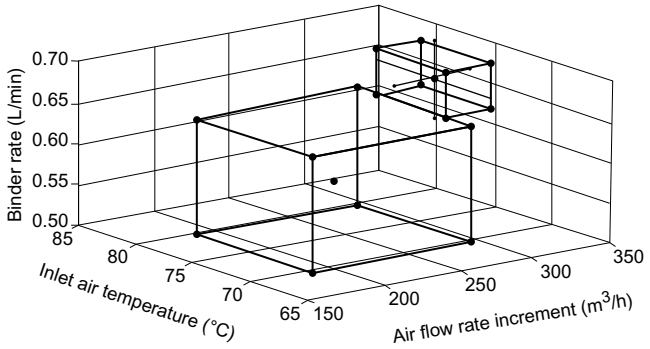

FIGURE 20.11 Pilot-scale design of experiments (Screening DOE: squares, optimization DOE: circles and stars).[91]

operating ranges is provided in Fig. 20.15. The original process consists of five spraying subphases (ie, the five white bars for air flowrate). Since the air flow rate was proven to be a noncritical process parameter for granule CQAs based on pilot-scale DOEs, a simpler process consisting of only one set of flow rate conditions is proposed.

Based on enhanced process understanding, granules quality variability due to seasonality effect can be decreased using an in-line moisture analyzer in combination with the mathematical model that correlates CPPs with moisture content and other quality attributes of the granules as control strategies. This approach offers process flexibility while accommodating the inlet air humidity variability. However, if such a strategy could not be implemented, the seasonality effect can be reduced or minimized by applying the

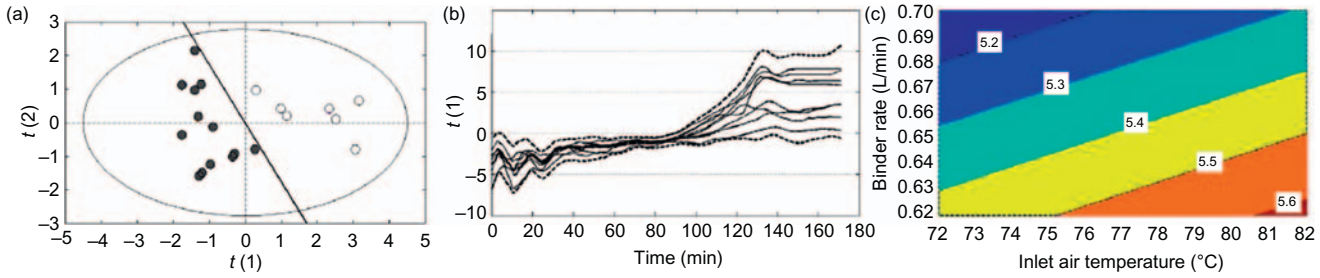

FIGURE 20.12 (a) Design space for granule attributes in the low dimensional space ($t1$ vs $t2$) of their mechanical properties, (b) design space for the granules moisture profile defined in the original variable, (c) design space for the critical process parameters (at the pilot scale).[91]

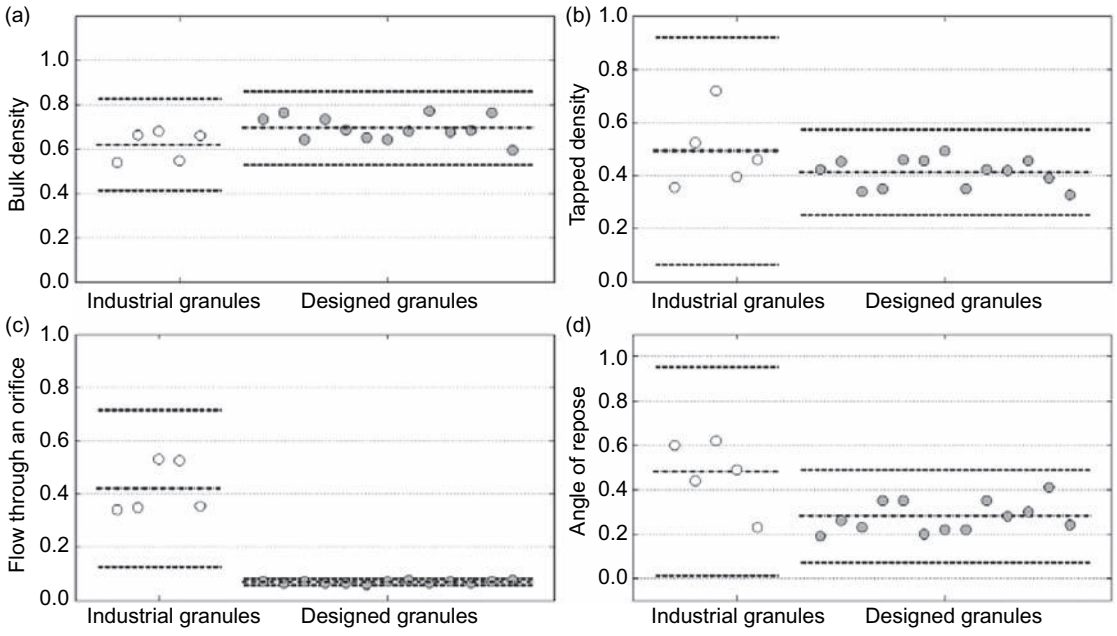

FIGURE 20.13 Physical properties comparison of pilot-scale granules generated within design space (filled circle) versus commercial-scale granules (empty circle).[91]

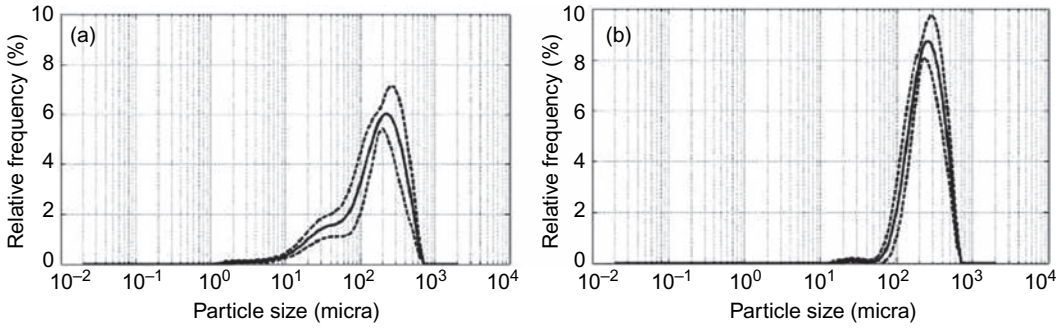

FIGURE 20.14 PSD comparison of pilot-scale granules generated within design space (filled circle) versus commercial-scale granules (empty circle).[91]

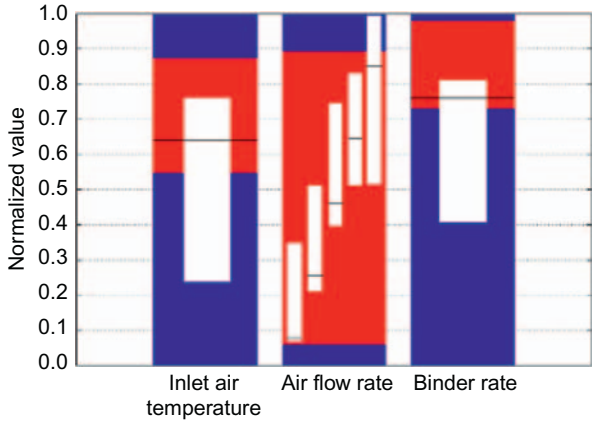

FIGURE 20.15 Range and set points for inlet air temperature, airflow rate, and binder spray rate (submitted limits: black, nominal operational range: white, proposed design space: grey).[91]

newly defined design space. Since the drying time profile shift shown in Fig. 20.9c is due to the seasonality effect in the spraying phase, the focus needs to be placed on consistently achieving sufficient granule moisture content during the spraying/granulation phase. Based on the mass balance, the final granule moisture is determined by the water introduced into the system and the moisture removed by airflow. The total water is introduced into the system via two routes: (1) binder solution which is normally well controlled and (2) moisture present in the inlet air which varies with season and is identified as the primary cause for the observed variable granule quality. Decreasing the portion of inlet air moisture presented in total water will translate to lower impact from the seasonality effect. Compared with the granule moisture profiles of the existing commercial-scale process, significant higher granule moisture with much tighter control range is proposed for the improved process (as shown in Fig. 20.16) and the higher granule moisture can be achieved by adjusting the controlled process parameters include increasing binder spray rate, decreasing air flowrate to lower the drying capacity, or the combination of both. This study shows that the seasonality effect on granule quality due to uncontrolled moisture brought into the system from the inlet air can be reduced to improve process capability through enhanced product and process understanding.

20.5 INTELLECTUAL PROPERTY CONSIDERATIONS

Intellectual property (IP) rights are central to the pharmaceutical industry because of the high R&D costs, low success rate, and lengthy product testing required before a drug product can enter the market. In general, IP estate of pharmaceuticals not only encompasses patents that protect innovations, but also regulatory or legislative exclusivity, trade secrets that are difficult to reverse-engineer. Among various types of patents, the most important are the composition-of-matter (ie, chemical entity) patents. However, the creation of an IP portfolio to cover a range of drug delivery characteristics and related dosage forms has also become a key strategic element in extending product life cycles. Life cycle management can often play a significant role by offering differentiated products with clinical benefits when the new product development, medical need, and market requirements are aligned. Over the past few decades, many companies have reaped great benefits from this type of IP generation. The patentable subject matter (or statutory subject matter) in dosage form development includes modifications of structure (eg, new solid phases, salts), formulation (eg, composition, technology, particle size or surface area of the API), method of treatment (eg, route of delivery, dosing regimen), process, methods of improving bioavailability or overcoming stability problems, newly discovered clinical benefits (eg, decreased adverse events, new indications), or performance (drug release profiles, PK or PD outcomes) resulting from MR delivery independent of delivery technologies applied.[94] One of the classic examples

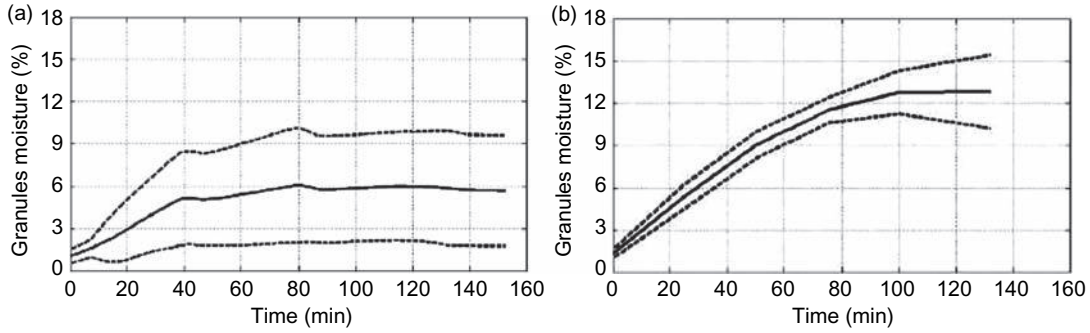

FIGURE 20.16 Granule moisture profiles during the spraying phase of (a) commercial-scale granules, (b) proposed granules.[91]

involves development of patents protecting niche products of nifedipine (Procardia XL and Adalat CC). Because the 3-year regulatory exclusivity expired in 1992, the ER products had to rely on the exclusivity provided by patents that claim benefits of ER delivery and controlled particle size for enhancing bioavailability. Among four patents listed in the "Orange Book,"[95] the most critical is US patent 5,264,446 that claims, "A solid pharmaceutical composition comprising as the active ingredient an effective amount of nifedipine crystals with a specific surface area of 1.0−4.0 m^2/g, in admixture with a solid diluent, to result in a sustained release of nifedipine." As a result, the innovator product retained exclusivity for an additional 9 years until a competitor utilized finer particle size and amorphous drug, as disclosed in the US patent 5,455,046. Examples of more recent successful drug delivery/product patents for marketed products include: Nexium (esomeprazole magnesium), Allegra (fexofenadine), Tricor (fenofibrate), Concerta (methylphenidate), and Ambien CR (zolpidem tartrate).

It should be noted that most of the above mentioned products were developed at a time when there were fewer companies with novel drug delivery development expertise and experience. Because of the increased scientific know-how and technical maturity, as well as more crowded patent landscape in drug delivery, formulation and drug delivery technology-based patents have become more difficult to obtain or have lower hurdles to get around after granting. In protecting innovation in the manufacturing process or method, trade-secrets or unpatented proprietary know-how may also be considered because process patents can sometimes be difficult to enforce. One of the classical examples is the successful protection of commercial manufacturing know-how of stable paclitaxel protein-bound nanoparticles that consist of 90% albumin and 10% API. Therefore, an effective and robust IP strategy for a new drug product should be built upon continuous development and review of both in-house and in-licensed opportunities throughout product life cycle. More specifics and examples can be found in Chapters 39 and 40 in the first edition of this book.

20.6 SUMMARY

Development of a new product consists of a sequence of stages, beginning with an initial product concept or idea followed by design, testing, development, technology transfer, and commercialization. To effectively and efficiently turn an idea on paper into a high-quality solid dosage form that is demonstrable, producible and manufacturable, it is imperative to integrate formulation and process design and utilize a systematic approach throughout the development process. In most cases, quality and manufacturing challenges or problems encountered during pharmaceutical development or commercial production can be attributed to a design deficiency or flaws due to inadequate product and process understanding. Efforts spent in addressing or "patching" these problems at later stages of a product lifecycle not only are costly and time-consuming but are also often unable to resolve the underlying cause. This chapter emphasizes the importance of applying multidisciplinary knowledge for the fundamental understanding of drug substance, excipients, delivery technology that matches drug properties, processing technology, and their interplay to enable rational design and development of solid dosage forms. A high level of product and process understanding during the design and development phase is the key to ensure that (1) a product can meet its predefined quality attributes and (2) the manufacturing process is capable of consistently producing drug products of the same quality while accommodating the expected variability of raw materials, operating conditions, process equipment, environmental conditions, and human factors.

[3]Regulatory Affairs Abbott Laboratories, Abbott Park, IL, United States

To ensure the quality of active pharmaceutical ingredients (APIs) and finished drug products, analytical methods must be developed and validated for the intended use. Method development and validation for submission for marketing application and for life cycle management of products is clearly outlined in guidance documents published by the agencies such as the International Conference on Harmonization (ICH)[1] and Food and Drug Administration (FDA).[2] However, the requirements of method development and validation during the earlier phases of product development vary, and this is a worthy topic for discussion. In addition to the many guidance documents that discuss method validation, there are several books available that provide a detailed interpretation of the existing regulations and discuss the appropriate techniques for method development and validation.[3,4] This chapter outlines a strategic approach to the development and validation of analytical procedures for solid oral dosage forms from early development, registration of marketing authorization, to postapproval of market products. With this information, as well as by giving details of case studies, we intend to aid readers in understanding the required aspects of method validation and method transfers.

21.1 ANALYTICAL METHOD DEVELOPMENT AND VALIDATION STRATEGY

A strategic approach to the development and validation of analytical methods is critical for the efficient operation of a product development group. This strategic approach balances the amount of validation required to ensure that a method is appropriately validated for the phases of product development with the need to be cost effective and meet tight project timelines.

Existing regulations allow a great deal of flexibility in terms of the amount of data that needs to be submitted during the course of drug development. For clinical studies in the United States, the expectations for what information needs to be provided are outlined in 21CRF 312.23(a)(7)(i) and guidance documents discussing the requirements in the different investigational new drug (IND) phases.[5–7] For studies performed in the European Union, similar guidance is provided for Investigational Medicinal Product Dossier (IMPD) content.[8] All the documents emphasize the graded nature of chemistry, manufacturing, and control information needed as development progresses. At all phases, sufficient information should be submitted to ensure the proper identification, strength, quality, purity, and potency of the investigational candidate. The amount of information that will provide assurance will vary with the phases of the investigational compound, the dosage form, the proposed duration of any planned clinical trials, and the amount of information already available about the compound. In addition, developing a defendable strategy for method development and validation can minimize the required resources while providing the appropriate assurance of quality that differentiates the most productive research and development (R&D) analytical group from the others.

Developing Solid Oral Dosage Forms
DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00021-2

Prior to developing any analytical method for finished products, the drug substance must be well characterized and understood. At these earliest stages of drug development, it is essential to gather information on the drug substance such as pK_a, crystal form, melting point, particle size distribution, solubility in different solvents, sink condition and intrinsic drug dissolution rate (useful later for dissolution method development), hygroscopicity, and UV/Vis characteristics. Another critical part of this early development work will focus on forced degradation studies. The results of these studies will help in both formulation development and method development. The first analytical methods that are developed may have minimal validation but should be sufficient to provide analytical support during early formulation development such as excipient compatibility study and prototype formulation development. The results from these early feasibility studies will determine which of the multiple formulation options are selected for further development and, ultimately, clinical study. Therefore, the methods should be able to indicate the significant decreases in potency or increases in related substances. These measures will be helping the selection of the preferred formulations.

In early nonclinical and clinical phases, it is important that the impurity profile observed from each drug substance and drug product lot be established for future reference and comparison. If the impurities present in the nonclinical studies can be confirmed, the information may be useful at later stages in the development course. To be able to generate an impurity profile in a reliable and repeatable fashion, emphasis must be placed on the methods for related substances, as well as the assay method that is used for product release and stability studies. In addition to the need to refer back to the impurity profiles, the material of First in Human (FIH) enabling Good Laboratory Practices (GLP) tox lot is normally manufactured and characterized in the early stages of development. One key component for calculating purity is to have a specific test that separates all impurities. An additional key component of this development is to establish the stability-indicating capabilities of the methods for drug substances and the selected formulation. Characterization of the impurities can be conducted at later stages of development, while in the early stages, identification reliance on the presence of impurities in the FIH enabling the GLP toxicology lot ensures patient safety.

By the time that a project enters Phase I study, sufficient method history for the drug substance and drug product should be available in order to have reasonable confidence in the methodology. At this point, if a method has not yet been validated, formal validation studies should be conducted. For Phase I, methods should be appropriately validated prior to testing the clinical drug substance and the clinical formulation. Partial validation is normally sufficient and acceptable for the early stages. Often, all parameters apart from intermediate precision and robustness are validated at Phase I. Intermediate precision is then completed at Phase II, and robustness is added at Phase III. One validation parameter which is not necessarily required but is strongly recommended is solution stability. By validating a minimum time for which the sample and standard solutions are stable, flexibility in laboratory procedures and the ability to store prepared solutions are achieved. Without validated solution stability, solutions must be prepared fresh prior to each analysis. Additionally, if significant degradation is observed during the solution stability validation experiments, it may indicate possible degradation during analysis.

Another reason for a strategic approach to method validation is that the validation studies may need to be repeated multiple times at different development stages. This revalidation may be required due to new impurities, changes in formulations, or possible improvements in the methodology to utilize new technologies or make methods more appropriate for quality control (QC) laboratories. The full validation of analytical methods to meet the applicable guidance documents is required by the time of filing of application for marketing authorization via the submission of common technical documents.[9] Additionally, every effort should be made to have the final methods in place by the start of the registration stability studies in order to avoid the need to discuss and justify method changes during the submission and review cycle.

The strategic approaches for method validation in each phase of drug development are outlined in Table 21.1.

TABLE 21.1 Phasing Approach for Analytical Method Validation in Each Phase of Clinical Trial Materials

Validation parameters	Preclinical	Phase I	Phase II	Phase III
Specificity	Yes	Yes	Yes	Yes
Repeatability	Yes	Yes	Yes	Yes
Intermediate precision	No	No	Yes	Yes
Linearity	Some	Yes	Yes	Yes
Accuracy	Some	Yes	Yes	Yes
Detection Limit (DL)	Yes	Yes	Yes	Yes
Quantitation Limit (QL)	No	Yes	Yes	Yes
Robustness	No	No	No	Yes
Analytical solution stability	No	Yes	Yes	Yes

21.2 CATEGORY OF ANALYTICAL METHOD AND METHOD DEVELOPMENT

The reliable analytical method is a key element of the quality system. Methods are developed and applied for identification, strength determination, purity measurement, and control of other quality attributes of the products. For the majority of solid oral dosage form drug products, the following tests are required: physical appearance, identification, potency assay, related substance assay, drug release (dissolution) testing, residual solvents (if applicable), and moisture determination. Microbial testing may be required for QC of solid oral products. (Method development and validation for microbial tests is beyond the scope of this chapter.) In addition, other tests may also be required, especially when the API has multiple polymorphs that may have different physical characteristics. These tests could include powder X-ray diffraction (PXRD), near-infrared (IR), and Raman spectrometry. It is extremely important that the polymorphic form of APIs in products is under control during the manufacturing process and stability studies. Additionally, chiral determination may be required during the development.

There are four categories of analytical methods, based on the United States Pharmacopoeia (USP), from analytical determinations to subjective evaluation of quality attributes[10]:

- Category I: Analytical methods for the quantitation of major components of bulk drug substances or active ingredients (including APIs, preservatives) in finished pharmaceutical products
- Category II: Analytical methods for the determination of impurities in bulk drug substances or degradation compounds in finished pharmaceutical products, including quantitative assays and limit tests
- Category III: Analytical methods for determination of performance characteristics (eg, dissolution or drug release)
- Category IV: Identification tests

The data elements normally required for each of the categories of assays will be discussed in Section 21.3. The specific requirement for each individual testing procedure should be taken into consideration and are discussed in the next sections.[2,10]

21.2.1 Identification

As one of the key elements in ensuring the quality of the products, the method intended for identification should be specific for the actives in the drug product. A specific identification test method, such as Fourier transform infrared spectroscopy (FT-IR), is preferred over a chromatographic method. FT-IR is often applied to drug substances. For drug products, the extraction of the actives and subsequent cleanup may be necessary to meet the specifications due to interference from excipients. If nonspecific methods are used, two independent analytical procedures are required. A single nonspecific method, such as UV-Vis or chromatographic retention time using thin layer chromatography (TLC) or high-performance liquid chromatography (HPLC), is not sufficient by itself for identification. However, HPLC equipped with a specific detector like a diode array detector (DAD) or mass spectrometer (MS) becomes a powerful analytical tool, as it obtains both the retention time and UV-Vis spectra simultaneously. Hence, it is considered an acceptable identification technique.

21.2.2 Potency assay

A specific, stability-indicating procedure should be developed and validated. A fully validated procedure, including interlaboratory precision and specificity based on stressed studies, should be part of the phase III method. Reduced validation at earlier phases is applicable, as discussed previously. Generally, it is considered to be acceptable and cost effective for two HPLC assay procedures for commercial products to be developed and validated: one with shorter run time for initial release, and the other with stability-indicating characteristics for stability research. For a method of initial release, it is required to ensure that the active peak is well clear of all known impurities, including those that may arise from the manufacturing process, while other degradants are unlikely to be present in the fresh products.

21.2.3 Impurities

Impurities in drug substances and drug products include organic impurities, inorganic impurities, and residual solvents. Organic impurities are generally called *related substances* since they are structurally related to the drug substance. These substances may be identified or unidentified degradation products and can arise from many sources, including the raw materials, starting materials, and purchased intermediates, during the manufacturing process or storage of a material. The earlier the impurities are identified during drug development, the more time there is to address them through process changes or qualification studies. Guideline Q3B outlines the identification and qualification thresholds for impurities in drug

substances and drug products. During drug development, validation of impurity methods for accuracy, detection limits (DLs), and quantitation limits (QLs) and response factors can be accomplished by spiking the impurities into the drug product or into a placebo mixture and by evaluating the analytical results of the spiked samples. In addition to the majority of impurities, see ICH guidance M7, which covers assessment and control of potential genotoxical impurities.[10–13]

21.2.4 Dissolution

Dissolution or drug release testing is commonly considered to be a critical QC for solid oral dosage forms. In the absence of in vivo data, it is a challenge for scientists to develop a procedure that not only guides the formulation development process but also can be used as a regulatory test to detect manufacturing deviation and ensure product consistency both upon release and over the products' shelf life. The primary goal is to develop a discriminating, rugged, and reproducible dissolution method, which must be able to highlight significant changes in product performance due to changes in the formulation or manufacturing process. The objective of dissolution testing varies during the life cycle of dosage form development. During the early stage of phase I, a method is developed to establish the mechanism of in vitro drug release. During phases II and III, the objective shifts to identifying a test method that can provide an in vitro–in vivo correlation (IVIVC) or other biorelevant information. By having a method that has a proven IVIVC, a significant increase in the guiding power of the dissolution method for developing bioequivalent multiple strengths of the product and a reduction in the regulatory burden caused by postapproval changes can be achieved. The inclusion of a new chapter in USP 30/NF 25 provides recommendations on how to develop and validate a dissolution procedure.[22] See chapter "Dissolution Testing of Solid Products" for more information on dissolution testing of drug products.[14–25]

21.2.5 Blend homogeneity and dosage uniformity

The term *uniformity of dosage unit* is defined as the degree of uniformity in the amount of the drug substance among dosage units. The harmonized compendial chapter on uniformity of dosage units outlines the release criteria to show uniformity. In addition to the uniformity at release, it is important during development to demonstrate the uniformity of blend samples and the uniformity of dosage units throughout the manufacturing run (lot uniformity). The analytical procedure for assay can be used to determine the drug content of uniformity samples. In the cases where a complicated procedure or long HPLC run time is required for assay but is not needed for blend uniformity/content uniformity (BU/CU) determinations, a separate testing procedure with shortened run time may be developed. Run time in the BU/CU chromatographic methods may be much shorter than in the assay method because stability-indicating capability may not be required. Generating BU and lot uniformity data is the key to understanding the manufacturing process during the development phases of the products. The procedures to demonstrate adequacy of mixing for powder blends using stratified sampling of blend and dosage units were published by Boehm et al. (2003)[26].

21.2.6 Cleaning test method development

Regardless of the stage of development, if reusable equipment is used during manufacturing, current good manufacturing practices (cGMP) require that cleanliness of the equipment be demonstrated to eliminate the risk of cross-contamination and to ensure that residual material is removed from the equipment after use. The validation of analytical procedures used to determine residual actives from swabbing or rinsing samples should be conducted as a critical step for cleaning validation.

In addition to the normal validation required for analytical methods, cleaning analytical methods must include confirmation of surface recovery. Depending on the equipment and how cleaning confirmation is performed, surface recovery studies may be conducted using both rinsing and swabbing samples from multiple surface types. For many types of equipment, cleaning is performed using large volumes of the appropriate solvent. A portion of the final rinse solvent can be collected and taken for analysis. In this case, confirming recovery based on rinsing is appropriate. For some pieces of equipment, the surface is swabbed and the swabs are taken for analysis following rinsing. In these cases, surface recovery using swabbing is appropriate. Common manufacturing materials include different grades of stainless steel (some of which have many different recovery characteristics), polymers, and glass. Spiking and recovery experiments need to be performed on coupons of the materials that will be used in manufacturing.

There are a number of challenges in validating a cleaning method. To reduce the possible challenges, scientists in analytical labs should work closely with

the manufacturing group to understand what is required for the method and eliminate unnecessary hurdles. These hurdles could include the use of solutions like bleach, which destroys the active molecule but results in degradation products that could have toxic characteristics; cleaning solutions that interfere with the chromatography or degrade the active substance in solution; or swabs that have extractables that interfere with the analysis. To reduce the risk of extra unknown peaks from the materials of swabs, the same materials that will be used in the manufacturing facility must be used during method development. The selection of the solvent should be based on the solubility of its active ingredient and ICH classification. The first choice of solvent should be water, isopropyl alcohol (IPA), or a mixture of the two. Minimum recovery requirements can be debated, but recoveries of <50% are difficult to justify. The final analytical method should include an adjustment factor based on the worst-case recovery to ensure that reported results are a true indication of the amount of residual drug substance left on the surface.

If water and IPA are not viable cleaning solvents, solvents that better solubilize the drug substance or cleaning agent may be required. Class 2 solvents should be avoided, and Class 1 solvents should never be used. The proposed solvents, which are commonly used, are listed in Table 21.2[12]. Depending on the final cleaning solution selected, it may be necessary to add an additional cleaning step with IPA, water, or both to the areas that were swabbed to ensure that all other solvents are appropriately removed.

TABLE 21.2 Proposed Swabbing Solvents

Number	Solvent	Boiling point (°C)	Relative evaporation rate[a,b]	Remarks[c]
1	Isopropanol	82.6	1.7	Class 3
2	Ethanol	78.1	1.95	Class 3
3	0.25% Aqueous acetic acid			Pharmaceutical acceptable excipient
4	Acetone	56.2	6.06	Class 3
5	Ethyl acetate	77.3	4.94	Class 3
6	Isopropyl acetate	85	3.0	Class 3
7	Methanol	64.6	5.91	Class 2
8	Acetonitrile	81.7	2.33	Class 2

[a] *All BPt and relative evaporation rate values were taken from MSDSs.*
[b] *All relative evaporation rates are relative to* n*-butyl acetate.*
[c] *Classification as per ICH Q3C for residual solvents.*

21.2.7 Other analytical techniques

Thus far in this chapter, we have focused on the key tests required to ensure the key quality attributes of solid oral dosage forms. In addition to the tests described up to now, many other tests may be required during development, and even as part of the filing to ensure the quality of the drug product. All methods should be appropriately validated for their intended use, and the amount of validation depends on the type of method and the stage of development. Some of the other methods that may be used include (but are not limited to) near-IR, Raman spectrophotometry, PXRD, gas chromatography (GC), optical rotation, and chiral chromatography; all of these could be applied to specific testing as well.[27–33] For example, PXRD may be used to monitor the change of polymorphs of drug substances in drug products during manufacturing process and storage.

21.3 ANALYTICAL METHOD VALIDATION

The analytical method must be validated for the intended use of the substance and will be applied for the release of clinical trial materials, market products, or both. Once the analytical method is validated and approved, it will be used to monitor the quality of a product over its life cycle. However, the performance of the method should be evaluated for appropriateness from time to time. The method may be required to be optimized by adjusting and revalidating the operational conditions. New methods may be developed and validated using new technologies (due to cost effectiveness and sensitivity) or required due to awareness of a new impurity or a recent decrease in the impurity limit. Therefore, analytical method development and validation are considered part of the lifecycle management of a product.

21.3.1 Verification of compendial methods

A compendial procedure is considered validated if it is published as official text in a pharmacopoeia such as the USP-NF, in a supplement, or as an interim revision announcement in *Pharmacopeial Forum (PF)*. When using compendial methods, full validation is not necessary, but verification of the procedure is very important. Verifications ensure that the procedure is suitable for

use with a specific ingredient or product, in a specific laboratory.[34] For example, titrimetric methods for water determination should be verified for accuracy (and absence of possible interference) when used for a new product or raw material. For impurity testing, the suitability of a compendial procedure may be an issue for several reasons (eg, impurity profile changes from different routes of synthesis, composition of formulation, or interference from excipients). It is recommended that the testing lab thoroughly evaluate the suitability of the pharmacopeia monographs prior to being applied to their own products.[35–37] For example, forced degradation may be applied to establish the suitability of the chromatographic conditions.

21.3.2 Characterization of reference standard

During method validation, a well-characterized standard should be used. A well-characterized reference standard is a critical factor for method validation. For potency assays, the purity of the standard must be assigned. For impurity assay validation, some impurity standards may not be of high purity, but they must be characterized to confirm their identity. It is important to ensure that any impurities contained in the impurity standard do not interfere with the analysis. If possible, the reference standard (used as the primary standard) should always be obtained from a recognized authority, such as the National Institute for Standard and Technology (NIST), USP, or European Pharmacopeia (Ph.Eur.). For new drugs, this is rarely possible; therefore, an in-house reference standard must be synthesized and characterized. The reference standard should be characterized by at least the following tests: physical appearance, identification, and purity assignment. The structure should be confirmed using multiple analytical techniques such as elemental analysis, IR spectroscopic analysis, UV-vis spectroscopic analysis, mass spectroscopy, ^{1}H-NMR, and ^{13}C-NMR. Purity assignment can be established by testing for the following: organic impurity, inorganic impurity, moisture, and residual solvents. The amount of total organic impurities may be determined by HPLC or other chromatographic methods. Moisture and residual solvents may be determined by thermogravimetric analysis or a combined Karl Fischer titration and GC method. The amount of inorganic residue can be determined using residue upon ignition. If the Karl Fischer method for the determination of water content and the GC method for residual solvents are applied, these methods should be validated (or verified if using a compendial method) prior to use. The in-house standard can be qualified against a primary standard following a well-defined qualification protocol.

21.3.3 Stability-indicating method

A stability-indicating assay, as required per the ICH guidelines,[38] should be used for any GMP stability program so that the procedure is able to detect the changes in the pertinent properties of the drug substance and drug product over time, without interference from degradation products, process impurities, excipients, or other potential system components. It is important that a comprehensive forced degradation study and HPLC coelution evaluation be conducted in order to demonstrate the ability of the procedure to detect any changes that are attributable to degradation.

21.3.4 HPLC coelution peak evaluation

HPLC with DAD or MS is a powerful tool that has the ability to detect very low levels of coeluting components. These techniques have the ability to evaluate the purity/integrity of chromatographic peaks via the HPLC method, which can be used in development and validation and are widely used in the pharmaceutical industry. Since impurities in the APIs and the actives themselves often have very similar chemical structures, the impurities are also likely to have very similar chromophores and ultraviolet (UV) spectra as the APIs. For this reason, the software provided with DAD generally includes algorithms that calculate peak purity. Additionally, during method development, forced degradation studies are performed to generate samples with exaggerated levels of likely impurities. These samples are used to evaluate and identify when coeluting components are present, at which time the increased level will offer the algorithm a greater chance of success. It is important to note that the peak purity check can only prove that the peak is impure or contains a coeluting component. DAD cannot prove that the peak is absolutely pure. However, if the peak purity check passes, the peak purity is normally considered acceptable.[39]

21.3.5 Forced degradation studies (stress studies)

Forced degradation studies, or stress studies, are the main tools that can be used to predict stability issues, develop analytical methods, and identify degradation products and pathways.[40] These studies should be performed prior to other validation parameters (eg, accuracy, repeatability, intermediate precision, specificity, DL, QL, linearity and range, solution stability, and robustness). An approved protocol is recommended before forced degradation studies can be performed.

For multiple strengths of drug products with the same excipient composition (including different ratios), forced degradation studies can be performed with

only one formulation. For multiple strengths or a formulation of drug product with different excipients, each different formulation composition should be evaluated using forced degradation studies.

If the assay methods for drug substances and drug products have different conditions that can cause changes in selectivity (eg, different HPLC columns, mobile phase compositions, gradient programs, flow rates, column temperatures, etc.), forced degradation studies should be done for both drug substance and drug product methods. In early IND phase products, if the assay methods for the drug substance and drug product have the same conditions, which result in the same selectivity, it is preferred to do forced degradation studies with drug substances for IND Phase 1 products, and with drug products for IND phase 2 products.

For IND Phase 3 phase applications and later, forced degradation studies should be done for both drug substances and drug products. Additionally, mass balance should be evaluated by the related substances detected to the assay results obtained for forced degradation samples. Generally, 5−20% degradation is optimal for forced degradation studies, although an excessive degradation is acceptable so long as it does not cause the peak purity check to fail. The more a sample is degraded, the more likely a loss in mass balance due to secondary degradation, loss of impurities in the solvent front, and loss of absorption due to ring-opening or other degradation pathways will be observed. The forced degradation studies for drug product should be performed before commencing stability studies of registration batches. The stress conditions described next are considered as extreme conditions. Alternative or less stressful conditions may be applied when excessive degradation or interference is observed.

During data acquisition, DAD should be used for HPLC, and all spectra of peaks should be collected.

The samples should include the drug substance, placebo, and drug product, and may be subject to the following conditions:

Acid/base:	Drug substance as is; 0.1 N of HCl/NaOH at RT for 1 day
Thermal:	Composite sample; 85°C for 10 days
Thermal-humidity:	Composite sample with 0.5 mL of D.I. water in a crimped vial; 85°C for 10 days
Photostability:	One layer of composite sample (thickness ≤3 mm; use a petri dish with a quartz plate cover, an open petri dish, or a dish covered with parafilm), 2−3× ICH option 2.[41]
Oxidation:	Composite sample; 3% H_2O_2 at RT for 10 days, light-protected

The following results must be included in the report: (1) assay results for parent compounds, (2) the results of coelution test of parent compounds, and (3) the profile of degradation products and other related compounds.

For Phase 3 studies, the mass balance results should also be described.

21.3.6 Method validation parameters for chromatographic methods

The steps for method validation are as follows:

- The protocols or general standard operating procedures to describe the detailed parameters, as per Table 21.3
- Execution of the protocol in the lab
- Redevelopment and validation if deviation or failure is observed during validation that is attributed to the analytical method
- Validation report

Validation parameters are included (but not limited to) linearity, precision, accuracy, robustness, QL, DL, and stability of the analytical solution. The analytical parameters such as system suitability and filter bias should be evaluated by the chromatographic method during method validation.[2,42]

21.3.6.1 Filter bias

In modern analytical techniques, the analysis is typically carried out by spectroscopy (UV-vis) utilizing a chromatographic method, either HPLC or ultra-performance liquid chromatography (UPLC). Often a filter or centrifuge is utilized to remove particulates that may clog the column or affect absorbance readings. The different types of syringe filters such as those made of nylon or polytetrafluoroethylene (PTFE), with a size ranging from 0.45 to 0.2 μm should be investigated depending on the samples. The filter should be validated by filtering a portion of the working standard solution or sample solution through each syringe filter, discarding the first 2−3 mL, and collecting the filtrate for analysis. The result from the filtered solution should be comparable to that of the unfiltered solution.

21.3.6.2 System suitability

System suitability demonstrates that the system is working properly at the time of analysis. The appropriate system suitability criteria are based on individual technology and the samples being analyzed. For all chromatographic procedures, system suitability should include injection repeatability expressed as the relative standard deviation (RSD) of peak responses obtained from five or six consecutive injections of a working

TABLE 21.3 Data Elements Required for Analytical Method Validation

Validation parameters	Identification method	Related substances and residual solvent methods		Assay, dissolution, and preservative methods
		Quantitation	Limit	
Specificity	Yes	Yes	Yes	Yes
Linearity	No	Yes	No	Yes
Range	No	Yes	No	Yes
Accuracy	No	Yes	No	Yes
Precision	No			
Repeatability		Yes	No	Yes
Intermediate precision		Yes[a]	No	Yes[a]
Detection limit	No	No	Yes	No[b]
Quantitation limit	No	Yes	No	No[b]
Robustness	No	Yes	No	Yes

[a]*Intermediate precision may be omitted if reproducibility is performed during method validation.*
[b]*Detection limit or quantitation limit may be required for methods such as determination of absence of active in placebo, dissolution testing of modified release drug products, eg, acid resistance of enteric coated tablets.*
Note: The system suitability should be evaluated for all quantitation methods.

standard solution, tailing factor (T), theoretical plate number, resolution, and relative retention time (RRT).[42] For nonchromatographic methods, system suitability tests are also used to confirm that the system is functioning correctly. For example, titration should always include a blank titration. For some particle size analyses, the solution with a known particle size is used to ensure that the system is functioning as expected.

Since HPLC methods are the most commonly used procedures, the parameters for system suitability are injection repeatability, check standard, T, theoretical plate number, system drift, and resolution, as discussed in detail in the following sections. Other system suitability parameters may be required, such as the peak-to valley ratio and signal/noise ratio for impurity testing.

21.3.6.2.1 Injection repeatability

The working standard solution will be injected five or six times into the chromatographic column. The mean and RSD for concerned peak responses such as area will be calculated as follows:

$$X(mean) = \sum_{i=1}^{n} X_i / n$$

$$\%\text{RSD} = \frac{100}{X(mean)} \sqrt{\frac{(X_i - X)^2}{n-1}}$$

where

X_i = peak response of individual injection
n = number of the repeatable injections

In general, the acceptance criteria are as follows:

The RSD for the peak area of interest from five or six injections of the working standard solution should be $\leq$2.0% for potency assay, $\leq$10% for impurity testing and residual cleaning testing, and $\leq$3.0% dissolution testing.
If the product has low strength or S/N of the active peak is less than 50, the RSD of the peak area of the active from the six consecutive injections of $\leq$3% may be acceptable for potency assay.
For API potency testing, a maximum permitted RSD is defined in USP based on specification limits.

21.3.6.2.2 Check standard

A check standard is often considered as part of integrated system suitability for a potency assay or dissolution assay. The percent recovery of the active from the check standard is calculated as follows:

$$\%\ \text{Recovery} = \frac{A_{CK}}{Wt_{CK}} \times \frac{Wt_{WSTD}}{A_{WSTD}} \times 100$$

where

A_{CK} = the peak area of the active from the check standard solution
A_{WSTD} = the average peak area of the active from the six injections of the working standard solution

Wt_{CK} = weight of the active used in the preparation of the check standard solution (mg)
Wt_{WSTD} = weight of the active used in the preparation of the working standard solution (mg)

It is acceptable that the percent recovery for the check standard solution is in the range of 100.0 ± 2.0. For a low dose/strength of the drug product, a 3.0% difference may be acceptable.

Additional standard solutions may be needed in some cases. For example, a QL or DL solution for an impurity test should be injected to ensure that the method is sensitive enough to detect impurities at the required concentration. The sensitivity could vary due to different laboratories, temperatures, columns and detectors. For a DL solution, a peak must be detected and integrated. For QL solutions, the peak area should be compared to the standard peak for recovery. For a QL solution, the recovery should be between 80.0% and 120.0%.

21.3.6.2.3 Tailing factor

The T of the active peak from the working standard solution is calculated as follows:

$$T = \frac{W_{0.05}}{2f}$$

where $W_{0.05}$ is the peak width at 5% of the active peak height from the baseline, and f is the distance from the peak maximum to the leading edge of the peak (the distance being measured at a point 5% of the peak height from the baseline). The peak is symmetrical if $T = 1.0$. It is generally considered to be reasonable if T is no more than 2.0, but the acceptable T should be confirmed during robustness experiments since excessive tailing or fronting could affect resolution between peaks.

21.3.6.2.4 Theoretical plate number

The theoretical plate number per column (N) for the peak can be calculated from the first injection of the working standard solution as follows:

$$N = 16\left(\frac{t}{w}\right)^2$$

where t is the retention time of the active peak and w is the peak width of the peak, which is obtained by extrapolating the relatively straight sides of the peak to the baseline. The appropriate requirements for this parameter should be derived from validation data.

21.3.6.2.5 System drift

Periodic injections of the working standard solution should be made after a certain number of sample injections and at the end of the run. The percent recovery of system drift injection can be calculated as follows:

$$\%\ \text{Recovery} = \frac{A_{SCK}}{A_{WSTD}} \times 100$$

where

A_{SCK}: peak area of the active from the system drifts injection of the working standard solution
A_{WSTD}: average peak area of the active from the first six system suitability injections of the working standard solution

For system drift, the percent recovery of system drift injection throughout the run should be the same level as that of the injection repeatability. If the system drift meets this requirement, the average peak response from the first consecutive injections can be used to calculate the samples. Otherwise, a bracketing procedure should be used. In addition to the peak area, the retention time should be evaluated. For identification, the retention times should not vary by more than 2%.

21.3.6.2.6 Resolution

The resolution factor (R) should be calculated to demonstrate that the critical pairs of adjacent peaks are adequately separated and therefore can be independently integrated. The value of R from the first injection of the working standard solution can be calculated as follows:

$$R = \frac{2(t_{n+1} - t_n)}{W_{n+1} + W_n}$$

where

t_n = retention time of peak n
t_{n+1} = retention time of peak $n + 1$
W_n = peak width of peak n
W_{n+1} = peak width of peak $n + 1$

The minimum resolution between each identified critical pair of adjacent peaks should be ≥ 1.5 since this represents the baseline separation of two neighboring Gaussian peaks. Resolution can also have an upper limit to make sure that peaks have not drifted too far away, minimizing the risk of significant changes in the retention properties of a column.

21.3.6.3 Accuracy

The accuracy of the method can be determined by spiking known amounts of the active at suitable levels of the label-claimed amount, as per Table 21.4, to the corresponding placebo powder (or an amount of placebo mixture containing all the ingredients for the

TABLE 21.4 Accuracy and Acceptance Criteria Proposed

Test	Accuracy	Acceptance criteria
Cleaning residual	70%, 100%, and 130%	Minimum lowest recovery at each level ≥50%
Potency (DS and DP)	70%, 100%, and 130%	Average recovery at each level is between 98.0 and 102.0
Dissolution (immediate release)	50%, 100%, and 120%	Average recovery at each level is between 97.0 and 103.0
Dissolution (controlled release)	20%, 100%, and 120%	Average recovery at each level is between 97.0 and 103.0
Dissolution (delayed release)	Acid stage: 1% and 10% Buffer stage: 50% 100%, and 120%	Average recovery at each level is between 97.0 and 103.0
Related substance (DS and DP)	QL, 100% and 200% of spec.	Average recovery at each level is between 90.0 and 110.0 For QL, 80.0−120
Residual solvent	50%, 100%, and 120% of spec.	Average recovery at each level is between 80.0 and 120.0

formulation except active), and then calculating the percent recovery of the active. For Phase 3 accuracy experiments, three sample preparations are required at each spiking level, and a minimum of three levels should be assessed. Table 21.4 describes the range and the levels for each individual testing procedure.

Percent recovery is calculated by the assayed amount divided by the known amount of analyte spiked in the sample. Typical acceptance criteria are also provided in Table 21.4. Percent recovery, average recovery from each level and overall levels, and confidence intervals should be evaluated.[43] For potency assay, the RSD of recoveries for each spiked level should be not more than 2.0%. For low strength of drug products (eg, ≤1 mg), a wider range such as 3.0% for potency and 5.0% for dissolution may be applied. For dissolution testing, the drug substance and placebo (or an analytically prepared placebo) may be spiked into the dissolution vessel. The mixture of drug substance and placebo may be considered to be useful if the recovery of the analyte of interest is less than expected. It could be due to the unique characteristic of drug substances in the dissolution media. For low strength of the drug product, it may not be possible to spike drug substance into the dissolution vessel, in which case spiking with drug solution may be used. Drug substance solutions with high concentrations should be prepared by dissolving in an organic solvent or dissolution medium. The dissolution medium to use is the first choice. If the medium is not suitable, organic solvents may be used, but the volume of solvent spiked should not be more than 5% of the total medium volume.

For recovery studies in impurity tests, an aging API or stressed API sample spiked into placebo may be used to demonstrate the recovery of impurities in the sample when the impurity standards are not available.

21.3.6.4 Precision

Precision should be evaluated through repeatability, intermediate precision, or reproducibility. These concepts are discussed in the next sections.

21.3.6.4.1 Repeatability

For related substances and residual solvent tests, repeatability can be evaluated by spiking impurities or solvents at the specification limit for the products. In early phases of development, little may be known about the impurities, so minimal repeatability data may be generated. For the potency assay, repeatability can be assessed using drug products (tablet or capsules) with a minimum of six determinations at 100% of the test concentration. Typically, the RSD of 2.0% for the % label claim (LC) of the active from six replicate sample preparations is achievable.

21.3.6.4.2 Intermediate precision

Intermediate precision is a measure of the method's sensitivity to minor changes in equipment performance and to variations in the operator's technique on a given day. A second analyst should perform the assay using different equipment and on a different day to confirm that acceptable results can be obtained in the intralaboratory settings. The absolute difference between the mean % LCs of the active generated by the variation of these factors, including analysts, time, and equipment, should be <3.0%, but the exact criteria are based on the type of test and ultimate specification (eg, if the drug substance assay specification is 98.0−102.0%, then the difference between laboratories should be <1.5%, but for a drug product with a specification of 90.0−110.0%, a wider criteria such as NMT 3.0% could be used).

21.3.6.4.3 Reproducibility

Reproducibility is a measure of the method's sensitivity to laboratory changes. It could be moderate changes in equipment performance or variation in the operator's technique and the lab environment. Reproducibility is generated by two separate laboratories running the test and is therefore also called *interlaboratory precision*. The absolute difference between the

mean % LCs of the active generated by the two labs should be <3.0%, but the exact criteria are based on the type of test and ultimate specification (eg, if the drug substance assay specification is 98.0−102.0%, then the difference between laboratories should be <1.5%, but for a drug product with a specification of 90.0−110.0%, a wider criteria such as NMT 3.0% could be used).

The results, such as mean, standard deviation, RSD, and confidence interval, should be evaluated and reported on for each type of precision.

21.3.6.5 Linearity

A linear relationship between the concentration and the respective response can be obtained by analyzing a series of standard solutions.

At least five standard solutions with a specific range, as specified in Table 21.5, should be prepared. One injection of each of the linearity standard solutions may be sufficient. The peak area of the active will be measured at different concentrations and plotted against the corresponding concentrations. The correlation coefficient (r), y-intercept, slope of the regression line, and residual sum of squares will be calculated by the method of least squares, and a plot of the data should be reported.

The correlation coefficient should not be less than 0.999 for potency assay, and not less than 0.99 for other tests. It is very useful to evaluate the difference between the estimated value from regression line and the actual value. Limits for the difference may be defined when applicable. For example, it is acceptable that the percent difference between the calculated value (concentration) from the regression line and the actual value is no more than 20% at the QL level for impurity assay.

In some cases, a combined method for potency and impurity assay is used. It is quite common that impurity standards are unavailable in the early stage of product development. The area percent or amount of impurity calculated from the standard at 100% level of LC is typically reported if it is linear from the reporting or the QL level to 120% of the label-claimed level of strength. Otherwise, underestimated results may cause some issues later if the degradation/impurity approaches or exceeds the qualification/identification level as defined in ICH Q3B(R2). If it is not linear from the QL to 120% of LC, a diluted standard should be used to minimize any bias in the impurity calculation. If impurities are available, impurity standards containing known impurities at the respective specification levels should be prepared. By comparing the slope of each impurity to the slope of the main standard, response factors or normalization factors can be established and a single point standard can be used to accurately quantitate the known impurities.

TABLE 21.5 Ranges in the Regression Line

Test	Linearity
Cleaning residual	QL to 130%[a]
Potency (DS and DP)	70% to 130% of LC
Dissolution (immediate release)	50% to 120% of LC
Dissolution (controlled release)	20%[b] to 120% of LC
Dissolution (delayed release)	Acid stage: QL to 10%; Buffer stage: 50% to 120%
Related substance (DS and DP)	QL or reporting level to 200% of spec.[c] QL or reporting level to 120% of LC if area percent is reported.
Residual solvent	50% to 120%[d] of spec.

[a]*Consider 200% when spec. is very low.*
[b]*Unless the spec. requires lower %*
[c]*If spec. is unknown, use 0.5%.*
[d]*Consider 200% when spec. is very low.*

21.3.6.6 Specificity

The specificity of the method must be investigated in order to confirm that an analytical procedure is specific for the analyte of interest in the presence of components such as impurities, degradants, and matrix components (excipients). For an HPLC procedure, the specificity can be demonstrated by the separation of the critical pair of components (i.e., API and impurity, two impurities, etc.). In such cases, a DAD is useful for detecting coeluted peaks in the samples spiked with an impurity when the impurity is available, as well as in the stressed samples. Also, a carryover study should be conducted. For HPLC methods, it is recommended to double the isocratic run time or the holding time of the last stage of a gradient elution program to detect any strongly retained eluents in the placebo or samples.

21.3.6.7 Stability of standard and sample solutions

It is essential that the sample and standard solutions are stable throughout sample preparation and analysis. Proving the stability of the standards should be part of the validation process.

The standard solutions should be freshly prepared, and the concentration of the standard solution is used as the initial value. Portions of the working standard solutions are stored under refrigeration (5°C ± 3°C) and at controlled and monitored room temperature.

These stored portions of the standard are assayed at various time points (such as 1 day, 3 days, etc.) to determine the concentration of the analyte of interest with reference to the freshly prepared standard solution.

For potency assays, the standard and sample solutions are considered to be stable if the percent difference between the initial values and those at a specific time is no more than 2.0%, but any downward trend in the data should also be evaluated for possible impact on the analysis.

For dissolution samples, the stability of the samples in the dissolution vessels is another parameter to be validated in addition to the stability of the standard and sample solutions discussed previously. The sample in the dissolution vessel should be stable at least up to the final sampling time. The sample solution can be obtained by spiking the analyte of interest (either by spiking a drug solution into the medium or by dissolving the API substance into the medium in the vessel within a very short time) and placebo at 37.0°C ± 0.5°C.

For impurity analysis, the sample solution is considered stable if the following conditions are met:

If 0.10% ≤ the individual related substance <0.50%, the absolute difference between the initial and specific time point values should be ≤0.10%.
If % individual related substance ≥0.50%, the percent difference between the initial and *t*-time point values should be ≤20.0%.
No new degradation product ≥ QL of analyte of interest should be detected.

If these conditions cannot be met at any of the time points and storage conditions, then the sample and standard solution must be analyzed within the time period in which these conditions do apply. In the worst-case scenario, the sample solution has to be freshly prepared prior to each injection to obtain consistent impurity profile results.

21.3.6.8 DL and QL

As defined in ICH Q2 (R1), the DL of an individual analytical procedure is the lowest amount of analyte in a sample that can be detected, but not necessarily quantitated as an exact value. The QL is the lowest amount of analyte in a sample that can be quantitatively determined with suitable precision and accuracy. The DL and QL are critical parameters of analytical procedure validation for residual solvent and impurity assay.

There are several approaches for determining DL and QL, which are described in ICH Q2 (R1) and discussed in the next sections.

21.3.6.8.1 Visual evaluation

Visual evaluation is most likely to be used for the noninstrumental method. They can be determined by the analysis of samples with known amounts of an analyte and by establishing the minimum level at which the analyte can be detected (DL) or quantified with acceptable accuracy and precision (QL). For QL determination, six replicate samples may be required to be prepared and tested.

21.3.6.8.2 Signal-to-noise-ratio approach

The signal-to-noise ratio of the peak of analyte of interest in the sample should be at least 3:1 from DL solution and 10:1 from the QL solution. For chromatographic techniques, the signal of the peak and the baseline noise can be measured manually or instrumentally using the built-in software. It is typical to follow USP procedures for the determination of signal-to-noise ratios.

For HPLC and GC, the DL and QL of an analyte may be determined by the serial dilution of a standard solution with diluent and injecting into the chromatographic systems for assay. Then QL and DL are determined by the signal-to noise ratio.

21.3.6.8.3 Standard deviation of the response and slope approach

DL and *QL* may be expressed as follows:

$$QL = \frac{10\sigma}{S}$$

$$DL = \frac{3.3\sigma}{S}$$

where

σ = the standard deviation of the response
S = the slope of the calibration curve

In this instance, σ may be estimated based on the blank standard deviation (measurement of the magnitude of analytical background response using six replicate blank samples), residual standard deviation of regression line, or the standard deviation of *y*-intercepts.

The reporting levels are defined as per ICH Q3B(R) based on daily intake and dose. The reporting threshold for impurity testing, 0.05%, is considered as the lowest level in most cases except for potential genotoxic impurities. Therefore, it is prudent that the concentration of the analyte in sample solution equivalent to 0.05% is prepared as the QL level. The signal-to-noise ratio for the peak of analyte should be more than 10:1. Then, QL solution should be injected as six replicates onto a chromatographic system for analysis. The RSD of the peak area of the analyte should be

≤20.0%. If the QL level cannot meet any of these criteria, the 0.10% level will be evaluated. If the 0.10% level still cannot meet any of the criteria, the method should be modified to meet all of the QL criteria.

21.3.6.9 Robustness

The robustness of an analytical procedure is critical for effective method validation and cost effectiveness in routine assays performed later. For abbreviated new drug application applications, it is recommended that the robustness of a method be evaluated during early stages of method development in order to better understand method performance over changes in operational parameters and samples. If development data support the validation of a method, they can be submitted in a validation report.

Robustness of chromatographic conditions will be performed on a sample solution, such as a repeatability sample solution with injections in triplicate, by varying the parameters specified in Table 21.6. Only one parameter at a time is altered, while the rest of the parameters remain unchanged. The design of experiment could also be used to allow multiple parameters to be varied in each experiment and thus reduce the number of experiments.

The instrument system must be equilibrated under each target and robustness condition. The system suitability requirements should be evaluated in each experiment to ensure the appropriate system suitability criteria are set for the method. Triplicate injections of the sample solution are then made under each condition. The individually determined mean values and the RSD of three injections for each robustness condition are reported. The percent of target value is calculated for each robustness test condition and should be 98.0−102.0%. If any of these robustness parameters fail to meet the acceptance criteria, a precautionary statement should be included in the method specifying the limitations.

When possible, equivalent research on different columns (lots or suppliers) should be evaluated. For related substance methods, additional evaluation should be made to determine the impact of variations on the specificity of the method.

21.3.6.9.1 Robustness on sample preparation

Robustness of the sample preparation for potency assays will be performed in duplicate sample preparations by varying the parameters specified in Table 21.7. Only one parameter is varied at a time while maintaining the remaining parameters at a target condition.

Robustness of the dissolution method will be performed on three tablets (or capsules) by varying the parameters such as medium pH value (±0.1 of target) and concentration of surfactant (±5% of target).

TABLE 21.6 Experimental Design for Chromatographic Parameters

	Parameters	Robustness test condition
HPLC	Mobile phase composition	Target: ±1%
		eg, Target: 50:50 (v/v0)
		Test-1: 49:51
		Test-2: 51:49
	Buffer pH (mobile phase)	Target: ±0.1
	Buffer molarity (mobile phase)	Target: ±10%
	Column temperature	Target: ±3°C
	Wavelength	Target: ±2 nm
GC	Temperature	±5°C
	Flow rate	10% of target

21.3.7 Nonchromatographic method validation

Additional tests to control the quality of the drug substances, excipients, and drug products such as particle size distribution, optical rotation, and methodologies such as DSC, PXRD, Raman spectroscopy, and near-IR spectroscopy should be validated prior to use. The validation parameters may be less extensive than for chromatographic methods, while in general they are likely to include repeatability, intermediate precision, and robustness; however, specificity and accuracy may also be applicable.

21.3.8 Failure and revalidation

During method validation, failure to meet validation acceptance criteria may be observed. If this occurs, investigations should be conducted to track the root causes. If these are attributed to the procedure, the validation will be terminated at this stage and new method development or revision will be initiated. The method is then appropriately revised and all changes are documented prior to revalidation. In case of a failure of comparison during repeatability and intermediate precision, all aspects should be taken into consideration (ie, chemist skills, lab equipment

TABLE 21.7 Experimental Design for Assay Sample Preparation

Parameters	Test conditions
Shaking time	Target: ±20%
Sonication time	Target: ±20%

variation, and sample variation). For any failures during validation experiments, a thorough evaluation is required to ensure that the failure is truly due to the method and not due to laboratory error or other unexpected issues like sample homogeneity.

The need to revalidate the method will be evaluated if there are changes such as column vendor, drug substance route of synthesis, and drug product composition. Some changes may not require revalidation or may require only partial revalidation (eg, new excipients would require specificity experiments), but the evaluation should always be made and the justification for not revalidating should be documented.

21.3.9 Life cycle management of test procedure

Life cycle management of approved test procedures is recommended in recently published FDA guidance for industry-analytical procedures and method validation for drugs and biologics.[2] As part of the continued improvement of quality of the products, the suitability of existing method performance should be evaluated at regular intervals due to manufacturing process changes, detection of new impurities, and decrease of specification limits of some impurity over a life cycle of the product. New test procedures may be developed and validated due to the emergence of new technologies to reduce cost and enhance efficiency. See the FDA guidance[2] for a detailed discussion of the requirements for life cycle management of analytical procedures regarding revalidation, analytical method comparability studies, and reporting postmarketing changes.

21.4 METHOD TRANSFERS

21.4.1 Definition

Any additional analytical laboratory that was not a part of the original validation process must be qualified to demonstrate that the lab executes the analytical procedure in an equivalent fashion to the originating lab. The method transfer usually occurs between the analytical R&D lab and a QC lab. This transfer can be within the same company but could also be between two different companies or different sites. There are two approaches of method transfer. Interlaboratory qualification (ILQ) is a common approach. The testing was performed on same lot of samples or spiking samples by two labs and the results obtained are comparable. Among other approaches is full or partial method validation by receiving lab. All involved methods must be assessed in order to determine the status of method transfer as necessary. Under certain circumstances, method transfer waiver for receiving lab is eligible (refer to USP38 <1224> for the requirement).

It is quite realistic or practical to avoid method transfer as a separate study if a QC laboratory or receiving lab can participate in the initial validation process or covalidation such as a reproducibility study. Under certain circumstances, it is very important to decide which approach of method transfer is more appropriate. It might be the case that partial validation of the method is more appropriate in early phases of drug product development between a contract research organization (CRO) and a sponsor, and ILQ in later phase stages.

The following steps will be required for method transfer:

1. Analytical procedure and testing materials, including reagent, instrument, and critical parameters, should be discussed and understood through technical teams between the originating lab and receiving lab.
2. The protocol must be defined and approved regarding parameters, acceptance criteria, time frame, and samples.
3. Deviation and investigation may be needed.
4. Closure and final report approval should take place.

The method transfer takes the form of a partial revalidation by the receiving lab and may include the following parameters, depending on the analytical procedure: system suitability, linearity, accuracy by recovery study, repeatability, QL/DL for related substance, and residual solvent tests.

For an ILQ, parameters may include system suitability, reproducibility, QL/DL for related substances, and residual solvent tests if QL/DL is not part of system suitability.

21.4.2 Potency

Typically, acceptance criteria for the potency assays in solid oral dosage forms are the same as that for intermediate precision in method validation. If there is any failure to meet the acceptance criteria, investigation will be conducted. For example, when the two results from two separately taken samples from the same batch are reliable but not in agreement with each other, drug product variation may be a cause. Product variation is not unusual for products like active coated tablets. In this case, it is necessary to prepare a composite sample in one lab and have this sample analyzed by both labs.

For the “drop” method (ie, preparing a sample by dropping certain units of tablets without grinding) for potency assays or separate analytical procedures for

CU testing, representative samples should be carefully evaluated in order to limit variation of the products. Another attention should be paid to purity of the reference standard if pretreatment of a reference standard such as the drying process is required. The predefined drying and testing procedure between two labs should be addressed.

21.4.3 Related substance assay

Typically, acceptance criteria should be followed based on an approved method validation report.

During ILQ practices, aged samples like the stability samples may be selected so that the samples contain impurities to aid in the evaluation of the data. If such samples are not available, the samples spiked with known impurities and stressed drug substances may be used where they are analyzed for recovery by both labs. In some cases, in order to ensure that each lab uses the same representative samples, a single laboratory is required to prepare the samples and the samples are then transferred to the second laboratory in a timely fashion.

21.4.4 Residual solvent assay

The acceptance criteria are similar to those defined in related substance assays except that samples spiked with solvents at the specification level should be used. It is most likely that the samples spiked with the solvent of interest are prepared by each individual lab and analyzed for recovery study. The absolute difference as generated by both labs in percent recovery should be no more than 20.0%, with 20.0% RSD for six replicate preparations from each lab.

21.4.5 Dissolution or release assay

Acceptance criteria should be established based on formulation (eg, immediate release or controlled/extended release) and sampling points (single or multiple). See chapter "Dissolution Testing of Solid Products" for more information on how to establish the acceptance criteria of dissolution tests for solid oral drug products. For immediate release products, there are at least two early sampling points for which percent release is less than 85% and one final sampling point. A total of 12 units should be tested in each individual lab. There are two acceptable approaches, direct comparison and model independent approach using similarity factor f_2 and difference factor f_1.

In general, the percent mean difference between both labs in percent release should be less than 10% for time points with less than 85% release, and no more than 5% for the final sampling point or Q-point.

The model independent approach using f_2 and f_1 can be used only if the criteria for f_1 and f_2 are met. The receiving lab is qualified if the f_1 value is within the range 0−15 and the f_2 value is within the range 50−100.

As per the FDA guidance for industry,[22] f_1 and f_2 are defined as follows:

$$f_1 = \left\{ \left[\sum_{t-1}^{n} |R_t - T_t| \right] / \left[\sum_{t-1}^{n} R_t \right] \right\} \times 100$$

where n is the number of time points, R_t is the dissolution value (in percent) of the reference (originating lab) at time t, and T_t is the dissolution wpvalue of the test (receiving lab) at time t.

$$f_2 = 50 \times \log \left\{ \left[1 + (1/n) \sum_{t-1}^{n} ((R_t - T_t)^2 \right]^{-0.5} \times 100 \right\}$$

The criteria to determine difference and similarity are as follows:

- 12 dosage units in each lab should be tested.
- Mean dissolution values at each time interval from both labs are used.
- Only one measurement should be used after 85% release.
- For mean values used, % RSD at the early time point should be less than 20%, and 10% for other time points.

21.5 CASE STUDIES

21.5.1 Case 1

21.5.1.1 Problem

A development Phase 1 batch of an API was analyzed for related substances. The HPLC test method was conducted using external standardization and using the API as the standard for any unknown impurities. For this purpose, the standard solution included a concentration of API equivalent to 0.10% of the API in the sample solution. The related substance specification for any unknown impurity was "Not more than 0.10%." The method had been validated to Phase 1 based on specified, identified impurities, and the QL was found to be 0.04%.

When one batch was analyzed in one laboratory (Lab 1), it was found to contain an unknown impurity with an estimated level of about 0.08%, which met the specification requirements. The same sample was then reanalyzed in another laboratory (Lab 2), and the reported level of the same impurity was 0.12%, which failed to meet the specification requirements.

21.5.1.2 Investigation

The out of specification (OOS) investigation conducted at Lab 2 confirmed that there were no analyst errors, and no assignable causes were identified. Retesting a new aliquot taken from the same sample confirmed the original result of 0.12%. The investigation was then extended to Lab 1, where again no analyst errors were identified, but retesting of a new aliquot taken from the same sample confirmed its original result of 0.08%.

The investigation was then extended to a closer examination of the chromatograms at both laboratories. Chromatograms were being monitored at a wavelength of around 230 nm, which corresponded with the maximum wavelengths for the API and each of the specified, identified impurities. As part of the further investigation, both laboratories repeated the analysis, but using DADs to check the spectra of the API and each impurity. It was verified that the maximum wavelengths for each known component was around 230 nm. For the unknown impurity, the maximum wavelength was around 223 nm, and the 230 nm reading actually coincided with a steep downslope of the spectrum. When both laboratories used 223 nm as the monitoring wavelength for this impurity, they then obtained agreeable results.

It should be noted that problems like this case can occur when chromatograms are being monitored using detector wavelengths that correspond to the edge of the spectrum for one or more components. The typical instrument specification of wavelength accuracy for UV detectors is ± 4 nm. The monitoring wavelength was set at 230 nm, but the true wavelength being monitored varies from 226 to 234 nm. Little difference for a component having its maximum absorbance at 230 nm is likely to be noted, since UV absorbance spectra of organic molecules normally show relatively broad peaks around 230 nm. However, this could lead to relatively large differences in the recorded absorbance values for any components that have peak edge at 230 nm.

To avoid this type of problem, it is recommended that the monitoring peak edge be eliminated wherever possible.

21.5.2 Case 2

21.5.2.1 Problem

During a validation study for a related substance test, the recovery was investigated by spiking with the impurities concerned. For one of those impurities, the recovery study was conducted using a solution at a concentration of 1 μg/mL. Although this level should be above the DL (which has not yet been verified in this validation study), no peak attributable to this impurity was observed in the chromatogram.

21.5.2.2 Investigation

The initial investigation verified that the spiking solution had been correctly prepared and all instrumental settings were correct, but no peak was generated from that solution. Further investigation could lead to a number of possibilities, discussed next.

21.5.2.2.1 Possibility 1

During method development, there may have been a change of monitoring wavelength to improve method sensitivity for another new component, but the analysts overlooked checking the effect of the change on other established components. It is very important during development to consider the impact of any changes on the overall analysis. In this circumstance, it may become necessary to have different monitoring wavelengths for different components to ensure adequate sensitivity for all components of interest.

It is usually recommended that the determinations of DL and QL be conducted as the first group of parameters during a validation study, which could have ensured the identification of this issue before further work was completed. In addition, these parameters are often required in order to design other portions of the validation program.

21.5.2.2.2 Possibility 2

The sample of the impurity or impurity standard that was used during development was from a different lot than that being used in the validation study, and the lots may not have the same quality. It is expected that API batches are synthesized under tightly controlled conditions in accordance with cGMP requirements. However, the same may not necessarily be true for impurities that are not the intermediates of the API and are being specially synthesized. So once an impurity of this type has been identified, it is very important to do the following:

1. Ensure that adequate controls are put into place so that we can be confident that we are really manufacturing the same compound each time. So it is important to put into place controls of the structural identity for different batches.
2. Ensure that the overall purities of different batches are kept reasonably constant.

21.5.3 Case 3

21.5.3.1 Problem

During the validation of precision and accuracy for the related substance test for a tablet product, a broad

peak was observed, which appeared in chromatograms after five sample injections. It accounts for a level of about 1.0%, which made quantitation of impurity peaks very difficult.

21.5.3.2 Investigation

The initial investigation showed no analytical errors, and the observed additional peak was genuine. This issue was unexpected, as the broad peak was not observed during method development and only noticed during the validation. The reason is likely due to sufficiently long runs applied during the validation, which would allow a component with strong retention to be eluted after five sample injections.

This additional component might be due to a tablet excipient, in which case it would not be a problem from the point of view of a new impurity, but the issue would need to be overcome to prevent interfering with this related substance test.

Alternatively, this peak might be due to a genuine unknown related substance, in which case, in accordance with ICH Guideline Q3B(R), it will need to be identified and then perhaps qualified, which could lead to delays in this product development program.

21.5.4 Case 4

21.5.4.1 Problem

While performing an accuracy experiment for the potency assay for a tablet, it was found that the recovery was 10% less than the theoretical value, although during method development, it was found that the sample extraction procedure had performed quite efficiently.

21.5.4.2 Investigation

During the investigation, it was discovered that a new batch of filters had been purchased for the validation study. Although a filter recovery study was completed satisfactorily with the previous batch, the new batch did not show a similar efficiency. Similar issues have also been experienced with HPLC autosampler vials when adsorption of an analyte on the surface occurs, which can happen in some cases.

21.5.5 Case 5

21.5.5.1 Problem

During a tablet stability study, it was observed that the assay values of the samples appeared to be declining for samples stored under accelerated conditions at 40°C/75% RH. There were no increases observed in degradation product peaks in the chromatograms.

21.5.5.2 Investigation

One possibility could be that the active ingredient degraded to products that were not being detected by the current analytical methodology. Normally, it would be expected that such a possibility would have been eliminated by conducting forced degradation (stress) studies prior to commencing the stability study, to ensure that the analytical methodology was suitable for monitoring the formation of tablet degradation products.

In this case, it was subsequently determined that under the accelerated storage conditions, the tablet matrix underwent some physical changes that reduced the efficiency of the extraction procedure during the sample preparation stage of the analysis. This type of issue is relatively common during development stages, and it is highly recommended that as part of an OOS investigation, the efficiency of the procedure for preparing analytical solutions be examined. Even though a method has been fully validated and the determination of accuracy using recovery studies has been deemed satisfactory, this can still be an issue. Validation studies are typically conducted using either freshly prepared product or product that has been stored at the suitable temperature conditions. They are not normally conducted using samples kept under accelerated storage conditions.

21.5.6 Case 6

21.5.6.1 Problem

During a stability study, trending analysis for the impurity profile demonstrates that the content of one known impurity at the 18M time point stored in 25°C/60% RH does not fall within the increasing trend over time.

21.5.6.2 Investigation

The product contains two active ingredients with more than 10 known impurities. The test method has been fully validated and implemented to monitor the impurity profile for release and stability testing for submission batches and market products over the years. It was observed that this specific known impurity increased over the storage time. Investigations indicated that the system suitability of the method met predetermined acceptance criteria. The reviews of all the chromatograms revealed that separation of this impurity from the main peak varies over the years. The problem is not resolved when a new column is used instead of using the aged column.

Upon further investigation, the problem could be solved if the performance of columns is screened and a good one selected from several new columns. Obviously,

this is impractical and not cost effective. Investigation then demonstrates that the resolution of these two peaks increases with the decrease of column temperature. However, the separation between other peaks was compromised at lower column temperatures. To solve the problem, the procedure with optimized column temperature was proposed to determine this impurity.

21.6 CONCLUSIONS

It is a regulatory requirement that all analytical methods that are used to generate data in a marketing authorization dossier be fully validated. It is generally considered acceptable in the industry to conduct phase-appropriate validation using the approaches discussed in this chapter as a product progresses through development. During the evolution of analytical methodologies, it is quite likely that methods will need to be applied in laboratories that did not participate in validation, and it is a cGMP requirement that the method be shown to function reliably under such circumstances via the applications of method transfers, as discussed in this chapter. Finally, regardless of how thoroughly validations and transfers are conducted, things will go wrong from time to time, and under such circumstances, it is very important to conduct thorough investigation and to be prepared to address a wide variety of root causes.

It is essential that clearly documented studies be conducted according to cGMP practices during analytical method development, validation, and method transfer.

CHAPTER

22

Statistical Design and Analysis of Long-Term Stability Studies for Drug Products

D. LeBlond

CMCStats, Wadsworth, IL, United States

This chapter is not intended to reiterate the very detailed and complete information that is already available in the research and textbooks on this subject. The literature in this area is vast, and an attempt to repeat it here would be a disservice to the reader. Instead, appropriate references are supplied, and the focus is on more recent statistical aspects, approaches, and recommendations that are important and useful and that are not discussed elsewhere. The material in Sections 22.1–22.3 is related to objectives, guidances, test methods, and data management. These sections can and should be profitably read and understood by formulation scientists, analytical chemists, and pharmaceutical development managers who have some understanding of the basic principles of experimental design. However, proper design and analysis of stability studies requires specific statistical expertise, and much of the material presented in the remainder of this chapter is technically quite complex and oriented to meet the needs and interests of professional statisticians.

22.1 STABILITY STUDY OBJECTIVES

The *stability* of a drug product is defined as the rate of change over time of key measures of quality on storage under specific conditions of temperature and humidity. A stability study should always be regarded as a scientific experiment designed to test certain hypotheses (such as equality of stability among lots) or estimate certain parameters (such as shelf life). Similar to any other scientific process, the outcome of a stability study should lead to knowledge that allows the pharmaceutical manufacturer to better understand and predict product behavior. Thus, a stability study is not merely a regulatory requirement, but also a key component in a process of scientific knowledge building that supports the continued quality, safety, and efficacy of a pharmaceutical product throughout its shelf life.

Understanding the stability of a pharmaceutical product (or any of its components) is important for proper quality design at many stages of the product life cycle. Table 22.1 lists some examples of pharmaceutical stability studies/analyses and their objectives.

Stability is intimately connected to many other key quality aspects of a drug product. For instance, interpretation of the rate of change of a key measure requires knowing the associated product release levels, recommended storage conditions, packaging, and stability acceptance limits. Proper interpretation of stability study data requires an understanding of the chemical-kinetic processes, the accuracy and precision of the associated test method, and the statistical limitations of the stability study experimental design. The statistical methodology used to achieve a given objective often depends on the quantity and quality of the data available and on the life-cycle stage of the product.

22.2 REGULATORY GUIDANCE

The regulatory aspects of drug product stability are governed by a number of interrelated guidance documents. In the United States, the European Union, and Japan, these guidances are provided through the International Conference on Harmonization of Technical Requirements for Registration of

Developing Solid Oral Dosage Forms
DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00022-4

TABLE 22.1 Applications of Stability Studies in Pharmaceutical Development

Product development stage	Objective
Chemical characterization	• Accelerated studies to define degradation pathways
Formulation development	• Establish retest period for active ingredient • Excipient/packaging selection and compatibility studies
Clinical studies	• Verify stability of clinical supplies.
Product registration	• Shelf life estimation • Release limit estimation • Determine process capability with respect to release or acceptance limits • Comparison of stability of clinical, development, and registration batches
Postapproval commitment	• Shelf life confirmation/extension with long-term studies • Annual stability monitoring
Marketed product	• Determination of predictive model from historical data • Shelf life extension • Assess risk of temperature excursions • Routine trending • Justification of scale-up, process, formulation, dosage strength, manufacturing site, packaging, or other postapproval changes • Establish equivalency with new formulations/packages • Annual stability reports

Pharmaceuticals for Human Use (ICH). Q1A-E[1–5] governs the stability testing of drug substances and products. Q2A-B[6,7] governs the validation of analytical methods used for (among other things) stability testing. Q3A-B[8,9] governs impurity levels in drug substances and products. Q6A-B[10,11] governs the acceptance criteria.

One must use caution when interpreting and using such regulatory guidances. Often, their individual scopes are somewhat narrow and may not always include the specific objectives of interest to the developer. There is no guarantee that following such guidances will lead to a manufacturable, approvable, high-quality product. Each individual guidance is established by a separate committee, and inconsistencies are inevitable. Blind adherence may have undesirable long-term consequences. Some common pitfalls are noted in the next discussion. A developer must always consider the specific study objectives and the approach taken should always be scientifically and statistically justified.

22.3 TEST METHODS AND DATA MANAGEMENT

Quantitative, precise, unbiased, stability-indicating test methods are essential components of stability experimentation. All information obtained from a stability study ultimately comes from the test methods used. No amount of statistical sophistication can compensate for a poor measurement system. The following recommendations are meant to promote the use of high-quality test methods and data management approaches:

- Use quantitative test methods that produce a result on a continuous measurement scale. These have higher information content than those that produce binary (yes/no), discrete (1, 2, 3, . . .), ordinal (low, medium, high), or categorical (A, B, C, . . .) responses.
- The validity of information obtained from a stability study ultimately depends on the test methods used. Where possible, the test methods used should be thoroughly characterized and validated prior to use. Partial validation may be acceptable for early development studies, but the uncertainties of the test method need to be accounted for in data evaluation. The validation should include the determination of bias and imprecision as a function of the true concentration level. The components of variance (replication, instrument, operator, day, lab, calibration run, etc.) should be identified and quantified. Such understanding is important in both study design (eg, assuring adequate sample size or study power) and analysis (eg, deciding whether to average replicated test values).
- Excessive rounding and binning of continuous measured values should be avoided, eg, the conversion of numerically measurable values to "below quantitation" because they are thought have unacceptable variability, or the rounding of results for minor components and degradation products to conform to specifications in regulatory guidelines (eg, ICH Q3A(R2) and Q3B(R2)). Such practices are common when reporting individual analytical results and may be required for the purpose of conforming to regulatory guidances when used in

this manner; however, when values such as stability testing results are used as input for further data analyses, overrounding and binning of test results lowers the data information content and distorts the measurement error structure. It should be the decision of the statistician performing the analysis of the data to round results appropriately after all data analysis has been completed. These abuses may limit the statistical procedures available for data analysis and lead to biased estimates or incorrect conclusions. All information contained in the original measurements should be used for efficient, sound decision making.

- Storage time should be well controlled. Regression procedures often assume that storage time is known exactly. Errors in the time scale may introduce bias and uncertainty that undermines the most accurate and precise response measurements. Stability studies typically follow predefined plans, in which sampling times are specified. However, for the purpose of data analysis, only the actual time at which a sample is taken is relevant; this must be accurately reported, especially if it deviates from the time specified in the plan. Company procedures should limit the time between sampling and analysis to as short a time as possible to prevent additional degradation; ideally, samples should be obtained immediately prior to analysis, even if this requires delaying sampling until after the time specified in the plan. Release test results (obtained at the end of manufacturing) should not be used in place of a true initial (zero time) test result when the release test date is substantially different from the starting date of a stability study. The storage conditions of the manufactured or sampled product should be appropriately controlled.
- Design stability databases with data analysis in mind. Statistical analyses may lead to approval of a longer shelf life, or they may provide the necessary information to better manage a product throughout its life cycle. Often statistical analyses are not performed or included in submissions because hand reentry of data is required, excessive reformatting must be performed, or there may be a delay in obtaining analytical results.
- Include a trained statistician on the study design and analysis team.[12]

Analytical data are obtained at great expense. The information contained within these data represents a proprietary advantage to the product developer. Thus, the analytical methods used to produce the data, as well as the computing/statistical methods used to extract information from them, should be of the highest possible quality.

22.4 MODELING INSTABILITY

22.4.1 Stability study variables

This section starts with shopping lists of key response, experimental, and controlled variables that often appear in drug product stability studies. These lists are by no means exhaustive. Then we will discuss how each item is typically incorporated into the kinetic model.

22.4.1.1 Responses

The response variable that is monitored over time should include, as appropriate, results from the physical, chemical, biological, microbiological, and key performance indicators of the dosage form. The potency level of the active ingredients and the levels of related degradants or impurities are always considered. In the case of instability due to degradation, mass balance should be accounted for. Only quantitative variables will generally be amenable to statistical analyses, as described later in this chapter.

Other critical or key quality attributes also need to be considered if they have acceptance limits. Dissolution may be especially critical for modified release products or products of poorly soluble compounds where bioavailability may change over time when dissolution is the rate-limiting step for drug absorption. Other responses that may be included in stability studies are color, moisture or solvent level, preservative, antioxidant, and pH.

22.4.1.2 Experimental fixed variables

Variables such as storage time, dosage strength, and packaging type are called *fixed* variables because the levels of such variables (eg, 3 months of storage or 300 mg) have specific meanings that are the same whenever that level is used in the study. Typically, except for storage time, fixed variables are categorical in nature and determined in advance by the experimenter.

Storage time is, of course, the primary experimental fixed variable always included in a stability study. ICH Q1A[1] recommends testing every 3, 6, and 12 months during the first, second, and subsequent years, respectively. Thus, for a typical 3-year study, testing would occur at 0, 3, 6, 9, 12, 18, 24, and 36 months. However, although storage times may be fixed by the study plan, they are actually measurable. Whenever and wherever possible, the exact measured elapsed time between the start of the study and the removal of a sample for analysis should be accurately reported, at least to the nearest whole day. Every effort should be made to minimize the elapsed time between when a sample is removed for analysis and the time at which the analysis is actually performed.

Other experimental fixed variables (also referred to as *factors* or *predictors*) that may be included as part of more complex studies include container type or size, closure type, fill size, desiccant type or amount, manufacturing site, batch size, and other covariates.

22.4.1.3 Experimental random variables

Variables such as test result replicate number or batch number are called *random* variables because the levels used (say replicate 1, 2, or 3) are not the same whenever they are applied; instead, these levels are assumed to represent experimental conditions drawn at random from a hypothetical infinite population of all possible replicates.

The ICH Q1A[1] guidance recommends that stability studies for new product registration include at least three batches of drug product (say batches 1, 2, and 3). If batch is considered a fixed variable, like dosage strength, then the estimated shelf life will reflect only the performance of the three batches in the study. If, on the other hand, batch is considered to be a random effect, like replicate, then the estimated shelf life will reflect the hypothetical infinite population of all future batches. To properly treat batch as a random variable requires the use of a so-called mixed regression model and specialized statistical software, such as the MIXED procedure in the SAS system.[13]

The shelf life estimate will generally be shorter if batch is regarded as random, but since the shelf life specification is meant to apply to all future batches, this may be more realistic. However, in most new product registrations governed by ICH Q1E,[5] where a minimum of three batches are available, batch is treated as a fixed variable and any inferences are strictly limited to the three batches on hand. This is done, quite simply, because data from only three batches are insufficient to project to the larger population of all future batches. This caveat must be kept in mind when interpreting the results of stability analyses.

22.4.1.4 Variable transformations

Sometimes the stability profile of a quality characteristic does not follow a straight line. Examples may include moisture level, which approaches equilibrium, or an intermediate degradation product, which follows a complex kinetic mechanism. In such cases, a nonlinear regression procedure should be considered. A description of nonlinear regression is beyond the scope of this chapter.

When the rate of change in the response measure is nearly constant over time and the change is monotonic, such that a transformation yields a nearly linear stability profile, linear regression (LR) may be used. LR provides a simple description that is easily grasped by nonstatisticians, requires few assumptions, and can be executed in widely available software. While the assumptions/approximations of LR are few, they must be satisfied for any estimates, inferences, or predictions made using LR to be valid. The assumptions of LR are:

1. The response is linearly related to the storage time.
2. There is no uncertainty in the storage time value.
3. Errors in the response measurements are normally distributed.
4. Errors in the response measurements are mutually independent.
5. The error variance in the response measurement is the same for all measurements.

Various statistical procedures that can be used to verify these assumptions are discussed in popular statistical texts.[14]

If the kinetic processes of instability are more complex, the profile may exhibit curvature. If a theoretical kinetic model is available, then nonlinear regression approaches (such as with the NLIN procedure of SAS) may be the best way to draw inferences, estimate shelf life, and make predictions from the stability data. In some cases, a nonlinear model can be linearized by transformation. For instance, the first-order kinetic model $y = A\exp(-kt)$ can be rewritten $\log(y) = \log(A) - kt$. Thus, a log transformation of the response, y, may improve conformance to assumption 1.

When the kinetic process is not well understood, various transformations of the response or time scales (or both) may be tried in an effort to allow LR to be used for analysis. It is important that the transformation be valid for all possible responses or time values. For instance, transformations such as $\log(y/(A-y))$ or $\log(t)$ are undefined for $y \geq A$ or $t = 0$, respectively.

Transformation of the time scale can have subtle effects on estimation efficiency but generally presents few statistical issues. However, transformation of the response scale may fundamentally change the error structure of the response measurements (assumptions 2–5). In favorable cases, a transformation may be found that will improve conformance to all five basic LR assumptions. However, if the transformation does not have a theoretical basis, extrapolations beyond the duration of the study must be made with extreme caution.

22.4.1.5 Controlled variables

Temperature and humidity are usually controlled during a stability study. The product label storage condition will dictate the conditions used in studies conducted to estimate shelf life. Table 22.2, taken from ICH Q1A,[1] gives typical conditions used.

For controlled room temperature products susceptible to moisture loss, lower relative humidity (RH) storage conditions may be appropriate (40% for long-term

TABLE 22.2 Temperature and Humidity Control of Stability Studies

Label storage	Long-term conditions	Intermediate conditions	Accelerated conditions
Controlled room temperature	25°C ± 2°C/60% ± 5% RH	30°C ± 2°C/65% ± 5% RH	40°C ± 2°C/75% ± 5% RH
Refrigerated	5°C ± 3°C		25°C ± 2°C/60% ± 5% RH
Frozen	−15°C ± 5°C		5°C ± 3°C/ambient RH
Minimum time period covered by data at submission	12 months	6 months	6 months

and intermediate and 15% for accelerated conditions). For controlled room temperature products stored in water impermeable containers, ambient RH might be appropriate for different temperature conditions.

While storage temperature and RH are quantitative variables that are often included in drug product stability studies, they are not generally included in a stability model. As specified by ICH Q1E,[5] each storage condition (ie, long-term, intermediate, or accelerated) is evaluated separately. An exception to this is with the analysis of accelerated stability studies, as described elsewhere in this book. Inclusion of storage condition variables as predictors in the stability model can be useful in judging the risk of temperature or humidity excursions, which can occur during the storage of finished drug products in warehouses or in a patient's environment. Such evaluations will not be discussed in chapter "Drug Stability and Degradation Studies."

22.4.2 A statistical model for instability

The design and analysis of a stability study requires the specification of a kinetic, predictive model for the instability of each key measure. A model should include mechanistic, experimental, and statistical aspects. That is, the model must take into account the physical or chemical mechanisms that result in changes in level over time. It must account for the fixed effects of variables whose levels are systematically varied as part of the stability study. Further, it must account for the statistical variation introduced by random variables whose levels are not specifically controlled, but vary in the study.

An understanding of the physicochemical mechanisms of instability of a drug product is an essential component of drug product life-cycle support. Knowing these mechanisms allows a developer to anticipate flaws, design an appropriate formulation and packaging system, and troubleshoot and support the product throughout its life cycle. The reader is directed to discussions elsewhere[15] for a discussion of kinetic mechanisms.

As indicated in ICH Q1A,[1] a linearizing transformation or use of an appropriate nonlinear model for the effect of storage time should be considered if the stability profile cannot be represented by a straight line. A thorough discussion of the important topic of physicochemical mechanisms is beyond the scope of this chapter. The chosen model for the effect of storage time should be scientifically and statistically justified.

Note to reader: The discussion thus far has been deliberately been kept at a level accessible to most nonstatisticians, but beyond this point, good familiarity with complex statistical methods is assumed. The advice of a professional statistician is strongly recommended before using any of the methods described next.

When the key measure changes only a small proportion (say, less than 15%) of its initial or potential level over its shelf life, a zero-order kinetic (straight-line) model is often found to be sufficient to describe the relationship between the level and storage time. Thus, a stability model often takes the form

$$\mathbf{y} = \mathbf{X}\beta + \mathbf{Zeta;}\gamma + \varepsilon \tag{22.1}$$

where

$\mathbf{y}$ is a column vector of test results.
β is a vector of fixed model parameters whose estimate is $\mathbf{b}$.
γ is a vector of random model parameters whose estimate is $\mathbf{g}$. It is typical to assume a multivariate normal distribution for γ.
ε is a vector of identically distributed and independent normal deviations with mean zero and true variance σ^2.

We take $\mathbf{X:Z}$ to be the design matrix for the stability study. $\mathbf{X}$ will contain a column of 1s for the intercept, a column of month values for storage interval (ie, the *actual* storage times, not the planned storage times), and columns of indicators for categorical fixed variables such as packaging or dosage strength. $\mathbf{Z}$ would contain columns of indicators for the levels of random variables such as batch. If batch is treated as a fixed variable, whose levels are specified in $\mathbf{X}$, and there are no other random variables, then the $\mathbf{Z}\gamma$ term is omitted.

22.5 LONG-TERM STABILITY STUDY DESIGN

22.5.1 Full and reduced designs

When a stability study includes all combinations of dosage strength, packaging, and storage times, the stability design is referred to as a *full-factorial* (or sometimes as just a *full* or *complete*) design. Conducting a full design on a new drug product with multiple strengths and packages can be prohibitively expensive and may stress a company's analytical resources beyond their limits. From a statistical point of view, when the number of study variables is large, a complete factorial may be unnecessary so long as certain assumptions can be made about the stability effects of the variables.

ICH Q1D[4] describes situations in which a reduced design can be applied without further justification, as well as some situations in which further justification will need to be provided. If a design deviates markedly from the principles of ICH Q1D[4], the protocol must be approved by the Food and Drug Administration (FDA) or other appropriate regulatory authority prior to the initiation of stability studies. Some additional clarification is provided in the literature.[16] In a reduced design, only a specific fraction of the possible combinations of dosage strength, packaging, and storage times are actually tested. ICH Q1D[4] refers to two general approaches to reduced designs: bracketing and matrixing.

22.5.2 Bracketing

In a bracketing approach, the sponsor relies on theory or past experience to identify a small number of variable combinations (say, of strength and packaging) that can be assumed to give worst-case stability. Often, these combinations will be extreme (eg, of active content, head space, moisture vapor transmission rate) and the sponsor is willing to estimate the product shelf life from a study of these worst cases alone. Bracketing assumes that the untested variable combinations will have equal or superior stability and therefore need not be tested at all. Bracketing requires a thorough understanding of the mechanisms of instability from theory or from studies on earlier development or clinical batches. Because bracketing makes strong assumptions about the underlying mechanism of instability, it is not applicable when dosage form formulations or package characteristics differ markedly. In a so-called pure bracketing design, the chosen combinations are tested at all time points. Often, those combinations not intended to be tested as part of the bracketing design are not even placed on stability.

Bracketing may be applied with no further justification across strength when different strengths have identical or closely related formulations (eg, capsules of different strengths made with different plug sizes from the same powder blend, or tablets of different strengths made by compressing varying amounts of the same granulation—formulations that differ only in minor excipients). Further justification should be considered when amounts of drug substance and excipients change in a formulation. When different excipients are used among strengths, bracketing is not generally applied.

Bracketing may be applied with no further justification across packages using the same container closure system where either container size or fill varies while the other remains constant. Further justification should be considered when the closure systems vary for the same container. Justification could include a discussion of relative permeation rates of the bracketed container closure system.

22.5.3 Matrixing

In a matrixing approach, the sponsor takes advantage of traditional principles of experimental design[17] to reduce study size without sacrificing statistical power, model structure, or parameter estimatability. Matrixing depends on choosing a balanced subset of the full factorial set of combinations that supports a predictive model that includes all main effects and critical interactions. Often, all combinations (even those not intended to be tested in the matrix design) are placed on stability should there be a need to revert to full testing.

Matrixing with respect to strength may be applied across strengths without further justification when the strength formulations are identical or closely related. Additional justification should be considered when different strengths differ in the drug substance content, excipients change, or different excipients are used. Matrixing across batches can be applied on batches that are made using the same process and equipment, or batches of drug substance. Matrixing across package size and fill is permitted when all packages use the same container closure system. Further justification should be provided when packages use different container closure systems, contact materials, suppliers, or orientations. Justification should be based on supportive data (eg, moisture vapor transmission rates or light protection for different containers).

Matrix designs can be complete (ie, all combination of factors are tested) or incomplete (ie, some combinations are not tested at all). In a complex design, combinations of strength and container size are tested and individual product batches are not tested in all strength and container size combinations. If the design

is broken during the course of the study, testing should revert to full testing through the proposed retest period or shelf life. Where testing exhibits moderate variability and moderately good stability, a matrix should be statistically justified.

Matrixing is not without risks. Highly fractional designs, involving factors other than time, generally have less precision in shelf life estimation and may yield shorter shelf life than a full design. With large variability and poor product stability, a matrix should not be applied. Techniques for comparing and assessing the statistical power of stability designs are discussed next.

22.5.4 Stability design generation

Before a reduced design is considered, assumptions should be assessed and justified. Then, as a starting point, either the design (including all possible combinations) or an appropriately bracketed subset is taken as the full design. Then reduced designs are obtained by matrixing the full design. The reduced designs may be compared with respect to the following criteria:

- Probability of justifying the desired shelf life as a function of study duration.
- Power to detect effects of experimental variables on stability. Any reduced design should retain the ability to adequately detect differences in stability.
- Balance (ie, each combination of factor levels is tested to the same extent) to ensure the orthogonality of model parameter estimates.
- The total number of tests required (or total study cost).
- Ergonomic spread of testing throughout the study to optimize analytical resources.

ICH Q1D[4] mandates full testing of all studied factor combinations at the beginning and end of the study, as well as at the time of submission. It also recommends that at least three time points for each studied factor combination be available at the time of submission (nominally at 12 months' storage). ICH Q1D[4] provides examples of study designs. These are not the only designs to be considered, but they illustrate many of the principles of balance, as well as the practical constraints. These are discussed next.

22.5.4.1 Matrixing on time points only

A key principle of fractional factorial design is to maximize testing of the extremes of continuous variables. In the case of storage time, this means that full testing is required at initial study completion and submission (typically 12 months). Thus reduced testing for a 36-month study can only be considered at five time points: 3, 6, 9, 18, and 24 months. Consider a study with six combinations: two strengths, with three batches per strength. Assume that a one-third reduction in testing is desired. Which 20 of the $5 \times 6 = 30$ test points should be tested? The principle of balance requires that:

- Each of the 2 strengths be tested 10 times ($2 \times 10 = 20$)
- Each of the 3 batches be tested Z times ($Z \times 3 = 20$)
- Each of the 5 time points be tested 4 times ($5 \times 4 = 20$)
- Each of the 6 strength × batch combinations be tested Y times ($Y \times 6 = 20$)
- Each of the 10 strength × time combinations be tested 2 times ($2 \times 10 = 20$)
- Each of the 15 batch × time combinations be tested W times ($W \times 15 = 20$).

Note that W, Y, and Z cannot be whole numbers. In fact, unless the number of tests is evenly divisible by 2 (strength), 3 (batch), and 5 (time), some loss of balance is inevitable. In this case, the lowest number of tests that allows balance is $2 \times 3 \times 5 = 30$, which does not allow for any testing reduction at all. Similarly, if a one-half reduction in testing was desired, which 15 of the 30 test points should be tested? Balance would require that the number 15 be evenly divisible by 2 (strength), 3 (batch), and 5 (time). Since 15 is not evenly divisible by 2, full balance is not possible in this case either. In the ICH Q1D[4] examples, the compromise made is to allow more testing on some batch, strength × batch, and batch × time combinations than others. However, the continuous time variable is robust to loss of balance because of the assumption of a linear change over time. Thus, the inevitable nonorthogonality in the Q1D[4] design examples is probably negligible.

An example illustrating complete and partial balance is as follows. Assume that the sponsor desired an analysis at 24 months (perhaps to justify shelf life extension). Then full testing would be required at 24 months, and matrixing would be on the four time points 3, 6, 9, and 18 months only. Thus, the full design would require (2 strengths) × (3 batches) × (4 times) = 24 tests. Since 12 is divisible by 2, 3, and 4, a completely balanced half-reduction is possible. A half-reduction would require 18 tests; however, 18 is only evenly divisible by 2 and 3, not by 4. Therefore, only a partially balanced design is possible if a half-reduction is desired. To identify which of the 12 or 18 tests to include, the mod arithmetic method of Nordbrock[18] can be used. The following steps illustrate this approach:

1. Assign code of S = 0 or 1 for each strength.
2. Assign a code of B = 0, 1 or 2 for each of the three batches within each strength.

3. Assign a code of T = 0, 1, 2, or 3 for the time points 3, 6, 9, or 18 months, respectively.
4. For each of the 24 possible strength × batch × time combinations,
   a. For a half-fold reduction, test only combinations where S + B + T mod 2 = 0.
   b. For a one-quarter-reduction, test only combinations where S + B + T mod 3 = 0 or 1.

Tables 23.3–23.5 show the testing schedule at these time points for these two cases.

The particular ½ or ⅓ fraction selected in Tables 22.3 or 22.4 are, of course, only one of two or three possible fractions. For instance, one could have decided to test S + B + T mod 2 = 1 in Table 22.3 or S + B + T mod 3 = 0 or 2 in Table 22.4 instead. The sum S + B + T can be generalized to $n \times S + B + m \times T$, where n and m are constants other than 1, in an attempt to find a design that achieves the desired balance. The same principles can be extended to more complex situations. The example in ICH Q1D[4] involves a product with 3 strengths, 3 packages, 3 batches, and 5 time points. It is typical to first identify a set of balanced (or approximately balanced) time vectors. Then the various strength × package × batch combinations

TABLE 22.5 Example of a Partially Balanced One-Third-Reduction Matrix Design on Time Points for a Product With Two Strengths

		S + B + T mod 3			
Strength	**Batch**	**3 Months (T = 0)**	**6 Months (T = 1)**	**9 Months (T = 2)**	**18 Months (T = 3)**
Low (S = 0)	1 (B = 0)	0	1	2	0
	2 (B = 1)	1	2	0	1
	3 (B = 2)	2	0	1	2
High (S = 1)	1 (B = 0)	1	2	0	1
	2 (B = 1)	2	0	1	2
	3 (B = 2)	0	1	2	0

0 or 1—test; 2—do not test.

are then assigned in a balanced (or approximately balanced) way to each of the vectors. The example in ICH Q1D[4] establishes the following testing vectors:

T1: {0, 6,9,12,18,24,36}
T2: {0,3, 9,12, 24,36}
T3: {0,3,6, 12,18, 36}

T1 calls for testing at 7 total time points, but T2 and T3 only 6. However, balance is achieved across the time points 3, 6, and 9. Because of the assumption of linear trend across time, lack of balance does not lead to serious degradation of estimation efficiency. A desirable feature of T1, T2, and T3 as given here is that each of the time points 3, 6, 9, 18, and 24 is represented twice. Thus, if the vectors are evenly spread across the combinations, a one-third-reduction of testing at these time points would be realized. The assignments of the vectors to each of the $3 \times 3 \times 3 = 27$ combinations is illustrated in Table 22.6.

22.5.4.2 *Matrixing on both time points and other variables*

Continuing the ICH Q1D matrix example, one can matrix further against batch, strength, and package by omitting the testing based on the value of B + S + P mod 3. In the ICH Q1D Table 3b example, the criterion for elimination depends on batch, as described in Table 22.7.

The resulting approximately balanced matrix provides about a 5/9 reduction in the amount of testing at the 3-, 6-, 9-, 12-, 18-, and 24-month time points. These examples are provided merely for illustration. Other matrixing designs are possible, and some may well be superior to those given. Once candidate designs are generated by the above-mentioned methods—or by other standard experimental design techniques—it is best to perform an assessment of their balance and operation feasibility. Those, which pass these assessments, may be examined further by the statistical methods described in the next section.

The level of reduction that would be acceptable to a regulatory agency such as the FDA can be addressed by examining the power of the design to detect differences in stability among the different batches, strengths, or packages and the precision with which shelf life can be estimated. These characteristics are compared between the candidate matrix design and the full design. If a candidate matrix design sacrifices little relative to the full design, then it should be acceptable from a regulatory point of view.

22.5.5 Comparing stability designs

Nordbrock[19] provided a framework for comparing stability designs with respect to their power to detect slope (stability) differences. This same framework can be applied to a comparison of the probability (power) of meeting a desired shelf life claim among competing stability designs.

22.5.5.1 *Review of preliminary statistical concepts*

Let R and H be mutually independent random variables with distributions $R \sim N(\delta,1)$ and $H \sim \chi^2(dfe)$. Then, by definition,

$$\frac{R}{\sqrt{H/dfe}} = W \sim \text{nct}(dfe, \delta) \tag{22.2}$$

where nct(dfe,δ) represents a random variable distributed as noncentral t with degrees of freedom dfe and noncentrality parameter δ. Further, let pnct($Q \mid dfe$,δ) be the cumulative distribution of the noncentral t random variable W relative to fixed Q such that

$$\text{Prob}\{W \le Q\} = \text{pnct}(Q|dfe, \delta) \text{ and } \text{Prob}\{W > Q\} = 1 - \text{pnct}(Q|dfe, \delta) \tag{22.3}$$

Noncentral t distribution functions are present in software packages such as SAS or R. The following approximations may be useful in implementing these calculations in packages that have a cumulative noncentral F (pf()), but not a noncentral t:

TABLE 22.6 Using Mode Arithmetic to Matrix on Time Points Only for the Example of Table 3a in ICH Q1D

	B + S + P mod 3								
Strength:	**Low (S = 0)**			**Med. (S = 1)**			**High (S = 2)**		
Package:	A (P = 0)	B (P = 1)	C (P = 2)	A (P = 0)	B (P = 1)	C (P = 2)	A (P = 0)	B (P = 1)	C (P = 2)
Batch 1 (B = 0)	0	1	2	1	2	0	2	0	1
Batch 2 (B = 1)	1	2	0	2	0	1	0	1	2
Batch 3 (B = 2)	2	0	1	0	1	2	1	2	0

0—use T1; 1—use T2; 2—use T3.

TABLE 22.7 Using Mod Arithmetic to Include Matrixing Against Design Variables in the Example of Table 3b of ICH Q1D

Batch	Do not test if B + S + P mod 3 =
1	2
2	1
3	0

$$\mathrm{pt}(t, dfe, \delta) = \mathrm{pf}(t^2, 1, dfe, \delta^2) + \mathrm{pt}(-t, dfe, \delta) \sim$$
$$= \mathrm{pf}(t^2, 1, dfe, \delta^2) \text{ for } \delta >> 0$$

In some software packages, algorithms for noncentral t do not converge when δ, dfe, or both are large. In those cases, the following approximation may be used:

$$\mathrm{pnorm}(t - \delta) \cong \mathrm{pt}(t, dfe, \delta)$$

with pnorm(z) the standard normal distribution function.

Now consider a LR to the fixed model:

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}, \tag{22.4}$$

with fixed model parameters $\boldsymbol{\beta}$ and $\boldsymbol{\varepsilon} \sim N(0,\sigma^2)$. In applying the concepts here, it is critical to understand the structure of $\boldsymbol{\beta}$ and $\mathbf{X}$. As an example, consider a stability design that includes measurements (y vector) at a series of time (T) points on three batches (B), each of three strengths (S), with three possible package (P) options. Assume that the design will support estimation of all main effects and certain interactions (ie, others known to be unimportant). In a high-level program like SAS, the model might be expressed as

$$\mathrm{Y} = \mathrm{intercept\ T\ B\ S\ P\ T*B\ T*S\ T*B*S}$$

The column vector $\boldsymbol{\beta}$ will be composed of one subvector for each model term. The length of each subvector is 1 for the continuous variables intercept and T. For categorical main effects B, S, and P, the subvector length will be number of categorical levels for that variable minus 1; therefore, the length will be 2 for each main effect. For interactions, the vector length will be the product of the vector lengths of each of the component main effects in the interaction. Working across in this model order, we see the length of β will be 1 + (1 + 2 + 2 + 2) + (2 + 2) + (4) = 16. Thus

$$\boldsymbol{\beta}' = (\beta_{\mathrm{int}}, \beta_T, \beta_{B1}, \beta_{B2}, \beta_{S1}, \beta_{S2}, \beta_{P1}, \beta_{P2}, \beta_{TB1}, \beta_{TB2}, \beta_{TS1}, \beta_{TS2}, \beta_{TB1S1}, \beta_{TB1S2}, \beta_{TB2S1}, \beta_{TB2S2})$$

Each element of $\boldsymbol{\beta}$ is an effect attributable to the presence of certain levels or combinations of levels of the variables T, B, S, and P.

The $\mathbf{X}$ matrix in this example will have 16 columns corresponding to each of the coefficients in β, and one row for each result in y. The intercept column in $\mathbf{X}$ will have a 1 in each row, and the T column in $\mathbf{X}$ will have the numerical storage time t at which the corresponding test result in y was obtained. For categorical main effects, the $\mathbf{X}$ columns corresponding to B, S, and P will contain codes that specify the level of each corresponding to the respective y test result. A convenient 0/1 coding is as follows (Table 22.8): in which the presence of a 0 in the first or second element indicates that the corresponding factor level is not acting to produce the corresponding result. If both the first and second elements are 0, then the third level must be active.

Subvector codes for interactions consist of the Kronecker product of the subvectors of the component main effects. Thus, the 2 T*B columns in $\mathbf{X}$ corresponding to a y result obtained at 3 months on Batch 2 would be encoded as $3 \otimes (0\ 1) = (0\ 3)$. The four T*B*S columns in $\mathbf{X}$ corresponded to a y result at 6 months on Batch 1, middle strength would be $6 \otimes (1\ 0) \otimes (0\ 1) = (0\ 6\ 0\ 0)$. In this way, the entire $\mathbf{X}$ matrix is constructed. Consider the y result corresponding to the 9-month test on batch 2 of low strength packaged in container type B. The corresponding row of the $\mathbf{X}$ matrix is, then,

$$X = \begin{pmatrix} \cdots \\ 1, 9, 0, 1, 1, 0, 0, 1, 0, 9, 9, 0, 0, 0, 9, 0 \\ \cdots \end{pmatrix}.$$

The estimates of interest in a stability analysis generally consist of linear functions of the elements of $\boldsymbol{\beta}$. Functions of interest might be slopes or differences between slopes for specific combinations of design variables, or averages across certain design variables. A linear function of $\boldsymbol{\beta}$, say $S = \mathbf{c}'\boldsymbol{\beta}$, will have an estimate $\hat{S} \sim N(S, \sigma_S^2)$ with a sampling variance as follows:

$$\sigma_S^2 = \mathbf{c}'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{c}\sigma^2, \tag{22.5}$$

TABLE 22.8 Coding of Design Variable Levels in the Construction of the $\mathbf{X}$ Matrix

Subvector code	B Interpretation	S Interpretation	P Interpretation
(1 0)	Batch 1	Low strength	Package A
(0 1)	Batch 2	Middle strength	Package B
(0 0)	Batch 3	High strength	Package C

based on degrees of freedom *dfe* where

$$dfe = \text{number of rows in } \mathbf{X} - \text{number of columns in } \mathbf{X} \tag{22.6}$$

The dimensions of the contrast column vector **c** will be identical to that of β. The elements of **c** will depend on which of the corresponding elements of β are active in defining a specific linear function of interest.

Finally, note that if $\hat{\sigma}_S^2$ is a sample estimate of σ_S^2 based on *dfe* degrees of freedom, then its sampling distribution is given by

$$\frac{\hat{\sigma}_S^2}{\sigma_S^2} \cdot dfe \sim \chi^2(dfe). \tag{22.7}$$

22.5.5.2 *Power to detect slope differences*

Let S represent a slope difference that is of interest, and consider a statistical test of H0: $S = 0$ against an alternative Ha: $S > 0$. H0 will be rejected at the 0.05 level of significance if

$$\frac{\hat{S}}{\hat{\sigma}_S^2} = \frac{\hat{S}/\sigma_S^2}{\hat{\sigma}_S^2/\sigma_S^2} > qt(0.95, dfe) \tag{22.8}$$

Now, under the assumption that $S = \Delta$,

$$\frac{\hat{S}}{\sigma_S^2} \sim N\left(\frac{\Delta}{\sigma_S^2}, 1\right) \tag{22.9}$$

Combining Eqs. (22.2), (22.3), (22.6)–(22.8), we may state that

$$\begin{aligned}\Pr\{\text{H0 rejected}|\Delta\} &= \Pr\left\{\frac{\hat{S}}{\hat{\sigma}_S^2} > qt(0.95, dfe)|\Delta\right\} \\ &= 1 - \text{pnct}\left(qt(0.95, dfe), dfe, \frac{\Delta}{\sigma_S}\right)\end{aligned} \tag{22.10}$$

Eq. (22.10) may be evaluated as a function of Δ to provide the operating characteristics of the statistical test. Since, by Eqs. (22.5) and (22.6), *dfe* and σ_S^2 depend only on **X**, which in turn is determined by the stability design, the operating characteristics can be compared for various designs and storage times as an aid in study planning.

As an example, consider three matrix designs presented in ICH Q1D[4] and the model as described previously. Let *S* be a slope difference between medium and low (medium minus low) strength averaged across all lots. Then the corresponding contrast vector is

$$\mathbf{c}' = \left(0, 0, 0, 0, 0, 0, 0, 0, 0, 0, -1, +1, -\frac{1}{3}, +\frac{1}{3}, -\frac{1}{3}, +\frac{1}{3}\right)$$

so that

$$\mathbf{c}'\boldsymbol{\beta} = \beta_{TS2} - \beta_{TS1} + \frac{\beta_{TB1S2} - \beta_{TB1S1} + \beta_{TB2S2} - \beta_{TB2S1}}{3}$$

Assume that the stability potency analysis for submission will occur at the 12-month time point. Let $\sigma = 1\%$LC, and let the true slope difference, Δ, vary between 0 and 0.25%LC/month. Fig. 22.1 shows the power (as given by Eq. (22.10)) for various true slope differences. Note that very little power is lost in going from the full design (135 tests required) to the matrix design on time only (ICH Q1D[4] Table 3a; 108 tests required). However, considerable power is lost when matrixing includes time, strength, batch, and packaging (ICH Q1D[4] Table 3b; 72 tests required).

22.5.5.3 *Probability of achieving a shelf-life claim*

Consider a stability-determining test, such as potency, with a lower acceptance limit, *L*. Let *D* be the desired shelf for the product. Further assume that the product will have a true release potency (intercept) of *I*, a true slope of *S* and a true analytical standard deviation of σ_S.

The regression slope estimate of *S* (ie, $\hat{S}$) will have a sampling distribution that can be defined by

$$\frac{\hat{S} - S}{\sigma_S} + \delta \sim N(\delta, 1) \tag{22.11}$$

Combining Eq. (22.11) with Eq. (22.7) and comparing with Eqs. (22.2) and (22.3), we see that

$$\Pr\left\{\frac{\frac{\hat{S}-S}{\sigma_S} + \delta}{\hat{\sigma}_S/\sigma_S} > Q\right\} = 1 - \text{pnct}(Q, dfe, \delta). \tag{22.12}$$

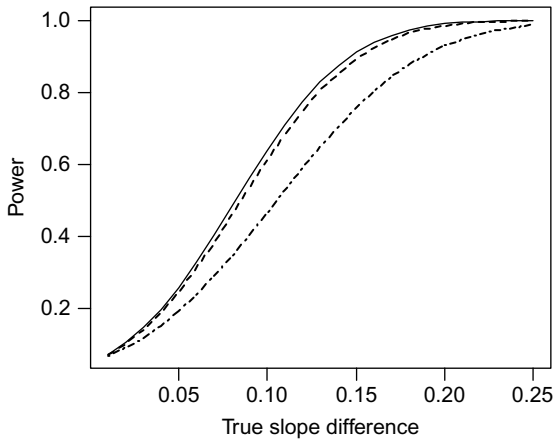

FIGURE 22.1 Comparison of power to detect slope differences at the 12-month time point for three stability designs in ICH Q1D. Solid line—full design; dashed line—matrix on time points only; dot-dashed line—matrix on both time points and design variables.

Now for a test with a lower limit, the desired shelf-life claim will be achieved whenever

$$I + D\cdot(\hat{S} - \hat{\sigma}_S \cdot qt(0.95, dfe)) > L$$

or

$$\frac{\hat{S} + (I-L)/D}{\hat{\sigma}_S} > qt(0.95, dfe)$$

or

$$\frac{\frac{\hat{S}-S}{\sigma_S} + \frac{(I-L)/D + S}{\sigma_S}}{\hat{\sigma}_S/\sigma_S} > qt(0.95, dfe)$$

Comparing this with Eq. (22.12), we see that

$$\Pr\{\text{Achieving desired shelflife claim}\} = 1 - \text{pnct}\left(qt(0.95, dfe), dfe, \frac{(I-L)/D + S}{\sigma_S}\right) \quad (22.13)$$

Note that a similar derivation in the case of an upper acceptance limit would yield

$$\Pr\{\text{Achieving desired shelflife claim}\} = \text{pnct}\left(qt(0.05, dfe), dfe, \frac{(I-L)/D + S}{\sigma_S}\right) \quad (22.14)$$

Eqs. (22.13) or (22.14) may be evaluated as a function of I, S, and σ_S to provide the operating characteristics of the shelf-life-estimation goal. Hypothetical I, S, and σ_S may be taken from preliminary stability and analytical studies. Since by Eqs. (22.5) and (22.6), dfe and σ_S^2 depend only on $\mathbf{X}$, which in turn is determined by the stability design, the operating characteristics can be compared for various designs and storage times as an aid in study planning.

As an example, consider three matrix designs presented in ICH Q1D and the model as described previously. Let S be defined as the slope that represents the stability for batch 2 of the low-strength formulation (and any package). The corresponding contrast vector is, then,

$$\mathbf{c}' = (0,1,0,0,0,0,0,0,0,1,1,0,0,0,1,0)$$

so that

$$\mathbf{c}'\boldsymbol{\beta} = \beta_T + \beta_{TB2} + \beta_{TS1} + \beta_{TB2S1}$$

Assume that the stability potency analysis for submission will occur at the 12-month time point. Let $\sigma = 1\%$LC, the lower acceptance limit for potency, L, be 90%LC, the true initial potency level, and I, be 100%LC, and let the true slope, S, for the combination of interest vary between -0.4 and -0.1%LC/month. Fig. 22.2 shows the probability of meeting a shelf life claim of $D = 24$ months (as given by Eq. (22.13)) for various true slopes. Note that very little risk is seen in going from the full design (135 tests required) to the matrix design on time only (ICH Q1D Table 3a; 108 tests required). However, considerable risk is encountered when matrixing includes time, strength, batch, and packaging (ICH Q1D Table 3b; 72 tests required) (Fig. 22.2).

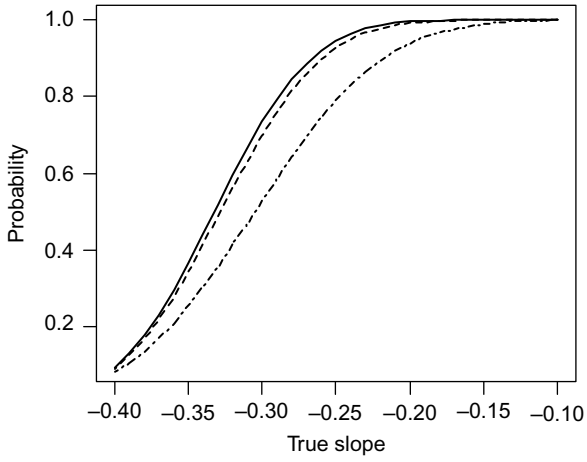

FIGURE 22.2 Comparison of probability of achieving a 24-month shelf-life claim at the 12-month time point for three stability designs in ICH Q1D. Solid line—full design; dashed line—matrix on time points only; dot-dashed line—matrix on both time points and design variables.

22.5.5.4 *Implementation in R*

The R language[20] provides a good matrix computation and graphics platform for making stability design comparisons of power and probability as described previously. The design matrix **X** (up to the time of proposed analysis) may be created manually in a Microsoft Excel spreadsheet and imported as a comma-separated text file to implement the power and probability calculations illustrated in the following R code:

```
XPXINV<-solve(t(X)%*%X) # information matrix
dfe<- dim(X)[1]-dim(X)[2]
var.e<- 1 # hypothesized analytical variance

# contrast vector for slope differences
c<-matrix(c
(0,0,0,0,0,0,0,0,0,0,-1,1,-0.334,0.333,

        -0.334,0.333),ncol=1)

# hypothesized true slope differences
DELTA<-seq(from=0.01,to=0.25, by=0.01)
var.c<-var.e*t(c)%*%XPXINV%*%c;var.c
# power of detection of a slope difference
power<-1-pt(qt(0.95,dfe),dfe,DELTA/sqrt(var.
c))
# contrast vector for individual combination slope
estimate
a<-matrix(c(0,1,0,0,0,0,0,0,0,1,1,0,0,0,1,0),
ncol=1)
# hypothesized true slopes
S<-seq(from=-0.1, to=-0.4, by=-0.01)
var.a<-var.e*t(a)%*%XPXINV%*%a;var.a
# prob of achieving shelf life goal
I<-100 # Initial potency level
L<-90 # Lower specification for dating
D<-24 # Desired dating (based on 12 month data)
prob<-1-pt(qt(0.95,dfe),dfe,(S+(I-L)/D)/sqrt
(var.a))
```

22.6 DETERMINATION OF SHELF LIFE

22.6.1 Definition of shelf life

A definition of *shelf life* for a given characteristic that is consistent with ICH Q1E[5] is the longest storage period for which there is at least 95% confidence that the lot mean level of the characteristic remains within its acceptance range. We must translate this definition into a procedure that we can apply for estimating the shelf life. The procedure used will depend on the type of data available and the statistical model employed. When the shelf life is estimated using LR, this definition is consistent with the storage period at which the one-sided upper or lower 95% confidence bound for the lot mean level intersects the product acceptance limit.

By this definition, the shelf life is clearly intended to control the mean level of critical characteristics of product lots. Because of analytical variance and content nonuniformity, even when the lot mean level of a characteristic is within a given specification, the measured levels of individual tablets may not be. The occurrence of individual out of specification (OOS) test results in lots tested annual stability monitoring can lead to a costly laboratory investigation. Thus, as part of a shelf-life justification, a sponsor may also want to evaluate the probability of individual failures.

Because this definition of shelf life does not control the spread of individual results, alternative definitions are proposed from time to time based on prediction or tolerance bounds.[21]

22.6.2 Model pruning

The first step in shelf-life estimation consists of pruning the full model to remove statistically nonsignificant terms. This process should follow the usual stepwise regression elimination that maintains model hierarchy. Generally, model terms that contain batch variables are eliminated at the $P > 0.25$ significance level, and other terms are eliminated at the more traditional $P > 0.05$ significance level. A good overview of the model building and fitting process is described by Chow and Liu[22] and by Shao and Chow.[23] The statistical aspects of the analysis for a fixed effects model are discussed by Fairweather et al.[24] and by Chen et al.[25]

When a mixed-effects model is used, the same pruning principles may be employed. Analysis of mixed effects stability models is described by Chen et al.[26] and by Chow and Shao.[27]

A set of SAS macros was made available from the FDA[28] that provided an analysis of the simple fixed-batch case with no other factors such as strength or packaging. However, this set of macros is not recommended because it is too limited in scope. It is not entirely compatible with the new ICH Q1E[5] guidance, nor with current versions of the SAS package. The MIXED procedure of SAS permits analysis of a mixed model (Eq. (22.1)) and is an excellent platform for shelf-life estimation. Therefore, examples of proc MIXED code are provided next.

22.6.2.1 *Simple ANCOVA for the fixed batch case*

In the simplest situation, stability data are available for at least three batches of a single strength and stored in a single package type. A good basic reference to ANCOVA is Brownlee.[29] The process begins with preliminary sequential *F*-tests for equality of degradation rates (slopes) and initial values (intercepts) among batches (Table 22.9).

Let us call the *P*-values of the Batch and Month*Batch tests *P*(B) and *P*(M*B), respectively. According to ICH Q1E, the final model is selected according to the following rules:

Select common intercept common slope (CICS) if $P(B) > 0.25$ and $P(M*B) > 0.25$
Select separate intercept common slope (SICS) if $P(B) < 0.25$ and $P(M*B) > 0.25$
Select separate intercept separate slope (SISS) otherwise.

An aspect of this model selection algorithm that is unique to the ICH Q1E[5] guideline is the use of a critical *P* value of 0.25 instead of the usual $P = 0.05$. The FDA has indicated that this should be done in order to protect against accidentally obtaining a favorable model (model 1 CICS generally leads to longer product dating) by the statistical accident of getting favorable data when in fact the real behavior is less favorable.[30] This is still a controversial aspect of the FDA/ICH procedure, but as this has been used for well over 15 years, it has become standard practice in industry.

The ANCOVA can be implemented simply using the MIXED procedure of SAS and will be illustrated using the data in Appendix A. Assume that the data for Batches 4, 5, and 8 are analyzed together (ie, *pooled*, in the drug stability vernacular[31]) and read into a SAS

TABLE 22.9 Simple ANCOVA Sequential *F*-Tests

Code name for the ANCOVA *F*-test	What is tested?
Batch	Differences among batch intercepts, assuming that batches have a common slope
Month*Batch	Differences among batch slopes, assuming that batches may have different intercepts

TABLE 22.10 Type 1 Tests of Fixed Effects

Effect	Num DF	Den DF	*F* Values	Pr > *F*
Month	1	18	100.99	<0.0001
Batch	2	18	72.12	<0.0001
Month*Batch	2	18	1.96	0.1704

data set with the variables Batch, Month, and Potency. The following SAS code:

```
proc mixed;
  class batch;
  model Potency = Month Batch Month*Batch/htype = 1;
run;
```

results in the output in Table 22.10.

The last column gives the P(B) and P(M*B) values on the second and third lines respectively. Since P(M*B) < 0.25, a SISS model is required to estimate the shelf life.

The reader may verify that, for the data in Appendix A, analysis of batches 3, 4, and 5 will lead to the SICS model and analysis of batches 2, 5, and 7 will lead to the CICS model.

22.6.2.2 *Model pruning for more complex studies*

Whether a full factorial or a reduced design is used, data should be treated in the same manner as data from a full design study. As an example, if the stability study includes multiple strength and packaging levels, and the design supports estimation of interactions to the second order, the following SAS code might be appropriate:

```
proc mixed;
  class batch strength package;
  model Potency = Batch Strength Package
                  Batch*Strength      Batch*Package
Strength*Package
                  Month  Month*Batch  Month*Strength
Month*Package
            /htype = 3;
run;
```

A model pruning procedure similar in spirit to the simple ANCOVA analysis given here should be used (eg, stepwise regression) to test for the statistical significance of model terms containing the various design variables. Model terms are eliminated in a stepwise manner based on an objective criterion, such as their corresponding Type III F test significance. Preliminary statistical tests for terms or interactions involving the Batch variable should be conducted at a level of significance for a rejection of 0.25. Statistical tests for main effects of matrixed or bracketed variables other than Batch should be conducted using the traditional level of significance for rejection of 0.05.

22.6.3 Simple fixed batch case

If the purpose of the stability analysis is to estimate stability parameters or predict performance of only those batches included in the study, the batch variable may be considered fixed. In this case, the **Z** matrix in Eq. (22.1) is null and the stability model is the usual fixed linear model:

$$y = \mathbf{X}\beta + \varepsilon. \tag{22.15}$$

where the **X** matrix encodes the levels of fixed effects, such as batch, strength, packaging, and storage time.

The estimated product shelf life depends on the final stability model. Assuming that model pruning has already been done, **X** will include columns only for effects and interactions deemed statistically significant whose estimation can be supported by the data. We consider here the single-strength, single-package case. Shelf-life estimation requires that the upper (or lower) one-sided 95% confidence bounds for the mean regression lines for each batch be calculated. The SAS MIXED syntax for the SISS model is given here:

```
proc mixed;
class batch;
  model Potency = Month Batch Month*Batch / Solution
alphap = 0.1
                                  outpm = outpm; run;
```

In SAS, confidence bounds are easily obtained for time points not studied by including missing values for desired months in the incoming data set. For the other models, the following SAS code should be substituted:

SICS: Potency = `Month Batch`

CICS: Potency = `Month`

The resulting outpm SAS data set will contain a listing of the data, as well as the appropriate predicted and confidence bounds for each time point in the incoming data set. Missing values may be included for time points of interest in order to estimate the shelf life. As an illustration, an analysis of Batches 4, 5, and 8 of the data in Appendix A will provide an `outpm` data set containing the following:

```
batch    Month    Lower
BATCH4    56    90.8585
BATCH4    57    90.6146
BATCH4    58    90.3708
BATCH4    59    90.1268 <--
BATCH4    60    89.8829
BATCH5    41    90.8015
BATCH5    42    90.5517
BATCH5    43    90.3017
BATCH5    44    90.0518 <--
```

```
BATCH5    45    89.8017
BATCH5    46    89.5516
BATCH5    47    89.3014
BATCH5    48    89.0512
BATCH8    25    90.9432
BATCH8    26    90.5079
BATCH8    27    90.0723 <--
BATCH8    28    89.6365
BATCH8    29    89.2004
```

The shelf life for a given batch is the maximum time (rounded to the nearest month) during which the upper and lower confidence bounds remain within the acceptance limit. The arrows in the previous listing give the maximum month at which the one-sided lower 95% confidence bound for each lot mean remains above an acceptance limit of 90.0%LC.

For the SICS and SISS models, the shelf life must be based on the worst-case batch. ICH Q1E specifies how much extrapolation is allowed. Generally the shelf life is limited to no more than two times the duration of the stability study (assuming that the 95% confidence bound remains within the acceptance specification for this period). In the example given here, shelf life is limited to 27 months based on projections for the worst-case Batch 8. When limited extrapolation of shelf life is accepted at time of approval, postapproval long-term data must be reported to FDA to verify the shelf life. Accelerated data are used to justify the temporary excursion of environmental conditions and support the limited extrapolation of long-term data.

22.6.4 Simple random batch case

If the goal of a stability analysis is to use the available stability data to predict stability performance for a *future* batch of product that (of course) was not studied, then the batch variable should be considered random. This should be reflected in the stability model and the analysis approach. A prerequisite for such a prediction is the availability of stability data from a reasonably large number of batches (hopefully more than three).

The appropriate predictive model is given by Eq. (22.1), where γ is a matrix of batch-specific random intercept and slope effect column vectors. The random intercept effect for a given batch may reflect random deviations from a target level of added active ingredients, whereas the random slope effect may reflect random deviations from nominal excipient levels or processing settings.

In this case, Eq. (22.1) simplifies to the following form:

$$y_{ij} = a_i + x_{ij}b_i + e_{ij} \tag{22.16}$$

where

y_{ij} is the observed test result for the ith batch tested at the jth time point
a_i and b_i are the random intercept and slope for the ith batch
x_{ij} is the storage time corresponding to the ith batch tested at the jth time point
$e_{ij} \sim iid\ N(0,\sigma^2)$ reflect measurement variance

If we assume that these batch-specific intercept and slope effects are normally distributed about process mean parameters α and β, respectively, and are mutually independent, then we take for the ith batch

$$\begin{pmatrix} a_i \\ b_i \end{pmatrix} \sim N\left(\begin{pmatrix} \alpha \\ \beta \end{pmatrix}, \begin{pmatrix} \sigma_a^2 & 0 \\ 0 & \sigma_b^2 \end{pmatrix} \right) \tag{22.17}$$

where σ_a^2 and σ_b^2 represent the variances of these random intercept and slope effects among batches. This model may be analyzed using the following SAS MIXED procedure syntax:

```
proc mixed data=stability;
    class Batch;
    model Potency=Month /solution alphap=0.1
outp=outp;
    random Intercept Month/ type=vc
subject=Batch;
run;
```

When this code is used to analyze the eight batches of data in Appendix A, the parameter point estimates listed in Table 22.11 are obtained.

If a future lot is included in the incoming data set, whose test results are all missing, then the outp data set will contain the estimated one-sided lower 95% confidence bound for Potency at the storage times of interest. A partial listing of the outp data set is given here:

```
batch      Month      Lower
FUTURE      40      90.9427
FUTURE      41      90.7299
FUTURE      42      90.5169
FUTURE      43      90.3038
FUTURE      44      90.0904 <--
FUTURE      45      89.8769
```

TABLE 22.11 Point Estimates From Proc MIXED Random Batch Analysis

Parameter	Point estimate
A	101.46
β	− 0.2063
σ_a^2	1.4774
σ_b^2	0
σ^2	0.8063

TABLE 22.12 Output From SAS Fixed Batch Analysis

Covariance Parameter Estimates						
Cov Parm					Estimate	
Residual					1.1568	
Solution for Fixed Effects						
Standard						
Effect	batch	Estimate	Error	DF	t Value	Pr > |t|
Intercept		100.82	0.3840	24	262.52	< .0001
Month		−0.2131	0.02433	24	−8.76	< .0001
batch	BATCH3	1.3556	0.4849	24	2.80	0.0100
batch	BATCH4	3.4352	0.5032	24	6.83	< .0001
batch	BATCH5	0	.	.	.	.

```
FUTURE      46      89.6632
FUTURE      47      89.4493
FUTURE      48      89.2353
FUTURE      49      89.0210
```

The arrow in this code fragment indicates that the estimated shelf life for a future lot is 44 months.

22.6.5 Shelf-life estimation in more complex studies

The principles illustrated in the previous sections apply as well when the study includes multiple levels of strength, packaging, or other design variables. A good review of model building aspects in complex cases is provided by Millikin and Johnson.[32]

22.7 RELEASE LIMIT ESTIMATION

The shelf life estimation discussed previously depends on the true level at release (ie, the intercept) being in control. Thus, the true release levels of batches used for shelf life determination are assumed to be representative of those of future lots. Often, a process control limit is established to ensure good control of the release level. If the measured release level exceeds the limit, the product is not released for sale.

In keeping with the definition of shelf life, a one-sided release limit should ensure with at least 95% confidence that the mean level of a released lot will remain above (or below) a given lower (or upper) stability specification at the end of shelf life. Generally, stability data are available, and the objective is to calculate a release limit (RL) from the estimated slope, its standard error of estimate ($\hat{\sigma}_{slope}$), along with the established shelf-life acceptance limit (SL) of the desired shelf life (D), the estimated total analytical standard deviation ($\hat{\sigma}$), and the number of replicates averaged to obtain the reportable release test result (n). Then the release limit estimate is given by[33]

$$RL = SL - \delta \cdot D + t_{p,df}\sqrt{\hat{\sigma}^2/n + D^2 \cdot \hat{\sigma}^2_{slope}}, \qquad (22.18)$$

where

δ = min[$slope$,0] or max[$slope$,0] for lower or upper RL, respectively
$t_{p,df}$ = pth quantile of the t-distribution with df degrees of freedom.
df = Satterthwaite degrees of freedom determined as described in (Allen et al., 1991, page 1211)
p = 0.95 or 0.05 for lower or upper RL, respectively.

To illustrate this application of Eq. (22.18), the data from Appendix A will be used. A fixed batch analysis of batches 3, 4, and 5 yields a separate intercept, common slope model. The multiple regression output from a SAS analysis is shown in Table 22.12.

With a stability lower acceptance limit of SL = 90.0% LC and using the methods discussed here, shelf lives of 48, 57, and 43 months are obtained for batches 3, 4, and 5, respectively. As a result, a shelf life of 43 months could be justified for this product. Thus, the development team feels justified in recommending a shelf life for this product of D = 36 months; however, they also decide to establish a lower release limit on the mean of n = 2 replicate tests to ensure that no future batch mean will be below 90%LC through 36 months with 95% confidence. From the SAS output in Table 22.12, the following inputs to Eq. (22.18) are obtained:

$slope$ = −0.2131%LC/month

$\delta = \min[slope,0] = -0.2131$ (for lower release limit)
$\hat{\sigma} = 1.1568$ (residual error)
$\hat{\sigma}_{slope} = 0.02433$
$df = 24$
$p = 0.95$ (for lower release limit)

Application of Eq. (22.18) yields a release limit of $RL = 99.7\%$LC for this product.

For a separate intercept, separate slope model, a conservative approach is to take the slope estimate from the worst-case batch. In cases where the estimated slope implies a favorable divergence over time from the limit of interest (eg, negative slope used to estimate an upper RL), the slope should be set to zero, as implied by the δ function given previously. This provides a worst-case, conservative estimate for the release limit and ensures that lot mean levels will remain in conformance throughout the storage period with at least 95% confidence.

When estimates of $\hat{\sigma}$ and $\hat{\sigma}_{\text{slope}}$ are not obtained from the same regression, then the evaluation of df can be problematic. However, the Satterthwaite[34] approximation may be applied in this case. In principle, a similar approach could be used in the random batch case.

22.8 PROBABILITY OF FUTURE OOS STABILITY TEST RESULTS

The approaches described in the previous sections for estimating product shelf life are meant to control batch mean levels, but they give no assurance that individual test results, for lots placed on annual stability, will remain within the stability acceptance limit. Stability failures can result in costly investigations or, in the worst cases, product recall or withdrawal. Thus, after ensuring that all regulatory guidance has been followed, it is in a sponsor's interest to predict the probability of OOS stability test results for future batches.

The problem of prediction is fundamentally different than that of hypothesis testing and estimation and requires a full probability model of the process being simulated. Traditional data analysis methods have yielded ingenious analytical tools, such as tolerance and prediction interval estimates, as aids to risk assessment. However, except in the simplest scenarios, the prediction problem is too difficult to be solved analytically; modern computer simulation approaches are required. Methods such as mixed model regression rely on approximations that may not hold in small samples. Traditional tolerance and prediction intervals do not adequately address estimation uncertainty, and they rely on the nonintuitive paradigm of repeated sampling.

The prediction problem can be tackled in a very direct, rigorous, and informative way by taking a Bayesian perspective. Bayesian estimates are directly interpretable as probabilities. Modern tools for implementing the Bayesian approach, such as WinBUGS or the SAS MIXED procedure, are now readily available and can be effectively used to enhance decision making in the stability arena. Thus, this chapter would not be complete without an illustration of the power of these important methods by analyzing the data from all eight batches in Appendix A using Gibbs's sampling in WinBUGS.

The central objective of a Bayesian analysis is to estimate $p(\theta \mid \mathbf{Y})$, the joint posterior distribution of unknown model parameters given the data. From the joint posterior, the distribution of any function of θ or of any quantity that may be predicted from the model can be obtained through Markov chain Monte-Carlo techniques. By sampling iteratively from the posterior distribution, WinBUGS produces a posterior sample of the model parameters, θ from $p(\theta \mid \mathrm{Y})$.

A sample from the distribution of any predicted quantity (say, Z_{pred}) can be obtained by integrating the relevant component distributions in the data model over the posterior as follows:

$$p(Z_{\text{pred}}|\mathbf{Y}) = \int_{\theta} f(Z_{\text{pred}}|\theta)\cdot p(\theta|\mathbf{Y})d\theta$$

As with the posterior distribution, the distributions for predicted quantities are obtained within the process of Monte-Carlo iterative sampling and no analytical integration is needed. The example given in the next section is practical in nature and assumes only general familiarity with the Bayesian paradigm. For more depth and discussion of important topics such as convergence verification, readers are referred to a general text on Bayesian data analysis like Gelman et al.[35] For details of WinBUGS operation and syntax, see the WinBUGS operator's manual.[36]

22.8.1 Random batch model for prediction

Prediction involving future batches requires a random batch assumption so the model of Section 22.6.4 will be used with minor modification of symbols and structure. In place of Eq. (22.16), we define the true potency, μ_{bi}, for a given lot, b, tested at the ith time, X_i, as

$$\mu_{bi} = \alpha_b + \beta_b\cdot(X_i - Xbar),$$

where $Xbar$ is the average of the storage period for all nonmissing individual measurements in the data set. For the eight batches in Appendix A, $Xbar = 9.25$ months. This centering is used in the model to improve the rate of convergence of the Gibbs sampler.

Each of the $b = 1, 2, \ldots 8$ batches is assumed to have a unique true intercept, α_b, and true slope, β_b. The true slope and intercept for batches are assumed to be independent and to follow a normal distribution among lots, with the eight batches on hand representing a random sample from the population of all possible batches. Thus, as with Eq. (22.17), we have

$$\begin{pmatrix} \alpha_b \\ \beta_b \end{pmatrix} \sim N\left(\begin{pmatrix} \alpha_c \\ \beta_c \end{pmatrix}, \begin{pmatrix} \sigma_\alpha^2 & 0 \\ 0 & \sigma_\beta^2 \end{pmatrix} \right)$$

The observed potency result, Y_{bi}, for lot b at time point i will vary about the true value due to analytical variance and is assumed to follow a normal distribution as follows:

$$Y_{bi} \sim N(\mu_{bi}, \sigma^2).$$

22.8.2 Prior distributions for model parameters

The probability model described previously depends on a vector of five model parameters:

$$\boldsymbol{\theta} = [\alpha_c, \beta_c, \sigma_\alpha, \sigma_\beta, \sigma]$$

A Bayesian perspective considers these parameters to be random quantities and thus to have a probability distribution. Prior to data collection, the distributions of these parameters are a quantitative expression of the subjective uncertainty about their value. When prior uncertainty is great, it is appropriate to assume prior distributions that are independent and very broad or noninformative. This was the approach taken here. The following noninformative distributions were used:

$$\begin{aligned} &\alpha_c \sim N(100, 10^{-6}) \\ &\beta_c \sim N(0, 10^{-6}) \\ &\sigma_\alpha = 1/\sqrt{\tau_\alpha} \sim U(0, 100) \\ &\sigma_\beta = 1/\sqrt{\tau_\beta} \sim U(0, 100) \\ &\tau_c = 1/\sigma^2 \sim G(10^{-3}, 10^{-3}) \end{aligned}$$

U(A,B) represents a flat uniform distribution with minimum and maximum values A and B, respectively. G(C,D) represents a gamma distribution with shape and rate parameters C and D, respectively. The parameters for all these distributions are chosen so that the probability density is essentially constant over the likely range of the true parameter values; thus, the choice of prior has essentially little or no impact on the final estimation. In cases were substantial prior knowledge and theory on a product, or like products, are available, it may be appropriate to use a more informative prior, but that will not be discussed here.

22.8.3 Predicted quantities of interest

The objective of the present analysis is to simulate probability distributions of various predicted quantities that are functions of the original parameters. These consist of posterior or posterior predictive distributions that summarize the available knowledge about each predicted quantity.

One quantity of interest is the initial mean potency for the overall manufacturing process, Y_0, where

$$Y_0 = \alpha_c - \beta_c \cdot Xbar$$

Ideally, Y_0, should be close to 100%LC. If this value is significantly below 100%LC, it may mean that the active ingredient is being lost in the manufacturing process, and an increase in overage is needed to correct this situation.

Certainly, it would also be of interest to estimate the distributions for a future batch slope, β_{pred}, and initial potency level, $Init_{\text{pred}}$, which can be obtained from the model parameters as follows:

$$\begin{aligned} &\beta_{\text{pred}} \sim N(\beta_c, \sigma_\beta^2) \\ &Init_{\text{pred}} = \alpha_{\text{pred}} - \beta_{\text{pred}} \cdot Xbar, \quad \text{where} \quad \alpha_{\text{pred}} \sim N(\alpha_c, \sigma_\alpha^2) \end{aligned}$$

From these distributions, one can also predict the true mean level, μ_{pred}, and individual potency test result, Y_{pred}, of some future lot after X_{pred} months of storage (for this example, we take $X_{\text{pred}} = 36$ months). This can be obtained as described in the following sections.

Also of particular interest would be the posterior probability distribution of analytical error, σ, and the predictive posterior distribution of the product shelf life. The shelf life for a given batch will be the storage period during which the true level remains above the stability acceptance limit SL:

$$Shelf.Life = \frac{SL - Init_{\text{pred}}}{\beta_{\text{pred}}}$$

For this example, we take $SL = 90\%$LC. Some care is needed in the definition of shelf life. Since the distribution of β_{pred} may include nonnegative slope values, which could result in inadmissible (negative or infinite) values of *Shelf.Life*. In the WinBUGS code given next, the *Shelf.Life* values are truncated in the interval at 0 and 100 months.

22.8.4 Implementation in WinBUGS

This application is easily programmed into the freely available WinBUGS software.[36] The WinBUGS code consists of the following three text sections that are placed in a WinBUGS file: Model, Data, and Initial values (to start the Markov chain Monte Carlo iterations). These are discussed briefly in the next sections.

22.8.4.1 Model

The Model code consists of the following text:

```
model;
{ for(batch in 1 : B) {

              alpha[batch]   ~   dnorm(alpha.c,tau.
alpha)
              beta[batch] ~ dnorm(beta.c,tau.beta)
              for(i in 1 : N) {
                mu[batch, i] <- alpha[batch] + beta
[batch] * (X[i] - Xbar)
                Y[batch, i] ~ dnorm(mu[batch, i],
tau.c)
              }
      }
          # Priors
            tau.c ~ dgamma(0.001,0.001)
            beta.c ~ dnorm(0.0,1.0E-6)
            alpha.c ~ dnorm(100,1.0E-6)
            sigma.beta ~ dunif(0,100)
            sigma.alpha ~ dunif(0,100)
            tau.beta <- 1 / (sigma.beta * sigma.beta)
            tau.alpha <- 1 / (sigma.alpha * sigma.
alpha)
            sigma <- 1 / sqrt(tau.c) # Total analyti-
cal SD
          # Predicted Quantities of Interest
              # Process Initial Target
              Y0 <- alpha.c - beta.c*Xbar
              beta.pred ~ dnorm(beta.c,tau.beta) #
Lot Slopes
              alpha.pred ~ dnorm(alpha.c,tau.alpha)
              # Lot Initials
              Init.pred <-alpha.pred - Xbar*beta.
pred
              #Shelf life constrained to [0,100]
              Shelf.Life<-max(0,min(100,(90-Init.
pred)/beta.pred))
              # Predicted Lot Means at Xpred
              mupred <-alpha.pred + (Xpred-Xbar) *
beta.pred
              # Individual Prediction at Xbar
              Ypred ~ dnorm(mupred,tau.c)
}
```

22.8.4.2 Data

The potency stability data used for analysis is given in Appendix A. These consist of data from eight batches. Measurements were taken at up to 11 nominal time points over a period of 24 months. The WinBUGS code for these data is given here:

```
# Data
list(X = c(0, 1, 2, 3, 3, 6, 6, 12, 12, 24, 24),
B = 8,N = 11,Xpred = 36,Xbar = 9.25,
Y = structure(.Data = c(102,NA,NA,101,
101,100.5,100.8,
100.1,99,96.7,97.2,
101,101.3,NA,99.8,99.2,99.5,97.8,97.4,97.2,
96.9,96,
104.8,NA,NA,103,101.2,100.8,99.2,98.6,97.2,
97.6,98,
104,NA,NA,103.2,NA,102.8,103.3,102.4,101.2,
99.1,99.5,
102,101.4,100.8,100.2,99.7,98.8,98.5,98,97.1,
96.6,96.1,
102.7,102,NA,100.6,99.9,99.2,98.5,98.1,97.6,
96.8,96,
101.3,101.5,NA,100.2,99.8,99,98.5,98.5,97.4,
96.6,96.4,
101.6,NA,NA,100,NA,99,NA,97.8,97,NA,NA),.
Dim = c(8,11)))
```

22.8.4.3 Initial values

Gibbs sampling uses Monte Carlo sampling from the various prior, model, and predictive distributions indicated previously. The sampling is dependent (not pseudorandom) because the sampling at any iteration depends on the values in the previous iteration; however, the sampling procedure is known to converge on the desired posterior distribution. Thus, starting values are needed to initiate the Gibbs sampling process. Examination of the iterative process showed that convergence to the final distribution was rapid and that the process did not depend on the initial starting values. However, the results reported here were obtained using the following set of starting values (the 0 superscript indicates a starting value for initiating Markov chain–Monte Carlo sampling).

Model parameters:

$$\alpha_c^0 = 100,\ \ \beta_c^0 = 0,\ \ \sigma_\alpha^0 = 1,\ \ \sigma_\beta^0 = 1,\ \ \tau_c^0 = 1$$

Latent quantities for the eight lots in the data set:

$$\alpha_b^0 = 100,\ \ \beta_b^0 = 0,\ \ b = 1, 2, \ldots 18$$

Predicted quantities:

$$\alpha_{\text{pred}}^0 = 100,\ \ \beta_{\text{pred}}^0 = 0,\ \ Y_{\text{pred}}^0 = 100$$

Missing Potency values in the data set:

$$Y_{bi}^0 = 100\ \ \forall\ \ Y_{bi} = NA$$

These initial values were specified by the following WinBUGS code:

```
# Initials
list(tau.c = 1,sigma.beta = 1,beta.pred = 0,beta.
c = 0,sigma.alpha = 1,

      alpha.pred = 100,alpha.c = 100,Ypred = 100,
        beta = c(0,0,0,0,0,0,0,0),
      alpha = c(100,100,100,100,100,100,100,100),

Y = structure(.Data = c(NA,100,100,NA,NA,NA,NA,
NA,NA,NA,NA,
```

```
NA,NA,100,NA,NA,NA,NA,NA,NA,NA,NA,
NA,100,100,NA,NA,NA,NA,NA,NA,NA,NA,
NA,100,100,NA,100,NA,NA,NA,NA,NA,NA,
NA,NA,NA,NA,NA,NA,NA,NA,NA,NA,NA,
NA,NA,100,NA,NA,NA,NA,NA,NA,NA,NA,
NA,NA,100,NA,NA,NA,NA,NA,NA,NA,NA,
NA,100,100,NA,100,NA,100,NA,NA,100,100),.Dim=c
(8,11))
```

22.8.4.4 *Burn-in period, sample size, and convergence verification*

A *burn-in period* is recommended for Markov chain–Monte Carlo sampling to give the dependent draws a chance to migrate from the initial starting values and approximate the target distribution. A close examination of the sampling process in WinBUGS showed it was very well behaved and rapidly converged. However a burn-in period of 5000 draws was still used before the samples were used to estimate the distributions of interest. A subsequent sample of 10,000 draws was used for estimation. This large sample size ensured that the Monte Carlo sampling error was insignificant compared to the variance of the target distributions of all quantities estimated.

The 1000-draw predictive posterior sample was exported from WinBUGS (coda option) and imported as a text file into JMP.[37] Kernel density histograms of the posteriors are provided in Fig. 22.3. The OOS probability was calculated as a percentage of the predictive posterior samples below 95%LC (given in Table 22.13).

22.8.5 Results

To obtain more specific information on any posterior or predictive posterior sample, it may be exported from WinBUGS and imported into a more general data analysis package such as SAS or JMP to conduct capability analyses or obtain more specific quantiles. The histogram obtained for *Shelf.Life* is shown in Fig. 22.4.

The shaded region in the figure identifies the 5% lowest *Shelf.Life* values. The fifth percentile of this distribution was 40.3 months. Thus, 95% of future batches are expected to have a *Shelf.Life* greater than 40 months. Therefore, a shelf-life estimate of about 40 months would be consistent with the FDA definition

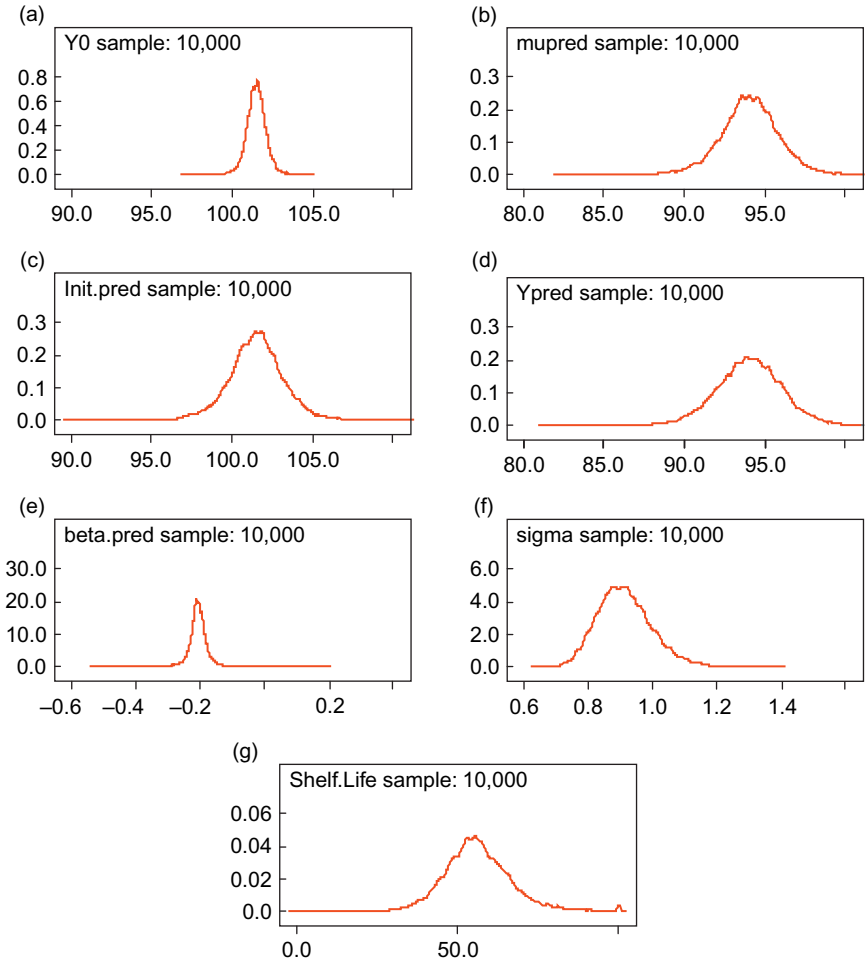

FIGURE 22.3 Kernel density smoothed posterior or predictive posterior distributions of quantities of interest. (a) Manufacturing process true initial mean. (b) True future batch potency at 36 months. (c) True initial means for future batches. (d) Future individual test results at 36 months. (e) True future batch slope. (f) Analytical standard deviation. (g) Shelf life for future batches.

TABLE 22.13 Posterior and Predictive Posterior Distribution Statistics for Quantities of Interest

Predicted quantity	Distribution mean	Distribution standard deviation	2.5% Percentile	Median (50% percentile)	97.5% Percentile
$Init_{pred}$	101.5	1.782	97.85	101.5	105.0
Shelf.Life	56.28	11.08	36.32	55.57	81.28
Y_0	101.5	0.6081	100.2	101.5	102.7
Y_{pred}	94.01	2.135	89.81	94.03	98.19
β_{pred}	− 0.2068	0.02959	− 0.2662	− 0.2071	− 0.148
μ_{pred}	94.03	1.922	90.1	94.04	97.79
σ	0.9139	0.08429	0.7675	0.9078	1.099

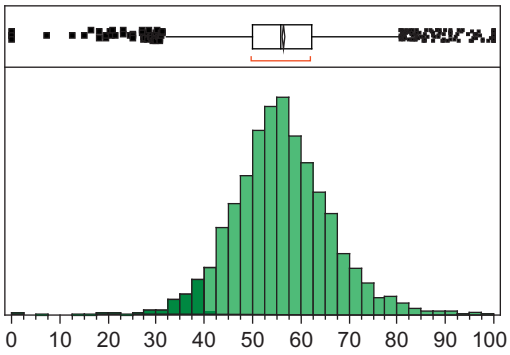

FIGURE 22.4 Predictive posterior distribution of shelf life.

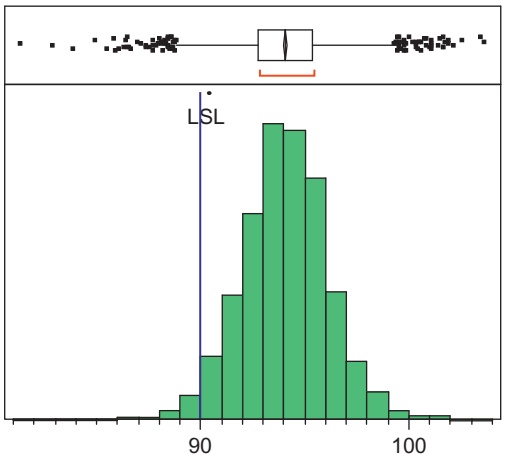

FIGURE 22.5 Process capability of predictive posterior of individual test results at 36 months.

that ensures that batch means will remain within acceptance limits with 95% confidence.

The process capability analysis conducted on Y_{pred} is shown in Fig. 22.5.

The area to the left of the acceptance limit of 90%LC contains 2.8% of the predictive posterior distribution. Thus, future lots can expect to have OOS test results at the 36-month time point with a probability of 0.028. In view of this risk, an appropriately shorter shelf-life or release limit could be considered to avoid the cost of investigations or (in the worst case) the disruption of a product recall.

In stability investigations, predictions of future stability test results for a particular batch of interest might be of interest. In the data set given in Appendix A, future values are missing (*NA*). In WinBUGS, missing values are treated as predictive quantities to be estimated. Thus, we may directly request predictive posteriors for future (missing) data values that have not yet been obtained.

22.8.6 Bayesian prediction using SAS proc MIXED

The SAS MIXED procedure can provide a posterior sample from a mixed model fit, such as the random batch model used with WinBUGS:

```
proc mixed;
   class Batch;
   model Potency = Month /solution alphap = 0.1
outp = outp;
   random Intercept Month/ type = vc subject = Batch;
   prior /out = posterior nsample = 10000;
run;
```

By default, noninformative priors are used for both fixed and random parameters. In this sample code, the posterior data set will contain 10,000 draws from the posterior. This data set may be used to further generate samples of parameter transformations, including predictive posterior for future results, as was illustrated in WinBUGS in the previous section.

TABLE A.1 Sample Data From Shuirmann[38]

Number of months	Batch 1	Batch 2	Batch 3	Batch 4	Batch 5	Batch 6	Batch 7	Batch 8
0	102	101	104.8	104	102	102.7	101.3	101.6
1	–	101.3	–	–	101.4	102	101.5	–
2	–	–	–	–	100.8	–	–	–

CHAPTER

23

Packaging Selection for Solid Oral Dosage Forms

Y. Chen

Novast Laboratories, Ltd., Nantong, China

23.1 INTRODUCTION

Drug products are always packaged in containers for storage and marketing for convenience of handling, use, and product protection. Stability information of a drug product in selected containers regarding the proposed shelf life is part of the quality information required to obtain approval from regulatory agencies to market any drug product, in addition to proof that the product is safe, efficacious, high quality, and made in compliance with current good manufacturing practices. Product stability is typically demonstrated through real-life, formal stability studies under ICH conditions.[1] Study designs and data analysis of long-term studies under the International Conference on Harmonization (ICH) conditions have been discussed in chapter "Statistical Design and Analysis of Long-Term Stability Studies for Drug Products." Due to the time-consuming nature of long-term studies, it is very important to select suitable containers to ensure the success of the studies, particularly when packaging protection of products is needed. Product stability may be imparted by formulation design and proper use of containers. Formulation design is most critical in developing stable drug products. However, formulation design itself may not always be sufficient to ensure that the product is stable during storage. Due to the vast diversity of drug properties and their interaction with environmental conditions, some drug products require protection against some degrading factors, such as humidity and oxygen. The selection process to identify the proper packaging for the needed protection is, therefore, an important part of product development. Although one could argue that the selection could be very simple by using the most highly protective, or the highest barrier container-closure systems for any product, the high cost for the use of such high barrier container closure systems may be difficult to justify, or impractical for commercialization unless the high barrier container closure system is needed for protection of the product. Therefore, one must select appropriate container closure systems to balance the need for product protection and the cost for commercialization. Formal stability study is the definite process to demonstrate the quality of any drug product during its shelf life in the selected container closure system. However, real-life stability study is not the best process to select containers because the process is empirical, time consuming, costly, and inefficient, making the study unsuitable for screening purposes. Any failure of a formal stability study could significantly delay the time-to-market for the product, diminish the opportunity for providing disease treatment to patients, and lead to significant financial losses for a drug maker. Instead, proper selection of containers can be achieved prior to the formal stability study, using science-based and quality-by-design (QbD) approaches throughout early development stages. Containers can be selected based on material characteristics, and by linking the properties of drug products with that of the containers. Formal stability studies can then be conducted to prove that the product is stable in the selected container closure systems. This chapter will focus on the science-based selection of containers and/or packaging materials for protection of solid oral dosage (SOD) forms.

Developing Solid Oral Dosage Forms
DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00023-6

23.1.1 Definitions

To avoid any possible confusion, several terms related to packaging and containers are defined according to FDA guidance.[2,3]

- A *packaging component* means any single part of a container closure system.
- A *container closure system* refers to the sum of packaging components that together contain and protect the dosage form. This includes primary packaging components and secondary packaging components (if the latter are intended to provide additional protection to the drug product).
- A *packaging system* is equivalent to a container closure system.

  In this chapter, container, container closure system, and packaging are interchangeable.
- *Primary packaging component* refers to a packaging component that is or may be in direct contact with the dosage form (eg, liners, bottles, desiccant containers in bottles with dosage forms, blister films, and lidding foils).
- *Secondary packaging component* means a packaging component that is not, and will not be, in direct contact with the dosage form (eg, cartons, and over-wraps for blister cards).

23.1.2 General considerations

Packaging materials used for pharmaceutical products must meet regulatory[2,3] and compendial requirements,[4] provide adequate protection of products against degrading and/or contaminating factors, function properly as intended, and be compatible with drug products and safe for use. In addition, packaging should be elegant for marketing, convenient for use, and low cost for the benefit of both patients and product manufacturers.

Containers are used for different types of products for different routes of administration. By routes of administration, pharmaceutical products can be classified as inhalation, injectable, ophthalmic, liquid oral, liquid topical, transdermal, suppository, and SOD forms. Container requirements for different types of products may be different. Concerns for container-drug interaction are the highest for injectable and inhalation products, and lowest for SOD forms. Therefore, a container closure system approved for one type of product cannot be assumed to be approved for another type of product. For detailed information on regulatory requirements for different types of drug products, refer to the FDA guidance *Container Closure Systems for Packaging Human Drugs and Biologics*.[2]

Proper use of container closure systems can provide protection of SOD forms from moisture, light, oxygen or other gases, microbial contamination, and mechanical stress, depending on the protection requirements of the product. In general, protection against moisture, light, and oxygen are the most important factors to consider. Resistance to microbial contamination can be readily achieved using well sealed containers with proper control of materials, manufacturing, and packaging processes under good manufacturing practice conditions. Protection against physical stress can be achieved by the use of containers with sufficient strength and minimized headspace, which prevents excessive movement of products during handling and shipping. Containers for finished products are normally incapable of protecting products from thermal stress. Heat-sensitive products are typically protected by refrigeration or freezing during storage, shipping, and end use. Therefore, protection against microbial contamination, mechanical stress, and thermal stress, will not be discussed in detail in this chapter.

As stated previously, formal stability studies are not desirable for screening containers for pharmaceutical products. Instead, containers should be selected based on scientific knowledge of the fundamental properties of containers and drug products. Rational selection of containers will minimize the risk of failure in stability studies, increase the efficiency of product development, and reduce the cost for both the pharmaceutical industry and patients.

23.2 MATERIAL CONSIDERATIONS

23.2.1 Containers

Containers can be classified by the dosage forms for which they are intended, by product contact, by container properties, or by purpose of use. Classifications based on dosage forms, such as injectable or SOD forms, and on product contact, such as primary or secondary packaging, were provided in the introduction section. Alternatively, containers can be classified based on their gas permeability—either as permeable or impermeable containers. In general, polymeric blisters and bottles, such as polyvinyl chloride (PVC) and polyvinylidene chloride (PVDC) blisters, and polyethylene terephthalate (PET) and high-density polyethylene (HDPE) or polypropylene (PP) bottles, are permeable to moisture and oxygen; while properly sealed glass bottles and aluminum foil/foil blisters can be considered impermeable to gases if there are no imperfections in the bottle seal or pinholes in the foil. Containers are also commonly classified as bulk containers and finished containers for use purposes.

Bulk containers are used for storage of bulk drug products prior to packaging or for shipping of bulk products to repackagers or contract packagers. Finished containers are for the final packages used to market and deliver drug products to patients. Finished containers are further classified into single-unit containers, and multiple-unit containers. Pharmacy containers for dispensing drug products to patients can be classified as finished containers. Stability data of products stored in the finished containers under ICH conditions are the main source of data required by regulatory agencies for approval of shelf life for products.

Bulk Containers: For bulk products of SOD forms, fiber and plastic drums with flexible liners, such as low-density polyethylene (LDPE, or PE) liners, are commonly used. The liners provide a controlled material contact surface for the products, and some protection of products against moisture and contamination. Regular fiber drums and PE liners are highly permeable to moisture and other gases. A fiber drum reinforced with aluminum foil may have significantly lower gas permeability than a regular one. Plastic drums or pails, such as HDPE drums, also have low gas permeability. With the use of heat-sealable laminated foil bags as liners, HDPE drums or fiber drums reinforced with aluminum foil are likely the second-best bulk containers for products that are sensitive to moisture or oxygen. Well-sealed stainless steel containers provide the best barrier for any gases. However, large steel containers are heavy, and thus inconvenient to use.

Finished containers: For finished pharmaceutical dosage forms, plastic bottles and flexible packages, such as blisters and pouches, are the most commonly used containers. However, plastic bottles, such as LDPE, HDPE, PET, polyethylene terephthalate G (PETG), and PP bottles, and polymeric blisters, such as PVC, PVDC, and polychloro-trifluoroethylene (PCTFE), are permeable to moisture and gases, although the permeability varies with materials. Glass bottles are not commonly used due to the safety concern for broken glasses during handling, and due to their heavy weight that can increase shipment cost, even though well-sealed glass bottles can be considered impermeable to gases. Foil/foil blisters or pouches in the absence of pinholes are impermeable to gases, but are not commonly used in the United States, due to the lack of transparency of the materials, and the low resistance to physical stress such that the blisters are easily deformed by external pressure or force. Foil/foil blisters are widely used in some countries in Asia for marketing reasons other than the need of product protection.

Container permeability is a critical factor to consider in selecting packaging materials for products that are sensitive to the respective permeants. Moisture and oxygen permeabilities of packaging materials are commonly measured, and reported as moisture/water vapor transmission rate (MVTR, or WVTR) and oxygen transmission rate (OTR), respectively. Table 23.1 lists examples of MVTR and OTR data from the literature for some packaging materials. It is important to note that the data listed in the table for blistering materials are for flat films. Permeation rate of the formed cavity of blisters will be larger than that of the flat films due to reduced thickness of the formed cavity. The actual dimensions, including surface area and thickness, of any given containers shall be accounted for in packaging design and evaluation. Increasing the thickness of the barrier material can reduce the MVTR of both the laminated flat films and the formed cavities, as shown for commercially available laminated film materials Aclar RX 160, SupRx 900, UltRx 2000, UltRx 3000, UltRx 4000, and UltRx 6000 (Table 23.2) if the dimension of the blister cavity is the same for different films with different thickness.

TABLE 23.1 Moisture and Oxygen Transmission Rates of Some Packaging Materials

Material	MVTR (g.mil/100 in^2 per 24 h, at 100°F, 90%RH)	OTR (cc.mil/100 in^2 per 24 h-atm, at 77°F)	Reference
Cold form foil	0.00	0.00	6
Polychloro-trifluoroethylene (PCTFE)	0.016	7.00	6
Polyvinyl dichloride (PVDC)	0.1–0.2[a]	0.15–0.90	7
High density polyethylene (HDPE)	0.3–0.4	139–150	6,8
Polypropylene (PP)	0.69–1.0	182	7,9
Low density polyethylene (LDPE)	1.0–1.5	463–500	6
Polyethylene terephthalate (PET)	1.2–2.0	3–5	7
PET modified with CHDM (PETG)	4	6.6	10
Polyvinyl chloride (PVC)	0.9–5.1	5–20	11
Ethylene vinyl alcohol (EVOH)	1.4–5.4[a]	0.05–0.90	7
Polystyrene (PS)	7–10	350–400	11
Nylon	16–20	1.0	11

UltRx 3000	76	0.0088
UltRx 4000	102	0.0065
UltRx 6000	153	0.0038

[a]*Data from https://www.honeywell-aclar.com/ProductInformation/Pages/Documentation.aspx*

The data in Table 23.1 show that materials that have a low MVTR may not have a low OTR. For example, the MVTR of nylon is approximately 1000 times larger than that of PCTFE. However, the OTR of nylon is actually smaller than the OTR of PCTFE. For the purpose of moisture protection, PCTFE is far superior to all other materials listed in the table, except for cold form foil. On the other hand, PVDC and ethylene vinyl alcohol (EVOH) are better choices for protection against oxygen. Packaging materials should therefore be selected based on the specific need for protection of each individual product. From a material development point of view, data listed in Table 23.1 show that combination of PCTFE with EVOH can produce a multiple-layer blistering material with excellent barrier properties against moisture and oxygen. In fact, commercial products of such composite laminated material, PVC/EVOH/Aclar, have become available on the market in recent years.

Although aluminum foil may be considered as the ultimate barrier for gases, thin foil (thickness <25 μm) may have pinholes,[5] and the foil may become permeable through the pinholes. Pinholes can be caused either by the presence of organic contaminates in the molten aluminum or by the stress of the rolling process during foil production. The number of pinholes per defined area of the foil increase as the thickness of the foil decreases. This property is important to consider in selecting foil materials, and also in the design of packages using thin foil as a barrier.

23.2.2 Determination of container MVTR

As previously discussed, container moisture permeability is an important factor to consider in packaging selection for moisture-sensitive products. Reliable MVTR is critical to ensure the selection of proper materials. Compendial methods for determining MVTR are currently described in the USP Chapter <671>[4] to evaluate the performance of containers. Since the 37th edition, the USP Chapter <671> provides different MVTR test methods for multiple-unit containers for SOD forms. These methods are intended for either barrier protection determination, or classification of containers. It is important to use the right method to obtain reliable MVTR. For container classification purpose, the USP method uses a single weight gain measurement over a 14-day study through the use of control bottles. Data in literature have shown that results obtained by this method may be highly variable. For example, the standard deviation of the single weight gain results was higher than the mean value[12] in some cases. In one case, the value obtained at 25°C/75%RH was unreasonably higher than that measured at 40°C/75%RH.[12] A high variability in permeability renders the data of little scientific value, either for packaging design or for justification of container postapproval changes. Therefore, this single weight gain method is not suitable for determining container barrier protection property.

For barrier protection determination, the current version of USP Chapter <671> provides a steady state method (Method 1) with multiple time-point measurements for multiple-unit containers, and for high barrier single-unit containers (Method 2), to ensure the MVTR data is reliable and specific for discriminating the barrier performance of containers. The theory that supports the use of the steady state method for MVTR measurement is discussed next.

For well-sealed plastic containers without gross defects, the mechanism of water ingression into a container is mainly by diffusion of moisture molecules through the container wall,[13] and through the seal. For a relatively large container with a thin wall, the wall can be approximated as a homogeneous planar barrier. If it is assumed that:

1. the diffusion coefficient D of water vapor in the wall is constant at constant temperature;
2. the concentration of moisture at the outside surface is maintained at a constant level of C_o; and
3. the concentration at the inside surface is kept at essentially zero or a "sink" condition; then the initial and boundary conditions for the packaging system under testing can be described as:

$$C = C_i,\ 0 < x < h,\ t = 0$$
$$C = C_o,\ x = 0;\ C = 0,\ x = h,\ t \geq 0$$

where:

x is the direction of diffusion
h represents the thickness of the wall

C is the moisture concentration in the wall
C_i indicates the initial moisture concentration in the wall
C_o is the concentration of moisture at the outside surface of the container wall
t is time.

If the quantity of water diffused through the wall and entered in the "sink" is measured as a result of net diffusion, Eq. (23.1) can be used to describe the permeation process.[14]

$$Q_{t,d}=\frac{DC_o}{h}\left(t+\frac{C_ih^2}{2DC_o}-\frac{h^2}{6D}\right)-\frac{2hC_o}{\pi^2}\sum_{n=1}^{n=\infty}\frac{(-1)^n}{n^2}\exp\left(-\frac{n^2\pi^2Dt}{h^2}\right)$$
$$-\frac{4C_ih}{\pi^2}\sum_{m=0}^{m=\infty}\frac{1}{(2m+1)^2}\exp\left(\frac{-(2m+1)^2\pi^2Dt}{h^2}\right) \quad (23.1)$$

where:
$Q_{t,d}$ is the amount of moisture diffused through unit surface area of the wall at time t.

If the amount of water entering the outer surface of the wall material is measured, such as by measuring total weight gain (wg) of containers per USP Chapter <671>, the measured quantity per unit surface area by weight gain, $Q_{t,wg}$, includes the amount of water absorbed by the wall and the backing material in the closure, and the amount of water diffused through the wall into a "sink" created by desiccants. In this case, Eq. (23.2) can be used to describe the permeation process:

$$Q_{t,wg}=\frac{DC_o}{h}\left(t-\frac{C_ih^2}{2DC_o}+\frac{h^2}{3D}\right)-\frac{2hC_o}{\pi^2}\sum_{n=1}^{n=\infty}\frac{1}{n^2}\exp\left(-\frac{n^2\pi^2Dt}{h^2}\right)$$
$$+\frac{4C_ih}{\pi^2}\sum_{m=0}^{m=\infty}\frac{1}{(2m+1)^2}\exp\left(\frac{-(2m+1)^2\pi^2Dt}{h^2}\right) \quad (23.2)$$

Eqs. (23.1) and (23.2) show that the initial moisture permeation profiles are not linear at onset, because the exponential terms are not yet negligible, and that the profiles are affected by the initial water concentration in the wall material, regardless of the methods of detection. These equations suggest that the data from the early stage of permeation will vary with the initial conditions and time. Such dependency on the initial conditions cannot be corrected using control containers because the driving forces are different for the test and control containers. Therefore, permeability cannot be determined from the early time point by a single weight gain measurement. However, if the permeation process is allowed to proceed for a sufficiently longer time, such that the exponential terms become negligible, MVTR can be reliably determined using the simplified forms of Eqs. (23.1) and (23.2), regardless of the initial water concentration in the wall and the methods of detection. The effects of initial water concentration on the diffusion profiles, and the advantage of using a steady state method for MVTR can be shown by the following analysis.

For the first method in which the amount of water diffused into the sink is measured, if $C_i=0$, and at $t\to\infty$, the exponential terms in Eq. (23.1) become negligible, and the quantity of water diffused through the wall in Eq. (23.1) can be simplified to a linear function as:

$$Q_{t,d}=\frac{DC_o}{h}\left(t-\frac{h^2}{6D}\right) \quad (23.3)$$

with a lag time t_L being

$$t_L=\frac{h^2}{6D} \quad (23.4)$$

If $C_i=C_o$, and at $t\to\infty$, Eq. (23.1) simplifies to

$$Q_{t,d}=\frac{DC_o}{h}\left(t+\frac{h^2}{3D}\right) \quad (23.5)$$

with a burst time t_B, which can also be called a lag time, being

$$t_B=-\frac{h^2}{3D} \quad (23.6)$$

Eqs. (23.3)–(23.6) show that the initial water concentration in the wall can change the initial diffusion profile to appear either as a lag or as a burst, even though the method of determination remains the same. However, the rate of diffusion over steady state, $dQ_{t,d}/dt=DC_o/h$, is not affected by the initial wall conditions.

For the second method, by which the total weight gain of the entire container is measured, when $C_i=0$, and at $t\to\infty$, Eq. (23.2) can be simplified to a linear function including a burst time in:

$$Q_{t,wg}=\frac{DC_o}{h}\left(t+\frac{h^2}{3D}\right) \quad (23.7)$$

When $C_i=C_o$, and at $t\to\infty$, weight gain simplifies to a linear function with a lag time in:

$$Q_{t,wg}=\frac{DC_o}{h}\left(t-\frac{h^2}{6D}\right) \quad (23.8)$$

Eqs. (23.3), (23.5), (23.7), and (23.8) show that the permeation rates, which are the slopes of the linear lines, are the same as Eq. (23.9) for different methods of detection and for different initial conditions of the

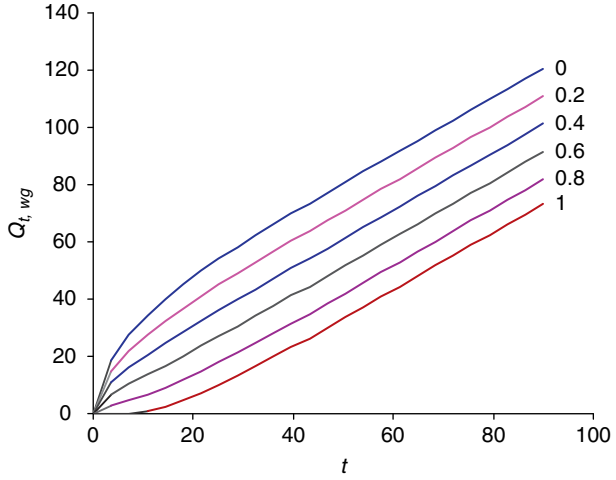

FIGURE 23.1 Simulated weight gain curves of containers filled with desiccants. Numbers at the end of the curves are the values of C_i/C_o. The x and y scales are arbitrary.

wall material, as long as steady state permeation is reached.

$$\frac{dQ}{dt} = \frac{DC_o}{h} \tag{23.9}$$

The definition and the measurement of steady state are discussed in chapter "Fundamental of Diffusion and Dissolution."

The constant rate, by different methods for different initial conditions, show that reliable container permeability can be determined from the steady state permeation data.

The dependency of weight gain profiles on the initial water concentration in the wall, and the advantages of using steady state weight gain data for MVTR, is further depicted in Fig. 23.1 for Eq. (23.2). The figure simulates the effects of initial conditions, to show that the initial weight gain profiles vary from a burst when the wall is initially completely dry, to a delay when the wall is initially equilibrated with external moisture under the test conditions, per Eqs. (23.7) and (23.8). However, if the permeation process is allowed to proceed for a sufficiently longer time to achieve steady state, rate of weight gain (slope of the linear line) is the same regardless of the initial water concentration in the wall if temperature and the driving force remain unchanged. A similar graph can also be constructed, but not shown, for Eq. (23.1), to show that the initial condition has no effect on the rate of permeation through the wall by net permeation if steady state is achieved.

Experimental data for weight gain for two sizes of HDPE bottles containing anhydrous calcium chloride, and closed with induction seal closures with paper backing in the closures, are shown in Fig. 23.2.

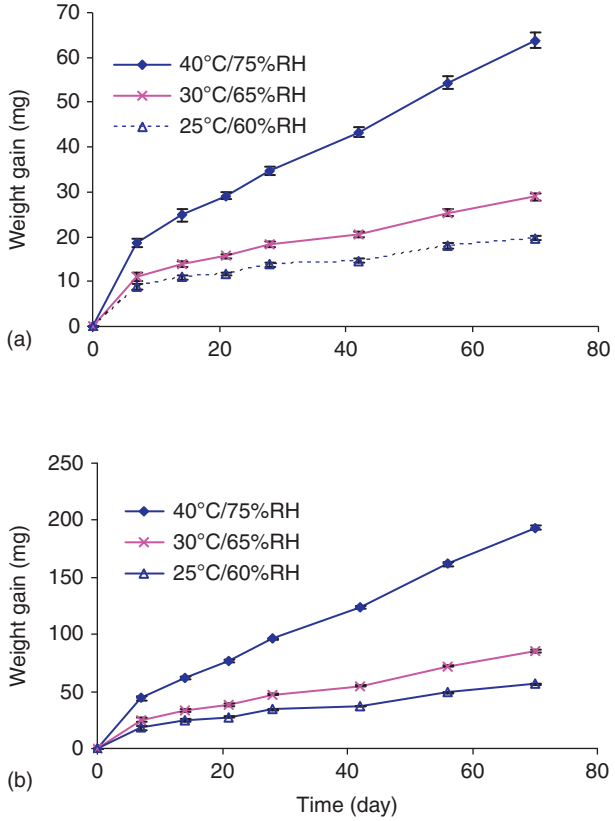

FIGURE 23.2 Weight gain profiles of HDPE bottles containing anhydrous calcium chloride and stored under ICH conditions. Bottle size: (a) 1 oz. (b) 4 oz.

The weight gain profiles agree well with the profiles predicted by theory.

In practice, water concentration in the container wall is not measured. However, it can be assumed that, at the outer surface, water concentration is proportional to the equilibrium external humidity, as measured by relative $\%RH$, by partition at a given temperature. Taking the container surface area into consideration, it can be shown that MVTR during steady state can be described by Eq. (23.10).

$$MVTR = \frac{AdQ}{dt} = \frac{ADK \times \%RH}{h} = \frac{AP \times \%RH}{h} \tag{23.10}$$

where A is the surface area, dQ/dt represents the rate of moisture permeation, D and K are the diffusion coefficient and the partition coefficient of moisture in the wall material, respectively, and P represents the apparent moisture permeability of the wall material.

Other factors to consider for ensuring that the measured container MVTR is reliable include maintaining a "sink" condition, balance sensitivity, and test conditions of humidity and temperature. A perfect "sink" condition is one in which an internal relative humidity of 0%RH can be maintained using a sufficient amount

of effective desiccant in the sealed containers. In real-life tests, maintaining no more than 5%RH of the internal relative humidity during the test may be considered acceptable. Suitable desiccant should be used to achieve a "sink" condition. If anhydrous calcium chloride is used, the desiccant must be activated at a temperature greater than 200°C to remove any potential hydrates on the surface of the desiccant. The current USP Chapter <671> recommends drying of anhydrous calcium chloride at 215°C for 7.25 hours. The moisture sorption capacity of anhydrous calcium chloride in the range below 10%RH at 25°C is less than that of silica gel. Therefore, a large amount of anhydrous calcium chloride must be used to assure the existence of a "sink" condition. Alternatively, some other types of desiccant with a higher moisture sorption capacity than calcium chloride at low humidity, such as silica gel or molecular sieve, may be used in a smaller quantity to achieve a "sink" condition.

For high barrier containers, a sensitive balance should be used to ensure that the variability caused by weighing is negligible compared with the measured MVTR value. The use of aggressive testing conditions in terms of temperature and humidity is helpful to achieve obvious weight changes over the test duration, and thus minimize the effect of weighing error on the MVTR results. The current USP Chapter <671> recommends the use of 40°C/75%RH as the testing conditions for the barrier protection determination of high barrier materials. However, for low barrier materials, such as PVC, the testing conditions should be mild to prevent the saturation of desiccants during testing. ICH conditions must be used if the MVTR data is intended for prediction of product moisture uptake during shelf life under the same conditions. Sample size, test interval, and balance sensitivity should be evaluated together with the estimated container MVTR prior to testing in order to minimize the % variability of the measured MVTR.

MVTRs of some HDPE bottles determined by steady state permeation method are listed in Table 23.3.[15]

TABLE 23.3 Moisture Vapor Transmission Rate (MVTR) and Moisture Permeability of Some HDPE Bottles

	MVTR (mg/day, mean ± SD, $n = 10$)			$P \times 10^6$ (mg · cm/(day · %RH · cm^2))

23.2.3 Gas absorbers

23.2.3.1 Desiccants and fillers

Desiccants are commonly used to keep products dry and stable. Dry desiccants can absorb moisture from air either by physical adsorption or by chemical reaction, and thus reduce the humidity in the headspace of sealed containers. Moisture sorption by silica gel is an example of physical adsorption, and sorption by calcium oxide is an example of a chemical reaction. Different types of desiccants and their moisture sorption capacities can be found in literature.[16] The most commonly used desiccants for solid pharmaceutical products are silica gel, clay, and molecular sieves.

Silica gel is an amorphous form of silica (SiO_2 xH_2O) and is highly porous. Silica gel particles are composed of an interconnecting network of microscopic pores (capillaries), and therefore have a very large surface area. The mechanisms of moisture adsorption by silica gel include surface adsorption and capillary condensation in the porous network. Silica gel works well at ambient temperature, but may have decreased adsorption rate and equilibrium moisture content at higher temperatures. The moisture in silica gel can be removed by drying at a temperature greater than 110°C. The current USP Chapter <671> recommends pre-drying silica gel desiccant at approximately 150°C to ensure the complete removal of adsorbed water.

Clay is a low cost and efficient desiccant at low temperature. The primary chemical composition of clay includes silica and aluminum oxide, magnesium oxide, calcium oxide, and ferric oxide. Moisture adsorption capacity may be different for different grades of clay desiccant. Therefore, their moisture adsorption isotherms must be verified during the desiccant selection process. Clay works well at ambient temperature, but at temperatures >50°C, it will likely lose moisture rather than absorb moisture. Similar to silica gel, clay can be dried at a temperature greater than 110°C.

A molecular sieve is a highly porous crystalline material with precise mono-dispersed pores into which certain sizes of molecules can fit, and thus, it can be used to separate one type of molecule from others.

These pores are the channels in the crystalline structure of a material such as zeolite. The pore sizes of molecular sieves differ from silica gel, in that the pore size of a molecular sieve is small and precise, while that of silica gel is much larger with a broad distribution. Molecular sieves are available with different effective pore sizes, such as 3, 4, 5, and 10 Å. A molecular sieve with a 3 Å effective pore size can selectively adsorb water molecules, since the diameter of water molecule is approximately 3 Å, while a molecular sieve with 4 Å pore size can also adsorb nitrogen and oxygen, in addition to water. Molecular sieve desiccants have a very strong affinity and a high adsorptive capacity for water in an environment of low water concentration. At 25°C/10%RH, molecular sieves can adsorb water to approximately 14% of their own weight. This property makes it possible to create an extremely low humidity environment with a small amount of material. However, at any humidity greater than 50%RH at 25°C, the adsorption capacity of a molecular sieve is less than that of silica gel. For example, at 70%RH/25°C, a molecular sieve can absorb approximately 22% of moisture, while silica gel can absorb approximately 32% of moisture at the same condition.[16]

Moisture sorption isotherms of different types of desiccants can be found in literature.[16] The equilibrium adsorptive capacities of silica gel and clay for moisture at different temperatures and humidities are shown in Fig. 23.3. At humidities lower than 35%RH, moisture sorption capacities are similar for the two desiccants. At higher humidities, silica gel has a higher moisture capacity than clay. It is important to know that different grades of the same type of desiccant may have significantly different moisture sorption capacities. This holds true for clay and zeolite desiccants. Therefore, moisture sorption isotherms of desiccants must be verified for the selected desiccants. In addition, the moisture sorption capacity of desiccants is a function of temperature. This temperature dependency should be characterized during the selection process, particularly when the isotherm is intended for modeling packaging design for moisture protection at different temperatures.

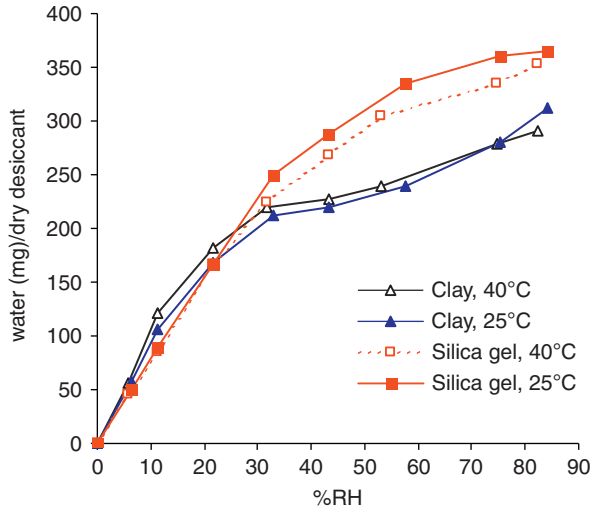

FIGURE 23.3 Moisture sorption isotherms of activated silica gel and bentonite clay.

The common process for using desiccants is to place a predetermined quantity of activated desiccant into containers with products and seal the containers. The quantity of desiccant to be used is important because an insufficient quantity will not provide the required protection, while excessive use of desiccant may lead to over-drying and an unnecessary increase in product cost. In many cases, overuse of desiccant is not a problem for product quality. However, over-drying of some hydrates may lead to the formation of unstable amorphous materials, and thus become detrimental to product quality. It is therefore important to understand the product characteristics, the degradation mechanism of the products, and the desired range of humidity for products before an appropriate quantity of desiccant can be determined. Once the desired range of humidity is determined, a suitable quantity of desiccant to use can be calculated based on the moisture sorption properties of both the desiccant and the drug product using a modeling method, as discussed later in this chapter.

The environmental conditions and packaging process for placing desiccants into product containers must be well-controlled in order to maintain the effectiveness of the desiccant because it may adsorb water vapor quickly when exposed to room air, thus reducing its protection capacity. For example, activated clay, silica gel, and molecular sieves can all absorb approximately 10% of water when exposed to 25°C/75%RH for 1 hour,[16] leading to a significant loss of protection effect for products. In fact, such an exposure can result in a complete loss of the protection effect of silica gel and clay if the desiccants are intended to maintain humidity lower than 20%RH. For container MVTR measurement, adsorption of water by exposure of desiccant to room air prior to filling into containers can lead to underestimation of container MVTR because the internal humidity may exceed the requirement for a "sink" condition. Environmental humidity and exposure time for placing desiccant into containers must clearly be minimized, in order to prevent loss of desiccant effect. Similarly, when active packaging is used where desiccants or oxygen scavenger are pre-sealed in the containers, such as in the bottle caps, the manufacturing, shipping, and handling processes for the containers must also be well-controlled to prevent the loss of the effectiveness of the active packaging.

Care should also be taken when desiccants are used for gelatin capsules to prevent brittleness from loss of moisture. Gelatin capsule shells need approximately 12–16% water to maintain their physical strength, which corresponds with a relative humidity of approximately 40–65%RH at 25°C. Humidity lower than 30%RH will likely cause the capsules to become brittle.[17,18]

Fillers such as cotton and rayon are also commonly copackaged with solid pharmaceutical dosage forms to restrain product movement during shipping. Cotton or rayon can sometimes cause instability problems for drug products. The reasons for this are that these fillers may contain residual oxidative agents that were used for their processing, and that fillers can unintentionally act as either a source of water or as a desiccant. The residual oxidative agents can cause degradation of some active pharmaceutical ingredients (APIs) or result in cross-linking of gelatin capsules or gelatin-coated tablets, if residual formaldehyde exists in the filler, leading to dissolution problems for the drug products. The moisture sorption capacity of cotton is another aspect to consider. The equilibrium moisture content of cotton is showed in Fig. 23.4. It can absorb more than 6% of water at humidity higher than 60%RH at 25°C. If dry cotton is used, it can act as a type of desiccant, and absorb water from the copackaged products. If equilibrated at high humidity during storage prior to use, cotton can be a source of water for the copackaged dry products if the products are hygroscopic. Although the amount of cotton used for pharmaceutical products is small, the effects of cotton on moisture transfer may still be significant in some cases. Quantitative evaluation of the effect of cotton on product moisture content can be carried out using a modeling method, as discussed later in this chapter.

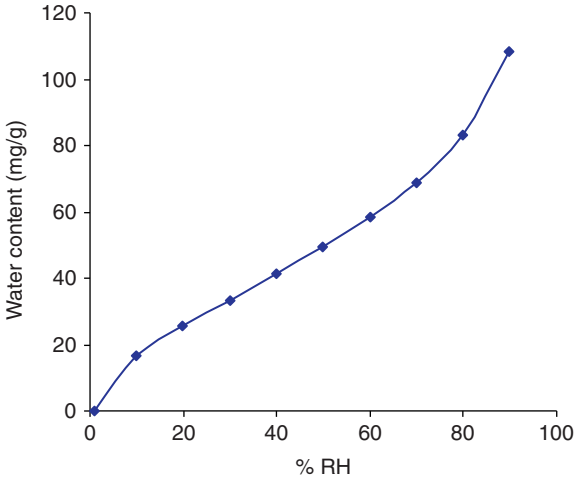

FIGURE 23.4 Moisture sorption isotherm of cotton at 25°C.

23.2.3.2 *Oxygen scavenger*

When products are sensitive to oxygen in the air, one could chose to either:

1. Formulate with antioxidants to stabilize the products;
2. Package the products in containers impermeable to oxygen, such as glass or aluminum containers, combined with purging the container headspace using an inert gas, such as nitrogen or argon;
3. Use oxygen scavengers in well-sealed containers;
4. Combine the techniques of stabilization by formulation and packing protection.

Stabilization by formulation is a complex subject, beyond the scope of this chapter, and will not be discussed here. Once the product is formulated, appropriate packaging can provide further protection of the product to maximize its shelf life. Normal air contains approximately 21% oxygen, and 78% nitrogen. Purging containers with inert gas can reduce the oxygen level to a range of approximately 0.5–5%. The use of a sufficient amount of oxygen absorbers can reduce oxygen content in the headspace of a sealed container to less than 0.1%. Combination of purging to reduce the initial level of oxygen, and the subsequent use of oxygen scavenger in a well-sealed container with low oxygen permeability, is probably the best method for packaging oxygen-sensitive products.

Oxygen scavengers, or oxygen absorbers, are materials that can react with oxygen from the air, eliminating the effects of oxygen when copackaged with products in closed containers. Oxygen scavengers are commonly used for food products, but are less common for pharmaceutical products. In the food industry, different types of materials used as oxygen scavengers include:

1. Inorganic oxygen absorbers, such as powdered metals or their intermediate oxides;
2. Organic antioxidants, such as vitamin C or salicylate; and
3. Polymer-based oxygen absorbers.

The mechanism of product protection by oxygen scavengers is the rapid oxidation of the scavengers with oxygen from the headspace of closed containers, and with the diffused oxygen during storage. According to Grattan and Gilberg,[19] the main reactions for the oxidation of powder iron with oxygen in the presence of moisture and sodium chloride, as in the commercially available oxygen scavenger Ageless, can be described by Eqs. (23.11)–(23.14).

$$Fe \rightarrow Fe^{2+} + 2e^{-} \tag{23.11}$$

$$O_2 + 2H_2O + 4e^{-} \rightarrow 4OH^{-} \tag{23.12}$$

$$Fe^{2+} + 2H_2O \rightarrow FeOOH + 3H^+ + e^- \text{ (rapid)} \quad (23.13)$$

$$3Fe^{2+} + 4H_2O \rightarrow Fe_3O_4 + 8H^+ + e^- \text{ (slow)} \quad (23.14)$$

The rate of oxidation of powder iron in air, and thus oxygen reduction in sealed containers, is rapid. It has been shown that the oxygen level was reduced from approximately 21% to less than 0.1% in approximately 20 hours by using one packet of Ageless Z-1000 in a 2L sealed container.[20] Due to its effectiveness and low cost, metallic iron is widely used to preserve food and museum items.

There are several disadvantages of using metal iron as an oxygen scavenger for pharmaceutical products.

1. The reaction of metal iron with oxygen requires a water activity as high as 65–85%RH in the system.[19] In fact, water was included in the form of saturated sodium chloride solution absorbed in molecular sieves as part of the oxygen scavenger, to maintain a critical relative humidity for reaction.[19] A high humidity environment may be detrimental for most solid pharmaceutical products.
2. The reaction is exothermic. The heat released by the reaction may create thermal stress for the copackaged products.
3. The reaction creates a vacuum due to the elimination of oxygen in the container, which may cause flexible containers to collapse. Therefore rigid containers are needed in order to maintain the geometry of product packages using this type of oxygen scavenger.

Unlike desiccants, oxygen scavengers are not yet well studied for pharmaceutical products. Therefore, much study, including the characterization of material properties and the oxidation-reduction mechanisms of oxygen scavengers and drug products, needs to be done to evaluate oxygen scavengers for protection of pharmaceutical products. Successful oxygen scavenger candidates for products must be effective, safe to use, clean (so as not to contaminate products), convenient to use, and low cost.

23.2.4 Drug products

While there are different types of containers available, selection of containers for product protection clearly depends on the specific protection requirements of any given product. In general, the protection requirements are identified during the early development stage with accelerated degradation studies or forced degradation studies using either the APIs or drug products. Details on stability studies were discussed in chapters "Drug Stability and Degradation Studies" and "Excipient Compatibility and Functionality." Once the drug sensitivity and protection requirements are identified, container design and selection may be made by matching the properties of containers with that of the drug products. If accelerated studies show that the product is not sensitive to moisture and/or other gases, the protection requirements for the product will mainly include the prevention of contamination and physical stress. If a product is sensitive to light, containers with low light transmittance should be the first choice, otherwise, secondary packaging will be needed if transparent primary packaging is used. If a product is sensitive to moisture, containers with low MVTR values are preferred, and desiccant may be used for additional protection.

Different pharmaceutical excipients have different moisture sorption capacities. The same is true for finished pharmaceutical products, since each product contains its own set of excipients. Product moisture sorption capacity is one of the critical factors that determine the rate and extent of moisture ingression into containers during storage, in addition to the container MVTR and storage conditions. The higher the capacity, the faster the ingression rate will be, assuming other factors are the same. If desiccants are used for products, it is important to understand the solid state chemistry of the APIs in the products. Some APIs may exist in different hydrates and/or crystal forms under different humidity. Over-drying caused by use of excessive desiccants may lead to lose of hydrates, and formation of unstable lower hydrates or amorphous materials. Therefore, drug product properties, including moisture sorption isotherm and the solid state response to environmental conditions, should be studied. This is particularly important if desiccants are used for quantitative design of packaging to protect moisture-sensitive products. The application of material moisture sorption isotherms and container moisture permeability in quantitative packaging selection for moisture-sensitive products are discussed in the next section.

23.3 LINKING PACKAGING PROPERTY WITH DRUG PROPERTY

MVTR is traditionally used to classify containers, and the use of desiccant for products is determined by trial and error. According to USP Chapter <671> prior to USP 37th edition, there was only one method using MVTR for classification, containers are *tight*

containers if not more than one of the 10 test containers exceeds 100 mg/day per L, and none exceed 200 mg/day per L. Containers are *well-closed containers* if not more than one of the 10 test containers exceeds 2000 mg/day per L, and none exceed 3000 mg/day per L. This type of classification is very loose, and does not take into account the properties of products in the containers. As a result, this classification is not meaningful in quantitative packaging design for the support of new product development. This problem has been acknowledged by the pharmaceutical industry and by USP. Therefore, new methods are now included in the recent USP38 Chapter <671> to provide reliable and precise MVTR of containers for differentiation of container performance in the section regarding barrier protection determination for packaging systems for SOD forms.

In product research and development (R&D), we must know if any container can provide adequate protection of a new product, prior to the use of the container for official stability studies. Therefore, vigorous evaluation is required for container selection. The conventional method of trial-and-error for packaging and desiccant selection is of low efficiency, and lacks a guiding power. A desirable approach should be science-based, and should allow the building of QbD. Two new methods have been developed in recent years to evaluate container moisture barrier properties for products. These methods are the use of MVTR/unit dose product,[13,21] and the modeling approach for prediction of moisture uptake by packaged products during storage.[22] The key element of these two new methods is the linking of packaging property with drug product property, and they are discussed in the next section.

23.3.1 The use of moisture vapor transmission rate per unit product for container comparison

For a given product in different containers, the moisture protection efficiency of the containers for the product can be evaluated using a criterion of "MVTR per unit quantity of product."[13,21] For solid products, the unit can be a tablet, a capsule, or the mass of a product. A smaller value of MVTR/unit product indicates that the container provides better protection for the product from moisture than a container with a larger value. This criterion can be used to rank containers/designs, and to guide packaging selection for new product R&D, or it can be used to evaluate the container moisture barrier equivalence for justification of postapproval container changes for a regulatory purpose.

23.3.2 Modeling of moisture uptake by packaged products

Moisture content of products in permeable containers stored at ICH stability conditions can be predicted by a modeling method[22] if it is assumed that:

1. Moisture content of a product is a function of the equilibrium humidity;
2. Moisture permeation through the container is the rate-limiting step;
3. A quasi-steady state of permeation exists; and
4. Moisture permeability of the container is constant at a given temperature.

At quasi-steady state, the rate of moisture permeation through a sealed container at constant temperature and external humidity can be expressed using Fick's first law as:

$$\frac{dQ}{dt} = k(RH_{\text{out}} - RH) \tag{23.15}$$

where

dQ/dt is the rate of moisture permeation through the container

k represents the apparent moisture permeability of the container

RH_{out} and RH represent the % relative humidity outside and inside the container, respectively.

If the water content of any unit component in the container is a function of the equilibrium humidity, the total quantity of water, Q, in a sealed package containing n components can be written as:

$$Q = \sum_{i=1}^{i=n} q_i f_i(RH) \tag{23.16}$$

where q_i and $f_i(RH)$ are the quantity and the moisture sorption isotherm of the ith component in the container, respectively.

Differentiation of Eq. (23.16) with respect to relative humidity leads to

$$\frac{dQ}{d_{RH}} = \frac{d}{d_{RH}}\left[\sum_{i=1}^{i=n} q_i f_i(RH)\right] \tag{23.17}$$

By mass balance, the quantity of moisture permeated through the container must be equal to the moisture content change in the container, as described by Eq. (23.18).

$$k(RH_{\text{out}} - RH)d_t = \frac{d}{d_{RH}}\left[\sum_{i=1}^{i=n} q_i f_i(RH)\right] d_{RH} \tag{23.18}$$

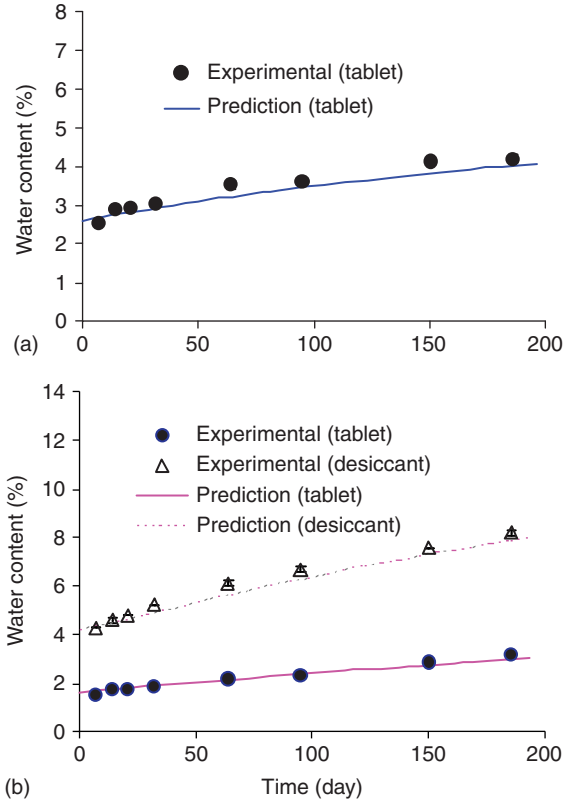

FIGURE 23.5 Experimental and predicted water content of 20 model tablets in sealed 3 oz HDPE bottles and stored at 40°C/75% RH. (a): no desiccant. (b): with 1 g bentonite desiccant.

Rearranging and integration leads to the *t-RH* profile inside the container as described by Eq. (23.19).

$$t = \int_{RH_{t=0}}^{RH_t} \frac{\frac{d}{d_{RH}}\left[\sum_{i=1}^{i=n} q_i f_i(RH)\right]}{k(RH_{out} - RH)} d_{RH} \qquad (23.19)$$

The water content of each individual component as a function of time can then be estimated by substituting the *RH* at time *t* into the corresponding moisture isotherm of the component, as given by the *t-RH* profile. Detailed procedures for using this modeling method can be found in literature.[22] Predicted moisture content for a model tablet product in HDPE bottles stored under accelerated and long-term ICH conditions agreed very well with experimental data (Figs. 23.5 and 23.6), demonstrating that this modeling method is highly reliable. The reliability makes it possible to practice a QbD approach in packaging selection for products. Using this modeling method, the effects of any packaging designs and storage conditions on product moisture content can be readily simulated to select the most suitable packaging for moisture protection. The selected packaging can then be confirmed

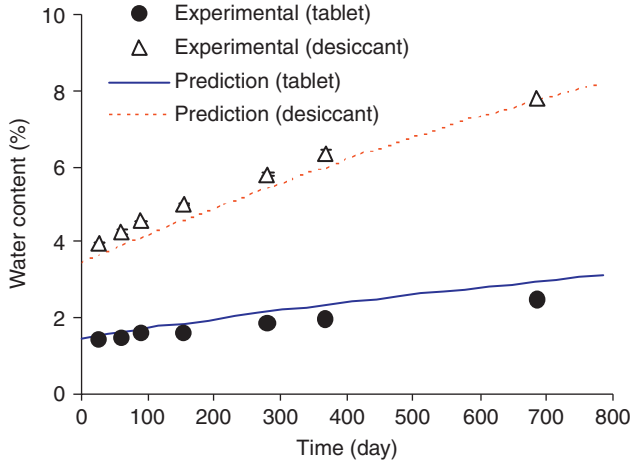

FIGURE 23.6 Experimental and predicted water content of 20 tablets in a sealed 3 oz HDPE bottle with 1 g bentonite desiccant and stored at 25°C/60%RH.

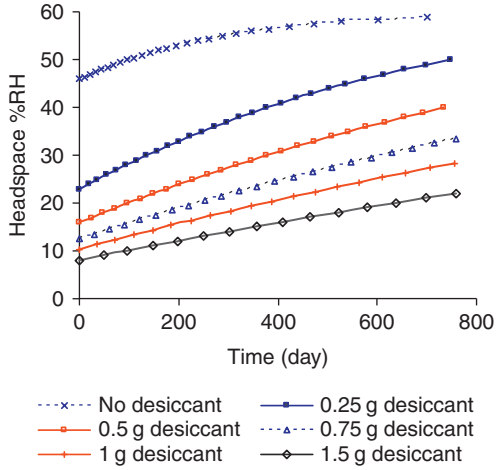

FIGURE 23.7 Simulation of headspace humidity for the same amount of a model product in a 1 oz HDPE bottle with different quantity of silica gel and stored at 25°C/60%RH.

by real-life stability study. Suppose it is known that the headspace humidity of a product must not be greater than 30%RH at room temperature over its shelf life, and that desiccant is to be used in HDPE bottles for the product. However, it is not known what quantity of desiccant should be used and what the effect of moisture permeation during the shelf life will be. With the moisture sorption property of the product, and the container permeability at hand, simulation can be conducted for different amounts of desiccant. The simulation results are shown in Fig. 23.7. Based on the simulation, it can be determined that at least 1 g of the desiccant must be used, in order to maintain the headspace relative humidity and not to exceed 30%RH over 2 years when stored at 25°C/60%RH. In another case, 7 and 90 tablets were packaged

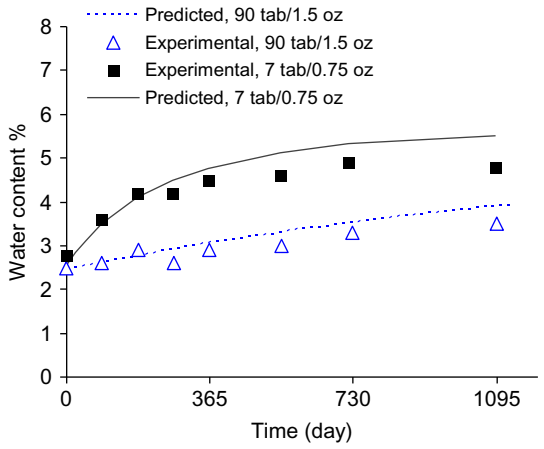

FIGURE 23.8 Predicted and experimental moisture content of tablets in different designs using HDPE bottles and stored at 25°C/60%RH.

without desiccant in 0.75 and 1.5 oz HDPE bottles, respectively. Simulation indicated that the moisture content of the 7 tablets in the 0.75 oz bottle would approach an equilibrium value in approximately 1 year when stored at 25C/60%RH, while that of the 90 tablets in the 1.5 oz bottle would not reach the same level of moisture content over 3 years. The simulated results were confirmed by formal stability study conducted under ICH conditions (Fig. 23.8). These examples show that the modeling method can be used as a scientific tool to evaluate the moisture protection capability of any proposed packaging design, prior to conducting stability studies for new product development, or to evaluate the container equivalence for postapproval container changes. Formal stability studies can then be conducted for confirmation purposes. Modeling is science-based, and can be used as an effective tool for QbD in packaging evaluation for product protection against moisture. Successful application of this method will reduce product development's time and cost.

23.4 POSTAPPROVAL PACKAGING CHANGES

Postapproval changes to packaging materials (PACPAC), including a change to a container closure system, to a component of the container closure system, to a material of construction for a component, or to a process involving one of these, must be reported to the regulatory agency.[2,23] Packaging changes are classified as either major, moderate, or minor, depending on the nature of changes. The categories of changes indicate the regulatory requirements, reporting categories, and thus the levels of burden on the FDA and on the pharmaceutical industry. Major changes require a prior approval supplement. Moderate changes need a changes being effective supplement, while minor changes can be reported to the FDA by annual report. Categorization of changes depends on the nature of the changes, and the intended use for products, such as for injectable, ophthalmic, liquid oral, solid oral, topical, or transdermal dosage forms. It should be understood that the degree of concern for product-packaging interaction, and thus categorization of packaging changes, is different for different types of dosage forms. For example, changes in the size or shape of a container for a sterile drug product may be considered as moderate changes, while the same changes might be treated as minor changes for SOD forms. Therefore, a category of PACPAC for one type of product cannot be assumed to be the same category for another type of product.

For SOD forms, there are several questions to answer before proposing postapproval packaging changes. These include, but are not limited to, the following;

1. Is the new packaging previously approved by the FDA for the same type of dosage form?
2. What type of protection does the product need?
3. Does the new packaging provide equivalent or better protection?
4. What type of packaging material information and what type of product stability testing in the new packaging are needed for submission?

Current FDA guidance to industry, changes to an approved new drug application or abbreviated new drug application,[23] provide some examples for each category of packaging changes and a general statement on the potential impact the changes may have on the identity, strength, quality, purity, or potency of a drug product as they may relate to the safety or effectiveness of the product. However, the guidance does not list specific requirement on information needed to report to the FDA for the changes. A regulatory guidance listing specific instructions on what and how to report for postapproval changes for packaging will be helpful to reduce the regulatory burden for the FDA and the pharmaceutical industry.

The reporting category of packaging changes may be reduced if the new packaging has been approved by FDA for the same type of dosage form, and if it is demonstrated that the new packaging can provide equivalent or better protection than the existing packaging. If it can be demonstrated that a product is not sensitive to environmental conditions, such as moisture, oxygen, or light, then the need to evaluate the protection equivalency is not applicable for packaging changes. Protection equivalency can be demonstrated either by formal stability studies or by comparative tests. A formal stability study is not preferred for

material characterization because it is time consuming and expensive. Thus, comparative tests are preferred to increase efficiency and reduce cost. For SOD forms, container MVTR is commonly used as one of the criteria to demonstrate the moisture protection equivalency of containers. Two aspects of MVTR that should be considered are the reliability of MVTR values and the correct use of those values. As discussed previously in this chapter, the current USP chapter <671> provides different methods for measuring the container MVTR for either container classification or for barrier protection determination purpose. Results of the classification method may be highly variable, and less reliable than that of the method for barrier protection determination. Thus, the author prefers the latter method to obtain container MVTR for container comparison.

Getting a reliable MVTR value does not yet provide the basis for evaluation of container equivalency for product protection. The correct use of the MVTR is equally important for drawing meaningful conclusions. For classification purposes, MVTR is reported in a unit of mg/L per day as per USP. This unit has limited utility, because it does not take into account the quantity of products in the containers. Alternatively, meaningful results can be obtained by using a new unit of "MVTR per unit product"[13,21] proposed by the PQRI container closure working group. According to the studies conducted by the PQRI workgroup, moisture activity, and hence product moisture content in sealed containers, is related to the value of "MVTR per unit product." The lower the "MVTR per tablet" value, the lower the product moisture content, and it does not matter if the container is an HDPE bottle or an Aclar unit blister. Several examples have been reported in previous publications by PQRI. More examples for using "MVTR per unit product" to rank container moisture protection property, and to link it to product moisture content by stability studies are listed in Table 23.4. Tablets of a same lot were packaged in unit blisters, and in two sizes of HDPE bottles, for formal stability study at 25°C/60%RH. The ranking of the MVTR/unit for the three types of packaging are in the order of blister > bottle 1 > bottle 2. At the 1-, 2-, and 3-year time points, significant differences in tablet moisture content were observed in the order of - blister > bottle 1 > bottle 2. These data clearly demonstrate that "MVTR per unit product" is a valuable criterion for evaluating moisture protection equivalency of containers.

To summarize, the unit of "MVTR per unit product" links container property with product quality. The unit provides a means of evaluating different types of packaging materials, such as bottles and blisters, as well as for comparison of different quantities of products in varying or the same sizes of containers. Protection capability is the same or better, as long as "MVTR per unit product" is the same or smaller if moisture protection is the main concern, regardless of the types of packaging materials and configurations. MVTR per unit product is therefore a science-based criterion for evaluating the moisture protection equivalency, and for justifying postapproval packaging changes.

TABLE 23.4 Ranking of Moisture Vapor Transmission Rate per Tablet and the Resulting LOD of a Model Product

Packaging	MVTR/tablet (mg/tab per day at 25°C/60%RH)	Product lot	%LOD at 25°C/60%RH				
			Initial	6M	12M	24M	36M
Unit blister	0.078	1	2.7	3.4	3.8	4.5	4.6
		2	2.8	3.5	3.8	4.5	4.6
		3	2.7	3.4	3.8	4.6	4.6
HDPE bottle 1	0.024	1	2.8	3.2	3.5	3.9	4.1
		2	2.7	3.2	3.3	3.9	4.0
		3	2.7	3.3	3.4	3.9	4.1
HDPE bottle 2	0.004	1	2.6	2.7	2.6	2.7	2.7
		2	2.6	2.8	2.6	2.8	2.7
		3	2.8	2.7	2.7	2.9	2.9

24.1 INTRODUCTION

The process of new drug discovery research, development, and commercialization is long, complex, and costly. It can take more than 10 years and cost $1 billion or more on average to bring a new chemical entity (NCE) to the market. The new drug development process can be characterized into different phases including Phases I, II, III, and IV. The objective for each phase is described in Table 24.1. From Phase I to Phase III, clinical investigation is one of the most important activities to prove the safety and efficacy of a new drug. Successful supply of clinical materials is key to assure that clinical studies are conducted as planned at the correct time with the correct dose and correct amount of materials. Manufacturing batch sizes of clinical supplies change with demand, availability of drug substances, and study phases. A strategy clearly must be developed to effectively manage the complex clinical supplies manufacturing process. This includes planning, collaborative communication among the cross-functional team, lean manufacturing, effective training programs, and application of new technologies to facilitate the manufacture of clinical supplies.

Clinical trials are designed to obtain safety and efficacy data for new drug candidates. A primary consideration in these studies is the safety of the clinical trial subjects. In addition, careful consideration must be given to the quality of the clinical supplies produced to ensure that there is no unintended consequence on the clinical trial results. Therefore, a comprehensive cGMP controls must be in place for the manufacture of clinical supplies to ensure the delivery of quality products. A cleaning verification and/or a cleaning validation program is a key component of the cGMP controls and quality system and an essential part of any pharmaceutical manufacturing facility. It must be demonstrated either through cleaning-validation effort that the cleaning process is under control, or through cleaning verification after each manufacture so that there is no cross-contamination from one lot to the next and the safety of product users is assured.

24.2 STRATEGY OF CLINICAL SUPPLIES MANUFACTURE

In the past few years, there have been major challenges facing the pharmaceutical industry regarding growing regulatory burdens and global clinical trials. More rules and regulations on good clinical practice (GCP) have been implemented or recommended because of ongoing concerns regarding unreported adverse events, inadequate protection of the clinical trial subjects (especially minors and incapacitated adults), inadequate oversight of clinical trials by Institutional Review Boards (IRBs),[1] unethical use of placebo-controlled trials, and insufficient informed consent practices. At the same time, the costs of drug development and discovery have increased substantially. Bringing a new drug to market can cost anywhere between $900 million and $1.7 billion, depending on development and marketing costs. Approximately only one in 10,000 compounds synthesized will pass regulatory approval and be commercialized, with only a few becoming potential

TABLE 24.1 Clinical Trials in New Drug Development

Stages	Time	Subject/study	Study objectives
Clinical Trials in Phase I	1–2 years	20–80 healthy volunteers Open study	Safety; Dose and schedule; Pharmacokinetics; Pharmacological actions
Clinical Trials in Phase II	2–3 years	100–200 patients Controlled studies-multicenter	Safety and efficacy; Dose, route and schedule; Toxicity profile; Clinical endpoints; Dose–response curve; Short-term adverse effects; Pharmacokinetics; Pharmacological actions
Clinical Trials in Phase III	2–4 years	>1000 patients Controlled studies-multicenter	Safety and efficacy in a large population; Patient population; Product claims; Final formulation and product stability; Drug-related adverse effects
Clinical Trials in Phase IV	2–4 years	Controlled studies-multicenter	Additional information about the drug's risks, benefits and optimal use such as other patient populations, other stages of diseases, over a longer period, extend claims of safety and efficacy

blockbuster drugs. In addition, the time required to bring a new drug to the market is becoming longer. The time from drug discovery to FDA approval for a NCE can be as long as 12 years. Pharmaceutical companies are being forced to examine how to streamline their manufacturing practices and products.[2] The faster the new drug product is approved by the FDA, the longer the effective life of market exclusivity for the product before its patent expires.

Pharmaceutical manufacturers often rely on various strategies to keep their new drug pipeline flowing freely. Effective management of clinical supply delivery prevents it from becoming a rate limiting step in product development, reduces the time for a new drug undergoing clinical trials, and ultimately increases the speed of bringing a new drug to market. Due to the complexity and long duration of clinical trial programs, success depends on precise timing, monitoring, managing, and coordination efforts as well as a smooth flow of information and materials. The primary goal is to help connect clinical trial management teams with clinical supply manufacturing. The proper planning process is crucial to ensure that the project timeline is met. The collaborative communication among team members including research and development (R&D) personnel, quality control/quality assurance (QC/QA) personnel, regulatory personnel, medical personnel, clinical investigators, clinical trial material manufacturing personnel, and clinical trial material packaging personnel is essential for the success of the project. An implementation of clinical plan, clinical supplies liaison, a lean manufacturing approach, a cross-functional training program for workers, outsourcing, the use of new technology; including modern computer technology and new methodologies in drug discovery and development and process analytical technology (PAT) are among the various strategies that can be used to improve clinical trial management. These topics will be discussed later in this chapter.

24.3 CLINICAL PLAN

For each new drug candidate targeted for eventual registration, marketing, and distribution, a clinical plan is generally required. The clinical plan provides a detailed listing of clinical trials required for FDA approval together with duration and the desired timelines.[3] In general, project plan rationale, workload, and cost are discussed at management meetings or at project team meetings. Planning must include short-term, intermediate-term, and long-term goals with assumptions for bulk drug substance requirements, dose strengths, and quantity of drug product to manufacture. Comparator drug products also need to be considered. The short-term and intermediate-term planning (1–6 months) must include final plans for manufacturing, including the bulk product request with an approximately 4- to 6-month lead time, and packaging requests, which should be received 2–3 months before the expected shipping date. Long-term strategic plans can be prepared based on equipment/facility capacity, volume prediction, budget or resources, preferred vendor or contractor relationships, and comparator or drug substance sourcing. There are many challenges in planning for distribution of the clinical trial supplies to multiple investigation centers, especially those in different countries. Regulation-specific requirements for each country running the clinical trials must be thoroughly understood and considered during planning.

Long-term strategic planning may be based on workload prioritization, contract arrangements, and inventory management. On the other hand, short-term or immediate planning is more related to completing jobs at hand. Clinical plans and process must be reviewed and updated on a regular basis to keep the liaison and other team members in the same pace with the possible changes for modification of protocols. It is generally a good idea to establish a frame of reference to define how, when, and who will change what—commonly referred to as a "change control" plan. This

change control should be complementary to the planning process. Planning is the process that requires management to ensure that the project is completed within the timeline. All the risks involved in the project should be identified and assessed during the planning process. The probability of the risk occurring, the impact of the risks on the project, and a contingency plan should be incorporated into the planning activities.

A clinical plan template can be developed because clinical studies usually follow the same basic tasks and flow, regardless of the product is being studied. Using the template approach helps accelerate the project timeline and bring in best practices learned from past development projects. Table 24.2 illustrates the tasks commonly required in Phase I clinical trial studies.

TABLE 24.2 Template for Phase I Clinical Trials

Activity name	# of days	Start date	End date	Responsible manager

24.4 CLINICAL SUPPLIES LIAISON

The clinical supplies liaison (or clinical trials materials manager/team leader, or medical coordinator or clinical logistic coordinator) plays an important role in the drug development-clinical trial process. The titles or names of this position may differ, but the tasks that need to be performed are essentially the same. The liaison must understand and be able to successfully lead the project, effectively communicate and convey the clinical study process and progress to team members, and prioritize task activities and timelines. The liaison should understand team member individuals and their cultures. He/she must be able to organize, manage, negotiate with, educate, and compromise with multidisciplinary team members to develop the best scenario for all parties involved. A successful liaison must have a strong scientific background and strong people management skills (ie, the ability to interact and effectively negotiate with other people). A successful liaison can lead his or her team or customers to achieve a sought-after goal and eventually push the project through the finishing line despite numerous setbacks, delay, adversity, and failures.

24.5 LEAN MANUFACTURING

Lean manufacturing is a business management philosophy that seeks to eliminate or reduce waste and maximize customer value through employee involvement. It evolved mostly from successful Japanese practices in production systems. The lean manufacturing paradigm calls for integration of employee involvement and technological practices. It focuses on the human-centered approach to the design and implementation of advanced manufacturing systems.[4,5] Lean

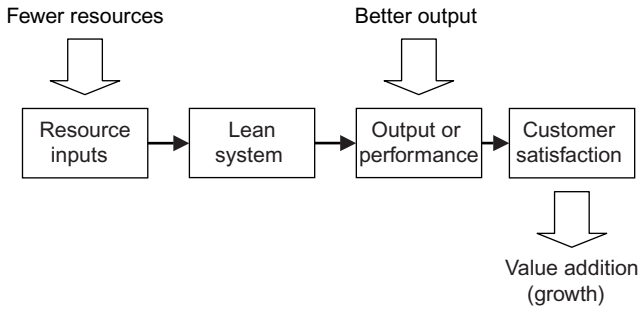

FIGURE 24.1 Lean manufacturing system.

manufacturing is a dynamic system that requires fewer resources, less material, less inventory, less labor, less equipment, less time, and less space. It is intended to eliminate waste while meeting and exceeding customer requirements, and yielding better output (eg, quality, variety, cost, time, and safety) (Fig. 24.1).

There are three main approaches in lean manufacturing that lead to better output. First, lean manufacturing involves a new philosophy of manufacturing, which focuses on better quality, exceeding customer requirements, and continuous improvement. Second, lean manufacturing involves establishment of a new culture and managerial system to incorporate the lean philosophy. The lean team leader and lean steering committee are included in their organizations to manage product development, supply chain relations, production operations, and coordination of the overall enterprise toward lean manufacturing. Third, lean manufacturing uses techniques that address specific problem such as just-in-time (JIT), total productive maintenance (TPM), total quality management (TQM), human resource management (HRM), scientific management, six sigma, quality circles, simultaneous engineering, and inventory systems. In a true lean organization, defects or problems are discovered immediately and solutions are sought at once using whatever techniques are required.

Fig. 24.2 shows a model for implementation of the lean manufacturing in clinical supplies manufacture in a pharmaceutical firm. The first step occurs when management commits to the lean philosophy illustrated by the three goals:

1. Zero waste is to eliminate what does not belong to the value stream;
2. Value Stream Mapping is to identify the scope of activities conforming the value stream; and
3. Pull (Kaizen) is to develop workforce capabilities by continuous, gradual, and persistent improvement.

As a new practice of manufacturing, lean manufacturing demands new capabilities from all employees at all levels: problem-solving focus,

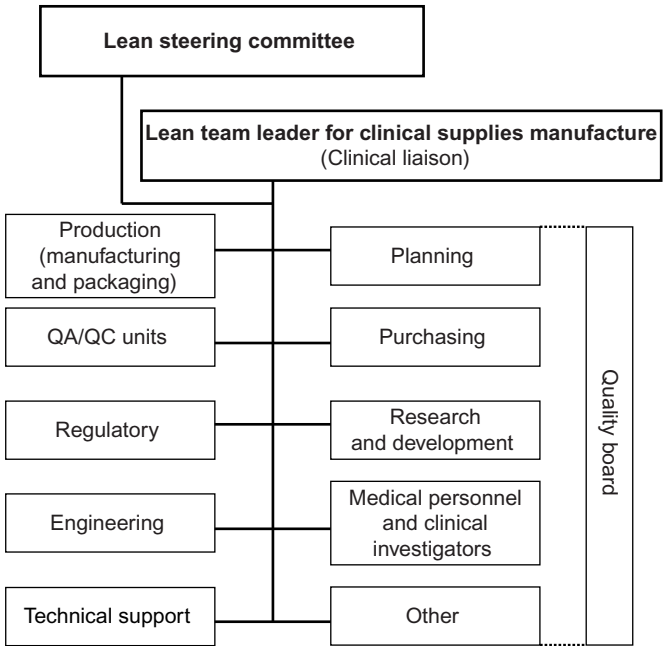

FIGURE 24.2 Implementation of lean manufacturing.

teamwork, and creative thinking. Lean manufacturing is not a fixed set of techniques, as has been discussed previously. As part of the implementation, new techniques unique to each business culture will emerge at each company. However, since businesses share the same interests and join a competitive market, common techniques are likely to appear. The examples of common techniques include:

- JIT: JIT is a philosophy of manufacturing that focuses on supplying the right materials to the right place in the right quantity JIT to achieve perfect work flow while minimizing waste. It depends on the pull process from the consumer (demand) end, not the push from the production (supply) end. Materials are supplied to the production line only when required. JIT can be achieved by using these techniques: lot size reductions, continuous flow production, pull systems, cycle-time reductions, focused factory production systems, agile manufacturing strategies, quick changeover techniques, bottleneck or constraint removal, and reengineered production processes.
- TPM: TPM aims to increase equipment effectiveness by eliminating the losses due to machine downtime using techniques such as predictive or preventive maintenance, maintenance optimization, safety improvement programs, planning and scheduling strategies, and new process equipment. TPM works on continuous flow of production. Any interruption to the flow such as machine breakdown is considered and treated as waste.

- TQM: TQM is designed to improve customer satisfaction and product quality by using several techniques such as quality systems, quality management programs, process capability measurements, six sigma, competitive benchmarking, and formal continuous improvement programs.
- HRM: HRM is designed to effectively use human resources to increase overall performance. It focuses on leadership, empowerment, communication, and training by using several techniques such as self-directed work teams, cross-functional frameworks, and open communications in order to bring out the best possible employee capabilities.

Clinical supplies manufacture provides cGMP compliant products at a capability that is designed to deliver on-time clinical supplies meeting or exceeding customer needs in support of clinical trials. Clinical supplies for the early phase clinical trials (Phases I and II) typically need to be acceptable to good stability, meet basic dosage form requirements (ie, assay, impurities, content uniformity), and specific release requirements (ie, dissolution), and be suitable for small to intermediate scale manufacturing (ie, from hundreds to thousands of units or from several to tens of kilogram). On the other hand, clinical supplies for the later phase clinical trials (Phase III) typically need to have good stability, meet all dosage form requirements (including in-process testing requirements) and specific release requirements (ie, dissolution), and be suitable for larger pilot scale manufacturing (ie, $\sim$50–100 kg) and scalable to production scale ($>$100 kg). The numbers of products and volume to manufacture also change as the study phase advances. In general, the number of products to manufacture and thus process variety for clinical supplies decreases and product volume increases with the advancement of clinical trial phases (see Fig. 24.3).

The JIT technique can be effectively applied to clinical supplies manufacture for early phase clinical trials because of the high variety and low product volume for this phase. When clinical trials advance into Phase III, lean manufacturing techniques, including JIT, total preventive maintenance, TQM, and HRM, can be applied to the clinical supplies manufacture because of low variety and high volume of the batches.

The lean manufacturing philosophy and methodology can be applied throughout the spectrum of development and manufacturing, from preclinical to clinical, from the overall strategic level of the development operation to the specific and detailed level of the manufacturing processes. The lean manufacturing provides a structured, disciplined, and logical progression for organizations to achieve quality improvement and breakthrough.

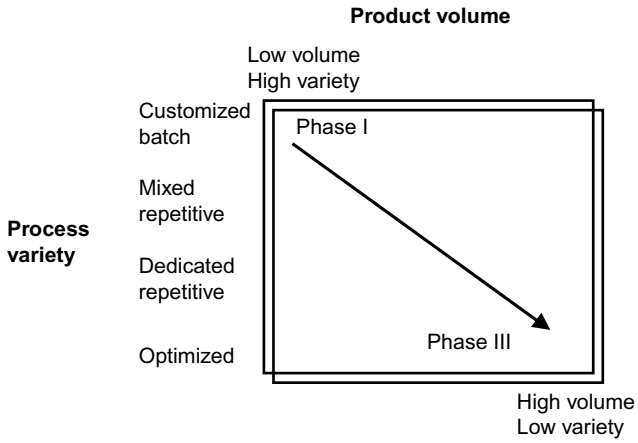

FIGURE 24.3 Relationship of clinical trial phases and process variety and product volume of clinical supplies manufacture.

24.6 CROSS-FUNCTIONAL TRAINING

Cross-functional training and education programs are an important consideration in the clinical trial supplies system. All team members should know the system and their role and contribution toward pushing projects through the finishing line. For example, ensuring that all clinical research associates understand why and how to order study medications and comprehend aspects of lead-time is a simple example of instantly recognizable, value-added education and training. Customer orientation and TQM, which are well known systems in Japanese manufacturing industries, can be used to improve performance within the clinical trial supplies system. Each department should consider how to improve customer satisfaction and the customer relationship. For example, contract manufacturing organizations (CMOs) and third party vendors hired by pharmaceutical manufacturers rely on data regarding clinical trials and supplies to plan and execute their work. Instead of considering these CMOs as suppliers to deliver the clinical supplies for the clinical trials, the CMOs become customers of the pharmaceutical manufacturer whose drug discovery department delivers their bulk active pharmaceutical ingredients (APIs). The bulk APIs and other related clinical trial data should be delivered to CMOs before or at least on schedule to satisfy CMOs. Any interruption in the process, such as a delay in the delivery of the bulk drug substance from pharmaceutical manufacturers, can seriously disrupt the timing and success of their work.

24.7 OUTSOURCING OF MANUFACTURING AND PACKAGING

A drug sponsor may want to contract out its clinical supplies manufacturing and packaging for several reasons. CMOs may provide an expertise or technology required for the project.[6] In addition, contracting out clinical supplies converts the fixed costs of maintaining the personnel and production facilities necessary for manufacturing and packaging the clinical supplies into variable costs of paying CMOs to perform the task and eliminates the need for a set number of people, facilities, and equipment in house. However, many drug sponsors choose to manufacture and package their clinical supplies in-house because they prefer the control and flexibility, as well as the in-house expertise. The question of who will benefit from outsourcing to a CMO might be addressed as why the sponsor cannot or should not do it in-house. The answer is mainly dependent upon just a few factors, such as how a drug sponsor and its board balance risk; whether its product pipeline is full; whether it sets for itself to manufacture and package the commercialized product after NDA approval. There are both advantages and disadvantages for contracting clinical trial supplies, as shown in Table 24.3.

TABLE 24.3 The Advantages and Disadvantages of Contracting Versus In-House Production of Clinical Supplies Manufacturing and Packaging

Advantages	Disadvantages
In-house	*In-house*
1. Maintain oversight of quality—reducing risks of production failures	1. High capital costs because facility/equipment may need to be upgraded or acquired
2. More direct control of outcome—reducing risks of bottlenecks	2. May delay another important project
3. Easy to set or change priorities on multiple projects	
4. Lower cost	
5. Easier for technology transfer process	
6. Gain expertise of manufacturing and packaging the new product	
7. Retain intellectual property	
Contract out	*Contract out*
1. CMOs have expertise and experiences with many companies	1. Resources are needed to manage the CMOs
2. Convert fixed costs into variable costs	2. Difference in culture of the two companies can take more time to work through
3. Save time and cost to upgrade or improve facility/equipment	3. Communication can be more cumbersome
4. Better system in specialized field	4. Less control of project's priority and schedule
5. Can test robustness of the process	5. Confidentiality breach

In general, small companies (especially small biotech companies) have fewer options and are most likely outsource. Their limited development pipelines, lack of capacity, and skill deficiency make the decision clear; the risk of investing in capital and experienced staff outweighs the benefit of in-house cGMP pilot or production plants. Mid-tier companies may have the capability to conduct the cGMP pilot or production plants in-house, but they and their investors must carefully assess the risks of product failure against their ability to survive such an event. Large pharmaceutical companies can build the capacity in-house, but they also see contract manufacturing as a way to reduce risk in their global manufacturing strategy.

Today, dedicated contractors can provide clinical trial manufacturing services. There are more CMOs offering a wide variety of competencies, reliable service, and competitive high quality. As a result, an increasing number of virtual biotech and large pharmaceutical companies are positioned to employ CMOs.

24.8 NEW TECHNOLOGY

The study of average cost for new drug development between 1995 and 2007 was released in Nov. 2014 by the Tufts Center for the Study of Drug Development (CSDD) at Tufts University, in Boston, MA.[7] The study indicated that the average cost of bringing a new drug to the market increased to $2.6 billion compared with the $802 million stated in the previous study released from the same center in 2003.[8] The study mentioned that costs have risen by 145% due to the larger and more complex clinical trials, a greater focus on chronic and degenerative diseases, and higher failure rates. There is no doubt that the clinical trials are more complex; involve more patients, more sites in different countries, more country-specific regulations, and more uncertainty. More and more companies choose to conduct clinical trials in the countries outside the United States in order to lower the trial expenses and increase patient recruitment. Many companies have recently begun to include the direct to patient (DTP) distribution method as an option for patients participating in clinical trials in order to provide more convenience for the patients. The DTP approach delivers clinical trial materials directly to patient's home and picks up biological specimens from the patient home for testing. This DTP approach not only improves patient's willingness and ability to participate in clinical trials, but also increases patient retention throughout the studies, which are the two biggest challenges in clinical trials. Many patients

are unable or unwilling to travel to the clinical trial site for medication refills and testing for many reasons, such as a lack of transportation, patient's deteriorated health condition, and inconvenient location of the clinical trial centers.

Therefore, delivery of the medication to the patient's home can increase patient recruitment and retention. The DPT approach provides advantages from both compliance and patient retention perspectives. However, it is more complex and difficult to control supply logistics. Companies need to ensure that clinical trial materials are properly packaged and delivered to the patient on time and within specifications. Other examples of complex issues affecting clinical supply chains include, but are not limited to, costly comparator drugs, complex clinical trial designs, intricate protocols, delicate investigative compounds and shelf-life, variable dosing schemes, country-specific regulation requirements, complex labeling and packaging approvals, temperature-controlled distribution, and costly shipping across the globe.

A well organized clinical trial planning together with regulatory knowledge and strategy will help companies avoid overproduction and still have enough overage of clinical materials to meet inventory expectation and changes, and be able to deliver the supply when and where it is needed. Timely and accurate forecasting of the clinical trial demand, as well as supply planning and execution, can avoid supply delay, which is very crucial for cost effectiveness and successful results of clinical trials. To prevent clinical trial supply shortage or delay, many companies integrate strategies and information technology to ensure smooth and secured supply of clinical trial materials to the location in a timely and accurate manner.

The use of the new technology and software for full traceability and tracking of supply throughout the life cycle will enable the company to be as efficient as possible. The traceability and tracking starts from order of the clinical material supply, manufacturing of API, randomization, packaging and labeling, release and distribution, until returns and destruction. The software allows a company to manage all clinical trial supply information and inventory from onset throughout its lifetime. In addition, it also increases the visibility of all material delivery and inventory maintained at the warehouse and depot. The traceability and tracking should be not only for investigational product, but also for concomitant medication and all ancillary materials throughout the life cycle. The full traceability and tracking can result in smooth and effective delivery of clinical supply at the lowest possible cost. This planning tool can help the clinical supply manager foresee and solve problems due to the trial design, regulatory, and operational complexities.

Several clinical supply logistic management software are currently commercial available. It is recommended that this type of software should feature 21 CFR-part 11[9] to be in compliance with the current US regulations. 21 CFR-part 11 requires system validation and security of all clinical data software used in conducting clinical trials. Other important features include, but are not limited to, accessibility from any location at all times, barcode/radio frequency identification scanning including 2D and 3D support, demand forecasting, document/report management, including electronic batch record, interfacing and integrating with multiple systems, inventory control management; including lot specific inventory control and tracking throughout the entire supply chain, operations-processing, and supply planning, labeling, and packaging management; including electronic routing of labeling and graphics design and approval, label generation and printing, and label translation to foreign languages, randomization capabilities to ensure accurate assembly of each patient kit per controlled randomization, shipping management; including control of shipment order, processing and returns, supplier and CRO management, supply chain collaboration, supply chain planning, transportation management, and warehouse management. For example, when study designs and dosing requirements are entered, the software can calculate the amount of kits, the dosage form, and all required active ingredients. The software can also analyze different study scenarios with different dosing and/or enrollment patterns to see the impacts on the study supply. This clinical supply management software can not only help the clinical supply manager, but also the warehouse and depot manager, CROs, and quality and regulatory personnel to control, track, and view the activities and status of investigational product from start to finish.

Confusion could easily occur because the clinical trial supply management involves many departments and outside CROs. For example, a CRO outside the country mistakenly destroyed a trial batch because they thought it was no longer needed. Then, when the trial material was needed, the company had to manufacture a new batch as quickly as possible, which could result in trial delay. With the use of clinical supply management software, these types of mistakes could be prevented. The CROs can directly interface with the clinical supply management software to know the status of the batch in real-time, and would not accidentally destroy the batch.

Integrated clinical trial supply management software solution and technologies are currently available to help pharmaceutical industry meet more stringent and complex compliance challenges. For example, clinical investigators in multiple countries worldwide can access a database at the same time using complex

planning tools, which allow clinical trials at multiple centers in many countries to view and track the clinical supply and coordinate and plan more effectively. Similar technologies are also available for clinical manufacturing and packaging groups to electronically view the supply orders in real-time, and effectively collaborate with clinical investigators, instead of using a paper-based system. New software and technologies allow pharmaceutical companies to more effectively address challenges, and improve their new drug development process.

On Nov. 27, 2013, the Drug Supply Chain Security Act (DSCSA) was enacted. The regulation intends to protect public safety by strengthening the security of the drug supply chain, improving detection and removal of counterfeit drug products from the distribution supply chain. The Act outlines a 10-year plan to build an electronic, interoperable system to both identify and trace prescription drugs through distribution across the United States. DSCSA[10–12] requires manufacturers, repackagers, wholesale drug distributors, third-party logistic providers, and dispensers to provide product-tracing information, including three pieces of information: transaction information, transaction history, and transaction statement to their trading partners along the supply chain. The DSCSA currently defines these prescription drugs as finished drugs intended for human use. As the DSCSA implementation plan continues, the FDA will develop and release more guidance during the next few years. Companies should closely follow the regulations and remain in compliance with additions and changes of the regulations as they are released. Comparators used in clinical trials must follow this act.

24.9 GMP CONSIDERATIONS ON MANUFACTURING CLINICAL SUPPLIES

24.9.1 cGMP considerations

The FDA and the pharmaceutical industry have recognized that most early-phase clinical studies are conducted long before the details of product formulation, manufacturing specifications, and production processes are fully defined and validated. Therefore, some of the cGMP requirements are simply not logically applicable to Phase I clinical studies. The FDA expressed a clear recognition of the difference between manufacturing investigational products and commercial products. The agency, however, has a firm commitment to enforce the cGMP requirements and ensure compliance throughout all phases of development, as stated in the 1991 Guideline on the Preparation of Investigational New Drug Products.[13] In Jan. 2006, the FDA published a draft Guidance for Industry: INDs—Approaches to Complying with cGMP's During Phase 1.[14] The FDA is working toward the goal of advancing public health by improving the product development process and increasing the speed of the approval process for new and better medical treatments. The draft guidance reflects the FDA's current thinking regarding quality systems and risk management (or hazard control) principles, which is consistent with the FDA's ongoing cGMP for the 21st century initiative.[15]

The Food, Drug, and Cosmetic Act stipulates that the FDA may approve a NDA only if the methods used in, and the facilities and controls used for, the manufacture, processing, packing, and testing of the drug are found adequate to ensure and preserve its identity, strength, quality, and purity. The FDA's role in the preapproval process is to review data submitted, evaluate, and approve specifications for the manufacture and control of the drug products based on the submitted data, assure cGMP compliance and verify the authenticity and accuracy of the data contained in the NDA application.[16]

The cGMPs are not directly concerned with business performance. The FDA's evaluation is usually directed toward compliance issues such as rejects, reworks, and complaints as indicators of inadequately validated production processes and process deviations as the examples of system noncompliance. In fact, the FDA inspection team frequently visits the reject area early in an inspection to identify failures. They can then go back into the respective batch records to evaluate the cause and to see if adequate remediation has been established and implemented.

FDA inspection teams, highly skilled in drug manufacturing, packaging, and analytical technology, may consist of investigators, analysts, engineers, and/or computer experts, as appropriate. Prior to NDA approval, FDA investigators or inspection teams may perform inspections/data audits, and will validate/verify the proposed methods.[16] The FDA can conduct preapproval inspections or audit any processes involved in the NDA submission including, but not limited to, manufacturing of drug substance(s), biobatch manufacturing, raw materials controls, composition and formulation of finished dosage form, container/closure systems, laboratory support of methods validation, product and process controls, product specifications and test methods, product stability, comparison of relevant preapproval batches and proposed commercial batches, facility-personnel-equipment qualifications, equipment specifications, packaging and labeling controls, process validations, reprocessing, and ancillary facilities (eg, contract testing laboratories, contract packagers). For example, the FDA may audit biobatch manufacturing batch record to determine if

the establishment is in compliance with cGMP requirements. This may include a data audit of the specific batches upon which the application is based (eg, pivotal clinical studies, bioavailability, bioequivalence, or stability batches).

The production of investigational drug products involves added complexity compared with marketed or commercial products due to a lack of fixed routines, variety of clinical trial designs, highly specific packaging designs, and needs for randomization and blinding that increase the risk of product mix up. It is clear that there may be added risk to clinical trial subjects compared with patients treated with commercial products. Compliance to cGMP or QA in manufacture of investigational drug product will minimize the risk to the clinical trial subjects. General cGMP considerations on manufacturing of clinical supplies include:

- Quality management: The investigational clinical trial products or investigational medicinal products (IMPs) must be manufactured under controlled processes per cGMP requirements, and the release of materials should not occur until they meet the predetermined specifications and are approved by the quality unit. This ensures that the investigational clinical trial products used for any trial centers have the same or equivalent quality, purity and safety. The cGMPs are enforced to ensure that there should not be any unsatisfactory manufacturing and packaging processes, which might increase the risk of substandard investigational clinical trial products given to human subjects during clinical studies. The clinical supplies manufacturer must have a qualified person to verify that the investigational clinical trial products manufactured, packaged, repackaged, and imported conform to the product specifications prior to releasing of the batches.
- Manufacturing and process control: In many cases, clinical trial runs of a new drug are produced in facilities other than those used for full-scale production. The facilities and controls used for the manufacture of investigational clinical trial products, especially the NDA biobatches, should conform with cGMPs regulations. Accurate documentation of batch records is essential so that the production process can be defined and related to batches used for early clinical, bioavailability, or bioequivalence studies of a new drug. Specifications, formulations, and manufacturing processes should be as completely defined as possible based on the current state of knowledge. Critical process parameters should be identified, and the respective in-process controls should be implemented. Specifications, formulations, and manufacturing processes should be periodically reassessed during development and updated as necessary. There should be sufficient manufacturing and process controls to ensure the consistency and reproducibility between clinical trial batches, bio/stability batches used in the same or different clinical trials, and a proposed commercial production process. Any changes from initial manufacturing procedures should be fully documented and carried out according to written procedures, which should justify and address any implications for product quality, purity, and safety.
- Documentation: The information and knowledge gained from pharmaceutical development studies provides scientific understanding to support the establishment of specifications and manufacturing controls. Therefore, it is essential that all information and knowledge be fully and properly documented. For example, the acceptance/rejection criteria may not be as specific at early stages; however, these criteria will become more specific and uniform as additional data become available. It is vital that the criteria used and scientific supportive data be fully documented at all stages. The product specifications file (eg, specifications and analytical methods, manufacturing processes, in-process testing and methods, stability data, and storage and shipment conditions) should be continually updated and documented as development of the product proceeds, ensuring traceability to the previous versions.
- Batch records: To prevent any potential mix up or ambiguity, the order in writing for the number of units and/or shipping of the clinical trial product should be received and authorized prior to manufacturing, packaging, and/or shipping of the clinical trial batches. The manufacturing batch records for an investigational drug product must be retained for at least 5 years[17] after the conclusion of the trial or formal discontinuation of the last clinical trial in which the batch was used. During that period, the record must be complete and readily available for inspection.
- Laboratory control: Laboratory equipment and procedures must be qualified and validated. At the early phase of clinical trials, analytical methods performed to evaluate the batches of API used for clinical trials may not yet be fully validated, however there must be enough control based on scientific information. FDA inspectors will review the authenticity and accuracy of data used in the development of a test method.
- Incoming materials for clinical supplies: When more than one supplier and source of each incoming material (especially the active ingredients) was used

during clinical trials, the sponsor should demonstrate that the clinical batches produced from different suppliers and sources of incoming materials are equivalent in terms of conformance with established specifications, including those stated in the NDA application. The sponsor should undertake due diligence to ensure that the incoming materials meet specifications and are produced under a state of control.

- Building and facilities: An addition of any new drug to a production environment must be carefully evaluated regarding its impact on other products already under production and changes that will be necessary to the building and facilities. Construction of new walls, installation of new equipment, and other significant changes must be evaluated for their impact on overall compliance with cGMP requirements. The toxicity, potency, and sensitizing potential may not be fully understood for investigational clinical trial products, which reinforces the need to minimize all risks of cross-contamination. The risk of cross-contamination can be minimized by using properly designed equipment and facilities as well as by having in place written comprehensive methods for manufacturing, packaging, inspecting, sampling, testing, cleaning and sanitizing procedures.[14,18]
- Equipment system: New products, particularly potent drug products, can present cleaning problems in existing equipment. There must be written procedures for sanitation, calibration, and maintenance of equipment, and specific instructions for the use of the equipment and procedures used to manufacture the drug product.[14,18] To prevent the risk of cross-contamination, many companies utilize isolators as well as single use or dedicated equipment during the production of investigational clinical trial products.
- Training program: All personnel involved with investigational products should be appropriately trained in the requirements specific to their duties. Trained, qualified, and experienced persons should be responsible for ensuring that there are systems in place that meet the cGMP requirements. Any training should be documented and kept on file.
- Specifications: Specifications (for starting materials, primary packaging materials, intermediate, bulk products, and finished products), manufacturing formulas, and processing and packaging instructions should be as comprehensive as possible given the current state of knowledge. They should be periodically reaccessed during development and updated as necessary. Each new version should take into account the latest data, current technology used, regulatory and pharmacopoeial requirements, and should allow traceability to the previous document. Any changes should be carried out according to a written procedure, which should address any implications for product quality, such as stability and bioequivalence. "The controls used in the manufacture of APIs for use in clinical trials should be consistent with the stage of development of the drug product incorporating these APIs. Process and test procedure change management should be flexible to provide for changes as knowledge of the process increases and clinical testing of a drug product progresses from preclinical stages through clinical stages."[18]

The FDA recognizes that the experimental nature of the drug substance, formulation, and dosage form at an early stage of development has an impact on establishing specifications. At early stages, the acceptance/rejection criteria may not be as specific; however, it is vital that such criteria be scientifically sound and based upon available scientific data. Specification used as the basis for approval or rejection of components, containers, and closures will become more specific and uniform as additional data become available.[19] The specifications for raw materials and excipients, in-process testing, process evaluation or validation, finished product testing and stability testing for IMPs should be set to assure that the appropriate quality of the product will be maintained.

- Stability: For Phase I clinical trials, it should be confirmed that an ongoing stability program will be carried out with the relevant batch(es) and that, prior to the start of the clinical trial, at least studies under accelerated and long-term storage conditions will have been initiated. When available, the results from these studies should be summarized in a tabulated form. Any supportive data from development studies should be summarized in a tabular overview. An evaluation of the available stability data related to storage conditions stated on the product labels and justification of the proposed period of use, expiration date or retest date assigned to the IMP in the clinical study should be provided.
- For Phase II and Phase III clinical trials, the available stability data should be presented to regulatory agents in a tabulated form. An evaluation of the available data and justification of the proposed shelf-life to be assigned to the IMP in the clinical study should be provided. Data should include results from studies under accelerated and long-term storage conditions.[20]
- Validation: Noncritical manufacturing processes for clinical trial products are not expected to be validated to the extent necessary for routine productions. However, there must be the

combination of controls, calibration, and equipment qualification to ensure that the manufacturing processes for clinical trial products are of the same standard as for commercial products.[21]

- Packaging and labeling control: Clinical trial supplies are normally packaged in an individual container for each subject in the clinical investigation. The packaging and labeling of investigational clinical trial products are usually more complex than commercial drug products, especially when placebo and active products are packaged in the same appearance and usage label for double-blinded clinical studies. Sufficient reconciliations and proper controls should take place to ensure the correct quantity of each product required has been accounted for at each stage of processing. Poor labeling control and accountability may have an adverse impact on the firm's ability to assure that the new drug will always be properly labeled.

> During packaging of investigational medicinal products, it may be necessary to handle different products on the same packaging line at the time. The risk of product mix up must be minimize by using appropriate procedures and/or, specialized equipment as appropriate and relevant staff training.[22]
>
> Packaging and labeling of investigation medicinal products are likely to be more complex and more liable to errors (which are also harder to detect) than for marketed products, particularly when blinded products with similar appearance are used. Precautions against mislabeling such as label reconciliation, line clearance, in-process control checks by appropriated trained staff should accordingly be intensified.[22]

- Distribution of clinical trial material: Distribution of clinical trial material to the trial sites must be in accordance with the local laws and regulations specific to the countries of destination. For example, many countries require clinical trial material labels to be translated into the local language. The clinical trial material must be secured and stored under conditions specified in the label.[17]

In a blinded study, a written emergency unblinding method must be established, trained on, and implemented. "De-coding arrangements should be available to the appropriate responsible personnel before investigational medicinal products are shipped to the investigator site."[22]

The investigator is responsible only for drug accountability at the site and the sponsor is responsible for overall clinical trial materials distributed for use in a trial. Clinical trial material is reconciled at the site level as well as country/affiliate level. Any discrepancies must be documented and investigated. "The delivered, used and recovered quantities of product should be recorded, reconciled and verified by or on behalf of the sponsor for each trial site and each trial period. Destruction of unused investigation medicinal products should be carried out for a given trial site or a given trial period only after any discrepancies have been investigated and satisfactorily explained and the reconciliation has been accepted. Recording of destruction operations should be carried out in such a manner that all operations may be accounted for. The records should be kept by the sponsor."[22]

> When destruction of investigation medicinal products takes place, a dated certificate of, or receipt for destruction, should be provided to the sponsor. These documents should clearly identify, or allow traceability to, the batches and/or patient numbers involved and the actual quantities destroyed.[22]

24.9.2 A risk-based approach

The FDA, the pharmaceutical industry, health care professionals, and patients share a common goal of reliable, high quality, safe, and effective products. There is a need for new products to improve public health. On the other hand, the knowledge about products and processes may not be fully understood for investigational clinical trial products, especially those used in the early phases of clinical study. Through manufacturing science, pharmaceutical firms accumulate knowledge about products, processes, and technology used to manufacture and control these processes, which in turn provide the foundation for a robust quality system. The quality system focuses on critical pharmaceutical quality attributes including chemistry, pharmaceutical formulation, manufacturing process, product quality and performance, and their relevance to safety and efficacy. To produce reliable, high quality, safe, and effective products including early phase IMPs, the desired state of manufacturing is:

- Product quality and performance are achieved and assured through the design of an effective and efficient manufacturing process.[23] Quality should be built into the product instead of relying on product testing alone to ensure product quality. Pharmaceutical firms must continue to move from a compliance mindset to quality by design (building in quality by defining design spaces of product and processes from the development phase and throughout the product's life cycle). The specifications and process parameters are determined and established by the technical experts who have a thorough understanding of

pharmaceutical science, equipment, facilities, and processes. Any variations in materials and processes that can affect the finished product's identity, purity, and quality should be considered during establishment of the specifications and process parameters.

- Innovative and new technologies are used to continuously improve manufacturing and QA. For example, a common risk associated with a highly potent investigational clinical trial material is cross-contamination during manufacturing of the product. Many pharmaceutical firms choose to use single-use disposable equipment and components such as disposable bags, tubing, filters, and storage containers to eliminate cross-contamination risk and reduce the time spent cleaning and setting up equipment. Proper process design, quality assurance, and component selection are important for the successful implementation of single-use disposable equipment and components. PAT is another example of an advanced technology that can facilitate building the knowledge base and mitigate risk. PAT can be used to aid designing, analyzing, and controlling manufacturing processes. PAT allows a better understanding of processes through timely measurement and can be used to quickly evaluate changes that impact product quality, thereby reducing risk during manufacturing processes. PAT changes the traditional concepts of process validation and leads to continuous quality verification strategies.[24]
- Manufacturing science is applied to understand process capability, to assure that the manufacturing processes are preformed in a reproducible manner, and to manage the risk impacting the processes or product quality throughout their life cycle. Elements of risk should be evaluated based on the intended use of a product, patient safety, and the availability of drug product supplies. Continuous improvement efforts must be employed to increase process capability and reduce risk.
- Knowledge is shared between pharmaceutical firms and the FDA. The firms should share sufficient knowledge to provide the FDA with process understanding and rationale for the development of specifications and analytical methods. Adequate pharmaceutical development information, including identification of critical quality parameters and attributes, as well as the justified formulations should be provided to aid in understanding the product and processes.
- Risk management review teams and framework are used by pharmaceutical firms. Pharmaceutical firms should prioritize activities or actions based on a risk assessment, including both the probability of the occurrence of harm and of the severity of that harm. Based on the level of risk, the firm should apply appropriate manufacturing science and develop control strategies in order to prevent or mitigate the risk of producing a poor quality product. The firm's risk-based decisions must be made to assure the identity, purity, potency, and quality regarding the safety and efficacy of new drugs throughout their life cycle (from IND to post marketing phases).

The desired state of manufacturing discussed previously is an objective for the pharmaceutical cGMPs for the 21st century: a risk-based approach, which was announced by the FDA in Aug. 2002 (a risk-based approach aims to ensure resources to be focused on high-risk areas).[25] However, it is the firms' responsibility to ensure that low- and medium-risk areas remain in appropriate states of control because these lower risk classes will receive less FDA regulatory attention. The FDA has expressed its commitment to modernize the pharmaceutical GMP regulations and to streamline the clinical development process to ensure that basic scientific discoveries can be translated more rapidly into new and better medical treatment. In Sep. 2006, the FDA published Guidance for Industry: Quality Systems Approach to Pharmaceutical cGMP Regulations.[23] The guidance, which was intended to serve as a bridge between the 1978 regulations[3] and the FDA's current understanding of quality systems, explains how implementing quality systems can help drug product manufacturers achieve compliance with current GMP requirements. Although the guidance applies to pharmaceutical finished-product manufacturers, it can also be used to guide the clinical supply manufacturing.

24.10 CLEANING VALIDATION AND VERIFICATION

The Code of Federal Regulations PART 211—Current Good Manufacturing Practice for Finished Pharmaceuticals—Equipment Sec. 211.67 on equipment cleaning and maintenance states that "Equipment and utensils shall be cleaned, maintained, and sanitized at appropriate intervals to prevent malfunctions or contamination that would alter the safety, identity, strength, quality, or purity of the drug product beyond the official or other established requirements" and that "written procedures shall be established and followed for cleaning and maintenance of equipment, including utensils, used in the manufacture, processing, packing, or holding of a drug product."[26] In accordance with 21 CFR 211.67, the International Conference on Harmonisation (ICH) has issued recommendations on equipment maintenance and cleaning (Q7A, section

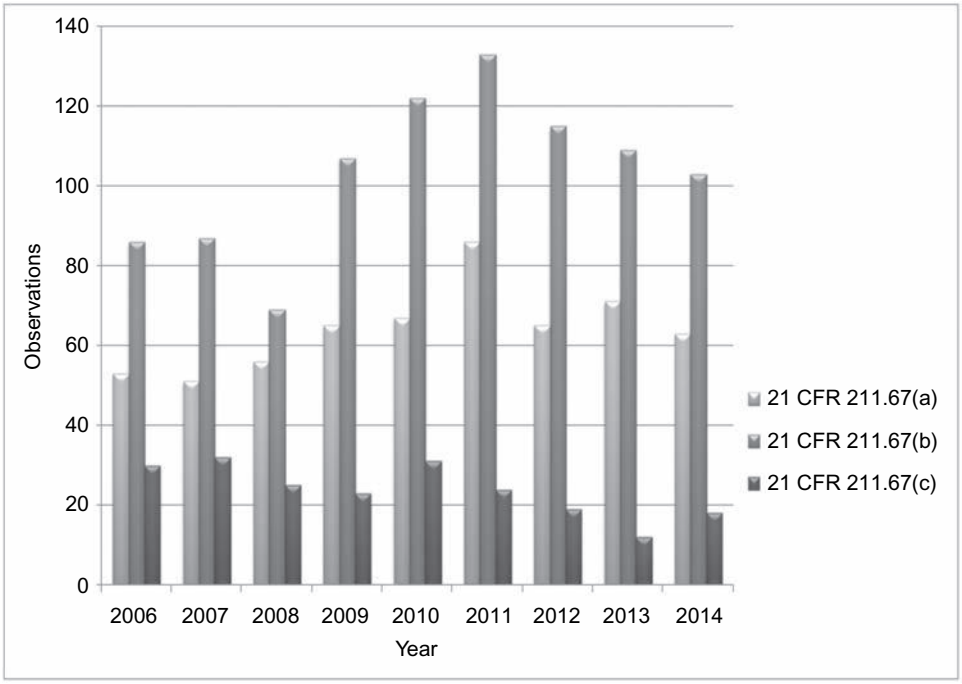

FIGURE 24.4 Frequency of FDA 483 warning letters issued for cleaning violations (21 CFR 211.67) from 2006 through 2014. The light gray columns represent violations of 211.67(a), the medium gray columns represent violations of 211.67(b), and the dark gray columns represent violations of 211.67(c).

5.20–5.26) for compliance and safety that include very similar requirements with more elaboration on specific details.[27] Again, there is a reiteration that written procedures must be established and that detailed cleaning agent selection and preparation, responsibilities, schedules, and cleaning acceptance limits must be documented with rationales. The purpose is to prevent cross contamination between different manufactured lots. This cross-contamination concern applies not only to the API, but also to residual cleaning solvents and detergents.

Even with the seemingly basic requirements outlined, there have been multiple 483 observations issued to pharmaceutical manufacturing facilities since 2006 due to violations of 21 CFR 211.67. 483 observations indicate that a FDA-regulated firm may be in violation of the Code of Federal Regulations (CFR). Fig. 24.4 illustrates the frequency of 483s issued where an infraction against 21 CFR 211.67 was cited (obtained from the FDA website); as stated on the website, this list may not include all of the 483 observations issued.[28] Within 21 CFR 211.67, part a infractions involve satisfying the requirement that "equipment and utensils shall be cleaned, maintained, and, as appropriate for the nature of the drug, sanitized and/or sterilized at appropriate intervals to prevent malfunctions or contamination that would alter the safety, identity, strength, quality, or purity of the drug product beyond the official or other established requirements." Part b infractions require that "written procedures shall be established and followed for cleaning and maintenance of equipment, including utensils, used in the manufacture, processing, packing, or holding of a drug product." Finally, Part c mandates that "records shall be kept of maintenance, cleaning, sanitizing, and inspection as specified in 211.180 and 211.182." Fig. 24.4 illustrates that there may be some ambiguity in compliance with the requirements of 21 CFR 211.67 based upon the number of observations per year, which was approximately 191 from 2006 to 2014, and peaked during this timeframe at 243 total (21 CFR 211.67 parts a–c) observation in 2011.

The ICH guideline on risk management outlines multiple approaches to make and document risk-based decisions.[25] It clearly outlines that the primary goal of risk management is to base the approach on scientific knowledge and to evaluate the impact on the patient. In addition, the level of effort, formality (eg, use of tools), and documentation of the quality risk-management process should be commensurate with the level of risk. The 1993 guidance on cleaning inspections states that for a swab method, recovery should be established from the surface.[29] There are no specific requirements on how to establish these recovery estimates or the acceptance limits, for that matter. It is the manufacturer's prerogative to document the cleaning

rationale (process and acceptance limits) that maintains the quality and purity of the subsequent drug product being manufactured. Therefore, by definition, cleaning validation and verification are areas built upon the premise of risk management.

The purpose of this section is to review the approaches for cleaning equipment used for product manufacturing. The difference between cleaning validation and cleaning verification is outlined first. Acceptance limit calculations are provided that represent either 1/1000 or 10 parts per million (ppm) product carryover in clinical trial operations. The analytical aspects of cleaning method developments are discussed from swab selection, surface selections, to the analytical methodologies that are used for both selective and nonselective approaches. In addition, a guideline for validating a cleaning verification assay is presented.

24.10.1 Cleaning validation versus cleaning verification

Cleaning validation is an extensive, multi-functional program where the entire manufacturing process is considered, ranging from the equipment that will be used to manufacture the products to the analytical methods that will be used to evaluate cleaning effectiveness.[30] Cleaning validation starts with the preparation of a validation protocol. The validation protocol would include rationales regarding cleaning agents and procedures,[31] equipment, equipment swabbing locations,[32] safety-based acceptance limits, selection of products used to demonstrate validation,[30] and validated analytical methodology.

When selecting representative products to validate a cleaning program, several approaches have been presented.[30] The most conservative approach would be to validate the cleaning procedure for all compounds manufactured, which is most likely the approach taken for a marketed product manufacturing facility. However, this approach is expensive, resource consuming, and may not be practical for a multi-compound facility used primarily to support of clinical trials. Therefore, manufacturers may choose to validate on a subset of compounds and examine such parameters as solubility, potency (which drives the acceptance limit), and cleanability. The location and number of swabbing locations for both verification and validation activities are dictated by the product contact surface area (eg, larger components may require a larger number of swabs), energy dissipation (eg, roller compaction or tablet pressing regions are more likely to accumulate product), composition of the product contact areas (ie, polycarbonate vs stainless steel), and cleaning difficulty (tight corners, bends, and hard-to-reach places result in hard-to-clean locations that should be swabbed).[32]

Cleaning verification, on the other hand, is a demonstration for each manufacturing run (typically by submission of cleaning swabs to analytical laboratories) that the API has been removed to a level below the pre-established acceptance limit.

24.10.2 Swab test acceptance criteria

There have been recent proposals that utilize the threshold of toxicological concern (TTC) to calculate an acceptable residue limit.[33,34] The TTC estimates a level of exposure that will not present an appreciable risk to human health. This concept is commonly applied to impurities in drug substances and drug products and a guidance has been recently published (ICH M7).[35] In addition, the European Medicines Agency (EMA) published a guideline outlining the expectation to develop a permissible daily exposure of residuals between veterinary and human products, but the guideline also applies the TTC concept when the residual is a genotoxic API.[36]

When determining the acceptance limit, a strong scientific rationale with relevant factors generally includes: Evaluation of the therapeutic dose of the actives; toxicity of the potential contaminant; solubility of the potential residue; difficulty of cleaning; visual examination; the batch size of the subsequent products on the same equipment; and how the product will be used.[37] Acceptance limit calculations take on the general form where two methods are typically used. Although some authors recommend adjusting the safety factor based upon the dosage form,[37] it is most common to utilize the 1/1000th minimum dose and 10 ppm methods.[38–42] The 1/1000th method assumes that pharmaceuticals are often considered to be nonactive at 0.1% of their prescribed therapeutic dosages.[42] The following equation demonstrates how an acceptance limit is calculated utilizing the 1/1000th method:

Equation (24.1): 1/1000 safety limit calculation

$$\text{Acceptance Limit}\left(\frac{\mu g}{\text{swab}}\right) = \frac{0.001 \times \text{Smallest Strength Product A(mg/day)}}{\text{Maximum Daily \# of Dosage Units Product B(units/day)}} \times \frac{\text{Lot Size Product B(\# of dosage units)}}{\text{Shared Surface Area(cm}^2\text{or in}^2\text{)}} \times \frac{\text{Swab area(cm}^2\text{or in}^2\text{)}}{1 \text{ swab}} \times \frac{1000\ \mu g}{1\ mg}$$

Product A is the product made on the equipment to be cleaned, and product B is the product to be

manufactured on the same equipment after it is used and cleaned for product A.

The second method uses the 10 ppm limit historically used to calculate commercial manufacturing limits. This method allows the maximum carryover of product to be calculated using lot sizes and shared equipment surface area. Eq. (24.2) shows the method used to develop the 10 ppm acceptance limits:

Equation (24.2): 10 ppm acceptance limit calculation

$$\text{Acceptance Limit}\left(\frac{\mu g}{\text{swab}}\right) = \frac{10\ \text{mg}}{1\ \text{kg}} \times \frac{\text{Lot Size Product B(kg)}}{\text{Shared Surface Area(cm}^2\text{or in}^2\text{)}} \times \frac{\text{swab area(cm}^2\text{ or in}^2\text{)}}{1\ \text{swab}} \times \frac{1000\ \mu g}{1\ \text{mg}}$$

After the two limits are calculated using Eqs. (24.1) and (24.2) for each product, the limits are compared. The smaller limit calculated for a product becomes the acceptance limit for the cleaning verification for that product. It is obvious from Eq. (24.2) that two variables drive the acceptance limit: the lot size of product B and the shared surface area. For example, if the shared equipment surface area is constant between two products and the lot size for product B is 50 kg as opposed to 100 kg, the acceptance limit would be calculated as one-half of that for the 100 kg lot size.

24.10.3 Swab selection

Although swab sampling is different conceptually from both the impurity and potency assays, the same scientific rationale governs the development of these assays. Many of the references listed in Tables 24.4 and 24.5 outline different validation approaches. Seno outlined validation practices in the Japanese pharmaceutical industry for cleaning verification,[43] and Kirsch outlined an approach for swab method validation that is consistent with ICH guidelines for method development.[44] An important aspect of any cleaning-verification assay begins with swabbing the surface. Swabs are typically constructed with a polyester knit that will not leave behind fibers after swabbing and possess minimal extractable materials.[45] Jenkins et al. did an extensive evaluation of swabbing materials as a function of the residual particles left on the surface after swabbing.[46] Quartz wool was found to give excellent recovery of analyte; however, it left an excessive amount of particles on the surface. Glass-fiber swabs and cotton swabs also suffered from high levels of residual particles left behind on the surface. Knitted polyester demonstrated the best balance between recovery, residual particle, and background levels. Yang et al. presented a guideline for swabbing techniques that discusses swabbing procedures, solvent selection, and recovery as a function of the coupon tested.[47]

24.10.4 Representative surface selection for method validation

The general expectation is that all product contact surfaces must be considered during cleaning verification in order to demonstrate that the equipment is clean; and it is an expectation that a recovery value is established for each product contact surface during method validation (how to establish this recovery will be discussed next). The recovery is used to correct the submitted swab result for incomplete removal of the residual analyte from the surface and then compare that result versus the acceptance limit. For example, if 80% recovery was obtained during method validation, that value would be incorporated into the analytical method. Let's assume that the uncorrected analytical result was 4.2 μg/swab compared with an acceptance limit of 5.0 μg/swab. After correcting for the recovery of 80%, the result is now 5.25 μg/swab, which constitutes a failing result in this example. In this case, the importance of the recovery value becomes apparent because it is the difference between an acceptable result and a failing result.

All product manufacturing product contact surfaces would ideally be represented by the analytical method. However, the number of product contact surfaces and the sheer number of manufacturing equipment types and suppliers makes verifying recovery of each analyte off of each surface quite onerous. For example, equipment in a CT manufacturing area is shared among many compounds in the portfolio, especially for a pipeline that is rich in Ph I compounds. As new equipment is purchased, it may have new product contact surface material of construction (MOC). Each compound in the portfolio that utilizes this piece of equipment would require a method revalidation in order to add a recovery factor for the new product contact surface MOC. As the number of different materials of construction increases along with the number of compounds being manufactured, the difficulty and complexity of sustaining that approach also increases.

However, there are approaches that allow for a subset of the total number of surfaces to be evaluated during method development. Stainless steel is the most common material in a manufacturing environment.[48] Thus, some companies establish recovery for stainless steel and apply that correction to all swab submissions. It could be outlined that if the product contact surface

area is less than, for example, 1.0%, that surface MOC is not a high risk for contamination and does not need to be included in the validation. Another option for MOCs not included in the analytical method validation would be to assume some percentage of recovery seen on stainless steel (eg, 10%), a percentage based upon similar materials, or possibly the lowest percent recovery seen on any evaluated MOC. All of these assumptions should be based upon a strong scientific rationale and supported by internal procedures and processes. Finally, two authors have advocated that all MOCs utilized in the manufacturing environment should be placed into groups.[48,49] At that point, a representative of a group would be included in the analytical method development. The authors advocate that many MOCs behave similarly when validating an analytical method; by choosing representative recovery surfaces for those surfaces other than stainless steel rather than doing recovery experiments on all surfaces, the effort can be focused proportionally on the risk while still maintaining patient safety.

This approach of grouping MOC for analytical method development in support of cleaning verification/validation activities is an excellent opportunity to apply a quality risk management approach.

24.10.5 Analytical methodologies

Cleaning verification methods for swabs are typically validated by demonstrating analyte recovery from a "test coupon." As discussed previously, this test coupon can be the exact MOC in the manufacturing area or it may be a scientifically defined "representative." While analyzing rinse solutions has its place in the manufacture of API, it is not a common practice in support of a solid oral drug product clinical trial manufacturing site. In these analyte recovery experiments, a known amount of an analyte will be spiked onto the coupon; the coupon will then be swabbed in a methodical manner illustrated in Fig. 24.5. For example, 10 swipes are performed in the vertical direction, the plate or test coupon is rotated, and 10 additional swipes are performed in the horizontal direction for a 10 cm × 10 cm coupon. For a larger surface (eg, 25 cm × 25 cm), 20 swipes in each direction may be required. Some researchers have advocated zig-zag patterns rather than horizontal and vertical swipes. Typically, there will be a training program required that teaches the swabber proper technique. It is important to be consistent (eg, the amount of pressure applied to the swab and potentially the angle of the swab head with regard to the surface) and that the validation mimics how the swabs will be collected from the manufacturing equipment. The swab will then be extracted in a solvent that maximizes solubility and is compatible with the detection technique, and ultimately analyzed. Depending upon the analyte, the acceptance limit, and the swab, 5–20 mL is an appropriate volume of extraction solvent to ensure a reproducible extraction without overdiluting the analyte, which could ultimately impact analytical detection.

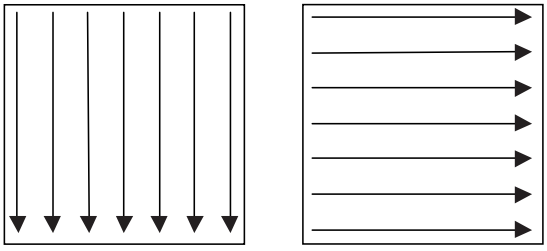

FIGURE 24.5 Illustration of typical swabbing practice. The arrows indicate the swabbing direction on the test coupon.

With the advances in analytical technology, it should be a rare exception that the toxicologically determined cleaning limit cannot be attained from the perspective of determination of the analyte; although it does become more difficult to quantitatively recover low amounts of analytes from surfaces. When selecting the appropriate analytical technique for cleaning verification, several parameters must be considered, such as the safety acceptance limit for the cleaning verification assay, solubility,[50] the molar absorptivity of the molecule, or ionization or oxidation potential if alternative detection techniques are an option. In addition, the benefits of requiring a selective assay versus a nonselective assay should be considered. In a nonselective assay, the blank of a rinse and swab blank are determined to ascertain if there is any deviation from the control (ie, the blank in the same solution). The advantage of this approach includes the fact that a variety of residues may be detected, which include cleaning agents, excipients, previously manufactured products, degradation products, and APIs. It should, however, be realized that the identity of the contaminant would remain unknown after this assay. The analyst would only know that the equipment had a detectable residue, which may or may not help improve the cleaning process on subsequent manufactures. Many nonselective analytical techniques are outlined in Table 24.4. Within this table are indicated the analytes, and the reported limit of detection (LOD) for the technique in association with the cleaning assay. The most prevalent of the nonselective assays is total organic carbon (TOC). It has the advantages of good sensitivity, short analysis time, and being capable of detecting all residual carbon—independent of the source.[51] For a selective technique, the target analyte is known before method validation. Table 24.5 outlines many of the feasible selective analytical techniques.

The list is not all-inclusive because of the multiple detection schemes that can be implemented with high performance liquid chromatography (HPLC). HPLC is commonly used in the pharmaceutical industry. As a result, cleaning verification assays by this approach outnumber all others. Typically, at the time of manufacture, a potency assay has been developed and validated for the drug product. From a conservative standpoint, anything that elutes, or coelutes, at the retention time of the analyte of interest will be attributed to the API. Therefore, the swab method is usually very similar, if not identical, to the potency method. Characteristic swab assays would most often be isocratic methods with reduced run times. In addition to HPLC with ultraviolet (UV) detection, many other detection schemes are outlined in Table 24.5. The analytical chemist chooses these techniques based upon the chemical properties of the target molecule and the cleaning acceptance limit, which was previously established based upon dose and equipment surface-area considerations. For example, a molecule that does not possess a chromophore and is somewhat potent would pose an interesting analytical challenge. The analyst might consider evaporative light scattering detection, electrochemical detection, or mass spectral detection, to name a few possibilities. There are a few examples of analytical techniques listed in Table 24.5 where a specific example for a cleaning verification assay could not be located; however, depending upon the molecular properties of the compound, the cited technique would be a viable option for a cleaning verification assay.

24.10.6 Analytical method validation

Regardless of the analytical technique chosen for cleaning verification, there are certain components that are expected of any method validation activity and outlined in the ICH guidelines on analytical methods Q7A.[27] For a quantitative impurity test, validation is required for specificity, limits of detection, and quantitation, linearity, accuracy, precision (repeatability and intermediate precision, depending upon the phase of development), and range (ICH Q2(R1)).[95] Each of these validation criteria is listed next with a brief explanation on the applicability to cleaning verification assays. A limit test for cleaning verification assays is often employed during clinical trials. With a limit test, a result of "pass" or "fail" is reported. The limit test significantly simplifies the validation of the cleaning verification assay. In order to validate a limit test, specificity, limit of quantitation (LOQ), accuracy, and stability must be evaluated at the acceptance limit. Linearity and range may be excluded. A drawback of the limit test is that the ability to trend the cleaning efficiency (except through failures) for a particular process, or compound, is eliminated because a quantitative result is not reported. Due to the fact that the formulation and process are likely to evolve and the attrition of compounds during development is high, one might argue that trending doesn't provide much value here. However, if the compound makes it to market, a quantitative assay is expected for commercial manufacturing.

24.10.6.1 Specificity

Specificity should be demonstrated using interferences (ie, extractables) that arise from the cleaning swabs and/or blank surfaces. Specificity between the excipients utilized in the drug product manufacture is desirable, but not required. If specificity is not achieved it must be assumed that the peak response is from the API. If the interference is low enough, it may be acceptable as long as it does not unduly bias the recovery results and/or it can be accounted for appropriately through background subtraction. Significant interference from a surface may indicate compatibility issues for the selected sampling solvent and may vary (drop) over time as surfaces on equipment are repeatedly cleaned.

24.10.6.2 Detection and quantitation limits

The LOQ, as opposed to the LOD, is the most important attribute of the swab method because it has been previously determined, from a safety and cross-contamination standpoint, that residual material above the cleaning acceptance limit is of serious concern. The LOQ is defined as a percent relative standard deviation (% RSD) of 10%, and the LOD is defined as a % RSD of 33%. These values are typically determined on low-level injections of the standard. The sensitivity of the method must be low enough to ensure sample responses near the lowest acceptance limit are quantifiable. For typical swab assays, this requirement may necessitate an LOQ of 1 μg/mL (5 μg/swab limit, 1 swab into 5 mL of solvent). When discussing an acceptable precision for a swab assay (including recovery from surfaces), larger % RSD values may be acceptable (eg, 20%). However, the assay pass-fail limit should be lowered so that this variability is accounted for. For example, if 80% recovery was obtained during validation with a 15% RSD for a 5 μg/swab limit, the assay pass-fail limit could be reasonably lowered to 68% to take into account the swabbing variability.

24.10.6.3 Linearity

Linearity is assessed to cover the full range of acceptance limits required by the method. Linearity has been performed in a couple of different manners. First, linearity has been performed through the preparation

of standards that are equal to the resulting swab solution concentration after putting the swab into solvent. The second approach would involve spiking plates at many different levels and evaluating the recovery at each level. The second approach is problematic because recovery is usually observed to decrease as the limit at the spiked level on the surface decreases. Thus, it may be unreasonable to expect linearity over a large range. However, if the range is kept narrow, either approach is suitable.

24.10.6.4 Accuracy and recovery

When compared with a typical potency assay, this validation parameter is the most variable.

Equation (24.3): accuracy/recovery calculation

$$\text{Recovery}(\%) = \frac{\text{spiked amount determined}(\mu g)}{\text{actual spiked amount}(\mu g)} \times 100$$

It is not uncommon to see RSDs of recovery results for a cleaning range from 2% to 10% or higher depending upon the surface. In addition, the recovery of an analyte from the test surfaces is not expected to be complete. Depending upon the surface's characteristics (eg, a smooth polished surface vs a rough surface), acceptance limit (eg, 0.5 mcg/swab vs 100 mcg/swab), and the solubility of the compound, recoveries as low as 20%, or lower, may be acceptable and accounted for in the method calculations through the use of recovery factors. The minimum sample response (extract concentration) must not be less than the quantitation limit of the assay to ensure that analyte levels close to the lowest acceptance limit are quantifiable.

24.10.6.5 Intermediate precision

With the previously mentioned variability that may be observed during accuracy/recovery determinations, it must be realized that acceptance criteria around intermediate precision must be set accordingly. For example, it is quite likely that if Analyst A could obtain a recovery of 80% for a 5 μg/swab limit, Analyst B could obtain a value of only 70% for the recovery. When looking at the residual surface analyte difference between the two analysts, Analyst B would have left only 0.5 μg (0.02 $\mu g/cm^2$ for a 2.5 cm × 2.5 cm test coupon) across the tested surface area. It is easy to see that swabbing technique can play a crucial role in swabbing success when such small amounts are considered. As the compound becomes more potent, the residual differences between Analyst A and Analyst B may be in the nanogram range.

24.10.6.6 Range

The range of acceptable method performance is based upon the LOQ and the linearity assessment.

24.10.6.7 Standard and sample stability

Stability of the unextracted swabs is determined in order to allow time for transport of the swabs between the swabbing site and the analytical testing site. Standard stability and swab extract stability are determined to facilitate analytical testing. Swab and extract stability must be assessed after contact with each of the product contact surface materials because sample stability can be affected by surface-specific contaminants.

24.11 CASE STUDY

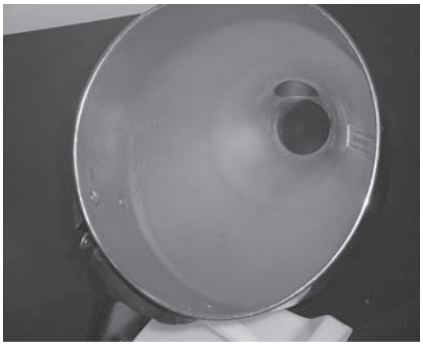
24.11.1 Example

The following case study is for a tablet manufactured on a Manesty tablet press in the clinical trial manufacturing area for a first human dose trial. The compound will be manufactured at doses of 1 mg/tablet, 25 mg/tablet, and 100 mg/tablet and has a good molar absorptivity. The 1/1000th minimum dose and 10 ppm methods were used to calculate the swab test acceptance limits, assuming an equivalent lot and dosage strength will be subsequently manufactured. The analysis shown next outlines the selection of swabbing locations, acceptance limit calculations, and analytical methodology based upon previously mentioned criteria.

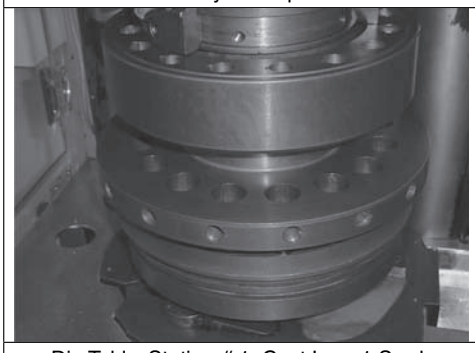
Fig. 24.6 is an illustration of the Manesty press. There are magnified views indicating swab locations. All of this information (picture, number of swabs, surface areas in Table 24.6, and MOC) is part of the cleaning master plan and is generated for each piece of manufacturing equipment and each swab location. This documentation practice serves as a guide for documenting swab locations and rationales for such locations.

Based upon product contact surface area (outlined in Table 24.7) the surface areas were calculated for each component and it was determined that three equipment components had large surface areas. In this case, the discharge port, the die table, and the hopper all had significant surface area contributions. In addition, the die table would be considered a high-energy dissipation area where it is likely that product would accumulate during manufacture. The materials of construction are stainless steel and cast iron; therefore both surface types are swabbed. In turn, an analytical method should be validated where the recovery from stainless steel and cast iron are evaluated. None of the other areas were evaluated as especially difficult to clean in this example. Thus, no additional swabs were added.

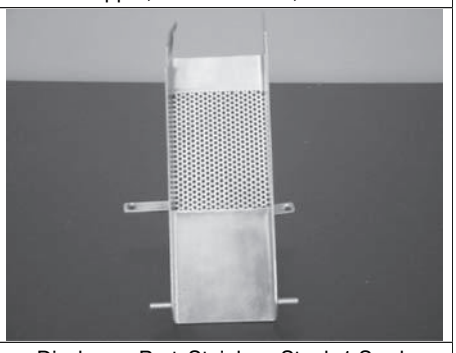
Manesty tablet press



Hopper, stainless steel, 1 swab



Die Table, Station # 1, Cast Iron, 1 Swab



Discharge Port, Stainless Steel, 1 Swab

FIGURE 24.6 Manesty tablet press with swab locations, material of construction, and number of swabs required per location indicated.

TABLE 24.6 Material of Construction and Surface Area Calculations for the Product Contact Surfaces Illustrated Above

Component	Material	Surface area (cm^2)	Surface area (%)	# Swabs
Discharge port	Stainless steel	42.0	5.4	1
Upper punch	Stainless steel	0.6	0.1	0
Lower punch	Stainless steel	1.1	0.1	0
Die	Stainless steel	0.9	0.1	0
Die table, station 1	Cast iron	126.5	16.3	1
Feeder bowl	Cast iron	145.5	18.8	0
Hopper	Stainless steel	458.9	59.2	1

TABLE 24.7 Lot Size and Dose Strengths for Case Study

Product	Lowest dose strength (mg/tablet)	Lot size (kg)	Lot size (units)	Maximum daily dose (units)	Shared surface area (cm^2)
A	1	20	10,000	1	
B	10	1	5000	5	775.5

24.11.2 Acceptance criteria

Using the 1/1000th minimum dose and 10 ppm methods, the following equations list the product and equipment characteristics used to calculate the swab acceptance limits for the case study.

1. 1/1000th Method:

$$\text{Acceptance Limit}\left(\frac{\mu g}{\text{swab}}\right) = \frac{0.001 \times 1 \text{ mg/day}}{5 \text{ units/day Product B}} \times \frac{\text{Product B}(5000 \text{ dosage units})}{\text{Shared Surface Area } 775.5 \text{ cm}^2} \times \frac{\text{Swab area } 25 \text{ cm}^2}{1 \text{ swab}} \times \frac{1000 \ \mu g}{1 \text{ mg}}$$

Acceptance Limit = 32.2 μg/swab

2. 10 ppm Method:

$$\text{Acceptance Limit}\left(\frac{\mu g}{\text{swab}}\right) = \frac{10 \text{ mg}}{1 \text{ kg}} \times \frac{\text{Lot Size Product B } 1 \text{ kg}}{\text{Shared Surface Area } 775.5 \text{ cm}^2} \times \frac{\text{Swab area } 25 \text{ cm}^2}{1 \text{ swab}} \times \frac{1000 \ \mu g}{1 \text{ mg}}$$

Acceptance Limit = 322 μg/swab

In order to keep the case study simple, only one piece of equipment was used to illustrate the selection of swab locations, images included in CT master plan, and calculation of limits. Tablet products are typically made with several steps using several pieces of equipment such as a granulator/dryer, mill, blender, press, or optional coater. The total product contact surface area of all equipment should be used for calculation of limits. The smallest limit calculated for a product using all of the calculations becomes the acceptance limit for the cleaning verification of that product. In this case, the acceptance limit would be 32 μg/swab. If product B, the lot to be manufactured next, is unknown at the time of product A's manufacture, the worst case should be assumed in the calculation. For example, if the smallest lot that has ever been manufactured in the facility is 1000 dosage units or 1 kg, those values should be used in the equation to generate a maximum allowable carryover of product A.

24.12 SUMMARY

This chapter presents a strategy to effectively manage the complex clinical supplies manufacturing process. This strategy includes planning, collaborative communication among the cross-functional team, lean manufacturing, effective training programs, and application of new technologies to facilitate the clinical supplies manufacturing. cGMP considerations to ensure the quality of the clinical materials during the clinical supplies manufacture are also discussed. The comprehensive clinical supply manufacture strategy and cGMP controls prevent clinical supply manufacture from becoming an obstacle to the clinical trial program and consequently reduce the total cycle time of introducing a new drug to market. In addition, various aspects of cleaning verification and considerations for a cleaning validation program are presented. Acceptance limit calculations and analytical methodology and validation were outlined to illustrate the vast interest in the topic of cleaning verification in a clinical trial manufacturing facility.

25.1 INTRODUCTION

The quality of drug products is determined by their design, development, process controls, good manufacturing practice (GMP) controls, process validation, and by specifications applied to them throughout development and manufacturing.[1,2] As part of GMP controls, the quality of any drug product must be evaluated using methods and criteria listed in its specifications. According to ICH Q6A, a specification is defined as[1]:

> A list of tests, references to analytical procedures, and appropriate acceptance criteria that are numerical limits, ranges, or other criteria for the tests described. It establishes the set of criteria to which a drug substance or drug product should conform to be considered acceptable for its intended use. Conformance to specification means that the material, when tested according to the listed analytical procedures, will meet the listed acceptance criteria.

In the pharmaceutical industry, specifications are required by regulatory bodies for any drug substance, intermediates, and finished drug product. Specifications are critical to ensure product quality and consistency, and are an important part of an integrated quality strategy for finished drug products in addition to GMPs (eg, using suitable facilities, an established/validated manufacturing process, validated test procedures, raw materials testing, in-process testing, and stability testing).[1–3] Specifications for the drug substance, in-process tests, and final product release tests must be based on development information (eg, batch history, stability, efficacy, and toxicity) and certainly evolve with the cumulative knowledge gained during product research and development. In all cases, specifications either in the clinical trial stages or in the commercialization stage are chosen to confirm the quality of the drug product and, thus, must focus on the product characteristics that ensure the identity, strength, and purity of the drug product at release, as well as throughout the duration of clinical trial or the shelf-life for commercial products. It is important to have solid rationale and scientific justification for including and/or excluding testing for specific quality attributes because specifications are used to confirm the product quality rather than to characterize the product.

The following are four fundamental principles that should be taken into consideration during setting specifications for both drug substance and drug product:

1. Specifications should be based on relevant preclinical development and clinical study data. These clinical data define the boundaries of key safety and efficacy.
2. Specifications should be related to a manufacturing process. Specifications must be based on data obtained from batches used to demonstrate product performance and manufacturing consistency. Product specifications, especially for process-related degradation products, must be related to the specific manufacturing process.
3. The stability of drug substance and drug product should be taken into consideration for setting specifications. Physical and chemical degradation of drug substance and drug product may occur during storage. These changes could affect product safety and performance.

DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00025-X

4. Specifications must be linked to analytical procedures. Critical quality attributes (CQAs) may include characteristics such as assay, impurity profiles, and in vitro dissolution. Such attributes can be evaluated by multiple analytical methods to yield different results. During the course of product development, it is common for analytical technology to evolve in parallel with the product. Therefore, analytical data generated during development should be correlated with those generated at the time when the new drug application (NDA) is filed.

For the purpose of this document, early phase development refers to phase 1 or 2 clinical trials before the start of primary stability studies or pivotal clinical trials. Late phase development refers to phase 3 or pivotal clinical studies. Early phase and late phase specifications refer to specifications established during early phase and late phase development, respectively. The regulatory specification refers to specifications established for the registration and commercial batches.

The specification setting process begins with identification of a set of attributes for testing, development of analytical procedures, and establishment of an acceptance criteria that can be used to measure product quality. Specifications are then refined during product development and the commercialization process. Once specifications are set, process controls need to be identified in order to monitor, and/or adjust the manufacturing process. The goal of process control is to ensure that an in-process material or finished drug product meets its respective specifications.

Specifications and the specification setting process for drug substances, clinical trial materials, and drug products are described in this chapter. Process controls, particularly in-process material tests, statistical methodology for process controls, and application of process analytical technology (PAT) in-process controls are discussed. The impact of analytical procedures on the specifications is also discussed.

25.2 SPECIFICATIONS FOR THE DRUG SUBSTANCE

The drug substance, the active pharmaceutical ingredient (API), is the most important component in a drug product. During the early phase of development, the number of API batches is relatively limited, the batch size is usually very small, and manufacturing experience is beginning to evolve. The primary emphasis for setting specifications for a new drug substance is on safety based on the purposes of clinical studies at this stage. During the later phase of development as sufficient data and experience become available, product quality becomes the focus for setting specifications based on manufacturing processes and analytical capability, in addition to safety considerations.

ICH guideline Q6A generally applies to products during late stage development because the guideline specifically states that it is "not intended to apply to the regulation of new drug substance used during the clinical research stage of development."[1] Nonetheless, the main principles of the guideline should be considered carefully throughout development. As discussed previously, the primary focus of specifications is safety during the early phase of development. To set specifications at this stage, the tests described in ICH Q6A should be reviewed to determine which tests must have limits and which tests can be performed "to be monitored." To-be-monitored tests refer to those that do not have established limits or acceptance criteria. During the early phase of development, some tests can be performed "to be monitored" because whether or not the test is quality-indicating may not yet be known, or there may be insufficient data to set a proper limit. During the late phase of development, specifications are gradually developed toward meeting the requirements for registration. Therefore the late phase specifications should include tests expected at registration, although there may not be enough data available to set appropriate limits until just prior to submission.

Manufacturing process controls for drug substances are not discussed in this chapter. Please refer to the FDA guidance for industry ICH Q11 Development and Manufacture of Drug Substances issued in November 2012,[4] which is applicable to drug substances as defined in the scope sections of the ICH guidance documents Q6A and Q6B. ICH Q11 provides clarification on the principles and concepts described in ICH Guidelines on Pharmaceutical Development (Q8[R2]),[5] Quality Risk Management (Q9),[6] and Pharmaceutical Quality System (Q10)[7] as they pertain to the development and manufacture of drug substance.

The following tests and acceptance criteria are described in ICH Guideline Q6A. An example of early phase and late phase specifications are provided in Table 25.1.

- *Description*: A qualitative statement about the physical state and appearance of the new drug substance should be provided. For the example in Table 25.1, the acceptance criteria are based on the drug substance's historical visual appearance data.
- *Identification*: Identification testing should ideally be able to discriminate between compounds of closely related structure that are likely to be present. The test should be specific to the new drug substance

TABLE 25.1 Example of Specifications for Drug Substance

Tests	Method	Limits for early phase	Limits for late phase/commercial batches
Description	Visual	White to yellow solid	White to yellow solid
Identity by IR	IR	Spectrum compares favorably with that of the reference standard.	Spectrum compares favorably with that of the reference standard.
Identity by HPLC	HPLC	N/A	Retention Time compares favorably with that of the reference standard.
Assay	HPLC	Not less than 93.0% and not more than 105.0%	Not less than 93.0% and not more than 105.0%
Related substances	HPLC		
Total related substances		Not more than 3.0%	Not more than 2.0%
Individual related substances		Not more than 1.0%	Not more than 0.7%
Chiral impurities	HPLC		
Form A		Not more than 0.7%	Not more than 0.3%
Form B		Not more than 0.7%	Not more than 0.4%
Residual solvents	GC		
Solvent A		Not more than 2.0%	N/A
Solvent B		N/A	Not more than 0.5%
Water	Karl Fischer Titration	Not more than 5.0%	Not more than 2.0%
Residue on ignition	USP 38 (2015)	To be monitored	Not more than 0.05%
Heavy metals	USP 38 (2015)	To be monitored	Not more than 20 ppm
Particle size	Laser diffraction	To be monitored	N/A
Crystal form	X-ray diffraction	To be monitored	N/A
Microbiological test	Compendial method	N/A	Meet compendial requirements

such as infrared spectrum (IR). Identification solely by a single chromatographic retention time is not regarded as specific. However, the use of two chromatographic methods, where separation is based on different principles or a combination of tests into a single procedure, such as high-pressure liquid chromatography (HPLC)/UV (ultraviolet) diode array, HPLC/mass spectroscopy (MS), or gas chromatography (GC)/MS is generally acceptable. If the new drug substance is a salt, identification testing should be specific to the individual ions. An identification test that is specific for the salt itself should suffice. New drug substances that are optically active may also need specific identification testing or performance of a chiral assay. For an early phase specification, only one identification method is generally included. A spectroscopic method such as IR is generally used. For late phase specifications, two identification methods are typically included (see Table 25.1).

- *Assay*: This test is used to determine the purity of the drug substance. A specific, stability-indicating analytical method should be included to determine the content of the new drug substance. In many cases, it is possible to apply the same method (eg, HPLC) for both assay and quantitation of impurities. Both early and late phase specifications require a proper assay limit, which is commonly expressed as a percentage for new drug substances. The limit usually specifies a correction for water and/or solvent (ie, anhydrous, volatiles-free, or dried). For the example in Table 25.1, the assay method separates all known related substances and degradation products from the drug substance. The lower limit is calculated to allow for related substances and assay variability. The upper limit allows for assay variability. The specification for assay is the same for the drug substances at the early and late phases.

TABLE 25.2 Classification of Impurities in New Drug Substance

Categories	Physical state	Source	Examples
Organic impurities	Volatile; Nonvolatile	Manufacturing process; Storage	Starting materials By-products Intermediates Degradation products Reagents, ligands, and catalysts
Inorganic impurities	Nonvolatile	Manufacturing process	Reagents, ligands, and catalysts Heavy metals or other residual metals Inorganic salts Other materials (eg, filter aids, charcoal)
Residue solvents	Inorganic or organic liquid	Manufacturing process	Acetone (class 3) Acetonitrile (class 2) Benzene (class 1)

TABLE 25.3 Thresholds of Impurities in New Drug Substance

Maximum daily dose[a]	Reporting threshold[b,c]	Identification threshold[c]	Qualification threshold[c]
≤2 g/day	0.05%	0.10% or 1.0 mg/day intake (whichever is lower)	0.15% or 1.0 mg/day intake (whichever is lower)
>2 g/day	0.03%	0.05%	0.05%

[a]*The amount of drug substance administrated per day.*
[b]*Higher reporting thresholds should be scientifically justified.*
[c]*Lower thresholds can be appropriate if the impurity is unusually toxic.*

- *Impurities*: Categories of impurities in a new drug substance listed in Table 25.2 included organic and inorganic impurities, and residual solvents. Table 25.3 provides the identification and qualification threshold.[8]

  Organic impurities include starting materials, reaction by-products, process intermediates, degradation products, reagents, ligands, and catalysts. They are process-related except for degradation products, and may be identified or unidentified, volatile or nonvolatile. Chemical structures of impurities present in the new drug substance at or above an apparent level of 0.1% (eg, calculated using the response factor of the drug substance) should be characterized. The early phase specification of new drug substance for organic purities should include limits for total and any unspecified impurity (the largest reported unspecified impurity). Any identified impurity with a potential toxicological risk (eg, carcinogen, teratogen, mutagen) should also be included in the early phase specification with a limit that is toxicologically acceptable without risking human health. A qualitative comparison of impurity profiles, generally an HPLC impurities test, is also performed during the early phase. The impurity profiles of the batches of drug substance to be used in clinical trials must be compared with the batches used in toxicology studies and/or previous clinical trials. The late phase or regulatory specifications of the new drug substance for organic impurities should be consistent with the ICH Q3A guideline and include, where applicable, limits for:
  - Each specified identified impurity
  - Each specified unidentified impurity at or above 0.1%
  - Any unspecified impurity, with a limit of not more than 0.1%
  - Total impurities

  Table 25.1 shows the limits of not more than 1.0% of any individual related substance and not more than 3.0% of total related substances for the example drug substance during early phase development. The limits in this example are designed to ensure that the clinical trial material will not be significantly different, or, at a minimum, not inferior in terms of impurities from the material used in toxicological studies. The limits are tightened based on the process capability and stability data for the late phase specification.

  Inorganic impurities can result from the manufacturing process and usually are known and identified (eg, reagents, ligands and catalysts, heavy metals, inorganic salts, filter aids, and charcoal). These impurities are normally analyzed using pharmacopoeial or other appropriate methods. Limits could be based on

pharmacopoeial standards or known safety data. The example in Table 25.1 shows that residue on ignition and heavy metals were monitored without specifications established at the early stage of the investigation. The limits at late stage were based on historical data.

Solvents are inorganic or organic liquids used as vehicles for the preparation of solutions or suspensions in the synthesis of a new drug substance. For an early phase specification, a toxicology review of the manufacturing process may be needed to identify the solvents that require limits. In general, solvents that are used in the final purification step require an appropriate limit. Solvents that are particularly hazardous should be controlled prior to the final drug substance whenever possible. Solvents that likely to be, or already are, carried through to the final drug substance at a level of concern should be controlled carefully with a proper limit. At the late phase of development, any solvent that may exist in the drug substance should be quantified using appropriate analytical procedures. Control strategy must be in place if the solvents are generally known to be toxic per ICH guideline.[9,10] Control limits should be based on pharmacopoeial standards, ICH safety limits, or known safety data with consideration of clinical dose, duration of treatment, and route of administration. For example, in Table 25.1 the drug substance in early phase was recrystallized from solvent A. Material manufactured at the late phase was recrystallized from solvent B. The limits proposed for solvents A and B were based on the projected dose and the relative toxicity of these solvents.

ICH Q6A decision tree #1 shows how to establish an acceptance criterion for a specified impurity in a new drug substance.[1] Any limits to control impurities in the specification are based on the body of data generated during development. It is unlikely that sufficient data will be available to assess process consistency at the time of filing an NDA with the FDA. Therefore, acceptance criteria should not tightly encompass the batch data at the time of filing. Impurities present in the new drug substance and exceeding the ICH threshold listed in Table 25.3 should be qualified. Qualification is the process to evaluate in vivo toxicity of an individual impurity or a given impurity profile at a specified level. After successful testing in safety and/or clinical trials, the level of the impurity is considered qualified. Higher or lower threshold limits for qualification of impurities may sometimes be necessary for some drug categories. If an impurity of a drug or therapeutic class has been known to have adverse effects in humans, qualification threshold limits should be lower than usual. However, when the level of safety concern is less based on patient population, drug class effects, and clinical considerations, a higher threshold limit may be appropriate. The decision tree in attachment 3 of ICH Q3A discusses critical considerations for the qualification of impurities when threshold limits are exceeded. In general, information from literature should be first searched to qualify an impurity. In many cases, it can be easier to control impurities below the threshold limit during the manufacturing process than to conduct toxicological evaluation.

To set specification limits of impurities, all data from available stability studies, chemistry development, and scale-up studies, and batches for clinical trials should be used to predict potential impurities that may exist in the commercial product. Only impurities that are observed in batches manufactured by proposed commercial synthetic routes will be included in the specification of the new drug substance.

In addition to the universal tests described previously, the following tests may be considered on a case-by-case basis for new drug substances.[1]

- *Physicochemical properties*: These are properties such as pH of an aqueous solution, melting point/range, or refractive index.
- *Particle size and size distribution*: The ICH Q6A decision tree #3 provides general guidance on when particle size testing should be considered. Testing for particle size and size distribution should usually be performed if particle size can have a significant impact on dissolution rates, bioavailability, stability, and manufacturability. Table 25.1 shows that particle size was monitored, but a limit was not established for the drug substance at the early phase of the investigation. The test was removed at the late phase because particle size did not impact the dissolution rate of the drug substance and drug product, the stability of the drug substance, or manufacturability of the drug product. Therefore no specification needs to be established for particle size distribution.
- *Polymorphic forms*: Different polymorphic forms may affect drug product performance, bioavailability, or stability. Polymorphism includes different crystal forms of a new drug substance and its solvates, hydrates, and amorphous forms. Following the ICH Q6A decision #4(1) through 4(3), polymorphism of the new drug substance should be understood and controlled with appropriate physicochemical measurements and techniques. These parameters must be controlled until data show that control is not necessary (ie, only one form can be generated during polymorphs generation studies). Table 25.1 shows that the crystal form of the example drug substance was monitored, but a specification was not established at the early phase of the

investigation. The test was removed at the late phase because polymorphism has not been observed as a result of the current synthetic route and no specification needs to be established.

- Chiral drug substances present additional technical challenges to pharmaceutical scientists. ICH Q6A decision tree #5 summarizes when and whether chiral identity tests, impurity tests, and assays may be needed for both new drug substances and new drug products. For a drug substance developed as a single enantiomer, control of the other enantiomer should be considered in the same manner as other impurities. An enantioselective determination of the drug substance should be part of the specification. In addition, identity tests should be capable of distinguishing both enantiomers and the racemic mixture. It is important for a chiral drug substance to control starting materials or intermediates and enantiomeric impurity during the manufacturing process. The example in Table 25.1 shows that the limits at early phase are to ensure that lots are not significantly different from the quality of the lots for toxicology studies and allow for assay variability. The limits at late phase were tightened based on process capability and stability data available.
- *Water content*: Control of water content is especially important if the new drug substance is hygroscopic or degraded by moisture or when the drug substance is known to be stoichiometric hydrate.
- *Microbial limits*: At the early phase, microbial test limits may not be needed for new drug substances used for solid oral dosage forms. At the late phase of development, a microbial limit is generally required unless a scientific justification can be provided. Appropriate microbial tests and acceptance criteria are based on the nature of the drug substance, method of manufacture, and the intended use of the drug product. Tests may include the total count of aerobic microorganisms, the total count of yeasts and molds, and the absence of specific objectionable bacteria (eg, *Staphylococcus aureus*, *Escherichia coli*, *Salmonella*, *Pseudomonas aeruginosa*). ICH Q6A decision tree #6 provides additional guidance on when microbial limits should be included in the specifications of a drug substance and excipient.

25.3 SPECIFICATIONS FOR CLINICAL TRIAL MATERIALS

In each phase of a clinical investigational program, sufficient information is required to be submitted to the FDA to ensure the proper safety, identification, strength, quality, purity, and potency of the investigational candidate. However, the amount of information to provide varies with the phase and the proposed duration of investigation, and with the amount of information previously available. Specification for clinical trial materials is developed based on these factors: compendial standards, process development studies, and stability of batches used for toxicological/in vivo studies. Often the specification evolves as more manufacturing experience is gained.

25.3.1 Early development stage (Phases 1 and 2)

During early development, safety of the drug for use in clinical trials is the most important factor to consider in determining the specifications. When setting the specification limits for the drug substance, the toxicological lots are the benchmark for future lots. Specifications for impurities in early phase clinical trial materials can be based on the quality of materials used in toxicological studies and the known toxicities of impurities. In addition, intended clinical usage, available clinical data, analytical methods, and process variability should also be considered.

The FDA guideline for Phase 1 investigation[11–13] requires quantitative composition of the product, which includes a brief description of test methods to ensure the identity, strength, quality, purity and potency, test results, or a certificate of analysis. Specified quality attributes should be monitored based on applicable acceptance criteria. For known safety-related concerns, acceptance criteria should be established and met. For some product attributes, all relevant acceptance criteria may not be known at this stage. An impurity profile is recommended to be established to the extent that future reference and/or comparison is possible. However, not all product impurities need characterization at this stage.

During Phase 2 studies, physicochemical tests and microbiological tests that have been added or deleted from the specifications established for Phase 1 studies are required to be reported to the FDA.[14] Physicochemical tests include identity, assay, content uniformity, degradants, impurities, dissolution, and particle size. Data on the particle size distribution and/or polymorphic form of the drug substance used in clinical trial materials should be included so that correlations can be established between data generated during early and late phase drug development and in vivo performance. Relaxation of acceptance criteria or any changes that affect safety should also be reported.

25.3.2 Late development stage (Phase 3)

As development progresses into Phase 3, growing data on batch history, process capability, analytical

capability, and stability become increasingly important in the specification setting. An updated specification with a detailed listing of all the tests performed on the product and the tentative acceptance criteria should be provided to the FDA. Test results and analytical data from batch release of representative clinical trial materials should be provided initially and when any changes are made in the specification. Data on particle size distribution and/or polymorphic form of the drug substance should also be included. Degradation products should be identified, qualified, quantified, and reported. Suitable limits should be established based on manufacturing experience, stability data, and safety considerations. A dissolution testing program or drug release program should be developed for drug products.

Typical Phase 3 specifications for an oral drug product include description, identification, assay, content uniformity of dose units, degradation products, dissolution, water content, and microbiological tests. Additional in-process tests during clinical trial manufacturing of a tablet/capsule dosage form include: dimensions, disintegration, and weight (including hardness and friability for tablet dosage forms). The quality of the product used in these clinical studies will form the basis for product approval and the quality of the registered product has to reflect that of clinical trial materials.

An example of drug product (capsule) specifications at early phase and late phase development is provided in Table 25.4. The example specifications include description, identification, assay, related substances, water, dissolution, uniformity of dosage unit, and microbiological test. The limit for description is based on historical visual appearance data of the drug product. During early phase development, only an IR method is used for an identity test. In late phase development, two identification methods are used (ie, IR and HPLC methods). The upper/lower assay limit is calculated to allow for related substances and assay variability. The limit is typical and the same for early and late phase drug products. Related substances (total related substances and individual related substances) are "to be monitored" during the early phase of development. The limits are established for the late phase after more data became available. The USP limit is used for the uniformity of dose units test. Limit for dissolution is based on the dissolution study in previous historical batches. At the late phase of development, the limit is set at an earlier time point based on the data collected during early phase development.

TABLE 25.4 Example of Specifications for a Capsule Drug Product

Tests	Method	Limits for early phase	Limits for late phase
Description	Visual	White capsule	White capsule
Identity	HPLC	N/A	The retention time of the main peak in the chromatogram of the assay preparation corresponds to that in the chromatogram of the reference standard preparation, as obtained in the Assay testing
Identity	IR	The IR absorption spectrum of the sample preparation exhibits maxima only at the same wavelengths as that of corresponding reference standard	The IR absorption spectrum of the sample preparation exhibits maxima only at the same wavelengths as that of corresponding reference standard
Assay	HPLC	Not less than 90.0% and not more than 110.0% of label claim	Not less than 90.0% and not more than 110.0% of label claim
Related substances	HPLC		
Total related substances		To be monitored	Not more than 1.0%
Individual related substances		To be monitored	Not more than 0.5%
Water	Karl Fischer titration	To be monitored	5%
Uniformity of dosage units	HPLC	Meet USP 38 (2015)	Meet USP 38 (2015)
Dissolution	USP 38 (2015)	$Q = 75\%$ at 45 min	$Q = 75\%$ at 35 min
Microbiological tests	Compendial method	N/A	Meet compendial requirements

25.4 SPECIFICATIONS FOR COMMERCIAL DRUG PRODUCTS

Specifications for commercial drug products, also known as regulatory specifications, are generally documented in a regulatory submission or in a compendial monograph. Commercial drug product must conform to the regulatory specifications throughout its shelf life. Full compliance with the ICH guideline Q6A is expected for commercial drug products' specifications.

Specifications for commercial drug products are refined from late phase specification based on analytical capability, process capability, and product stability. These considerations augment the safety requirements. At the time of registration, the number of stability batches representative of the future commercial batches is often limited, and shelf-life stability testing has not been completed. Statistical extrapolation of limited stability data to the proposed shelf life is necessary. It is important that specifications are not set too tightly, which could result in unnecessary rejection and time-consuming investigations. On the other hand, controlling patients' risk of using products that do not meet requirements should be a top priority. Wessels et al. has proposed a strategy to statistically set an appropriate specification for pharmaceutical products.[15] The authors use linear regression to extrapolate the stability data available at the time of registration. They recommend that a confidence limit of 99% for individual results be used to determine specifications after batch-to-batch variability is tested according to the ICH guideline on stability testing.[16] Patient risk can be controlled by tightening the specification (eg, using a confidence limit of 95% instead of 99%).

The following universal tests described in ICH Q6A for drug product specifications are generally applicable to all new drug products:

- *Description*: A qualitative description of the finished product such as size, shape, and color should be provided.
- *Identification*: Identification testing is able to discriminate between compounds of closely related structures that might be present. Identity tests should be specific for the new drug substance. A single chromatographic retention time, for example, is not deemed specific. However, the use of two chromatographic procedures is acceptable if the separation is based on different principles. The combination of tests into a single procedure such as HPLC/UV diode array, HPLC/MS, or GC/MS is also acceptable.
- *Assay*: Assay methods should determine the drug product strength/content using a specific and stability-indicating method. In cases where use of nonspecific assay is justified, additional supporting analytical procedures should be used to attain overall specificity.
- *Impurities*: Impurities include organic and inorganic impurities, as well as residual solvents. Detailed information can be found in the following ICH guidelines: "Q3B (R2) Impurities in New Drug Products"[17] and "Q3C (R5) Impurities: Residual Solvents."[9] Organic impurities that are degradation products of the new drug substance and process-related impurities from the new drug product should be monitored. Acceptance limits for individual specified degradation products should be established. Table 25.5 provides the identification and qualification threshold. The emphasis is on

TABLE 25.5 Thresholds for Degradation Products in New Drug Products

Maximum daily dose[a]	Reporting threshold[b,c]	Maximum daily dose[a]	Identification threshold[b,c]	Maximum daily dose[a]	Qualification threshold[b,c]
≤1 g	0.1%	<1 mg	1.0% or 5 μg TDI, whichever is lower	<10 mg	1.0% or 50 μg TDI, whichever is lower
		1–10 mg	0.5% or 20 μg TDI, whichever is lower	10–100 mg	0.5% or 200 μg TDI, whichever is lower
>1 g	0.05%	>10 mg–2 g	0.2% or 2 mg TDI, whichever is lower	>100 mg–2 g	0.2% or 3 mg TDI, whichever is lower
		>2 g	0.10%	>2 g	0.15%

[a]*The amount of drug substance administrated per day.*
[b]*Thresholds for degradation products are expressed either as a percentage of the drug substance or as total daily intake (TDI) of the degradation product. Lower thresholds can be appropriate if the degradation product is unusually toxic.*
[c]*Higher reporting thresholds should be scientifically justified.*

impurities arising from drug product manufacture or from degradation. The impurity profiles of batches representative of the proposed commercial process should be compared with the profiles of batches used in development, and any differences should be discussed. The specifications of the new drug product for impurities should be consistent with the ICH Q3B guideline, which include, where applicable, limits for:

- Each specified identified degradation product
- Each specified unidentified degradation product
- Any unspecified degradation product, with a limit of not more than the identification threshold
- Total degradation products

The following additional tests described in the ICH Q6A are specific to solid oral drug products:

- *Dissolution*: Dissolution testing measures the rate of release of the drug substance from the drug product using a specific apparatus. Specification of dissolution should be set based on the data of bio-batches. Analysis of the quantity of drug released at a single time point is commonly used for immediate release (IR) formulations when the drug substance is highly soluble. On the other hand, appropriate test conditions and sampling procedures should be established for modified release formulations. Multiple time point sampling is appropriate for IR products of poorly soluble compounds and for extended or delayed release formulations (see ICH Q6A decision tree 7(1)). In cases where changes in dissolution rate have been demonstrated to significantly affect bioavailability, testing conditions that can discriminate between acceptable and unacceptable bioavailability are desirable (see ICH Q6A decision tree 7(2)). In vitro–in vivo correlation may be used to establish acceptance criteria for extended release drug products when human bioavailability data are available for formulations exhibiting different release rates. Acceptance criteria should be established based on available batch data when bioavailability data are not available and drug release is not shown independently of in vitro test conditions. The variability in mean release rate at any given time point should not exceed a total numerical difference of $\pm 10\%$ of the labeled content of the drug substance unless a wider range is supported by a bioequivalency study (see ICH Q6A decision Tree 7(3)).
- *Disintegration*: Disintegration testing can be substituted for dissolution for rapidly dissolving products containing drugs that are highly soluble throughout the physiological pH range. Disintegration is most appropriate when a relationship to dissolution has been demonstrated or when disintegration is shown to be more discriminating than dissolution (see ICH Q6A decision tree 7(1)).
- *Hardness/friability*: Hardness/friability testing is usually performed as an in-process control. The test should be included in the specification only when the characteristics of hardness/friability have a critical impact on product quality (eg, chewable tablets).
- *Uniformity of dosage unit*: Testing the uniformity of dosage units includes measurement of both the mass of the dosage form and the content of the active ingredient in the drug product. Pharmacopoeial methods should be used. Often this test is performed as an in-process evaluation. In Dec. 2011, USP published an alternative condition that allows hard capsules, uncoated tablets, and film-coated tablets not meeting the 25 mg/25% requirement to be tested by the weight variation procedure if the relative standard deviation of the drug substance in the final dosage unit is not more than 2% demonstrated in process validation or development data. In Jun. 2014, the FDA issued Guidance for Industry, Q4B Evaluation and Recommendation of Pharmacopoeial Texts for Use in the ICH Regions Annex 6 Uniformity of Dosage Units General Chapter.
- *Water content*: A quantitation procedure that is specific for water is preferred (eg, Karl Fischer titration). A loss on drying procedure may be adequate in some cases. Acceptance criteria should be based on data regarding the effects of hydration or water absorption on the drug product. Table 25.6 shows a water specification of not more than 7% for an example tablet product. The water in this product is mainly contributed by the water of hydration from excipients. Primary stability data indicate that the packaged tablets absorb water under the long-term storage condition. Based on the stability data, the absolute change through the expiration-dating period and uncertainty in the estimated change are statistically computed. The water specification of not more than 7% is then established based on the process capability, change, and uncertainty of the change estimated from the stability data, as well as the method variation.
- *Microbial limits*: The type of microbial testing and acceptance criteria used should be based on the nature of the drug, method of manufacture, and the intended use of the drug product. Such testing may not be necessary with acceptable scientific justification (see ICH Q6A decision tree 8).

TABLE 25.6 Example of In-House Release and Regulatory Specification for a Tablet Product

Tests	Method	In-house release limits	Regulatory limits
Description	Visual	Colored, shaped, and debossed tablet	Colored, shaped, and debossed tablet
Identity by IR	IR	The IR absorption spectrum of the sample preparation exhibits maxima only at the same wavelengths as that of corresponding reference standard	The IR absorption spectrum of the sample preparation exhibits maxima only at the same wavelengths as that of corresponding reference standard
Identity by HPLC	HPLC	The retention time of the main peak in the chromatogram of the assay preparation corresponds to that in the chromatogram of the reference standard preparation, as obtained in the Assay testing	The retention time of the main peak in the chromatogram of the assay preparation corresponds to that in the chromatogram of the reference standard preparation, as obtained in the Assay testing
Assay	HPLC	Not less than 97.0% and not more than 106.5% of label claim	Not less than 90.0% and not more than 110.0% of label claim
Related substances	HPLC		
Total related substances		Not more than 1.09%	Not more than 2.0%
Individual related substances		Not more than 0.52%	Not more than 1.0%
Water	Karl Fischer titration	Not more than 3.8%	Not more than 7.0%
Uniformity of dose units	HPLC	Meet USP 38 (2015)	Meet USP 38 (2015)
Dissolution	USP 38 (2015)	$Q = 75\%$ at 30 min	$Q = 75\%$ at 30 min

25.4.1 Product in-house release specifications and regulatory specifications

Regulatory specifications are legal commitments that a commercial product must conform to throughout its shelf life. In order to meet the regulatory specification, more restrictive in-house release specifications are commonly established for drug products. For examples, tighter assay and impurity (degradation product) in-house release limits can be established to ensure that a product can meet regulatory specifications at the end of its shelf life. In Japan and the United States, the concept of release specification may only be applicable to in-house criteria, and not to the regulatory release criteria. In these regions, the regulatory acceptance criteria are the same from release throughout shelf life. However, many companies choose to have tighter in-house limits at the time of release to provide assurance that the product will remain within the regulatory acceptance criterion throughout its shelf life. In the European Union, distinct specifications for release and for shelf life are a regulatory requirement.

Degradation of drug product needs to be factored into specification setting, particularly for analytical properties (eg, potency and impurities) that are affected by the degradation. The in-house release limits for quantitative analytical properties can be calculated from regulatory limits based on the stability change (increase or decrease) and the measurement variability. The calculated in-house release limits are narrower than regulatory limits to compensate for measurement variability and/or product instability. The buffer between regulatory limit and in-house limit typically consists of the estimated absolute change through the expiration-dating period (change), uncertainty in estimated change (S_{change}), and measurement variation (S_{m}).

For an analytical property that degrades during storage, the upper and lower in-house limits (UL and LL) can be calculated from upper and lower regulatory limits (URL and LRL) using the following equations. Allen et al. used a similar equation to calculate the setting of in-house limits for a product that degrades during stability storage.[18]

$$UL = URL - t \times \sqrt{S_{\text{m}}^2}$$
$$LL = LRL + \text{Change} + t \times \sqrt{S_{\text{change}}^2 + S_{\text{m}}^2}$$

Where, t is determined from a t-table using appropriate degree of freedom and level of confidence.

For an analytical property that increases during stability storage, the UL and LL can be calculated from URL and LRL using these equations:

$$UL = URL - \text{Change} - t \times \sqrt{S_{\text{change}}^2 + S_{\text{m}}^2}$$
$$LL = LRL + t \times \sqrt{S_{\text{m}}^2}$$

For an analytical property absent of instability, the buffer between in-house limits and regulatory limits typically consists of measurement variability only.

An example of in-house release and regulatory specification for a tablet product is provided in Table 25.6. The assay limits in Table 25.6 are based on the safety, efficacy, process variability, and assay variability. The upper/lower in-house release limits for assay are calculated to protect against exceeding the regulatory limits from stability and assay variability. The regulatory limits of not more than 1.0% of any individual related substance and not more than 2.0% of total related substances are the same for drug substance because there is not significant degradation observed during drug product manufacturing process. The UL/LL are calculated based on stability and assay variability to protect the regulatory limits.

25.4.2 Product stability and expiration date

Once specifications are set, the expiration-dating period of a drug product is then established based on the stability data obtained from long-term stability studies. The FDA guideline[16] requires that at least three batches be tested to allow for a good estimate of batch-to-batch variability. Stability data from all batches should be combined to estimate an expiration-dating period for a drug product. Batch similarity should be tested before all stability data are combined for statistical analysis. Batch similarity is examined by testing the similarity of intercepts and slopes of degradation lines from different batches. If the hypotheses of comparable intercepts and slopes are not rejected at the 0.25 level of significance, the expiration-dating period can be estimated based on the pooled stability data of all batches. On the other hand, if the hypotheses of comparable intercepts and slopes are rejected at the significance of 0.25, the expiration-dating period should be estimated based on the shortest expiration-dating period calculated from the worst batch.

An estimate of an expiration-dating period is illustrated in the following example: four different batches (ie, Lots A, B, C, and D) of a single tablet formulation were placed on long-term stability. Lot B completed 36-month stability. Lots A, C, and D completed 24-month stability. The analysis assumes that zero-order change (linear modeling on the original data scale) is appropriate. Before pooling the data from the four lots to estimate the shelf life, a preliminary statistical test was performed to determine whether the regression lines from different lots have a common slope and/or time zero intercept. The statistical model with the effects of age, lots, and age × lots was used. The probability associated with the interaction term age × lots was 0.0063, which is smaller than 0.25. This indicates that there is sufficient evidence that the slopes across lots are statistically different and the prediction for each lot must be evaluated separately. The individual slope and 95% confidence intervals for each lot are then estimated. The values for both the upper and lower confidence intervals were compared with the regulatory specifications of 95−105%. The confidence interval with the shortest expiry dating was identified as Lot A. The projected expiration-dating period of Lot A supports the 36-month dating. Therefore the expiration-dating period of the product is set at 36 months.

For more details on shelf life determination, readers should refer to chapter "Statistical Design and Analysis of Long-Term Stability Studies for Drug Products."

25.5 PROCESS CONTROL FOR SOLID ORAL DRUG PRODUCTS

Process control is an all-inclusive term used to describe the controls used during production to monitor and, if appropriate, adjust the process, and/or to ensure that an in-process material with an established specification or the finished drug product will conform to its respective specification.[2] By using quality by design principles during process and product development, a robust process can be developed. Per ICH Q8(R2) and Q9, the relationship between critical process parameters and CQAs are obtained, and the acceptable operating ranges are established during process development. Using this established operating range of process parameters; the product meeting required quality attributes can be produced. As stated in ICH Q8(R2), working within this operating range of process parameters is not considered a change because it still produces the product meeting required quality attributes. This chapter will not discuss how to establish the ranges for process parameters. Four types of process controls are:

- *Operating parameters*: Conditions that can be adjusted to control the manufacturing process (eg, temperature, pH, mixing time, and mixing speed)
- *Environmental controls*: Conditions associated with the manufacturing facility (eg, facility temperature, humidity, clean room classification)
- *Process tests*: Measures used to monitor and assess the performance of the process (eg, product temperature or exhaust temperature during drying in fluid-bed drier)
- *In-process material tests*: Measures used to assess the quality attributes of an in-process material and ultimately decide to accept or reject the in-process material or drug product

Steps in the manufacturing process should have the appropriate process controls identified. All in-process material tests and any of the operating parameters,

environmental conditions, and process tests that ensure each critical manufacturing step is properly controlled should be established in order to meet the predetermined specifications of the final drug product. All critical process controls and their associated ranges, limits, or acceptance criteria should be identified and justified by experimental data. For critical operating parameters and environmental controls, numeric ranges, limits, or acceptance criteria typically can be based on the experience gained during the development of the manufacturing process.

25.5.1 In-process material tests and quality attributes

In-process material tests are one of the critical components of the process controls. They may be performed during the manufacture of drug substance or drug product, rather than as part of the formal battery of tests that are conducted prior to product release.[1] In-process tests that are only used for the purpose of adjusting process parameters within an operating range (eg, hardness and friability of tablet cores that will be coated and individual tablet weight) are not included in the specifications. Table 25.7 lists typical in-process material tests for solid oral dosage forms.

The process material tests directly assess the quality attributes of the in-process materials. Quality attributes are important chemical, physical, and microbiological properties or characteristics of the drug product and intermediate material that must be maintained for proper product performance. Quality attributes of the process are those process parameters that are controlled to ensure the process reproducibly meets the drug product quality attributes. These attributes are identified during product and process development and become the basis for ensuring the control of product quality.

During the compression/encapsulation process, in-process material testing is performed on solid oral dosage forms to assure consistency throughout these unit operations. Moisture content is typically performed for granules before tableting and encapsulation. Tablet weights, hardness, thickness, friability, and disintegration testing are typically performed for tablets. Weight testing is performed for capsules. Hardness and disintegration specifications are established during development and bio-batch production. Testing performed during commercial production is to demonstrate both comparability and consistency.

All in-process material tests are critical process controls because they directly assess the quality attributes of an in-process material and ultimately lead to a decision to accept or reject the in-process material or drug product. Well-defined proven acceptable ranges (PARs) should be established for these tests, so that the impact on product quality of operating outside the PARs is understood or can be predicted. Data from in-process tests should be routinely evaluated. Statistical tools such as control charts can be used to aid the evaluation process.

TABLE 25.7 Examples of In-Process Tests for Solid Oral Dosage Forms

Process step	In-process tests	Effects on process and quality attributes
Drying in wet granulation	Loss on drying	• Product stability
Blending/mixing	Blending uniformity	Uniformity of dose unit
Blending/mixing	Particle size distribution	Uniformity of dose unit
Blending/mixing	Bulk and tapped density[a]	Uniformity of dose unit
Blending/mixing	Flow ability	Uniformity of dose unit
Tablet compression	Weight	Uniformity of dose unit
Tablet compression	Thickness	Disintegration/dissolution
Tablet compression	Hardness	• Coating quality • Disintegration/dissolution
Tablet compression	Friability[b]	• Coating quality • Potency • Shipping
Capsule filling	Weight	Uniformity of dose units
Capsule filling	Joint length	Shipping (breakage due to improper lock) Packaging (blistering)
Tablet/capsule	Disintegration	Dissolution

25.5.2 Powder blending uniformity

Powder blending is a fundamental process of mixing for solid dosage forms to ensure the content uniformity of final drug products.[19–21] Current GMPs in 21CFR PARTS 210 and 211 state "such control procedures should include adequacy of mixing to assure uniformity and homogeneity." In 2003, the FDA issued a guidance document on powder blends and finished dosage units to promote a science-based policy and regulatory enforcement.[22,23] The guidance

described the procedure for assessing powder-mix adequacy, correlating in-process dosage unit test results with powder blend test results, and establishing the initial criteria for control procedures used in routine product manufacturing. However, in Aug. 2013, the FDA withdrew the draft guidance document for industry, Powder Blends and Finished Dosage Units—Stratified In-Process Dosage Unit Sampling and Assessment. The guidance document was withdrawn because sections V and VII of the guidance document no longer represented the FDAs current opinion.[24] Section V (Exhibit/Validation Batch Powder Mix Homogeneity) recommended that at least 3 replicate samples be taken from at least 10 different locations in the powder blender, but only 1 of the 3 replicates be evaluated to assess powder blend uniformity. The FDA currently prefers that all replicate samples taken from various locations in the blender be evaluated in order to demonstrate the homogeneity of powder blend by using a statistically valid analysis. The acceptance criteria for Section VII (Routine Manufacturing Batch Testing Methods) were based on the limits published in the United States Pharmacopeia (USP) General Chapter <905> Uniformity of Dosage Units. However, the results should not be extrapolated to a larger population since USP <905> does not use a statistical sampling plan. The procedure and acceptance criteria in Section VII provided only limited statistical assurance that batches of drug products met appropriate specifications and statistical quality control criteria. Therefore, the FDA does not support the use of the results for batch release. The withdrawal of the document resulted in some uncertainty for manufacturers; however, manufacturers can still demonstrate blend uniformity as required per GMP using science and risk-based approach. The FDA recommends that ASTM E2709,[25] "Standard Practice for Demonstrating Capability to Comply with as Acceptance Procedure" and ASTM E2810,[26] "Standard Practice for Demonstrating Capability to comply with the Test for Uniformity of Dosage Units" should be used for application such as blend uniformity and uniformity of dosage unit. International Society for Pharmaceutical Engineering (ISPE) recently sponsored Blend Uniformity and Content Uniformity Working Group published recommendations for the assessment of blend and content uniformity with modifications to withdrawn FDA draft stratified sampling guidance.[27] The ISPE article focuses on statistical analyses assuming traditional sampling and analytical techniques that are widely used in the pharmaceutical industry for the assessment of blend and dosage unit uniformity. It recommends that statistical approaches and acceptance criteria including the level of confidence and coverage associated with the method should be selected using a risk-based approach that balances consumer's and manufacturer's risks, and other factors such as the therapeutic index of the drug. Two statistical approaches that may be used are the ASTM E2709/E2810 method and tolerance interval approach. The paper also links testing of blend and content uniformity with three stages of validation throughout product life cycle, including process design, process qualification, and continued process verification stages.

Powder blend uniformity is a process control (ie, in-process material test) that critically impacts the uniformity of dosage form. In-process sampling and testing is essential to determine blend uniformity. The sampling method and technique is crucial to obtain samples that adequately represent the powder mix. The traditional sampling device is a powder sample thief. However, certain sampling techniques may falsely introduce significant variations. The orientation, angle, and depth of sampling thief insertion, as well as insertion force and smoothness, impact the consistency of the sampling. Potential powder segregation during powder transfer and storage, and powder properties (eg, flowability, particle size distribution, and density) also add to the challenge of obtaining representative in-process samples. Therefore, the reliability of the sampling method should be evaluated as part of analytical methods development if a thief sampling method is used. The FDA encourages pharmaceutical companies to adopt a science and risk-based sampling approach, as well as more innovative technology such as PAT and statistical process control to ensure powder blend uniformity. To address sampling variations, the FDA recommends the use of a stratified sampling scheme when the batch contains locations that may have different results for a measured quality characteristic. Stratified sampling is the process of collecting a representative sample by selecting units deliberately from various identified locations within a lot or batch, or from various phases or periods of a process. With stratified sampling, a sample dosage unit is obtained to specifically target locations throughout the compression/filling operation that have a higher risk of producing failing results in the finished product tests for uniformity of content. This sampling method allows for collection and analysis of powder samples and dosage unit samples. Between- and within-location variability in the powder blend is a crucial component of finished product homogeneity and quality. The sampling and testing should demonstrate that no differences exist between locations in a powder blend that could adversely affect finished product quality. The sample variability can be attributed to either the blend's lack of uniformity or sampling error. Significant within-location variance in the

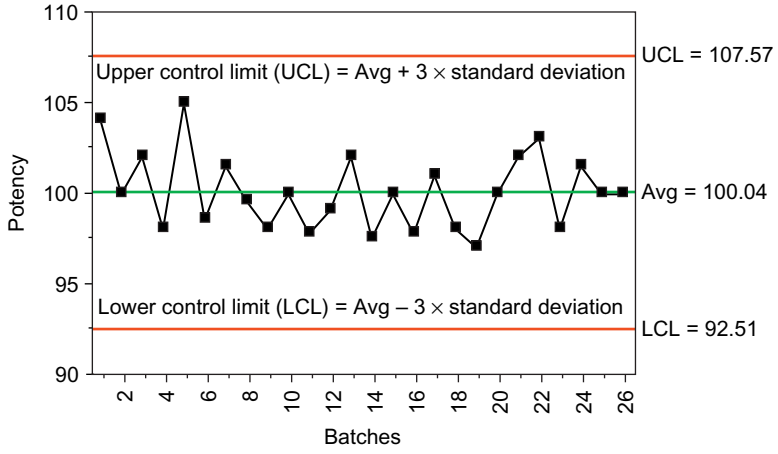

FIGURE 25.1 Example of control chart.

blend data represents sampling error, while high between-location variance in the blend data and high variance over time of one location can indicate that the blending operation is either inadequate, or sampling is biased, or the combination of inadequate mixing and sampling bias.

25.5.3 Statistical methodology for process control

In-process material testing results can be graphed in a control chart for routine evaluation. A control chart is a line graph displaying the results of repeated sampling of a process over time together with the control limits statistically established from historical process data. Control charts are commonly used to monitor the quality attributes and process stability. Control charts are one of the most important and effective statistical tools for quality control to monitor the process performance and trend detection. They can be applied for both in-process testing and finished product testing.

Process variability is the result of common cause variation and special cause variation. Common cause variation is a normal and consistent variation that occurs regularly. It is the random fluctuation expected in testing and follows a predictable distribution over time. The following are some examples of common cause variations:

- Environmental (eg, humidity, temperature) changes
- Baseline noise caused by regular electric interference
- Normal drift in a balance

Special cause variation is inconsistent and abnormal variation. It happens infrequently, and is an unexpected event. The only way to reduce special-cause variation is to investigate its cause and then implement countermeasures to prevent the cause from reoccurrence. The following are some of examples of special cause variations:

- Power outages causing changes in stability chamber storage conditions
- Equipment failure
- Incorrectly prepared stock standard in analysis

An example of a control chart is provided in Fig. 25.1. The centerline of the graph indicates the mean. The control limits typically include mean (μ) and $3\times$ standard deviation (σ) lines. The control chart limits represent the common variation of a process and are established from historical data. If process data are approximately normal, approximately 99.73% of the data will be located within ± 3 standard deviation from the process mean. Values falling outside of these limits are alarming signals because statistically individual values from a normal distribution will be within 3.0 standard deviations of the mean 99.73% of the time. If a process is only subject to common cause variation, a value more than three times the standard deviation is highly unlikely (only 2.7 occurrences per 1000 observations). Therefore, a value outside of control chart limit can be considered an indication of special cause variation. An example of control chart with a value outside of limit is provided in Fig. 25.2.

In addition to a value outside of control chart limits, special cause variation is shown by one or more of the following common out-of-control alarms[28]:

- 7 sequential points are on one side of the mean (a run)
- 7 sequential points increase or decrease steadily (a trend)

A run of 7 is probably not random statistically, assuming the observed values are from a normal distribution. The probability of 7 consecutive values being below the mean is $(1/2)^7 = (1/128) = 0.8\%$. The occurrence of such an event often suggests that the process

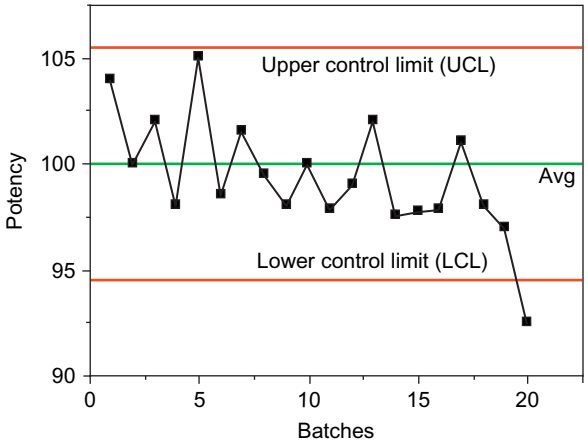

FIGURE 25.2 Example of control chart with a value outside of the limit.

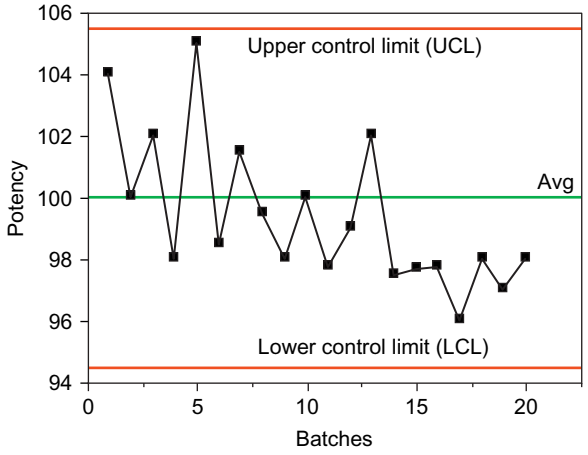

FIGURE 25.3 Example of control chart with 7 or more sequential points on one side of the mean.

should be carefully investigated. An example of control chart with 7 or more sequential points on one side of the mean is provided in Fig. 25.3.

The goal of control charting is to separate variability into common-cause and special-cause, with the knowledge that special-cause variability can be addressed and eliminated.

When a control chart alarm is observed, an investigation should be performed to identify the assignable cause.

25.5.4 PAT and in-process controls

The FDA's PAT Guidance[29] and 21st Century GMP Initiatives[30] promote a technology-based regulatory environment that encourages the pharmaceutical industry to implement innovative development, manufacturing, and quality assurance practices. The agency is encouraging the industry to utilize science and engineering-based principles to characterize and understand their processes. With this understanding, a manufacturing process is expected to become more efficient, consistent, and robust, providing the scientific rationales for the development of product specifications. For characterization and control purposes, PAT is a promising technology platform to accomplish these goals.

A PAT platform consists of an automated analyzer system that is integrated with process equipment for operation in a manufacturing environment. The system is capable of generating, analyzing, displaying, and transmitting product and process trend data continuously as a process unit operation is executed. For example, PAT can be used to monitor the critical unit operations of drying and blending to ensure optimal product dryness and the uniformity during blending to allow a homogenous blend for forward processing. This results in a more consistent product quality, faster forward processing and batch release. Wildfong et al. demonstrated that near-infrared (NIR) can be used to monitor the moisture content of the granules as they dry in real time.[31] Frake et al. showed that continuous in-line NIR monitoring of water content and particle size data are suitable means of process control and end-point determination for a fluid-bed granulation drying process.[32] Hailey et al. also demonstrated that NIR spectroscopy interfaced with process equipment and in combination with a fully automated system, can be used for real-time on-line powder blend homogeneity analysis.[33]

PAT can also be used in finished product analysis. Cogdill et al. developed and validated NIR models for the analysis of API content and hardness of tablets.[34] Spencer et al. demonstrated the feasibility of predicting active drug content in commercial-grade pharmaceutical tablets by NIR spectroscopy.[35] A PAT platform of at-line or in-line tablet analysis provides early warning in case of problems. It also offers a near real-time confirmation that the finished product is in compliance with product specifications. More detailed discussions of PAT and real-time release testing applications in the development and commercial manufacturing of oral dosage forms are provided in chapter "Commercial Manufacturing and Product Quality" of this book.

25.6 ANALYTICAL PROCEDURES

Analytical procedures evolve with the course of the product development. Analytical procedures may also change as knowledge of process controls (eg, what the critical impurities are) increases. Comparability of

results from changed analytical procedures must be considered during specification setting. It is important to confirm that data generated during development correlate with those generated at the time NDA is submitted.

An appropriate performance of the analytical procedures is critical for specification setting. For potency assay, the variability of the procedure must be taken into account for the specification setting in addition to the primary concern of patient safety and batch-to-batch variability. An intermediate precision study may be used as an estimate for the assay variability. For impurity and residual solvent testing, the requirements are outlined in the ICH guidelines.[8,9,17] The testing procedure must be able to determine the levels of impurities with appropriate accuracy and precision. For a specification limit of 0.1% for unknown impurities, the ICH reporting threshold of 0.05% can be used as the required quantitation limit to provide a reliable quantitation at the specification limit. For impurities with potential toxicity, toxicology should be consulted early in the drug development process to ensure methods with appropriate detection limits are developed and validated.

Analytical procedures must be validated for setting specifications. The performance and validation of a particular analytical procedure is influenced by other testing procedures used in setting the specification because a drug substance or drug product is tested by a set of complementary and supplementary testing procedures. It may not be necessary to optimize an individual analytical procedure to its best performance as long as it, together with other testing procedures, adequately tests the drug substance or product.

Validation of analytical procedures is an important part of the registration application for a new drug. chapter "Analytical Development and Validation for Solid Oral Dosage Forms" of this book discusses development and validation of analytical procedures in more detail.

25.7 CONCLUSIONS

Specifications are based on relevant development data, pharmacopoeial standards, test data of drug substances and drug products used in toxicology and clinical studies, and results from accelerated and long-term stability studies. In addition, analytical and manufacturing variability should be taken into consideration. Since specifications evolve through development and commercialization phases, specifications should be evaluated and updated periodically as additional data become available. Rationale for changes to specifications must be scientifically sound, and documented to allow traceability to previous versions.

To ensure specifications are met and product quality attributes are maintained, process controls must be identified, implemented, and effectively controlled during the manufacturing process.

Setting specifications is to establish the quality criteria for drug substance and product. The quality of drug product cannot be tested into the product. Instead quality should be built in by design. Setting proper specifications and maintaining effective process controls requires mechanistic understanding of how formulation and process design impact product quality and performance. Using science-based and risk-based approaches, the knowledge gained during different phases of development can be used to justify the tests and criteria in specifications to ensure the safety, efficacy, and quality of drug substances and products.

Process Development, Optimization, and Scale-Up: Providing Reliable Powder Flow and Product Uniformity

T. Baxter and J. Prescott

Jenike & Johanson, Inc., Tyngsboro, MA, United States

26.1 INTRODUCTION

Objective of the chapter

The primary focus of this chapter is to provide guidance in designing bulk solids (powder) handling equipment to provide consistent, reliable flow, and the required product uniformity by minimizing segregation. The principles discussed in this chapter can be applied to analyzing new or existing equipment designs. These principles can also be used to compare different powders, using the various test methods discussed.

The chapter will focus on the equipment used from the final blend step to the inlet of the press/encapsulation machine used to create the unit dose. This chapter is divided into these primary topics:

26.1. Introduction: A review of introductory concepts, such a flowability, blending, and segregation

26.2. Common Powder Handling Equipment: A description of the common handling equipment, and the equipment parameters that affect powder flow and product uniformity (segregation potential)

26.3. Typical Flow and Segregation Concerns: A review of common flow and segregation concerns, and the two primary flow patterns (mass flow vs funnel flow)

26.4. Measurement of Flow Properties: A summary of the flow properties that need to be measured to obtain the equipment design parameters required for consistent, reliable flow

26.5. Basic Equipment Design Techniques: A review of the basic design techniques for the blender-to-press equipment to provide reliable flow, and minimize the adverse effects of segregation

At the end of this chapter, the reader should have a working knowledge of what flow properties need to be measured, how to measure them, and how to apply them to analyze or design handling equipment for reliable flow, as well as to minimize segregation.

Motivation for the chapter

Many pharmaceutical processes include powder handling, such as blending, transfer, storage, feeding, compaction, and fluidization. A full understanding of powder flow behavior is essential when developing, optimizing, or scaling-up a process. This may include designing new equipment or developing corrective actions for existing equipment for a batch or continuous manufacturing process. There are several instances where the robustness of a process is adversely affected by flow or segregation problems that develop.

Common flow and segregation problems can have an adverse effect upon:

1. Production costs, due to reduced production rates (eg, tableting rate limitations, required operator intervention), restrictions on raw ingredient selection (eg, percentage of lubrication used, excipients selected), method of manufacturing (wet granulation vs dry granulation vs direct compression), equipment selection (type of blender, bin, press), and overall yield;

Developing Solid Oral Dosage Forms
DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00026-1

2. Product quality due to variation of tablet properties (weight, hardness, etc.) or segregation and content uniformity concerns; and
3. Time to market, due to delays in product/process development and failed validation or commercial batches because flow problems may not occur until the process has been scaled-up.

This chapter primarily focuses on batch processes, but provides comments on continuous manufacturing process where pertinent.

26.1.1 Introduction to flowability

A bulk solid is defined as a collection of solid particles. The term "powder" is often used to describe a fine bulk solid, especially in the pharmaceutical industry. This common term will be used predominantly throughout this chapter. The concepts discussed in this chapter apply to many types of powders with different particle sizes, shapes, and distributions. The powders may include dust, granulations, and granules. The powder could either be a single substance, such as an excipient or active pharmaceutical ingredient (API), or a multi-component blend (final blend). As the pharmaceutical industry begins to adopt more continuous manufacturing of solid oral dosages, reliable feed of the individual blend components, including the API, will be more critical. The principles outlined in this chapter can be used to design for all these different types of powders.

A simple definition of "flowability" is the ability of a powder to flow through equipment reliably. By this definition, there is often a tendency to define flowability as a single parameter of a powder, ranked on a scale from "free-flowing" to "nonflowing." Unfortunately, a single parameter is not sufficient to define a powder's complete handling characteristics. In addition, a single parameter is insufficient to fully address common handling concerns encountered by the formulator and equipment designer. In fact, several design parameters may need to be known for a successful design. The behavior of a powder will depend upon several different parameters or "flow properties." Flow properties are the specific properties of a powder that affect how flow that can be measured. Therefore, a full range of flow properties will need to be measured to fully characterize the powder. Section 26.4 discusses the measurement of these flow properties.

In addition, the "flowability" of a powder is a function of the powder's flow properties and the design parameters of the handling equipment. For example, "poor flowing" powders can be handled reliably in properly designed equipment. Conversely, "good flowing" powders may develop flow problems in improperly designed equipment. Our definition of "flowability" is, therefore, "the ability of powder to flow in the desired manner in a specific piece of equipment."

The flow properties of the powder should be quantitative and scalable design parameters. The term "flow properties" often refers to the physical characteristics of the powder that were measured. For example, one might report "the tapped density of a final blend was measured to be 0.6 grams per cubic centimeter." The term "powder flow" often refers to an observation of how the powder flowed through a given piece of equipment. For example, one might report "the powder flow through the press hopper was consistent." In discussing or reporting flowability, both the powder flow properties and the handling equipment must be included. Therefore, the measurement of the powder flow properties can be used to predict behavior in specific equipment during scale-up.

The flow properties that should be measured (Section 26.4), and how to apply the results to a reliable equipment design (Section 26.5), will be discussed in this chapter.

26.1.2 Introduction to blending

Solid blending processes are used during the manufacture of products for a wide range of industries, including pharmaceuticals. In the pharmaceutical industry, a wide range of ingredients may be blended together to create the final blend used to manufacture the solid dosage form. The range of materials that may be blended (excipients, API), presents a number of variables that must be addressed to achieve products of acceptable blend uniformity. These variables may include the particle size distribution (PSD) (including aggregates or lumps of material), particle shape (spheres, rods, cubes, plates, and irregular), presence of moisture (or other volatile compounds), particle surface properties (roughness, cohesivity), and many other variables.

The quality of the solid dosage form depends on the adequacy of the blend. Producing a uniform mixture of the drug and its excipients is paramount for being able to deliver the proper dose of the drug to the patient. Once an adequate blend is obtained, it is also critical to ensure that it does not segregate in the post-blending handling steps. Millions of dosage units may be created from a single batch, and each and every dose must be of acceptable composition to ensure the safety and efficiency of the product. Therefore, the homogeneity of pharmaceutical blends and dosage units is highly scrutinized by both manufacturers and regulatory bodies worldwide. Formulation components and process parameters involved with blending operations should be carefully selected, and validated,

to ensure uniform blends and dosage units are produced. Blend and dosage unit uniformity data is provided in regulatory submissions, and often examined during preapproval inspections. This is to ensure that blending processes produce homogeneous blends that do not segregate upon further processing into dosage units. Finally, pharmacopeias require an assessment of content uniformity to be performed on every batch of solid dosage forms manufactured.

The scale of blending operations for the preparation of pharmaceutical dosage forms ranges from the extemporaneous compounding of a few capsules by pharmacists, to large-scale production of batches containing millions of dosage units. The complexity of the blending process can vary substantially. Large-scale production batches often use equipment capable of blending hundreds of kilograms of material. Continuous blending operations require not only the mixing components within the blender itself, but also controlled feed of the incoming material, and monitoring, feedback, and control systems. Depending on the dose and characteristics of the drug substance, commercial-scale blending processes can be complex, and may require screening operations, the preparation of pre-blends, and/or the inclusion of milling operations to achieve acceptable content uniformity. Regardless of the scale of manufacture, the goal remains the same: to prepare a blend that is adequately blended, and can be further processed into dosage units that deliver the proper dose of the drug to the patient.

Blending should not be seen as an independent unit operation, but rather as an integral part of the overall manufacturing process. Blending includes producing an adequate blend, maintaining that blend through additional handling steps, and verifying that both the blend and the finished product are sufficiently homogeneous. Therefore, a complete approach should be used to assess the uniformity of blends and the subsequent dosage forms produced from them.

A review of the common types of blenders is provided in Section 26.2 and the details of scaling-up common final blending process steps (wet granulation, fluid-bed granulation, roller compaction) are discussed in other chapters.

26.1.3 Introduction to segregation

"Segregation" can be defined as having particles of similar properties (ie, size, composition, density, resiliency, static charge, etc.) preferentially distributed into different zones within given equipment or processes. Segregation most notably affects the localized concentration of the drug substance. This can result in blend and content uniformity problems. In addition, the segregation of other components of the blend can be responsible for variations in properties such as dissolution, stability, lubrication, taste, appearance, and color. Even if the blend remains chemically homogeneous, variations in particle size can affect flowability, bulk density, weight uniformity, tablet hardness, appearance, and dissolution. In addition, segregation can create concentrations of dust, which can lead to problems with agglomeration, yield, operator exposure, containment, cleanliness, and increased potential for a dust explosion. Segregation can occur in a batch or continuous manufacturing process.

Segregation can occur any time there is powder transfer, such as when discharging the final blend from the blender into a bin. Segregation can also occur when forces acting on the particles in the blend, such as air flow or vibration, are sufficient to induce particle movement. This may include handling steps upstream of a blender, including segregation of raw materials at a supplier's plant or during shipment, movement within the blender, during its discharge, or in downstream equipment. Of all of these potential instances where segregation can occur, the most common area for issues is post-blender discharge. Therefore, this chapter will focus on segregation of the final blend in the post-blending handling steps.

The current state of understanding segregation is limited to empirical descriptors of segregation mechanisms (see Section 26.4), and prior experiences with diagnosing and addressing specific segregation behaviors (Section 26.5). Unlike the flow properties tests used to assess how a powder flows though equipment, there are no current "first principle" models that adequately describe the various segregation mechanisms that may occur in a process. Therefore, one cannot currently input the particle properties of the blend components (eg, particle size and chemical composition of the excipients, and API) into a mathematical model, and obtain a prediction of segregation potential and the resulting content uniformity of the product. However, as computational models, such as discrete element modeling, continue to evolve they will able to be tuned to match specific segregation behaviors that are created in physical models to gain further insight into blending and segregation behavior. As these models evolve, they will become more powerful and have fewer assumptions and limitations. When assessing segregation concerns, it is critical to utilize as many resources as possible, such as laboratory-scale tests, to assess different segregation mechanisms (Section 26.4) and stratified blend and content uniformity data to assess potential segregation trends.

The empirical tests that can be conducted to assess the segregation potential of a final blend (Section 26.4), and how to apply the results to a reliable equipment design (Section 26.5), are discussed later in this chapter.

26.2 COMMON POWDER HANDLING EQUIPMENT

Objective of the section

The primary objective of this section is to describe the common powder handling equipment used in pharmaceutical processes. This section will also define common terms for powder handling equipment, and provide background for Section 26.3 of this chapter, which will focus upon typical flow and segregation problems.

We will review the common handling equipment and process steps that may affect the flowability and segregation of a powder. In particular, we will review the process steps for the final blend used to manufacture the dosage units commonly used in a batch process, including:

1. processing steps prior to final blending, such as milling, screening, drying, and granulation;
2. final blending;
3. discharge from the final blender;
4. intermediate bulk containers ("IBCs," "totes," bins, drums);
5. transfer from the IBC to the press (or encapsulator); and
6. feed from the hopper to the die cavity or dosator.

As continuous manufacturing in the pharmaceutical industry continues to become more common, different processing equipment may become more crucial, such as reliable feed and metering of the API, but the equipment terms outlined in this section will still often apply to understanding how powders flow. For each of these different process steps, we will review the key equipment parameters that affect the flowability and segregation of a powder. These typical handling steps serve as examples of the concerns with powder handling, but virtually any solids handling application can be analyzed in the same way.

26.2.1 Processing steps prior to final blending

It is critical to understand the physical properties of the raw ingredients (API, excipients), and how they affect the flowability and segregation of the final blend, when selecting and designing the powder handling equipment. A full understanding of the properties of the blend components is especially critical in a continuous manufacturing process. Therefore, the process steps and equipment parameters prior to the final blend step are often critical to the flowability and segregation of the final blend. There are several common pre-blending process steps that may affect the final blend, including:

1. Storage conditions of the raw ingredients, such as the temperature, relative humidity, container dimensions, and days stored at rest (inventory control) can all influence the flowability of the final blend, especially if any of the raw ingredients are hygroscopic.
2. Milling and screening steps that alter the raw ingredients', and thus the final blend's particle size, shape, and distribution. Therefore, milling and screening process parameters, such as the mill type, mill speed, screen size, mill/screen feed method (controlled vs noncontrolled feed) may all influence on the flowability and segregation potential of the final blend, especially in a direct blending process.
3. Granulation (dry roller compaction, wet granulation, fluid-bed granulation) of the API, together with select excipients, can often have a positive effect on the flowability of the final blend, especially for blends with high active loadings. The granulation parameters, especially those that influence particle size/shape/distribution, will have a significant effect on flowability and segregation potential. For roller compaction, the process parameters that dictate the PSD and shape distribution of the final blend may include the roller compactor speed, roll compactor pressure, mill type, and the screen size. The wet granulation process parameters that affect PSD and shape, as well as the moisture content, are often critical to flowability. Therefore, wet granulation parameters, such as the blade and impeller design/speed, binder addition rate, and method and identification of granulation end point, are critical to flowability, as are the granule milling conditions. Similarly, the fluid-bed granulation parameters that affect the moisture content and particle size, such as the binder addition rate/method, inlet air flow rate and temperature, drying time, end point determination (target moisture, powder temperature, exhaust air temperature), and fluidization behavior for the powder bed are all critical to flowability and segregation. The details of scaling-up different granulation processes are discussed in other chapters.
4. Pre-blending of selected raw materials, such as pre-blending a cohesive powder with a less cohesive powder to reduce the likelihood of flow problems during subsequent handling steps. Pre-blending may also be conducted to achieve a more uniform blend and reduce the segregation potential.

The measurement of flow properties and the design parameters they provide are discussed in Section 26.4,

but they can also be applied for trouble-shooting and developing corrective actions for flow problems in the pre-blending steps if needed.

26.2.2 Final blending

Final blending may be accomplished on a batch or continuous basis. In the pharmaceutical industry, batch blenders are most common, but continuous manufacturing of oral solid dosages has progressed significantly over the last decade. Therefore, this chapter focuses on different batch blending processes.

Batch blending processes consist of three sequential steps: weighing and loading the components, blending, and discharging. Unlike a continuous blender, the retention time in a batch blender is rigidly defined and controlled, and is the same for all of the particles. Batch blenders come in many different designs and sizes, and make use of a wide range of blending mechanisms.

All blenders use one or more of the following mechanisms to induce powder blending: convective blending, shear blending, and diffusive blending.[1,2] Another classification system for blenders is based on their design. This system categorizes blenders into two categories:

- those that achieve blending within a moving vessel; and
- those with fixed vessels that rely on internal paddles or blades to move the materials.

There are many common blenders, or other techniques for making a uniform material, used in the pharmaceutical industry on a batch basis, including:

1. wet granulators;
2. fluid-bed granulators;
3. roller compactors; and
4. direct blending via tumble blenders (reviewed briefly in this chapter).

Many of these blending processes, including high-shear wet granulation, fluid-bed granulation, roller compaction, and direct blending in mixer can also be conducted in a continuous manufacturing process. There are other types of blenders, such as pneumatic blenders, extruders, ribbon blenders, planetary blenders, and orbiting screw blenders, which are not discussed in this chapter.

As a result of the multiple classification systems, a number of terms have evolved throughout the industry to describe families of blenders. Regardless of the terminology used to classify the blender, it is important for the pharmaceutical scientist to understand the capabilities and limitations of the equipment when selecting an appropriate blender for a particular product. This is especially important during process scale-up, when equipment with a different design and operating principle may need to be used. The optimization and scale-up of the wet granulation, fluid-bed granulation, and roller compaction processes are discussed in other chapters. The optimization and scale-up of tumble blenders is discussed in the literature.[3]

Note that some types of tumble blenders, such as bin blenders, serve a dual purpose. In addition to providing the container in which blending is accomplished, bin blenders can also be used to transfer the powder blend to the next unit operation in a batch process. This is of particular value when manufacturing blends that tend to segregate when discharging the blend onto the compression or filling equipment. This also makes the use of bin blenders desirable during the manufacture of potent drug products that must be processed in high containment facilities. In addition, by decoupling the blending bin from the drive mechanism, the bin filling, discharge, and cleaning take place at a separate time and location, which increases the efficiency and utilization of equipment.

26.2.2.1 Discharge from a blender or processing vessel

Powder that has been blended must be discharged from the blender for further processing, including the creation of the unit dose at the press or encapsulator. In many dry blending processes, such as tumble blending, the discharge is driven by gravity alone. As an example, the final blend step may be conducted in a V-blender or a double-cone blender. In these cases, the blender geometry often consists of a converging cross-section to the outlet, through which the powder must be discharged reliably. In these cases, the blender is essentially acting as a "bin," so the equipment parameters of interest are those that are crucial to a bin design. These crucial bin design parameters are discussed in the next section on IBCs.

For fluid-bed granulation processes, it is not uncommon for a conical "hopper" to be attached to the "bowl" of a fluid-bed granulator, inverted, and discharged to a downstream process step via gravity.

For wet granulators, the final blend may be discharged using mechanical agitation by continuing to operate the plow blade (typically at a lower speed) to discharge the final blend through a central or side outlet. Although the plow blade typically ensures that the blend is discharged from the granulator "bowl" reliably, the design of the transition chute from the blender to the downstream process is also critical. This is especially critical if the equipment below the

granulator has a converging cross-section that is full of material, as discussed further in Section 26.5.

When a blender/vessel is discharged manually (hand-scooping), flowability may not be a primary concern, but segregation concerns and other factors (eg, production rate concerns, operator exposure and safety) may limit the extent to which a blender/vessel can be manually unloaded.

The transfer of the material from the final blender to the downstream equipment, whether it is into an IBC or directly to the press, is critical to the segregation potential. Therefore, parameters such as the transfer method (eg, manual, gravity, pneumatic), transfer rate, transfer chute height and geometry, venting, and other items will be critical in assessing and minimizing the segregation potential during the blender-to-press transfer steps. Design techniques to minimize segregation during these transfer steps are further discussed in Section 26.5.

26.2.3 Intermediate bulk containers

The flowability and segregation potential of the final blend is especially critical during storage and discharge from an IBC. The IBC may be a bin (tote) or a drum that is used to store and transfer the final blend from the blender to the press. When a drum is used, an attachment such as a conical hopper may be attached to the cone to connect the drum to downstream equipment with a smaller inlet (eg, press hopper). This section focuses on the use of IBCs to store the blend in a batch process, but the concepts can also be applied and are critical to the storage of blend components in a continuous process.

An IBC consists of two primary sections (see Fig. 26.1):

1. A cylinder or straight-sided section with a constant cross-sectional area that is often rectangular (with or without radiused corners) or circular;
2. A hopper section with a changing cross-sectional area that is often a converging conical or pyramidal hopper.

IBCs may be used to store the blend for extended periods of time. During this time, the flowability may deteriorate as the blend is subjected to consolidation pressures due to its own weight during storage at rest. In addition, IBCs may be used to move the blend from one process step to another, during which time the blend may be subjected to vibration

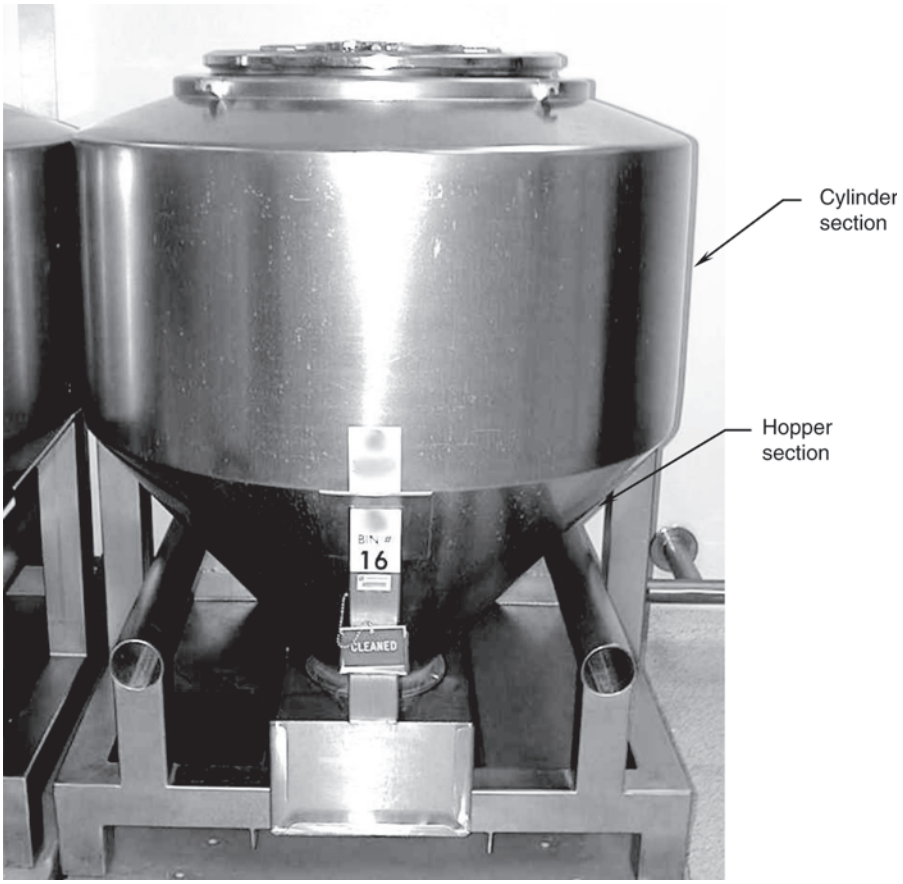

FIGURE 26.1 Intermediate bulk container ("IBC," "bin," "tote").

that may adversely affect flowability. Therefore, it is important to determine what consolidation pressures will act on the powder as it is stored and transferred in an IBC.

The key IBC equipment parameters with respect to flowability and segregation potential include:

1. The cylinder cross-sectional area and height which, along with other parameters such as the fill height, will affect the consolidation pressure acting on the blend.
2. The hopper geometry (eg, planar vs circular) and angles, which will affect the flow pattern that develops during discharge. The flow pattern, discussed in Section 26.3, will also affect the segregation potential.
3. The interior surface finish of the hopper section, which will affect the flow pattern that develops during discharge.
4. The IBC outlet size and shape (slotted vs circular), which will affect whether the blend will discharge reliably without arching or ratholing.
5. General flow impediments, such as upward facing ledges or partially opened valves, that may act as flow obstructions.

Section 26.4 discusses the measurement of the flow properties and segregation potential that are used to obtain the key bin design parameters. The application of these design parameters to provide reliable flow and minimize segregation from the IBC to the press is discussed in Section 26.5.

26.2.3.1 Transfer from intermediate bulk containers to the press/encapsulator

The flowability and segregation potential of the final blend is also critical during transfer from the IBC to the press/encapsulation machine/etc. This transfer step may be a manual transfer (hand-scooping), in which case flowability may not be a primary concern. The transfer step may also be conducted via pneumatic conveying, in which case the flowability of the blend may not be a primary concern, but equipment and material parameters affecting conveying (conveying gas pressure and flow rate, conveying line diameter and layout, etc.) need to be considered. Pneumatically conveying the final blend may also raise segregation concerns, as further discussed in Section 26.3.

The transfer step may also be conducted via gravity transfer via a single or bifurcated chute (see Fig. 26.2), depending on the press configuration. These chutes are often operated in a flood-loaded manner, and may consist of converging sections where the cross-sectional area of the chute is reduced. If this is the case, the chute will need to be designed for reliable flow in a similar manner to the IBCs.

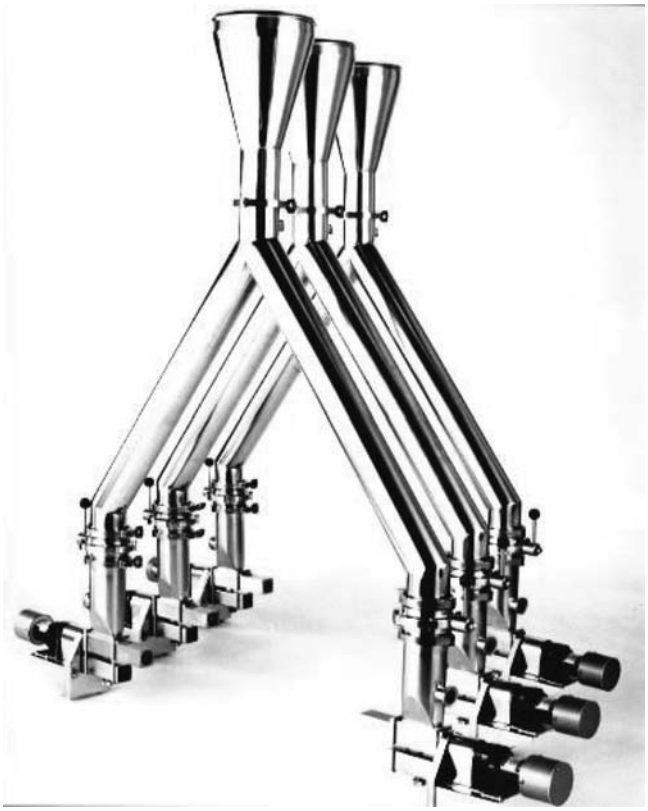

FIGURE 26.2 Bifurcated press feed chute.

The key transfer chute parameters with respect to flowability and segregation potential include:

1. The chute cross-sectional area and height, which will affect the consolidation pressure acting on the blend, and how it may segregate.
2. Valving and venting of the transfer chute may affect how readily a blend segregates.
3. For converging and nonconverging sections of the chute, the chute geometry, angles, and interior surface finish will affect the flow pattern that develops during discharge through the chute.
4. For converging sections of the chute, the outlet shape and size will affect whether the blend will discharge reliably without arching or ratholing.
5. General flow impediments, such as upward facing ledges (mismatched flanges), sight glasses, level probes, or partially opened valves may act as flow obstructions.

The measurement of the flow properties and segregation potential used to obtain the key chute design parameters are discussed in Section 26.4. The application of these design parameters for equipment from the IBC to the press is discussed in Section 26.5.

26.2.3.2 *Feed from the press hopper to the die cavity*

The press feed hopper must also be designed to provide reliable flow, and minimize segregation. Most presses utilize a small press hopper that is, in essence, a miniature IBC designed to provide a small amount of surge capacity. The press hopper often consists of a cylinder section and a hopper section similar to a larger IBC. The hopper section may be asymmetric, as opposed to the symmetric hopper designs commonly used for larger IBCs. The press hopper is typically flood-loaded from the IBC/chute above via gravity feed. However, in some instances, the material level in the press hopper may be controlled via a feeder at the IBC outlet (eg, rotary valve or screw feeder), and/or use agitation to promote flow. Some modern presses do not have press hoppers with a converging hopper, but instead consist of vertical, nonconverging chutes from the press inlet to the feed frame inlet.

The key equipment parameters with respect to flowability, which are outlined in the preceding section for IBCs/bins, are also applicable to the press hopper. Since the press hopper outlets are often much smaller than an IBC outlet, flow problems, such as arching or ratholing (discussed further in Section 26.3), may be more pronounced at this location. As a result, press hoppers may include mechanical agitators to assist gravity discharge, such as a rotating agitator mounted to a vertical shaft (Fig. 26.3).

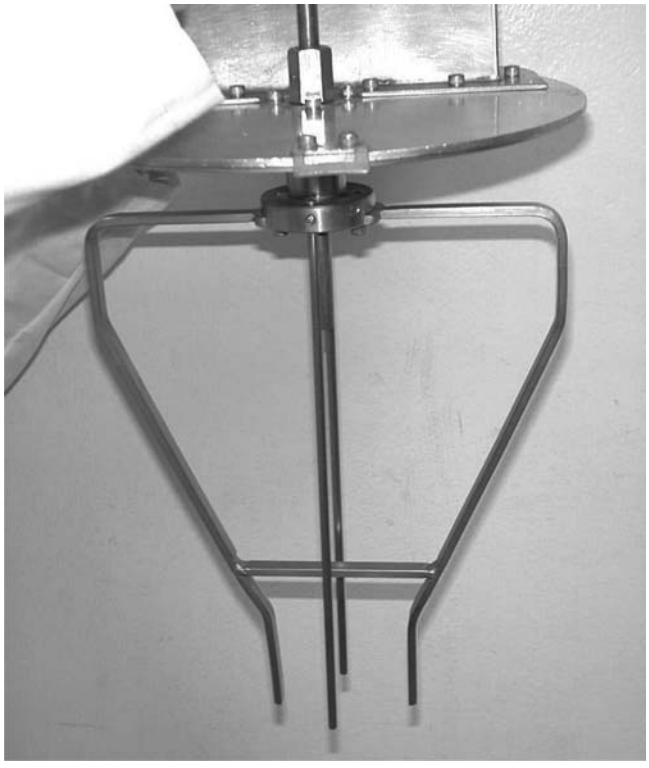

FIGURE 26.3 Agitator for use in small-scale hopper.

The same design parameters used for a reliable IBC design (see Section 26.4) can also be used to design a press hopper (see Section 26.5).

26.3 TYPICAL FLOW AND SEGREGATION CONCERNS

Objective of the section

This section will focus on typical flow and segregation concerns that occur during transfer operations from the final blender to the press. This section will also provide a summary of common flow problems, segregation mechanisms, and the flow patterns that can occur during gravity discharge.

26.3.1 Common flow problems

A number of problems can develop as powder flows through equipment such as bins, chutes, and press hoppers. If the powder is cohesive, an arch or rathole may form, resulting in "no flow" or erratic flow. In addition, flooding or uncontrolled discharge may occur if a rathole spontaneously collapses. A deaerated bed of fine powder may experience flow rate limitations or no flow conditions due to the two-phase flow effects between the powder and the interstitial air. These flow problems are primarily reviewed with respect to batch processes, but also commonly apply to continuous processes. Each of these flow problems is discussed in more detail next.

- No flow: no flow from a bin/hopper is a common and significant solids-handling problem, especially when handling fine/milled APIs and high active loading blends. In production, it can result in problems, such as starving downstream equipment, production delays, and the requirement for frequent operator intervention to reinitiate flow. No flow can be due to either arching (sometime referred to as "bridging" or "plugging") or ratholing (also referred to as "piping") as described next.
  - Arching: occurs when an obstruction in the shape of an arch or bridge forms above the bin outlet, and prevents any further material discharge. It can be an interlocking arch, where the particles mechanically lock to form the obstruction, although this is less common with fine pharmaceutical powders. An interlocking arch occurs when the particles are large compared with the outlet size of the hopper. The arch could also be a cohesive arch where the particles pack together to form an obstruction (Fig. 26.4). Both of these problems are strongly influenced by the outlet size of the hopper the material is being fed through. Powder flow

FIGURE 26.4 Cohesive arch.

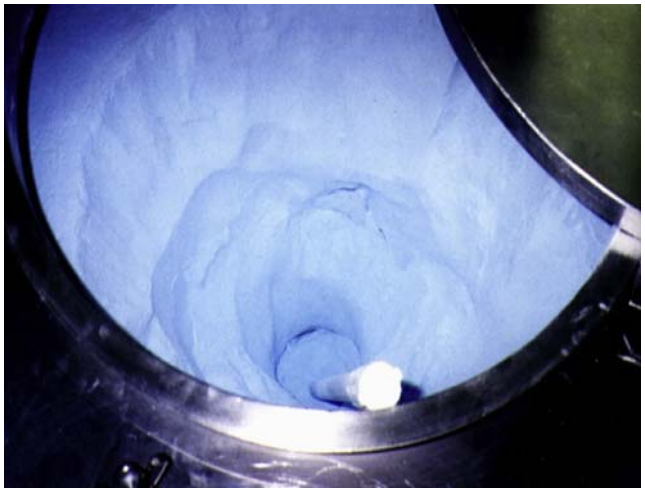

FIGURE 26.5 Rathole.

properties, discussed in Section 26.4, can be used to determine if these problems will occur and used to address them during scale-up. In particular, the cohesive strength of a powder will dictate what size outlet it can arch over (the greater the cohesive strength, the higher the likelihood of arching).

- Ratholing: can occur in a bin when the powder empties through a central flow channel, but the material at the bin walls remains stagnant and leaves an empty hole (rathole) through the material, starting at the bin outlet (Fig. 26.5). Ratholing is influenced by the bin/hopper geometry and outlet size the material is fed through. Similar to the problem of arching, this problem will arise if the material has sufficient cohesive strength. In this case, the material discharge will stop once the flow channel empties.
- Erratic flow: erratic flow is the result of obstructions alternating between an arch and a rathole. A rathole may collapse due to an external force, such as vibrations created by surrounding equipment or a flow-aid device, such as an external vibrator. While some material may discharge, falling material may impact over the outlet and form an arch. This arch may then break, due to a reoccurrence of the external force, and material flow may not resume until the flow channel is emptied and a rathole is formed again. This not only results in erratic feed to the downstream equipment (press), but can also result in a nonuniform feed density.
- Fine powder flow concerns (two-phase flow effects): additional flow concerns can arise when handling fine powders, generally in the range below 100 μm in average particle size. These concerns are due to the interaction of the material with entrained air or gas, which becomes significant in describing the behavior of the material. This interaction can result in two-phase (powder/interstitial gas) flow effects. There are three modes that can occur when handling fine powders that are susceptible to two-phase flow effects: steady flow, flooding (or flushing), and a flow rate limitation.[4] These three flow modes are discussed in more detail next.
  - Steady flow: will occur with fine powders if the target flow rate (feed rate through the system) is below the "critical flow rate" that occurs when the solids stress is balanced by the air pressure at the outlet. The target flow rate is often controlled by a feeder, such as at the inlet to a compression machine (press feed frame). The critical flow rate and the flow properties tests used to determine it are described in more detail in Section 26.4. At target flow rates exceeding the critical flow rate, unsteady flow can occur by two different modes:
    - Flooding: (or "flushing") is an unsteady two-phase flow mode that can occur as falling particles entrain air and become fluidized. Since powder handling equipment often cannot contain a fluid-like powder, powder can flood through the equipment (feeders, seals) uncontrollably. Flooding can also occur when handling fine powders in small hoppers with high fill and discharge rates. In such situations, the powder does not have sufficient residence time to deaerate, resulting in flooding through the feeder. One adverse effect of flooding or flushing may be high variation in the tablet weight and strength.

– Flow rate limitation: is another unsteady two-phase flow mode that can occur with fine powders. Fine powders have very low permeabilities, and are affected by any movement of the interstitial air (air between the particles). This air movement will occur due to the natural consolidation and dilation of the powder bed that takes place as it flows through the cylindrical and hopper geometries. As the material is consolidated in the cylinder, the air is squeezed out. As the powder flows through the hopper and outlet, it dilates and additional air must be drawn in. The air pressure gradients caused as a result of this air movement can retard discharge from a hopper, significantly limiting the maximum achievable rates. This may be observed when the speed of a high-speed press is increased, and the tablet weight variation increases.

During unsteady two-phase flow modes, the material's bulk density can undergo dramatic variations. This can negatively impact downstream packaging or processing operations. Problems can result, such as excessive tablet weight variation, a required reduction in filling speeds, and even segregation. Equipment and process parameters will govern whether such problems occur, and are further discussed in Section 26.5. These parameters include hopper geometry and outlet size, applied vacuum and other sources of air pressure differences (such as dust collection systems), material level, time since filling, and of course the target feed rate.

Material properties, such as permeability and compressibility (discussed in Section 26.4) will also play important roles, as will variations in the material's state of aeration that can occur based on its residence time or degree of compaction from external forces and handling.

One of the most important factors in determining whether a powder will discharge reliably from a hopper is establishing what flow pattern will develop, which is discussed in the next section.

26.3.2 Flow patterns

Two flow patterns can develop in a bin or hopper: funnel flow and mass flow. In funnel flow (Fig. 26.6), an active flow channel forms above the outlet, which is surrounded by stagnant material. This results in a first-in, last-out flow sequence. It generally occurs in equipment with relatively shallow hoppers. Common examples of funnel flow bins include hopper geometries, such as asymmetric cones and rectangular-to-round transitions (Fig. 26.7).

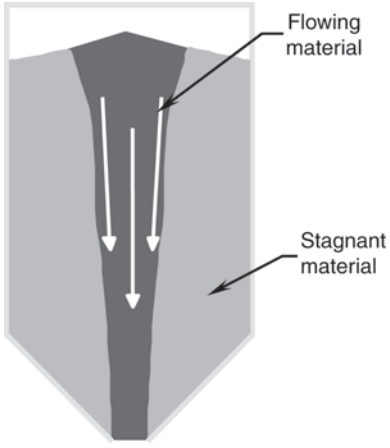

FIGURE 26.6 Funnel flow discharge pattern.

FIGURE 26.7 Examples of funnel flow bins.

FIGURE 26.8 Mass flow discharge pattern.

As the level of powder decreases in funnel flow, stagnant powder may fall into the flow channel if the material is sufficiently free-flowing. If the powder is cohesive, a stable rathole may develop. Funnel flow occurs if the powder is unable to flow along the hopper walls, due to the combination of friction against the walls and hopper angle. Funnel flow's first-in-last-out flow sequence can also have an adverse effect upon segregation, and result in a nonuniform feed density to the downstream equipment (tablet weight variation).

In mass flow (Fig. 26.8), all of the powder is in motion whenever any is withdrawn. Powder flow occurs throughout the bin, including at the hopper walls. Mass flow provides a first-in-first-out flow sequence, eliminates stagnant powder, provides a steady discharge with a consistent bulk density, and provides a flow that is uniform and well-controlled. Ratholing will not occur in mass flow because all of the material is in motion. A mass flow bin design may also be beneficial with respect to reducing segregation (further discussed in Section 26.5).

The requirements for achieving mass flow are:

1. sizing the outlet large enough to prevent arch formation; and
2. ensuring the hopper walls are steep and smooth enough to allow the powder to flow along them.

These mass flow design parameters are discussed further in Section 26.4, and their implementation is discussed in Section 26.5.

26.3.3 Common segregation mechanisms

The term "segregation mechanism" refers to the mode or motive force by which the components of the blend separate. There are many different segregation mechanisms that can adversely affect uniformity,[5] but three primary segregation mechanisms are of interest in typical pharmaceutical blend handling operations. These three primary segregation mechanisms are:

1. sifting segregation (sometimes referred to as "percolation segregation");
2. fluidization segregation (sometimes referred to as "air entrainment"); and
3. dusting segregation (sometimes referred to as "particle entrainment in an air stream").

The three segregation mechanisms are described in more detail next. These terms are not universally defined, so one must use caution when using them. Segregation may occur as a result of just one of these mechanisms or a combination of several mechanisms.

26.3.3.1 Material properties that affect segregation

Whether segregation occurs, to what degree, and which mechanism or mechanisms are involved depends on a combination of the properties of the blend, and the process conditions encountered. Some of the primary material properties that influence segregation tendencies include:

1. The mean particle size and PSD of the API, excipients, and final blend: segregation can occur with blends of any mean size, but different mechanisms become more pronounced at different particle sizes, as further discussed next.
2. Particle density: the particle density will affect how the blend components fluidize.
3. Particle shape: rounded particles may have greater mobility than irregularly shaped particles, which can allow more segregation.
4. Particle resilience: this property influences collisions between particles and surfaces, which can lead to differences in where components accumulate during the filling of a bin or press.
5. Cohesive strength of the blend: as a general rule, more cohesive blends are less likely to segregate. However, if enough energy is added to dilate the blend and/or separate particles from one another, even a very cohesive material can segregate.
6. Electrostatic effects: the ability of components to develop and hold an electrostatic charge, and their affinity for other ingredients or processing surfaces, can also contribute to segregation tendencies.

Of all of these, segregation based on particle size is by far the most common.[6] In fact, particle size is the most important factor in the three primary segregation mechanisms considered here, as further described in the following sections.

26.3.3.2 Sifting segregation

Sifting segregation is common for many industrial processes. Under appropriate conditions, fine particles tend to sift or percolate through coarse particles. For segregation to occur by this mechanism, four conditions must exist:

1. There must be a range of particle sizes. A minimum difference in mean particle diameters between components of 1.3:1 is often more than sufficient.[6]
2. The mean particle size of the mixture must be sufficiently large, typically greater than approximately 100 μm.[7]
3. The mixture must be relatively free-flowing to allow particle mobility.
4. There must be relative motion between particles (interparticle motion). This last requirement is very important because without it even highly-segregating blends of ingredients that meet the first three tests will not segregate. Relative motion can be induced in a variety of ways, such as when a pile is formed when filling a bin, vibration from surrounding equipment (such as a tablet press), or as particles tumble and slide down a chute.

If any one of these conditions does not exist, the mix will not segregate by this mechanism.

The result of sifting segregation in a bin is usually a side-to-side variation in the PSD. The smaller particles will generally concentrate under the fill point, with the coarse particles concentrating at the perimeter of the pile (Fig. 26.9).

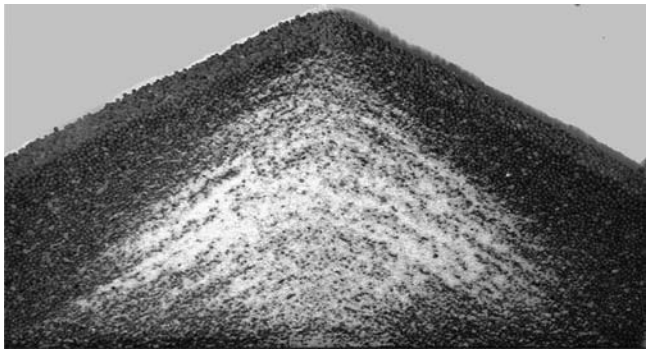

FIGURE 26.9 Example of sifting segregation in a 2-D pile. Note the black particles are approximately 1200 μm, while the white particles are approximately 350 μm. *Source: Photo provided courtesy of Jenike & Johanson, Inc.*

26.3.3.3 Fluidization segregation

Variations in particle size or density often result in vertically segregated material when handling powders that can be fluidized. Finer or lighter particles often will be concentrated above larger or denser particles. This can occur during filling of a bin or other vessel or within a blending vessel once the blending action has ceased.

Fluidization segregation often results in horizontal gradation of fine and coarse material. A fine powder can remain fluidized for an extended period of time after filling or blending. In this fluidized state, larger and/or denser particles tend to settle to the bottom. Fine particles may be carried to the surface with escaping air as the bed of material deaerates. For example, when a bin is being filled quickly, the coarse particles move downward through the aerated bed, while the fine particles remain fluidized near the surface. This can also occur after blending, if the material is fluidized during blending.

Fluidization is common in materials that contain a significant percentage of particles smaller than 100 μm.[8] Fluidization segregation is most likely to occur when fine materials are pneumatically conveyed, when they are filled or discharged at high rates, or if gas counterflow occurs. As with most segregation mechanisms, the more cohesive the material, the less likely it will be to segregate by this mechanism.

Fluidization via gas counterflow can occur as a result of insufficient venting during material transfer. For example, consider a tumble blender discharging material to a drum, with an airtight seal between the two (Fig. 26.10). As the blend transfers from the blender to the drum, air in the drum is displaced, and a slight vacuum is created in the blender. If both are properly vented, air moves out of the drum and, separately, into the blender. If the bin and drum are not vented, the air must move from the drum to the blender through the blender discharge. In doing so, the fines may be stripped off of the blend, and carried to the surface of the material still within the blender.

26.3.3.4 Dusting segregation

Like fluidization segregation, dusting is most likely to be a problem when handling fine, free-flowing powders with particles smaller than about 50 μm,[8] as well as a range of other particle sizes. If dust is created upon filling a bin, air currents created by the falling stream will carry particles away from the fill point (Fig. 26.11). The rate at which the dust settles is governed by the particle's settling velocity. The particle diameter is much more significant than particle density in determining settling velocity.

As an example of this mechanism, consider a mix of fine and large particles that is allowed to fall into the

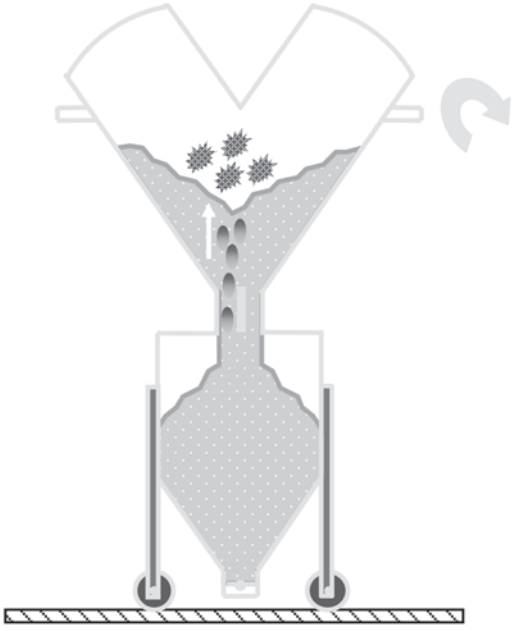

FIGURE 26.10 Example of fluidization segregation from blender to bin.

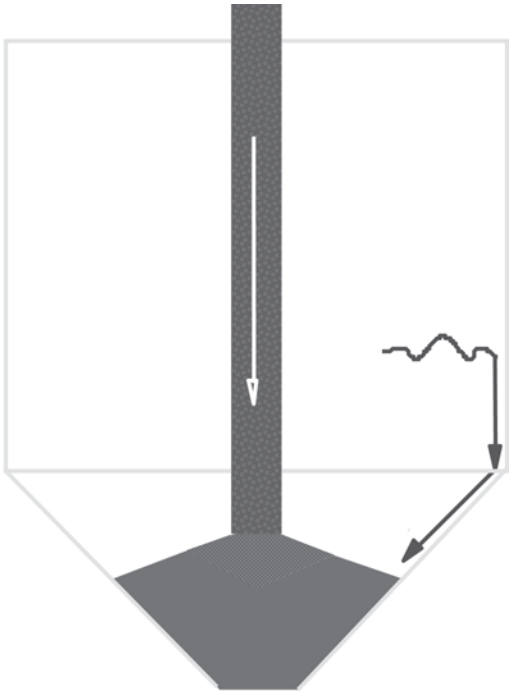

FIGURE 26.11 Example of dusting segregation during filling of bin.

center of a bin. When the stream hits the pile of material in the bin, the column of air moving with it is deflected. The air then sweeps off the pile toward the perimeter of the bin, where the air becomes highly disturbed. After, the air generally moves back up the bin walls in a swirling pattern. At this point, the gas velocity is much lower, allowing many particles to fall out of suspension. The finest particles (with low settling velocities) will be carried to the perimeter of the bin because settling velocity is a strong function of particle diameter. The larger particles will concentrate closer to the fill point where the air currents are strong enough to prevent the fine particles from settling. Dusting segregation can also result in less predictable segregation patterns, depending on how the bin is loaded, venting in the bin, and dust collection use and location.

The empirical tests used to assess these segregation mechanisms are reviewed in Section 26.4, and the application of their results to design equipment to minimize segregation is presented in Section 26.5.

26.4 MEASUREMENT OF FLOW PROPERTIES

Objective of the section

The primary objective of this section is to provide a description of the different quantitative flow properties that should be measured, as well as the empirical segregation test methods used to assess segregation potential by different mechanisms. This section also reviews the calculation of equipment parameters required for consistent, reliable flow in powder handling equipment for gravity discharge.

The following primary topics are reviewed in this section:

1. Cohesive strength tests: a review of different shear test methods, the Jenike Direct Shear Test method, and the calculation of the design parameters to prevent arching and ratholing.
2. Wall friction tests: a review of the Jenike Direct Shear Test method for measuring wall friction, and the calculation of the design parameters to provide mass flow (mass flow hopper angles).
3. Bulk density test: a review of different bulk density test methods, the compressibility test method, and the application of the compressibility test results.
4. Permeability: a review of the permeability test method, and application of the results (critical flow rate).
5. Segregation tests: a review of two empirical test methods to assess segregation potential.

Note that additional powder characterization methods are discussed in chapter "Fundamental of Diffusion and Dissolution."

26.4.1 Cohesive strength tests: preventing arching and ratholing

Dr Andrew Jenike developed his mathematical model of the flow of powders by modeling the powder as a rigid-plastic (not a visco-elastic) continuum of solid particles.[9] This approach included the postulation of a "flow–no flow" criterion that states the powder would flow (eg, from a bin) when the stresses applied to the powder exceeded the strength of the powder. The strength of a material will vary, depending on how consolidated it is. For example, the strength of wet sand increases as the consolidation pressure is increased (eg, the more one packs it). Therefore, it is critical to be able to measure the cohesive strength of a powder when scaling-up a process and designing equipment.

26.4.1.1 Test methods

One of the primary flow problems that can develop in powder handling equipment is a no-flow obstruction due to the formation of a cohesive arch or rathole, as discussed in Section 26.3. The required outlet size to prevent a stable cohesive arch or rathole from forming is determined by applying the flow-no flow criterion, and using the results of a cohesive strength test. In order to apply the flow-no flow criterion we need to determine:

1. The cohesive strength of the material as a function of the major consolidation pressure acting on the material: the consolidation pressure acting on the powder changes throughout the bin height due to the weight of material above it. Therefore, the cohesive strength must be measured over a range of consolidation pressures. The cohesive strength can be measured as a function of major consolidating pressure using the test methods described in this section.
2. The stresses acting on the material to induce flow: gravity pulls downward on a potential arch that may form. The stresses acting on the powder can be determined using mathematical models.[9]

To further illustrate the concepts of strength and consolidation pressure, consider an "idealized" strength test, as shown in Fig. 26.12. In this idealized test, the cohesive strength of the powder is measured in the following distinct steps:

1. Consolidation of the powder: the powder is consolidated using a prescribed consolidation pressure (P). In the idealized test shown, the sample is contained in a cylinder and the consolidation pressure is applied from the top (Step 1 in Fig. 26.12).
2. Fracture of the powder: once the consolidation pressure is applied, the cylinder containing the powder would be removed without disturbing the powder sample (Step 2a in Fig. 26.12). After, the strength of the powder can be measured by applying pressure to the column of powder until it fails or fractures (Step 2b in Fig. 26.12). The applied pressure at which the powder failed is referred to as the yield strength (F) (cohesive strength). This idealized test could be repeated several times to develop a flow function (FF), which is a curve illustrating the relationship between the yield strength (F) and the major consolidation pressure (P). An example of a flow function is shown in Fig. 26.12.

This idealized strength test is not possible for the broad range of powders that might be tested.

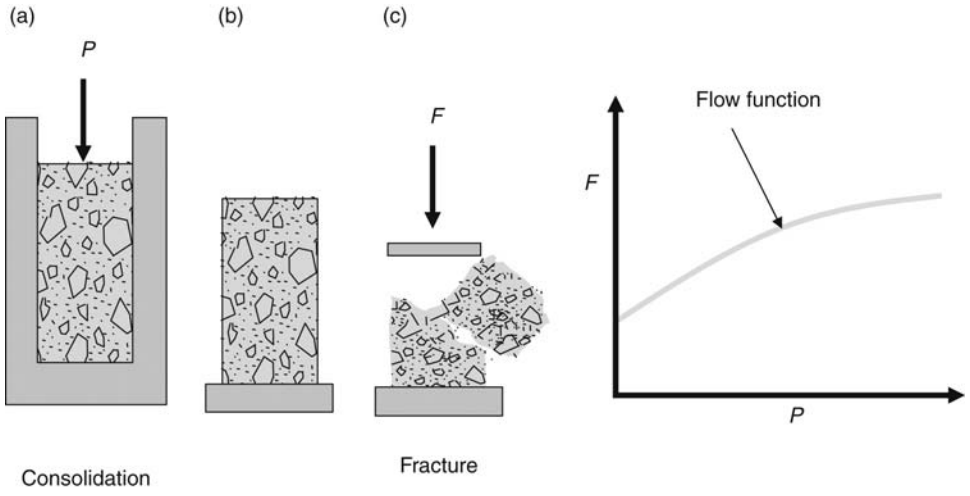

FIGURE 26.12 Schematic of "idealized" strength test: (a) Step #1; (b) Step #2a; (c) Step #2b.

Therefore, several different cohesive strength test methods have been developed. The respective strengths and weaknesses of these different cohesive strength tests are reviewed in the literature.[10,11] Although many different test methods can be used to measure cohesive strength, this chapter focuses specifically upon the Jenike Direct Shear Test method. The Jenike Direct Shear Test method is the most universally accepted method, and is described in ASTM standard D 6128.[12] It is important that these tests be conducted at representative handling conditions, such as temperature, relative humidity, and storage at rest, because all these factors can affect the cohesive strength. An arrangement of a cell used for the Jenike Direct Shear Test is shown in Fig. 26.13. The details of the Jenike Direct Test Method are provided in Jenike,[9] including the generation of:

1. Mohr's circle to plot the shear stress (τ) versus the consolidation pressure (σ);
2. Effective yield locus; and
3. Flow function.

The data generated experimentally from the Jenike Direct Shear Test can be used to determine the following derived parameters:

1. The flow function that describes the cohesive strength (unconfined yield strength, f_c) of the powder as a function of the major consolidating pressure (σ_1). The flow function is one of the primary parameters used to calculate the minimum outlet diameter/width for bins, press hoppers, blender outlets, and others, to prevent arching and ratholing. The calculation of the minimum outlet diameter/width is discussed in more detail next.
2. The effective angle of internal friction (δ) that is used to calculate the minimum outlet to prevent arching and the required hopper angles for mass flow (described next).
3. The angle of internal friction for continuous flow or after storage at rest (ϕ and ϕ_t). The static angle of internal friction (ϕ_t) is used to calculate the minimum outlet to prevent ratholing (described in the next section).

There are other testing methods that utilize the same principles of consolidation and shearing to determine the cohesive strength of a bulk powder. Annular (ring) shear testers produce rotational displacement between cell halves containing material, rather than a lateral displacement. The loading and shearing operations are more readily adapted to automation, since unlimited travel can be achieved with this type of test cell. The successful use of an annular ring shear tester to measure cohesive strength has been discussed in the industry.[13–16]

26.4.1.2 Calculation of minimum required outlet dimensions to prevent arching (mass flow bin)

The flow behavior of powders through bins and hoppers can be predicted by a complete mathematical relationship. This is very beneficial when scaling-up a process, and designing powder handling equipment. If gravity discharge is used, the outlet size required to prevent a cohesive arch or rathole from forming over a bin outlet can be calculated. The term B_c refers to the minimum outlet diameter for a circular outlet

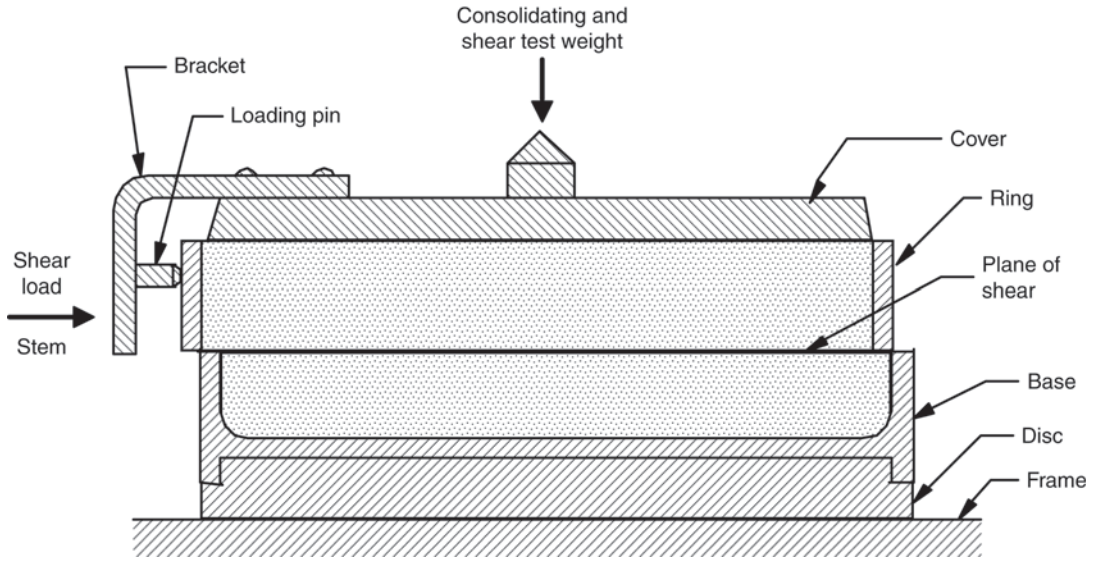

FIGURE 26.13 Jenike Direct Shear Test, cohesive strength test set-up.

to prevent a cohesive arch from forming in a mass flow bin. The term B_p refers to the minimum outlet width for a slotted outlet (B_p), in which the length: width ratio exceeds 3:1, to prevent arching in a mass flow bin.

The majority of bins used in pharmaceutical processes utilize hoppers with circular outlets. Therefore, we will focus our discussion on the calculation of the B_c parameter. It is worth noting that the outlet diameter required to prevent arching over a circular outlet (B_c) will typically be about two times greater than the required outlet width of a slotted outlet (B_p). The calculation of B_p is provided in Jenike.[9]

For mass flow, the required minimum outlet diameter to prevent arching is calculated in Eq. (26.1):

$$B_c = H(\theta')f_{crit}/\gamma \tag{26.1}$$

where:

$H(\theta')$ is a dimensionless function derived from first principles (mathematical model) and is given by Fig. 26.14. The complete derivation of $H(\theta')$ is beyond the scope of this chapter, but is provided in Jenike.[9]

f_{crit} (units of force/area) is the unconfined yield strength at the intersection of the hopper flow factor (ff) and the experimentally derived flow function (FF), as shown in Fig. 26.15. The flow factor (ff) is a mathematically determined value that represents the minimum available stress available to break an arch. The calculation of the flow factor (ff) is also beyond the scope of this chapter, but is provided in Jenike[9] and is a function of the flow properties and the hopper angle (θ).

γ (units of weight/volume) is the bulk density of the powder at the outlet.

This calculation yields a dimensional value of B_c in units of length, which is scale-independent. Therefore, for a mass flow bin, the opening size required to prevent arching is not a function of the diameter of the bin, height of the bin, or the height-to-diameter ratio.

The determination of B_c is especially valuable in making decisions during process scale-up. As a formulation is developed, a cohesive strength test can be conducted early in the development process to determine the cohesive strength (flow function). This material-dependent flow function, in conjunction with Eq. (26.1), will yield a minimum opening (outlet) size to prevent arching in a mass flow bin. For example, this opening size may be calculated to be 200 mm. This 200 mm diameter will be required whether the bin holds 10 or 1000 kilos of powder, and is scale-independent. In this example, feeding this material through a press hopper or similarly small openings would pose problems with an arch developing over the outlet because a 200 mm diameter opening is required. This information could then be used early in the development process to consider reformulating the product to reduce the cohesive strength, and improve flowability.

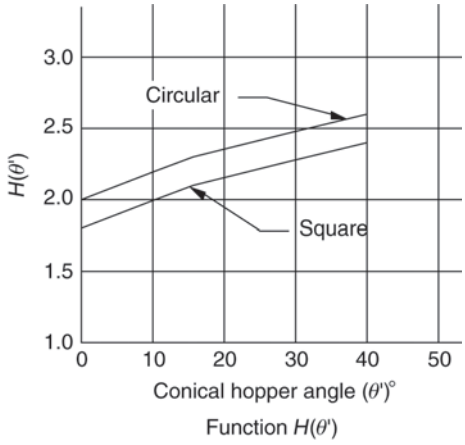

FIGURE 26.14 Plot of derived function $H(\theta')$ used to calculate arching dimensions for mass flow bins.

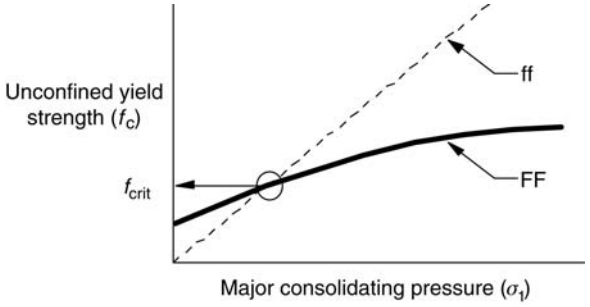

FIGURE 26.15 Example of flow function (FF) and flow factor (ff) intersection, showing f_{crit} at their intersection.

26.4.1.3 Calculation of minimum required outlet dimensions to prevent ratholing (funnel flow bin)

If the bin discharges in funnel flow, the bin outlet diameter should be sized to be larger than the critical rathole diameter (D_f) to prevent a stable rathole from forming over the outlet. For a funnel flow bin with a circular outlet, sizing the outlet diameter to exceed the D_f will also ensure that a stable arch will not form (because a rathole is inherently stronger than an arch). The D_f value is calculated in Eq. (26.2), and additional details of the calculation are provided in Jenike.[9]

$$D_f = G(\phi_t)f_c(\sigma_1)/\gamma \tag{26.2}$$

where:

$G(\phi_t)$ is a mathematically derived function from first principles and is given by Fig. 26.16.

$f_c(\sigma_1)$ is the unconfined yield strength of the material. This value is determined by the flow function (FF) at the actual consolidating pressure σ_1 (discussed next).

The consolidation pressure σ_1 is a function of the "head" or height of powder above the outlet of the bin, and takes into account the load taken up by friction along the walls, as derived by Janssen[17] in Eq. (26.3):

$$\sigma_1 = (\gamma R/\mu k)\ (1 - e^{(-\mu k h/R)}) \qquad (26.3)$$

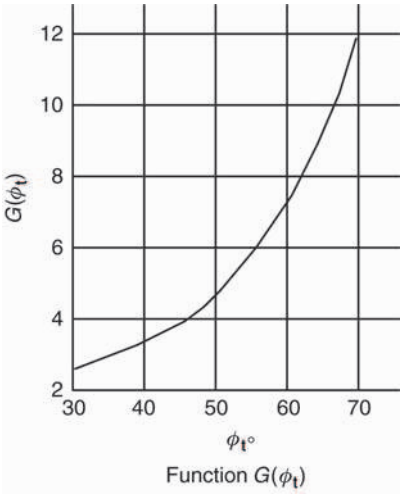

FIGURE 26.16 Plot of derived function $G(\phi_t)$ used to calculate critical rathole diameter for funnel flow bins.

where:

γ is the average bulk density of the powder in the bin
R is the hydraulic radius (area/perimeter)
μ is the coefficient of friction, (μ = tangent ϕ'). The value of ϕ' is determined from the wall friction test (discussed in the next section)
k is the ratio of horizontal to vertical pressures. A k value of 0.4 is typically used for a straight sided section.
h is the depth of the bed of powder within the bin.

This relationship in Eq. (26.2) cannot be reduced further (eg, to a dimensionless ratio) because the function $f_c(\sigma_1)$ is highly material-dependent.

The application of these parameters (B_c, D_f) to design new equipment or develop corrective equipment modifications is further discussed in Section 26.5.

26.4.1.4 *Wall friction: determining hopper angles for mass flow*

Test Method: The wall friction test is crucial in determining whether a given bin will discharge in mass flow or funnel flow (mass flow and funnel flow are discussed in the previous section). Wall friction is caused by the powder particles sliding along the wall surface. In Jenike's continuum model,[9] wall friction is expressed as the wall friction angle (ϕ'). The lower the wall friction angle, the shallower the hopper or chute walls need to be for powder to flow along them. This coefficient of friction can be measured by shearing a sample of powder in a test cell across a stationary wall surface using a Jenike Direct Shear tester.[9,12] One arrangement of a cell used for the wall friction test is shown in Fig. 26.17. In

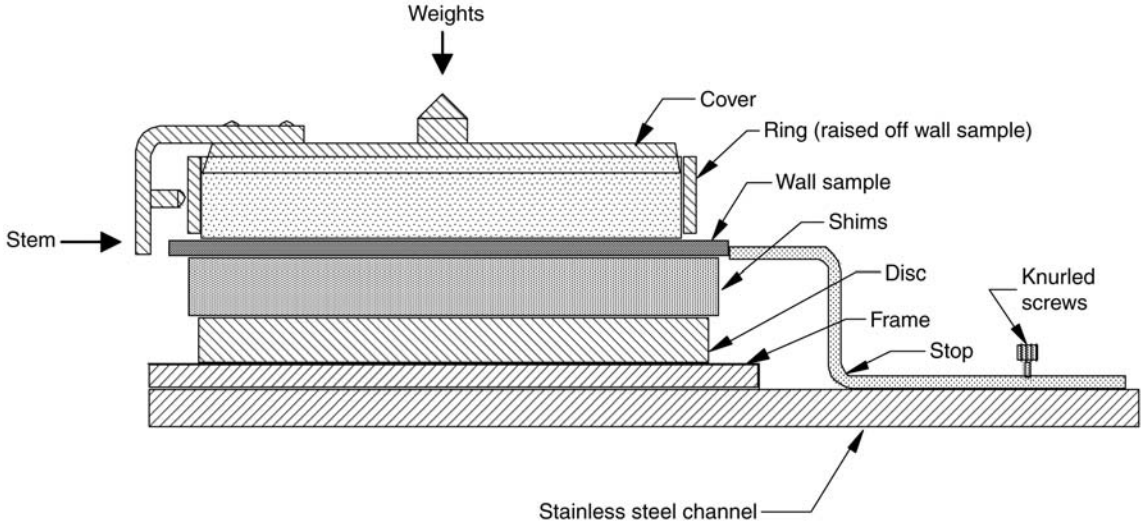

FIGURE 26.17 Jenike Direct Shear Test, wall friction test set-up.

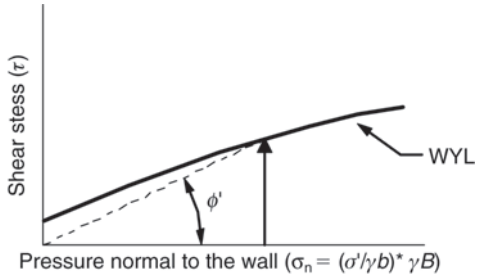

FIGURE 26.18 Example of wall yield locus generated from wall friction test data.

this case, a coupon of the wall material being evaluated is held in place on the frame of the tester, and a cell of powder is placed above. The coefficient of sliding friction (μ, μ = tangent ϕ') is the ratio of the shear force required for sliding (τ) to the normal force applied perpendicular to the wall material coupon (σ_n). A plot of the measured shear force (τ) as a function of the applied normal pressure (σ_n) generates a relationship known as the wall yield locus (see Fig. 26.18).

The wall friction measured is a function of the powder handled and the wall surface (type, finish, orientation) in contact with it. Variations in the powder, handling conditions (eg, temperature/RH), and/or the wall surface finish can have a dramatic effect on the resulting wall friction coefficient.[18] The results of the wall friction test are used to determine the hopper angles required to achieve mass flow and will be discussed in the next section.

26.4.1.5 Calculation of recommended mass flow hopper angles

Based upon mathematical models, design charts[9] have been developed to determine which flow pattern is to be expected during gravity discharge from a bin. The design charts use the following inputs for the powder being handled, and the bin design being considered:

1. the hopper angle ("θ_c" for a conical hopper or "θ_p" for a planar hopper), as measured from the vertical;
2. the wall friction angle (ϕ'), as measured from the wall friction tests;
3. the internal friction angle (δ), as measured from the cohesive strength tests.

This chapter will focus on the calculation of the recommended mass hopper angles for a conical hopper (θ_c) because the majority of pharmaceutical processes utilize bins with a conical hopper. The methods to calculate the recommended mass hopper angles for a planar hopper (θ_p) with a slotted outlet are

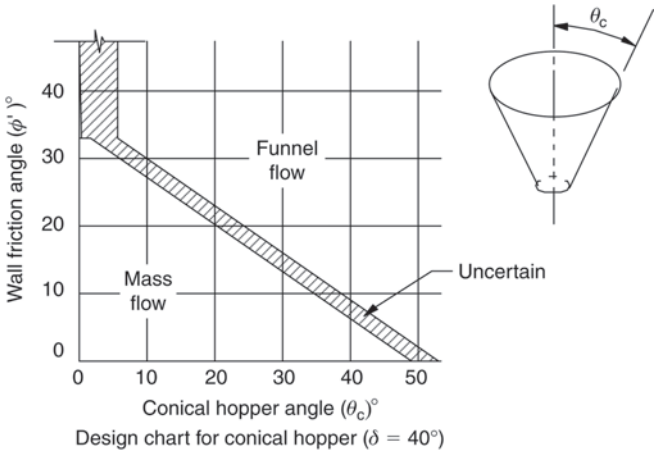

FIGURE 26.19 Mass flow/funnel flow design chart for conical hopper handling a bulk solid with an effective angle of internal friction (δ) of 40 degree.

similar in approach, and are outlined in Jenike.[9] It is worth noting that the recommended mass flow angles for planar hopper walls (θ_p) can often be 8–12 degree shallower than those for a conical hopper (θ_c), for the same sized opening.

An example of such a design chart for a conical hopper is shown in Fig. 26.19. The design chart shown is specifically for a powder with an effective angle of internal friction (δ) of 40 degree; the design charts will be different for different values of δ.[9] Hopper angles required for mass flow are a function of δ, since flow along converging hopper walls involves interparticle motion of the powder. For any combination of ϕ' and θ_c that lies in the mass flow region, mass flow is expected to occur. If the combination lies in the funnel flow region, funnel flow is expected. The "uncertain" region is an area where mass flow is expected to occur in theory, but represents a 4 degree margin of safety on the design, to account for inevitable variations in test results and surface finish.

As an example of using the design chart, a bin with a conical hopper angle (θ_c) of 20 degree from vertical is used. Wall friction tests are conducted on the hopper wall surface, and a wall friction angle of 35 degree is measured for the normal pressure calculated at the outlet. Based upon the design chart, this bin would be expected to discharge in funnel flow. In that case, the designer would need to find another wall surface, with a wall friction angle that is less than 20 degree, to ensure mass flow discharge.

The wall friction angle (ϕ') is determined by the wall friction tests described previously. The value of ϕ' to use for the hopper design charts will be selected for

the expected normal pressure (σ_n) against the surface at the location of interest in the bin (eg, the hopper outlet). For many combinations of wall surfaces and powders, the wall friction angle changes, depending on the normal pressure. When mass flow develops, the solids pressure normal to the wall surface is given by the following relationship:

$$\sigma_n = (\sigma'/\gamma b) * \gamma B \tag{26.4}$$

where:

$(\sigma'/\gamma b)$ is a dimensionless parameter that can be found in Jenike[9];
B (units of length) is the span of the outlet: the diameter of a circular outlet or the width of a slotted outlet;
is the bulk density at the outlet.

Generally, ϕ' increases with decreasing normal pressure (σ_n). The corresponding normal pressure to the wall (σ_n) is the lowest at the outlet where the span (B) is the smallest. Therefore, it is at the outlet where the wall friction angle (ϕ') is the highest for a given design, provided the hopper interior surface-finish and angle remain constant above the outlet. As a result, if the walls of the hopper are steep enough at the outlet to provide mass flow, mass flow should be expected at the walls above the outlet (regardless of total bin size).

The hopper angle required for mass flow is principally dependent on the outlet size selected for the hopper under consideration. The hopper angle required for mass flow is not a function of the flow rate, the level of powder within the bin or the diameter or height of the bin. A steeper hopper is often required to achieve mass flow for a bin with a smaller outlet because the wall friction angle generally increases with lower normal pressures.

26.4.2 Bulk density

The bulk density of a given powder is not a single or even a dual value, but varies as a function of the consolidating pressure applied to it. There are various methods used in industry to measure bulk density. One prominent method is utilizing different sized containers that are measured for volume after being loosely filled with a known mass of material ("loose" density), and after vibration or tapping (tapped density), such as the USP Chapter <616> method.[19] These methods can offer some repeatability with respect to the conditions under which measurements are taken. However, they do not necessarily represent the actual compaction behavior of a powder being handled in a bin, chute, or press hopper. Therefore, it is necessary to measure the bulk density over a range of consolidation pressures, via a compressibility test,[9,20] for design purposes. The results of the compressibility test can often be plotted as a straight line on a log–log plot (see Fig. 26.20). In powder handling literature, the slope of this line is typically called the "compressibility" of the powder.

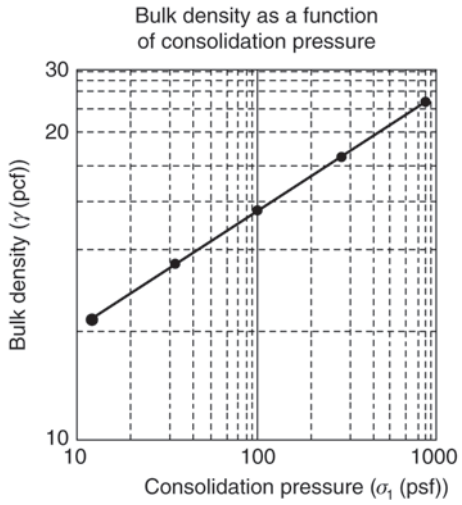

FIGURE 26.20 Example of bulk density versus consolidation pressure plot from compressibility test data.

The resulting data can be used to determine capacities for storage and transfer equipment, and evaluate wall friction and feeder operation requirements. As an example, when estimating the capacity of a bin, the bulk density based upon the average major consolidation pressure in the bin can be used. For the calculation of the arching dimensions (B_c), and recommended mass flow hopper angles (θ_c), the bulk density based on the major consolidation pressure at the bin outlet can be used.

26.4.3 Permeability

The flow problems that can occur due to adverse two-phase (powder and interstitial gas) flow effects were reviewed in Section 26.3. These problems are more likely to occur when the target feed rate (eg, tableting rate) exceeds the "critical flow rate," based on the powder's physical properties. The results of the permeability test are one of the primary flow properties used to determine the critical flow rate. The permeability of a powder is a measurement of how readily gas can pass through it. The permeability will have a controlling effect on the discharge rate that can be achieved from a bin/hopper with a given outlet size. Sizing the outlet of a

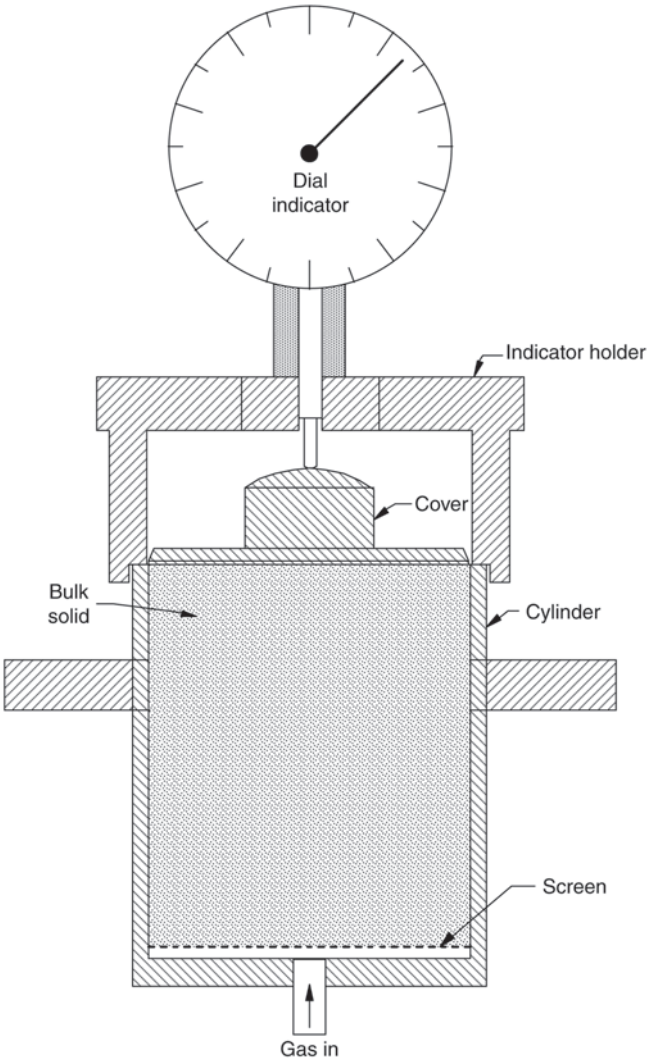

FIGURE 26.21 Schematic of permeability test set-up.

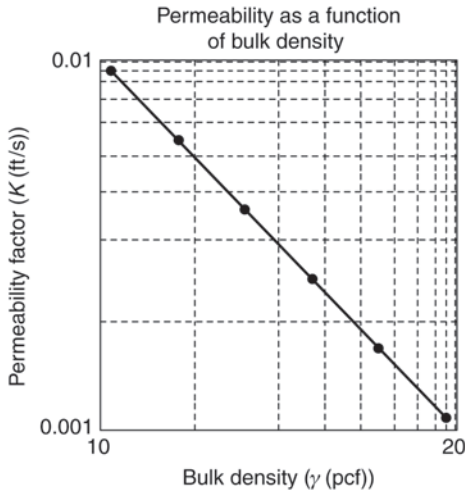

FIGURE 26.22 Example of permeability versus bulk density plot from permeability test data.

piece of equipment or choosing the diameter of a transfer chute should take into consideration the target feed rate.

Permeability is measured as a function of bulk density.[20] A schematic of the permeability test is provided in Fig. 26.21. In this test set-up, gas is injected at the bottom of the test cell through a permeable membrane. During the test, the pressure drop and flow rate across the powder are measured. The method involves measuring the flow rate of air at a predetermined pressure drop through a sample of known density and height. The permeability is then calculated using Darcy's law. The permeability of a powder typically decreases as the bulk density increases, so the test is conducted over a range of bulk densities.

Once the permeability/bulk density relationship is determined (see Fig. 26.22), it can be used to calculate the critical flow rates that will be achieved for steady-flow conditions though various outlet sizes. The critical flow rate is dependent upon the permeability, bin geometry, outlet size, and consolidation pressure. The details of calculating critical flow rates are outside the scope of this chapter, but mathematical models have been developed for these calculations.

Higher flow rates than the calculated critical flow rate may occur, but may result in unsteady or erratic feed and resulting adverse effects, as discussed in Section 26.3. Permeability values can also be used to calculate the time required for fine powders to settle or deaerate in equipment.

26.4.4 Segregation tests

When developing a product or designing a process, it is beneficial to know whether the blend will be prone to segregation. If the blend is prone to segregation, it is beneficial to know what segregation mechanism(s) will occur, since this information can be used to modify the material properties (eg, excipient selection, component PSD, etc.) to minimize the potential for segregation. An understanding of the potential for segregation can alert the equipment or process designer to potential risks that may then be avoided during the scale-up process. In some cases, significant process steps, such as granulation, may be required to avoid potential segregation problems.

There are two ASTM standard practices on segregation test methods.[21,22] These tests are designed to isolate specific segregation mechanisms, and test a material's tendency to segregate by that mechanism. A brief description of these test methods is provided next.

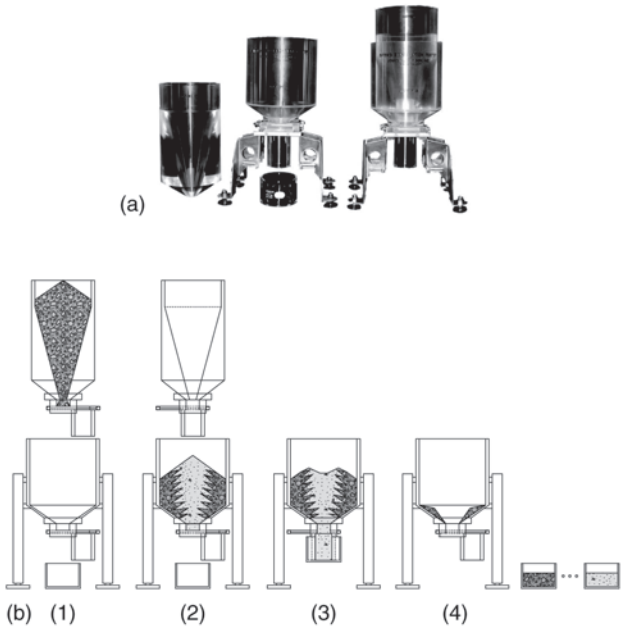

FIGURE 26.23 Sifting segregation testers (a); and sifting segregation test sequence (b). *Source: Photo provided courtesy of Jenike & Johanson, Inc.*

FIGURE 26.24 Fluidization segregation tester (controls not shown). *Source: Photo provided courtesy of Jenike & Johanson, Inc.*

26.4.4.1 Sifting segregation test method

The sifting segregation test (Fig. 26.23a) is performed by center-filling a small funnel flow bin, and then discharging it while collecting sequential samples. If sifting segregation occurs either during filling or discharge, the fines content of the discharging material will vary from beginning to end. Samples are collected from the various cups (ie, the beginning, middle, and end of the discharge). These collected samples can then be measured for segregation by particle size analyses, assays, and/or other variables of interest.

The sequence for performing the sifting segregation test is depicted in Fig. 26.23b, and is:

1. the blend is placed in mass flow bin;
2. the material is discharged from a fixed height, dropping into a funnel flow bin. This transfer of material will promote segregation if the material is prone to segregate due to sifting;
3. the material is discharged from the funnel flow bin. The discharge pattern will cause material from the center to discharge first, and material from near the walls to discharge last; and
4. the collected samples are then measured for segregation.

26.4.4.2 Fluidization segregation test method

The fluidization segregation test (Fig. 26.24) is run by first fluidizing a column of material by injecting air at its base. After the column is thoroughly fluidized, it is held near a minimum fluidization velocity for a predetermined period of time. The air is then turned off, and the material is allowed to deaerate. The column is then split into three equal sections (top, middle, and bottom) and the resulting samples are measured for segregation.

Several other researchers and companies have developed various segregation testers, including methods that induce vibration,[23,24] shearing in a cell,[25] and methods that capture material from a pile after it has formed.[25–27] Improvements and variations to the ASTM test methods have also been made. A fluidization segregation tester that utilizes a different mechanism to fluidize the bed has been developed.[28] It uses a smaller test sample, and provides unit-dose samples for analysis. As another example, an alternate way to run the ASTM sifting segregation test involves cycling the blend multiple times to strengthen the segregation "signal."[29]

Segregation tests are useful for identifying the:

1. segregation mechanism(s) that might be active for a given blend;
2. general segregation trend that may be observed in the process; and
3. comparisons between different formulas, variations of the same formula, etc.

However, the test results have limitations. Most notably, the segregation results are not scaleable from the tester to the manufacturing process, and therefore cannot be tied quantifiably to the process. The segregation test results do not necessarily mean that a highly segregating material cannot be handled in a manner that

prevents content uniformity problems. Therefore, the segregation test methods are primarily used as a stress test to identify the dominant segregation mechanism(s) expected to occur. This information enables the equipment designer to take the appropriate precautionary measures during scale-up or make corrective actions to existing equipment. Design techniques to minimize the potential for segregation are outlined in Section 26.5.

26.5 BASIC EQUIPMENT DESIGN TECHNIQUES

Objective of the section

The primary objective of Section 26.5 is to review basic design techniques for the bin-to-press feed system, to provide consistent, reliable flow for gravity feed, and minimize segregation. In particular, we will review the following basic design techniques:

1. reliable funnel flow bin design;
2. reliable mass flow designs for bins, transfer chutes, and press hoppers;
3. minimizing adverse two-phase flow effects (eg, feed/tableting rate limitations, flooding);
4. minimizing segregation during blender to press transfers.

For each of these different design concerns, we will review the key equipment design parameters. Regardless of whether the equipment being designed is a bin, transfer chute, or press hopper, a crucial first step in designing a reliable feed system is determining the flow pattern, and designing the equipment accordingly. These design techniques will focus on equipment commonly used in batch processes, but can also be applied to continuous manufacturing equipment. Section 26.4 discussed the wall friction tests and design charts used to determine if a hopper will discharge in mass flow or funnel flow.

26.5.1 Reliable funnel flow design (preventing a rathole)

Funnel flow occurs when the hopper walls are not smooth and/or steep enough to promote flow at the walls. Funnel flow bins can be prone to ratholing if the material is cohesive enough. A funnel flow bin design can be considered if all of the following design criteria are met:

1. Segregation of the final blend is not a concern. Since a funnel flow bin will discharge in a first-in-last-out flow sequence, any side-to-side segregation that occurred as the bin was filled will often be exacerbated in funnel flow discharge.
2. The final blend has low cohesive strength, therefore the formation of a stable rathole is not a concern. This can be checked by comparing the bin outlet diameter/diagonal length to the critical rathole diameter (D_f) for the estimated major consolidation pressure (σ_1) for the bin design in question as per Eqs. (26.2) and (26.3) (see Section 26.4). If the outlet diameter is less than D_f, ratholing is a concern.
3. Flooding due to a collapsing rathole is not a concern. Flooding can result in highly aerated (low density) powder being fed from the bin to the press, which may have an adverse effect on the tablet properties (weight, hardness, dissolution variation), and can result in segregation.
4. A nonuniform feed density is not a concern. Variation of the feed density into the press feed frame can result in tablet weight variation because tablet presses operate as volumetric feeders.

If all of these design criteria are met, a funnel flow bin design can be considered. If a funnel flow bin design is acceptable, the first concern is checking that the outlet diameter is greater than the critical rathole diameter (D_f), to ensure that a stable rathole will not form. If the diameter of the funnel flow bin is not greater than D_f, the following steps can be considered to reduce the likelihood of ratholing:

1. Enlarge the bin opening: this may require using a slotted outlet, which would require a feeder capable of feeding uniformly across the entire outlet (eg, mass flow screw feeder) or a valve capable of shutting off such an outlet. Using a larger outlet diameter may not be a practical modification, since the opening may need to be increased to be larger than standard valve or feeder sizes.
2. Reduce the material level in the bin: the critical rathole diameter typically decreases with a reduction in the major consolidation pressure (σ_1), which is a function of the fill height.
3. Use an internal, mechanical agitator: an internal, mechanical agitator, such as an agitator with "arms" that rotate about a central vertical shaft, may be a practical modification on a small scale for a press hopper. A bin with a discharge valve (eg, Matcon discharge valve) could also be considered a means of failing a stable rathole, but may need to be assessed via full scale trials to determine the operating parameters required (valve "stroke" setting, etc.).
4. Use external vibrators: the effectiveness of external vibrators to collapse a stable rathole would need to be assessed via full-scale trials prior to installation, since vibration may actually increase the strength on the blend in the bin and increase the likelihood of ratholing. Trials would be required to assess the optimum vibrator type

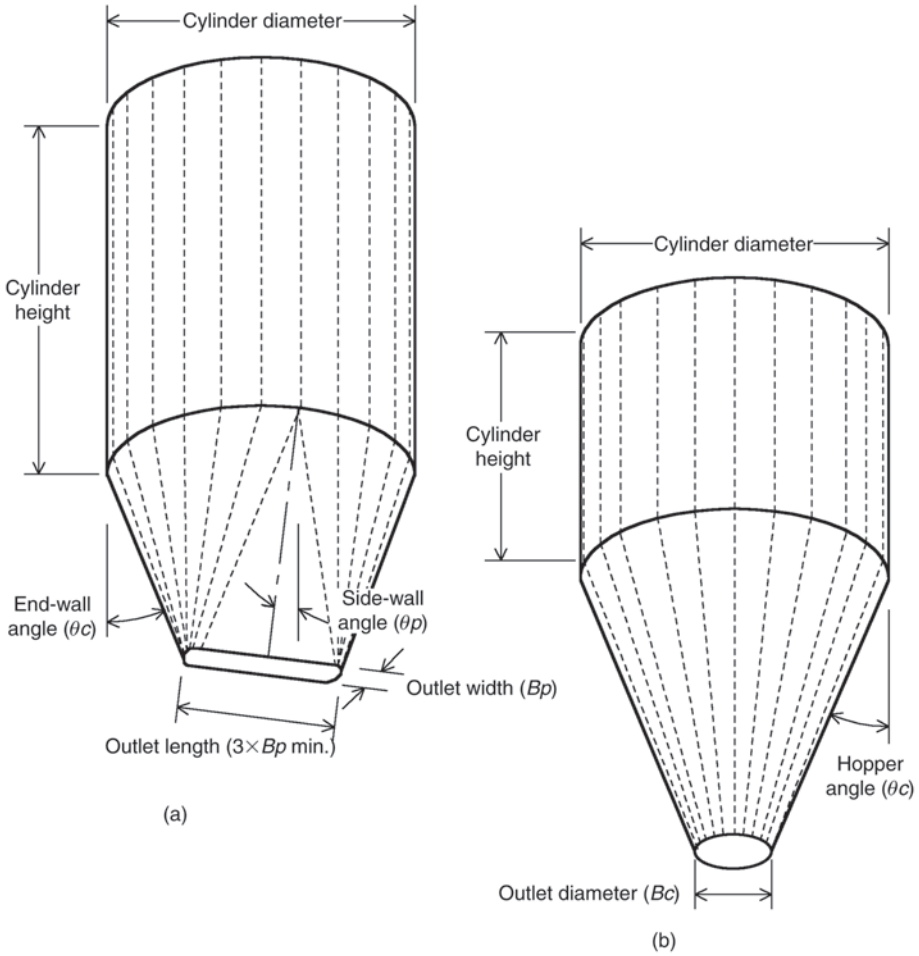

FIGURE 26.25 Mass flow design parameters (B_c, B_p, θ_c, θ_p). (a) Transition hopper; (b) Conical hopper

(high-frequency/low-amplitude vs low-frequency/high-amplitude), number of vibrators required, location, frequency settings, and other design considerations.

There are several adverse effects of using a bin that discharges in funnel flow (first-in-last-out flow sequence, nonuniform feed density, exacerbation of segregation). In addition, the potential options to prevent a rathole are often limited or impractical. Therefore, a common design technique for preventing ratholing is to redesign the bin for mass flow. The design techniques for mass flow are discussed in the following section.

26.5.2 Reliable mass flow designs for the bin, chute, and press hopper

Mass flow discharge from a bin occurs when the following two design criteria are met:

1. The bin walls are smooth and/or steep enough to promote flow at the walls;
2. The bin outlet is large enough to prevent an arch.

The wall friction tests and design charts used to determine if a bin will discharge in mass flow or funnel flow were discussed in Section 26.4. This section focuses on design techniques for mass flow bins, but these techniques may also be extended to obtaining mass flow in a transfer chute and press hopper. These techniques may be applied to designing new equipment or modifying existing equipment to provide mass flow.

When designing the bin to provide mass flow, the following general steps should be taken:

1. Size the outlet to prevent a cohesive arch: the bin designer should ensure that an arch will not form by making the outlet diameter equal to or larger than the minimum required outlet diameter (B_c, see Fig. 26.25). If a slotted outlet is used (maintaining a 3:1 length:width ratio for the outlet), the outlet width should be sized to be equal to or larger than the minimum required outlet width (B_p, see Fig. 26.25). The outlet may also need to be sized based upon the feed rate and two-phase flow considerations, as discussed next. If the outlet

cannot be sized to prevent an arch (eg, press hopper outlet that must mate with a fixed-feed frame inlet), an internal mechanical agitator or external vibrator could be considered, as discussed in the preceding section.

2. Make the hopper walls steep enough for mass flow: once the outlet is sized, the hopper wall slope should be designed to be equal to, or steeper than, the recommended hopper angle for the given outlet size, and selected wall surface. For a conical hopper, the walls should be equal to, or steeper than, the recommended mass flow angle for a conical hopper (θ_c, see Fig. 26.25). If the bin has a rectangular-to-round hopper, the valley angles should be sloped to be equal to or steeper than, θ_c. For planar walls, the walls should be equal to, or steeper than, the recommended mass flow angle for a planar hopper (θ_p, see Fig. 26.25).
3. Pay careful attention to the interior wall surface finish: when conducting the wall friction tests, it is beneficial to conduct tests on several different finishes (eg, #320 grit finish, #2B cold rolled finish, #2B electro-polished finish, etc.). This will provide the bin designer with a range of design options for the bin. Testing multiple wall surfaces will also enable the designer to assess the sensitivity of the wall friction results to different finishes. It is insufficient to simply test a 304 or 316 stainless steel with no regard to the interior finish. The wall friction of the blend may vary significantly from finish to finish. The orientation of directional finishes, such as a mechanical polish, is also critical to assess and control during fabrication. In addition, it cannot be assumed that an interior surface finish with a lower average roughness (R_a) will provide the best wall friction properties.
4. Consider velocity gradients: even when a bin is designed for mass flow, there still may be a velocity gradient between the material discharging at the hopper walls (moving slower) versus the center of the hopper (moving faster), assuming a symmetric bin with a single outlet in the center. Depending upon the application, the bin designer may want to increase the velocity gradient to enhance blending between vertical layers of material in the bin. Alternatively, the bin designer may want to reduce the velocity gradient to enhance blending on a side-to-side basis. The decision to increase or decrease the velocity gradient will be depend upon the segregation that occurs upon filling the bin, and its effect upon content uniformity. The velocity gradient is reduced by making the hopper slope steeper, with respect to the recommended mass flow hopper angle (θ_c). The velocity gradient is increased by making the hopper slope closer to (but still steeper than) the recommended mass flow hopper angle. Changing the interior surface to reduce friction or using an insert (discussed more next) are other methods used to control the velocity gradient. Asymmetric hoppers, which are common for press hoppers, are especially prone to velocity gradients since the material will move faster at the steeper hopper wall. In addition, a velocity gradient cannot be completely eliminated, especially as the material level in the hopper empties. Velocity profiles, and their effect on blending material, can be calculated a priori given the geometry of the bin (θ_c) and measured flow properties that were discussed in Section 26.4 (ie, ϕ', δ, ϕ).
5. Avoid upward-facing lips/ledges due to mismatched flanges (eg, see Fig. 26.26), level probes, view ports, partially opened valves, etc., especially in the hopper section. Interior protruding devices should be ideally located in the straight-sided (nonconverging) section of a bin/press hopper if possible, where they will be less detrimental in upsetting a mass flow pattern.

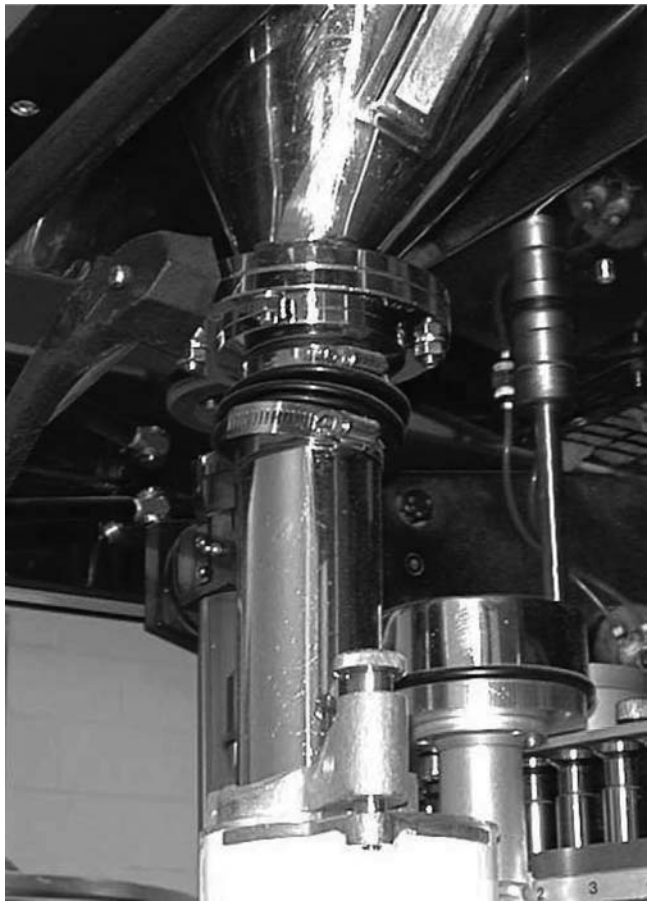

FIGURE 26.26 Example of an upward-facing ledge at a flange connection.

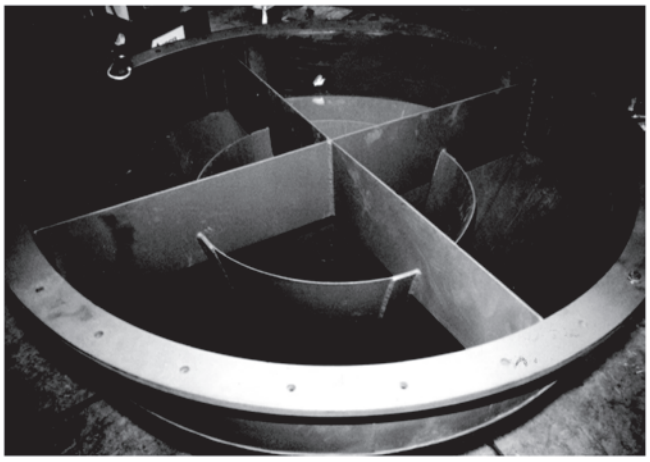
If the bin designer is modifying an existing funnel flow bin to provide mass flow, several different options can be considered, including:

1. Using a different interior surface finish with better wall friction properties (ie, lower wall friction). The bin designer should conduct wall friction tests on alternative wall surfaces, to assess if changing the surface finish (eg, electro-polishing an existing #2B finish) will convert the bin from funnel flow to mass flow. This is often one of the most cost-effective modifications to obtain mass flow.
2. Using a flow-controlling insert such as a Binsert (Fig. 26.27) to obtain mass flow within the same bin. A properly designed insert can change the stresses that develop in the bin during discharge, so that mass flow can be obtained at a wall where the material was previously stagnant.
3. Modifying the hopper geometry. Use a different geometry that is more likely to provide mass flow (eg, conical instead of a rectangular-to-round hopper with shallower valley angles). If the hopper is modified to have a slotted outlet, it is crucial that the feeder the hopper mates to withdraws material across the entire outlet.



(a)

(b)

FIGURE 26.27 (a) Example of an "open" Binsert design; (b) Example of a "closed" Binsert design.

In addition to these design techniques for bins, there are several additional design techniques for designing transfer chutes for reliable mass flow including:

1. For converging sections that have a full cross-section (ie, hoppers) use the same design criteria discussed previously for a mass flow bin.
2. For nonconverging sections of the chute, the chute should be sloped to exceed the wall friction angle (ϕ') by a least a 10 degree margin of safety. As an example, if the measured wall friction angle for the given wall surface (from the wall friction test results) is 40 degree from horizontal, the recommended chute angle for the nonconverging portion of the chute would be at least 50 degree from horizontal.
3. If a bifurcated chute is used, the sloping chute legs should be symmetric, to prevent velocity gradients and the possibility of stagnant material in the shallower leg.
4. Use mitered joints between sloping and vertical sections.

26.5.3 Minimizing adverse two-phase flow effects

The primary focus in preventing adverse two-phase flow affects is to ensure that the powder handling equipment is designed so that the critical flow rate through a given outlet is greater than the target feed rate. The critical flow rate is determined using mathematical models, with permeability and compressibility test results as primary inputs. The critical flow rate is also a strong function of the outlet size, and increases as the outlet size increases. The target feed rate is often set by the required maximum tableting rate for the process. Adverse two-phase flow effects are typically most pronounced at the press feed hopper because it often has the smallest outlet in the entire press feed system. Therefore, the press hopper will typically have the lowest critical flow rate.

When designing the powder handling equipment to minimize adverse two-phase flow effects, the following general design techniques are beneficial:

1. Design the equipment for mass flow: mass flow will provide consistent feed and a more uniform consolidation pressure acting on the powders. In

addition, having a first-in-first-out flow sequence will allow the material more time to deaerate before being discharged through the outlet. This will reduce the likelihood of flooding. Mass flow will also prevent collapsing ratholes that can result in the powder aerating and flooding as it falls into the central flow channel. It is worth noting that mass flow can result in a lower critical flow rate than funnel flow, but will be more stable. Therefore, simply using a mass-flow bin design may not be the only corrective action required if a flow rate limitation occurs. However, designing the equipment for mass flow is often the first step in addressing adverse two-phase flow effects.

2. Use larger outlets for the handling equipment: the critical flow rate is a strong function of the cross-sectional area of the outlet. Therefore, increasing the outlet can often be highly beneficial in reducing two-phase flow effects. The goal would be to increase the outlet size until the critical flow rate for the selected outlet size exceeds the target flow rate. Since this may not be feasible for a press feeder hopper, in which the outlet size is fixed to mate with the press feed frame inlet, additional design techniques are discussed next. Computer software can be used to model the two-phase flow behavior to assess the effect of changing the outlet diameter.
3. Reduce the fill height in the handling equipment: the critical flow rate through a given outlet increases as the major consolidation pressure (σ) decreases. Therefore, reducing the fill height will be beneficial, but much less effective than increasing the outlet size.
4. Reduce the target feed rate: if possible, reducing the target feed rate (tableting rate) to be less than the critical flow rate will be beneficial, but is often impractical because it will result in decreased production rate.
5. Consider gas pressure differentials: a gas pressure differential can have a beneficial or adverse effect upon two-phase flow effects. A positive gas pressure differential at the outlet (ie, bin at a higher gas pressure than the equipment downstream) may be beneficial in overcoming a feed rate limitation. In this case, the air pressure is forcing the material in the direction of flow. Conversely, a negative gas pressure differential at the outlet can further reduce the critical flow rate because the negative gas pressure acts to further retard the flow rate.
6. Add air permeation: air permeation may be added to the system actively via an air injection system or passively through a vent. In particular, adding judicious (often very small) amounts of air at the location in the press feed system where the interstitial gas pressure is lowest can often be beneficial. However, this can be very unstable for small systems and/or very low permeability materials.
7. Changing the PSD of the powder: the permeability of a powder is a strong function of its PSD. Powders with a finer PSD are often less permeable and, therefore, more prone to adverse-two phase flow effects. Even a reduction in the percentage of fine PSDs can often be beneficial in increasing the permeability of a powder, and decreasing the likelihood of adverse two phase-flow effects.

The key to implementing any corrective actions designed to reduce adverse flow-effects will be using a mathematical two-phase flow analysis to assess the effects on the bulk solids' stresses and interstitial gas pressure. This analysis would need to use inputs such as key flow properties (ie, permeability, compressibility), and equipment/process parameters (ie, tableting rate, bin/hopper geometry, and gas pressure gradients) to assess the effect of the potential corrective actions outlined previously.

26.5.4 Minimizing segregation in the blender-to-press transfer steps

It may be challenging for a designer to determine which segregation mechanism(s) is dominant, and develop appropriate corrective actions. This requires knowledge of the material's physical and chemical characteristics, as well as an understanding of the segregation mechanisms that can be active. One must identify the process conditions that can serve as a driving force to cause segregation. Flow properties measurements (ie, wall friction, cohesive strength, compressibility, and permeability) can help to provide understanding of the behavior of the material in storage and transfer equipment. Consideration should be given to the fill/discharge sequence, including flow pattern and inventory management, which gives rise to the observed segregation. Testing for segregation potential (see Section 26.4) can provide additional insight about the mechanisms that may cause segregation. Sufficient sampling is required to support the hypothesis of segregation (eg, blend samples and final product samples, samples from the center vs periphery of the bin). Finally, one must consider the impact of analytical and sampling errors specific to the blend under consideration, as well as the statistical significance of the results, when drawing conclusions from the data.

From the previous discussion about segregation mechanisms, it can be concluded that certain material properties, as well as process conditions, must exist for segregation to occur. Elimination of one of these will prevent segregation. It stands to reason, then, that if segregation is a problem in a process, one should look for opportunities to either: (1) change the material or

(2) modify the process equipment or conditions. This chapter focuses on the equipment and process design techniques to minimize segregation in batch processes.

Some generalizations can be made when designing equipment to minimize segregation. The complete details on how to implement these changes correctly are beyond the scope of this chapter. However, all equipment must be designed based on the flow properties and segregation potential of the blends being handled.

Primary equipment and process design techniques to minimize segregation during the final blender-to-press transfer include:

1. Minimize the number of material transfer steps. The tendency for segregation increases with each transfer step and movement of the bin. Ideally, the material would discharge directly from the blender into the tablet press feed frame, with no additional handling. In-bin blending is as close to this as most firms can obtain practically. This assumes that a uniform blend can be obtained within the bin blender in the first place.
2. Storage bins, press hoppers, and chutes should be designed for mass flow. In mass flow, the entire contents of the bin are in motion during discharge. In funnel flow, stagnant regions exist.
3. Minimize transfer chute volumes to reduce the volume of displaced air, and the volume of potentially segregated material. However, the chute must remain large enough to provide the required throughput rates.
4. Use a storage bin with a larger height:diameter aspect ratio. A mass flow bin with a tall, narrow cylinder will minimize the potential for sifting segregation, compared with a short, wide bin. A disadvantage is that the taller drop height may exacerbate other segregation mechanisms.
5. Bins and blenders should be vented to avoid gas counterflow. Air in an otherwise "empty" bin must be displaced out of the bin as powder fills it. If this air is forced through material in the V-blender, it can induce fluidization segregation within the blender. A separate pathway or vent line to allow the air to escape without moving through the bed of material can reduce segregation.
6. Velocity gradients within bins should also be minimized. The hopper must be significantly steeper than the mass flow limit to achieve this. A steeper hopper section may result in an impractically tall bin. Alternate approaches include the use of inserts (discussed previously). If an insert is used, it must be properly designed and positioned to be effective. Asymmetric bins and hoppers should be avoided if possible, and symmetrical ones should be used whenever possible.
7. Dust generation and fluidization of the material should be minimized during material movement. Dust can be controlled by way of socks or sleeves, to contain the material as it drops from the blender to the bin, for example. Some devices are commercially available. An example of this is a solids decelerator shown in Fig. 26.28.
8. Drop heights should be minimized where possible. Drop heights may aerate the material, induce dust, and increase momentum of the material as it hits the pile. This will increase the tendency for each of the three segregation mechanisms to occur.
9. Valves should be operated correctly. Butterfly valves should be operated in the full open position, not throttled to restrict flow. Restricting flow will virtually assure a funnel flow pattern, which is usually detrimental to uniformity.
10. Use a symmetrical split whenever a process stream is divided. A symmetrical split, such as a bifurcated chute to feed two sides of a press (a Y-branch), will eliminate potential differences in the flow between the two streams. Consideration must be given to any potential for segregation upstream of the split. Even seemingly minor details, such as the orientation of a butterfly valve prior to a split, can affect segregation. Proper designs should be utilized for Y-branches to avoid stagnant material and air counterflow.

FIGURE 26.28 Example of a solids deceleration device. *Source: Photo provided courtesy of GEA Process Engineering.*

Other specific solutions may become apparent once the segregation mechanism has been identified. For example, mass flow is usually beneficial when handling segregation-prone materials, especially materials that exhibit a side-to-side (or center-to-periphery) segregation pattern. Sifting and dusting segregation mechanisms fit this description.

It is important to remember that mass flow is not a universal solution because it will not address a top-to-bottom segregation pattern. As an example, consider the situation in a portable bin where fluidization upon filling the bin has caused the fine fraction of a blend to be driven to the top surface. Mass flow discharge of this bin would effectively transfer this segregated material to the downstream process, delivering the coarser blend first, followed by the fines.

In summary, when addressing segregation concerns it is crucial to know the chosen process, and how the blend will segregate before implementing equipment designs or corrective actions.

Capsules Dosage Form: Formulation and Manufacturing Considerations

S.W. Hoag

University of Maryland, Baltimore, MD, United States

27.1 INTRODUCTION—CAPSULES AS A DOSAGE FORM

Capsules are a unique dosage form with a long history of use in pharmacy. The original patent was issued in 1834 to a Parisian pharmacist, Joseph Gérard Dublanc, and pharmacy student, François Achille Barnabé Mothès, for the invention and manufacture of gelatin capsules.[1] The basic idea of a capsule is to enclose the drug or active pharmaceutical ingredient (API) in an odorless, tasteless, elegant, easy-to-swallow, and easy-to-fill shell. Today there are two main types of capsules: the hard gelatin capsule and the soft gelatin capsule, often called softshells. This chapter will focus on hard gelatin capsules. The hard gelatin capsule can be used for dry fills such as powder, liquids, and semisolids, while the softshell is exclusively used for liquids and semisolids. The typically capsule shell is made of gelatin, but in recent years, there have been a variety of gelatin alternatives introduced to the market. The vast majority of capsule applications are for oral delivery of an API; however, there are specialty applications such as capsules that can be loaded into dry-powdered inhalers, add reagents as part of a diagnostic kit, and occasionally as a suppository base with glycerin.[2] The majority of capsules are filled with a dry powder; however, semisolids, nonaqueous liquids, and other dosage forms such as beads, mini tablets, and even mini capsules can be filled into a capsule shell. These applications will be discussed. In terms of production, capsules are one of the most flexible forms. They can be made one a time in a compounding pharmacy, in small-scale production for clinical studies, and all the way up to commercial production with machines that can make hundreds of thousands of capsules per hour. Given the importance capsules have in the pharmaceutical industry, the objective of this chapter is to give a broad overview of capsules, gelatin, capsule manufacture, capsule filling, and capsule formulation.

From the patient perspective, capsules have many advantages, making them among the most popular dosage forms on the market. Generally speaking, most patients consider capsule shells to be smooth, slippery, and easier to swallow than tablets.[3] In addition, capsules eliminate all contact between the drug and the mouth, which makes them tasteless and odorless, as most drugs have a bitter taste with an unpleasant aftertaste. This greatly improves patient compliance and consequently therapeutic outcomes. In addition, capsules can be made with a clear, high-gloss film that can be attractively colored and printed on, and they can have an elegant appearance, which also enhances patient acceptance. For patients who have trouble swallowing, the capsule can be opened up, and the contents sprinkled on a food such as applesauce, which is advantageous for pediatric and geriatric patients.

From a drug delivery point of view, capsules have many advantages. For immediate-release (IR) dosage forms, a key step is the breakdown of the capsule shell, which is analogous to disintegration in a tablet. For capsules, this occurs readily; see the discussion of gelatin cross-link in Section 27.2.2. Thus, capsules are ideally suited for IR delivery. In addition, capsules can be used for other types of release profiles as well. In addition to dry powder fills, multiparticulate beads can be filled into capsules, as shown in Fig. 27.1. For example, morphine sulfate has a short half-life, and with an IR delivery system, it requires dosing every 8 hours, but with a

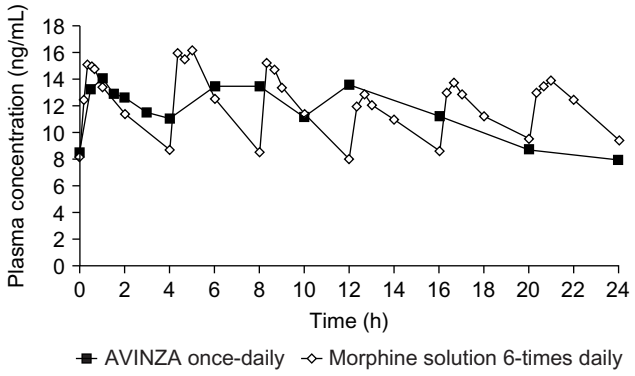

FIGURE 27.2 Multiparticulate dosing of morphine sulfate with Avinza, from the official FDA label.

controlled-release dosage such as Avinza or Kadian, it can be dosed once a day, as seen in Fig. 27.2, which is a big advantage in terms of compliance. For patients in an institutional environment, it has greater convenience for the nursing staff. In addition, with multiparticulate beads, you can have a mixture of beads with different release rates. If you look at the initial phase of the plasma concentration versus time pharmacokinetic profile in Fig. 27.2, you can see the initial onset is the same as the oral solution. This is because the coated beads are mixed with uncoated beads for rapid onset of pain relief. In addition to putting multiparticulate beads in a capsule, with modern filling equipment, you can also fill capsules with other dosage forms such as mini tablets and all possible combination of beads, tablets, capsules, powders, and even liquids, as shown in Fig. 27.1.[4]

From the company perspective, capsules can be used throughout the entire drug development process from preclinical studies in rodents to first-in-human studies all the way through the commercial manufacturing of a marketed product. While capsules are not as cost effective as tablets to manufacture, capsules are still relatively inexpensive to manufacture, and being a solid dosage form with a dry powder fill, capsule formulations promote good stability compared to other delivery systems such as liquid formulations. Another advantage of capsules is the relative ease of formulation. For initial formulations, the formulation requirements are minimal; however, as the speed of production goes up, the formulation requirements also go up. For capsules, the formulation requirements are that a consistent plug with a consistent weight is formed. For tablets, the formulation must flow well and be very compressible, which is a more stringent requirement than forming a plug with a consistent weight. The relative simplicity of capsule formulations can speed up the development process, especially for high-dose, poorly compressible drugs. This formulation simplicity makes capsules popular for clinical trials where speed is critical. Perhaps one of the biggest advantages of capsules is that they can be self-administrated, which is required for a drug to be a top seller, because of the high cost of administration by a health care worker such as with parenteral products. Nonself-administration products that are big sellers are typically only used for life-threating diseases such as diabetes where the patient must regularly give himself or herself an injection.

One big advantage of capsules from the marketing and patient perspective is the wide range of colors, sizes, and printings that are available for capsules shells (see Fig. 27.3). Having unique colors or printings of a logo can help companies establish the brand ID of a product for marketing purposes. A good example of this is Nexium (esomeprazole magnesium), which is an over-the-counter proton-pump inhibitor for gastroesophageal reflux. The unique "purple pill" has been successfully used to establish a recognizable product brand, and this could not be done without the unique purple color of the capsule shell and the printing of the gold bands and name on the capsule shell (see Fig. 27.3). Also, color is the most remembered trait of a medication and important for patient acceptance. For example, you wouldn't want to make an antidepressant capsule black or a sleep aid sunrise yellow and red. This is one area that capsules can easily accommodate a wide range of consumer tastes and preference requirements to produce an elegant dosage form that is appealing to patients.

Despite many advantages, capsules also have some important disadvantages. In common with all oral delivery systems, the capsule exposes the drug to the gastrointestinal (GI) tract and the GI tract to the drug. For example, some drugs when exposed to the GI tract

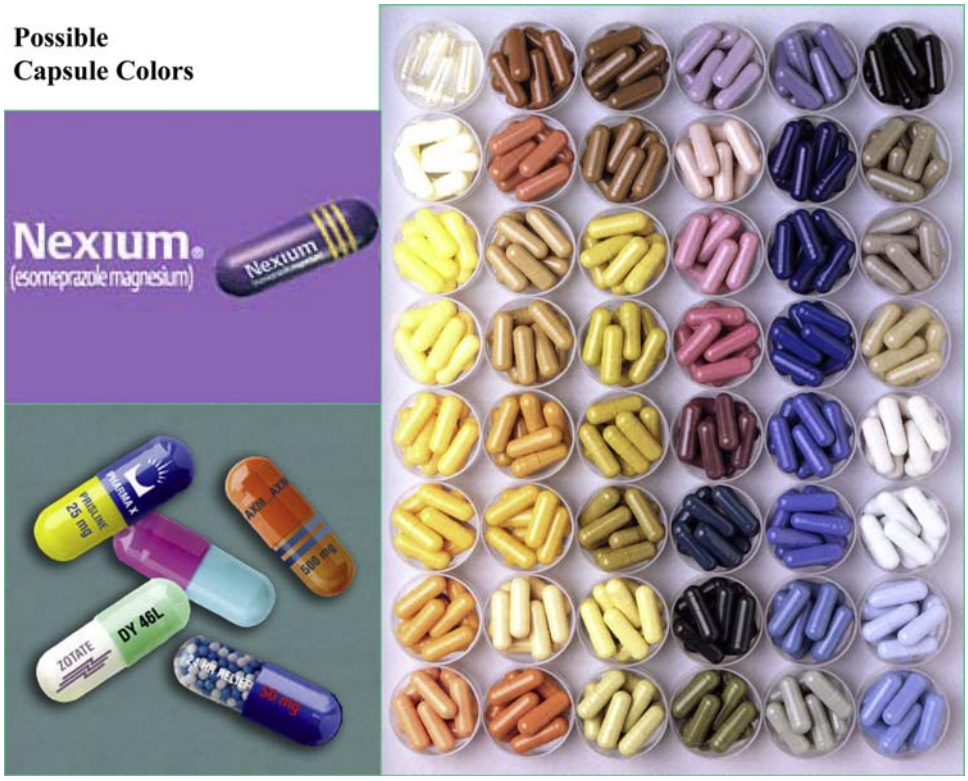

FIGURE 27.3 Diversity of capsule shell showing printing and colors.

can cause nausea, vomiting, and diarrhea. Other drugs such as iron in prenatal supplements and fish oil capsules have an unpleasant "burp back" effect, which reduces patient compliance. In addition, some drugs that are readily degraded in the GI tract, either due to stomach acids or enzymatic degradation in the stomach and small intestine, don't make good candidates for capsules. Also, for controlled-release dosage forms, the maximum duration of action is limited to the GI transit time.

Some disadvantages unique to capsules include interactions between the drug, the excipients, and the capsule shell. Hydroscopic materials may dry out the capsule shell and cause it to become brittle. A typical capsule shell has between 12% and 16% water, and if the water content drops much lower, the shell can crack during normal handling. Conversely, the capsule shells can absorb water from the environment and develop problems with drug stability due to too much water, and the capsule shell can become tacky. Another disadvantage of gelatin capsule shells is you have to make sure the shells are made from a bovine spongiform encephalopathy (BSE)–free source. In addition, capsule plugs are made with a lot less force than tablets, so for high-dose bulky materials such as botanical supplements, the dosage form size will be much bigger, and patients prefer smaller dosage forms. Tablets are less expensive to manufacture because you don't have to buy the capsule shells, and tablets have higher rates of production, which reduces capital expenditures. In my experience, capsule-filling machines are more complex than a tablet press and take a longer time to setup up, break down, and do cleaning validation due to all the moving parts. When doing a change over from one capsule size to another, you need to replace the dosing disk, the tamping pins or dosator, and all the bushings involved with separating the capsule shell. The change over from one size to another can take many hours to complete.

27.2 GELATIN AND CAPSULE SHELL COMPOSITION

Today, gelatin is the most commonly used material to make hard capsule shells; however, as gelatin alternatives gain in popularity, this may change in the future. Since the first patent in 1834, gelatin has been used to make capsule shells, and it has a long history of use in pharmaceutical capsules and as a food additive. Gelatin is cost effective and nontoxic with an excellent safety profile; the issue of BSE is discussed in Section 27.2.4. In addition, gelatin has many excellent mechanical properties such as the ability to form films

with precise dimensions and mechanical properties that can withstand the rigors of high-speed processing on commercial-scale production equipment. With gelatin, the film formation and gelling properties occur over a narrow temperature range.[5] The tribology surface properties and shell clarity are also critical for patient acceptance of a capsule shell. Also, gelatin has many excellent delivery properties. It is readily soluble in water and softens at body temperatures for rapid release; the issue of gelatin cross-linking is discussed in Section 27.2.2.[6] Gelatin is recognized in all the major pharmacopeias throughout the world. For these reasons, gelatin is the most popular material used to make two-piece hard capsule shells.

Gelatin is made up of proteins derived from the skin and the bones of cattle and pigs and is a byproduct of the meat industry, which helps make it cost effective. Gelatin is made up of primarily collagen, which is one of the main proteins in connective tissue. For example, 46% of pig skin and 29.4% of bovine hides are made of collagen.[6] Gelatin undergoes reversible thermal gelation at 35°C. This temperature and a narrow transition range are critical because capsules are made by a dipping process in a gelatin solution and when cooled must rapidly form a thin, uniform film on the dipping pin.[7] In addition, gelatin is readily soluble in water and softens at 30°C. These properties make it an excellent ingredient from a manufacturing and drug delivery point of view.[6]

There are different types of collagen found in different parts of the body. For example, skin is mainly made up of type I collagen and to a lesser extent type III collagen.[6] Collagen is composed of three chains that form a triple-helix structure. The chains have a high percentage of the amino acids glycine, proline, and hydroxyproline in a repetitive sequence.[6] When the three chains are linked together, they form a very stable triple helix that is stabilized by intrachain and interchain hydrogen bonds (see Fig. 27.4). Upon heat treatment, the triple helix can denature (other factors can lead to denaturation, but they are not relevant for this discussion), and depending upon temperature and water content, the chains can exist in different states with different degrees of cross-linking via the formation of a triple helix (see Fig. 27.5). Once denatured, they can form gels, and the extent of gel formation depends upon the temperature, moisture content, and how fast the gel solution was dried.[6,8,9] It is these changes in state with different degrees of cross-linking/triple-helix formation that contribute to the gelling behavior of gelatin and give gelatin its unique properties for forming capsules and drug release.

Gelatin is made by either acid or alkaline processing of cow bones or cow and pig hides. The process has many steps and requires a long time to complete.

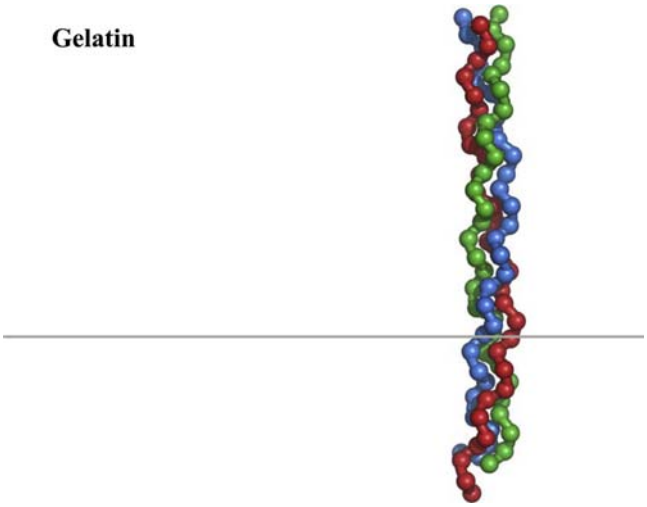

FIGURE 27.4 Structure of collagen. *Source: Wikipedia collagen.*

Fig. 27.6 shows the basic steps.[10] The gelatin made from pork skin via acid treatment is called Type A gelatin, and the gelatin made from bones and animal skin by alkaline processing is called Type B gelatin. Each gelatin type has its own properties (see Table 27.1). Type A gelatin has a higher degree of plasticity and clarity, and Type B gelatin forms tougher films and is a little hazier. A capsule shell is made from the mixture of the two gelatins, so the capsule shell has the right clarity and mechanical strength properties to run well on a filling machine.

The first step in the gelatin-making process is to pretreat the bones and hides (see Fig. 27.6). For bones, this means crushing, degreasing, and demineralization of the bones to remove all the calcium phosphate, $Ca_3(PO_4)_2$, using diluted hydrochloric acid (HCl) to solubilize the tricalcium phosphate, which can then be removed by washing. The spongy organic material left after the demineralization of the bones is called ossein.[11] The goal of the pretreatments is to produce a relatively purified collagen than can be converted into gelatin. After pretreatment, the gel can either be limed (alkaline treatment) or acid treated. The goal of liming is to condition the collagen so it produces gelatin with the desired physical properties and to do so with good yields.[10] The liming process causes both chemical and physical changes in the collagen. For example, during liming, deamination of the collagen amino acids such as glutamine and asparagine occurs with the evolution of ammonia, and the alkali labile cross-links between the chains are broken. For acid treatment, the gelatin has a higher isoelectric point (see Table 27.1) because the glutamine and asparagine residues remain in the amide form and are not converted to carbocyclic acid form as with the alkali treatment. As with liming, the

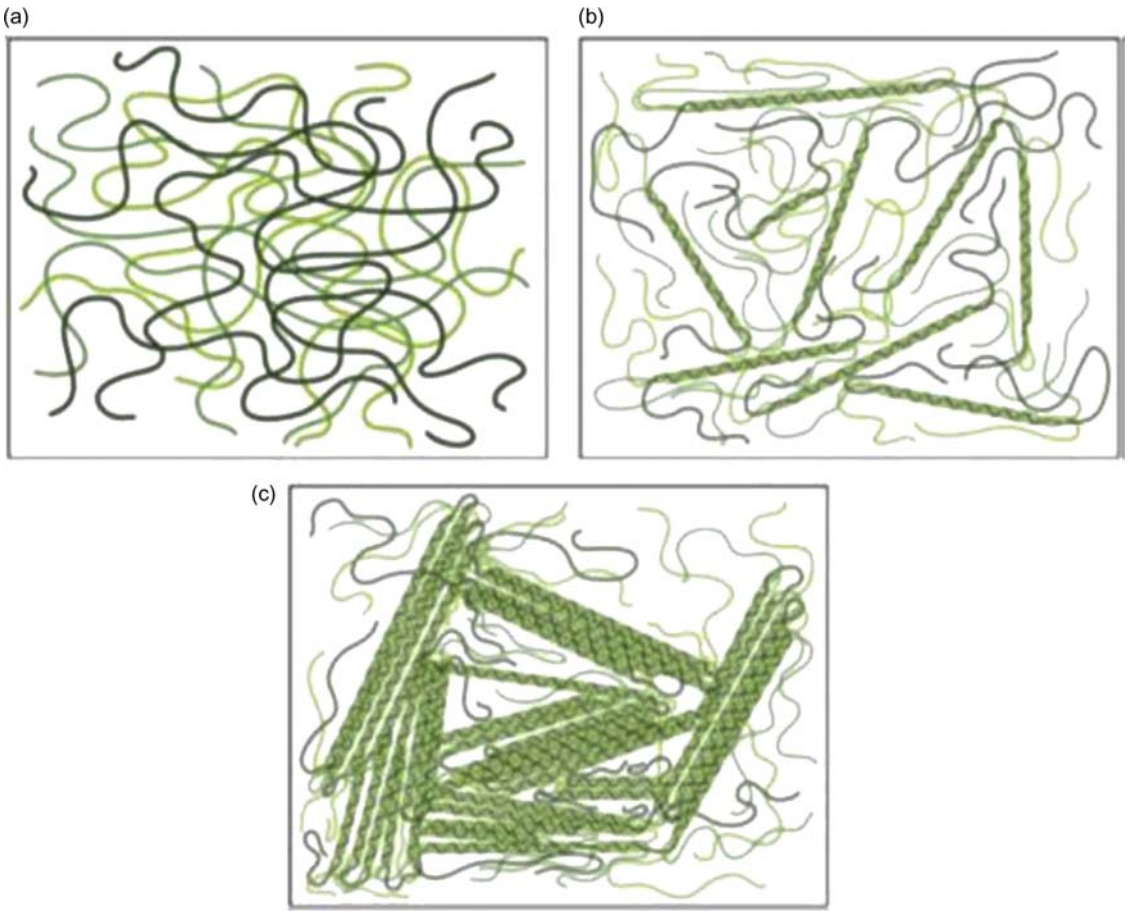

FIGURE 27.5 Changes in collagen structure that influence gelling properties. *Duconseille A, et al. Gelatin structure and composition linked to hard capsule dissolution: a review. Food Hydrocol 2015;43:360–76.*

acid treatment breaks up the collagen chains. The acid treatment is faster (on the order of 24 hours) than liming (8–12 weeks), but it has poor yields for many collagen sources such as bones and cattle hides.

After alkali or acid treatment, the collagen must be extracted from the liquor. The pH, time, temperature, and number of extractions (typically 3–6) vary with the product. The goal of extraction is to heat up the liquor under carefully controlled conditions to the point where the gelatin solubilizes; typically this is between 50°C and 60°C for the first extraction. The soluble materials are then filtered and or washed to remove the insoluble components. The soluble material is deionized, typically by ion exchange. The cleanup process is repeated several times until the material is very pure (Fig. 27.6). Then the soluble gelatin is concentrated and cooled until it gels and can be processed into a powder for shipping (Fig. 27.6).[10,11] The gelatin produced by the first extraction typically has a higher molecular weight, higher viscosity, higher gel strength, and lighter color, which is preferred for making capsules as compared to later extractions.

27.2.1 Capsule storage

A key component of gelatin is water. Newly made capsules will have a water content between 13% and 16%. If the amount changes, the capsule can become brittle and fracture when running on a commercial machine. Also, in our experience, if the water content changes, the dimensions can slightly change, leading to problems of capsule separation, rejoining, and solvent sealing. For example, when sealing fish oil hard-shell capsules, if the dimension change so the gap between the cap and the body increases, oil can leak into this space. This prevents the tight sealing of the cap to the body because the sealing solvent can't get into this space. Thus, capsule shells must be carefully stored. At a minimum, they should be stored in a tightly sealed box, and ideally, they should be stored in a temperature- and humidity-controlled room. For example, the Capsugel company recommends that for Coni-Snap capsules, the ideal storage conditions in the original corrugated box and tightly sealed polyethylene bag are 50% RH at 21°C. However, if the facilities are maintained

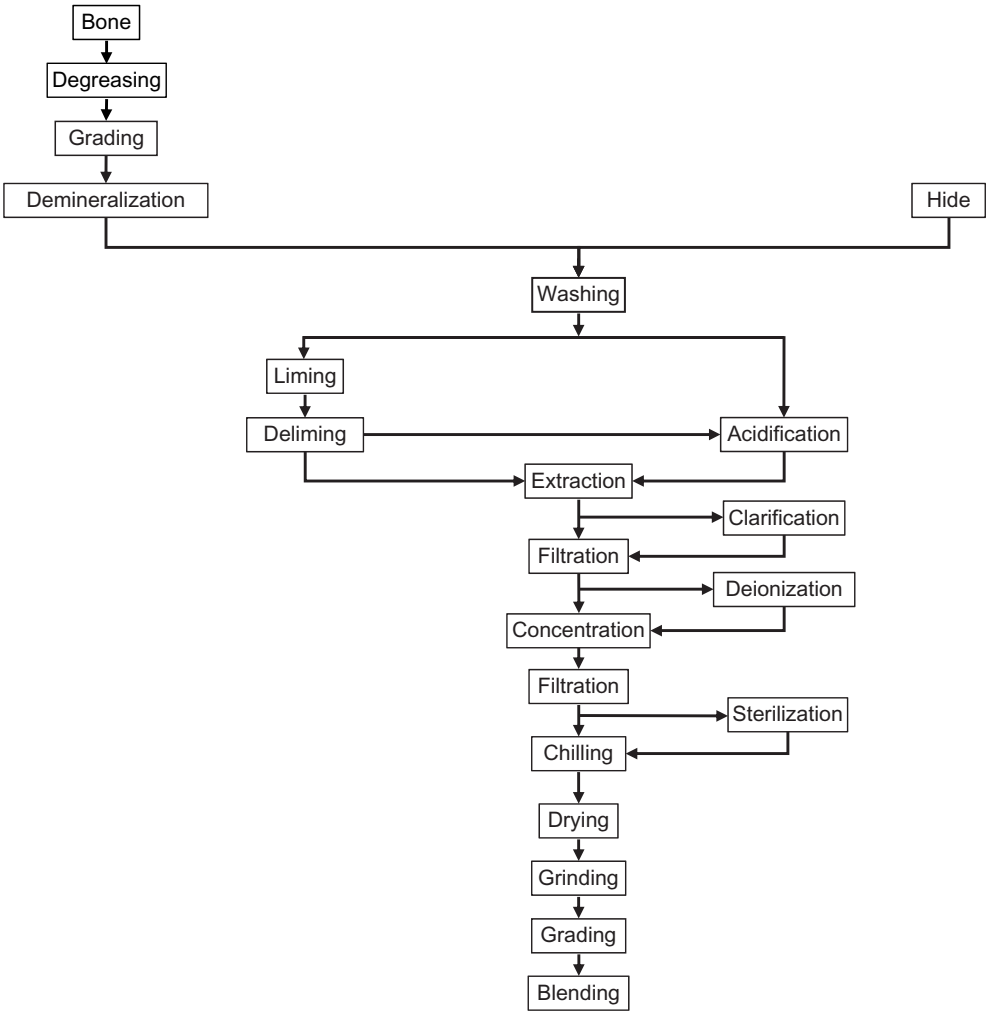

FIGURE 27.6 Gelatin manufacturing process. *Adapted from Jones.*

with a relative humidity in the range of 35–65% RH and temperatures in the range of 15–25°C, you should be able to keep them for the full 5-year shelf-life.

27.2.2 Gelatin cross-linking during storage

As discussed, gelatin undergoes a reversible thermal gelation due to the physical interactions such as hydrogen bonding between the protein chains (Fig. 27.4), and it is this gelation process that is in part responsible for the rapid drug release from a capsule. However, there are a whole host of irreversible chemical reactions that can occur between the gelatin protein chains that can cross-link the protein chains together.[12] When the extent of cross-linking becomes great enough, the gelatin becomes insoluble, and the capsule shell forms an insoluble film around the API. This swollen, rubbery, water-insoluble membrane is called a pellicle, and when it forms during dissolution testing, the drug release is greatly slowed, and the capsule fails to meet its dissolution specification. Common causes of gelatin cross-linking include aldehydes (in the active or excipients), peroxide impurities, storage in high heat and humidity, and rayon coilers.[12–15] When testing a moderately cross-linked gelatin capsule, it will fail dissolution due to pellicle formation; however, when tested in vivo, it may still have good bioequivalence compared to a noncross-linked capsule due to proteolytic enzymes in the gut.[12,16] These results indicate that the in vitro capsule dissolution test may not be predictive of what happens in vivo due to the digestive enzymes. Thus, the United States Pharmacopeia (USP) came up with a two-tier dissolution test, and if the capsules fail in the regular dissolution medium, they can be retested in medium containing proteolytic enzymes.

27.2.3 Capsule shell additives

Besides a structural polymer gelatin or hydroxypropyl methylcellulose (HPMC), there are other additives

in the capsule shell. Coloring agents are often added to gelatin because pure gelatin is clear, which allows light to contact the API and the patient to see the powder inside of the capsule. The most popular dyes added to capsule shells are synthetic water-soluble dyes (eg, azo, indigoid, quinophthalone, triarylmethane, and xanthene), pigments such as titanium dioxide and iron oxides, and natural dyes such as carotenoids.[17] When adding a coloring agent, one can either add a dye or a lake to the capsule shell.[18] In general, dyes impart a transparent or translucent color to the capsule shell, and the patient can still see though the shell, albeit a colored view. In contrast, pigments block the light and opaquely color the capsule shell, blocking light from reaching the inside of the capsule. Titanium dioxide (TiO_2) is the most commonly used opacifying agent. It has a white color and is mostly inert. TiO_2 can help the dye better opacify the shell; thus, they are often added together.

Printing inks are not really part of the gelatin, but they are materials applied to the capsule shell and could affect the product. Capsule printing is often done to meet Food and Drug Administration (FDA) product identification requirements, and the printing ink colorants must meet the same regulatory requirements as those for the capsule shell.[1] Generally, inks are made up of insoluble colorants dispersed in a volatile solvent and a film former.[19] The colorants must be insoluble, or when the solvent evaporates, it will bleed, making the printing look blurry. The coloring agents can either be added as a pigment like the iron oxides, which are insoluble but limited in colors, or as lakes. Lakes are made by precipitating a dye onto an aluminum hydroxide or titanium dioxide carrier, thus, making them insoluble.[18] Lakes have the advantage of coming in a wide range of colors and are insoluble. A common ink film former is shellac, which has broad acceptance in the major pharmacopeias and adheres well to gelatin. Typical solvents used in the capsule printing inks include ethyl alcohol, isopropyl alcohol, *n*-butyl alcohol, and water. Obviously, one has to be sure that the residual solvent levels don't exceed regulatory limits. Fortunately, the amount of ink applied is small, so this is typically not a problem if dried properly.

A warm gelatin solution can support rapid microbial growth, so care must be taken to keep the total microcount low when working with these solutions. A properly stored capsule will have a water content in the 13–16% range, which is low enough to not support microbial growth. Thus, preservatives are not used in gelatin capsules manufactured in Europe and in the United States. However, in older products, preservatives such as methyl and propyl parabens and sodium metabisulfite were added to gelatin solutions to control microbial levels during production.[7]

Sometimes processing aids can be in a capsule shell. For example, sometimes a surfactant such as sodium lauryl sulfate can be used in capsule shell manufacturing. Also, there can be proprietary pin-release agents used to help the capsule shell be stripped from the pin after dipping. Also, things such as silicon dioxide have been used in gelatin manufacturing. Some additives are allowed in the USP, while others are disclosed with a confidentially agreement with the capsule shell manufacturer. If there are stability problems, gelatin additives should be considered when trying to solve the problem.

27.2.4 Mad cow disease

In the 1980s and 1990s, BSE (also known as mad cow disease) was found in cattle in Europe, and in the United Kingdom people were actually infected, most likely from eating animal products containing brain or spinal cord parts. While the process of producing gelatin is very harsh with either an acid or alkaline treatment and reduced the infectivity to undetectable levels, there is still a very slight possibility that the prion that causes BSE could survive the process.[6] Given that prions are difficult to detect, suppliers of gelatin must have preventative measures in place so their products do not contain prions. These measures include obtaining gelatin from certified BSE-free production areas. Only healthy slaughtered animals can be used, and the gelatin must not contain animal parts exposed to neurological tissues such as the skull and backbone vertebrae. The regulations for certifying that gelatin is BSE-free varies from country to country. For example, Japan and Argentina require only hide gelatin. Thus, make sure that suppliers can supply a BSE-free certificate, as this will be needed for release. Typically manufacturers have these on their websites for download, and the certificate should be kept as part of the batch records for clinical studies and product release to the market.

27.3 CAPSULE SHELL MANUFACTURING

The first step in making a hard-shell capsule is to produce a well-mixed dipping solution; the history of capsule making is discussed by Jones et al.[7] In addition to gelling polymers, gelatin, or HPMC, the solution could contain other additives such as coloring agents.[7] The key quality attributes of the gel solution include viscosity and gelation temperature. To achieve the necessary attributes, the gelatin solution is made from a combination of Type A and B gelatin for the best combination of shell strength and clarity.

Capsule shells are made by dipping pairs (body and cap) of room-temperature stainless-steel pins into a heated gelatin solution. Because the pins are below the gelling temperature, the gelatin begins to form a thin gelatin layer or film on the pins (Fig. 27.7).[20] After a short time in the gel solution, the pins are removed and rotated several times to evenly distribute the gel over the pin. Once the gel is evenly distributed on the pin, a blast of cool air is used to set the gelatin on the pin. At this point, the gelatin is dried, and the pins are sent through a long series of continuous ovens until the moisture content is at the desired level (Fig. 27.8). The drying is primarily done using dry, slightly warmed air to avoid softening or melting the gelatin in the drying oven; recall the gelling temperature of gelatin is about 30°C. After the gelatin is dried, the capsule is striped off the pin and trimmed to the proper length. Once trimmed, the two halves are put back together in the prefit position. At this point, printing is done if needed before packing in cartons for shipping.

27.4 ALTERNATIVES TO GELATIN

Issues with BSE, religious dietary restrictions with pork-based products, consumer preferences for healthy veggie products, and animal rights concerns have led to the demand for nonanimal-based capsule shells. Given the exacting processing requirements where capsule shells have to run smoothly on the same commercial filling machines as the gelatin capsules and the drug delivery requirements of capsule shells, it has been hard to find cost-effective alternatives to gelatin capsule shells. Despite these difficulties, there are now a range of gelatin alternatives readily available on the market, but these products were not easy to develop.

The most common alternative to gelatin is hypromellose in USP official nomenclature, also known as HPMC. All major suppliers of capsules now produce HPMC capsules. HPMC is a cellulose ether of vegetable origin, which eliminates concerns with religious restrictions and dietary preferences against animal products. Like gelatin, HPMC has a long-use history in the pharmaceutical industry for things such as a wet granulation binder, layering binder, controlled-release matrix former, film coating material, and suspending agent. It has an excellent safety profile, is considered GRAS (generally regarded as safe), and is listed in all the major pharmacopoeias.[5] HPMC has lower water content, on the order of 4–7% compared to gelatin, which is in the range of 13–16%. This reduces problems with brittleness due to loss of water because water does not plasticize HPMC as much as it does gelatin, and a lower water activity level generally is good for moisture-sensitive drug stability.[1] There are also differences in water and oxygen permeability, which is important for drug stability.[1,21]

HPMC capsules are made by the same dipping process as gelatin. To form an HPMC capsule, the HPMC solution must rapidly form a film on the dipping pin. Currently, this film can be formed either by thermal gelation or gelling via a gelling system. Unlike gelatin, HPMC undergoes reverse thermal gelation; in other words, HPMC forms a gel at higher temperatures, whereas gelatin forms a gel at lower temperatures.[22] For cellulose-based polymers such as HPMC, it is not unusual for them to be more soluble at lower temperatures, because at higher temperatures, the hydrophobic interactions predominate more than the hydrophilic interactions, and the hydrophobic interactions lead to aggregation between the polymer chains. As the number of aggregates goes up, the gelation occurs. This transition temperature can also be affected by environmental factors such as ionic strength.[23] Silva has shown

that the sol-gel transition temperature occurs at about 55°C; however, this transition temperature is affected by environmental factors and differences in the HPMC polymers such as the molecular weight and the degree of substitution.[22,23] Thus, to make HPMC capsules on the same dipping pin system, the HPMC solution is kept cool at room temperature, and the pins are heated to above the gelation temperature.[5] The hot pins are dipped into the cool HPMC solution, removed from the solution, spun on the pins to form a uniform film, and then dried, much like the gelatin capsule-making process.

The disadvantage of thermal gelation using a cold HPMC solution and hot pins to make the capsules is that very expensive capsule-making equipment must be modified or developed to accommodate these differences in processing. Another approach is to add gelling agents to the HPMC solution, and these gelling agents have the property of being a solution at cold temperatures and a gel at higher temperatures. This allows the use of the same cold solution/warm pin equipment when making HPMC capsules.[5] Currently there are two commercial polymer gelling agents: kappa-carrageenan and gellan gum. Kappa-carrageenan is a structural polymer obtained from red seaweed. It is a sulfonated polysaccharide that is widely used in the food industry as a gelling and thickening agent, and it has an excellent safety profile. Kappa-carrageenan has the unique feature that it forms helical structures at room temperature, and the gelation occurs via interactions between the helixes. Being a sulfonated polymer, the sulfate group is unionized at the typical working pHs of κ-carrageenan, which makes the polymer very sensitive to ions, and small changes in ionic strength can affect the gelling behavior of κ-carrageenan.[24,25] This sensitivity is used to control the gelling temperature of κ-carrageenan, so it can be processed on commercially available dipping machines.

The other polymer used commercially as a gelling agent for capsule manufacturing is gellan gum. Relative to κ-carrageenan, gellan gum is new polymer that was only discovered in the late 1970s. It is produced by the bacterium *Sphingomonas elodea*. Gellan gum is a linear anionic polysaccharide that has one carboxyl side group and one 0-acetyl substituent per chemical repeat unit.[26] The carboxylic group, which can ionize at the typical working pH of the polymer, makes the gelation temperature sensitive to environmental factors such as ionic strength. Like κ-carrageenan, the ionic strength and the pH of the gelling solution can be controlled so that gellan gum gels at a good temperature for making capsules on commercially available dipping machines.

Examples of commercially available HPMC capsules made by thermal gelation include Vcaps Plus, also called tg-HPMC. Commercial capsules made with κ-carrageenan include QualiV, also called c-HPMC, and commercial capsules made with gellan gum include Vcaps, also called g-HPMC.[5] A critical issue with capsule performance is how these three types of capsules compare to each other and with gelatin. The key properties such as water uptake, mechanical strength, color-hiding power, stability, esophageal transit time, in vitro dissolution, and in vivo bioequivalence of these different types of capsules have been extensively studied.[5,27–29]

These studies and others are hard to summarize because the results depend upon the type of drug and the test conditions used, but in general, they found that the performance was similar, but there were important differences between the different types of capsules shells. Thus, without some type of evaluation, one cannot assume that the capsule shells types are interchangeable because there could be conditions where the differences could affect in vivo performance and patient outcomes. A purchasing agent should not make the decision to switch from one type of capsule shell to another, as this should be done within the confines of a company's change control procedures.

Currently, HPMC capsule shells have been developed to the point of being commercially available from all the major suppliers; however, in the future, there will be many new developments in capsules shells. Some of these new technologies include pollen capsule shells, starch hydrolysate capsule shells, HPMC softgel shells, and capsule shells that are designed for modified release; for example, there are enteric capsule shells and controlled-release capsule shells for colonic delivery. Because these new innovations are not as widely available as HPMC, they will not be discussed further, but they have been reviewed by Stegemann.[5]

27.5 HARD SHELL

The most commonly available capsule shells are the hard gelatin capsule shell. This shell comes in two parts: the body and the cap (Fig. 27.9). These capsule shells are made of a hard gelatin or HPMC, which is ridged and can be handled and run though processing equipment. This is in contrast to soft gelatin shells, which have to be formed and are typically used for liquids and semisolids. Originally, the cap and the body just fit together without a locking mechanism, but this lead to problems, as sometimes the cap and the body separate during handling and shipping; thus, most capsule shells today come with a locking mechanism that keeps the cap and the body from separating. The Coni-Snap capsule shell is one such example, as you can see in Fig. 27.10. There is a locking ring that, once engaged, holds the cap and the body together.

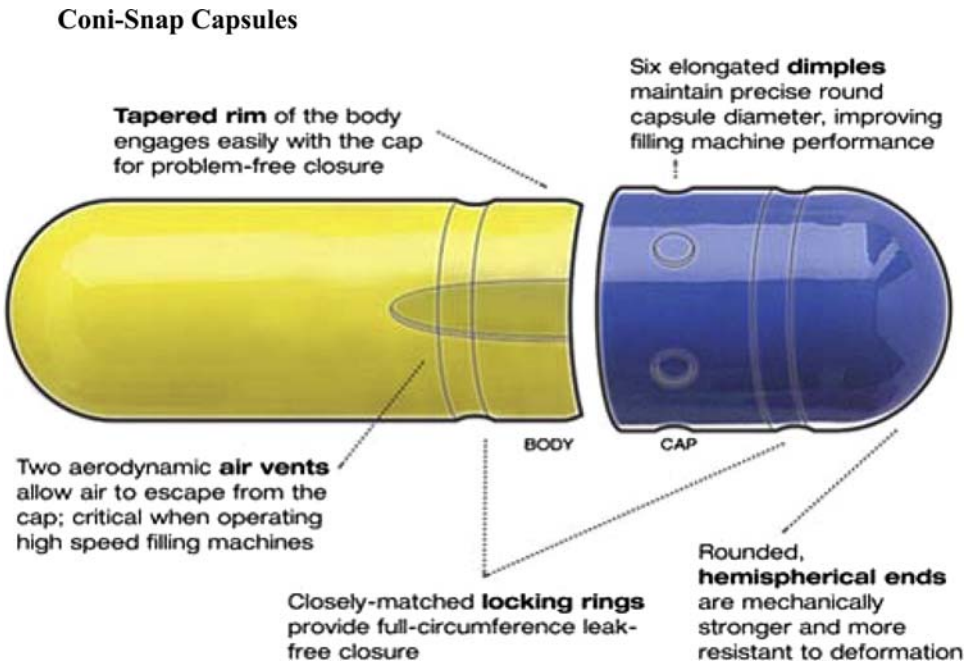

FIGURE 27.9 Capsule shells showing features.

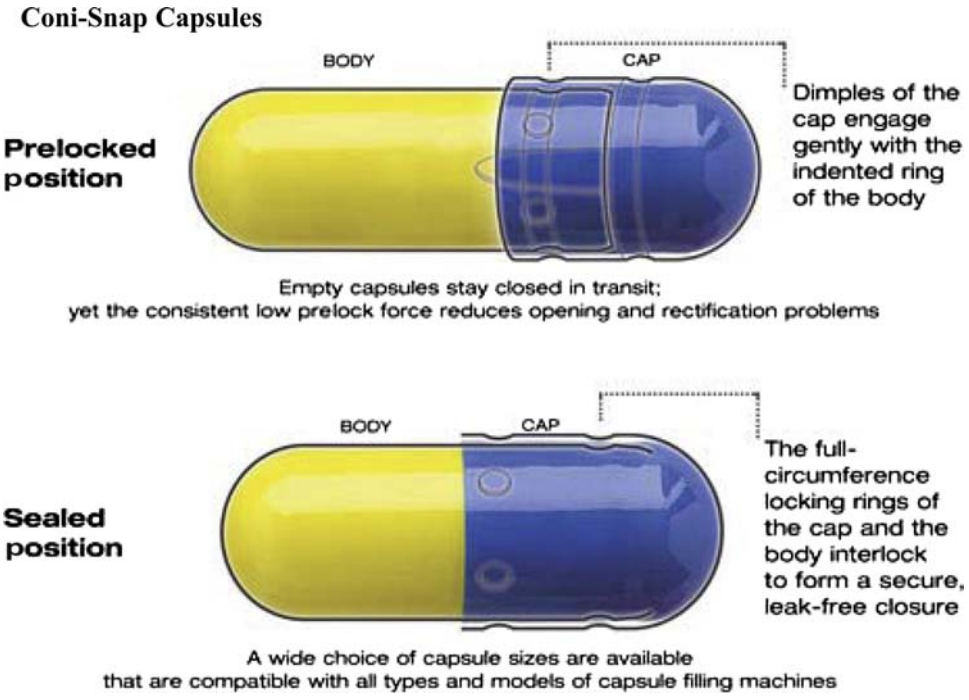

FIGURE 27.10 Capsule shells.

As shown in Fig. 27.10, the shells come from the manufacture in the prefit position, and after filling, they are pushed together to lock. Note that in this context locked is not the same as sealed.

Modern capsule-filling equipment can fill up to 200,000 capsules per hour. For a capsule shell to run on such a high-speed machine, it places a lot of performance requirements on the capsule shell. Things such as the mechanical strength of the gelatin film, dimensional accuracy of the shell, the ability to vent air during high-speed closure, closure-locking mechanism, prefit locking strength, the ability to align for rectification, and

closure are all essential qualities that are needed to run on a high-speed machine. How these features are engineered into a capsule shell is part of a company's patent portfolio and used as special features to sell capsule shells.[1] Traditionally, three of the biggest manufacturers of capsules were Capsugel, who made the Snap-Fit and Coni-Snap capsule shells; Pharmaphil (now part of Qualicaps), who made the Lox-it capsule shells; and Shionogi Qualicaps (now called Qualicaps), who made the Posilok capsules. This is not a complete list of all manufacturers current or past. During the past decade, a lot of companies in China, India, and other parts of the world have started to manufacture capsule shells; they are too numerous and transitory to review here.

27.5.1 Capsule sizes

Capsules come in standard sizes (Fig. 27.11). These sizes range from 000 to 5, which have volumes from 1.36 to 0.13 mL, respectively. To estimate the fill weight of these capsules, one can use the basic bulk or tapped density if you compress during filling. The bulk density will give you an approximate fill weight, which can then be adjusted by trial and error. A more quantitative method for determining the fill weight is to use the method developed by Khawam.[30,31]

27.5.2 Use in preclinical and clinical studies

For clinical research, when one wants a blinded placebo or to make a comparison to a particular formulation or existing product, it can be very difficult because making an exact look-alike copy of a product can be very difficult and time consuming. Thus, capsule manufacturers have developed special-sized capsules with a wide body specifically designed to make it easier to be directly filled with an intact tablet (Fig. 27.12).

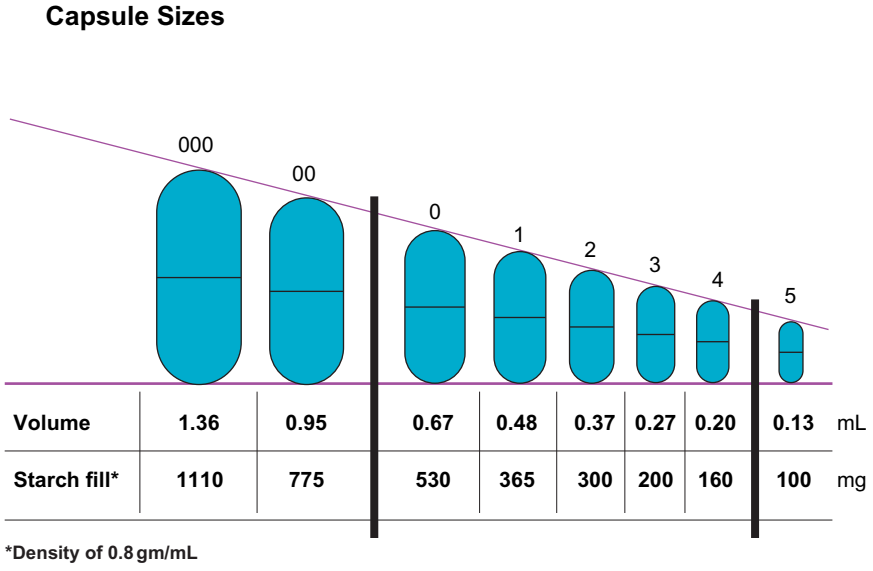

FIGURE 27.11 Standard capsule sizes. *Source: Dennis Murachanian, Capsulgel.*

FIGURE 27.12 Double-blinded capsules for clinical studies.

There are eight different sizes of double-blind (DB) capsules: AAA, AAel, AA, A, B, C, D, and E; see the Capsugel website for size details. These capsules can be filled by a compounding pharmacist. This can avoid the expense of good manufacturing practice (GMP); however, many compounding pharmacists lack the capacity to support even small clinical studies. The double-blinded capsules have some unique features that make it hard to break the blind. For example, the body is extended, and the cap fits into the body, making it very difficult to pull them apart without destroying the capsule, which makes it almost impossible for the patient and curious nurses or physicians to break the blind without obvious signs of damage, which can alert researchers to this possibility. Obviously this is not a foolproof method of blinding, but it will at least stop the casual patient or health care worker from breaking the blind.[32]

27.5.3 Animal testing

Administration of an API to an animal is one of the important initial steps in preclinical research. If you are administering the drug to an animal such as a dog, pig or primate, you can use human dosage forms, but if you need to administer an API to a rodent, then human dosage forms are too large. For preclinical research, the API is typically administered as a solution, emulsion, or suspension via gavage; however, some APIs may have poor stability, and a liquid preparation would not have the needed shelf life for testing. Some APIs may be very difficult to formulate as a liquid predations, and if the study questions have to do with the API in the solid state, then a liquid preparation will not answer your questions. For these situations, capsules have been specifically developed and designed to be delivered to mice, hamsters, rats, and guinea pigs (Fig. 27.13). In addition, they have developed specially filling apparatus and tools for capsule administration, also shown in Fig. 27.13. These capsules are hand-filled one a time (see Section 27.6.1 for a discussion of hand-filling), so their use is limited to preclinical studies. Also, these capsules can be filled without excipients, which is an advantage when compactability and stability are a concern. On the other end of the spectrum are large specialty capsules for livestock. For example, there are capsules that can deliver gram quantiles of medication orally, rectally, and vaginally to cattle.

27.6 CAPSULE FILLING

As mentioned previously, capsules are shipped with the cap and the body prefit together. Thus, to fill a capsule, the basic steps are: separate the cap from the body, fill the formulation into the body, put the cap back onto the body, and lock the cap and the body together. One of the beauties of capsule filling is that it is very flexible in terms of scale. Capsules can be hand-filled one at a time, as done in a compounding pharmacy, or they can be hand-filled using a jig, a semiautomated capsule-filling machine, or filled on commercial-scale machines making over 150,000 capsules per hour.

The primary differences between small-scale filling and commercial production is in how the powder is transferred into the capsule body. Small-scale production is done by directly filling the powder into the capsule shell and relying on the bulk/tapped density of the powder to get the correct dose for the volume of the capsule shell used. Capsules can also be made by direct weighing of the API into the capsule body. For commercial production, the capsule is filled in a process called *indirect filling*, which is done by forming a plug that is transferred into the capsule shell. Forming a plug has several advantages over direct filling. The plug is made by compressing the powder into a cohesive mass, which holds together during the transfer to the capsule body. This can be done by multiple

FIGURE 27.13 Capsule used for administration to rodents.

tamping on a dosing-disk machine or by compression in a dosator. The advantage of forming a plug is that the powder can be compressed to higher density, which allows for higher capsule fill weights, which given the patient preference for swallowing smaller capsules can be important. This is very important for botanical products that typically have very low bulk densities and if not compressed can lead to the patient having to swallow very large capsules. In addition, the machine operating parameters of the dosing-disk or dosator machine can be adjusted to accommodate the natural variation of the formulation components to product more consistent fill weight, thus, improved dose uniformity.

27.6.1 Hand-filling capsules

Hand-filling is the easiest and the slowest method. It has the least formulation requirements and can accommodate just about any API that is compatible with the capsule shell materials, but this method is not scalable to faster modes of production. Hand-filling is typically done to prepare a small number of capsules for toxicity and bioavailability studies in animals and humans. Using a capsule-filling jig, one can produce enough capsules to support a phase I study or clinical research studies. Hand-filling can either be done one capsule at a time or by using a capsule-filling jig.

Hand-filling one capsule at time is what is commonly done in a compounding pharmacy, where you form a little pile of powder on a pill tile and then push the inverted capsule body into the powder blend until the capsule body is filled up and has the desired weight. Alternatively, you can weigh the API directly into the capsule body, but this is very slow process. In recent years, an automated weight system has been developed for direct filling of the API into a capsule shell; the system is called the Xcelodose system, which is described in Section 27.6.3. The capacity of hand-filling is about 5–20 capsules per hour depending upon the material being filled and operator skill.

To increase manual production rates from that of a pill tile, one can use a capsule-filing jig, also called a hand-filling capsule machine (Fig. 27.14), such as those sold by CroPharm Inc., Torpac Inc., and Capsugel Inc. Typically, these jigs can make from 100 to 500 capsules per fill (Fig. 27.14). The basic steps are to (1) rectify the capsules, (2) separate the cap from the body, (3) fill the powder, (4) join the cap and the body together, and (5) eject the filled capsules from the jig. These steps are shown in Fig. 27.14. Because the cap and the body have slightly different dimensions, the basic idea of the hand-filling jig is to use a series of plates with different sized holes to independently manipulate the cap and the body for all the filling steps. To rectify the capsules, they are randomly poured onto a tray that has a series of slots, one slot for each capsule. The middle of the slot is bigger than the ends, so the capsules fall into a hole body first. At the bottom of the hole are four plates with a hole for each capsule. The top plate has a hole that allows the body to pass through but not the cap. Below the top plate are three plates (Fig. 27.14). The middle plate is on an eccentric cam, which moves the middle plate relative to the other two plates in order to lock the capsule body in the three plates. Once the capsule bodies are locked in place, the top plate is removed along with the caps, resulting in the separation of the cap from the body. The capsule bodies can be pushed flush with the top of the three lower plates so when a powder mass is poured onto the jig plate, it can be evenly distributed to each capsule. Often during the filling of the capsules a tamper is used to slightly compress the powder. This increases the bulk density of the fill and helps distribute the powder into each capsule. Once the capsules are full, they are rejoined by putting the top plate back on and squeezing the stand so the capsule bodies are pushed up through the three middle plates and into the top plate where the caps are held. Then the top plate is removed, the capsules are manually pushed into the locked position, and they are dumped into a tray for packaging or further processing.

27.6.2 Liquid filling two-piece capsules

For some drugs, a liquid fill can be better than a dry powder; for example, for drugs with low solubility, the delivery can be enhanced with a self-emulsifying drug delivery system.[33] Also, with highly potent, for example, hormones, or cytotoxic drugs where worker exposure to dust is a problem, a liquid fill can provide better containment, and with low-dose drugs, content uniformity can sometimes be easier to maintain in a liquid formulation rather than a hard-to-mix powder.[34] Typically, liquids are filled in soft-shell capsules, but with special modification of traditional filling equipment, liquids and semisolids can be filled in two-piece capsules. Liquids can also be hand-filled into two-piece capsules for feasibility studies and clinical studies.

For liquid fills, all the steps are the same as with the powder fills, but instead of filling a powder into the capsules, a pipet or liquid manifold is used to fill each capsule with a liquid (Fig. 27.15). For liquids, the cap and the body must be sealed to prevent leaking. This is very important for oils such as omega-3 fatty acids that turn brown when oxidized, which is a very obvious defect on the surface of a capsule shell. Thus, once the capsules have been filled, it is important to quickly

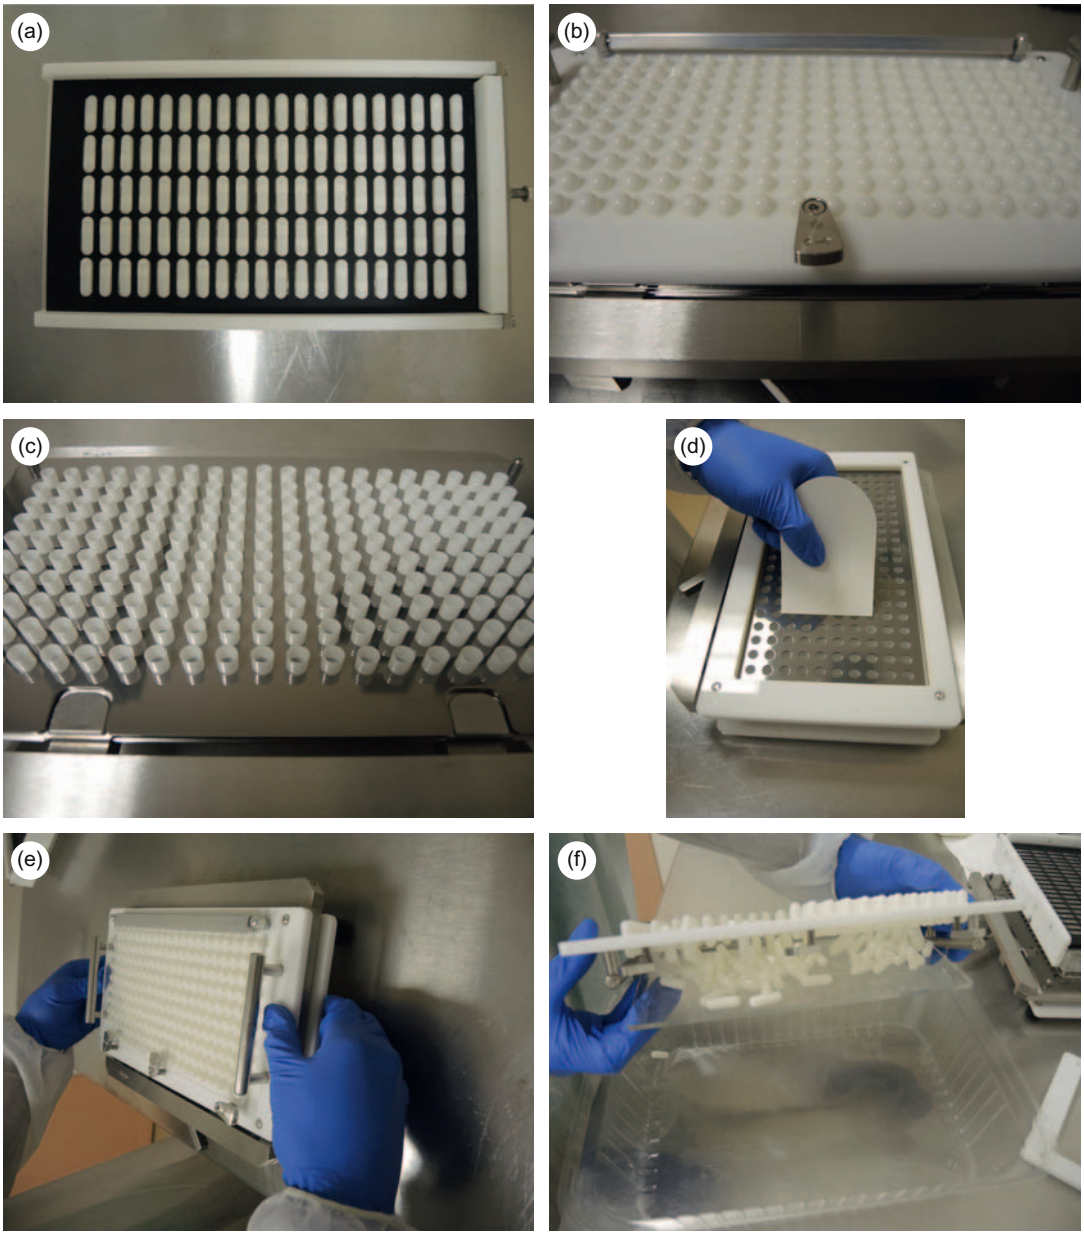

FIGURE 27.14 Steps for using a hand-filling jig: (a) rectification of capsules, (b) capsule separation, (c) separated capsules ready to fill, (d) using plastic scraper to distribute powder in capsule shells, (e) closing capsule shells, and (f) emptying filled capsule shells.

seal them. Capsules can be sealed either by banding with heated gelatin or a hydroalcoholic solution fusion process.[35] In addition to liquid filling for over-the-counter product, capsules should be banded so as to be tamper evident.[36]

To seal a two-piece capsule using a hydroalcoholic solution, the solution is either sprayed onto the capsule shells in a pan coater or, if hand-sealing, via a swab. When the liquid comes in contact with the gap between the cap and the body, the liquid surface tension wicks the solution into the gap, and then gentle heat is applied, typically between 40°C and 50°C, for a minute. Typically a 50:50 water-ethanol solution is used. The water in the alcohol solution softens the partially dissolving the gelatin, and when heated, the two pieces fuse together. Then the water evaporates, and the gelatin returns to its dry state, but the two halves are bonded together. If pure water is used, too much softening occurs. The capsule may develop ripple defects, and sometimes the gelatin bubbles when heated. If too much water is applied, this can lead to twinning (when two capsule shells stick together), and at the point where the shells are conjoined, there is typically a spot defect in the gelatin. To band a capsule requires special

FIGURE 27.15 Liquid filling of hard gelatin capsules.

equipment that heats up the gelatin and then applies a thin band around the joint between the body and the cap.[34,35] When liquid filling two-piece capsules, it is best to use capsule shells specifically designed for liquid filling. These capsules have features such as no vents and are designed for improved sealing of the liquid or semisolid. Liquid filling can also be done on a commercial scale, but this is beyond what will be covered here, and the interested see reader can see Cole et al.[34] and Niederquell.[37]

27.6.3 Powder in capsule automated filling

It is well known that only a small fraction of the compounds synthesized make it to the market. Given the extreme risk of developing new compounds, the goal of most companies is to make a go-no-go decision as soon as possible for any compound in development. A pivotal point in the development process is the first studies in humans, and to conduct these studies, one needs a formulation to administer to the patient. One way to develop a formulation rapidly is to directly weigh only the API into the capsule, which is called the powder-in-capsule (PIC) method. With only the powder in a capsule, you don't have to worry about adding an excipient to make the capsules. For example, you don't have to worry about lubricants and flow aids in the formulation, and consequently, you don't worry about excipient compatibility and how much to add to make the process run well.

To meet this need for rapid PIC formulation manufacture, companies such as Capsugel Inc. have developed an automating weighting system that can fill between 100 μg to 100 mg per capsule, and according to the company, it can do this with a 2% RSD. The trade name for this system is Xcelodose. The system accommodates up to a size 00 capsule, and the automated version of Xcelodose can fill up to 600 capsules per h. As discussed, hand-filling via direct weighing is very slow, and without an automated system, hand-weighing would not be practical for a phase I study. A more detailed description of the Xcelodose system and its operation for filling capsules to put in a dry powder inhaler can found in the review by Edwards.[2]

27.6.4 Semiautomatic

The next level of filling is a semiautomatic capsule-filling machine, shown in Fig. 27.16. Conceptually, this is the same as the hand-filling jig, that is, with no plug formation. The only differences are that a few more steps are automated and scaled up, and the powder is fed into the capsule shells using an auger rather than by manual feeding (Fig. 27.16). Some semiautomatic-style systems use vibration to fill the powder into the capsules, but to the best of the author's knowledge, these systems are not that popular and won't be discussed further. In the old days, semiautomatic machines were commonly used for commercial production, but over the years, the plug-forming indirect-filling machines have largely replaced the semiautomatic machines for commercial production, and today these machines are typically used for small-scale, flexible manufacturing of batches for feasibility studies and early-phase clinical trials.

With a semiautomatic capsule-filling machine, the process of capsule rectification is automated (Fig. 27.16). With these systems, the capsules are randomly fed into a slot, and then a finger pushes in the middle of the prefit capsule. Because the body is smaller, it moves first, which orientates the capsules so they are all facing in the same direction (Fig. 27.17). Once the capsules are all aligned, they are pushed into the dosing rings. As with the capsule-filling jig, when the rings are manually separated, the cap is separated from the body. After separation, the body ring (Fig. 27.16) is placed under an auger-driven hopper and rotated on a turntable. To fill the capsules, the body ring is rotated, and the hopper auger is turned on so the powder is fed from the hopper at a fixed rate as the body ring rotates. The fill weight is determined by a combination of the turntable speed and the auger speed. The faster the turntable rotates, the lower the fill rate. As there is less time under the auger, which dispenses powder at a fixed rate, the faster the auger rotates, the higher the fill weight, as a faster auger speed pushes the powder out faster into the capsule bodies. Once all the capsule have been filled, the rings are pushed back together to rejoin the cap and the body, and finally the capsules are ejected from the rings (see Fig. 27.16).

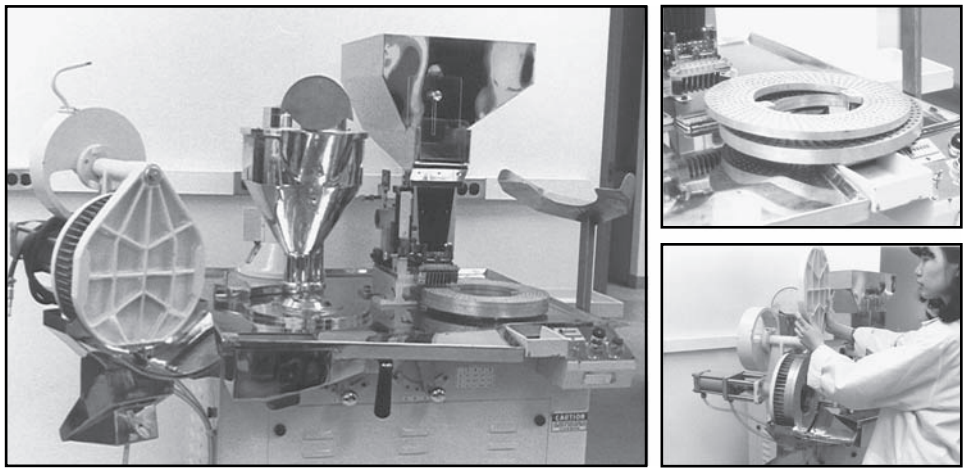

FIGURE 27.16 Semiautomated capsule-filling machine (eg, Colton Type 8).

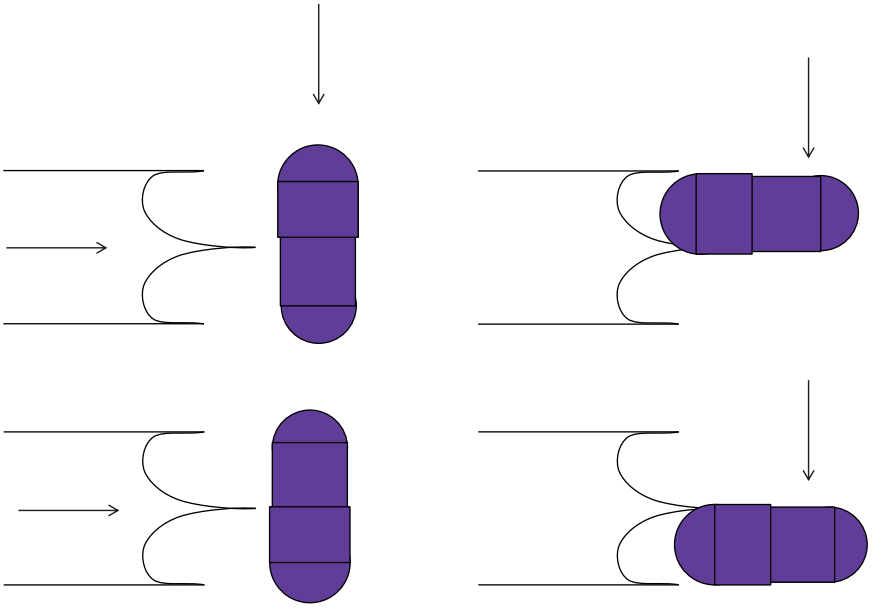

FIGURE 27.17 Capsule rectification.

Typically these machines can produce up to 10,000–15,000 capsules per hour, depending upon the ease of formulation handling and operator skill. The formulation requirements are essentially the same as hand-filling, but the powder has to flow out of the hopper with the aid of an auger, so the formulation can't segregate, and it needs to be relatively free flowing. Lubricants and flow aids may be necessary if discharge from the hopper is problematic. If the material is known to be sticky, that is, adhere to metal, then formulation changes must be made for the formulation to run well. Formulation strategies for API sticking to capsule-filling machine parts are similar to those for dealing with sticking and picking in tablets.[38]

27.6.5 Commercial production methods

The indirect method of capsule filling involves forming a plug and then ejecting the plug into the capsule body. This method of capsule filling is used in the vast majority of commercial filling operations. There are two principal methods for making a plug, the dosing disks and the dosator methods, and these commercially available capsule-filling machines can make 150,000 or more capsules per h. To reliability fill at high speeds requires a very good formulation. It is a misnomer to say there are no formulation requirements for a capsule because all you have to do is get the drug into the capsule shell. While this may be true for hand-filling or

slow filling on a semiautomatic capsule-filling machine, for high-speed production, this is not the case. In the next sections, we will discuss in general terms the steps of capsule filling for the dosing-disk and dosator method of filling followed by a discussion of capsule formulation. For a history of capsule filling and a detailed discussion of capsule-filling machines, see Lightfoot.[39]

27.6.5.1 Dosing disk

The dosing-disk method of filling uses a disk with holes and tamping pins to form a plug (Fig. 27.18). This type of machine is exemplified by the Bosch (formerly Hofliger Karg) GKF models and the Harro Hofliger (H&H) KFM models. The dosing-disk setup, shown in Fig. 27.18, has the powder bed above the dosing disk, and it uses tamping pins to push the powder into holes in the dosing disk. A typical dosing disk has from 12 to 100 holes drilled in the dosing disk. To simplify the discussion and match the discussion to the illustrations, I will refer to the H&H machine, which has a dosing disk with 12 holes. This discussion can be easily extended to other machines such as the Bosch GKF machine, which has 72 holes, so the same things are happening, but instead of 12 holes, there are 72 holes in six groups, and the dosing disk rotates 60° instead of 90° like the H&H machine. The matching tamping pin assembly has a tamping pin to match each hole. These are mounted onto a single assembly, with all tamping pins going up and down simultaneously. Typically, the tamping pin assembly tamps, that is, goes up and down, 2–5 times for each hole to form a plug. Then the disk rotates to the next set of tamping pins and compresses the plug three to five times more. With each tamp, the capsule plug become taller and denser. After three sets of tamps, the dosing disk rotates to the final hole, which is open on the bottom so that the capsule plug is unsupported. The capsule body is below the final position of the dosing disk, and when tamping pin comes down, it ejects the plug into the capsule body. The tamping pins are spring loaded to prevent overloading the capsules, which are not designed to take large forces. Typical tamping forces range from 20 to 200 N (see Fig. 27.19). For a more detailed description of this process and the monitoring of plug formation, see Shah and Augsburger.[40] To have a consistent fill weight, it is essential to keep the powder bed at a constant bulk density. Thus, there are typically moving baffles in the powder bed that sweep across the dosing disk to keep the bed a uniform density. The primary factors controlling the fill weight are the thickness of the dosing disk, the thickness of the powder bed, and the tamping pressure.

27.6.5.2 Dosator

A dosator, shown in Fig. 27.20, is made up of a dosing tube and a piston that slides up and down in the dosing tube. Typical dosator machines include Zanasi, MG2, Dott. Bonapace, and Macolar machines. To make a plug, the dosing tube is inserted into a powder bed, and the piston compresses the powder to form a plug. Then the dosing tube is withdrawn from the powder

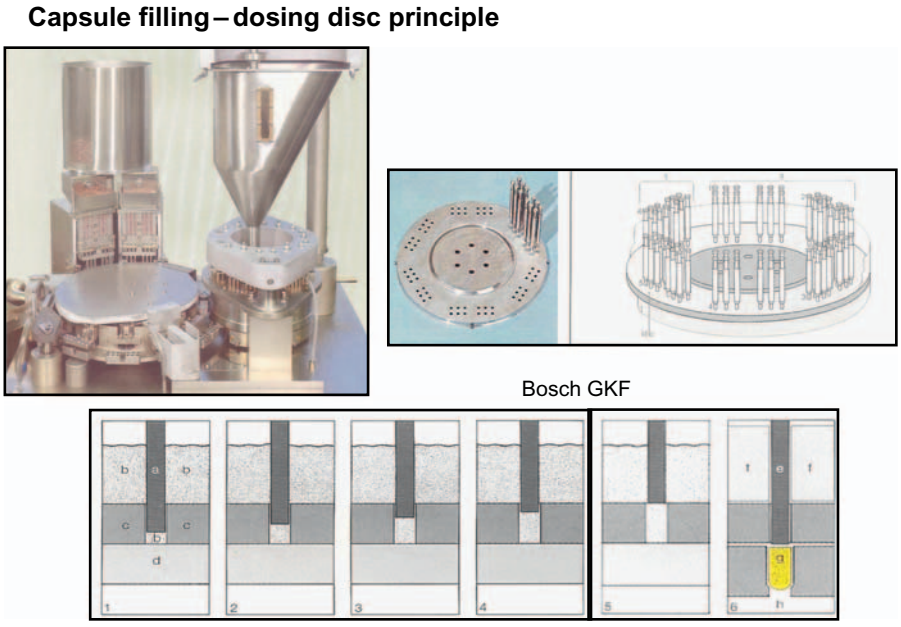

FIGURE 27.18 Schematic of Bosch dosing-disk capsule-filling machine.

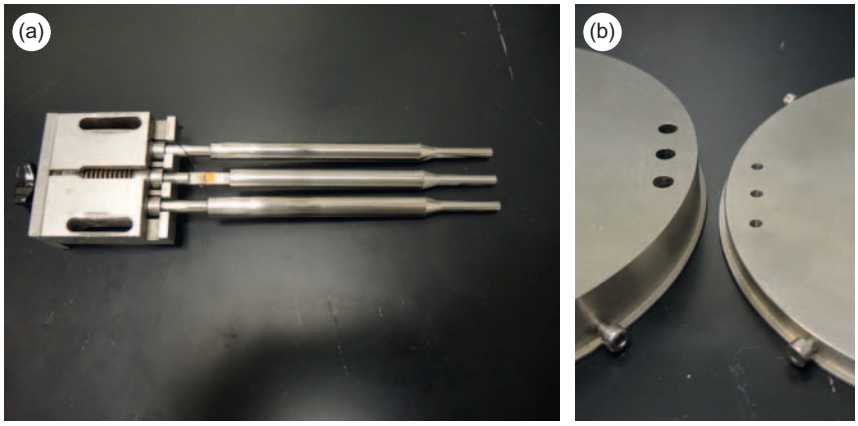

FIGURE 27.19 (a) Spring-loaded tamping pin with strain gauge instrumentation and two different dosing disks showing size differences. (b) Spring-loaded tamping pin with strain gauge instrumentation and two different dosing disks showing size differences.

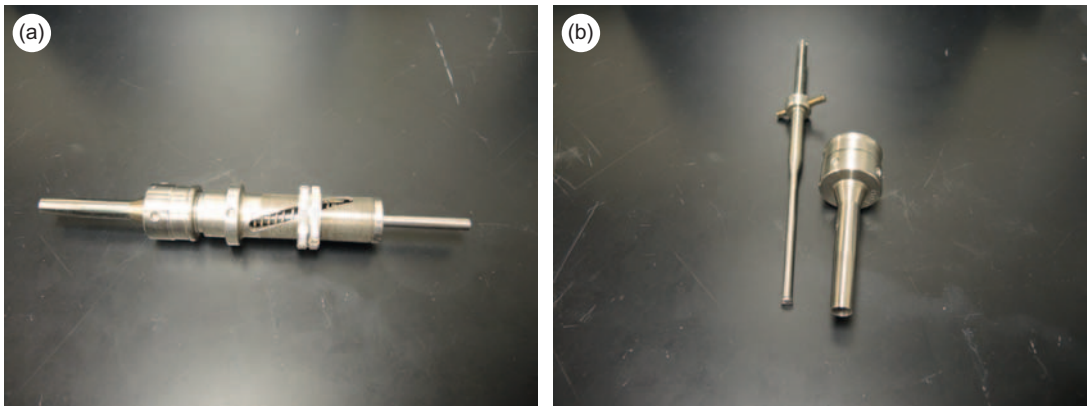

FIGURE 27.20 (a) Close up of a dosator and (b) Dosing tube and piston.

bed and positioned over an open capsule body, and the piston ejects the plug into the capsule body, (Fig. 27.21). The first step to forming a plug is to insert the dosing tube into the powder bed of a set height. This height is usually greater than the height of the piston, that is, the powder bed height is greater than the height of the open length of the tube. By inserting the dosator into a powder bed, the powder is precompressed in a manner analogous to the precompression during tablet compression in a die (Fig. 27.20). Following precompression, the powder is compressed by the piston to form a plug. Then the dosator is withdrawn from the powder bed and positioned over the empty capsule body, and the piston ejects the plug into the capsule body (Fig. 27.20). For a more detailed description of the process and the monitoring of plug formation, see Small and Augsburger.[41] Like the dosing-disk method, to have a consistent capsule fill, it is essential that the powder bed be kept at a constant bulk density. Thus, in the powder bed, there are typically moving baffles that move through the powder bed to keep the density and the height of the bed constant. This is important because the dosator is always inserted in the same location of the powder bed. The primary factor controlling fill weight is the height of the piston in the dosing tube (ie, the volume of open space in the dosing tube), and the second-most-important factor is the height of the powder bed.

27.7 CAPSULE FORMULATION REQUIREMENTS

As mentioned previously, to reliably produce capsules on a high-speed filling machine, you need at a minimum a formulation that (1) flows well, (2) consolidates to form a plug, (3) has sufficient lubricity to be efficiently ejected into the capsule body, and (4) when the capsule shell dissolves, the formulation must disintegrate for drug release. Obviously there are other criteria such as stability, but these are drug specific and beyond the scope of this chapter. In the following

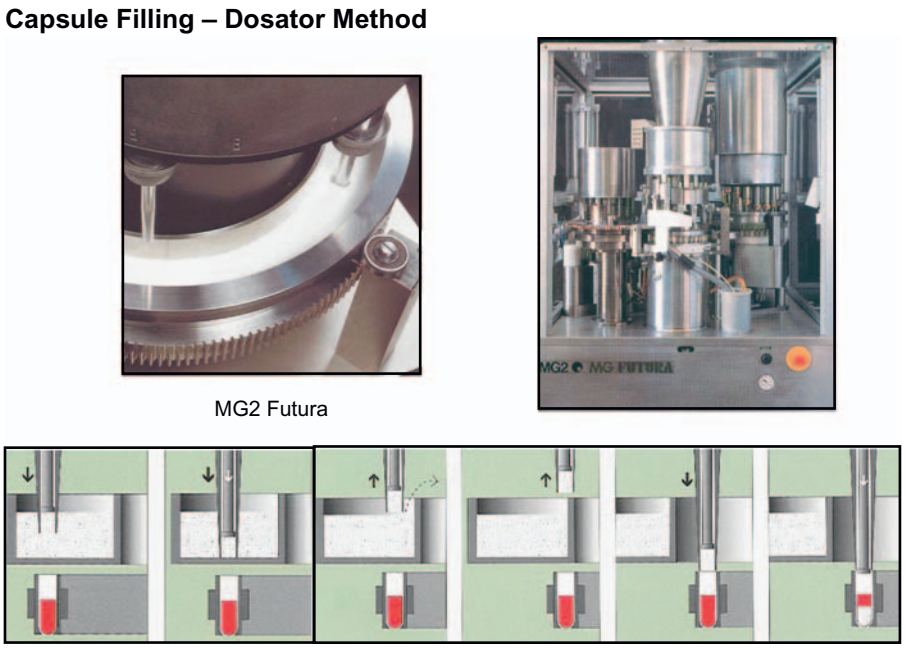

FIGURE 27.21 Dosator filling principles.

sections, we will discuss these fundamental properties that every formulation must have and the typical excipients used to create a robust formulation.

27.7.1 Flowability

For both the dosing-disk and the dosator-filling methods, a uniform powder bed density is essential to getting a consent capsule fill weight on a high-speed machine. Because for each capsule the volume of powder is repeatedly removed from the same location in the powder bed, the powder bed must reform, or the fill weight will drop and vary. Replenishing the powder bed is accomplished via the intrinsic flow properties of the powder and with the aid of baffles or agitators that move in the powder bed to redistribute the powder to the locations where the powder was removed. With all this movement of the powder bed, another formulation requirement is that the formulation does not segregate. The problem of segregation is formulation specific and beyond the scope of this chapter, but the interested reader can see Xie et al.[42] In addition, for the dosing-disk machine, fluidity is important because as the powder flows into the tamping pin holes at faster speeds, the less time the powder has to flow into the tamping pin hole, which is why sometimes with poorly flowing formulations when the speed goes up, the fill weight decreases.

As discussed by Hardy et al., flow is a critical factor affecting fill weight uniformity for dosing-disk machines.[43] Thus, when developing a formulation, the ability to measure flow in the laboratory before doing full-scale experiments on a high-speed machine will save a lot of time and resources. Much research has been done on flow measurements. One problem with most of the current flow measurements is they do not measure the fundamental physical properties, so the flow measurement can't be directly related to the performance in a capsule-filling machine. Another issue is that different flow methods look at slightly different powder flow properties. For example, in static versus dynamic flow and flow at low-bulk versus high-bulk density, the different methods won't always have the same rank correlation. Thus, one must look at several flow parameters to gain a thorough understanding of a formulation's fluidity; see Ramachandruni and Hoag for a more complete discussion of these issues.[44] Thus, with these empirical methods, experience is needed to apply them to the formulation development.

For capsule filling, some of the most commonly used methods to measure flow are the angle of repose, Carr index, Hausner ratio, funnel flow rate, FT4, and a minimum orifice diameter.[45,46] Other methods such as a shear cell are more fundamental measurements of powder flow from which flow predictions can be made, but these methods require specialized and often expansive equipment.

Two of the most commonly used methods of characterizing flow are the Carr compressibility index and the Hausner ratio. The Carr index is defined as

$$CI = \frac{\rho_t - \rho_b}{\rho_t} \times 100 \qquad (27.1)$$

where ρ_t is the tapped bulk density, and ρ_b is the loose bulk density. The Hausner ratio is defined as

$$H = \frac{\rho_t}{\rho_b} \tag{27.2}$$

Both of these methods are based upon a change in density when the powder bed is subjected to force by tapping. The principle of these methods is that when the powder is loosely packed cohesive powder will form many bridges due to the cohesive bonds between the particle at the point of contact between the particles, and when the powder bed is tapped, these cohesive bonds are broken. The powder bed collapses to a smaller volume and hence a higher density, whereas less cohesive powders won't undergo as much change in bulk density, as they do not form the bridging cohesive bonds.[48] Thus, small changes in density as a result of tapping are indicative of a good flowing powder as they don't form cohesive bonds or large changes in bulk density. From empirical experience, typical values of the Carr index and Hausner ratio for powders are given in Table 27.1. One reason these methods are so popular is that they are easy to measure, and because bulk density is important for the choice of mixer and the capsule shell size, they are often measured as part of formulation development. Because these methods are empirical, the next question is how does this correlate to fill weigh and fill weight variation, which has been the subject of much research.

Nair et al. studied the relationship between the Carr index, the flow rate index, and the minimum orifice diameter in relation to machine settings such as tamping pin height, fill weight, and fill weight variation.[49] They found that the flow is critical to the fill weight and the fill weight variation. In general, they found that pin height setting and the bed height could be set to minimize weight variation, and flow measurements were helpful in making such decisions. In another study, Osorio and Muzzio found results consistent with Nair et al., in which several flow parameters are needed to understand the relationship between weight variation and content uniformity.[50] Heda et al. compared the filling requirements of formulations run on the Zanasi LZ64 dosator and the Hofliger-Karg (H&K) GKF 70.[51] They found that poor flow measured by the Carr index was correlated by poor weight uniformity, and a Carr index in the range from 20 to 30 was ideal for weight variation.

To improve the flow of capsule formulation, glidants such as colloidal silica, cornstarch, talc, and magnesium stearate can be added to the formulation; of all these materials, colloidal silica is the most commonly used glidant. It should be noted that magnesium stearate has some effect on powder flow, but its principal effect is as a lubricant. Glidants typically have very small particle sizes and work by disrupting the cohesive forces between the particles.[52] There are many theories on how glidants function, but the mechanism by which they work is not well understood; see Armstrong for a discussion.[53] It is generally believed that to reduce cohesion between the particles, glidants coat the particles.[52] Thus, there is an optimum level for best flow, which is generally less than 1% and typically 0.1–0.25%, and empirical observation by the author has found that if the concentration of colloidal silica exceeds that needed to coat the powder surfaces, the excess colloidal silica will not improve flow and can actually reduce flowability, so the optimal glidant concentration is a critical parameter that needs to be determined.

TABLE 27.1 Empirical Relationship Between the Carr Index and Hausner Ratio

Observed flowability	Carr index	Hausner ratio
Excellent	5–10	1.05–1.11
Good	11–15	1.12–1.18
Fair	16–20	1.19–1.25
Passable	21–25	1.27–1.33
Poor	26–31	1.35–1.45
Very poor	32–37	1.47–1.59
Exceedingly poor	38–45	1.16–1.82

Adapted from Carr RL. Evaluating flow properties of solids. Chem Eng 1965; 72:415–9; Wassgren C, Pedersen H. Particle and powder flow characterization; 2010. http://pharmahub.org/resources/362.[47]

27.7.2 Compressibility and compactability of capsule plugs

With the indirect method of capsule filling, a plug is formed and then ejected into the capsule body. The typical capsule plug can be handled but will easily crumble when squeezed between your fingers. There are many similarities and important differences between capsule plug formation and tablet compaction.[43,54] Both capsule plugs and tablets are formed by the compression of a powder in a confined space. Generally, capsule plugs are compressed at forces under 200 N, while tablets are made by compression forces that range from 10 to 15 kN. A typical capsule plug has a much higher porosity, typically greater than 30%, with typical values ranging from 40% to 60%. In contrast, tablets have porosities less than 20%, and typical values are from 5% to 15%. In diametric compression, the typical breaking force for a capsule plug is under 1 N, and for tablets, the range is from 100 to 300 N. Another difference is the height-to-diameter ratio. For capsules, this is typically from 3:1 to 4:1 depending upon capsule size, and for tablets it is typically less than one, with a 0.3:1 ratio being typical.

Plug integrity is critical to the filling performance and in particular weight variation, because during the transfer from the powder bed to the capsule body, any powder that falls from the plug will result in a capsule weight variation. For dosing-disk machines, this can occur just before ejection when the dosing disk is moved over an open space where the capsule plug is unsupported to the position the plug over the capsule body. For dosator machines, this can occur when the dosing tube is withdrawn from the powder bed and moved over the capsule body.[55,56] In addition, during plug formation, differences in consolation can also lead to a plug weight variation and consequently dose uniformity problems. Thus, the ability of the plug to be transferred to the capsule body without a loss of powder is a critical quality attribute that must be controlled if a formulation is to be run successfully on a high-speed capsule-filling machine. Another key issue with plug compressibility for high-dose drugs and botanical products in particular is that you want to minimize the capsule size; thus, increasing the bulk density is important to optimizing the fill weight that can be put in the smallest size capsule possible. Note this requirement of forming a cohesive plug is at odds with the requirement of a free-flowing powder, so when developing a capsule formulation, one must balance the need for a free-flowing powder with the need to form a cohesive plug.

One way of assessing the propensity of a capsule plug to lose mass during transfer to the capsule body is to measure the mechanical strength of the plug and, in particular, plug compactability. In this chapter, I will use the notation commonly adopted by many authors such as Leuenberger: The term "compressibility" is defined as the ability of a powder to decrease in volume under pressure, and the term "compactibility" is defined as the ability of the powdered material to be compressed into a tablet of specified strength (ie, radial tensile strength or deformation hardness).[57] One of the most common ways to measure plug strength is by measuring the diametric crushing force or strength. This test is similar to measuring tablet-crushing force using diametric compression (Fig. 27.22). This method has been studied for capsule plugs.[51,55,56,58] In general, increasing the compression force increases the plug hardness and the bulk density. However, there is a point where more force, in the range of typical capsule forces, does not increase the plug-crushing force and can actually adversely affect the weight variation. The compressibility of a formulation is very dependent on the ingredients in the formulation and the compactability of the API, and each formulation must be optimized for optimal filling.

27.7.3 Lubricity

As mentioned previously, capsule plugs are typically made using compression forces less than 200 N, but forces as 300 N have been reported. While these forces are much lower than those used to make tablets, there is still a need for lubricants in a capsule formulation that is to be run on high-speed filling machines. Like tablets, traditional lubricants have been shown to significantly reduce the ejection force and improve

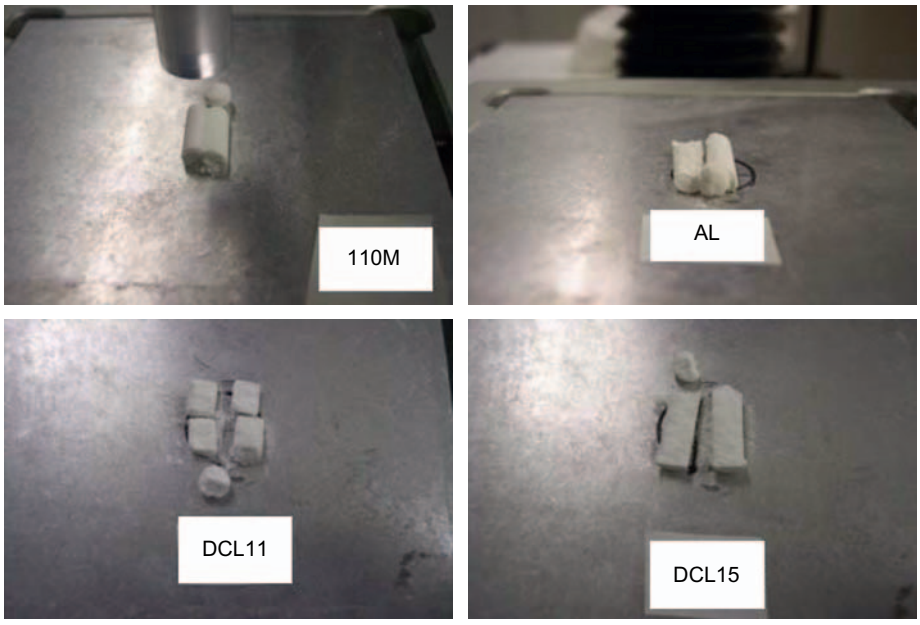

FIGURE 27.22 Diametric compress of a capsule plug; see Moolchandani et al.

capsule filling.[41,55,56] In addition, like tablets, there is an optimal lubricant level. Too little lubricant will create problems with ejection, and too much lubricant will create problems with weight uniformity and dissolution. The optimal level of lubricant depends upon the nature of the formulation. As a general rule, for plastic materials such as microcrystalline cellulose and starch, concentrations from 0.25% w/w to 0.5% w/w works best, and for brittle materials such as dibasic calcium phosphate and intermediate materials such as lactose, higher concentrations around 1.0% w/w may be needed.

27.8 CAPSULE FORMULATIONS

27.8.1 Filler binders

The nature or requirements of the capsule formulation is very dependent upon the filling method (Table 27.2). As discussed previously, for slow-speed direct-filling methods, the excipients requirements are minimal, and for PIC filling, there are no excipients in the capsule. When hand-filling using a jig, one needs a filler binder to bulk up the API volume such that the powder fill volume matches the capsule shell volume. Thus, the only excipient requirements are for a consistent bulk density, compatibility with the API, and no interference with the drug release. When filling capsules using the semiautomatic or auger principle, one needs a better flowing formulation that can undergo uniform mass flow out of a hopper without rat holing in addition to having the correct bulk density and not interfering with the drug release. When filling by the indirect methods, one needs a formulation that can form a plug, and the plug must be ejected into a capsule shell, be compatible with API, and not inhibit the drug release. To achieve these objectives, one must come up with the right combination of excipients that meets these requirements.

A typical capsule formulation for each of filling methods discussed in this chapter is shown in Table 27.2. The first thing to consider when developing a formulation is the nature of the API. The formulation must be built around the nature of the API. This discussion applies to a typical API. For very low-dose drugs of less than a couple of milligrams, special formulation and blending techniques must be applied to ensure content uniformity; see Garcia and Prescott.[59] Also, if the drug has other constraints such as low solubility, special techniques must be applied, which are beyond the scope of this chapter. If we consider the API to be one part, then the first thing to be added is the filler binder; typically the filler binder is added in two to three parts of the formulation. For example, if the dose is 50 mg, then the filler binder would typically be added in an amount of 100–150 mg as a starting point and then optimized from there.

Commonly used filler binder types include lactose, starch, dibasic calcium phosphate, and the cellulosics such as microcrystalline cellulose (MCC). Each of these excipient types comes in a variety of grades, and as a general rule for capsule filling, the direct compression grades are preferred for capsule formulation as they tend to have the best combination of flowability and compactability. When selecting the filler binder for a drug with poor solubility, it is best to choose water-soluble binders such as lactose. One should avoid high

TABLE 27.2 Typical Excipient Amounts Used in Capsule Formulations

	Direct filling methods			Indirect filling methods	
Ingredient	**PIC**	**Hand-filling**	**Auger-filling**	**Dosing disk**	**Dosator**
API	1 part	1 part	1 part	1 part	1 part
Filler-binder	NA	2–3 parts	2–3 parts	2–3 parts	2–3 parts
Disintegrants					
• Traditional • Super	NA	10%–20% wt; 4%–8% wt	10%–20% wt; 4%–8% wt	10%–20% wt; 4%–8% wt	10%–20% wt; 4%–8% wt
Lubricants					0
• Hydrophobic • Water soluble	NA	NA	0.5%–1.0% wt 2%–4% wt	0.5%–1.0% wt 2%–4% wt	0.5%–1.0% wt 2%–4% wt
Flow aids					
• Silicas • Starches	NA	NA	0.25%–0.5% wt 2%–4% wt	0.25%–0.5% wt 2%–4% wt	0.25%–0.5% wt 2%–4% wt
Surfactants	NA	0.5%–2% wt	0.5%–2% wt	0.5%–2% wt	0.5%–2% wt

concentrations of excipients that are known to gel; for example, HPMC would not be a good filler binder for low-dose drugs with poor solubility. Also, in high concentrations (ie, for low-dose drugs), MCC can form a gellike structure that can inhibit release. Thus, for a low-dose formulation, is it good to add some lactose or starch in with the MCC.

Minimizing API segregation when selecting a filler binder is a critical factor for content uniformity. As a general rule, the most important thing affecting the segregation tendency of a formulation is particle size differences between the filler binder and the API; that is, big differences in particle size should be avoided. In the author's personal experience with free-flowing noncohesive powders, ideally, I like to keep the API filler binder-to-particle size ratio somewhere between 1:3 or 3:1, with a target of 1:1. Of note, this range is the ideal range; however, in the real world, this might not be practical. Formulations with particle size ratios outside of this range may work perfectly well, but a formulator should verify the segregation tendency of the formation.[42] This also applies to free-flowing noncohesive powder systems. For cohesive powder systems, such as a micronized powder of less than 20 μm, the problem is typically not segregation but deaggregation of the micronized powder during mixing.[59]

The issue of ingredient compatibility with each other and the capsule shell is complex and very API dependent, so it won't be covered further.[60] However, the Maillard reaction between reducing sugars such as lactose glucose, galactose, maltose, and maltodextrines and drugs with primary and secondary amino groups such as peptides and proteins is a common reaction and should be considered when developing a formulation. From a practical point of view, when the reaction occurs, yellow and brown spots are formed, and as the reaction proceeds, the reactants turn black; the reaction is promoted by high temperatures and alkaline pHs.[14] Also, the Maillard reaction requires some free water, and only a small amount may be required for the reaction to occur. Thus, the hygroscopicity of the overall formulation and the type of lactose used must be considered to maintain good stability. From a moisture point of view, lactose is either in an anhydrous or a monohydrate form. The differences between them are that the monohydrate forms have a low propensity for water, while the anhydrous forms readily absorb water. In addition, the water in the monohydrate form is crystalline water and thus does not significantly react.[61,62] In summary, the capsules can be filled with lactose and have good stability for long-term storage as long as sufficient care is taken to ensure that the free water content is kept low. This requires a tight container closure system and a formulation that does not promote water absorption.[63]

27.8.2 Disintegrants

Disintegrants are added to a formulation to promote the drug release. They do this by increased water wicking into the plug, and they promote deaggregation of the plug particles. For IR tablets disintegrants are essential, but for capsules, they are less important because the plug is less of a barrier to the drug release than a compressed tablet. (See the discussion in Section 27.7.2 about the differences between a capsule plug and a tablet.) Adding a disintegrant to a capsule formulation does facilitate the drug release, which makes the formulation more rugged to the inevitable variation in excipient properties and processing conditions that occur during production over the manufacturing life of a product.

There are two classes of disintegrants: traditional disintegrants, such as starch, and super disintegrants, which include croscarmellose sodium, crospovidone, and sodium starch glycolate. Currently, these three supper disintegrants are the most popular disintegrants. In capsule formulations, super disintegrants are typically used at levels from 4% to 8% (Table 27.2), which is about twice that used in a typical tablet formulation.[64,65] The reason for this is that when a disintegrate breaks apart the plug, it does so by swelling, and this expansion of the disintegrant particles pushes the adjacent particles apart, but because plugs have a much higher porosity and the particles are not packed as close together, a given amount of expansion does not push the particle apart as much as in a tablet where the particles are much closer together. Sodium starch glycolate is known to swell more than other super disintegrants, which makes it a popular choice for capsule formulations.

27.8.3 Lubricants and flow aids

The requirements for formulation lubricity and flowability have been discussed, and in this section, the lubricants and flow aids for capsule formulation will be discussed. In common usage, the terms lubricant and flow aid are sometimes used synonymously, but for this discussion, we will use the term lubricant or true lubricant to describe an excipient that reduces the friction between the capsule plug and the metal surface of the dosing tube or the dosing disk. A glidant is something that improves the flowability of the powder. In addition, sometimes lubricants are added to reduce powder adhesion to metal surfaces. For some drugs, such as amlodipine, adherence to metal surfaces can be a significant problem; if the powder builds up, it can adversely affect content uniformity.

Lubricants can be broken into hydrophobic and water soluble. Of the hydrophobic lubricants, the most popular and efficient lubricant is magnesium stearate. In this context, efficiency refers to the ability

of a lubricant to reduce powder metal friction. Hydrophobic lubricants include the metallic stearates such as calcium stearate and stearic acid. Magnesium stearate typically uses about 0.5% wt, while the metallic stearates are included at between 0.5% and 1.0% wt, and stearic acid in the range of 1–5% wt is commonly used. For some capsule formulations, it is important that all the ingredients be soluble; for example, capsules used in a diagnostic kit need to be completely soluble. For these formulations, lubricants such as polyethylene glycol (PEG) can be used. These lubricants are not as efficient as magnesium stearate and must be used at a higher concentration; in the range of 5–15% wt is typical. To improve flow, the most common glidant is colloidal silica, but also starch and talc can be used to improve flow in a capsule formulation; the typical amounts used are given in Table 27.2.

27.8.4 Surfactants

For some drugs with low bioavailability, surfactants can be added to increase the wetting of powder mass. By improving API wetting, this can increase the rate of water uptake, which can improve the dissolution and the bioavailability of the formulation. Two commonly used surfactants are sodium docusate (SDS) and sodium lauryl sulfate (SLS). Typical use levels for SDS are in the range of 0.1–0.5% wt, and for SLS, they are in the range of 1–2% wt (Table 27.2).

Design, Development, and Scale-Up of the High-Shear Wet Granulation Process

S. Badawy and P. Pandey

Bristol-Myers Squibb, New Brunswick, NJ, United States

28.1 INTRODUCTION

The high-shear wet granulation process is one of the more traditional and commonly used granulation processes in design and development of a solid oral drug product. It is used to achieve the desired bulk density, flow, and compaction properties of the formulation.[1] It also helps minimize segregation and offers better content uniformity.[2] In certain instances it can also be used to improve the bioavailability of a formulation by providing intimate contact between a poorly water-soluble drug and a surfactant, and was shown to mitigate food effect.[3,4] Another known benefit of the wet granulation process is the robustness of the process to handle changes in active pharmaceutical ingredient (API) powder properties. This can be important during the early stages of drug product development where the API manufacturing process undergoes optimization and scale-up, thus producing materials with some variations in powder properties. Other manufacturing processes, such as direct compression and dry granulation, usually experience a more significant impact of any changes to API powder properties.[5,6] Direct compression has the advantage of short manufacturing time, but requires formulation with adequate density, flow, and compaction properties. These criteria are not commonly met for high drug loading formulations. On the other hand, low drug loading formulations may present a high risk of blend segregation and poor content uniformity when using a direct compression process. There are also some significant challenges with dry granulation (using roller compaction), such as flow into the roller compactor (especially at high drug loading), sticking to the rolls, and loss of compaction after passing through the rolls,[7,8] all of which are not present for the high-shear wet granulation process. Wet granulation is the preferred manufacturing method for formulations with high drug loading. However, the use of water and/or high degree of shear during wet granulation offer a different set of challenges for APIs that are sensitive to water and shear and can undergo transformation (eg, form conversion) that may lead to a worse drug product stability profile.[9–14] The wet granulation process also requires an additional unit operation of drying. There are other variants of wet granulation process that may be used as alternatives to the high-shear process, such as low-shear, fluid bed, and twin-screw granulation based on the specific formulation and process challenges of the drug product. For APIs sensitive to shear, a low-shear process may be preferrable.[15] Fluid bed granulation has the advantage of providing short exposure of the granulation to the water compared with high-shear granulation. It imparts less shear and densification of the granulation and results in more porous granules that can have a higher dissolution rate and better compaction properties. A choice between these manufacturing processes can be made by manufacturing process risk assessments based on prior drug product formulation knowledge, such as sensitivity to moisture, shear, and/or temperature.

A typical high-shear wet granulation formulation consists of API, filler (eg, microcrystalline cellulose and/or lactose), disintegrant (eg, superdisintegrants such as croscarmellose sodium), binder (eg, polyvinylpyrrolidone (PVP), hydroxypropyl cellulose (HPC)), and lubricant (eg, magnesium stearate). In some cases it may also contain a surfactant (eg, sodium

Developing Solid Oral Dosage Forms
DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00028-5

lauryl sulphate) and a flow aid (eg, silicon dioxide). The components that are added in the granulation bowl and undergo granulation are called intragranular components and are incorporated into the granules. The use of a polymeric binder in this step helps to form solid bridges between the particles when the granules are dried up, which dictates mechanical properties of the formed granules in conjunction with process parameters. The extragranular components of a typical formulation can include the use of filler (for providing compaction enhancement), disintegrant (to help disintegrate the overall tablet), and lubricant (aids in compaction process). Extragranular components are generally kept low in concentration (unless needed for a specific purpose) to reduce the possibility of blend segregation during blend transfer and compaction process.

A high-shear wet granulation process involves a granulation bowl equipped with an impeller blade that provides agitation and imparts high-shear to the powder during granulation. The bowl contains a chopper that helps to break-up large agglomerates formed during granulation. The binder is usually added (sprayed through a nozzle or pumped through a tube) as part of a binder solution from the top of the bowl. The binder may also be added in a dry manner, in which it is included as part of the powder formulation and water alone is used as a granulating liquid. This mode of dry binder addition is gaining popularity because it removes the additional processing steps of ensuring binder solution mixing, dispersion, and appropriate storage.[16,17] However, it can be argued that dry binder addition does not allow enough time for the binder to be fully hydrated, and thereby renders it less effective.

A schematic of a high-shear wet granulator is shown in Fig. 28.1.[18] The overall process can be subdivided into various steps. The first step ("preblending" or dry mixing) involves charging the intragranular portion of the formulation into the granulator bowl and mixing all the components to ensure a uniform mixture. The second step is when the granulating liquid is added at a certain rate to the moving powder bed, and is called the "water-addition" step. In this stage the binder gets distributed on the powder surfaces as the powder is moved by the impeller, promoting particle-particle collisions and thereby causing particle agglomeration. In the third and final step of granulation, the wet mass of granules is mixed in the granulator for some additional time, and is termed the "wet-massing" step. This step ensures further uniform distribution of water and is mainly dominated by granule consolidation and breakage.

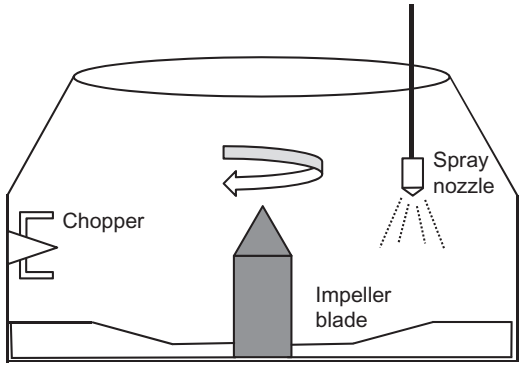

FIGURE 28.1 Schematic of a high-shear wet granulation process.

At the end of granulation, the wet granules typically require a wet milling step through a relatively coarse mesh to break up oversized agglomerates that may have resulted from local overwetting. Routinely at the end of granulation, a normal distribution of granule size is not obtained and there is a portion of large-size agglomerates that require some form of milling. At a small-scale (<200 g), this can be done by passing the wet granules through a coarse mesh (eg, US mesh size 8). For pilot and larger scale batches, a mill may be used to eliminate the coarser granules and obtain a more uniform granule size distribution. The coarser wet granules (if not eliminated) carry an additional risk during the drying step, especially when drying in a fluidized bed, where the larger granules will fluidize differently than the rest of the granules and may not dry as efficiently. Large granules have a higher risk of "case hardening," where granules dry mostly on the outside surface while retaining a wet core.

After the wet milling, the following step is to dry these granules, which is done either using a tray oven or a fluidized bed. The choice between the drying equipment is often based primarily on the batch size, but other factors such as the physical/chemical characteristics of materials, production capacity, drying characteristics, and initial and final desired moisture content all play a role in the selection. Tray oven is often used for early-stage development work (eg, formulation screening studies) where batch sizes are small (<500 g). During tray drying, the granules should be spread over a larger area using multiple trays so as not to form a deep granule bed, or else caking of powder might be observed during drying. This can then have an impact on the granule particle size distribution (and sometimes granule porosity), especially if a high amount of binder is present in the formulation.

Fluidized bed drying is the method of choice for pilot-scale and commercial scale batches. Fluidized bed drying is a more efficient and quicker process than the tray drying method and produces more

porous granules, but relies on the ability of the powder to be fluidized appropriately. Too high of an airflow at the start of the process may result in a wet mass of granules being carried all the way up the fluidized bed, sticking to the filter bags, and this wet mass may not be dried completely and remain stuck to the filter bags. On the other extreme, too low of airflow will result in a "bubbling" fluidized bed that does not provide efficient drying. The risks of case hardening and powder consolidations exist if the process conditions are not chosen appropriately (eg, high temperatures and low airflow/fluidization). Fluidized bed drying method is likely to result in more fines than the tray drying method due to higher granule attrition in the fluid bed. A comparison of granule size distribution before and after the fluidized bed drying process can give an indication of the granule strength and contributes to deciding the amount of binder to be used in the formulation. Granules coming out of the dryer are passed through a screen (typically using a conical mill) that helps to break-up any large granules and result in a more uniform granule size distribution, thus reducing segregation potential. The dry milled granules are blended with the extragranular excipients and lubricant in the final blending step(s) to form the "final blend," which is then compressed into tablets.

28.2 RATE PROCESSES IN WET GRANULATION

The high-shear wet granulation is a complex process with several and simultaneous rate processes, such as nucleation, coalescence, consolidation, and attrition, governing the overall granulation outcome. The net effect of all the rate processes depends on the processing conditions and also on the formulation components (material properties). For example, higher impeller speed may promote higher aggregation, but may also promote higher attrition, depending on the other process and formulation factors. This section provides a fundamental description of the different factors governing each of the rate processes.

28.2.1 Liquid distribution and nucleation

As liquid is added to the granulator, it wets the powder particle and creates liquid bridges between them, resulting in the formation of initial granules or nuclei. Wetting of the powder particle by the liquid is essential for successful nucleation and is governed by the spreading coefficient of the liquid on the solid, λ_{LS}:

$$\lambda_{LS} = W_A - W_{CL} \tag{28.1}$$

where W_A is the work of solid-liquid adhesion and W_{CL} is the work of cohesion of the liquid.[19,20] A positive spreading coefficient indicates that spreading of the liquid on the solid surface is thermodynamically favorable and conducive to nucleation.

In addition to the thermodynamics of wetting, size distribution of the formed nuclei is also dependent on kinetics of nucleation.[21] Kinetics of nucleation is a function of liquid addition and powder mixing parameters. In pharmaceutical wet granulation, liquid is traditionally added as bulk by pouring into the granulator bowl, metered though tubing using a pump, or atomized with a nozzle. Granule size distribution is dependent on droplet size of the liquid in cases where liquid is added by atomization into small droplets with an addition rate that is low relative to the speed of powder surface and droplet penetration time into the powder bed. If this is the case, powder flux in the spray zone is fast and droplet penetration into the bed is rapid compared with liquid addition rate and thus, liquid droplets do not overlap on the surface of the powder bed. Nuclei size distribution is determined by droplet size distribution of the granulating liquid.

Dimensionless spray flux[22–27] is a measure of the density of droplets falling on the powder bed surface, and is defined by Eq. (28.2):

$$\Psi_a = \frac{\dot{a}}{\dot{A}} = \frac{3\dot{V}}{2\dot{A}d_d} \tag{28.2}$$

where Ψ_a is the dimensionless spray flux, $\dot{A}$ is the powder flux or spray area in the nucleation zone per unit time, $\dot{V}$ is the volumetric spray flow rate, d_d is the average droplet size, and $\dot{a}$ is the total projected area of drops per unit time. A very low value of Ψ_a ($\ll 1$) indicates low droplet density, which do not coalesce with one another before hitting the powder surface.

Droplet penetration time into a powder bed, t_p, is given by:

$$t_p = 1.35\frac{V_d^{2/3}}{\varepsilon^2}\frac{\mu}{R_{eff}\gamma_{lv}\cos\theta} \tag{28.3}$$

which shows that droplet penetration time is increased (slower penetration) at higher liquid viscosity, μ, and decreased at higher bed porosity, ε, and bed pore radius, R_{eff}.[28,29] V_d is drop volume, γ_{lv} is liquid surface tension, and θ is liquid-solid contact angle.

Hapgood et al.[25] proposed a nucleation regime map in terms of spray flux and drop penetration time (made dimensionless by normalizing to particle

circulation time). In regions with low spray flux (<0.1) and fast drop penetration, each individual droplet forms a separate nucleus granule, and the nucleation process is described as being in the "droplet-controlled" regime. In this case, the initial nuclei size will be directly related to the droplet size, and therefore can be controlled by atomization parameters. On the other hand, a very high value of Ψ_a (>1) will result in the spray area being covered by droplets that have coalesced and the individual initial droplet size information bears little meaning. In that case, the water distribution is governed by the mechanics of the granulator (eg, impeller speed and design, chopper speed and design) and is called the "mechanical dispersion" regime. Local overwetting may occur when operating in the mechanical dispersion regime if shear forces are not sufficient for effective liquid distribution. This was shown to result in initial bimodal distribution of the granulation, which slowly changes to unimodal distribution by continued mixing in the granulator.[30] Nucleation is always in the mechanical dispersion regime when liquid is added as bulk by pouring into the granulator.

28.2.2 Consolidation

Porosity of granules decreases by mixing in the high-shear granulator as granules collide with each other, with the granulator wall, and with the impeller. Forces imparted on the granules as the result of such collisions cause primary particles within the granules to move closer to each other, resulting in reduced granule porosity. As porosity is decreased, granule strength increases, which makes it more resistant to breakage. Interparticle frictional forces are typically the main barrier to consolidation of pharmaceutical granules, particularly for cohesive materials with small and wide particle size distribution.[31,32] Granulating liquid acts as a lubricant which reduces interparticle friction and thus facilitates granule consolidation.[33]

28.2.3 Coalescence and growth

As granules collide in the granulator they can either stick together (coalesce), resulting in growth, or they may bounce back with no increase in granule size. Layering is the term used for a special type of coalescence when fine particles or granules coalesce with larger ones. Probability of successful coalescence is inversely related to particle size and as granule size in the granulator increases, rate of coalescence decreases and granule growth tends to slow down. Coalescence is a dynamic process that begins as soon as nuclei are formed during the initial phase of liquid addition and continues until a maximum granule size is achieved (a_{cr}^{coal}). The probability of successful coalescence between granules depends on mechanical properties of the granules and on the presence of granulating liquid on the granule surface. Probability of coalescence is enhanced by the increase in plastic deforming ability of granules because granule deformation increases the surface area of granule contact available for bonding between granules. Granule deformation also squeezes liquid to the granule surface, which forms liquid bridges between colliding granules and aids in coalescence.[34]

Granules liquid saturation, which is defined as the portion of pores within a granule that are filled with liquid, was shown to be a key factor in controlling granule coalescence.[34] Granule liquid saturation takes into account both the volume of available pores as well as the liquid volume as follows:

$$S = \frac{w\rho_s(1-\varepsilon)}{\rho_l \varepsilon} \tag{28.4}$$

Where S is granule liquid saturation, w is the mass ratio of liquid-to-solid, ρ_s is solid density of primary particles, ρ_l is liquid density, and ε is granule porosity. As liquid saturation increases, granules become more plastic and the thickness of liquid layer on granule surface increases. Granule growth was found to increase at higher liquid saturation because coalescence is enhanced by both of these factors.[34–36] Liquid saturation increases as granules consolidate and porosity decreases, and thus, consolidation was found to enhance granule growth in many cases.

Iveson and Litster[37] proposed a granule growth regime map in which granule growth behavior is dependent on granule deformation behavior (defined by a granule deformation number) and granule pore saturation. They described two regions of granule growth behavior, steady growth and induction growth, depending on granule deformability and pore saturation. Steady growth occurs in deformable granules and is characterized by linear increase in granule size as function of time. Induction growth is exhibited by strong granules with little deformation upon impact resulting in an initial phase of minimal growth. Once sufficient consolidation occurs, liquid saturation is increased which is followed by a phase of rapid growth.[38] In addition to steady growth and induction growth regions, the regime map also included a nucleation-only region at low liquid saturations, where nuclei can form but coalescence does not take place due to the low liquid saturation. To the contrary, at very high liquid saturations, rapid growth and eventually slurry formation can occur. For very weak materials, a crumb region is described where permanent granules cannot form.

Different models have been reported for granule coalescence, which can be broadly classified into two classes.[21] In Class I models,[39,40] coalescence takes place if the kinetic energy of colliding granules is fully dissipated during collision. As a result, granules do not bounce back and it is assumed that the formed bond between the granules is sufficiently strong to result in permanent coalescence. Class II models[31,41] assume that granules are sufficiently plastic to dissipate the kinetic energy and establish contact between the granules for a finite amount of time. However, depending on the strength of the formed bond, granules may permanently stick together or separate due to shear forces in the granulator. The model of Liu et al.[39] is a prominent example of Class I models. They proposed two types of coalescence for deformable surface wet granules. In type I coalescence, kinetic energy of colliding granules is dissipated by the viscous forces in the liquid layer on granule surface before their surfaces come in contact with each other. This results in the formation of a larger granule consisting of the two colliding granules held together by a liquid bridge. Type I coalescence can also occur for nondeformable granules because it does not involve granule deformation. In type II coalescence, kinetic energy is not completely dissipated by the viscous forces in the liquid layer. Further dissipation of the kinetic energy occurs via plastic deformation as granule surfaces come in contact, resulting in complete loss of the kinetic energy. For nonsurface wet deformable granules, only type II coalescence is possible.

28.2.4 Attrition and breakage

High-shear mixers typically have a wide distribution of particle velocities and shear forces. A granule formed by coalescence in one region of the granulator can break up as it goes through another region with a higher shear intensity. Granule breakage was shown by tracer studies using colored tracer granules.[42,43] Tardos et al.[44] defined a limiting granule size (a_{cr}^{break}) above which a granule will break, which is inversely related to shear rate. This is analogous to the limiting granule size for successful coalescence, a_{cr}^{coal}, which was mentioned previously. Granules would grow up to the a_{cr}^{coal}, but would tend to break if a_{cr}^{coal} exceeds a_{cr}^{break}. Large granules formed by local overwetting in the liquid addition zone will also tend to break up if they are larger than a_{cr}^{break}. As mixing continues in the granulator, a steady state with a stable granule size distribution may be reached that depends on the relative magnitude of $a_{cr}^{break}$and a_{cr}^{coal} and distribution of shear forces in the granulator.

TABLE 28.1 A Summary of Potential CMAs, CPPs and Potential Critical Granule Properties as they Relate to High-Shear Wet Granulation

Potential CMAs (Input material properties)	Potential CPPs (Process parameters)	Potential critical granule properties
Particle size distribution	Impeller speed	Particle size distribution
Surface area	Wet massing time	Pore volume distribution
Particle shape and morphology	Water addition time	Granule morphology
Solubility	Spray rate	Granule mechanical properties and strength
Binder viscosity	Nozzle properties	Bulk, tap density
Surface tension of granulating liquid	Water amount (water to solids ratio)	Flowability
Bulk density	Bowl fill	Compaction properties
Water uptake capacity	Granulator geometry	Content uniformity
Contact angle (wettability)	Impeller design/ configuration	
Particle surface properties

It should be obvious from the previously stated overview that high-shear wet granulation is a complex unit operation that involves multiple simultaneous rate processes. In order to design a robust drug product and achieve the desired target product profile (TPP), it is important to have a good understanding of the critical material attributes (CMAs) and critical process parameters (CPPs) of the process and how these CMAs and CPPs are related to the drug product critical quality attributes (CQAs). A summary of potential CMAs, CPPs, and potential critical granule properties impacted by them is shown in Table 28.1, and are discussed in detail in the subsequent sections.

28.3 MATERIAL PROPERTIES IN WET GRANULATION

There are various physical attributes of the excipients and API that govern the granulation process and thereby the final characteristics of the resultant drug product. While it may be thought that physical properties of the API are more important than the

"inactive excipients," the latter play an equally important role in the granulation process. Examples of physical properties of input materials (excipients and drug substance) that have been shown to have an effect on granulation process include particle size and shape, surface area, solubility, and contact angle with the binder solution. The granulation phenomenon is also affected by the properties of the granules that are formed during the process, such as the granule strength and granule porosity. A discussion on some of the main attributes is provided in this section.

28.3.1 Powder properties

28.3.1.1 Particle size

Strength of wet agglomerates is directly impacted by particle size distribution of the starting materials. According to the model proposed by Rumpf,[45] the static strength of moist agglomerates of a single component is expressed as:

$$\sigma_T = SC\left[\frac{(1-\varepsilon)}{\varepsilon}\right]\left[\frac{\lambda_v \cos\theta}{d_p}\right] \tag{28.5}$$

where σ_T is the tensile strength of a moist agglomerate, S is liquid saturation of the agglomerate, ε is agglomerate porosity, λ_v is liquid surface tension, θ is liquid-solid contact angle, d_p is diameter of primary particles (assuming monosized spheres), and C is a material constant. While the Rumpf equation was derived for a single component with monosized particles, it can be possibly useful for a mixture of components with a particle size distribution using relevant approximation of mean particle size and liquid-solid contact angle.

Small particle size of the starting material also results in moist agglomerates that are more resistant to densification and produce more porous granules under similar process conditions.[33] Moist compacts prepared with smaller particle size lactose were more resistant to densification in a uniaxial compaction test than the larger particle size fraction, which was also in agreement with the higher porosity of the granules prepared in the high-shear granulator using the material with smaller particle size.[46] Kristensen et al. also reported a similar observation for dicalcium phosphate.[31] They proposed a model relating agglomerate tensile strength to intrinsic interaction parameter of particles within the agglomerate and showed that this interaction parameter increased with the decrease in particle size and increase in the width of particle size distribution.[32] Granule porosity for the development compound DPC 963 was also found to be higher when using smaller drug substance particle size under the same process conditions[47] (Fig. 28.2).

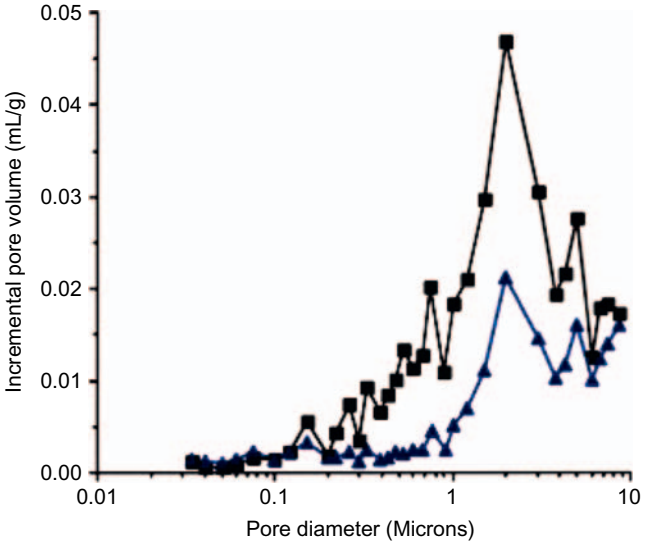

FIGURE 28.2 Porosity of DPC 963 granulation fraction manufactured using small (■) and large (▲) drug substance particle size. *Source: From Badawy SI, Lee TJ, Menning MM. Effect of drug substance particle size on the characteristics of granulation manufactured in a high-shear mixer.* AAPS PharmSciTech *2000;1(4):E33.*

The increase in granule strength at the smaller particle size is attributed to the increased volume density of interparticle contacts, which consequently increases frictional forces that contribute to the strength of wet granules.[21] The higher strength of moist agglomerates at the liquid distribution stage is conducive to more robust nucleation and reduced attrition. Increasing material particle size decreases strength of formed granules and moves the systems up the growth regime map described in Section 28.2.3 from induction to steady growth and eventually to the crumb region. A minimum particle size is hence required for a given solid/liquid system above which stable granules cannot form.[21] At the coalescence phase, granule growth is enhanced by higher plasticity and lower yield stress of the granules.[39] Therefore, at the same porosity and liquid saturation, granules formed from larger particle size material are expected to have lower yield stress and more rapid coalescence. However, the effect of particle size on coalescence is confounded by its effect on consolidation tendency and, thus, liquid saturation. Granules with larger starting material particle size are more easily densified and possess lower porosity and higher liquid saturation at the same solid-to-liquid ratio. The lower porosity increases yield stress while the higher liquid saturation tends to increase plasticity and reduces yield stress.[46] The effect of starting material particle size on yield stress and granule coalescence will thus depend on the system-dependent balance of these opposing mechanisms. For many

pharmaceutical systems, increased porosity outweighs the impact of lower liquid saturation[46] and therefore smaller starting material particle size was found to enhance granule growth in many cases.[29,46,47] In their study of 25 pharmaceutical compounds and excipients, Vemavarapu et al. found a statistically significant enhancement in granule growth resulting from the decrease in starting material particle size.[29] However, an opposite effect of particle size on granule growth was reported for dicalcium phosphate, where larger particle size showed faster growth.[31] Dicalcium phosphate demonstrated induction growth with brittle granule behavior and minimal coalescence until very high liquid saturations. The impact of increased liquid saturation for the low-porosity granules with larger stating material particle size appeared to be predominant in this case. For cohesive materials like dicalcium phosphate, the effects of increased liquid saturation and diminished interparticle friction are significant; resulting in lower yield strength and rapid coalescence for the denser agglomerates prepared using the larger particle size material.

28.3.1.2 Surface area

Surface area determined by a gas adsorption method represents the sum of external and internal (within particle) surface area. Surface area is inversely related to particle size for materials with minimal internal porosity or surface irregularities and therefore increased surface area resulting from the decrease in particle size of these materials is expected to have the same effects as described above for particle size. However, the effect of a material's internal surface area on the wet granulation process is mediated through a different mechanism and should therefore be considered independently from particle size. As a result, Vemavarapu et al.[29] did not find a correlation between the effect of inverse particle size and surface area on granule growth. Granule growth was found to decrease as both surface area and particle size increased. Inclusion of both terms in the regression model was necessary to optimize model fit. It appears, therefore, that the two factors affect granule growth through independent mechanisms. The contribution of internal porosity to surface area was more significant than the impact of particle size on surface area. Surface area was primarily construed as the internal area (intraparticle porosity) with additional contribution of surface irregularities. The penetration of water into the pores of the primary particles during granulation makes less of it available at the particle surface which decreases liquid film thickness and granule pore saturation, thus reducing the chances of coalescence and growth.

28.3.1.3 Contact angle

Wetting of the powder particles by the granulating liquid (low solid-liquid contact angle) is necessary for robust nucleation. High contact angle results in slow nucleation and low strength of wet granules. Slow nucleation is the result of decreased spreading coefficient and the less thermodynamically favorable wetting at the higher contact angle. In addition, the static strength of the wet granule is also lowered at high contact angles, as predicted by the Rumpf equation (Eq. (28.5)). Once formed, the wet granule should withstand the high-shear and impact forces generated in the mixer. Such lack of strength due to poor wetting results in breakage of wet granules, thus reducing granule growth. For example, granulation of sulfur with different polymer solutions was not successful due to the poor wetting of the sulfur particles by the granulating liquid.[35] The increase in solid-liquid contact angle by the addition of the hydrophobic salicylic acid to lactose resulted in the reduction of the resulting granule particle size.[21] Vemavarapu et al.[29] reported low growth ratio (defined as ratio of granulated blend particle size to particle size of starting material) at the same granulation conditions for materials with a high contact angle with water. Jaiyeoba and Spring also reported a similar negative influence of high contact angle and poor wettability on granule growth.[21,48]

Poor wettability and high contact angle also results in decreased tendency for densification. Poor wetting by the granulating liquid reduces its effectiveness in lubricating and reducing fractional forces at interparticle contact points, which resists movements of particles.[37] Consequently, poor wetting of the particles by the granulating liquid results in porous, weaker granules.

28.3.1.4 Solubility

During wet granulation, dissolution of soluble components in the granulating liquid takes place as liquid is added and mixed with the solids in the granulator. If the formulation contains a large fraction of a highly soluble active or excipient, a significant portion of the formulation can dissolve during wet granulation, resulting in the decrease in the solid-to-liquid ratio and an increase in granulating liquid viscosity. The decrease in solid-to-liquid ratio shifts the system to the rapid growth and overwet mass regions of the growth regime map. The increased viscosity can also affect granule growth as described next. Consequently, formulations with highly soluble component(s) require a lower amount of granulating liquid to achieve desired growth and to avoid "overgranulation" and uncontrolled granule growth. Granule growth was

reported to be uncontrolled in highly soluble compositions, as reflected in the large oversize fraction of the resulting dried granules (defined as weight fraction of granules >1.4 mm).[29] In the same study, highly soluble compositions also demonstrated wider size distribution for the dried granules, which was attributed to the higher tendency for uncontrolled growth. The increased viscosity of the granulating liquid upon dissolution of the highly soluble material, which hinders liquid distribution, was also suggested as a contributing mechanism to the formation of the wide granule size distribution.

28.3.2 Granulating liquid properties

28.3.2.1 Viscosity

Granulating liquid viscosity impacts all rate processes in wet granulation: nucleation, consolidation, coalescence and breakage.[11] Since its effect on the different rate processes can be in opposite directions, the impact of viscosity on final product attributes is system dependent. Oftentimes, the binder (eg, PVP or HPC) is dissolved in the granulating liquid, which increases its viscosity depending on binder type, concentration, and molecular weight. High viscosity impedes liquid dispersion for systems in the mechanical dispersion nucleation regime, resulting in localized overwetting. Longer times and higher impeller energy are required for uniform dispersion of the viscous granulating liquid and, subsequently, achieving uniform growth takes a longer time. Short or low-energy granulation processes with viscous granulating liquid often result in oversize granules and wide granule size distribution. Granulation of calcium carbonate with PEG 4000 aqueous solutions resulted in a wide bimodal granule size distribution attributed to the poor dispersion of the highly viscous binder.[49] For systems operating in the droplet-controlled nucleation regime, the increase in binder viscosity may lead to larger droplet size and increased droplet penetration time, which can eventually shift the system to the mechanical dispersion regime. Dry mixing of the binder with other formulation ingredients and granulating with water is a frequently used strategy to reduce viscosity and improve granulating liquid dispersion. However, rapid hydration of the binder as water is added to the formulation may still impede rapid dispersion of the granulating liquid.

High viscosity increases strength of the liquid bridges between primary particles within the granule according to Eq. (28.6)[11]:

$$F_v = \frac{3\pi\mu r_p^2}{2h}\frac{dh}{dt} \tag{28.6}$$

where F_v is the dynamic strength of the liquid bridge, μ is liquid viscosity, r_p is the primary particle radius, h is the distance between the two primary particles held by the liquid bridge, and t is time. The increased strength of liquid bridges resists particle movement within the granule, thus decreasing consolidation and resulting in more porous granules.[40] In addition, higher viscosity hinders liquid movement through the intragranular space, which makes liquid squeezing during consolidation more difficult.[33] Accordingly, the strength of dried calcium carbonate granules was reduced by the increase in polyethylene glycol 4000 concentration and viscosity of the granulating liquid. The higher viscosity of the more concentrated PEG 4000 solutions decreased granule consolidation propensity resulting in more porous and weaker final granules.[49] Similarly, Iveson et al. showed that the rate of granule consolidation increases as liquid viscosity decreases.[33]

Granulating liquid viscosity has a pronounced effect on the different coalescence mechanisms described in Section 28.2.3 (type I and type II with surface wet or surface dry granules). Higher binder viscosity on granule surface dissipates kinetic energy of colliding granules and increases probability of successful type I coalescence for surface wet granules.[40] Viscous Stokes number (St_v), which describes the balance between kinetic energy of colliding granules and dissipating viscous forces in the liquid bridge, decreases with the increase in liquid viscosity as follows:

$$St_v = \frac{8\rho_g r u}{9\mu} \tag{28.7}$$

where ρ_g is granule density, r is the mean granule radius, u is relative velocity of granule impact, and μ is the viscosity of the liquid on granule surface. A limiting value for St_v exists for each system below which successful type I coalescence takes place.

For deformable granules, the higher liquid viscosity and enhanced granule strength increases yield stress, which increases the Stokes deformation number (St_{def}) and decreases probability of type II coalescence. St_{def}, a measure of the ratio of granule kinetic energy to energy lost by plastic deformation of colliding granules, is described as[39]:

$$St_{def} = \frac{mu^2}{2D^3 Y_g} \tag{28.8}$$

where D and m are the mean granule diameter and mass, respectively, and Y_g is the granule yield stress. For surface wet deformable granules, increased binder viscosity has two competing effects on coalescence with the net effect determined by the contribution

of each of them to coalescence in a given system. For surface dry deformable granules, higher binder viscosity can only reduce coalescence.

28.3.2.2 *Surface tension*

Static strength of moist agglomerates is enhanced by the higher surface tension of the liquid according to the Rumpf equation (Eq. (28.5)). Increased strength of the moist agglomerates at the nucleation phase reduces their attrition, resulting in more robust nucleation. Maximum stable granule size is increased with higher surface tension granulating liquids.

The stronger liquid bridges formed by granulating liquids with higher surface tension are also more capable of pulling primary particles together, resulting in lower granule porosity. Granule density increased progressively with the reduction in surface tension as ethanol was added to water in the granulating liquid.[50] Ritala et al. also found that granule porosity was lower when the higher surface tension PVP solution was used to granulate dicalcium phosphate compared with the lower surface tension PVP/polyvinyl alcohol copolymer and hydroxypropyl methylcellulose (HPMC) solutions.[35] Growth was also faster with the higher surface tension PVP solutions, which was attributed to the lower porosity and enhanced liquid saturation. The authors found that granule growth is strongly dependent on liquid saturation and showed that relationship between granule size and liquid saturation is independent of the granulating solution used.

The lower strength of granules due to low liquid surface tension makes plastic granules more easily deformable, which increases probability of type II coalescence. However, the low surface tension decreases the bond formed between the two colliding granules, which makes the resulting granule more susceptible to breakage.[11]

28.4 DESIGN OF THE PHARMACEUTICAL WET GRANULATION PROCESS

There is a significant interaction between formulation components and process variables that dictate the granulation outcome. The two main components of the process include the granulator equipment and granulation liquid. The factors associated with granulator equipment would be the granulator design, bowl volume and fill, impeller blade design (size, shape, angle), impeller blade placement (top or bottom driven), impeller and chopper speed, chopper design, and process time. The factors associated with granulation liquid include amount, liquid introduction method (spray vs drip), spray rate, spray characteristics (droplet size, velocity, spray area, etc.), liquid addition time, addition location, liquid properties (viscosity, surface tension, etc.), and binder addition method (wet vs dry). The previous section discussed the input material properties (formulation aspects), while this section focuses on the main process variables that govern the wet granulation process.

28.4.1 Impeller and chopper speeds

Speed and frequency of particle collisions in the granulator increase as the impeller speed is increased. Increasing collision energy enhances deformability and growth of plastic particles,[39] while increasing attrition in brittle granules with low liquid saturation.[51] At low water level and liquid saturation, granules are more brittle and high collision velocity is more likely to result in granule breakage rather than coalescence and growth. In other words, granule behavior when yield stress is exceeded determines the effect of impeller speed. For brittle granules, which break at their yield stress, a maximum stable granule size is achieved under given conditions according to the model proposed by Tardos et al.,[44] which predicts the maximum stable granule size to be inversely related to impeller speed.

$$a_{\mathrm{cr}} = \frac{(2\tau_{\mathrm{y}} St_{\mathrm{def}}/\rho_p)^{1/2}}{\gamma} \tag{28.9}$$

where a_{cr} is the is the maximum stable granule size, τ_{y} is the yield stress, ρ_{p} is the granule density, γ is the average shear rate in the granulator, and St_{def} is the Stokes deformation number. This model predicts the maximum stable granule size to be inversely related to impeller speed because γ is directly related to the impeller speed.

In contrast to brittle granules, plastic granules, which deform rather than break at their yield stress, demonstrate increase in probability of coalescence with the increase in impeller speed, according to the model of Liu et al.[39] The effect of impeller speed on granule size thus depends on granule mechanical properties where plastic granules are likely to have more pronounced growth as the impeller speed is increased, while brittle granules can undergo more attrition and reduction in granule size at the higher impeller speed. Consequently, the increase in granule size with impeller speed was found to be dependent on water level used for granulation in case of razaxaban and brivanib formulations.[51] For both formulations, the increase in granule size at the higher impeller speed was predominantly observed at the high water level where granules have sufficient liquid saturation and plasticity.[51] Other

studies also reported increased granule growth rate at higher impeller speed.[52,53]

In addition to the granule mechanical properties, the effect of impeller speed on granule size can also depend on the impeller's effect on liquid distribution in the granulator. As pharmaceutical high-shear wet granulation usually operates in the mechanical dispersion regime for nucleation where mechanical forces are responsible for liquid distribution and nucleation,[25] a low impeller speed that does not efficiently distribute the liquid can result is localized overwetting and formation of lumps.[51] These lumps or oversize granules are distinct, at least from a mechanistic point of view, from large granules that result from granule coalescence and uniform growth. The oversize lumps represent a larger particle size than would be achieved if the granulating liquid is uniformly dispersed and the granulation process is allowed to proceed to steady state. Higher impeller speed can thus increase the efficiency of water distribution and reduces oversize lumps and granule size is also reduced as a result. Consequently, pexacerfont formulation showed significant reduction in granule size as the impeller speed was increased.[51] In this case, the reduction in particle size at the high impeller speed was more predominant at the higher water level. This was attributed to the improved water distribution at the higher impeller speed and the breakage of lumps resulting from localized overwetting at the high water level.[51]

The higher impeller speed also results in higher consolidation forces in the granulator and decreased granule porosity.[49,51,52,54] As the porosity is decreased, granule liquid saturation is increased at the same level of granulating liquid. According to Iveson and Litster's regime growth map,[37] this increase in liquid saturation shifts the system's behavior from the nucleation to the growth regions, resulting in faster granule growth as the increased consolidation squeezes the liquid to the granule surface, which enhances coalescence.

Increasing impeller speed may result in a more spherical shape for deformable granules at high liquid saturation.[54,55] Granule shape can affect its performance as more spherical granules have higher bulk density due to their closer packing ability. Spherical granules will thus tend to have improved flow properties. On the other hand, more irregularly shaped granules may have improved volume reduction behavior and compactability.[55]

Chopper speed is not usually as critical as impeller speed. Chopper may be useful in breaking up overwetted lumps and aids in liquid distribution. Chopper may also provide shear forces contributing to granule growth. In addition, the chopper may disrupt uniform flow pattern of powders and improve mixing in the granulator. Knight[53] reported narrowing of the granule size distribution when the chopper was switched on, which was attributed to the chopper's preferential breakage of large granules. Despite the narrower distribution, mean granule size distribution was not impacted by chopper action.

28.4.2 Amount of granulating liquid

The ratio of liquid to solid used for granulation determines granule liquid saturation, which researchers reported to be a critical factor with respect to granule growth and consolidation.[32,35,36,51,52,56–59] As granule liquid saturation is increased, granules move from the nucleation to the growth regions on the growth map. Increased liquid saturation makes granules more deformable and enhances coalescence.[33] Granulating liquid also lubricates particle movements within the granules, reduces interparticle friction, and facilitates consolidation. Consequently, granule porosity is reduced as liquid saturation in increased. Iveson et al.[33] reported decreased granule porosity at the higher liquid saturation when low viscosity liquid was used for granulation. An opposite effect was found when high viscosity liquid was used. In the latter case, the disruption of interparticle friction by the liquid was outweighed by the increased strength of the liquid bridges of the viscous liquid, which resists densification.

28.4.3 Process duration

Process duration is usually defined as the time taken from the beginning of granulating liquid addition until mixing is stopped. It is typically broken down into two phases: (1) liquid addition phase during which granulating liquid is added to the granulator while mixing, and (2) wet massing time which is the term used to describe mixing that takes place in the granulator after granulating liquid addition is complete. It is usually beneficial to delineate the duration of the two phases as their impact on the granulation process may be different, and thus, controlling the duration of one of the phases may be more effective than controlling total process duration.

Wet massing phase helps provide even distribution of water along with some further agglomeration, reduction of fines, consolidation, and attrition of granules. During wet massing, granule coalescence and growth may take place, but large granules may also undergo breakage until a steady state particle size distribution is achieved.[44] Wet massing can result in an increase[53,60] or decrease[61] in particle size. Increasing wet massing time has been reported to reduce granule d_{90} due to attrition of large granules, while increasing

d_{10} and d_{50} resulting in a narrower granule size distribution.[58] Wet massing time in pharmaceutical wet granulation, however, is not usually long enough to achieve true steady state.

During wet massing, granules that were formed during water addition can also get further consolidation. Granule densification, which takes place during wet massing, can affect granule liquid saturation and mechanical properties and thus, particle size distribution of the granules. For systems with induction behavior, consolidation, and subsequent increase in liquid saturation during wet massing is required to induce coalescence and granule growth. Typically, an exponential decay of porosity is observed during this phase[62,63] as shown in Eq. (28.10).

$$\frac{\varepsilon-\varepsilon_{\min}}{\varepsilon_0-\varepsilon_{\min}}=\exp(-k_c t) \tag{28.10}$$

where ε is the average granule porosity, $\varepsilon_{\min}$ is the minimum achievable porosity at given process conditions, ε_0 is the initial porosity, k_c is the granulation consolidation rate constant and t is the wet massing time. Consolidation rate during wet massing is usually also dependent on other process conditions, including impeller speed and the amount of water used during granulation.

The wet massing time should generally be kept short because higher porosity is generally a desired property. High-shear wet granulation processes should therefore be designed with sufficient granulating liquid added to achieve adequate granule liquid saturations to be in the steady growth regime[37] at the end of liquid addition phase, which results in coalescence and desired granule growth. Design of induction systems that require long wet massing times and consolidation to increase liquid saturation and induce growth should be avoided. Increasing the granulating liquid amount to achieve desired growth is thus, a preferred strategy than using lower liquid amount and long wet massing time. Despite the short wet massing used in steady growth systems, significant reduction in porosity and subsequent decrease in compactability of granules and dissolution rate of tablets have been reported.[64] Increasing the wet massing time for brivanib from 10 to 50 s showed a statistically significant decrease in porosity and tablet dissolution rate. Significant increase in granule density and reduction in compactability was observed for razaxaban upon the increase in wet massing time from 30 to 180 s. Similarly, reduction in granule porosity and compactability was reported for a lactose-based granulation[52] (Fig. 28.3) and for a lactose/microcrystalline cellulose system[65] upon increasing wet massing time to 90 and 180 s, respectively. The high liquid saturation for the steady growth systems makes them prone to rapid densification and therefore design strategy should aim to minimize or eliminate[52] wet massing time.

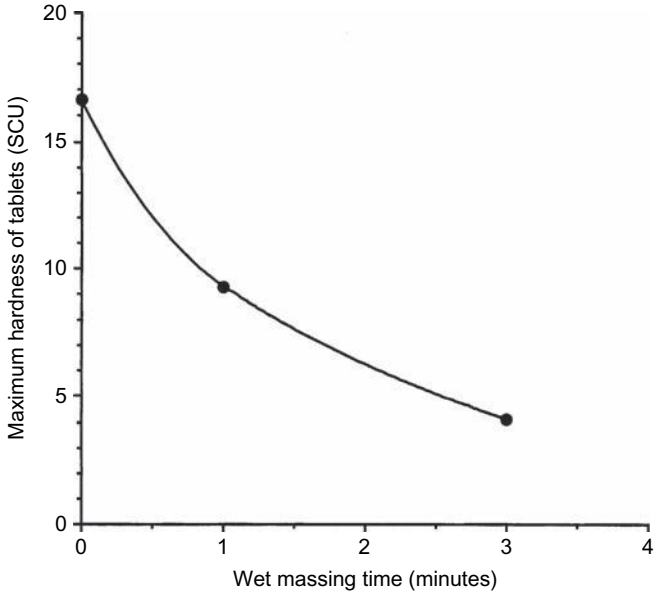

FIGURE 28.3 Effect of wet massing time on compressibility of granulation manufactured in the PMA-65 high-shear granulator. *Source: From Badawy SI, Menning MM, Gorko MA, Gilbert DL. Effect of process parameters on compressibility of granulation manufactured in a high-shear mixer.* Int J Pharm *2000;**198**(1):51–61.*

While the increase in mixing time after complete water addition (wet massing time) resulted in a significant effect on granule densification, the increase in mixing time during water addition (water addition time) showed minimal impact on granule porosity for the same formulations.[52,64] This suggests that the effect of mixing on granule porosity is dependent on the water level (granule liquid saturation). Mixing after complete water addition tends to be more effective in decreasing granule porosity (due to the lubricant effect of water mentioned previously). On the other hand, mixing during water addition, when granule liquid saturation is still low, is not as effective in reducing granule porosity and consequently prolonging water addition time has little or no effect on granule porosity. It is therefore prudent to control wet massing time as a separate parameter distinct from water addition time and not to lump both as one parameter representing total processing time.

In many cases, liquid addition rate mainly affects liquid dispersion under conditions where mechanical dispersion of the granulating liquid is not very effective. In these instances, reducing liquid addition rate aids in the dispersion of the liquid, decreases overwetted lumps, and produces narrower granule size distribution. This is more likely to be the case for viscous granulating liquids, when the binder is dissolved in the granulating liquid, or if the formulation

contains a high concentration of polymeric material such as cellulosic, polymer-based, controlled-release matrix formulation that hydrates rapidly when it comes in contact with water. Water addition time had a statistically significant effect on mean granule size for pexacerfont and the increase in water addition time (slower water addition) resulted in smaller granule size.[51] A statistically significant term for the two-way interaction between water amount and water addition time was also observed, which showed a more pronounced effect of water addition time at the higher water level. Batches manufactured at the higher water level are more likely to have a higher content of the overwetted lumps and thus, the slower water addition is more beneficial in improving water dispersion for those batches.[51] Particle size of paracetamol granules manufactured at the low impeller speed and highest liquid addition rate showed the widest distribution, likely because of the poor liquid distribution at these conditions.[66]

28.5 QUALITY ATTRIBUTES OF WET GRANULATED PRODUCTS

Microscale granule properties, such as size, morphology, porosity, and strength dictate the macroscale attributes of the granulation and final product. In the previous sections, the impact of starting material attributes and process parameters on granule microstructure were discussed. In this section, the effect of wet granulation process on performance-indicating macroscale product quality attributes is reviewed.

28.5.1 Solid state form

Solid state phase transformation is a common occurrence in wet granulation. Phase transformation in wet granulation can be classified into the following categories: (1) transformation to a more stable polymorphic form, (2) formation of a hydrate/solvate, (3) formation of a high-energy metastable form (eg, amorphous), and (4) transformation of a salt form to the less-soluble free form. Solid state transformations present quality and regulatory challenges to drug product development and commercial manufacturing. Thus, careful risk assessment, mechanistic understanding, and appropriate control strategy should be in place if wet granulation is to be used for a drug substance that is prone to such transformations.

Transformation of a metastable polymorph to the more thermodynamically stable polymorph can take place via solvent-mediated mechanism during wet granulation. For example, transformation of form A to the more stable tautomeric polymorph B was reported to take place during wet granulation of an irbesartan formulation.[67] Polymorphic conversion of the metastable form I of flufenamic acid to the stable polymorph III was also observed during wet granulation with ethanol.[68] As the more soluble metastable polymorph dissolves in the granulating liquid, it forms a supersaturated solution with respect to the stable polymorph, which subsequently crystallizes from the supersaturated solution. The less-soluble polymorph may have lower dissolution rate and bioavailability compared with the metastable form.[69,70] The extent of conversion to the more stable polymorphic form depends on the kinetics of phase transformation relative to processing time. Rate of phase transformation is a function of dissolution rate of the metastable form, volume of granulating liquid used in the process, and crystallization kinetics of the stable polymorph.[71] Extent of transformation can thus be dependent on granulation parameters that impact these factors. Processing time is dependent on liquid addition rate and wet massing time, while dissolution rate may be a function of impeller speed.

Compounds which exist in a hydrate form can potentially convert to the hydrate if the anhydrous form is used in aqueous wet granulation because water activity during wet granulation is usually higher than the critical humidity for the formation of the hydrate. Hydrate formation can also take place through a solvent-mediated mechanism, as described previously for polymorphic transformations. Many literature articles exist on the transformation of the anhydrous form to hydrate during wet granulation.[11–13] The lower solubility of hydrates can potentially lead to a lower dissolution rate and bioavailability.[70,72] The hydrate form may partially or completely convert back to the anhydrous form during drying of the granulation, so a mixture of forms can potentially exist in the final product. Wikström et al.[12,13] used Raman spectroscopy to follow hydrate formation of theophylline during wet granulation. They concluded that hydrate formation takes place via a solvent-mediated mechanism and showed that the rate of transformation increased by the increase in agitation speed. Formation of theophylline monohydrate in the wet mass was inhibited by granulation at elevated temperature (50°C).[73] Theophylline monohydrate, formed by granulation at lower temperatures (27–40°C), was found to convert back to the anhydrous form by drying at 70°C.[73]

Hydrate formation of an excipient can also take place during wet granulation. Formation of lactose monohydrate upon wet granulation of anhydrous lactose was reported.[74] Anhydrous lactose has superior compaction properties compared with lactose monohydrate due to its particle morphology.[74] Anhydrous lactose particles

have high surface roughness and porosity, in contrast with the smooth low-porosity lactose monohydrate particles. Interestingly, lactose monohydrate particles created from anhydrous lactose particles in wet granulation still retained the morphological features of the initial anhydrous lactose particles and consequently maintained higher compactability compared to the "as is" lactose monohydrate.[74]

Formation of a high-energy metastable form can take place when the starting lower energy polymorph dissolves in the granulating liquid and is kinetically trapped into a high energy form during drying.[71] A high energy disordered phase can also form through a nonsolvent mediated mechanism where shear forces applied during wet granulation in the presence of water cause disruption of crystallinity and create crystal defects or amorphous phase. Formation of an amorphous phase can also increase formulation hygroscopicity after wet granulation.[75] Wet granulation of BMS-561388 resulted in partial transformation to the less stable, amorphous form.[9] Similarly, aqueous wet granulation of either polymorph A or B of dexketoprofen trometamol with microcrystalline cellulose caused transformation to the amorphous form regardless of the initial polymorph used in granulation.[76]

Salts of weak bases or weak acids may covert to the free form (free base or free acid) during aqueous wet granulation. As the salt dissolves in the granulating water, it will form a saturated solution with respect to the free form if the solution pH is higher (for a weak base) or lower (for a weak acid) than the pH of maximum solubility (pH_{max}). The free form subsequently precipitates from this saturated solution, resulting in the salt-to-free-form transformation. If this solution pH requirement is not met, the salt would be the thermodynamically stable form in equilibrium with solution and consequently there would be no conversion to the free form. As for polymorphic transformations, wet granulation parameters (amount of granulating liquid, impeller speed, and process duration) can potentially affect the extent of solvent-mediated transformation of the salt to the free form.

Excipients can be used to stabilize a drug substance against form conversion during wet granulation. Excipients may inhibit solvent-mediated polymorphic and hydrate transformations by absorption of the solvent (water), thus making it less available to dissolve the active. In addition, specific interactions between a drug molecule and an excipient can slow down nucleation and/or crystal growth. In a study of the effect of several polymers on hydrate formation of three model compounds in wet granulation, Gift et al.[11] found varying degrees of inhibitory effect on hydrate formation depending on the compound and polymer used. Cross-linked poly(acrylic) acid was found to completely inhibit caffeine hydrate transformation and both HPMC and cross-linked poly(acrylic) acid completely inhibited the carabamazepine hydrate formation. On the other hand, sulfaguanidine transformation was rapid even in the presence of polymers. Airaksinen et al.[77] found that hygroscopic, partially crystalline excipients hindered hydrate formation of nitrofurantoin in wet granulation, likely due to their significant uptake of granulating water. Form transition from a metastable to a stable form of theophylline during wet granulation was also inhibited by povidone. Higher molecular weight of povidone was more effective in inhibiting the transition than the lower molecular weight polymer.[78]

28.5.2 Chemical stability

The wet granulation process was reported to affect chemical stability of drug molecules. In some cases, the effect of wet granulation process on chemical stability manifests itself by enhancing degradation reactions during processing whereby an increase in degradant content is observed at the end of manufacturing. Exposure of a moisture-sensitive compound to the high water activity experienced in aqueous wet granulation may be the underlying mechanism. Alternatively, degradation in the solution phase, as a fraction of the active dissolves in the granulating liquid, can be the causal mechanism. Actives with high solubility in the granulating liquid are expected to be more susceptible to the latter mechanism. Degradation during manufacturing, however, is not frequently observed in wet granulation due to the short processing time relative to reaction rates even for moisture-sensitive compounds.[9,10,79]

Enhanced degradation caused by wet granulation is more commonly observed upon storage (accelerated and long-term stability) and not at the end of manufacturing. While this may be attributed in some cases to a high level of residual water in the drug product, it is more frequently the result of creation of high-energy disordered states during wet granulation. Rate of degradation reaction in the high-energy phase is significantly higher than the crystalline phase and thus drug degradation in the solid state usually takes place in disordered regions or in crystal defects.[80] The higher molecular mobility in those disordered regions results in a faster degradation rate than in the crystal lattice. In addition, disordered regions have higher water content due to absorbed water, which further enhances degradation rate in those less-ordered regions for reactions in which water acts as a reactant.[81] As described in the previous section,

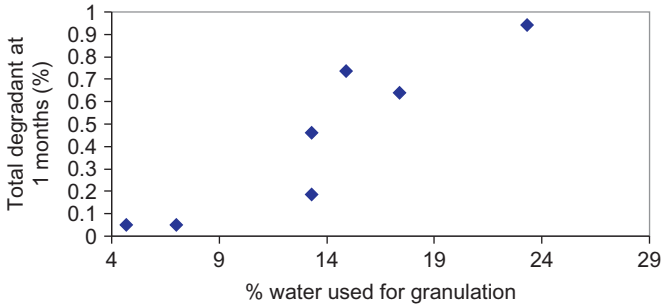

FIGURE 28.4 Effect of water amount used for granulation on the stability of compound I tablets at 40°C/75% RH.

amorphous regions of the active could form in wet granulation, and although the fraction of the drug in amorphous state may be small, this still leads to a measurable impact on stability because the acceptable specification limit of a drug product degradant is usually very low.[81] The rate of degradation of a highly water-soluble triazine derivative (compound I) on accelerated stability was thus dependent on the amount of water used for granulation (Fig. 28.4), despite the similar granulation moisture content at the end of drying. This was attributed to the higher amorphous content resulting from the increased fraction of the active dissolving in the larger volume of granulating liquid. The fraction dissolving during granulation was shown to form amorphous material after drying.[10]

In some cases, wet granulation can result in the formation of a high-energy state of one or more excipients, which increases formulation hygroscopicity and negatively impacts stability of moisture-sensitive compounds. For example, wet granulation increased moisture uptake and degradation rate of the unbuffered lactose-based formulation of the low dose compound, DMP 754, which was attributed to the formation of amorphous lactose during wet granulation.[75]

The effect of wet granulation on product stability can also be caused by enhanced contact between drug and excipients. Partial dissolution of an excipient and/or the drug substance during wet granulation and subsequent crystallization during drying (albeit to the same initial form) results in higher surface area of drug/excipient contact. This intimate contact of the drug and the excipient enhances rate of drug degradation caused by drug-excipient interaction and results in a less stable drug product.

The intimate contact of drug and excipients resulting from wet granulation was leveraged to enhance stability in some cases. For formulations containing a pH modifier, dissolution of the buffer components in the granulating liquid results in better distribution of the pH modifier in the formulation and in a more effective pH control, thus maximizing drug product stability.[82] Thus, while the rate of acid-catalyzed hydrolysis of compound I was enhanced by wet granulation compared with a dry blend in formulations without pH modifier, the opposite effect of wet granulation was observed in formulations containing sodium carbonate as a pH modifier.[10] The wet granulation process enhanced the pH modifying effect of the carbonate, which outweighed the destabilizing effect of crystallinity disruption caused by wet granulation (Fig. 28.5). The loss of crystallinity appeared to have no negative effect on stability when the pH was not sufficiently acidic to promote the acid-catalyzed reaction.[82] Similarly, improved stability of a formulation containing pH modifier was also reported for DMP 754 tablets and capsules when a wet granulation process was used for product manufacture. Disodium citrate was used as the pH modifier and was dissolved in the binder solution used for wet granulation. Both

ester and amidine hydrolysis rates of DMP 764 were shown to decrease in the wet granulated dosage form compared with the dry granulated product. This was also attributed to the more effective pH control due to the uniform distribution of the pH modifier, which was confirmed by an x-ray imaging technique of the tablets. It is noteworthy that the improved stability of the wet granulated product in this case was observed despite the increased formulation hygroscopicity.[75]

28.5.3 Dissolution and bioavailability

Agglomeration of drug substance particles in wet granulation can potentially affect dissolution rate. Agglomerated particles have lower surface area available for dissolution and thus, dissolution rate would be reduced by granulation, unless granules disintegrate rapidly upon contact with the dissolution medium. For slowly disintegrating granules where granule erosion is the predominant mechanism for dissolution, dissolution rate is dependent on granule size. On the other hand, for rapidly disintegrating granules, granule size usually has no effect on dissolution. Disintegration of granules, however, is affected by porosity and thus, in this case, dissolution rate may be dependent on granule porosity. As porosity is lowered, granule disintegration and subsequently dissolution rate slow down. As granule pore diameter is decreased, dissolution medium ingress into the granule and subsequent granule disintegration becomes slower, resulting in the slower tablet dissolution. Thus, depending on the predominant mechanism of dissolution, granule porosity and/or size distribution may impact drug product dissolution rate. The dissolution rate of brivanib tablets was strongly dependent on granule porosity. The amount dissolved in 10 min showed a strong correlation with granule pore diameter (Fig. 28.6) and poor correlation with granule mean diameter. To the contrary, pexacerfornt tablet dissolution correlated with granule mean diameter and showed no dependence on blend density.[51] As both granule size and porosity are affected by granulation parameters and starting material and granulating liquid properties, wet granulation process can thus be modulated to optimize dosage form dissolution. Depending on the biopharmaceutical properties of the drug molecule, the effect of granulation process on dissolution rate may also impact bioavailability.

Apart from the impact of wet granulation on dissolution rate through its effect on granule size and structure, wet granulation may also affect dissolution rate of primary drug substance particles. The intimate contact of drug substance and excipients achieved in wet granulation can be leveraged to increase effectiveness of surfactants as wetting agents. For compounds with dissolution rate limited bioavailability, the resulting improvement in drug particle wetting by the dissolution medium can enhance dissolution rate and bioavailability. In a recent article, Pandey et al. showed that for a formulation exhibiting a dramatic positive food effect, the type and level of surfactant and binder were able to modulate the dissolution rates

and, in turn, the bioavailability.[3,4] The incorporation of a surfactant such as Vitamin E TPGS and poloxamer via a high-shear wet granulation process was found to significantly enhance dissolution of the tablet formulation. The study data showed that the presence of Vitamin E TPGS in dogs was essential in enhancing the bioavailability in the fasted state, and this was confirmed in human subjects where this formulation was successful in mitigating the food effect.[3]

28.5.4 Compaction and flow properties

Wet granulation can have considerable effect on compaction properties of the resulting granulation. Change in compaction properties (tablet tensile strength vs applied compression pressure) upon wet granulation is a combined effect of loss in porosity and size enlargement of the constituent particles, and the concomitant increase in the bonding and plasticity of particles upon uniform application of the binder. While the former is known to decrease compactability following wet granulation, the latter enhances the compactability through activation of the binder. In their study of a group of 25 pharmaceutical compounds and excipients, Vemavarapu et al.[29] concluded that the latter mechanism is more dominant than the former with more compounds/excipients showing enhanced compactability upon wet granulation. The increase in compactability upon wet granulation was found to be highest in materials with low initial compactability, which are more likely to gain compatibility benefit from the application of a uniform binder layer in wet granulation. To the contrary, more hygroscopic materials with high surface area resulting from high internal porosity showed decreased compatibility after wet granulation. These materials are more likely to have diminished intraparticle porosity as the result of high-shear wet granulation and thus, deterioration in compactability. Microcrystalline cellulose is a notable example of these materials. The change in pore structure of microcrystalline cellulose was shown to correlate with reduced compatibility in wet granulation, even without the increase in particle size.[83]

Despite the enhancement in compactability observed for many compounds under the granulation conditions used by Vemavarapu et al., it should be emphasized that excessive granule densification can greatly diminish compactability. Growth of overly densified granules results in reduced volume reduction behavior and compressibility (density vs compression pressure) of the granulated material.[55,84–86] Thus, many studies reported decrease in compactability with the increase in amount of granulating liquid and wet massing time and at higher impeller speed—all are factors which were shown to concomitantly decrease granule porosity.[51,52,65,87]

Improving blend-flow properties is one of the main objectives of wet granulation. The improved flow properties in wet granulation is usually the result of increased particle size and/or density of the blend. The contribution of increased size versus density was shown to vary among different formulations. The enhanced flow rate for brivanib by wet granulation was mainly attributed to increased granule density with little contribution from particle size enlargement. On the other hand, the increase in particle size (with reduction in fines) appeared to be the main mechanism for improvement in flow properties for pexacerfont formulation. The increase in both particle size and density contributed to reduced angle of repose and enhanced flow properties of razaxaban.[51]

28.6 SCALE-UP OF THE HIGH-SHEAR WET GRANULATION PROCESS

The scale-up of high-shear wet granulation process is highly relevant to the pharmaceutical and food industries. This topic has been a subject of extensive research over the years and many publications exist to date proposing different ways to scale-up this process. This section discusses the main challenges associated with scale-up and broadly categorizes the various scale-up methodologies into two main categories or strategies (Fig. 28.7).

28.6.1 Challenges in scale-up of high-shear wet granulation

The challenges associated with scale-up of high-shear wet granulation process arise from the short processing times (typically ~3–5 min), and relatively high-intensity process conditions in terms of shear, particle velocities, and particle collision frequency and energy, that are inherent to this process.[87] Change in drug substance material properties throughout the product development life cycle presents an additional challenge to scale-up. In a quality by design paradigm, there is a need for an increased understanding of the process and to establish a design space of process parameters and material properties. If such experiments are done at the large scale, it would lead to significantly higher costs. Therefore, it is important to establish the scalability of the process and be able to conduct more experimentation at the lab and/or pilot scales.

The underlying strategy during scale-up is to ensure that particles experience the same overall process

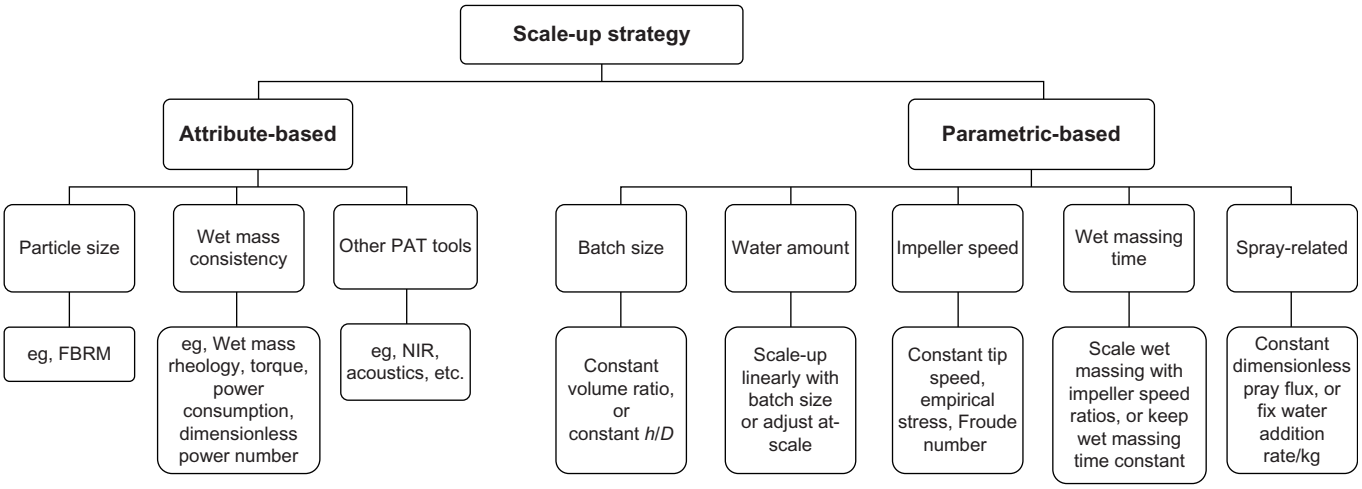

FIGURE 28.7 Scale-up strategy for high-shear wet granulation process. In parametric-based scale-up, all the parameters must be scaled-up simultaneously based on certain rules (as shown) in order to achieve success during scale-up. *Source: From Pandey P, Badawy S. A quality by design approach to scale-up of high-shear wet granulation process.* Drug dev ind pharm *2015;**42**(2):175–89.*

conditions across scales so that the same granule quality can be achieved. In order to accomplish that, there are three types of similarities required across scales: geometric, dynamic, and kinematic similarity.[18,88,89] In relation to high-shear wet granulation process, the geometric similarity refers to the granulator bowl geometry, including impeller design, and can be maintained if the ratio of linear dimensions across scales is maintained. The dynamic and kinematic similarities refer to the forces experienced by the particles inside the granulator and the particle velocities, respectively. The forces or shear experienced by the particles inside the granulator result mainly from particle-particle, particle-wall, and particle-impeller collisions. The impeller design and speed generally dictate the magnitude of shear experienced by the particles, which in turn governs the interplay between the various granulation mechanisms, such as aggregation, consolidation, and breakage (discussed in previous sections).

It is challenging to maintain geometric, dynamic, and kinematic similarities across different scales of high-shear granulators. Geometric similarity is a prerequisite to obtaining the other two similarities, and is easier to maintain if the same granulator design is used. In such cases, batch size is increased proportionally to granulator volume, which results in the same powder-bed-height-to-bowl-diameter ratio. Equipment manufacturers have recognized the importance of granulator design effects during scale-up in recent years and started offering granulators that can be set-up with different size granulators that have the same design. However, this may not be the case at the commercial scales, where routinely the granulator manufacturers are different from lab and pilot-scale manufacturers, or have a different granulator design. Sometimes the difference can be as drastic as having a top-driven versus a bottom-driven granulator, both of which will have significantly different particle flow patterns. Even though lab and pilot-scale equipment often get upgraded with new capabilities (such as monitoring torque profiles), this is generally not the case at the commercial site, where good manufacturing processes regulations are in effect and changes to equipment could be a significant undertaking, both in terms of costs and procedures. The geometrical differences across granulators result in different distribution profiles of particle velocities and forces at the different scales, which make the goal of attaining dynamic and kinematic similarities more complicated. In addition, it is also challenging to simultaneously obtain similar peak particle velocity and force across scales. As a result of these challenges, the concept of granulation "endpoint" is quite common in high-shear wet granulation. In this case, granulating liquid amount and/or wet massing time are based on an in-process measurement, which is used to determine when the granulation reaches desired properties (or endpoint) and consequently the process is stopped when this endpoint is achieved.[18]

In looking at the various scale-up rules proposed in the literature, it is observed that the scale-up methodologies can be categorized broadly into two main strategies: (1) parametric-based scale-up strategies in which target parameters identified at the small scale and shown to provide the desired final product attributes are scaled up using certain empirical calculations or; (2) attribute-based scale-up strategies in which parameters are adjusted at the different scales to achieve target in-process attributes or endpoint,

as determined by an in-process measurement.[18] A combination of the two approaches is often utilized in practice. A more detailed discussion on each of these categories is provided in the subsequent subsections.

28.6.2 Scale-up principles

28.6.2.1 Parameter-based process scale-up strategies

A parametric-based scale-up strategy is one in which the process parameters at the larger scale are determined from the small-scale parameters using certain scale-up principles for each or many of those parameters. These scale-up factors are most commonly related to the impeller speed, wet massing time, water amount, and sometimes to the granulating liquid addition (eg, spray rate, water addition time, droplet size, mode of addition). The first step in a parametric-based approach is to conduct small- or pilot-scale experiments in order to help identify CPPs that govern the granulation properties for that formulation and then scale-up those critical parameters appropriately.[61,90,91] Scale-up rules for the frequently used CPPs are listed next.

28.6.2.1.1 Water Amount

The water amount can be considered as the most critical parameter that governs the granulation process. It can be sometimes considered as a formulation factor, but given that water is introduced first and then taken out at the end (drying), it acts more as a process aid/parameter. The general strategy for scale-up of water amount is to increase it proportionally to the batch size at the large scale, in order to keep the ratio of water to intra-granular solids constant at the different scales.[92] This approach makes sense because the water amount required should be governed by the formulation components (powder properties), which do not change during scale-up. If other parameters have been scaled appropriately, there should be no need to make further adjustments in the water amount at the larger scale. However, amount of water is sometimes adjusted to compensate for other changes during granulation.[87,90] The amount of water may need to be adjusted at the large scale in some cases in order to achieve similar growth and consolidation across scales because it is usually not possible to exactly match particle velocity and force distributions at the different scales. Altering water amount at the large scale becomes an iterative approach and demands such experiments be conducted at the large scale, which can be costly. The general understanding is that a higher amount of water may be needed at larger scales to match granule properties across scales.[87]

28.6.2.1.2 Impeller Speed

Impeller speed is directly related to the shear that is applied to the granules, and also governs the flow pattern of the powder in the granulator. There are numerous publications that discuss impeller speed–related scale-up rules.[2,92–96] The most commonly used methods of scaling impeller speed use a power law correlation, as shown in Eq. (28.11).

$$\frac{rpm_2}{rpm_1} = \left(\frac{D_1}{D_2}\right)^n \tag{28.11}$$

where rpm_2 and rpm_1 are the impeller speeds in revolutions per minute, D_1 and D_2 are the impeller diameters in the two granulators, and n is the power law number. The three most commonly used values of n are 0.5, 0.8, and 1. A value of $n = 0.5$ corresponds to the case when Froude number across the scales is kept constant. In a high-shear granulator, the Froude number is essentially the ratio of angular acceleration to the gravitational acceleration. A constant Froude number maintains similar forces at the different scales, which would aid in maintaining dynamic similarity across scales. A value of $n = 1$ corresponds with keeping the tip speed constant across scales and is the more commonly used value of n, which aims to keep similar particle velocity (kinematic similarity) across scales. A constant tip speed aims to maintain constant shear rate and particle velocity at the tip of the impeller across scales.[18]

An experimental study conducted by Tardos et al.[95] suggested that neither approach matches average shear force experienced by the granules. The study used tracer pellets to measure the stress experienced by the granules across scales and suggested that a value of $n = 0.8$ results in similar shear stress across different scales. Thus, empirical matching of the stress in the granulator based on this study results in large-scale impeller speed between constant tip speed and constant Froude number approaches. This empirically derived value of n (constant empirical shear stress) was used successfully to scale-up the wet granulation process.[44,94,95] Another scale-up parameter found in the literature that is related to impeller speed is known as "relative swept volume."[34,94,97–101] It is defined as the volume swept by the impeller per second divided by the volume of the granulator. This is associated with the work input on the material that provides densification of the consolidated mass.[91]

There is disparity in literature on which impeller speed scale-up rule works best for high-shear wet granulation. One of the limitations when using Froude number, which is more fundamental in nature, is the constraints with the equipment itself. Depending on the scale difference, this rule may predict impeller

speed values that are not achievable with certain granulators. Therefore, a practical limitation with this rule often limits the use of Froude number. The most commonly used rule is where tip speed is kept constant across scales. However, there is existing literature that suggests that a constant tip speed will not ensure similar mixing patterns inside the bowl, which means that the granulation process will be different.[22,95,102] In a recent study by Tao et al., the commonly used impeller speed scale-up rules were evaluated using a microcrystalline cellulose—lactose-based low drug loading formulation with a comprehensive characterization of granule properties.[87] It was shown that the constant tip speed rule produced slightly less granulated materials at the larger scales and that a longer wet massing time at the larger scale can be used to produce granules of comparable properties across scales. Constant Froude number and constant empirical stress rules yielded granules that were more comparable across different scales, but it was pointed out that there may be practical equipment constraints limiting the use of constant Froude number approach, especially if there is a big scale-up factor between the small and large scales.

28.6.2.1.3 Wet Massing Time

There is no universal rule of how wet massing time should be scaled-up. Typical wet massing time at the lab and pilot-scale range from 15 s to 1 min, and 2−4 min at the commercial scales. A constant wet massing time across scales is sometimes used. Alternatively, wet massing time can be adjusted based on a ratio of impeller speeds from one scale to the other in order to keep the same total number of impeller rotations across scales.[92] A similar number of impeller revolutions across scales are intended to maintain constant residence time of the particles in the higher shear regions. If the impeller speed is scaled up by constant tip speed, then the constant number of impeller rotations rule would result in wet massing time that is proportional to the granulator bowl diameters. Limitations may exist for a constant number of impeller rotations rule when scaling between granulators that vary greatly in size. This approach implicitly assumes that granule growth and consolidation is predominantly limited to the regions of peak force in the granulator and thus, the same number of rotations across scales aims to maintain similar number of "passes" in these peak force regions. An opposite extreme would be to keep wet massing time constant at the different scales, assuming a narrow distribution of forces within the granulator.[18] In some cases, wet massing time is used as a means to reach a desired endpoint during scale-up, as described next under the attribute-based approach. This means that the wet massing phase is continued until a desired set of granule properties is reached. This method may ensure that some of the granule properties are matched between scales, but this may not be a desirable approach given that an extended wet massing time is generally detrimental to most of the important granule properties, such as granule porosity.[87]

28.6.2.1.4 Spray-related Parameters

There are factors to be considered during scale-up in terms of water addition, namely liquid addition time or liquid addition rate and nozzle properties (which dictates droplet size, spray area, droplet velocity, etc.). Some of these spray-related factors can be combined into a single parameter: the dimensionless spray flux described in Section 28.2.1. Given that dimensionless spray flux is not a scale-dependent property, it has been a subject of several scale-up studies as a parameter to be kept constant during scale-up.[102,103] It can serve as a good mechanistic basis for scale-up of spray-zone conditions in order to achieve equivalent liquid distribution and nucleation across scales. It has also been shown that at low dimensionless spray flux, a narrow nuclei size distribution is obtained.[22] However, in practice, pharmaceutical high-shear wet granulation usually operates in the mechanical dispersion regime in the production scale equipment. While it may be possible to operate in the droplet-controlled regime at the small scale using an appropriately selected nozzle and spray rate, scale-up of such a process is usually not feasible from a practical perspective. If the liquid addition time is kept constant across scales, then the liquid spray rate has to increase significantly when scaling up. This means that the dimensionless spray flux would increase significantly, which would shift the nucleation regime. On the other hand, if spray rate is kept constant, then it would lead to a significant increase in liquid addition time, which can affect the granule agglomeration and consolidation process, in addition to increasing the overall process time. A way to handle this would be to increase the number of spray nozzles used,[104] which may not always be a practical solution, and would require re-engineering of the granulator bowl. In addition, batch size generally increases by volume during scale-up and it would be difficult to proportionally increase the number of spray nozzles. Another challenge with the spray flux approach is the need to have full characterization of the spray properties (eg, spray area, droplet size).[105]

A practical approach to scale-up of liquid addition in the mechanical dispersion regime has been to keep liquid addition time constant, thus increasing spray rate in proportion to batch size. This usually works well if there is sufficient mixing and mechanical

forces to dispense the liquid at the large scale.[18] If this is not the case, then local overwetting stemming from poor liquid distribution can be observed at the larger scale where liquid/solid mixing is less efficient, which results in large, oversized granules and wide size distribution. Therefore, as a general practice, water is often added using a nozzle (with or without atomization) that helps to spread the water over a broader area to reduce local overwetting. This is especially important if the formulation contains highly water-soluble components.

28.6.2.2 *Attribute-based process scale-up: granulation endpoint*

An attribute-based scale-up strategy focuses on granule attributes or properties rather than the process parameters themselves. In this approach, the equipment process parameters are adjusted such that equivalent granule attributes are obtained across scales.[18] An in-process in-line or at-line measurement using a process analytical technology (PAT) tool is typically used to monitor progress of the granulation and to guide process parameters, mainly granulating liquid amount and/or wet massing time. In other words, an in-process granulation attribute is used to provide feedback control on process parameters and eventually dictate granulation endpoint.

There are various challenges when using the attribute-based endpoint approach for scale-up. Given that there are several in-process properties that can be potentially monitored, the key to using this scale-up strategy successfully is to first identify the appropriate endpoint measurement that ensures desired product quality for that particular formulation/system. This can be formulation-specific and is governed by the desired quality attributes for a particular drug product. In some cases, using one attribute for endpoint determination is not sufficient to ensure that the final product meets all the desired quality characteristics; a situation which may undermine the feasibility of an attribute-based scale-up strategy.

Endpoint measurements have been studied extensively, but the findings vary greatly on the best way to determine granulation endpoint. Some endpoint methods published in the literature include near-infrared, particle size by focused-beam reflectance microscopy (FBRM), power or torque, acoustics, wet-mass rheology, imaging, etc.[31,32,106–119] One of the most commonly used granule properties when using this type of scale-up strategy is particle size distribution. In-process measurement of granule size distribution using FBRM has been recently utilized.[120] FBRM probe measures chord length of particles that pass through a spinning laser beam and therefore tracks real-time changes in particle size and distribution in the granulation process. FBRM technology (Lasentec, C35 probe, Mettler-Toledo) gained attention over the past few years with the development of a modified probe with a mechanical scraper on the sapphire window that prevents probe fouling. Such real-time monitoring of the process provides a great opportunity for scale-up purposes and for matching granulation kinetics across scales to ensure successful scale-up, and also to enhance process and equipment understanding.

There are other existing PAT techniques to monitor the granulation kinetics that have gained more attention recently, such as capacitive sensor, strain-gauge torque sensor, near-infrared (NIR), Raman, acoustic monitoring, etc.[13,111,119,121–127] Rantanen et al. and Luukkonen et al. both demonstrated the utility of an in-line NIR spectroscopy to high-shear wet granulation process.[124,126] Rantanen et al. concluded that this technique can be valuable for scale-up, but should be used in combination with other measurements, such as power consumption and torque, to provide full characterization of the process because NIR does not measure directly the properties of the wet mass. Acoustic monitoring is another monitoring technique that is shown to provide a signature of the granulation process. It is noninvasive in nature and can be correlated with dynamic changes in granule particle size, flow, and compaction properties.[111,123] These PAT techniques provide valuable real-time information about the progression of the granulation process and can be used for process endpoint determination and control.

Another approach for endpoint determination of the wet granulation process is related to the rheological or "consistency" changes of the wet mass during granulation. There are several ways in which this is accomplished in the literature. In some cases, this was done "at-line" by taking a sample of the wet mass from the granulator and using a mixer torque rheometer to determine sample "viscosity."[128–131] In-line measurements related to wet mass consistency are also common by using an instrumented impeller to measure impeller torque, impeller power, or other derived parameters based on impeller power (eg, work done) in order to define the granulation endpoint and guide scale-up.[96,98,106,108,114,115,132–134] Similar to the other previously mentioned PAT tools, this method captures the kinetics of the granulation process, and the data have often enabled researchers to identify different phases of granulation.

A major limitation of using a power-based approach is that the motor power differs between different equipment and can even change for a given equipment over time.[34,35,112] Therefore, some normalization techniques, such as normalized impeller work, were

proposed by researchers to account for differences in scale and impeller blade design, which can be different between granulators during scale-up.[106,133] Dimensional analysis has also been applied to the scale-up of the wet granulation process. One dimensionless number derived from such analysis is the Newton power number shown in Eq. (28.12):

$$N_p = \frac{\Delta P}{\rho \omega^3 R^5} \tag{28.12}$$

where ΔP is the power consumption (corrected by the baseline power during dry mixing stage), ρ is the wet mass density, R is the impeller radius, and ω is the rotational speed. The Newton power number can be expressed as a function of other dimensionless numbers such as Froude number, pseudo-Reynolds number, and fill or geometric ratio[62,96] as shown in Eq. (28.13).

$$\log_{10}(N_p) = a.\log_{10}(\varphi Re.Fr.fillratio) + b \tag{28.13}$$

where a and b are scale-independent regression constants, φRe is the pseudo-Reynolds number (defined by Eq. (28.14)), Fr is the Froude number, and fill ratio is the granulator volume to wet mass volume ratio.

$$\varphi Re = \frac{\rho R^2 \omega}{\mu} \tag{28.14}$$

where μ is the wet mass viscosity.

The validity of Eq. (28.13) has been shown across several scales and granulators.[108,135,136] In order to use this scale-up approach, experimental data need to be generated at different scales using geometrically similar granulators and different granulation times (or endpoints), which result in granulations with different wet mass density and viscosity. Once the relationship in Eq. (28.13) is verified and values of a and b are established for a particular formulation, this dimensionless relationship can be used to predict the power endpoint at a larger scale for the desired wet mass viscosity.[18] In absence of wet mass density and viscosity data, impeller torque measurements can be used to estimate the pseudo-Reynolds number. The Froude number during scale-up can either be kept constant or estimated if the impeller speed for the larger scale is determined by another impeller speed–related scale-up rule (eg, constant tip speed) as described previously.

In practice, often a combination of the two scale-up strategies (attribute-based and parametric-based) is utilized, with certain process parameters being scaled-up using the discussed scale-up principles (eg, impeller speed based rules), but also controlling some of the process parameters (eg, wet massing time) such that the desired endpoint or equivalent granule properties (eg, particle size and porosity) are achieved.

28.7 MODELING AND SIMULATION IN HIGH-SHEAR WET GRANULATION

There has been increased interest in modeling and simulation of wet granulation in recent years. Wet granulation models can potentially be utilized to increase understanding of the effect of process parameters on resulting product attributes and can aid in process scale-up. A fully predictive model can also be used for process control. At this time, high fidelity predictive models of pharmaceutical wet granulation are not yet available and, therefore, existing models are predominantly applied to enhance mechanistic understanding during process design and scale-up, rather than process control. The various modeling approaches utilized for high-shear wet granulation process include regime-map based models, population balance modeling (PBM), discrete element modeling (DEM), PBM coupled with DEM, PBM coupled with computational fluid dynamics, PBM with compartmental model and DEM, and PBM coupled with volume of fluid models.[65,137–145] Kayrak-Talay et al. provided a recent review of regime-map based models for *a priori* design and scaling.[146] This section discusses the more commonly used PBM and DEM-based approaches, and the more recently used hybrid approach between PBM and DEM.

28.7.1 Population balance modeling

PBMs are number balance models around each granule size (volume) fraction where the change in the number of granules in a given size is equal to the number of granules formed minus the number of granules leaving the size fraction. Particles in any size fraction are assumed to interact with each other and with the environment, which results in the change in the number frequency of particles in the size fraction over time. For a wet granulation system with only aggregation (coalescence) rate process, the PBM to describe the system can be written as[147]:

$$\frac{\delta n(u,t)}{\delta t} = B_{coal}(u,t) - D_{coal}(u,t) \tag{28.15}$$

where $n(u,t)$ is the number frequency of granules of size u at time t. $B_{coal}(u,t)$ and $D_{coal}(u,t)$ represent the rate of formation and disappearance of granules of size u due to the binary coalescence of granules of size v with u-v and u with v, respectively. These are given by

$$B_{coal}(u,t) = \frac{1}{2N(t)} \int_{v=0}^{u} \beta^*(v, u-v) n(v,t) n(u-v,t) dv \tag{28.16}$$

$$D_{coal}(u,t) = \frac{1}{N(t)} \int_{v=0}^{\infty} \beta^*(u,v) n(u,t) n(v,t) dv \qquad (28.17)$$

where $\beta^*(u,v)$ is referred to as the coalescence kernel, which is the normalized frequency of collisions between granules of sizes u and v that result in coalescence, and $N(t)$ is the total number of granules per unit volume in the granulator. Similarly, $\beta^*(v, u\text{-}v)$ is the coalescence kernel of granules v and u-v. Early work by Annapragada and Neilly[148] demonstrated that PBM based on aggregation term alone does not adequately describe experimental data for wet granulation and proposed the addition of breakage term to the PBM equation, such as the one proposed by Ramachandran et al.[145] In addition to breakage, other terms can be also added to Eq. (28.15) to describe all relevant rate processes in the granulator that result in creation or death of granules, as shown in Eq. (28.18).

$$\frac{\delta n(u,t)}{\delta t} = B_{nuc}(u,t) + B_{coal}(u,t) - D_{coal}(u,t) + B_{break}(u,t) - D_{break}(u,t) \qquad (28.18)$$

where B_{nuc} is the rate of nucleation and $B_{break}(u, t)$ and $D_{break}(u, t)$ represent the rate of formation and disappearance of granules of size u due to breakage.

The coalescence kernel $\beta^*(u,v)$ is at the core of the PBM model. The value of the PBM depends on the success of the kernel to accurately define coalescence in the system. There are numerous literature reports describing different expressions for $\beta^*(u,v)$.[142,144,149–151] Earlier reports used empirical kernels where the kernel form was assumed and its value was estimated by fitting data from granulation studies to the model.[152–154] The validity of the kernel was concluded if the model provided good fit to the experimental data. Such an empirical approach has significant limitations due the kernel's lack of physical relevance and because predictions can be made only for the same scale and within a certain process space spanned by the experimental design. Recently, development of physical-model-based kernels is becoming more common where microscale (particle level) models of granulation are used to define the kernels, thus increasing the scope and applicability of PBM models. Kernels based on models that account for these factors are expected to be more successful in describing the granulation process because granule and liquid properties as well as granule collision velocity dictate probability of coalescence. Earlier attempts to establish physical-based kernels were limited to invoking physical models to only select kernel form, but were not predictive in nature as rate constants were still obtained by data fitting. For example, Liu and Litster[151] proposed a coalescence kernel the value of which depends on the type of coalescence (type I or II). Adetayo and Ennis[149] defined a critical granule size based on Stokes viscous number. All granule collisions where the effective mean granule size of the colliding granules is less than the critical size were considered successful and modeled by a size-independent kernel. On the other hand, collisions with mean granule size greater than the critical size were considered unsuccessful with zero rate of growth. Ideally, models with physical-based kernels should be predictive with no fitted parameters where the kernel is completely defined *a priori* based on physical models of coalescence. Physical parameters in the model are preferably determined by independent calibration experiments, rather than fitting of granulation study data to the PBM. More recent PBM models have moved in this direction,[65,138,141,144,155] but kernels still include some fitting parameters that make the PBM not entirely mechanistic in nature. Accounting for the particle collision velocities in the coalescence kernel still remains as one of the key challenges due to the wide and scale-dependent distribution of particle velocities in the granulator. One approach to address this challenge would be to model the granulator as several segregated regions with different collision velocities in each region and size-dependent rates of transfer of granules between each zone.[147] Once model development is completed, model performance should be verified using new studies independent of the data set used to establish the model.

The coalescence kernel is often split into two components[150,156]:

$$\beta^*(u,v) = C_{u,v}\beta(u,v) \qquad (28.19)$$

where the first term $C_{u,v}$ is related to collision frequency of particles u and v and while the second term, $\beta^*(u,v)$, is a function of collision efficiency (ie, the probability that a collision of the two particles results in successful coalescence). $C_{u,v}$ accounts for process parameters, such as impeller speed and some granule properties such as granule size. $\beta^*(u,v)$ has traditionally been dependent on granule size alone in the one-dimensional PBM models where the probability of successful coalescence is assumed to depend only on particle size of colliding granules. However, physical models of coalescence clearly show that probability of coalescence is dependent on other granule properties, such as liquid content and porosity. Therefore, a fully predictive PBM model needs to include multidimensional granule distributions of size, porosity, and liquid content as independent

variables that evolve with time.[147] A three-dimensional PBM is expressed as:

$$\frac{\delta n(m,\varepsilon,l,t)}{\delta t} = B_{\text{coal}}(m,\varepsilon,l,t) - D_{\text{coal}}(m,\varepsilon,l,t) + C(m,\varepsilon,l,t) + L(m,\varepsilon,l,t) \tag{28.20}$$

where m is the mass of granule solid phase, l is granule liquid to solid ratio, and ε is granule porosity. In addition to the coalescence terms, the equation also includes terms for evolution of porosity, C, and liquid content, L, due to consolidation and liquid addition, respectively. The coalescence terms are expressed as

$$B_{\text{coal}}(m,\varepsilon,l,t) = \frac{1}{2N(t)}\int_{m_1=0}^{m}\int_{\varepsilon_1=0}^{1}\int_{l_1=0}^{\infty}\beta^*(m_1,m_2,\varepsilon_1,\varepsilon_2,l_1,l_2)\, n(m_1,\varepsilon_1,l_1,t)n(m_2,\varepsilon_2,l_2,t)dm_1d\varepsilon_1dl_1 \tag{28.21}$$

$$D_{\text{coal}}(m,\varepsilon,l,t) = \frac{n(m,\varepsilon,l,t)}{N(t)}\int_{m_1=0}^{\infty}\int_{\varepsilon_1=0}^{1}\int_{l_1=0}^{\infty}\beta^*(m_1,m,\varepsilon_1,\varepsilon,l_1,l)\, n(m_1,\varepsilon_1,l_1,t)dm_1d\varepsilon_1dl_1 \tag{28.22}$$

where granule with property m,ε,l is created by coalescence of granules m_1,ε_1,l_1 and m_2,ε_2,l_2 and disappears by coalescence with granule m_1,ε_1,l_1. The resulting is a complex, three-dimensional integro-differential equation which is computationally expensive to solve. While conventional numerical methods have been used to solve the multidimensional PBM equations, more efficient computational methods such as Monte Carlo techniques have been recently utilized to reduce computation times.[142,157,158]

One of the utilities of PBM is the ability to conduct a sensitivity analysis of some of the main formulation and process parameters (eg, viscosity, impeller speed, contact angle, and spray rate) using minimal experiments.[159] Such a sensitivity analysis can be useful in establishing a process and formulation design space of a drug product. PBM predictions can also be used to reduce experimentation once a good model is established using some initial experimentation that is required for determining the kernel parameters for the system being modeled.[65,140]

28.7.2 Discrete element modeling

DEM is a numerical simulation technique which tracks the position of every particle within the defined geometry of the granulator and estimates the velocity and force exerted on every particle.[18] In contrast to PBM models, which are meso- and macro-scale models, DEM models bridge the gap between the micro- and meso-scale and have some advantages over PBM simulations. DEM provides detailed information about the particle dynamics, such as time evolution of individual particle velocities and shear experienced by the particles.[140,143,160–162] Two distinct DEM methods have been used, which are the hard sphere and soft sphere methods. While the hard sphere method is computationally less demanding, it is generally less applicable to the pharmaceutical granule due to the porosity and liquid content associated with granule microstructure. The soft sphere method is more capable of simulating particles in pharmaceutical wet granulation, but is computationally more expensive and capable of handling fewer particles than the hard sphere method.[142] As a result, DEM simulation of a pharmaceutical wet granulation system is computationally demanding and not currently capable of simulating the large number of particles present in the high-shear granulator. DEM simulation is usually carried out using larger particle size (in the few mm range[143]) than what is typically used in the pharmaceutical granulation because DEM can only handle few hundred thousand to a million particles. Calibration of microscale particle properties also presents another challenge to DEM. As result of these complexities, some literature reports used DEM to study a limited aspect of wet granulation, rather than applying it for complete prediction of the wet granulation process. DEM proved to be a useful tool in studying flow patterns and force distributions in the granulator across scales.[143,150,163,164] Such applications do not provide a predictive model of wet granulation, but are still valuable in process design and scale-up. In one such example, DEM was used to understand differences in flow patterns and particle velocity distribution between different granulators and scales, which are useful from a scale-up perspective.[143]

28.7.3 Combined PBM/DEM approach

A combined approach using both PBM and DEM has been proposed to model high-shear wet granulation process because PBM and DEM are different scale models. Multiscale DEM/PBM molding is emerging as a potentially powerful approach for high-shear wet granulation.[150,165–167] Microscale DEM is used to model particle flow in the granulator and characterize particle collisions. In addition, DEM is also used to establish collision efficiency at the microscale.[143] The two feed into the PBM coalescence kernel for meso-scale simulation of wet granulation. Gantt et al. provided an

example of the combined approach [140,150] in which they integrated DEM and the physical model of coalescence in parallel for simultaneous microscale particle analysis. Relative velocities of colliding particles were calculated by DEM simulation. These velocities, together with granule porosity and liquid content, were used to determine whether coalescence will take place based on the physical coalescence model. The data obtained from the DEM/coalescence model were used to estimate the coalescence efficiency term of the PBM kernel. Simple regression was used to map particle collision and coalescence information from the DEM/coalescence model to a four-dimensional coalescence efficiency term, which is dependent on particle diameter, pore saturation, porosity, and collision velocity. DEM was also used to establish frequency and size dependence of granule collisions in the granulator and estimate the collision frequency component, $C_{u,v}$, of the PBM kernel.

28.8 SUMMARY

High-shear wet granulation is a complex unit operation that involves multiple simultaneous rate processes. In addition, the outcome of wet granulation is strongly impacted by input material and granulating liquid properties. In order to design a robust drug product, it is important to have a good understanding of the CMAs and CPPs and how they are related to the drug product's CQAs. Various material properties, such as particle size, surface area, contact angle, and solubility have profound effects on the wet granulation process together with granulating liquid surface tension and viscosity. In addition, there are usually significant interactions between formulation components and process variables dictating the granulation outcome and thus, successful design of a robust wet granulation process should account for these interactions. Key process parameters known to affect wet granulation were discussed in this chapter and their role in the design of a robust process was articulated.

Scale-up of the wet granulation process presents another challenge. A section in this chapter discussed the challenges associated with scale-up of the high-shear wet granulation process, the various scale-up principles that are commonly used, and their broad classification into attribute-based and process parameter-based approaches. In addition, modeling tools that can be used to enhance understanding of the process, and potentially allow for in silico design space development in the future were also discussed.

Process Development, Optimization, and Scale-Up: Fluid-Bed Granulation

K. Yamamoto[1] *and Z.J. Shao*[2]

[1]Pfizer Global Research and Development, Groton, CT, United States
[2]Arena Pharmaceuticals Inc., San Diego, CA, United States

29.1 OVERVIEW OF THE FLUID-BED GRANULATION PROCESS

One commonly used strategy to improve undesirable powder characteristics of the active pharmaceutical ingredient (API) is to granulate the API with other excipients. There are two widely used methods to make granules: dry granulation, which involves mechanical compaction (slugging or roller compaction) followed by a dry-sizing process; and wet granulation using a liquid binder (low shear wet granulation, high shear wet granulation, or fluid-bed granulation). While separate drying equipment is required following a low-shear or high-shear wet granulation process, fluid-bed wet granulation is a one-pot process that can blend, wet-granulate, and dry, all in one piece of equipment.[1]

A typical fluid-bed wet granulation sequence consists of dry blending, wet granulation, and drying steps. Raw materials are first fluidized by hot inlet air for blending. Granulation fluid is then sprayed onto the preblended material until the desired moisture content or granule size is achieved. At this point, drying begins until a predetermined product temperature is reached. Binder solution is commonly used as a granulation fluid. However, it can also be added as a dry ingredient to the powder bed. Granules produced using the fluid-bed process have the advantages of being homogeneous, free-flowing, and less dense. Generally, these granules require lower pressure to compress into tablets than granules made by other granulation methods.

The amount of solvent removed during fluid-bed wet granulation and drying steps can be calculated using heat and mass transfer theory. By taking process variables, such as spray rate, dew point, volume of inlet air, and powder characteristics of raw material into consideration, a robust manufacturing process can be developed for a variety of formulation compositions and manufacturing scales.

Being a self-enclosed system, the fluid-bed is a preferred technology for highly potent compounds requiring containment. When coupled with a clean-in-place (CIP) system, fluid-bed becomes the preferred granulation method for such potent compounds.

29.2 EQUIPMENT DESIGN

29.2.1 Batchwise models

Among the three well-established batch fluid-bed methods, top spraying is commonly used for granulating purposes due to its ability to produce highly porous particles with better dispersibility and compressibility for downstream compression. The bottom-spray design (Wurster) is very popular for layering of active component and coating to modify drug release due to its good film formation in such units. Drug-layering on sugar beads using Wurster inserts is widely reported in the research literature. Tangential spray (rotary) methods are mostly used in pelletization and coating of the formed pellets. The operating mechanisms are shown in Fig. 29.1. The design and operational details for the three methods are described in the next sections.

Developing Solid Oral Dosage Forms

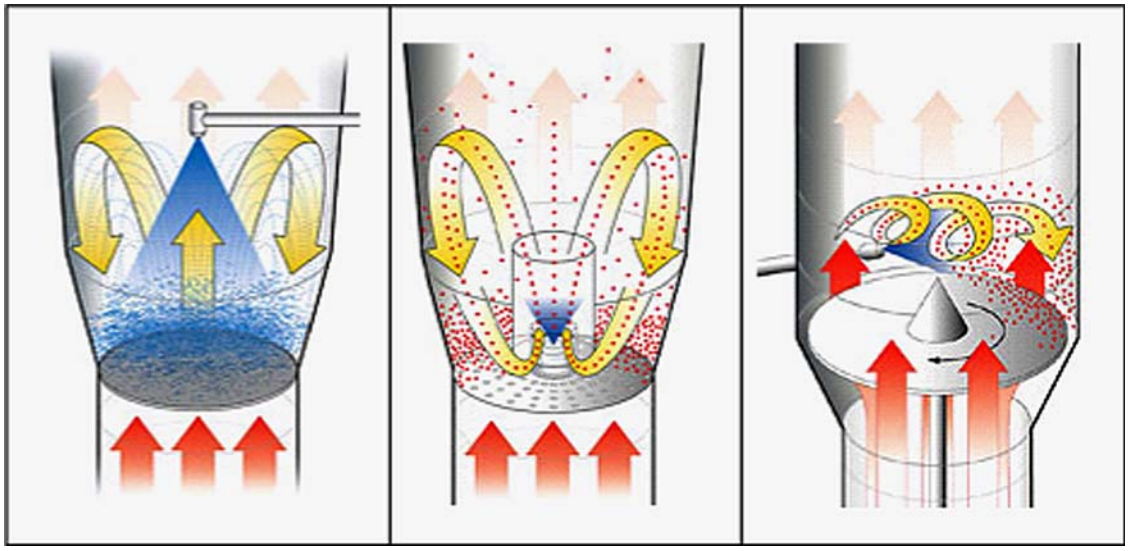

FIGURE 29.1 Top spray, bottom spray, and tangential spray mechanisms (from left to right) used in batch fluid-beds. *Source: Courtesy Glatt Air Techniques, Inc.*

29.2.1.1 Top spray

The main components for a top-spray processor are:

- An air-handling unit optionally equipped with humidification and dehumidification for dew-point control
- A product container
- An expansion chamber
- A spray system containing single or multiple nozzles
- An exhaust system with a filter and, optionally, an explosion suppression system

Glatt expansion chambers come in models known as tall conical GPCG design or the shorter and wider WSG design. GPCG machines are suitable for top-spray and bottom-spray granulation, while the WSG design is suited for drying of wet granules, and occasionally for top-spray granulation processes.

Top spray has a simple setup, offers a high capacity, and is typically used for either granulating powders or spray-drying. When a binder solution is sprayed through the nozzles, the droplets produced bind to fluidizing powder particles, forming agglomerates. There are cases when water is sprayed into the powder bed, which contains a dry binder, to form granules. Granulation with water, also referred to as *instantizing*, is mostly used in the food and diagnostic industries. Granules formed by instantizing are generally more loosely formed and friable. Controlling inlet air dew point and bed temperature is important for batch-to-batch consistency.

A top-spray fluid-bed can also be used as an alternative to the traditional spray-drying process using hot air. Since the air volume in a fluid-bed can be increased easily, it does not demand a high temperature to dry-sprayed droplets. This is especially attractive to protein formulations, which can be denatured if the processing temperature is too high. Particles formed through a top-spray fluid-bed method are larger in size due to the effect of layering. Flowability of these particles is generally better, as a result of larger particle formation with narrow size distribution.

Since the particles formed are very porous, the top-spray method is not suitable for coating of beads and fine particles for controlled-release products. One exception is hot-melt coating, where molten materials are sprayed onto fluidized particles. Jones and Percel[2] used all three methods to produce sustained-release chlorpheniramine maleate pellets by spraying molten, partially hydrogenated cottonseed oil, and found that the top-spray method resulted in a smooth surface and a decreased dissolution rate.

29.2.1.2 Bottom spray

Bottom spraying, originally developed by Dale Wurster in the late 1950s, is most commonly used in the coating of particulates and tablets. There are several unique features with a Wurster-type column design. First, the nozzle is mounted at the bottom of the product container and above the air distribution plate. Second, the air distribution plate has larger holes in the middle than on the outer rim. This allows more air flow through the middle portion of the plate. Finally, an insert (partition) is placed above the plate. This configuration ensures that particles are fluidized upward in the insert, fall outside the insert, pass under

the insert, and are lifted again inside the insert. The region inside the insert is commonly referred to as the *up-bed region*, while that outside the insert is known as the *down-bed region*. Particles are sprayed in the up-bed and dried in the down-bed many times, until the desired film thickness is achieved.

Since coating solution is sprayed from the bottom, coating efficiency is typically much higher than by top spraying. Mehta and Jones[3] demonstrated that bottom spraying produced a much smoother coating than top spraying, especially when organic solvent-based solution was sprayed. Top-spraying solvent-based solution leads to flash evaporation and more spray-drying, resulting in a rough surface.

29.2.1.3 *Tangential spray*

The tangential-spray process involves a variable-speed rotating disk inside the product bowl. The spray nozzle is mounted at the side of the bowl near the bottom and is buried in the batch during processing. The gap between the disk and bowl wall can be adjusted to allow varying amounts of air through. During granulation, the rotating disk imparts a centrifugal force to the material, forcing the particles to move to the outer part of the disk. The air flow then provides a lifting force. These two forces, along with natural gravity, make the material travel in a spiraling helix. This motion results in the compaction of the material to produce uniform and dense granules, thereby enabling the manufacture of high-dose loading products. An added advantage is that further coating of the formed pellets can be done in the same processor, without having to discharge the pellets. Disk speed and air volume need to be reduced, compared to the granulation stage, in order to avoid film breakage potentially caused by abrasion.

29.2.2 Semicontinuous design

The best known case of implemented semicontinuous fluid-bed technology is the Glatt MultiCell,[4,5] which combines high shear granulation and fluid-bed drying (Fig. 29.2). Typically, three fluid-bed dryers are set up side by side, along with a horizontal high shear granulator and a wet sieving mill. After wet granulation, the wet mass is wet-screened and loaded in the first fluid-bed for partial drying (predrying). Partially dried granules are then pneumatically conveyed to the second fluid-bed unit for continued drying (final

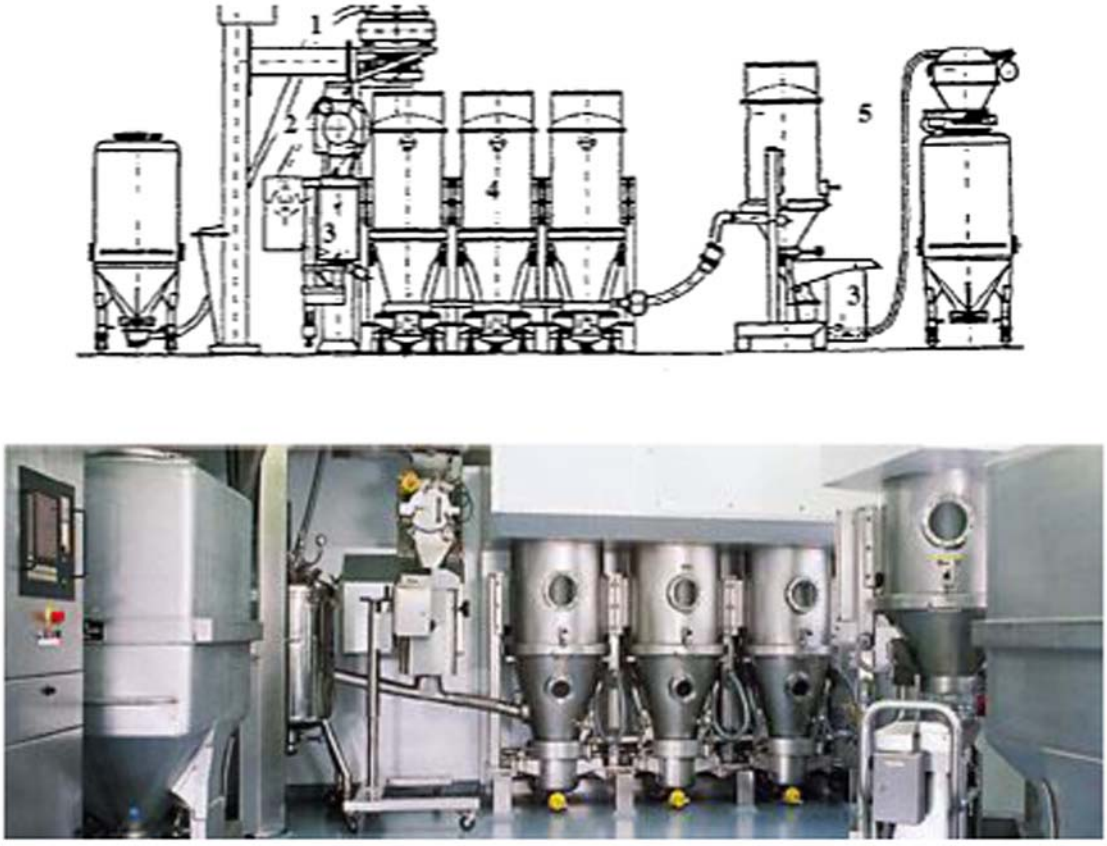

FIGURE 29.2 Semicontinuous fluid-beds, Glatt multicell: 1. Dosing unit; 2. high-shear granulator; 3. sieve; 4. fluid-bed; 5. pneumatic transport system. *Source: Courtesy Glatt Air Techniques, Inc.*

drying), then to the third unit for final drying and equilibration (cooling). The dried granules are then conveyed to a dry mill for milling.

The three fluid-bed units are designed for different air temperature and humidity conditions, with the first one typically set at high temperature (60°C), and the last cell at ambient temperature and humidity.

GEA Niro Pharma Systems (Columbia, MD) demonstrated a new version of a semicontinuous fluid-bed coater a few years ago, the SUPERCELL.[6,7] This device is capable of automatically preweighing small batches of tablets (typically 30–120 g) into the coating chamber, coating them rapidly (typically <10 minutes), and finally pneumatically conveying them out of the chamber. The ability of SUPERCELL to coat tablets and capsules rapidly and uniformly is claimed to be due to uniquely patented designs (ie, a special gas distribution plate), and a two-fluid spray nozzle located below it.

The atomizing gas is mixed with low-pressure drying gas, thereby reducing the momentum of the atomizing air. Attenuation of the spraying momentum, along with a very short processing time, is expected to reduce tablet wear and tear, thereby improving tablet appearance. Conceivably, friable or hygroscopic tablets can also be processed in such a unit due to its rather short coating time. A vendor-sponsored study of coating an enteric film on aspirin tablets confirmed good acid resistance for tablets coated with >9% weight gain. No tablet edge defects after coating were found. A prototype model is shown in Fig. 29.3. Acceptance and use of this device by the pharmaceutical industry has yet to be seen.

29.2.3 Continuous models

Glatt developed various continuous fluid-bed models with the GF and AGT units shown in Fig. 29.4. In the GF model, the inlet air plenum is divided into multiple chambers, each with adjustable temperature and air flow control. By this means, spray agglomeration, drying, and cooling can all be done in this single unit. By controlling air flow in the various chambers, the overall powder flows in a plug fashion toward the discharge port.

In the 1980s, Glatt commercialized the AGT technology, which has a discharge pipe right in the middle of the bottom screen. The air velocity in this pipe determines what size particles can be discharged. Heavy particles with sinking velocity greater than the air velocity inside the pipe will be discharged, while smaller particles are blown back to the fluid-bed and are exposed to layering again.

Continuous processors are typically used in the chemical, food, and agricultural industries.

29.3 FLUID-BED HYDRODYNAMICS

29.3.1 Product temperature and moisture content profiles through fluid-bed processing

A fluid-bed, wet-granulation process consists of dry blending, wet granulation, and drying. A typical example of product temperature and moisture content profiles through fluid-bed processing is that product temperature initially increases during the blending step. It then decreases after spraying starts and eventually bottoms out. Assuming that there is no heat loss from the equipment surface, and that the materials are well mixed by fluidization air, product temperature could reach:

- Wet bulb temperature of the inlet air when the spray rate is greater than the drying capacity of the inlet air. In this case, product temperature is kept constant at the wet bulb temperature, even after drying begins. This continues until water levels in the wet mass become less than the drying capacity, at which time the product temperature rises.
- Between the inlet air temperature and the wet bulb temperature of the inlet air, if the spray rate is lower than the drying capacity of the inlet air. In this case, the product temperature starts increasing immediately after spraying is stopped.

Once product temperature starts rising, a good correlation between the moisture content of granules and product temperature can be established. Product temperature becomes a good indicator for predicting the drying end point.

Following moisture level changes through fluid-bed processing yields more information than monitoring product temperature. The moisture level of starting materials first decreases during the blending step, and then it increases when spraying starts and keeps increasing until spraying stops. The accumulation of moisture depends on processing parameters (inlet air and spraying conditions). A good correlation between moisture content and size of wet granules can also be established. When the spraying step is completed, accumulated moisture within the wet mass starts to be removed. It has also been demonstrated that a good correlation between moisture content and size of dry granules exists.

29.3.2 Moisture mass balance during the fluid-bed process

Moisture profiling throughout the fluid-bed process not only can be used as a fingerprint for the formulation and process, but is also useful for process development and troubleshooting purposes. When wet granules contact the hot inlet air, the hot inlet air exchanges its heat for moisture. The temperature of the air drops due to evaporative cooling and exits the process chamber as exhaust air. Water in wet granules is vaporized instantly by heat at this temperature. Since the granules are suspended into fluidization (inlet) air, and contact surface area between air and wet granules is considered to be huge, heat and mass transfer reach equilibrium instantaneously.

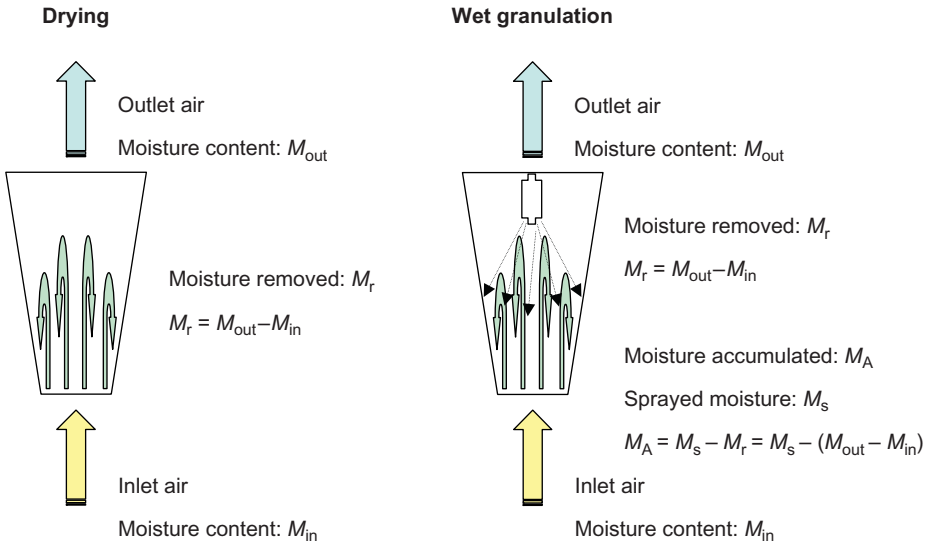

FIGURE 29.5 Moisture mass balance during fluid-bed process.

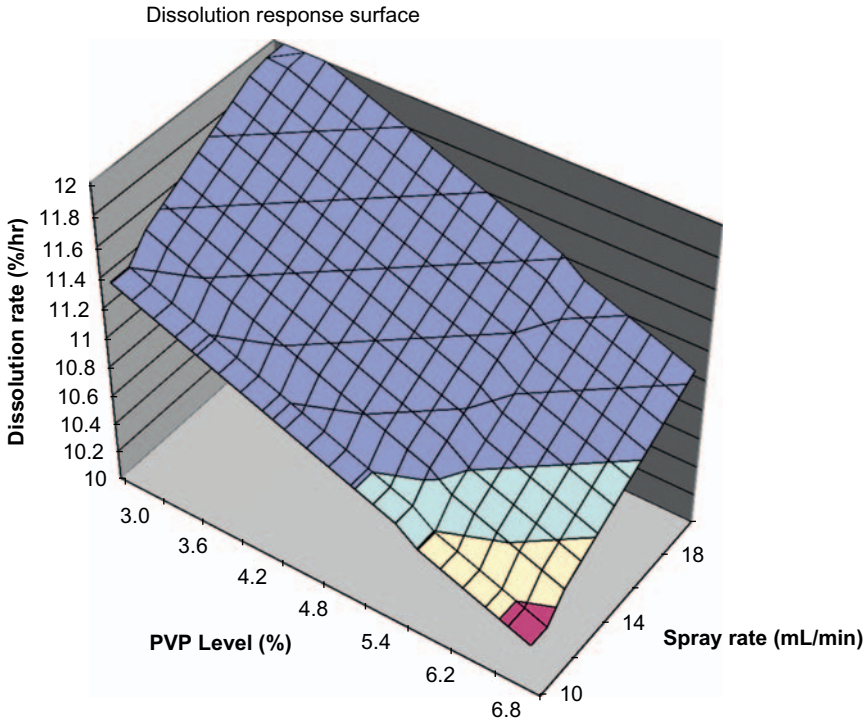

FIGURE 29.6 Dissolution response surface from a DOE.

29.3.2.1 *Drying process*

Fig. 29.5 shows moisture balance during fluid-bed operation. In the drying process, moisture in wet granules is removed by dry inlet air. During wet granulation, there is another source of moisture, which is sprayed binder solution.

As shown in Fig. 29.6, moisture removed (M_r) during the drying process can be calculated from the moisture content of inlet (M_{in}) and outlet air (M_{out}) as follows:

$$M_r = M_{out} - M_{in}$$

where M_{in} and M_{out} can be determined by monitoring the temperature and relative humidity of inlet and outlet air. Using moisture content (M_{end}) and weight (W_{ini}) of wet granules at the wet-granulation end

point, the moisture content of wet granules during the drying process can be calculated:

$$M_g = \frac{(M_{end} - M_r)}{W_{ini} - M_r} \times 100$$

29.3.2.2 Wet-granulation process

To predict moisture balance during the wet-granulation process, two parameters need to be taken into consideration: moisture removed (M_r), and moisture accumulated in the wet granules (M_A) for the wet-granulation process (Fig. 29.5). Since the binder solution is sprayed onto the powder bed during this process, moisture in the sprayed binder solution (M_s) needs to be built into the equation in order to calculate the moisture level accumulated in wet granules:

$$M_A = M_s - M_r = M_s - (M_{out} - M_{in})$$

The moisture content of wet granules can be calculated using the initial conditions, which include the batch size (W_{ini}), and initial moisture content of the powder bed (M_{ini}):

$$M_g = \frac{M_{ini} + M_A}{W_{ini} + M_A} \times 100$$

29.3.2.3 Prediction of moisture profile during the fluid-bed process

By taking air factors, including air volume per unit time and specific volume, into consideration, the moisture profile during fluid-bed operation can be predicted. Briefly, a given inlet air drying capacity is expressed as

$$DC = H_{in\_wb} - H_{in\_db}$$

where H_{in_wb} and H_{in_db} are the absolute moisture content of the wet bulb and the dry bulb temperature of inlet air, respectively.

The rate of moisture removal (X_r) is expressed as

$$X_r = \left(H_{in\_wb} \times \frac{V_{in}}{VH_{sp\_out}}\right) - \left(H_{in\_db} \times \frac{V_{in}}{VH_{sp\_in}}\right)$$

where V_{in} is inlet air volume per unit time, and VH_{sp_in} and VH_{sp_out} are specific volume of the inlet air and outlet air, respectively.

Then the moisture content for the drying process is expressed as

$$M_g = \frac{(M_{end} - X_r \times t)}{W_{ini} - X_r \times t} \times 100$$

and the moisture content for the wet-granulation process is expressed as

$$M_g = \frac{M_{ini} + (X_s - X_r) \times t}{W_{ini} + (X_s - X_r) \times t} \times 100$$

where X_s and t are spray rate and running time, respectively.

29.4 MECHANISMS OF AGGLOMERATION

29.4.1 Phases in granule growth

The main objective of granulation is to improve the undesirable powder characteristics of raw materials (poor powder flow, fluffiness, segregation, etc.); therefore, the specific needs first must be identified. Granulation properties after the process are likely different, depending on the target of the process.

The moisture content of wet granules can be controlled by process parameters. If there is a target moisture range in mind, it can generally be achieved through process controls (air and spray conditions). At the beginning of the process, the powder bed is assumed to be dry, with no aggregation. Following binder spraying, the powder bed becomes wet, and then aggregation starts and granule size increases with the spraying of more binder solution. The granule growth rate during the wet-granulation process can vary from slow progress in the beginning, to rapid growth exceeding the desired end point. To develop a robust wet-granulation process, the basic concept of granule growth and its influencing factors need to be understood.

29.4.2 Bonding mechanisms

Rumph[8] classified particle–particle bonding mechanisms into five categories:

1. Solid bridges
2. Interfacial forces and capillary pressure in movable liquid surfaces
3. Adhesion and cohesion forces in bonding bridges which are not freely movable
4. Attraction between solid particles, such as van der Waals forces, electrostatic forces, and magnetic type interactions
5. Form-closed bonds, such as particles interlocking or entangling

Category 1 is the moisture-mediated bonding mechanism, with interfacial and capillary forces between particles playing important roles to form particle–particle bonds during the wet granulation process. Particle–particle bonds are classified into four categories, based on the phase of interaction between liquid and particles: pendular, funicular, capillary, and droplet, according to Newitt and Conway-Jones and Barlow.[9,10] Assuming that a binder solution is used as the granulation fluid, which is sprayed into fine droplets, liquid bridges between particles can be viscous and adhesive. Formed solid bridges will remain after drying.

Upon spraying binder solution onto the powder bed, moisture content increases and the surface of powders becomes self-adhesive due to coalescence of the binder solution. During the coalescence, water may be absorbed into particles, resulting in high void saturation with increased deformation capability (plasticity) which helps to bind particles together (see Huang and Kono,[11,12] and Abberger[13]). Once liquid bridges start to be formed between particles (nucleation), the progress of granule growth is determined by a balance of cohesive and adhesive forces between particles (viscosity of the liquid bridge), and impact from collision of particles during the wet-granulation process.[14] Since two or more particles are held together with liquid bridges, granule size could be regulated by number, size, and viscosity of the liquid bridges. If the liquid bridge size is small or less viscous, then the bridge can hold only small particles or breakage may occur. If the liquid bridge size is large, viscous, or both, the liquid bridges could hold heavier and larger particles, as well as granules, together.

29.5 FORMULATION AND PROCESS VARIABLES AND THEIR CONTROL

Like many other unit operations, many variables can affect manufacturability and product quality in the fluid-bed wet-granulation process. In order to develop a robust process, it is necessary to evaluate the effects of these variables at an early stage. These variables can be classified into three groups: equipment-related, formulation-related, and process-related variables. The performance of a fluid-bed wet granulator depends on equipment-related variables, such as equipment size (dimensions) and shape, position of spray nozzle (top, bottom, tangential), number of spray guns, etc. These variables need to be assessed during the scale-up activity from one scale to another. This aspect was covered in Section 29.6, earlier in this chapter.

Due to the basic mechanism of granule growth during the wet-granulation process, particle size and its distribution, density, wettability, solubility, and hygroscopisity of starting materials impact product quality (bioperformance, content uniformity, chemical stability, etc.), and manufacturability of the formulation. It is also well known that cohesiveness and static charge of raw material can cause undesirable homogeneity and low-yield problems after the wet-granulation process. On the other hand, inlet air conditions (relative humidity of dew point, temperature, air volume, or velocity), and spraying conditions (spraying rate, atomizing air pressure, spray gun position), are key variables to make a consistent quality product batch after batch (reproducibility).

29.5.1 Formulation variables

There are a variety of excipients commercially available for fluid-bed formulation development, and each excipient has different material properties. It is important to understand excipient functionality and its behavior during processing. Since multiple excipients are put into a formulation, it then becomes complicated to understand the impact of all these excipients on manufacturability and the final product quality.

Schaefer and Worts investigated the influences of starting material property and its mixing ratio in the fluid-bed granulation process, using crystalline lactose and starch as raw materials. It was shown that the granule size depended on the ratio of lactose and starch, with higher lactose content generating larger granule sizes. It was also indicated that the higher the surface area of starting materials, the smaller the granule size that was obtained after granulation.[15] Wan et al. also demonstrated that, after fluid-bed wet granulation, the granule size of lactose, a water-soluble excipient, is larger than the granule size of cornstarch, a water-insoluble excipient.[16] Since different excipients have different particle sizes and interact differently with water, processing conditions will need to be different in order to obtain similar granule properties.

A binder is an essential component of the granulation process, which provides binding ability in the formulation after drying. The binder can be added either as powder or sprayed as a solution to the powder bed during the wet-granulation process. Wan and Lim reported that larger granule size and higher density is obtained when the binder is added as a powder, rather than by spraying as a solution.[16] Schaefer and Worts demonstrated that the droplet size of the binder solution is influenced by the viscosity of the binder solution. However, it was also shown that viscosity is not the sole factor that affects granule size.[17] The type of binders and the binder concentration could be critical variables when the binder solution is sprayed using a nozzle system. Binders such as hydroxypropylcellulose, polyvinylpyrollidone (PVP), hydroxypropylmethylcellulose (HPMC), and pregelatinized starch are commonly used for fluid-bed wet granulation with a range of 2–5% w/w solution.[18]

29.5.2 Key process variables

As discussed in the previous section, there are three major factors influencing the fluid-bed wet granulation process: namely, air conditions, spray conditions, and equipment-related factors. The equipment-related factors include design of equipment, bag filter, distributor, shape of bowl and extension chamber, shaking mechanisms, and the position and number of spray

nozzles. These factors need to be carefully evaluated when batch size is changed or a formulation is transferred from one site to another.

29.5.2.1 Inlet air conditions

Air conditions, including temperature, dew point (or absolute humidity), and inlet air volume, are the three key factors influencing drying and wet granulation. Since moisture from wet granules is evaporated and removed as exhaust air during the wet granulation and drying process, exhaust air contains a higher amount of moisture than inlet air. As described in Section 29.3.2 earlier in this chapter, the amount of moisture that inlet air can remove (*DC*) is

$$DC = H_{\text{in\_wb}} - H_{\text{in\_db}}$$

Absolute moisture values depend on inlet air, which is the reason why the dew point of inlet air and inlet air temperature are the critical factors for the wet-granulation and drying processes. The same inlet air temperature and inlet air volume could result in a different *DC* value due to a different dew point. If no dew point controller or dew point monitoring system is available, it is recommended to measure inlet air relative humidity and temperature to make the *DC* consistent (manufacturing process reproducible). These absolute moisture values can be obtained from the psychometric cart.

The powder bed is fluidized by inlet air, and it is important to keep sufficient fluidization throughout the process; otherwise, the bed may collapse. It may be necessary to adjust inlet air volume during the wet-granulation and drying processes because of weight change of wet versus dry materials. Inlet air volume needs to be reduced in order to minimize attrition during the drying process. The amount of moisture removed per unit time is expressed as

$$\frac{\text{Amount of moisture removed}}{\text{minute}} = DC \times \text{air volume/minute}$$

When inlet air volume is adjusted, the amount of moisture removed per unit time will change.

29.5.2.2 Spray rate, droplet size, and spray pattern

Since formation of liquid bridges among particles is the main mechanism of granule growth, it is reasonable to expect that spray rate and droplet size significantly affect the wet-granulation process and influence granule size and size distribution. The effects of spray rate and droplet size on fluid-bed wet granulation are not much different from those for the high-shear wet-granulation process. If the spray rate is too fast, rapid granule growth occurs, and the process could be sensitive to subtle changes in raw material and process conditions. Water-soluble components may be dissolved into the binder solution, which accelerates granule growth. If the spray rate is too slow, it takes a long time to reach the desirable end point, and in the worst cases, no granule growth occurs. Large droplet size tends to produce larger and denser granules, while a fine mist may result in spray-drying the binder solution. Spray pattern and atomizing air influence droplet size. Shaefer and Worts[17,18] reported that a broad spray pattern creates insufficient air and liquid mixing, which causes the droplet size to become larger (Table 29.1). Small changes of air and liquid flow ratio (air-to-liquid mass ratio) influence droplet size changes (Table 29.2).

The effect of droplet size and powder material particle size on granule size after fluid-bed melt granulation using polyethylene glycol 3000 was examined by Abberger et al. [19] It was concluded that the mechanism of agglomeration depended on the ratio of the binder droplet size to the particle size of the solid powder. When the solid powder particle size is smaller than the binder droplet size, immersion of the solid particle in the surface of the binder solution is the main mechanism of nucleation. Distribution of the binder solution to the solid particle makes the solid particle's surface sticky and deformable. When the solid particle size is greater than the binder droplet size, these sticky and deformable wet particles stick together, which becomes the dominant nucleation mechanism.

29.5.3 Granule growth under drier conditions (low moisture content of wet granules during the granulation process)

AbuBaker et al.[20] investigated the effects of processing conditions on granule properties using a $2^{5-1}+2$ factorial design of experiment (DOE), using a fluid-bed granulator/dryer. The factors evaluated were fine and coarse drug particle size, binder solution concentration (11% and 16%), spray rate (70 and 110 g/minutes), atomizing air pressure (1 and 3 bar), and inlet air dew point (-5°C and 15°C). Statistical analysis from the study indicated that the spray rate and atomization air pressure ratio significantly influence granule size. Due to the very low moisture content (less than 2%) of granules, distribution of binder solution to solid particle surface makes the particle surface ready for aggregation, which is likely to be the main mechanism of granule growth. In this case, factors such as the spray rate and atomization pressure (liquid-to-air) ratio, which controls the droplet size of binder solution, become dominant factors for granule growth. The level of moisture content in wet granules may not be a good parameter to monitor, due to the very small change of the moisture level during the process.

29.5.4 Granule growth under wetter conditions (high moisture content of wet granules)

When moisture is accumulated in wet granules, more liquid bridges are formed, which increases the contact surface area between particles. As a result, the bonding capability of wet particles becomes higher than that for drier particles. It was reported that granule size is proportional to the humidity level inside the fluid-bed,[21] so granulation size can be monitored by measuring the moisture content of the wet mass. Watano et al.[22,23,24] introduced an infrared (IR) sensor to monitor the moisture level during fluid-bed granulation and established a good correlation between moisture content and granule size.

29.6 SCALE-UP CONSIDERATIONS

Scale-up of fluid-bed processes from small laboratory units to large commercial machines has been a continuing activity in the chemical and pharmaceutical industries for over half a century. In spite of this, fluid-bed scale-up is still not an exact science; it remains a mix of mathematics, engineering, and personal judgment. There are many simplifications, approximations, and educated guesses involved in fluid-bed granulation and drying. Better data, more realistic models, and more exact equations are always sought after in this field. The secret to successful fluid-bed scale-up, however, lies in the recognition and management of uncertainties rather than finding the fluid-bed's exact attributes.[25] Generally, equipment variables, such as the type and size of the equipment, and key process variables, such as spray rate, atomization pressure, and inlet air temperature, affect the product quality attributes. Control of such parameters, in order to yield a consistent product at a large batch size (scale), thereby constitutes a successful scale-up strategy. Equally important is the consistent quality of incoming raw materials (API and excipients). A change in particle size distribution of the API is known to affect granulation characteristics, and ultimately compressibility.

Of the three steps involved in fluid-bed agglomeration (dry mixing, spray agglomeration, and drying), the spray agglomeration stage is the most critical phase to monitor. During this phase, dynamic granule growth and breakdown takes place, along with solvent evaporation. Schaefer and Worts[21] demonstrated that granule size is directly proportional to bed humidity during granulation. Therefore, controlling bed humidity becomes critical. Gore et al.[26] studied various processing parameters and concluded that air temperature, spray nozzle location, spray rate, and atomization pressure can all affect granule characteristics. If one has to limit the number of process parameters to control for scale-up purposes, bed humidity and atomizing air pressure should be chosen. Atomization pressure affects granule growth through its effect on droplet size and spray pattern. Maintaining binder droplet size, when performing scale-up activities, is regarded as the key to scale-up success. Along with atomization pressure, nozzle atomization air volume should be recorded.

The primary consideration in scaling up the fluid-bed process is to maintain drying efficiency between the laboratory and production equipment. In a larger unit, inlet air temperature may need to be lowered, due to its higher air volume, in order to maintain the same drying efficiency as in smaller units. Otherwise, spray-drying of binder solution can occur. Another commonly used method is to maintain bed temperature, which can be achieved by balancing air temperature, dew point, air flow, and spray rate.

An additional consideration during scale-up is material handling procedures and transfer methods. While hand-scooping into and out of the bowl is convenient for small-scale processors, it is physically demanding and may not even be acceptable from a worker safety perspective. Vacuum transfer becomes a preferred option and a common practice. This is achieved through the creation of negative pressure inside the unit by running the blower with the inlet air flap minimally open and leaving the outlet flap fully open. Ingredients can be charged one by one via vacuum, and then the mixing and granulation phases can be started. For granule discharge, the

product can be vacuum transferred, bottom discharged by gravity, or side discharged into another intermediate bulk container (IBC) for further mixing and compression. Fully contained IBCs aided by vacuum transfer that can be linked to the discharge port of the fluid-bed processor are commercially available. These units keep the bowl from opening during product discharge and are typically used for potent compounds. If the fluid-bed is equipped with CIP cleaning nozzles, it can then be washed down before the bowl disengages from the expansion chamber.

29.6.1 Batch size and equipment selection

Scale-up from small laboratory sized fluid-bed machines can be made much easier if the same line of equipment is used. Manufacturers generally keep scale-up issues in mind when designing their line of processors. However, if equipment from a different manufacturer is to be used at the commercial site due to availability limitations, efforts will need to be spent on modifying process parameters. This is because of differences in air flow pattern, expansion chamber geometry, gun-spray pattern, and other factors.

Minimum and maximum batch size within selected top-spraying equipment can be approximated using the following equations:

$$S_{\min} = V \times 0.5 \times BD$$

$$S_{\max} = V \times 0.8 \times BD$$

where S is batch size in kilograms, V is the product bowl working volume in liters, and BD is the bulk density of finished granules in grams per cubic centimeter.

Linear scale-up can be used as a rough estimate in the beginning. Assuming that 6-kg scale batches have been made in a 22-L bowl at 60% volume, and that the next scale-up will be done in a 100-L bowl, a starting batch size of 30 kg is recommended. One must be kept in mind that as the batch size increases in the larger units, the powder bed will become more compacted, resulting in a higher bulk density in the bowl. Jones[27] predicted that approximately 20% higher bulk density should be factored in when comparing larger units to smaller ones.

For tangential-spray in a rotary fluid-bed granulator, minimum and maximum batch sizes can be determined as follows:

$$S_{\min} = V \times 0.2 \times BD$$

$$S_{\max} = V \times 0.8 \times BD$$

Rotor granulation is amenable to a wider range of batch size changes in the same bowl, although one should keep in mind that a larger batch load typically produces denser granulation due to the increased mass effect. Similar to a top-spraying model, a good starting point would be for the finished product to occupy 60% of the working capacity or volume of the rotor product chamber.

For bottom-spraying in a Wurster-type of equipment, the minimum and maximum batch size can be calculated using the following expressions:

$$S_{\min} = \frac{1}{2}(\pi R_1^2 H - N\pi R_2^2 H) \times BD$$

$$S_{\max} = (\pi R_1^2 H - N\pi R_2^2 H) \times BD$$

where R_1 is the radius of the chamber, R_2 is the radius of the partition, N is the number of partitions, and H is the length of the partition.

29.6.2 Spray rate scale-up

Spray rate scale-up is determined by the drying capacity of the equipment rather than by the increase in batch size. In other words, spray rate change should be based on similarities in fluidization patterns at different scales. However, one should keep in mind that at a given atomization pressure and air flow volume, change in liquid spray rate affects droplet size, which in turn affects particle agglomeration.

Two methods can be used to determine spray rates. If air volume can be read directly from the equipment, spray rate can be simply calculated as follows:

$$S_2 = S_1 \times \frac{V_2}{V_1}$$

where S_1 is spray rate in the laboratory scale equipment, S_2 is spray rate in the scaled-up equipment, V_1 is air volume in the laboratory scale equipment, and V_2 is air volume in the scaled-up equipment.

If there is no direct air volume readout on the equipment, cross-sectional areas of the product bowl screens can be used for approximation as follows:

$$S_2 = S_1 \times \frac{A_2}{A_1}$$

where A_1 is the cross-sectional area of the laboratory scale equipment, and A_2 is the cross-sectional area of the scaled-up equipment.

Using a 22-L bowl as the starting point, scale-up and scale-down factors have been tabulated for ease of use, as listed in Table 29.3.

Recently, AbuBaker et al.[20] proposed that the ratio of spray rate/atomization pressure is the most important factor controlling the droplet size of the spray. The authors reached this conclusion while working on scaling up an eroding tablet formulation with a high

TABLE 29.3 Approximate Scale-Up Factors for Fluid-Bed Granulators

Unit volume (L)	Screen diameter (mm)	Spray rate scale-up factor	Run-time scale-up factor
1.75	100	0.21	0.38
4.50	150	0.47	0.44
22	220	1.0	1.00
45	350	2.5	0.82
100	500	5.2	0.87
215	730	11.0	0.89
420	900	16.7	1.14
670	1000	20.7	1.47
1020	1150	27.3	1.70
1560	1250	32.3	2.20
2200	1750	63.3	1.58
3000	1740	62.6	2.18

drug load. By maintaining a constant ratio, scale-up from 8 to 70 kg was successful despite differences in drug particle size, granulator geometry, and number of nozzles used.

The authors have further devised a new process parameter termed *driving force*, which is the product of spray rate, binder concentration, and droplet size, and then normalized by batch size. Granule growth rate was shown to correlate well with calculated driving force:

$$\text{Driving Force} = \frac{\text{Spray Rate} \times \text{Binder Concentration} \times \text{Droplet Size}}{\text{Batch Size}}$$

Conceivably, if driving force is maintained constant at different scales, scale-up can be done with ease, resulting in granules with the same particle size.

29.6.3 Rotary disk speed scale-up

A simple way to scale-up disk speed is by maintaining radial velocity (V) constant as the diameter of the disk increases:

$$N_2 = N_1 \times \frac{d_1}{d_2}$$

where N is the disk speed (rpm) and d is the diameter of the disk (m), and the subscripts 1 and 2 represent the first and second set of conditions, respectively.

Radial velocity (V, m/s) can be calculated from

$$V = \frac{\pi d N}{60}$$

TABLE 29.4 Glatt RSG and GRG Rotor Parameters

Model	Disk diameter	Radial velocity (m/s)	Speed (rpm)	Air volume (m^3/h)	Number of nozzles
RSG 1/3	295	0–27	0–1800	80–580	1–2
RSG 5/15	485	0–30	0–1200	120–750	1–3
RSG 15/30	620	3.7–22	113–680	200–1500	2–4
RSG 60/100	780	4.4–22	108–540	600–3000	2–4
GRG 100	1000	5–25	100–500	800–4500	3–6
GRG 200	1400	5–25	70–340	1000–6000	3–6
GRG 300	1600	5–25	60–300	1400–8000	4–8

Alternatively, radial acceleration can be held constant in order to keep steady the centrifugal force (F_c) acting on the bed. Since radial acceleration equals to $2 \times V^2/d$, the following scale-change equation can be derived:

$$N_2 = \sqrt{\frac{N_1^2 d_1}{d_2}}$$

Assuming that a disk speed of 200 rpm was used in a 485-mm rotor, the scaled-up disk speed for the 780-mm rotor would be

$$\text{Using radial velocity method: } N_2 = \frac{200 \times 0.485}{0.780} = 124 \text{ rpm}$$

Using radial acceleration method:

$$N_2 = \sqrt{\frac{(200)^2 \times 0.485}{0.780}} = 158 \text{ rpm}$$

The known equipment parameters for the Glatt RSG and GRG rotor granulators are listed in Table 29.4.

Scale-up in a rotor granulator can also be done by maintaining F_c constant for different-sized rotors or the same rotor with different amounts of material loading. Horsthuis et al.[28] used the Froude number for scale-up in high shear Gral compounders. Chukwumezie et al.[29] modified the Froude number method to maintain F_c in rotor granulation. By maintaining an F_c of 41,667 N for a 1-kg batch in a 12-in. rotor at 500 rpm, these authors were able to scale the process up to a 10-kg load in a 19-in. rotor at 200 rpm:

$$F_c = \frac{W \times V^2}{R}$$

where W is the batch weight, V is the radial velocity, and R is the plate radius.

TABLE 29.5 CPCG, RSG, and GRG Batch Size Ranges

GPCG	RSG	GRG	Disk (mm)	Maximum working volume (L)	Typical batch size range (kg)
1 & 3	1	N/A	300	4.5	0.5–3.0
5 & 15	5	N/A	500	30	3–20
30 & 60	30	30	620	60	5–40
60 & 120	60	60	780	105	10–75
N/A	N/A	100	1000	180	25–125
N/A	N/A	200	1400	430	50–300

Typical batch size ranges for the GPCG, RSG, and GRG lines of machines are listed in Table 29.5.

29.6.4 Rational scale-up

Due to the large numbers of interrelating parameters affecting product attributes, scale-up efforts can be significantly improved by employing rational approaches, such as DOE. DOE allows the scientist to narrow down the most critical formulation and process parameters to monitor during scale-up trials. Full factorial designs afford the identification of factor-to-factor interactions that cannot be revealed by the one-parameter-at-a-time method.

As an example, a controlled-release formulation was granulated in a small-scale GPCG-3 top-spray granulator in the authors' laboratory. A $2^3 + 2$ design (three factors, two levels, with two center points) was utilized in this study, with the factors being PVP level, spray rate, and HPMC viscosity variation within the same commercial grade. Resulting granulations were compressed into tablets and tested for dissolution. The response surface plot is shown in Fig. 29.6. While there were no significant effects of spray rate and HPMC viscosity on dissolution, the PVP level did appear to be a statistically significant factor. Therefore, controlling PVP levels in the formulation is important, although how PVP affects HPMC gelation during dissolution still remains unclear.

Process analytical technology (PAT) also proves to be a valuable tool in process monitoring. Among well-established PAT methodologies is the near-infrared (NIR) spectroscopy technique via fiber-optic probes placed inside the bowl of the granulator. Since a wide spectrum (1100–2500 nm) of signals is captured in real time along the granulation process, it can then be processed to reflect water and particle size changes. Frake et al.[30] installed an inline NIR system in a Glatt GPCG 30/60. The second derivative changes in absorbance at 1932 nm were used to correlate with moisture, while the zero-order absorbance at 2282 nm was selected to reflect particle size increase during granulation. This continual inline NIR monitoring has been shown to provide a suitable means of end-point determination for a top-spray granulation process.

Rantanen et al.[31] employed a multichannel NIR detector in a Glatt WSG-5 unit to monitor moisture level during granulation and drying of blends and pellets. Moisture detection was performed at 1990 nm throughout the mixing, spraying, and drying phases. Together with bed temperature measurements, NIR moisture monitoring provides a value-added tool for better process understanding.

Watano et al.[32] utilized an IR moisture sensor for a laser scattering spray size analyzer for their work with agitation fluid-beds. They recommended that if the ratio of spray area to vessel cross-sectional area is kept constant, localized overwetting can be prevented. By means of moisture control, drying efficiency during wetting and agglomeration phases can be maintained constant among the different sized vessels. In a follow-up article,[33] these researchers further correlated the relationship between IR absorbance and granule moisture content. Except for very dry conditions, such as low spray rate or high air temperature, there appears to be excellent correlation between measured moisture level (by offline drying) and IR absorbance.

Another method in monitoring real-time granule growth is by image analysis. Watano and Miyanami[34] developed an image processing system by coupling a particle image probe (ie, a charge-coupled device camera), and an image-processing unit. A close agreement in granule size between image process and the traditional sieve analysis was obtained. The authors further automated this system to make it capable of controlling the spray rate at the end of the granulation phase or in order to avoid excessive agglomerate formation.[35] Modulation of spray rate was accomplished via fuzzy logic, a linguistic algorithm employing if-then rules, and a process lag element. Good control of granule growth was reported.

29.6.5 Scale-up via semicontinuous (batch-continuous) processing

The principle of using continuous processing to improve cost efficiency is well established in the food and bulk chemical industries. The pharmaceutical industry has been rather slow to adopt such a strategy due to relatively high profit margins, constant product changeover at the manufacturing site, and equipment qualification concerns. Semicontinuous processes, however, offer several advantages over traditional batchwise processing. The most important of these is

the ability to manufacture small and large volumes in the same equipment setup, thereby eliminating scale-up needs. Other advantages include ease of automation and less product risk in case of batch failure.[36]

Betz et al.,[37] using the Glatt MultiCell and two placebo formulations, demonstrated that consistent yield (discharge from the high shear granulator), compression profiles, and tablet disintegration can be generated throughout many subunits manufactured. This method has been extensively tested by Roche Basel, with more than 30 marketed products. It was postulated that 600 subunits can be manufactured to constitute a large "batch" of 4200 kg.[37] One other such subunit set-up has been installed in Pfizer's facility in Freiburg, Germany.

29.6.6 Scale-up via continuous processing

True continuous fluid-bed processing equipment is rarely used by the pharmaceutical industry, although suitable equipment lines are available. The primary applications are the chemical and food industries. An example is the Glatt GF series, which were developed over a decade ago in order to improve the throughput of fluid-bed processes. Originally designed for drying solids, various models are available today for granulation, coating, pelletizing, drying, and cooling applications.

The design feature of the GFG (granulator) is its inlet air plenum, which is divided into multiple chambers, thereby enabling the introduction of air with different temperatures and velocity in each chamber. Together with the correct placement of spray nozzles above each chamber, it is possible to create very different conditions in different sections of the process chamber. Agglomeration, drying, and cooling, therefore, can be done as the product travels from chamber to chamber within the same unit.

29.7 APPLICATION OF QUALITY-BY-DESIGN TO FLUID-BED GRANULATION

The inter-related nature of fluid-bed granulation process parameters can be approached more effectively via quality-by-design principles, especially with the aid of PAT. Critical quality attributes (CQAs) defined during granulation and drying steps typically encompass granulation particle size distribution, moisture content, bulk density, tapped density, and flowability index. Through the appropriate use of DOE, data analysis, and modeling, critical process parameters can be identified and suitable design space defined in the regulatory filing for operational flexibility. It is perfectly feasible to envision real-time batch release of granules from granulators upon successful implantation of online or inline PAT techniques which are validated to provide instantaneous data on CQAs. Drying can be terminated using real-time data and built-in feedback loops in the batch manufacturing recipe.

Peinado et al.[38] described a case study on the establishment of a validated NIR method to monitor granulation moisture level at commercial scale and compared with data generated using traditional loss on drying (LOD) methodology. A 300-L Glatt fluid-bed dryer was instrumented with an inline NIR spectrophotometer and signals captured between 1178 and 2075 nm, upon which a partial least squares model was then built. After proving that applicable validation criteria (specificity, linearity, accuracy, robustness, and precision) were all met, this method has been approved as the primary drying end-point control for this product, yielding much improved precision over the conventional LOD method.

Lourenço et al.[39] reported another design space case study on a large scale (WSG200 drier, 500 kg) by leveraging an inline moisture analyzer based on microwave resonance technology and another inline particle size analyzer based on spatial filter velocimetry (SFV). Samples were also characterized offline using optical microscopy, laser diffraction, and Karl-Fisher titration. A partial factorial DOE was executed to evaluate inlet air temperature, air flow rate, and binder spray rate during the spray phase. Inlet air temperature and air flow rate during drying were also included as process parameters in this DOE. Granulation moisture content has been shown to be affected by inlet air temperature, binder-spray rate, and air flow rate increment (recipe changes) during the granulation phase. Based on this study, a design space for the commercial scale granulation process has been proposed (which happens to be within previously filed limits).

In addition to NIR and SFV, there are other technologies that are capable of determining granulation particle size inline (ie, focused beam reflectance measurements, acoustic emission, particle image velocimetry, etc.). These techniques, along with data interpretation through statistical treatments,[40] can help in delineating critical process parameters and their multivariate interactions, which ultimately define a design space in regulatory applications.

29.8 SUMMARY

Fluid-bed granulation is a widely used and well-characterized unit operation in the pharmaceutical industry. With proper selection of equipment design, operating conditions, and suitable excipients, it has been shown that this technology can be scaled up from

the laboratory to commercial production. Although the wet-granulation process can vary from formulation to formulation, it is important to understand the basic concepts of equipment design and fundamental granulation theory, in order to develop robust and scalable formulations and processes. Application of PAT and DOE can help establish a design space for the fluid-bed process, as well as serving as great tools for scale-up and technology transfer. When a formulation and process are optimally developed using fluid-bed technology, the granules will ultimately impart superb quality to the end product (tablet, capsule, etc.).

Formulation, Process Development, and Scale-Up: Spray-Drying Amorphous Solid Dispersions for Insoluble Drugs

B. Vig[1] *and M. Morgen*[2]

[1]Bristol-Myers Squibb Company, New Brunswick, NJ, United States [2]Bend Research, a division of Capsugel Dosage Form Solutions, Bend, OR, United States

30.1 INTRODUCTION

A majority of new active pharmaceutical ingredients (APIs) in development exhibit low aqueous solubility and poor dissolution limiting oral bioavailability. A number of approaches have been used to improve aqueous solubility and bioavailability.[1–4] These have included particle size reduction[5]; creation of amorphous solid dispersions (ASDs)[6,7]; use of solubilization formulations (eg, using complexing agents, cosolvents, and lipid-based formulations)[8,9]; crystal modification (eg, using salts and cocrystals)[10]; and chemical modification (eg, prodrugs).[11]

Amorphous solids offer a number of advantages for the delivery of APIs (also referred to as compounds or drugs) with low aqueous solubility. Amorphous solids promote faster dissolution and higher dissolved drug concentrations because they lack long-range order, exhibit weak interactions between individual molecules, and have higher enthalpy, entropy, and free energy than their crystalline counterparts.[12] However, some formulations based on amorphous solids may present challenges, including physical instability, poor manufacturability at a large scale, inconsistent performance, and materials handling difficulties. This chapter is focused on the use of ASDs, which overcome a number of these issues by achieving a kinetically stabilized amorphous form.[7] ASDs, which are molecular dispersions of drug, polymer(s), and/or other excipient(s), can be prepared using a number of processes and are applicable to a wide range of API types, offering an attractive means to increase the aqueous solubility and bioavailability of problematic compounds. This chapter addresses the formulation, process development, scale-up, and drug product considerations for preparing spray dried dispersions (SDDs), a particular class of ASDs, for APIs with low aqueous solubility.

30.2 BACKGROUND

In this section, we provide background information on ASDs in general, and SDDs in particular.

30.2.1 Background: assessment of ASD applicability

ASDs are increasingly used commercially and clinically because of their utility.[13,14] Successful use of ASDs, however, depends on careful assessment of the suitability of this approach for the specific application. Following this assessment, care must also be taken in the selection of the dosage form, taking into account performance (solubility enhancement and sustainment for biologically relevant timeframes), chemical and physical stability, manufacturability, and adequate drug loading, as described in the next sections.

The low aqueous solubility of compounds is generally attributed to strong interactions in the crystal lattice (high melting point) and/or hydrophobic

Developing Solid Oral Dosage Forms
DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00030-3

groups (as indicated by a high octanol/water partition coefficient, log *P*).[15] Insight into the utility of a particular solubilization application can be gained by assessing the dose-to-solubility ratio required to achieve high oral bioavailability for the compound. This can be done using a technology map, such as that shown in Fig. 30.1, which shows the applicability of ASDs versus other technologies. The top-most solid diagonal line in the map (Fig. 30.1) traces the maximal solubility (S_{max}) of the lowest-energy, neutral form of the compound, calculated using a modified general solubility equation (Eq. (30.1)). Eq. (30.1) assumes that compound solid-state interactions are negligible (ie, the compound is a liquid at ambient temperature).

$$S_{max}(\text{mg/mL}) = 1000 \times 10^{(-\text{Log } P)} \qquad (30.1)$$

Decreasing aqueous solubility at a constant log *P* value is driven primarily by an increase in the solid-state interactions, which are directly proportional to melting temperature (T_m). Generally, the further a compound falls below the diagonal line, the higher its T_m value. In the upper region of this map, crystalline solubility is high enough to achieve good bioavailability at a 100-mg active (mgA) dose using a crystalline drug form. Decreasing solubility associated with increasing log *P* and/or increasing T_m requires a solubilization-enabling technology to maintain good in vivo performance.

As Fig. 30.1 shows, particle-size-reduction technologies (eg, creating microcrystals or nanocrystals via micronization or milling) can offer acceptable bioavailability at a 100-mgA dose when solubility falls below 1 mg/mL. This is achieved by increasing the surface area to overcome the slow dissolution rate of a crystalline drug, keeping the drug at its equilibrium concentration in the gastrointestinal (GI) tract.[5,16]

However, as solubility decreases further, the utility of such technologies diminishes because absorption is inadequate even if high (including instantaneous) dissolution rates are achieved. At such low solubilities, technologies are required that increase the drug concentration in the GI lumen above its equilibrium solubility and/or that increase drug transport across the unstirred water layer via submicron-sized colloids. For compounds with high lipophilicity (ie, log $P > 6$), the addition of lipidic excipients can help solubilize and enhance transport of the compound through the unstirred aqueous boundary layer—a process that can otherwise be slow and limit absorption of lipophilic drugs.

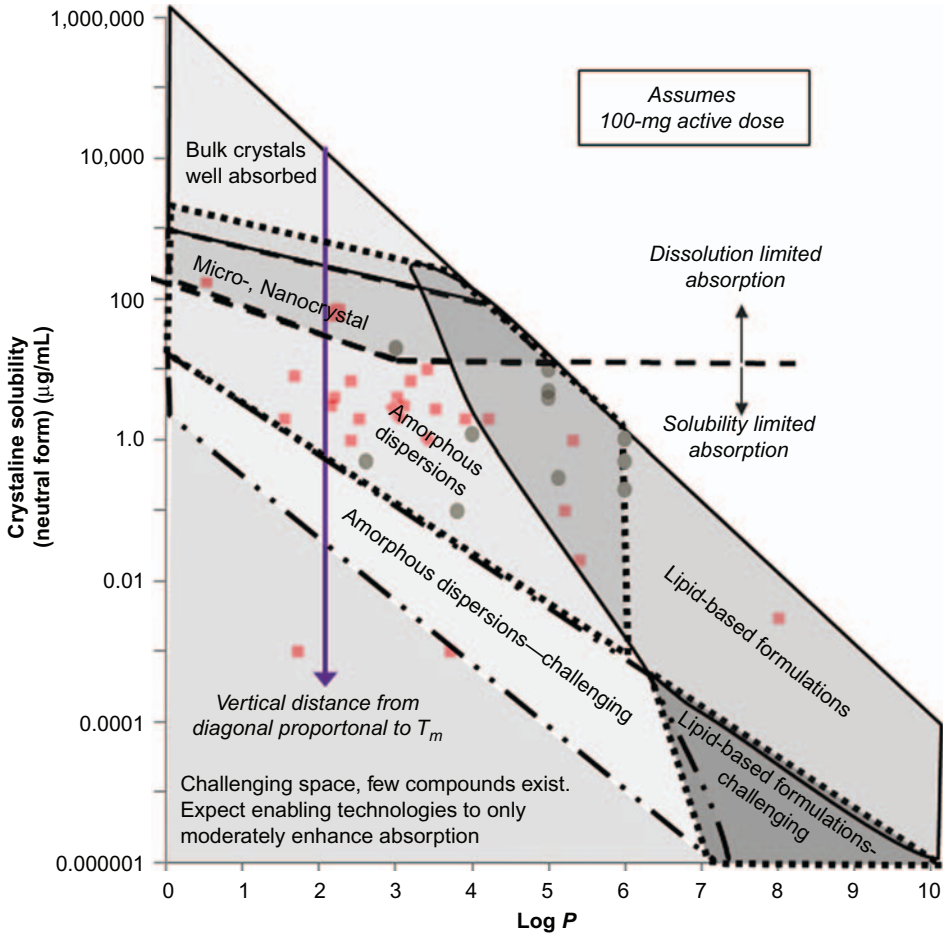

FIGURE 30.1 Crystalline solubility versus Log *P* of compounds showing applicability of Amorphous Solid Dispersions (ASDs) compared with other technologies. Assumptions: the figure is based on solubility of the neutral bulk crystalline form at pH 6.5, assuming the fraction of dose ionized at pH 7 is less than 50%, the molecular weight of the compound is less than approximately 700 Da (so permeability is not adversely affected by molecular size), and the human dose is 100 mgA. If the dose is higher or lower than this, the property space in which high bioavailability can be achieved changes.

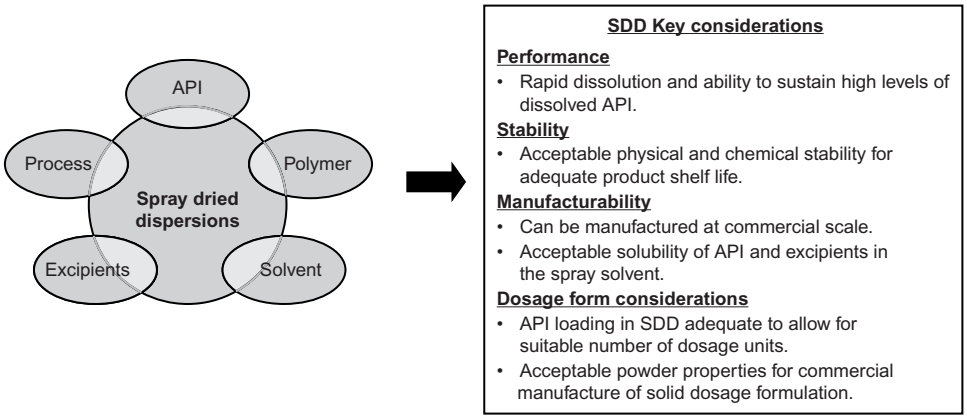

FIGURE 30.2 Spray Dried Dispersions (SDDs) Target Product Profile—Performance, stability, manufacturability, and dosage-form considerations.

Due to their rapid dissolution rate and higher drug activity relative to bulk crystalline drug, ASDs are useful where the drug at the desired dose is dissolution- or solubility-limited, often with a dose number >1.[17] ASDs are most readily applied to compounds that have low to moderate log *P* values, although the technology can be extended to compounds with higher log *P* values.[13,18] ASDs have been shown to keep dissolved drug levels high and enhance bioavailability significantly in preclinical and clinical settings.[19,20]

Typically, ASDs are used instead of pure amorphous API because the physical stability of the latter is usually not sufficient to avoid rapid API crystallization in the solid state or in the use environment. ASDs can be made by a number of processes, including spray-drying,[21] spray coating of API and excipient onto substrates,[22] solvent-controlled precipitation,[23] freeze drying,[24] fusion-based process,[25] and hot melt extrusion (HME).[26] Processing temperatures, miscibility of API and solvent, time spent in a high-mobility state, particle properties (eg, size and density), and equipment availability can all affect the choice of the process for making ASDs. For example, an API with a high T_m can present challenges for preparation using HME due to the need for higher processing temperatures that, in turn, increases the risk of API and/or excipient degradation.[26] This chapter is focused on ASDs made using spray-drying—one of the most common processes for converting API and excipients (typically polymers) into an ASD. The SDD shares some, but not all characteristics of ASDs made using other processes.

30.2.2 SDD key considerations

SDDs are prepared by spray drying a solution of API, polymer, and possibly other excipients, in a volatile spray solvent. SDD development, like other formulation development, should begin with a well thought out target product profile (TPP), which can guide the development process and be refined as additional information becomes available.[27,28] Ideally, SDD formulations for bioavailability enhancement should meet several manufacturing and performance criteria, as shown in Fig. 30.2. On the manufacturing side, the API and excipients should have relatively high solubility in one or more high-volatility spray solvents and have good chemical stability in solution. The solvent should be easy to remove during spray-drying and/or subsequent secondary drying. On the performance side, the formulation typically should have a rapid dissolution rate and sustain high dissolved-drug concentrations. Other key attributes include good physical stability with respect to amorphous phase separation and drug crystallization, and good solid-state chemical stability of the drug and excipients. Ideally, all these criteria should be met using a SDD with a high enough drug loading to meet the TPP, allowing delivery of the desired dose using an acceptable number of dosage units. Finally, SDDs should have acceptable powder properties for commercial manufacture of solid dosage formulation (eg, capsules or tablets). Table 30.1 lists common critical to quality attributes (CQAs) that can impact TPP and the formulation and process parameters that commonly define the SDD attributes.

30.3 SDD FORMULATION COMPOSITION

As shown in Fig. 30.2 and Table 30.1, SDD CQAs and, thus, performance is dependent on the formulation composition (eg, API and polymer chemistry, API:polymer ratio, and other excipients); choice of spray solvent(s); and the manufacturing process parameters (eg, droplet size, drying rate, and secondary drying). It is important to understand the interdependencies between the formulation composition and manufacturing process to ensure manufacture of a consistent SDD product that meets the desired performance criteria.

TABLE 30.1 Potential SDD Critical to Quality Attributes and Important Formulation and Process Parameters and Their Potential Product Impact

Potential SDD CQA	Potential product impact	SDD composition considerations	SDD process parameters consideration	Typical analytical tools
Physical state (presence of crystalline API)	• Product physical stability (presence of crystalline API) • Dissolution, in vivo performance	• API physicochemical properties eg, T_g, T_m, Log P, counterion, API-polymer miscibility • API to polymer ratio • Polymer chemistry and MW • Spray solvent • Spray solution solids content	• Droplet size and drying rate • Incomplete dissolution of API in spray solvent. • Secondary drying parameters • Exposure to humidity	• DSC • PXRD • SEM and PLM • FT-IR • Raman • ssNMR • Dissolution tests
Potency	• Potency	• API to polymer ratio • Spray solution solids content	• Incomplete API and/or polymer dissolution in spray solvent	• HPLC • In-line spectroscopy tools
Impurities	• Impurities	• Impurities from API, solvent and polymers	• Chemical stability of API, polymer and solvent during SDD process	• HPLC
Chemical stability	• Degradant level upon release and storage	• API physicochemical properties • Polymer, excipient, and solvent choice • Reactive impurities in polymers, excipient, and solvent	• Spray solution temp and hold time • Spray drying and secondary temperature and duration • Exposure to humidity and temperature	• HPLC
Water content	• Potency • Physical and chemical stability	• SDD, API and polymer hygroscopicity	• Secondary drying parameters • Exposure to humidity	• Karl Fischer
Residual solvent	• Residual solvent • Physical & chemical stability	• Solvent choice	• Droplet size and drying rate • Secondary drying parameters	• GC-MS • QNMR
Particle size	• In vivo performance • Downstream processing and final product quality attributes (eg, dissolution, assay, content uniformity, tablet hardness)	• Polymer chemistry and MW • Spray solution solids loading	• Droplet size • Particle attrition during agitated secondary drying	• Malvern • G3-Morphologi • Dissolution tests
Bulk density and morphology	• Downstream processing and final product quality attributes (eg, assay, content uniformity, tablet hardness)	• Polymer chemistry and MW • Spray solution solids loading	• Droplet size and drying rate	• Scotts volumeter • G3-Morphologi • SEM

30.3.1 API properties

The SDD performance attributes are highly dependent on the physicochemical and biopharmaceutical properties of the API. As exemplified next, a fundamental understanding of the impact of API properties on SDD performance can guide development of a robust SDD formulation. API properties that can impact SDD performance include: melting point (T_m); glass-transition temperature (T_g); Kauzmann temperature (T_k), the temperature at which the difference in entropies becomes zero; crystalline form (including counterions for salts); acid dissociation constant at logarithmic scale (pK_a); miscibility in polymers; hydrogen bond donors and acceptors; lipophilicity (eg, log P); epithelial membrane permeability; solubility in aqueous biorelevant media and spray solvents; and chemical stability.[29–34] Trasi et al. and Van Eerdenbrugh et al. recently demonstrated the importance of API molecular properties on ASD physical stability. The authors found that the crystal growth rates of compounds could vary by about five orders of magnitude between the fastest growing compounds and the slowest growing compounds.[33,35,36] The authors found that physicochemical properties of the compounds that had fast crystal growth rates had lower molecular weights, higher T_m values, lower T_g values, fewer rotatable bonds, lower melt entropies, lower melt viscosities, and higher crystal densities.

T_g is one of the important API characteristics that is used to predict the physical stability of the SDD. T_g is the temperature at which the amorphous solid converts from a glassy state (solid) to super-cooled liquid state, as shown in Fig. 30.3.[37] Structural factors, such as molecular size and shape, and the extent, strength, and direction of hydrogen bonding can affect T_g. A higher T_g value and a lower T_m/T_g ratio generally indicates that amorphous API will have a lower propensity to crystallize.[33] Generally, APIs with T_g values much higher than the storage temperature (T_s) will have a low tendency to crystallize, and SDDs made with such APIs tend to be physically stable.[38] In addition to the driving force for crystallization in the solid phase, the API lipophilicity (indicated by log P) is an important factor because highly lipophilic compounds often form SDDs that wet poorly and, consequently, dissolve poorly.

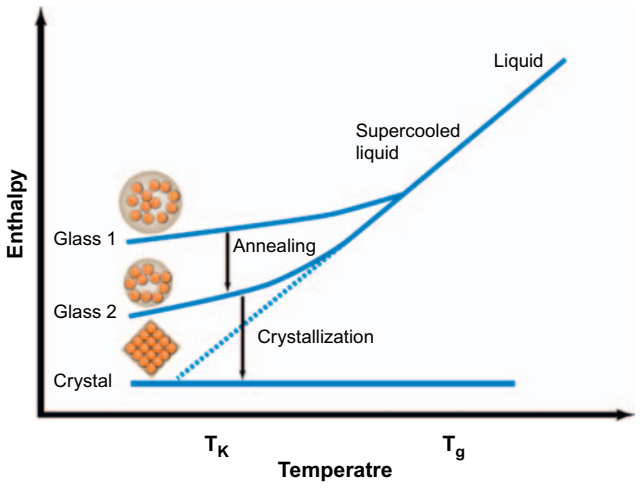

FIGURE 30.3 Temperature versus enthalpy (E). Depending on thermal history, glasses can form with slightly different energies, resulting in variable T_g values.

An API's tendency to crystallize and its lipophilicity can be used to guide the selection of the polymer and excipients and determine the maximum drug loading for an SDD.[32] In general, compounds that have higher tendency to crystallize require a higher ratio of polymer-to-drug to form SDDs that resist crystallization. Compounds with high log P values may also require a larger ratio of polymer to drug and excipients to reduce drug–drug interactions, improve wetting, and achieve the desired dissolution performance. Wetting and, hence, dissolution of SDDs can also be improved by incorporating surfactant in the SDD or in the dosage form.[39]

API is generally isolated in a crystalline form even if it is later converted to an amorphous dispersion for bioavailability purposes because the crystalline drug form has many processing advantages. Different drug forms (eg, salts, free forms, solvates) and polymorphs can have different solubilities in spray solvents, which can affect processing ease. Therefore, it is important to select a suitable crystalline drug form for SDD development and to evaluate the solubility of the selected form in the desired spray-drying solvent or solvent mixture. The API's tendency to form a solvate with the spray solvent should also be examined because these solvates will have lower solubility than the neat form. When dealing with acidic or basic drug compounds, acid–base equilibria can take place in the amorphous state, leading to unanticipated changes in various solid-state properties. In cases where a salt of the crystalline form is isolated and used to form an SDD, special attention should be paid to the choice of counterion because it can affect properties of amorphous materials. Towler et al. reported that use of counterions with high electrophilicity indices resulted in stronger intermolecular interactions, producing dispersions with higher T_g values.[40] Towler et al. also found that T_g is affected by the pK_a of the counterion, with higher T_g values observed for counterions with lower pK_a values.[40] Sonje et al. evaluated the effect of monovalent sodium and bivalent calcium and magnesium counterions on the properties of

amorphous salts of atorvastatin prepared by spray-drying.[30] They found that the choice of counterion affected the T_g, fragility (ie, temperature dependence of molecular mobility), crystallization tendency, and chemical stability of the drug.[30]

30.3.2 Polymer choice

Other than the physical and chemical properties of the API, the polymer has the most significant impact on SDD's ability to achieve and maintain supersaturation, physical and chemical stability, and powder properties.[41,42] SDDs employ polymers as a matrix material to achieve desired performance criteria (Fig. 30.2) that typically cannot be achieved with pure amorphous API. Key polymer properties that influence choice of dispersion polymer include: (1) miscibility with the drug over the desired range of compositions; (2) functional groups (eg, acidic, basic, and hydrogen bond donors/acceptors that can result in drug–polymer interactions); (3) T_g (higher is typically better); (4) low hygroscopicity; (5) aqueous solubility; (6) precipitation inhibition characteristics; and (7) solubility in organic solvents suitable for spray-drying. Table 30.2 lists common polymers used for SDDs.

TABLE 30.2 Polymers Commonly Used in Spray Dried Dispersions (SDDs)

Polymer (grade)[a]	Structure	T_g (°C)		Water content at 25°C/75% RH (wt%)	Typical spray solvents[c]	Ionizable groups
		<5% RH[b]	At 75% RH			
HPMCAS (M)		125	73	6	Acetone, methanol, THF, DCM	Acidic
HPMC (E3)		142	43	11	Methanol/water	None

Polymers stabilize SDDs by reducing the molecular mobility of the drug by forming intermolecular interactions between drug and polymer, and by reducing the chemical potential of the drug.[43] An amorphous drug is typically most stable when drug and polymer are mixed homogeneously at the molecular level.[44,45] An advantage of spray-drying, as opposed to HME for example, is that rapid drying kinetics trap drug and excipients in a well-mixed state in the low-mobility polymer matrix. Therefore, in an SDD, the drug does not have to be miscible in the polymer to the level at which it is loaded. Nevertheless, the miscibility of drug in the polymer matrix can play a role in the physical stability of the dispersion with respect to phase separation, including crystallization. The strong interactions between an API and a polymer via ionic interactions, hydrogen bonding, halogen bonding, van der Waals forces (eg, dipole–dipole, dipole-induced dipole, London dispersion forces), and hydrophobic interactions are expected to facilitate miscibility of the drug in the polymer and may increase physical stability.[46–48] Thus, a molecular-level understanding of the interactions between the drug and polymer can aid in the selection of an appropriate dispersion polymer and drug loading for the SDD.

One of the key mechanisms by which polymers stabilize amorphous SDDs is by reducing drug mobility. Polymers with high T_g values are preferred to limit drug mobility and the resulting potential for drug-excipient phase separation. Typically, a molecular dispersion will have a T_g that is between that of the drug and polymer. The T_g of the drug–polymer mixture can be estimated using several approximations, including the Fox equation (Eq. (30.2))[49] and the Gordon-Taylor equation (Eq. (30.3)).[50] In these equations, T_{g1} and T_{g2} and w_1 and w_2 are the T_g values and weight fractions of drug and polymer, respectively, and K_{GT} is a constant that indicates interaction between two components. Eq. (30.4) shows the calculation of K_{GT}, with ρ_1 and ρ_2 being true densities (g/cm^3).

$$\frac{1}{T_g} = \frac{w_1}{T_{g1}} + \frac{w_2}{T_{g2}} \tag{30.2}$$

$$T_g = \frac{w_1 T_{g1} + K_{GT} w_2 T_{g2}}{w_1 + K_{GT} w_2} \tag{30.3}$$

$$K_{GT} = \frac{\rho_1 T_{g1}}{\rho_2 T_{g2}} \tag{30.4}$$

In many cases, the theoretically predicted T_g values for the drug–polymer system deviate from the experimental value. The reason for this deviation is nonideality in mixing and/or interaction of the drug with polymer, which could be because drug–drug and polymer–polymer interactions are different than the drug–polymer interaction. A strong or equal interaction between drug and polymer due to ionic interactions, hydrogen bonding, halogen bonding, van der Waals forces (eg, dipole–dipole, dipole-induced dipole, London dispersion forces), and hydrophobic interactions will lead to a more stable SDD.

Besides physical stability, polymers have a significant impact on the ability of the SDD to achieve and sustain supersaturation in solution.[51,52] The general concept behind almost all solubilization technologies is termed the "spring-and-parachute" effect, where the "spring" portion relates to the ability of the SDD to achieve supersaturation and the "parachute" portion relates to the ability of the SDD to maintain supersaturation long enough for drug absorption to take place.[53] Most of the polymers used for SDDs are hydrophilic or at least amphiphilic (Table 30.1). Charged or ionizable polymers include substituted acrylates (eg, polymethylacrylate (PMA) and hydroxypropylmethylcellulose acetate succinate (HPMCAS)). Uncharged polymers include hydroxypropylmethylcellulose (HPMC), polyvinylpyrrolidone/vinyl acetate (PVP-VA), and polyvinylpyrrolidone (PVP). Neutral water-soluble polymers can be useful for applications where rapid dissolution of the drug in the stomach is needed and where sustainment of supersaturated drug is not made difficult by a drug's strong tendency to crystallize. The rapid dissolution can be advantageous to maximize the time of exposure of high concentrations of dissolved drug in the small intestine.

Enteric polymers, such as HPMCAS, can be useful for applications where rapid gastric dissolution in the gastric is not needed or desired. For example, the high solubility of some weakly basic drugs in the low-pH gastric environment can result in high supersaturated drug levels, especially upon transit and subsequent neutralization of the drug in the higher pH of the small intestine, which can lead to rapid crystallization. In these instances, it can be advantageous to use an enteric polymer in the SDD to retard dissolution of the drug until the material reaches the small intestine, where the supersaturation will be more moderate and rapid crystallization of the drug to a lower-energy form will be less likely.[32,54]

On the other hand, depending on the SDD particle-size distribution and on the specific interactions between the drug and polymer in a hydrated environment, drug release can be rapid without concomitant dissolution of the enteric polymer. In this scenario, use of the enteric polymer can be a disadvantage if the supersaturated drug precipitates before the enteric polymer can dissolve in the higher pH of the small intestine and interact favorably with the drug to inhibit crystallization.

For acidic APIs that may have low solubility in the gastric environment and higher solubility in the

higher-pH intestinal environment, an enteric polymer is often not necessary to prevent premature release and supersaturation. In these cases, use of a neutral water-soluble polymer can sometimes result in more rapid release when a drug travels to the small intestine. Therefore, the choice of optimal polymer for the SDD is often dictated by a number of drug properties, including solubility, ionizability, lipophilicity, and propensity to crystallize, as well as the required SDD drug loading.

The impact of polymer selection on the in vivo performance of SDDs has been reported in the literature.[13,42,55] Qian et al. described the impact for SDDs made with BMS-A and PVP-VA or HPMCAS.[42] In this case, BMS-A was miscible with both PVP-VA and HPMCAS, with the former better solubilizing the drug. The in vitro dissolution performance of both SDDs was similar, as shown in Fig. 30.4, but in in vivo testing, the BMS-A/HPMCAS SDD had a higher maximum drug concentration (C_{max}) and area under the time-concentration curve (AUC) than the BMS-A/PVP-VA SDD, as shown in Fig. 30.5. The authors found that the fast dissolution of the PVP-VA resulted in elevated drug loading in partially undissolved particles and facilitated drug recrystallization before complete release. In contrast, the hydrophobicity and slower dissolution of the HPMCAS prevented BMS-A recrystallization within the HPMCAS matrix, effectively prolonging BMS-A supersaturation.

The enteric polymers tend to be some of the more amphiphilic polymers used in SDDs and therefore form drug–polymer colloids more readily. Such colloids provide a high-activity, high-surface area source of drug that can readily replenish a dissolved drug as it is absorbed.[32] In addition, colloids may act to shuttle the drug across the unstirred boundary layer. On the other hand, acidic polymers can be incompatible with drugs that have acid-sensitive chemical stability liabilities. For these drugs, it can be advantageous to use nonacidic polymers to avoid the potential for chemical instability. In some cases, modestly reducing the number of acid groups on the polymer—for example, changing from the (L) grade to the (M) or (H) grade of HPMCAS—can have a significant positive effect on chemical stability.[56]

30.3.3 Additional excipients

Drug and polymer are typically the two primary components of an SDD, but sometimes additional excipients are included in the SDD formulation. These excipients might include antioxidants to improve the oxidative stability of the drug in the amorphous state; pH modifiers to improve stability or mitigate a pH effect[57,58]; superdisintegrants to improve disintegration/dissolution; glidants to improve bulk material properties[59,60]; complexing agents (eg, cyclodextrins) to bind and solubilize drug[61]; or surfactants to improve wettability and maintain supersaturation.[62,63]

The addition of other excipients, such as surfactants or lipids, to the SDD can be advantageous in specific

circumstances. For example, addition of low-molecular-weight surface-active agents such as sodium lauryl sulfate (SLS) or Vitamin E d-alpha tocopheryl polyethylene glycol 1000 succinate (TPGS) can enhance dissolution rates for some SDDs, particularly those containing highly lipophilic drugs, and may also promote the formation of mixed micelles with bile salts in the small intestine to increase the micellization of drug.[64–66] In addition, some low-molecular-weight surface-active agents, such as Vitamin E TPGS and polyethylene oxide oligomers (PEO) have been reported to interact with the gut epithelium to enhance absorption.[67] The addition of excipients can change solution-state interactions and can affect the spray-drying process, which in turn can influence SDD particle properties (eg, shape, morphology, physical structure, surface chemistry) and performance. Therefore, it is important to understand the interactions at the molecular level where possible, and their impact on SDD processability, performance, and stability. SDD process involves solubilization of all formulation components in solvent that is removed during the manufacturing process. Solvent is not considered an excipient, but its choice and residual level can have a plasticizing effect that potentially influences the SDD's physical and chemical stability.

30.3.4 Drug loading

The target drug exposure is a critical factor, as dose and bioavailability are interrelated, and therefore impact the drug loading requirements for the SDD. The TPP is typically based on the size and a maximum number of dosage units to deliver the target dose.[27,28] Generally, a higher drug loading (drug to polymer ratio) in the SDD is desirable to minimize the final product size and units. The maximum drug loading in the SDD will depend on the physical and chemical stability, dissolution performance, and powder properties of the SDD as a function of drug loading. Typical achievable active loadings are 25–50%A, but in the authors' experience, loadings from 1%A to 90%A have been used.[68] The maximum achievable loading is often limited for drugs with high T_m and low log P values that have a strong tendency to crystallize from the amorphous state, as shown in the map in Fig. 30.6.[32] Dilution of these drugs in the excipient matrix can help promote physical stability during spray-drying, storage of the SDD in the solid state, and help limit precipitation when the SDD is introduced into the use environment. The maximum drug loading for a particular drug depends not only on the drug properties, but also on the characteristics of the polymer. Polymers in which the drug is more miscible or that offer a lower mobility environment can help stabilize the drug against crystallization or amorphous phase separation. In many cases, the drug has a lower T_g than the polymer. In these cases, the T_g of the SDD typically decreases as drug loading is increased, which can increase the risk of phase separation due to the potential for increased drug mobility at typical storage conditions (ie, temperature and relative humidity, RH).

High drug loadings in the SDD can also result in poor dissolution properties, especially for highly lipophilic drugs that may wet poorly in the aqueous milieu of the GI tract. Often, the dissolution mechanism of such SDDs is by slow erosion. In such cases, a lower drug loading and a water-soluble polymer can be used to enhance the dissolution rate through faster erosion or by changing the dissolution mechanism from erosion to disintegration. These mechanisms are described in more detail later.

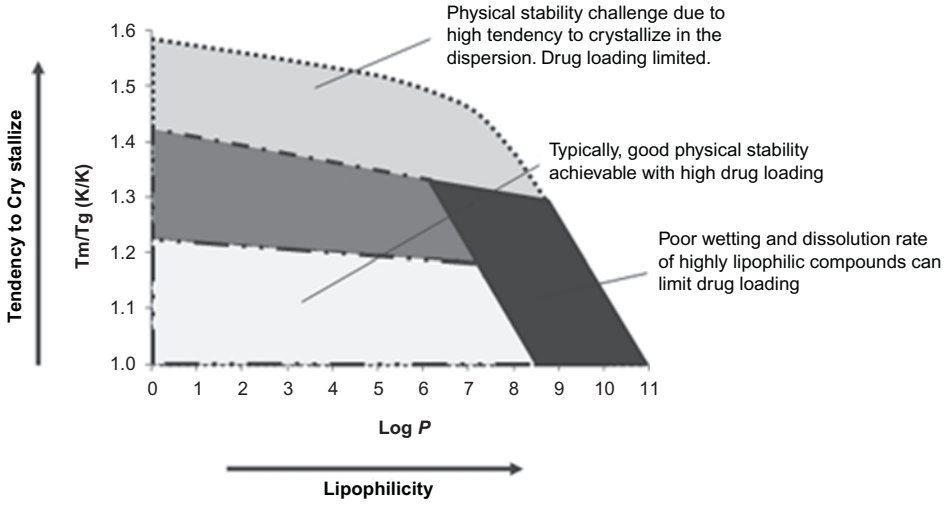

FIGURE 30.6 Physical stability map for SDDs, showing crystallization tendency as a function of lipophilicity. *Source: Modified from Vodak DT, Morgen M. Design and Development of HPMCAS-Based Spray-Dried Dispersions. In: Shah N, Sandhu H, Choi DS, Chokshi H, Malick W, editors. Amorphous Solid Dispersions. New York: Springer; 2014. p. 303–22.*

30.3.5 Spray solvent

Since the choice of solvent has a large impact on process and product quality and performance, it is important to identify a solvent that: (1) can dissolve the polymer (which is generally hydrophilic), the drug (which is generally hydrophobic), and any additional excipients at sufficient concentration; (2) has high volatility that enables rapid drying of spray-droplets; (3) is chemically compatible with the formulation components and spray-drying equipment; (4) has acceptable rheological properties; (5) is chemically stable; (6) is nontoxic[69]; (7) has acceptably low levels and types of impurities; (8) is noncombustible under spray-drying conditions; and (9) is eco-friendly. The solvent-dependent parameters, such as evaporation rate, diffusion coefficient, API/polymer solubility, API/polymer/solvent interactions, rheological properties, and chemical compatibility can have a significant impact on SDD characteristics such as particle morphology, particle density, particle size, API-polymer miscibility, yield, dissolution, residual solvent, and physical and chemical stability.[70] Table 30.3 provides some of the relevant physical properties for common spray solvents.[29] In many cases, a single solvent with the desired characteristics cannot be identified, so a mixture of solvents may be used to achieve the desired solution characteristics.

The solubilization capacity of the solvent is highly dependent on its dielectric constant, dipole moment, total solubilization parameter, and hydrogen bonding characteristics.[29,71] The development and optimization of the spray-drying process requires screening of the API solution solubility as a function of temperature and solvent composition using manual or high-throughput screening systems. Due to the structural requirements needed to address new drug targets, many of the drugs in current development programs are poorly soluble not only in aqueous media, but also in typical spray-drying solvents. Rigorous solvent screening protocols involving a combination of experimental and theoretical methods[72] are required to identify optimal spray-drying solvents in which the drug has sufficient solubility for acceptable throughput, yield, and particle properties.

Solvents can influence the conformational properties of polymer and, thus, the properties and physical stability of the SDD.[29,70,73,74] A polymer in a "good" solvent will typically be better solvated and "extended" than the same polymer in a "bad" solvent, where it might assume a more "compact" structure. Al-Obaidi found that spray-drying griseofulvin, poly[*N*-(2-hydroxypropyl) methacrylate] (PHPMA) and PVP from an acetone/methanol solvent system produced SDDs with dramatically different morphology, stability, and dissolution properties compared with a similar SDD prepared using acetone/water as the solvent system.[73] The authors attributed the differences in SDD properties to the conformational variations of the polymers in solution before spray-drying. Al-Obaidi et al. and Paudel et al. showed that choice of a poor spray-drying solvent can impact SDD phase behavior and, thus, the physical stability and in vitro/in vivo performance of the SDDs.[70,73]

In a case study involving a BMS-A/PVP (K30) SDD, the authors (Qian F, AAPS Webinar, March 2011) showed that BMS-A and PVP (K30) were miscible based on the negative Flory–Huggins interaction

parameter. Further, infrared (IR) and solid-state nuclear magnetic resonance (ssNMR) spectroscopy showed nonlinear interaction between BMS-A and PVP (K30), indicating drug–polymer specific interaction. A 50/50 (w/w) BMS-A/PVP (K30) SDD was made using either an acetone/water solvent system or pure methanol as solvent. The SDD sprayed from the acetone/water solvent system showed two T_g events (at 78°C and 128°C), whereas the SDD sprayed from methanol had a single T_g of 90°C. Further, the SDD prepared with acetone/water showed the presence of crystalline API peaks when stored for 2 weeks at 25°C/60% RH in open containers, whereas no signs of crystallization were seen when the SDD prepared from methanol was stored under similar conditions.

Solvent properties such as boiling point, enthalpy of vaporization, and vapor pressure influence the energy required and, thus, the process parameters needed to remove the solvent during spray-drying. Rheological properties, such as viscosity and surface tension, affect the atomization of the spray solution. The composition and the viscosity of the spray solution significantly affect droplet formation, drying, and the particle properties of the dry SDD.[75]

The solvent's thermal properties largely influence the residual solvent level. Solvent levels should be controlled per ICH guidelines because an excess of residual solvent can be toxic.[69] In addition, the residual solvent can plasticize the SDD, reducing its T_g and potentially causing physical instability.[76] Residual solvent levels are usually reduced to well below the recommended ICH guidelines. The vast majority of the solvent is removed during the spray-drying process. A secondary drying process (the fourth step in the spray-drying process) is then used to remove residual solvent to the desired level. The solvents used in the spray-drying process often contain impurities that can be more toxic than the solvents themselves. For example, acetone is often tainted with mesityl oxide (MO) and diacetone alcohol (DAA), and methanol can contain trace levels of benzene. During the spray-drying process, the higher boiling points of these impurities can result in their concentration in the SDD. Therefore, it is usual to assess levels of potential impurities, especially if they are toxic. In one case, Quirk et al. developed a sensitive and validated headspace gas chromatography (GC) method to determine residual levels of acetone and acetone-related impurities (ie, MO and DAA) in SDDs.[77] Yue et al. recently proposed a control strategy for benzene impurity in HPMCAS-based SDDs. To eliminate risk of residual benzene reaching patients, the authors developed a science- and risk-based approach to establish upstream control of benzene in solvents and in-process control of residual solvents in polymer-stabilized SDDs.[78]

30.4 SDD PROCESS CONSIDERATIONS: MANUFACTURING AND SCALE-UP

The spray-drying process involves atomizing and drying solution of drug, polymer, and potentially other excipients in a volatile spray solvent. As shown in Fig. 30.7, the spray-drying process typically involves four steps: (1) preparation of spray solution, (2) atomization and drying of spray solution, (3) collection of

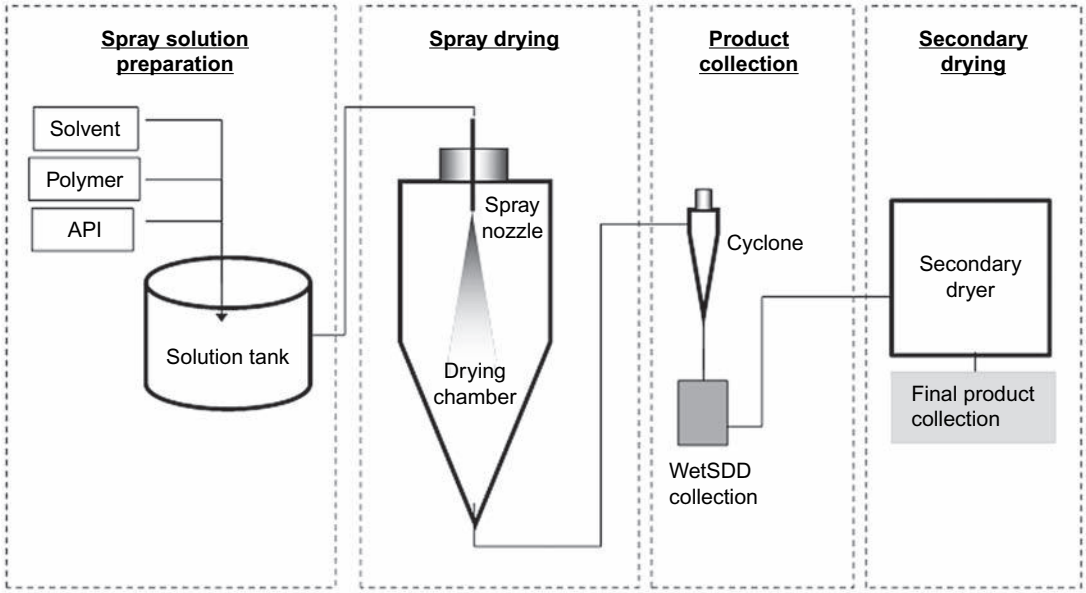

FIGURE 30.7 Spray-drying process overview.

the wet (ie, solvent-laden) SDD, and (4) secondary drying of the wet SDD to remove residual solvent.

Spray dryers are available in a variety of scales: lab units that can process milligram quantities, pilot units that can process gram to kilogram quantities, and commercial units that can process metric tons. Although the fundamental principles for the spray-drying process remain the same, the large units are more efficient and the powder properties of the materials from small units can be significantly different from those produced at larger scale.

30.4.1 Spray-solution preparation and considerations

Spray-solution preparation is the first step of the spray-drying process in which all the components—drug, polymer, and any additional excipients—are dissolved in solution prior to atomization. A number of considerations during this step can impact SDD quality attributes and processability. These include: (1) the solvent choice; (2) the solution composition and solids content (ie, API, polymer, and excipient concentration); (3) solution rheological properties (eg, viscosity, surface tension, and density); (4) chemical stability (of spray solution, including solvent); (5) polymer conformation; (6) solution mixing (especially for processes in which the spray solvent is heated to facilitate dissolution of components and increase organic solubility); and (7) spray solution stability. Selection of the spray solvent is very important for generation of SDDs with desired stability and material properties. The key considerations during selection of the spray solvent were covered in the previous section.

The achievable spray solution concentration is largely dependent on the solubility of API in spray solvent because the solubility of common SDD polymers is sufficiently high in common spray solvents. Typically, spray solution solids concentration ranges from 2–20% w/v. The spray solution concentration has a direct impact on its rheological properties and thus, the droplet formation and drying. Increase in spray concentration generally results in bigger and denser particles. This is due to higher spray solution viscosity, less liquid to evaporate, and lower diffusion of solutes within the droplet. In contrast, dilute spray solutions typically results in smaller and lower density particles.[70] However, an increase in the spray concentration can result in phase separation, while lower spray concentration can increase hygroscopicity (and hence physical instability) due to higher effective surface area of the SDD.[70,73] Therefore, when developing a spray-drying process, the impact of spray solution concentration of droplet size, drying, and SDD physical stability and performance should be evaluated.

The spray-drying process can take several hours to days, depending on the manufacturing scale. Therefore, it is important to establish the stability of spray-solution for an appropriate duration (generally several days) and temperature range. The spray solution hold-time should cover manufacturing time and additional time to cover unforeseen issues that might arise during manufacturing. Chemical stability of the API in the presence of other spray solution components (polymer, excipients, and solvent) is generally of highest concern. The likelihood of API degradation due to reactive impurities is high because all components are in solution. In addition to chemical stability, physical instability due to API form change (eg, solvate formation), polymer aggregation should be monitored. The spray solution temperature should be properly controlled or their impact understood because small changes in temperature can impact stability and rheological properties (and thus, SDD powder properties). Physical stability and degradation kinetics of spray solution at various temperatures should be evaluated during lab stability studies to enable hold-time for spray solution.

30.4.2 Warm and hot spray drying processes

Drugs with high T_m values can have limited solubility in organic spray solvents, resulting in a spray-drying process with unacceptably low throughput, as well as the production of particles with poor properties (eg, small size). To efficiently process such high-T_m compounds, the temperature of the spray solution can be increased to increase the solubility of active in the spray solvent. In some cases, only a modest increase in the solvent temperature—such that the solvent is still below its boiling point—is required. This is known as a "warm process." In other cases, especially where a large enhancement in solubility is required, the spray-solution temperature is increased to well above the ambient-pressure boiling point of the solvent.[79] In this high-temperature spray-drying "hot process" the drug is dissolved immediately before it is introduced into the spray-dryer, as shown in Fig. 30.8. The drug suspension is constantly stirred to ensure homogeneity and an in-line heater exchanger is used to heat the suspension above the solvent boiling temperature. The pressure of the solution is controlled to prevent the solution from boiling before it exits the heat exchanger and is fed through the spray nozzle. Typically, the temperature is chosen so that the concentration of drug is 30–50% of the solubility of the drug in the spray solvent at that temperature to ensure production of homogenous particles. A flash nozzle is typically used to achieve solution atomization.[80,81] The drying resulting from the hot process is generally faster than for the standard

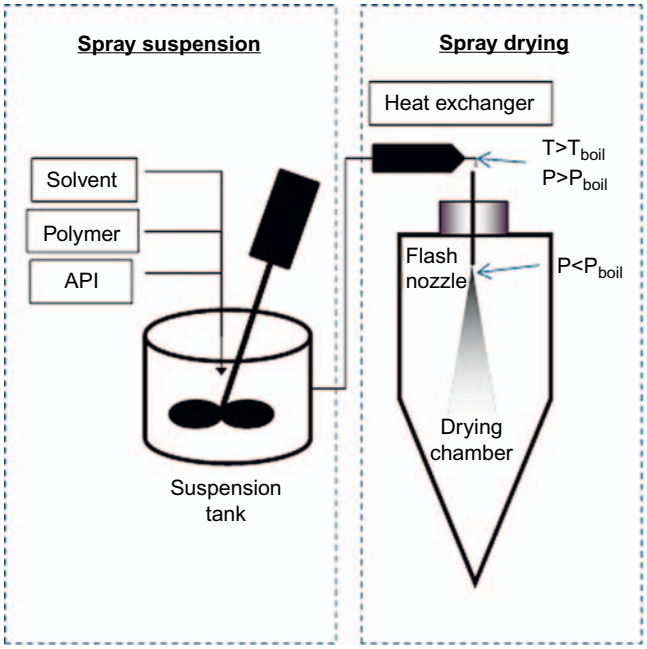

FIGURE 30.8 Schematic of SDD manufacture by hot process (*T*, temperature; *P*, pressure).

spray-drying process, resulting in shorter solidification times for the particles; which can be advantageous for making homogeneous dispersions.

30.4.3 Atomization and drying of spray solutions

The spray-drying process starts with atomization of the spray solution into droplets, which dry when they contact heated gas in the drying chamber. Atomization of the spray solution depends on (1) spray-solution flow rate and pressure, (2) nozzle geometry, and (3) spray-solution viscosity and surface tension. Drying of the atomized droplets depends on (1) droplet size, (2) inlet temperature, (3) outlet temperature, (4) relative saturation at the spray-dryer outlet, (5) and the specific drying ratio (ie, the mass ratio of liquid to drying-gas flow rate). These steps and process variables are described next.

30.4.3.1 Atomization

The purpose of atomization is to convert the spray solution into fine droplets. The resulting increase in the surface area improves efficiency for heat and mass transfer, promoting rapid drying of droplets in the spray-drying chamber. Due to rapid atomization, the drying material never reaches the inlet temperature of drying gas, which makes spray drying a method of choice for heat-sensitive APIs. SDD composition and process can be tuned to allow control of particle size and morphology.[75,82]

Atomization of the spray solution is achieved by using scale-appropriate spray nozzles. There are several types of spray nozzles including: (1) rotary atomizers, (2) two-fluid or pneumatic nozzles, (3) pressure nozzles, (4) ultrasonic nozzles, and (5) flash atomizers.[83,84] Rotary atomizers (disk or wheel type) achieve atomization by discharging liquid from the edge of a wheel rotating at high speed (ie, 10,000–50,000 rpm). These nozzles, which have a spray angle of about 180 degree, are generally used in wide-diameter spray-dryers at large scale. Rotary nozzles typically produce droplets in the range of 20–200 μm, with the droplet size being inversely proportional to the disk or wheel speed. The high energy provided by the rotary nozzles makes them ideal for atomizing slurries, suspensions, and high-viscosity solutions. Two-fluid or pneumatic nozzles use pressurized gas to break the liquid feed into small droplets. These nozzles typically produce droplets in the range of 5–75 μm. These nozzles provide very good control over the droplet size because the spray-solution feed rate and gas flow rate can both be controlled independently. One disadvantage of these nozzles is that the use of pressurized gas for atomization can limit their use at industrial scale.

Pressure nozzles generate droplets by pressurizing the spray solution and forcing it through a nozzle orifice. These nozzles generally include a chamber or swirl insert that imparts swirling motion to the liquid inside the chamber. The swirling motion pushes the liquid to the wall in a hollow sheet, leading to the desired hollow cone spray pattern when the spray solvent is ejected. These nozzles typically produce droplets in the range of 30–200 μm. The droplet size is inversely proportional to the atomization pressure and directly proportional to the spray-solution feed flow rate. However, these two parameters are interdependent because an increase in atomization pressure also increases spray-solution feed-flow rate. The drawback of this interdependency can be overcome with the multitude of commercially available nozzle geometries.

Ultrasonic nozzles produce droplets in a fine mist spray using high-frequency sound vibrations (ie, 20–120 kHz). The liquid spreads over a vibrating small horn after exiting the nozzle orifice, generating a uniform, narrow droplet-size distribution ranging from 20 to 100 μm in a low-velocity spray. However, the limited throughput of these nozzles limits their use at commercial scale. Flash atomization occurs when a solution that is heated above the boiling point at ambient temperature reaches the equilibrium vapor pressure. Boiling and nucleation can start and the energy from this process drives droplet formation.[80] Flash atomization is not often used for SDD atomization, although it is preferred while using the hot process.

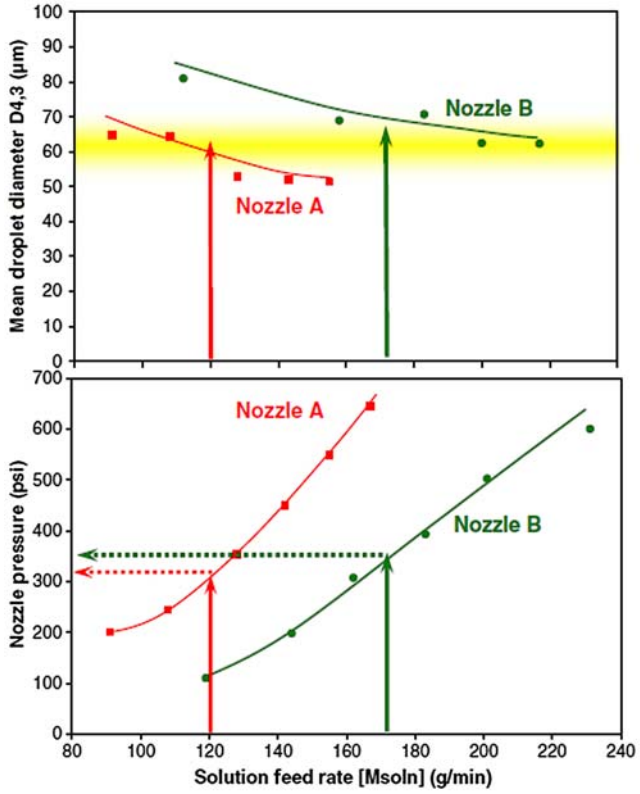

FIGURE 30.9 Results of phase doppler particle analyzer (PDPA) testing, showing representative droplet diameters and nozzle pressures as a function of solution feed rate. *Source: From Dobry DE, Settell DM, Baumann JM, Ray RJ, Graham LJ, Beyerinck RA. A model-based methodology for spray-drying process development. J Pharm Innov 2009;4:133–42. Published with permission of Springer.*

The choice of atomizer is dictated by the spray-dryer scale, solution properties, throughput, and desired particle-size distribution. In SDD production, pressure nozzles are preferred for their (1) ease of use and cleaning, (2) robust operation, (3) ability to handle variety of feeds with broad rheological properties, (4) narrow droplet-size distribution, and (5) scalability. Pressure nozzles have been well studied and characterized.[85] The size of the dried particle is directly correlated with the size of the droplet and the solids content of the spray solution, as described by Eq. (30.5)[86]:

$$D_{\text{particle}} \cong D_{\text{droplet}} \times \sqrt[3]{x_{\text{solids}} \times \frac{\rho_{\text{droplet}}}{\rho_{\text{particle}}}} \qquad (30.5)$$

where D_{particle} is the diameter of the dried particle; D_{droplet} is the diameter of the droplet; x_{solids} is the mass fraction solids in the spray solution (ie, API, polymer, and excipient concentration); ρ_{particle} is the density of the dried particle; and ρ_{droplet} is the density of the spray solution. This relationship assumes a solid sphere morphology of a fixed density.

Droplet size can be measured experimentally with a phase Doppler particle analyzer (PDPA), using either the actual spray solution or a placebo solution with matching rheological properties. Fig. 30.9 shows representative droplet sizes produced using two pressure nozzles at various atomization liquid pressures and solution feed rates.[86] Such data can be used to select a nozzle and atomization parameters that yield the desired particle-size distributions.

30.4.3.2 *Drying*

Particle are formed during spray-drying by atomizing the feed solution to form droplets and subsequent drying of the droplets. The atomized droplets mix with the drying gas maintained at the appropriate temperature and humidity to dry the solvent from the droplets. To maximize the heat and mass transfer, the atomizer and drying-gas inlets are positioned at the top of the drying chamber and liquid spray-solution feed and drying-gas flow are cocurrent. As the droplets begin to dry, a film forms around the outer edges of the droplet in a process known as "skinning." As drying progresses, the remaining solvent is driven off, increasing the solid density and generating the SDD particle. Following drying of the solvent, a particulate aerosol forms. Depending on the gas flow, these particles may recirculate in the drying chamber for some time before exiting into a cyclone separator and/or bag filtration system for separation of the solid SDD particles from the drying gas. The drying gas that exits the spray-dryer must be filtered to avoid contamination.

On larger pilot-scale and commercial systems, the drying gas then continues through a condenser unit, which removes much of the solvent vapor. The drying gas is then reheated and continuously recycled for the spray-drying process. Process parameters that have a large influence on the properties of the spray-dried SDD particles include: (1) the solids content of the spray solution; (2) the drug–polymer ratio; (3) the properties of the drug and polymer; (4) drying rate; (5) the outlet temperature of the spray-dryer; and (6) the identity and relative saturation of the spray-drying solvent.

30.4.3.3 *Scale-up considerations*

Improper atomization and drying can lead to a number of issues during spray drying, some of which are mentioned next.

30.4.3.3.1 Atomization

Improper atomization can lead to undesired droplet sizes, SDD particles with undesirable properties, and dripping of spray solution. Improper atomization conditions can produce droplets that are too small or too large. Small droplets will result in SDD with a large fraction of fines (small particles less than $\sim 5\,\mu m$) and poor flow properties. Large droplets are difficult to dry because they possess enough momentum to escape the gas whirl and deposit on the equipment

walls. Insufficiently dried material can phase-separate and be physically instable. Another issue with improper atomization is filament formation, which can happen if the viscosity of the spray solution is too high or if atomization energy is too low.

30.4.3.3.2 Product accumulation

Product accumulation on the walls of the equipment (eg, spray-drying chamber, cyclone, collection bags, ducts, filters) is a common issue. Product buildup is related to nonoptimal spray-drying parameters and may result in wet SDD with a higher residual-solvent content and lower T_g. The problem can be mitigated by optimizing the process conditions—for example, by either reducing the spray-dryer outlet temperature or by reducing outlet relative saturation by reducing condenser temp or reducing solution feed rate.

30.4.3.3.3 Bearding

Buildup of the product on the nozzle tip and around the nozzle (also known as bearding) is another common issue. Bearding can interfere with spray formation and droplet size—and, thus, product quality—and can clog the nozzle A number of approaches to overcome bearding, including repositioning the nozzle, changing the atomization conditions, using an additional gas stream concentric to the nozzle tip, and using an antibearding cap.

30.4.3.3.4 Condensation

Relative saturation of the drying gas can be significant when operating in recycle mode, particularly if water is used as a cosolvent. Condensation in the spray-drying chamber should be avoided by selecting conditions that will not encroach on the dew point, particularly as the drying gas leaves the insulated spray-drying chamber. During its transit, the drying gas may cool down further from the target process conditions.

30.4.4 Secondary drying

After spray-drying, the solid particles in the drying chamber may contain significant residual solvent, The residual solvent content of this so-called "wet" SDD must be reduced to a concentration below the ICH guideline.[69] Removal of residual solvent is also desirable because the presence of this solvent can plasticize the SDD and lower its T_g, leading to phase separation of the API and polymer.

Residual solvent is removed using the secondary drying process. This commonly involves vacuum desiccation at small scale, and tray-drying or agitated vacuum drying at larger scales. Agitated vacuum drying can, at least in principle, cause SDD particle attrition, which can affect powder properties and subsequent downstream processing into solid dosage forms.[68] Therefore, it is useful to understand the secondary drying mechanism and kinetics, as well as how the drying process affects the SDD particle quality attributes.

Hsieh et al. recently elucidated the fundamental drying mechanisms, developed a mathematical mass-transfer model, and used this model to predict the fate of organic solvents and solvent-related impurities, such as benzene in SDD products.[87] The authors concluded that the kinetics of solvent removal during secondary drying follows a Fickian diffusion model described by:

$$\frac{M_t}{M_0} = \sum_{n=0}^{\infty} \frac{8}{(2n+1)^2\pi^2} \exp\{-(2n+1)^2 t\beta\} \qquad (30.6)$$

and

$$\beta = \frac{D\pi^2}{4l^2}$$

where M_t is the weight of solvent in the SDD product at drying time t, M_0 is the weight of solvent in the wet SDD before secondary drying, n is an integer, and β is the diffusion parameter that is described by the diffusion constant (D) and diffusion length (l). The ratio of M_t to M_0 represents the fraction of solvent remaining in the wet SDD. As shown in Fig. 30.10, at the beginning of the diffusion ($t = 0$), the ratio of M_t to M_0 equals 1, and when the solvent is completely removed

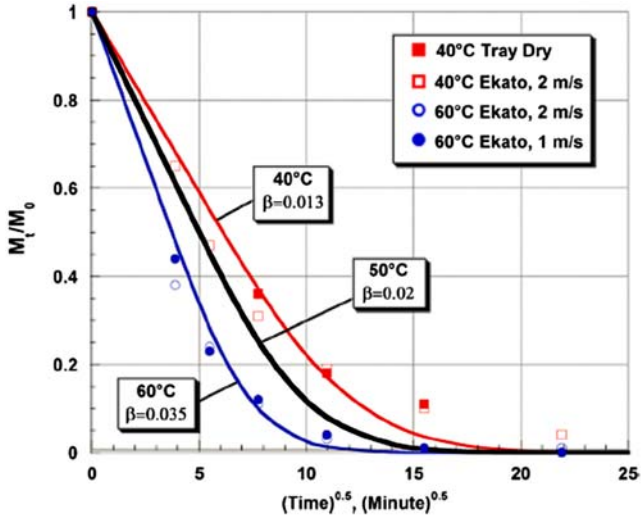

FIGURE 30.10 Representative results for scale-up of a secondary-drying process at various temperatures and drying scales for SDD particles. Conditions: SDD particles dried using a tray dryer and an Ekato agitated-vacuum dryer at 1 and 2 m/s. *Source: From Hsieh DS, Yue H, Nicholson SJ, Roberts D, Schild R, Gamble JF, et al. The secondary drying and the fate of organic solvents for spray dried dispersion drug product. Pharm Res 2015;32:1804–16. Published with permission of Springer.*

from the wet SDD, the ratio equals 0. For a given value of M_t/M_0, the secondary drying time will increase with diffusion length (l) and decrease with increase in the diffusion coefficient (β). Authors demonstrated that the diffusion coefficient can be sensitive to the secondary-drying temperature, depending on the relationship between T_g and the residual-solvent content of the SDD.

When a mixture of solvents (A and B) is present in a wet SDD, the relative diffusion rate of the two solvents can be described by Eq. (30.7). Where α_{AB} is the relative diffusion rate of Solvents A and B, β_A and β_B are the diffusion coefficients of Solvents A and B, D_A and D_B are the diffusion constants for Solvents A and B, and l^2_A and l^2_B are the diffusion lengths of Solvents A and B. Assuming that both solvents have the same diffusion length, the relative diffusion rate (α_{AB}) is simply the ratio of the diffusion coefficient of Solvent A (β_A) to the diffusion coefficient of Solvent B (β_B). This equation can also be applied to predict the fate of residual-solvent impurities in the primary spray solvent during the secondary drying process. Using this model, Hsieh et al. successfully predicted levels of residual benzene, an impurity in methanol, during the spray-drying process.[87]

$$\alpha_{AB} = \frac{\beta_A}{\beta_B} = \frac{D_A l_B^2}{D_B l_A^2} = \frac{D_A}{D_B} \tag{30.7}$$

30.4.5 SDD process and impact on bulk material properties

SDD material properties, such as SDD particle-size distribution, particle density, and morphology and derived properties such as flow, bulk density, and compressibility are dependent on SDD feed solution composition (API-polymer ratio, polymer chemistry, solvent, spray solution solid content) and SDD process parameters (droplet size, drying rate, and secondary drying).[88] As described previously, particle formation during spray-drying is achieved by atomizing the feed solution to form droplets, the size of which are dependent on the nozzle type, spray pressure, spray rate, and feed-solution viscosity, density and surface tension.[89] As the droplets begin to dry, a film is formed around the outer edges of the droplet in a process known as "skinning." As drying progresses, the remaining solvent is driven off, increasing the solid density and thereby creating void space within the SDD particle. The properties of API and excipients and the drying rate of the process determine the morphology of the SDD particles, which can range from hollow spheres to more dense, raisin-like structures.[75,90] Fig. 30.11 shows the tensile strength of particles as a function of compression strength for SDD dried at three sets of conditions. The scanning electron micrography (SEM) images show the effect on particle

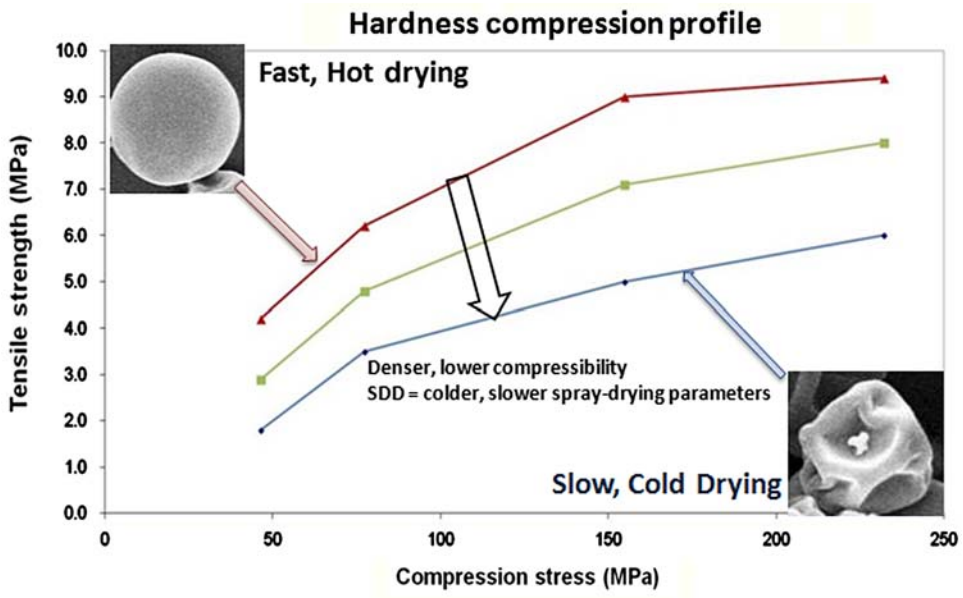

FIGURE 30.11 Effect of spray-drying conditions on SDD particles, showing tensile strength as a function of compression strength for three sets of conditions.

morphology for fast-hot drying conditions and slow-cold drying conditions.

Fig. 30.12 shows the effect of particle size on dissolution rate that can sometimes occur for SDDs prepared on different size spray-dryers (ie, laboratory, PSD-1, and PSD-2 scales). At the PSD-1 scale, SDD batches with two sets of solids contents are shown.

30.4.6 Scale-up considerations

When spray-drying processes are scaled up, the goal is often to maintain the SDD properties attained at small scale (eg, particle-size distribution, particle density and morphology, and the homogeneous amorphous state), while achieving the throughput needed for a later stage drug development program. Scale-up typically affects the atomization and droplet drying rates. In particular, as the spray-solution flow rate increases through a pressure-swirl nozzle, additional energy is needed to achieve the same droplet (and particle) size. The additional energy is provided by applying increased atomization pressure.

During scale-up, the droplet drying rate is affected by two main factors. First, droplet density in the spray plume increases due to the higher spray-solution flow rate. Second, larger dryers are typically run in "recycle mode," where a fraction of the spray solvent is condensed from the drying gas before being recycled through the dryer during subsequent passes. Because not all the solvent is removed in the condenser, the solvent level in the drying gas can be higher for large-scale processes than for small-scale processes, which are typically run using a single pass of the drying gas.

To match the particle characteristics of SDDs made at large scale with those made at smaller scale, it is helpful to develop correlations of droplet size to solution viscosity, nozzle characteristics, and atomization parameters (eg, pressure). To complement these measurements, thermodynamic mass-energy-balance relationships can be modeled that take into account relative and absolute gas and spray-solution flow rates, process input and output temperatures, and relative residual-solvent vapor levels to define the thermodynamic operating space. This space can be assessed within the context of process equipment and plant constraints (eg, inlet drying-gas temperature).

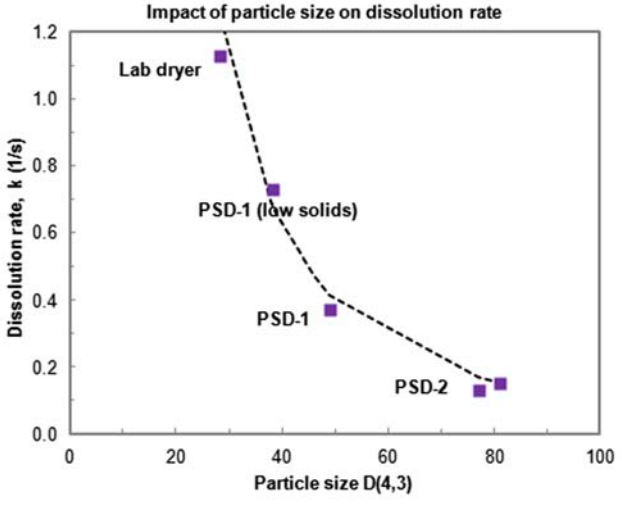

FIGURE 30.12 Effect of spray-drying scale and solids content on SDD particles, showing dissolution rate as a function of particle size.

30.5 SDD CHARACTERIZATION

A number of tools and techniques are available for characterizing SDD attributes including those shown in Table 30.4. These include tests for assessing physical characteristics, physical and chemical stability, powder properties, and in vitro dissolution performance.

30.5.1 Physical characteristics

Table 30.4 lists common analytical tools and techniques typically used to assess key physical properties of the SDD. These techniques range from particle properties (eg, size, morphology, density, wall thickness, hygroscopicity), the physical state of matter and stability (eg, dispersion homogeneity, crystallinity, propensity to crystallize, T_g, T_c).

30.5.2 Speciation testing

When dispersed in an aqueous environment, SDDs generally provide higher dissolved-drug concentrations than crystalline forms of the API because of the higher free energy of the amorphous form relative to the crystalline form. In addition, SDDs can produce drug–polymer colloids that can influence drug absorption. The mechanism and rate of SDD disintegration/dissolution and the relative abundance of various drug-containing species depends on (1) the drug properties; (2) the absolute and relative concentrations of the drug, polymers, and any other excipients in the SDD; and (3) the properties of the dissolution medium (eg, pH, the presence and abundance of bile-salt micelles).

Although the mechanism of drug release from SDDs can be complex, there are two mechanistic limits of SDD dissolution: (1) the rapid separation of drug- and polymer-rich phases, and (2) surface erosion, as shown in Fig. 30.13. In the former case, ingress of water induces a phase separation in which the SDD disintegrates into two or more phases, one of which tends to be drug–polymer colloids that are typically rich in drug relative to the initial SDD composition. These resulting drug-rich polymer colloids typically

TABLE 30.4 Analytical Techniques to Assess Performance of SDDs

SDD quality attributes	Typical analytical tools	Comments
Physical state and stability (presence of crystalline API, phase separation)	Dissolution tests	
	Powder X-Ray (PXRD)	Quantifying crystal formation and polymorphism. Sensitive to >5 wt% crystal formation can go <1 wt% crystal formation with high resolution PXRD
	Scanning Electron Microscope (SEM)	Evaluating particle morphology changes such as fusing and crystallization. Qualitative observation of crystals, but very sensitive
	Polarized Light Microscopy (PLM)	Presence of crystalline API. Qualitative observation of crystals, but very sensitive
	Modulated Differential Scanning Calorimetry (mDSC)	Evaluate SDD homogeneity, measure T_g, T_c, and T_m. Most sensitive for phase separation
	Isothermal Calorimetry—Thermal Activity Monitor (TAM)	Measure phase separation and crystallization kinetics. Very sensitive, but dependent on sample size
	Fourier Transform Infrared Spectroscopy (FT-IR)	Quantifying crystal formation and polymorphism
	Raman spectroscopy	Quantifying crystal formation and polymorphism
	Solid state NMR (ssNMR)	Quantifying crystal formation and polymorphism
Potency	High Performance Liquid Chromotograph (HPLC)	Method dependent
	In-line spectroscopy tools	
Chemical stability (impurities and degradation products)	HPLC	Impurity and method dependent. Additional analytical techniques (eg, NMR, LC-MS), may be used for identification
Dissolution	Evaluate ability of SDD stability samples to maintain supersaturation and sustainment	Estimated to be reproducible to 10%
Water content	Karl Fischer	50–100 ppm for coulometric KF
Residual solvent	Gas chromatography mass spectrometry (GC-MS)	Solvent and method dependent
	Quantitative Nuclear Magnetic Resonance (qNMR)	
Particle size	Laser light scattering particle size analysis	Optical or laser diffraction methods
	G3-Morphologi	
Surface area	Gas adsorption analysis	
Bulk density and tap density	Scott's volumeter	
True density	Helium pycnometer	
Morphology	G3 Morphologi	Morphology, particle structure, wall thickness
	SEM	
Hygroscopicity	Moisture-sorption	

provide rapid dissolution of drug. In the latter case, the polymer and drug on the SDD surface both dissolve, releasing more or less free drug and free polymer into the medium. The two mechanistic models suggested here are limits, and any particular SDD may dissolve by some combination of "erosion" and "disintegration."

Drug species typically provided by SDDs upon disintegration/dissolution include freely dissolved or solvated drug, drug in bile-salt micelles, and drug–polymer colloids. Significant numbers of drug–polymer colloids are typically formed only when using amphiphilic polymers, such as HPMCAS. These

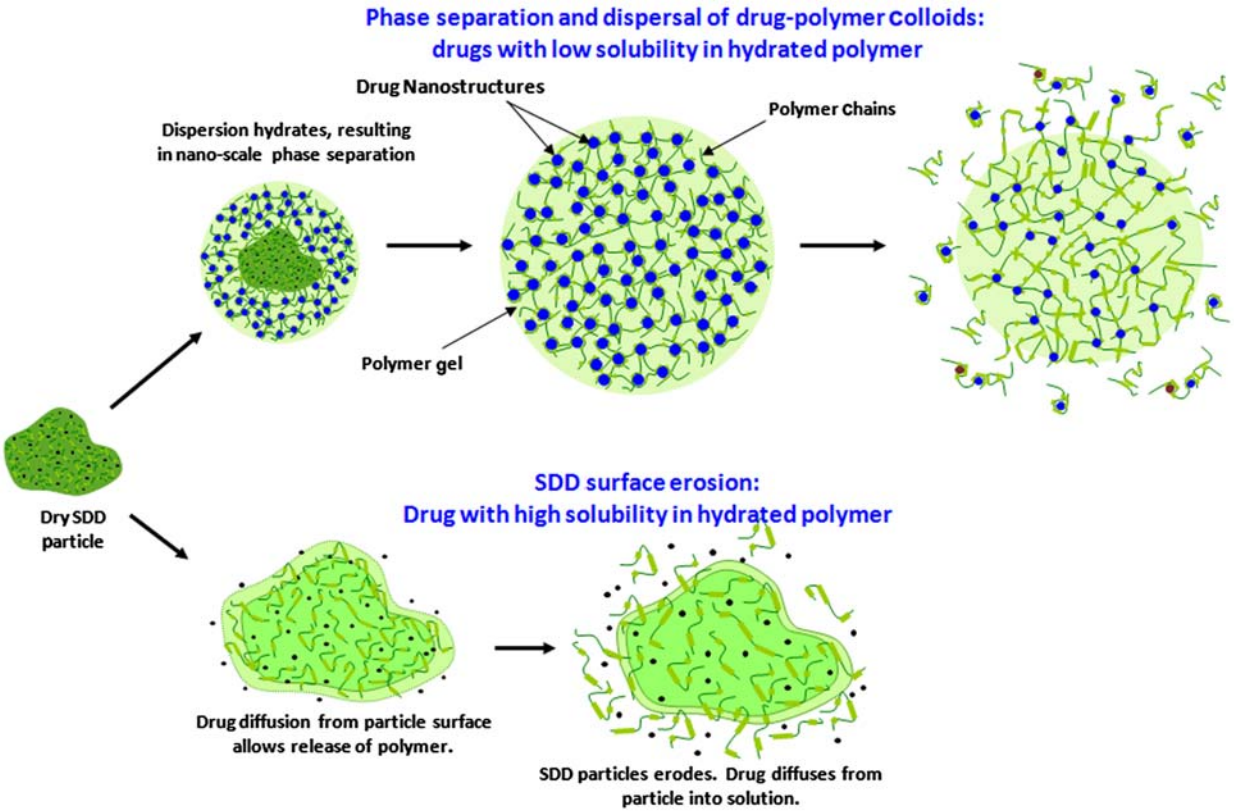

FIGURE 30.13 Two limits Of SDD dissolution mechanism: phase separation and dispersal of drug-rich polymer colloids (top) and surface erosion (bottom). *Source: Modified from Vodak DT, Morgen M. Design and Development of HPMCAS-Based Spray-Dried Dispersions. In: Shah N, Sandhu H, Choi DS, Chokshi H, Malick W, editors. Amorphous Solid Dispersions. New York: Springer; 2014. p. 303–22.*

colloids are high-energy, high-surface-area species that can enhance absorption by rapidly resupplying freely dissolved drug and drug in bile-salt micelles in the small intestine.[32] In addition, depending on their size, these drug–polymer colloids may enhance absorption in situations where absorption is limited by transport of drug through the unstirred mucus boundary layer of the epithelium by serving as drug carriers that transit this boundary layer. The SDD drug speciation and absorption mechanism is shown schematically in Fig. 30.14. Table 30.5 shows the types of tests that are performed to determine the drug species present.

30.5.3 In vitro dissolution testing

The general strategy behind solubilization technologies is to create a supersaturated solution and maintain the supersaturation long enough for drug absorption to take place in the intestine. Therefore, the main performance criteria for an SDD in in vitro testing are often rate, extent, and sustainment of dissolution in biorelevant aqueous media, such as simulated gastric fluid (SGF) or simulated intestinal fluid (SIF). Fig. 30.15 shows a representative dissolution-performance test plot showing the enhancement in drug concentration enabled by SDDs.[91] A number of in vitro dissolution tests have been used to assess performance, some of which are described next.

The solubilization performance of SDDs can be assessed in vitro using a wide variety of dissolution testing apparatuses and procedures. Dissolution testing often consists of, or is coupled with, additional analytical methods that lend insight into the SDD performance. Such methods are often aimed at determining the species of drug present, and ideally providing time-concentration profiles of the drug-containing species shown in Eq. (30.8). Where $[D_{total}]$ is total drug concentration, $[D_{free}]$ is free drug, $[D_{micelles}]$ is drug in bile-salt micelles, and $[DPN]$ is drug in drug/polymer nanoparticles.

$$[D_{total}] = [D_{free}] + [D_{micelles}] + [D_{PN}] \qquad (30.8)$$

An example of a performance-indicating in vitro test has been used by the authors is a small-scale dissolution test based on centrifugation to separate drug species. In this so-called "microcentrifuge test," SDD powder is added to a biorelevant medium in a

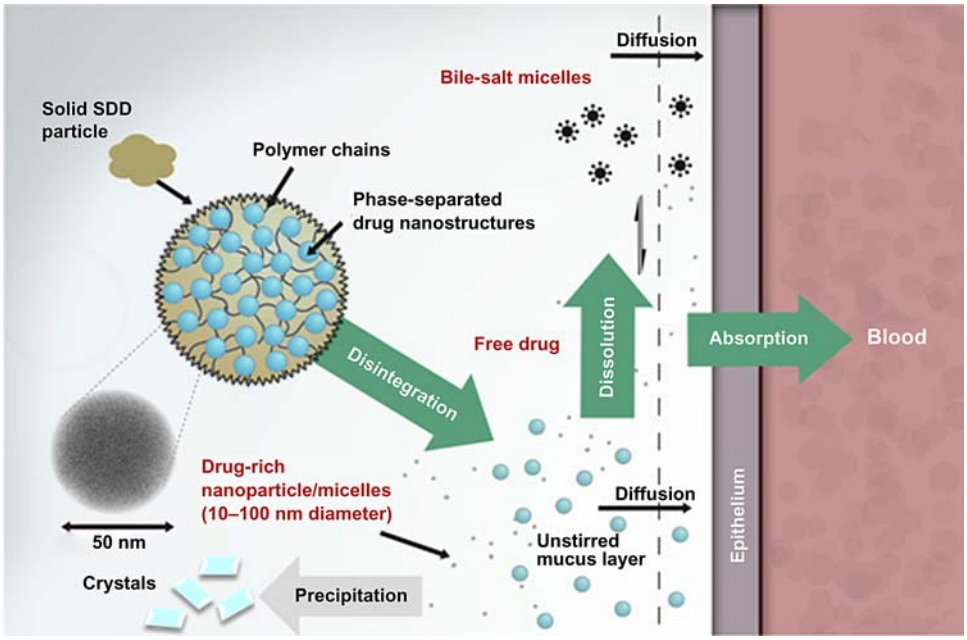

FIGURE 30.14 Schematic of SDD bioavailability enhancement, showing typical drug-containing species and absorption mechanisms.

TABLE 30.5 Drug Species During SDD Dissolution and Tools to Characterize Them

Drug species	Importance	In vitro determination
Undissolved drug or precipitate	• Source for high-energy drug • Evidence for conversion to low-energy form	• Microcentrifuge dissolution test • Collection and analysis of solids from solution (eg, potency, powder X-ray diffraction (PXRD))
Drug–polymer assemblies (ie, colloidal drug species or nanoaggregates)	• Relatively mobile source of high-energy drug	• Microcentrifuge dissolution test • Ultracentrifugation • Dynamic light-scattering (DLS) analysis
Drug in bile-salt micelles (or other micelles sourced from formulation)	• Highly mobile (mass transfer across unstirred boundary) • Critical in bioavailability of lipophilic compounds	• Partition coefficient determination • Microcentrifuge dissolution test • Membrane permeability test • Equilibrium solubility measurements • NMR and/or ultracentrifugation
Freely dissolved drug	• Highly mobile (mass transfer across unstirred boundary) • Driver for permeability • Driver for bile-salt micelle partitioning	• Membrane permeability test • Equilibrium solubility measurements • NMR and/or ultracentrifugation

microcentrifuge tube and vortexed to make a well-mixed suspension. The suspension is then periodically centrifuged, and the supernatant is sampled and analyzed for drug. The measured drug concentration typically consists of all three species shown in Eq. (30.8), all of which can play a role in absorption.

Ultracentrifugation can often be used to separate the drug in colloids from dissolved drug and drug in micelles. This process tends to pellet such colloidal material, depending on the colloids size and density. To confirm pelleting of colloidal material, dynamic light-scattering (DLS) can be used to detect any remaining colloids in the supernatant after micro- or ultracentrifugation.

NMR spectroscopy is another complementary tool that can be used to measure the concentration of dissolved drug and drug in micelles. Typically, drug in colloids is not visible by NMR due to the relatively slow tumbling of colloids in solution relative to the NMR frequency.

Any precipitate that forms or remains during such dissolution testing can be collected and analyzed by a variety of methods. Polarized light microscopy (PLM) can often be instructive in determining whether the

drug has crystallized during the test. Powder X-ray diffraction (PXRD) can be used as a more definitive technique to determine whether crystalline drug is present in the precipitate and to verify the crystalline form. To avoid crystallization of dissolved drug during drying of PXRD samples, wet precipitates can be collected and quickly frozen and lyophilized.

A second type of dissolution performance test that can be done at the small scale is a membrane-permeation test in which the SDD is placed in a biorelevant aqueous medium (eg, SIF) on one side of a semipermeable membrane and the concentration of drug in a permeant on the other side of the membrane is measured. The authors have used a polypropylene membrane treated to make the feed surface hydrophilic and used a low-volatility organic or an aqueous phase in which the drug is highly soluble as the sink or permeant.

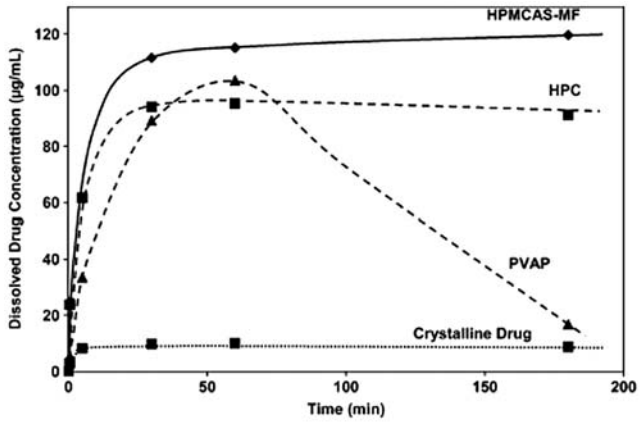

FIGURE 30.15 Dissolution performance of SDDs made with Compound 2 and various polymers, at 50% drug loading. Dissolution was carried out using the syringe dissolution test in MFDF at 37°C, with a 500 μg/mL total concentration (dissolved plus undissolved drug). *Source: From Curatolo W, Nightingale JA, Herbig SM. Utility of hydroxypropylmethylcellulose acetate succinate (HPMCAS) for initiation and maintenance of drug supersaturation in the GI milieu. Pharm Res 2009;26:1419–31. Published with permission of Springer.*

The dissolution test methods described previously are typically a sensitive measure of SDD performance and can be done at various stages of drug development for a variety of purposes. Early in formulation development, such testing can be done to screen various formulations to rank the performance of SDDs made with different polymers, drug loadings, or various other excipients, such as surfactants. At later stages of development, dissolution testing can be used to confirm the robustness of SDD manufacturing scale-up by comparing the performance of SDDs made at larger scales with those made early on at smaller scales. For example, the particle-size distribution can increase as the process is scaled from the smallest spray-dryers, producing larger SDD particles with reduced dissolution performance for some SDDs, as shown in Fig. 30.16.

Dissolution testing is often performed on an SDD after accelerated aging studies (eg, storage at high temperatures and humidities) to predict the long-term physical stability of the formulation. The dissolution performance is typically very sensitive to fusing of SDD particles, drug crystallization, or amorphous phase separation. Finally, the speciation data obtained from the comprehensive dissolution studies described previously can be used as inputs to mechanistic physiologically based pharmacokinetic models to predict oral absorption of various SDD formulations relative to each other and other formulation approaches.

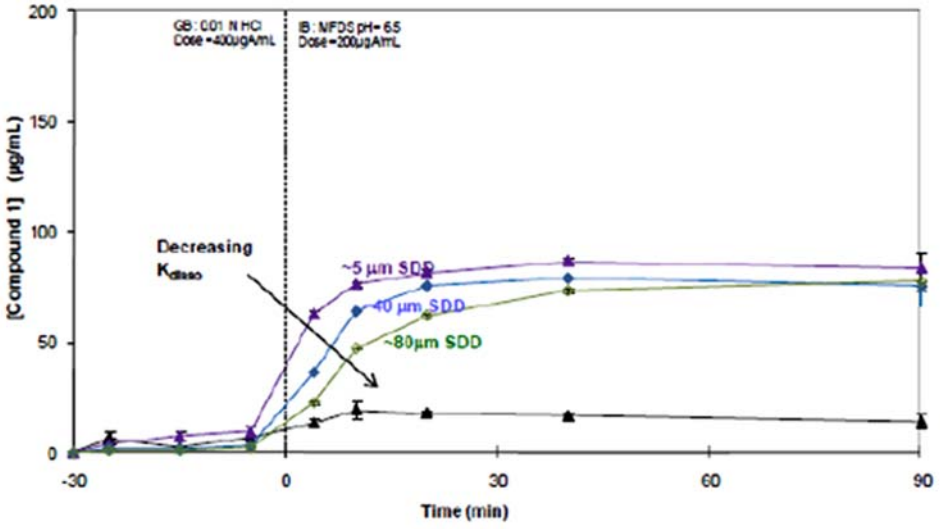

FIGURE 30.16 Dissolution test results showing the impact of larger particle sizes on dissolution performance in a SGF/SIF transfer test. Conditions: SGF = 0.01 N HCl at 400 μgA/mL, SIF = DEFINE at 200 μgA/mL.

TABLE 30.6 Purposes of Typical Dissolution Tests, Uses, and Outputs

Purpose	When	Scope	Output
Formulation screening	SDD feasibility	Dissolution in SGF-SIF and SIF, free drug and dynamic light scattering	Rank ordering of SDD performance
Process robustness	Scale-up or change in process	Differences in rate, C_{max}, or AUC with process/scale change	Performance risk with increasing scale, particle size, or process parameters
Physical stability	Advanced SDD screening or IND supporting stability	Differences in rate, C_{max}, or AUC relative to SDD physical stability during accelerated aging	Performance risk related to physical or chemical changes with long-term storage
Mechanistic absorption model	SDD feasibility	Dissolved, micellar, and colloidal drug levels SGF-SIF vs. SIF alone	Time-concentration profile of drug species that are inputs for oral absorption model—level of sophistication fit for purpose

SGF—Simulated Gastric Fluid.
SIF—Simulated Intestinal Fluid.
SGF-SIF—A two step transfer dissolution method.
C_{max}—Maximum concentration.
AUC—Area Under Curve.

Table 30.6 summarizes the various applications for dissolution testing and the key output from such tests.

30.5.4 Physical/chemical stability during storage as suspension or powder

The physical and chemical stability of the SDD during short- and long-term storage is important. As high-energy solid forms, SDDs can be prone to physical instability, including amorphous phase separation or drug crystallization. Likewise, due to the lack of crystalline order, the drug in an SDD can sometimes be more prone to chemical degradation than when in crystalline form. The increased susceptibility of amorphous drug forms to chemical degradation makes it important to assess the compatibility of the API with the SDD excipients, particularly the polymer. In addition, it may be necessary to use additives, such as antioxidants, to protect APIs that are susceptible to specific mechanisms of degradation.

The typical two modes of physical instability—amorphous phase separation and drug crystallization—are shown schematically in Fig. 30.17. Drug crystallization often follows after separation of amorphous domains has occurred because once amorphous domains of pure or enriched drug phases have formed, less drug mobility is needed for crystallization to occur.

Phase separation in SDDs is driven by molecular mobility of the polymer matrix and drug within the matrix. One indicator of the molecular mobility is the difference between T_s (Storage Temperature) and T_g. As the T_s approaches the T_g of the SDD, mobility increases, viscosity decreases, and the time to phase separation, including crystallization decreases.

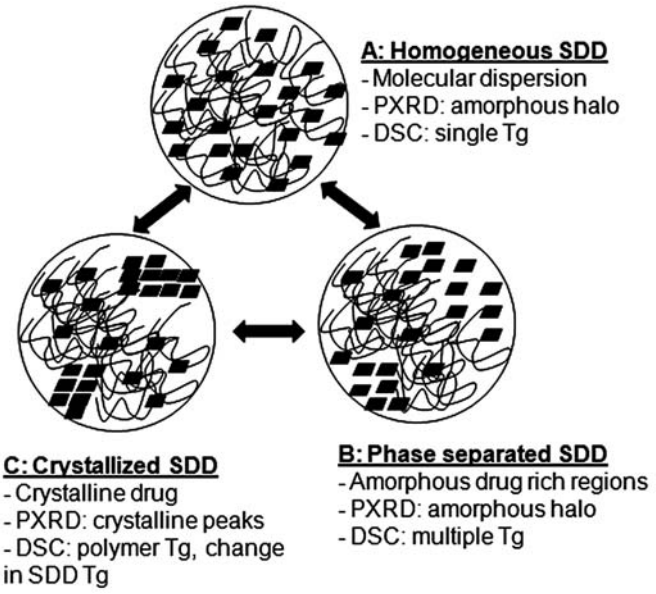

FIGURE 30.17 Possible structures of SDDs where curvy lines and parallelogram symbol represent polymer and drug, respectively. A is homogeneous molecular dispersion, B is phase-separated SDD containing amorphous-rich drug region, and C is crystallized SDD containing crystalline drug. *Source: Adapted from*[14] *Huang Y, Dai WG. Fundamental aspects of solid dispersion technology for poorly soluble drugs. Acta Pharm Sin B 2014; 4:18–25.*

Since water can plasticize the SDD lowering the T_g, it is useful to understand SDD physical stability as a function of RH.

Early in a SDD-development program physical stability predictions of the SDD are often based on T_g versus RH curves (Fig. 30.18). It is assumed that if T_g values are significantly higher than the anticipated

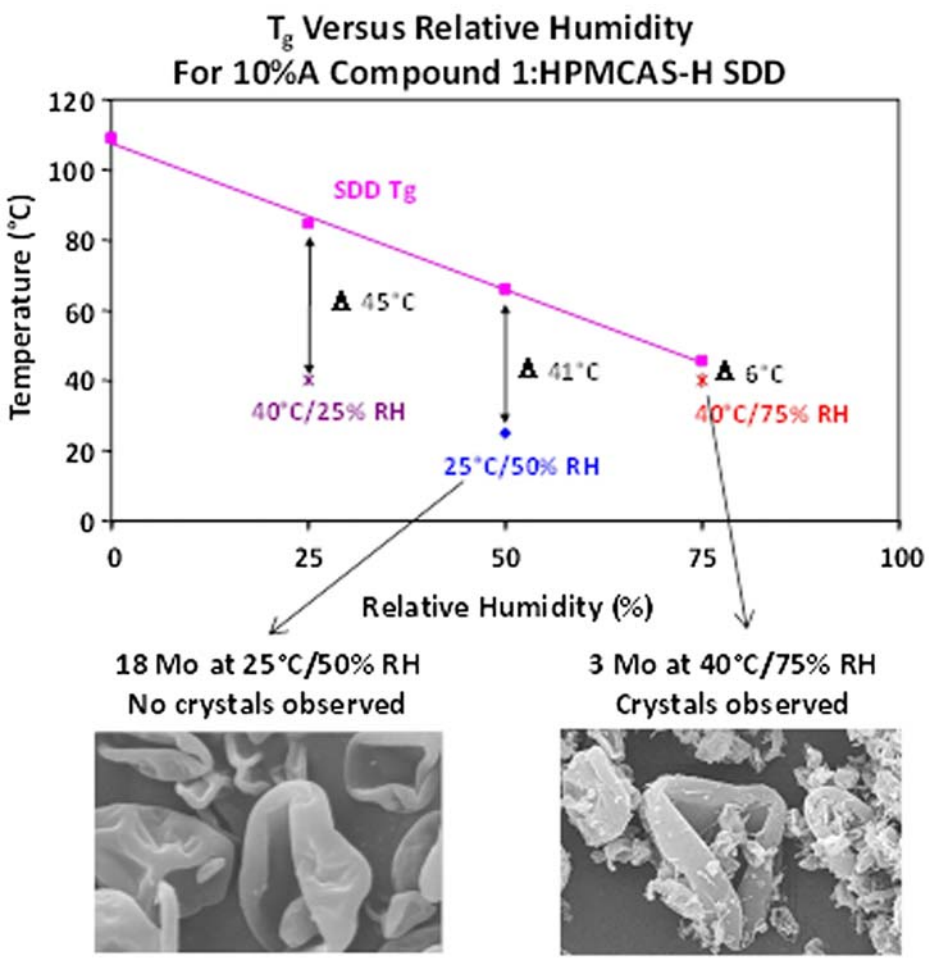

FIGURE 30.18 T_g versus RH for an example 10%A HPMCAS SDD.

T_s, physical stability will be acceptable. For SDDs with a T_g close to or below the anticipated T_s, physical stability could become an issue. Historically, a good rule of thumb was that storage at 50°C below the T_g should result in good long-term physical stability.[38] This turned out to be a conservative metric with regards to ensuring a 2-year shelf life for SDD pharmaceutical products. In the example shown in Fig. 30.18, a 10%A HPMCAS SDD demonstrated good physical stability when stored for 18 months at 25°C/50% RH when the T_g was only 41°C above the T_s, whereas when stored at 40°C/75% RH (at a T_g 6°C above T_s), the SDD crystallized within 3 months.

Fig. 30.19 shows the fraction of SDDs that were found to be physically stable at 6- and 13-week time points as a function of $T_g - T_s$. The data, taken from a variety of development programs, suggest that when the T_g is well above T_s, the SDD has good stability. As the T_g drops relative to T_s, the risk of physical instability increases. In this instance, physical stability was defined as no significant change in thermal characteristics (by differential scanning calorimetry (DSC)), morphology (by SEM), or in vitro dissolution performance.

30.6 DOSAGE FORM CONSIDERATIONS

SDDs are amenable to administration in a wide range of dosage forms, including as a suspension or in a solid dosage form, such as tablets and capsules.

30.6.1 Aqueous SDD suspension formulations

It is becoming increasingly common to use aqueous SDD suspensions to support (1) animal safety and efficacy studies, where dose multiples are significantly higher than clinical doses; and (2) exploratory clinical studies as powder-in-bottle formulations. Typically, a suspending agent such as methyl cellulose is used to increase the viscosity of the SDD suspension to improve homogeneity and stability. Buffers, additional polymers, surfactants, and other excipients may be used to improve physical stability of the aqueous suspension.[92] Suspension formulations are generally prepared and administered within a short period of time, depending on physical and chemical stability. In many cases, it is possible to achieve suspension stability of

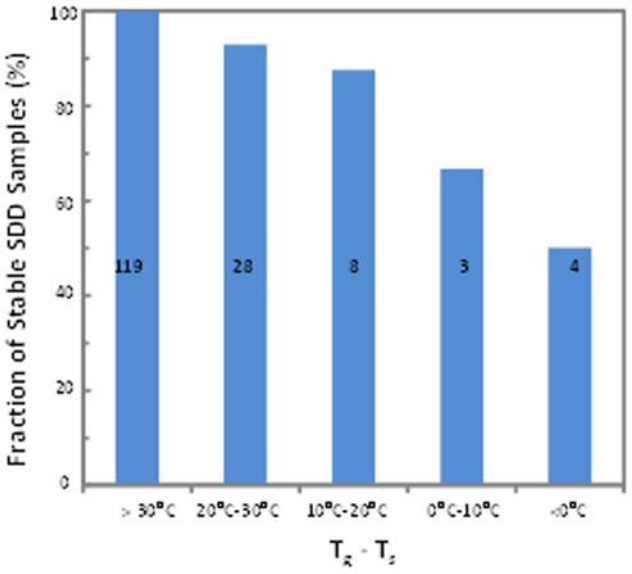

FIGURE 30.19 Fraction of SDDs that are Stable after storage for up to 13 weeks as a function of $T_g - T_s$. Key: Numbers in columns indicate the number of stability samples tested at 6 or 13 weeks for compounds transferred into good manufacturing practice (GMP) production. Stability is defined as no change in dissolution performance, thermal characteristics (by DSC) or morphology (based on SEM analysis) from that of initial samples.

TABLE 30.7 Typical Syringable Volume and Dose for SDD Formulations Prepared Using HPMCAS-M and 0.5% W/W Methocel E4M Premium as a Suspending Agent

SDD drug loading (%Active)	Maximum syringable concentration (mgA/mL)	Deliverable dose (mg/kg) at 10 mL/kg
10	17	167
25	50	500
33	75	749
40	100	1000
50	150	1500
75	450	4500

days to a week. Typical doses achievable in safety studies are shown as a function of API loading in the SDD provided in Table 30.7.

30.6.2 Solid dosage forms

Traditionally, immediate-release tablets are the most common solid dosage forms for SDDs, although capsule formulations have also been used. The dosage form should allow fast disintegration and release of native SDD particles in the stomach or small intestine. Designing the dosage form to quickly and uniformly disperse the SDD avoids the gelling and subsequent slow disintegration and release that is typically undesirable for bioavailability-enhancement applications.

For tablet formulations, the SDD is typically dry granulated (using roller compaction) or directly compressed. Wet granulation is usually avoided due to the risk of process-induced physical instability.

Some of the key considerations during tablet formulation development include: rapid disintegration, drug-excipient compatibility, physical and chemical stability during processing and storage, drug loading and maximum achievable dose, and choice of granulation/compression process.

One of the important considerations during solid-dosage-form development is the maximum unit strength, which is governed by the SDD loading in the solid dosage form and the API loading in the SDD (Fig. 30.20). For low-dose compounds, the strategy is generally to have a lower API loading in the SDD and a higher SDD loading in the tablet. For high-dose compounds, API loading in the SDD and the SDD loading in the tablet both must be maximized, which can result in performance and manufacturability risk for the SDD and tablets. Some of the constraints to consider are the maximum tablet size allowed, the effect of SDD loading in tablet on dissolution, and the effect of SDD material properties on tableting.

30.6.3 Effect of formulation and process on performance (physical, chemical, dissolution)

Although the impact of drug-product processing on crystalline API phase transformation is well-studied, there is limited literature describing the effects of solid-dosage-form processing on SDD stability. It is reasonable to expect that the physical stability of the SDD may be affected by the formulation composition and manufacturing process. Leane et al. recently demonstrated a marked difference in physical stability of ibipinabant SDD tablets (20/75/5 ibipinabant/PVP K30/SLS SDD, $T_g = 130$ºC, 5% w/w SDD in tablet formulation) in the presence of different fillers. Microcrystalline cellulose (MCC) provided the best stability profile and mannitol provided the worst, as shown in Fig. 30.21.[62] As expected, the physical instability (ie, crystallization of API in SDD) resulted in a corresponding decrease in dissolution rate. The authors attributed the higher stability achieved with MCC to the cushioning it provided during compaction, preventing fracturing of the SDD particles. Dhumal et al. had previously shown that the tablets manufactured with amorphous coprecipitate of celecoxib with PVP and carrageenan had better stability than tablets manufactured with amorphous celecoxib and an SDD

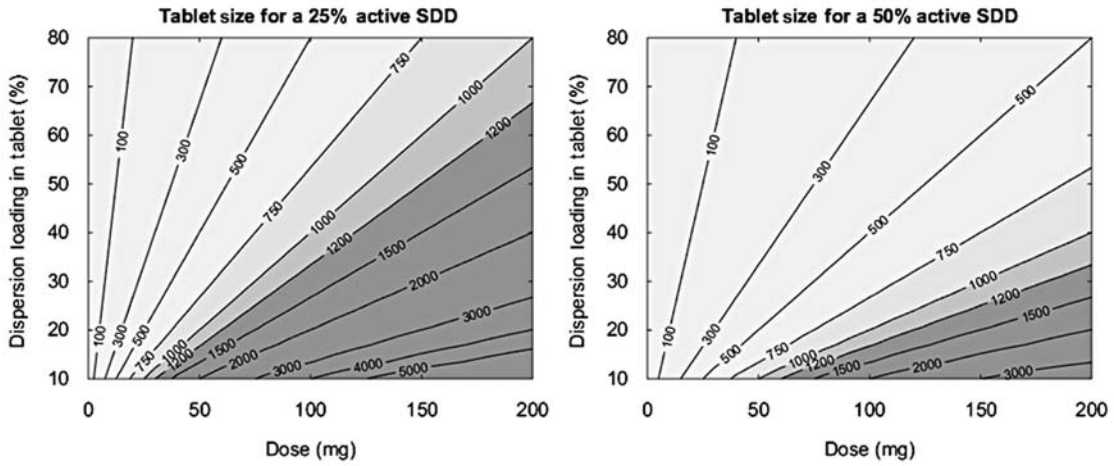

FIGURE 30.20 Effect of SDD loading in the tablet and dose on tablet size for 25%A and 50%A SDDs.

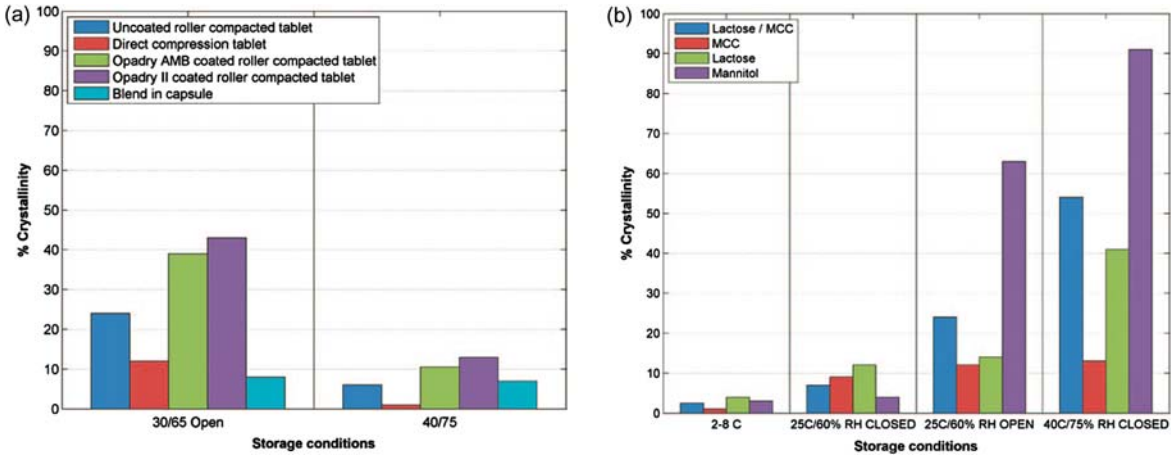

FIGURE 30.21 Raman results for formulations containing different excipients (a) and different processing conditions (b) following storage under controlled conditions for 3 months. *Source: From Leane MM, Sinclair W, Qian F, Haddadin R, Brown A, Tobyn M, et al. Formulation and process design for a solid dosage form containing a spray-dried amorphous dispersion of ibipinabant. Pharm Dev Technol 2013;18:359–66. Published with permission from Taylor & Francis Ltd., http://www.informaworld.com.*

of celecoxib with PVP.[93] The authors attributed the improved physical stability of the coprecipitate to the cushioning provided by the viscoelastic polymer carageenan and hydrogen-bonding interaction between celecoxib and PVP.

Crystallization of amorphous solids can involve bulk and surface crystallization. Surface crystal growth has been observed to be orders of magnitude faster than bulk crystal growth due to the enhanced surface mobility and energy of the drug molecules. An understanding of surface–surface interactions and the impact of excipients on surface crystallization is helpful in designing the SDD formulations because SDDs have an intimate contact with other excipients within a solid dosage form. Zhang et al. recently reported a simple microscopic method for studying the effect of common tablet excipients on the surface crystallization of amorphous drugs.[94] In this method, amorphous samples of the drugs were covered by excipients and stored in controlled environments and rates of surface crystal nucleation and growth were measured in real-time.

When considering the choice of excipients, excess manipulation (eg, compression, milling) during manufacture of the solid dosage form and exposure of the solid dosage form to moisture and heat during the coating process can lead to physical instability of SDD formulations.

30.7 CONCLUDING REMARKS

Amorphous SDDs are ideally molecularly dispersed mixtures of drug, polymers, and optionally, other

excipients (eg, surfactants, stabilizers). SDDs stabilize amorphous drug, resulting in reduced crystallization by inhibiting molecular mobility and reducing nucleation. SDDs typically provide higher apparent solubility and faster dissolution than bulk drug crystals, affording superior bioperformance for poorly soluble drugs. Spray-drying is a robust and scalable technology that has been successfully applied to a number of commercial products including Kalydeco (Ivacaftor), Incivek (Telaprevir), Intelence (Etravirine), and Zortress (Everolimus). On the basis of a literature survey, Newman et al. estimated that 82% of the amorphous dispersions showed improved bioavailability over a reference formulation.[13] SDDs of more than 500 different drugs showed 1.5- to 100-fold higher absorption than crystalline drug in various animal models. In humans, SDDs of 65 different drugs showed at least twofold higher relative bioavailability than the poorly absorbed control formulation. A high success rate in enhancing oral absorption of poorly absorbed compounds, versatility, good fundamental understanding, and availability of spray dryers that can make SDDs from milligram to metric ton quantities has made SDDs a common approach for developing of compounds in preclinical and clinical development.

Successful development of SDDs requires careful consideration of CQAs (eg, physical and chemical stability, in vitro and in vivo performance, residual solvents, and material properties for downstream processing) that can impact the TPP. It also requires a good understanding of the formulation (eg, API and polymer chemistry, API:polymer ratio, excipient, and solvent) and process parameters (eg, droplet size, drying rate, and secondary drying) that define the SDD attributes.

31.1 INTRODUCTION

Extrusion processing is intended to physicochemically transform powder into molten or wet mass and enable the continuous production of highly homogeneous products through the accurate control of processing conditions. It is used to produce a wide range of food and feed products, ceramic, metal, plastics, chemicals, and more recently pharmaceutical products. There are different types of extrusion machines depending on the material extruded or the extrusion technology. Extrusion equipment used today to process pharmaceutical products typically includes extruders with a single or twin-screw auger powered by an electric motor (Fig. 31.1). While single-screw extrusion (SSE) is a mechanically simple and low-cost processing option, twin-screw extrusion (TSE) has been used extensively for mixing, compounding, or agglomerating a variety of ingredients to produce a wider range of products.

In manufacturing solid dosage forms, TSE can be used for hot-melt extrusion (HME), wet and melt granulation. During HME and wet or melt granulation, liquids and powders can be fed accurately and continuously throughout the run to ensure consistency of the formulation. HME is one of the most common processing options to enable the formation of amorphous solid dispersion (ASD) for enhancing dissolution and bioavailability of poorly water-soluble drugs. It is a solvent-free process that transforms a powder blend of active pharmaceutical ingredients (APIs), polymers, and other excipients into an extrudate containing a molecularly dispersed API in a polymer matrix through either melting and mixing the molten drug with molten polymer or dissolving the API in the molten polymer(s) during the extrusion process. The extrudate can be subsequently directly shaped or converted into granules or pellets for downstream processing. Wet and melt granulation via TSE refers to the process of mixing powdered excipients and APIs together with a liquid or meltable binder in the extruder to produce granules with characteristics suitable for manufacturing solid dosage forms. It is more scalable and capable of processing materials consistently with greater process flexibility and higher efficiency when compared to the traditional low-shear, high-shear, fluid-bed, or spray-congealing process. Due to the high mixing efficiency and accurate process control, extrusion granulation usually requires less quantity of binder than other processes. It can be optimized to generate more uniform granules with respect to physicochemical characteristics. It also offers a great flexibility in producing granules with diverse characteristics and requires significantly less materials for process development, scale-up, and optimization. As shown in Table 31.1, the TSE process has been successfully applied to manufacture a growing number of commercial drug products covering a wide range of therapeutic areas.

In essence, TSE offers many advantages over conventional pharmaceutical process, including: (1) continuous processing with increased efficiency and productivity and the ability to handle multiple processing functions in series (such as conveying, melting, distributive and dispersive mixing, granulating, and devolatilizaton); (2) solvent-free processing with a small equipment

footprint; (3) considerable flexibility in achieving specific mixing characteristics to meet different product and process requirements and produce a wide range of pharmaceutical dosage forms with fewer unit operations; and (4) exceptional mixing capability for achieving superior product homogeneity and content uniformity. When the extrusion process is used as a continuous processing technology in commercial production, it is essential to establish and implement a sound control strategy, such as real-time release testing (RTRT). However, in pharmaceutical manufacturing, a process train typically consists of a combination of batch (eg, blending, coating) and continuous unit operations (eg, compression). Thus, batch and lot definition becomes a key consideration. In most cases, a batch can be defined based on the limiting factor(s) of the upstream or downstream unit operations. For a process train involving TSE, batch size of the preblend can often be used to determine product batch size, enabling thus converting back-to-back extrusion runs into a semicontinuous process to meet the requirement for uniform quality while preserving the advantage of high manufacturing efficiency.

This chapter describes the design and basic principles of (1) the TSE process, (2) the design and functionality of the extruder and screw elements, (3) process parameters, and (4) material considerations in process development. The fundamentals of product and process development using TSE are presented, including the HME process for ASD products, and continuous wet and melt granulation for immediate-release (IR) and extended-release (ER) dosage forms. Process scale-up and critical issues are also discussed, including general principles, common approaches, and modeling. Case studies are provided to illustrate the versatility of TSE and some of its successful applications in manufacturing different types of solid dosage forms.

31.2 TWIN-SCREW EXTRUDER AND EXTRUSION PROCESS

31.2.1 Extruder design and components

An extruder can be roughly divided into three sections based on functionality: (1) the drive section, which includes the motor, gear box, shaft linkage, and thrust bearings; (2) the process section, which is composed of the barrel, screw, optionally an endplate/die, and various sensors; and (3) the control section (ie, human machine interface, HMI). The drive and control sections of the extruder are generally defined by equipment specifications, and modification of these portions for individual process requirements is not common. This chapter will mainly focus on the process section of the extruder.

There are two common types of commercially available extruders: the ram type and screw type. Compared to a ram extruder, a screw extruder is preferred due to its continuous manufacturing capability. Depending on the number of screws, screw extruders can be classified as SSEs, TSEs, and multiscrew extruders. SSE is a relatively simple process, and it has served as a fundamental operation for polymer processing since the early 1900s. Due to its superior mixing capability and shorter material residence time, a TSE is more preferable for the pharmaceutical industry. A TSE consists of two parallel rotating screws inside a stationary cylindrical barrel. The two screws can rotate either in the same direction (ie, corotating) or in opposite directions (ie, counterrotating). When a counterrotating extruder is employed, materials are subject to high-shear regions; thus, this setup should be considered when higher shear regions are required. Based on the centerline distance between the two screw shafts, TSEs can be

TABLE 31.1 Commercial Drug Products Manufacturing Using TSE

Product	Indication	Type of dosage form	Company	Year approved
Lacrisert (HPC rod)	Dry eye syndrome	Shaped system Ophthalmic insert	Merck	1981

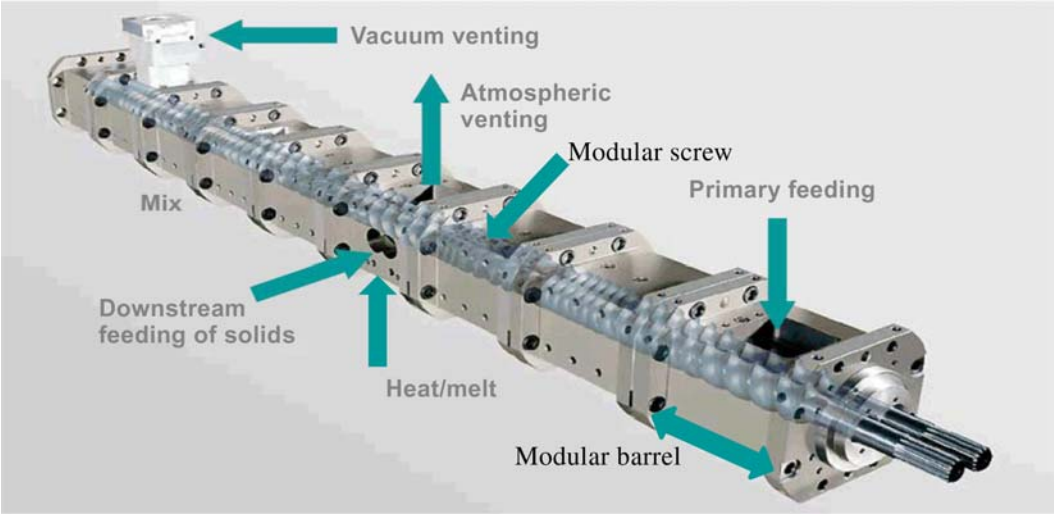

FIGURE 31.2 Extruder barrels and screws.[1]

further classified as fully intermeshing TSEs (ie, the centerline distance is less than the screw diameter) or nonintermeshing TSEs (ie, the centerline distance between two screw shafts is equal to the screw diameter). The detailed classification of screw extruders can be found in Fig. 31.1. Fully intermeshing corotating TSE offers self-wiping or self-cleaning feature, and is the most widely used and studied setup for pharmaceutical applications.

31.2.1.1 Barrels

Extruder barrels are the housing for the screws. The barrels are generally electrically heated and water cooled. During the extrusion process, the barrel temperature is monitored by thermocouples. Depending on the design and manufacturer, the barrel can be either a one-piece or a modular design. Compared to the one-piece design, modular barrels are more widely used in the pharmaceutical industry due to their greater flexibility to meet processing or product requirements. Modular-designed barrels and screws are shown in Fig. 31.2. The typical length of an extruder should be determined based on the screw configuration required for the process. However, the individual modular barrel can be in different lengths and diameters. The barrel temperature can also be controlled individually or in grouped zones. In addition, the modular barrels could be configured differently (see Fig. 31.3).[1] Some common barrel configurations are closed barrel, feed barrel, vented barrel, and combi barrel.[1] The closed barrels generally comprise the majority of an extruder design. Liquid feed, if needed, can be introduced into the system through an injection nozzle connected to a closed barrel or a combi barrel.

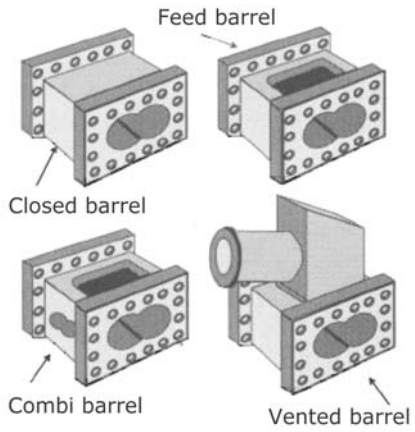

FIGURE 31.3 Different types of barrel section.[1]

The feed barrel, with either a circular- or rectangular- shaped opening on the top, is generally the first section in the extruder and is normally kept near room temperature. To maximize the free volume for material to enter the extruder, the screw in the feeding section should have a long pitch to keep the material moving forward rapidly (see detailed discussion on screw design in Section 31.2.2). However, depending on formulation, the number and locations of the feed barrels should be carefully considered. Adding material downstream reduces its residence time and the amount of shear the material experiences. Bruce et al. reported that using a side-stuffing port close to the die could successfully incorporate heat-sensitive

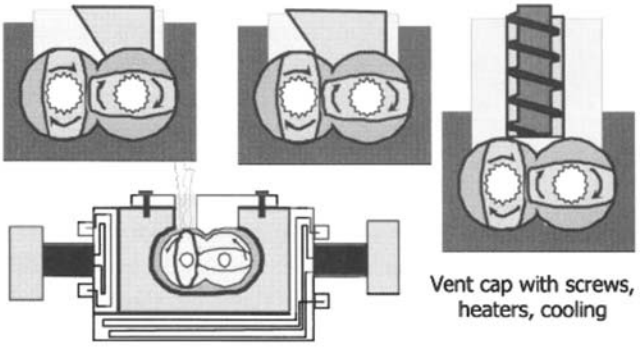

FIGURE 31.4 Vent cap configurations.[1]

dextromethorphan hydrobromide granules with a molten polymer plasticizer while avoiding exposure of the material to the high process temperature required for melting the carrier polymer.[2]

The vented barrel is used to remove air and/or volatiles from the extruder; this process is also referred as devolatilization. The vent barrel also possesses an opening on the top, which can be connected to atmosphere or vacuum. Devolatilization may be critical to the extrusion process. The proper venting (or devolatilization) should allow air and/or volatiles to escape from the barrels while preventing the material from being lost. A variety of vent-port designs, including vent stuffers, elongated vent barrels, and side vents, have been developed for corotating TSEs to accommodate a wide range of applications and materials. In general, the vacuum port covers approximately half of the screw surface; this can be achieved by either the vent port design or addition of vent caps. Some typical vent cap configurations are shown in Fig. 31.4.[1] Besides regular-shaped openings, the barrel can also house dynisco ports (ie, standard high-pressure/temperature instrumentation ports) for installing various process monitoring probes.

31.2.1.2 Screw elements

Screw design can significantly impact product characteristics and quality because it affects mechanical shear and residence time.[3] Thompson and Sun reported that changes in screw elements could influence the size and shape of lactose-polyvinylpyrrolidone granules for a wet granulation process.[4] Nakamichi et al. showed that a kneading paddle play an important role in the preparation of ASD of nifedipine.[5] Therefore, special attention should be given when designing screws. The design must consider both the process requirements and the material properties. Screw configurations can be designed as shear-intensive or shear-passive according to the process requirements. With modular designs (see

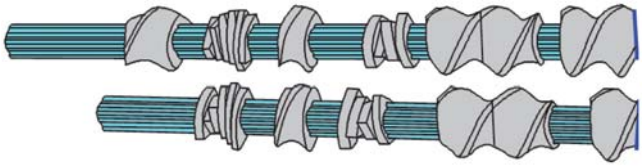

FIGURE 31.5 Modular screw design.[118]

Fig. 31.5),[118] there are seemingly infinite possibilities of screw variations. However, considering the discrete zones, including the solid feed/conveying zone, mixing/melting zone, the melt conveying/metering zone, and potential devolatilization/venting zones as shown in Fig. 31.6 for a basic extrusion operation, there are predominately two types of screws: (1) flighted (threaded) screws to achieve conveying and (2) non-flighted screws for mixing and melting by creating shear regions.[6,7] One example of a complete modular screw design is shown in Fig. 31.6.[8] During extrusion, material can be transported mainly through drag flow and pressure flow. The pressure flow is due to the pressure buildup at specific regions, while the drag flow is created from the volumetric displacement of screw.

31.2.1.2.1 Conveying screws

One typical flighted screw is the conveying screw. The helix geometry of a single-flight conveying screw is shown in Fig. 31.7.[9,10] The pitch is defined as the distance between consecutive flights. The helix angle is the angle between the screw flight and the plane perpendicular to the screw axis. The pitch is directly related to the helix angle. The optimum helix angle/pitch should be designed based on the material properties and design requirement. Fight clearance, with a rule of thumb of 0.1% of the screw diameter, is the space between the screw outer diameter D_o and the barrel wall. D_i is the inner screw diameter.

Conveying screws are the primary constituent of the screw configuration in the feed zone and metering zone. The feed section is responsible for conveying materials such as pellets and powder forward to the transition section. The metering section, also called melt conveying or pumping zone, delivers the melt toward the discharge end of the extruder. The helix geometry enables material transportation through the open channel downstream. The capability of the screw conveying is directly related to the volumetric displacement or free volume of the channels. The screw conveying capacity can be calculated in many different ways. One example is shown in Eq. (31.1); the conveying capacity is expressed as drag flow Q_d during the extrusion process.[10]

$$Q_d = 0.5 \times a \times z \times \cos(\theta) \times N \tag{31.1}$$

FIGURE 31.6 Example of a complete modular screw design.[6,118]

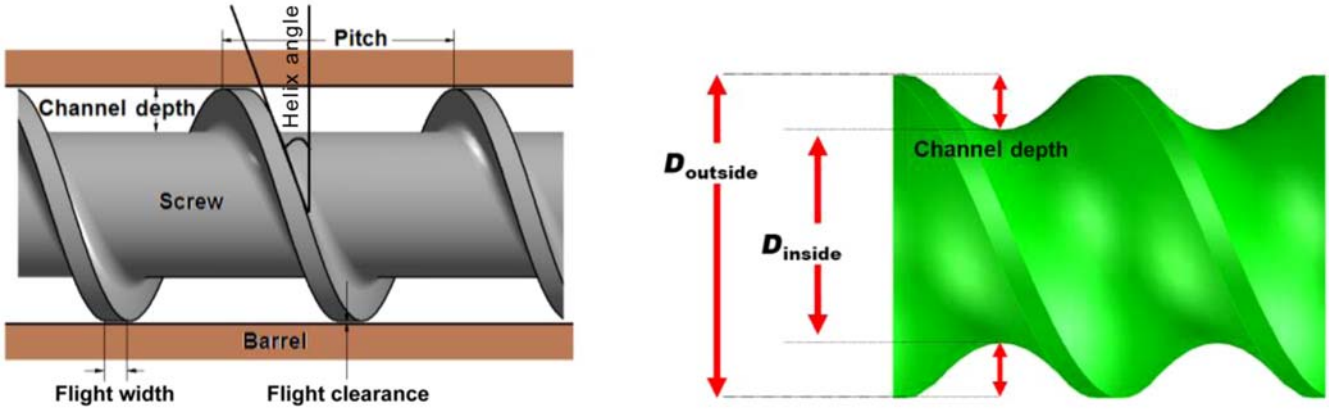

FIGURE 31.7 Basic geometry of a conveying screw element.

where Q_d is the drag flow; α is the area of the open section of the screw; z is the lead length of the screw; θ is the helix angle; and N is the screw speed. The lead length is proportional to the screw pitch. For a single-flight screw element, the lead length is equal to pitch (ie, the axial distance that screw travels in one complete revolution of 360°), while for a double-flighted screw, the lead length would be twice of the pitch.

Regardless of the various mathematical expressions, it is clear that the screw conveying capacity is primarily a function of the screw open section or the free volume. The screw design, including the number of flights, ratio between D_i and D_o, and pitch, has a significant impact on the free volume. Zimmermann listed the free volume of various screw designs.[11] The comparison among three commonly used conveying screw designs is shown in Table 31.2.[118] The impact of pitch on volumetric displacement and general guidance of its use are summarized in Table 31.3.[118] The screws in the feeding zone usually have a greater pitch; the pitch reduces in the metering/compression zone to increase pressure by increasing the degree of fill while removing entrapped air. For a HME process, the screw with a pitch less than one screw outer diameter ($<D_o$) is employed in the melt-conveying section to generate pressure and pump the melt uniformly out to the die cavity. As the degree of fill could also impact the average shear rate (energy input), as shown in Fig. 31.8,[12] the optimum design should be defined based on the main function of the processing zone and rheology of the materials being processed.

TABLE 31.2 Comparison Among Common Conveying Screw Design[118]

Screw design	Free volume	Conveying efficiency	Pros	Cons
	+	+++	Low leakage flow High pumping efficiency	Lower conveying capacity
	++	++	Good balance between free volume and conveying efficiency	Higher shear than one-flighted screw
	+++	+	High conveying capacity	Some back-mixing

When evaluating the screw design, the compression ratio is an important parameter that should be assessed. The compression ratio is the ratio of the channel depth (or channel volume) in the feeding zone to that in the metering zone. This ratio is closely related to the slope of the transition section. During HME, the compression ratio and the close of the transition section should be carefully matched with the polymer melting rate to ensure an efficient process. A screw with a high compression ratio is generally recommended for processing materials with high compressibility.

31.2.1.2.2 Mixing screws

Although typical helix conveying screws provide efficient material transportation, they may not be able to provide sufficient distributive and dispersive mixing, which is particularly important for generating a molecularly dispersed formulation. Distributive mixing is a low-shear process; it promotes homogeneity by diving and recombining the material without significantly reducing particle size. In contrast, dispersive mixing is a high-shear process; it breaks up large particles and disperses them throughout the material. Mixing that accompanies melting is dispersive in nature, as the high-shear stresses open an opportunity for the elongation and breakup of material. A diagram of both distributive and dispersive mixing is shown in Fig. 31.9.[13] Staggered kneading blocks are widely employed mixing element configurations. A kneading block element generally consists of several kneading disks. The number and width of kneading disks, as well as the stagger angle (offset angle) between successive disks, are the three most important

TABLE 31.3 Impact of Conveying Screw Pitch[118]

Screw pitch	Volumetric displacement	Degree fill	Uses
High (1.5–2 D_o)			
	+++	+	Feeding materials into extruder
Medium (1–1.5 D_o)			
	++	++	Compression after Feeding Melt transport
Low (<1 D_o)			
	+	+++	Pressure generation Melt pumping

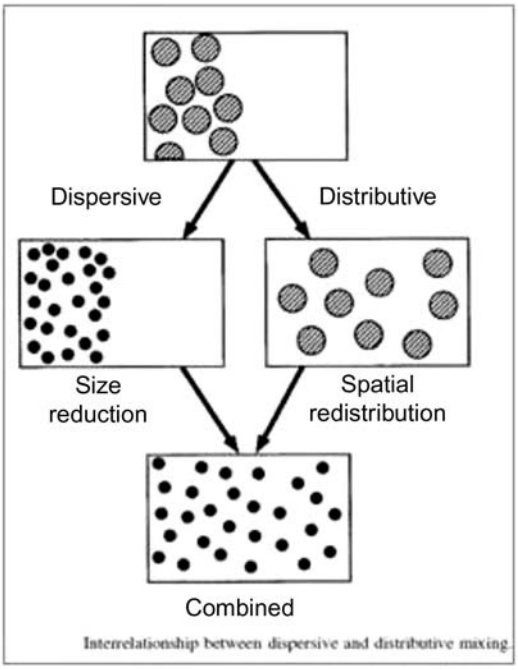

FIGURE 31.9 Comparison of distributive and dispersive mixing.[13]

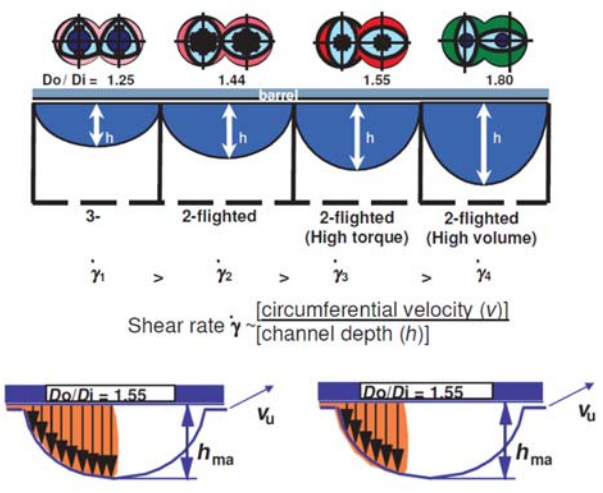

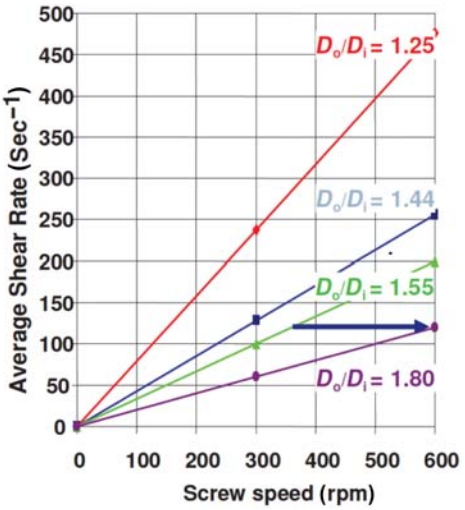

FIGURE 31.8 Impact of D_o/D_i on shear rate.[12]

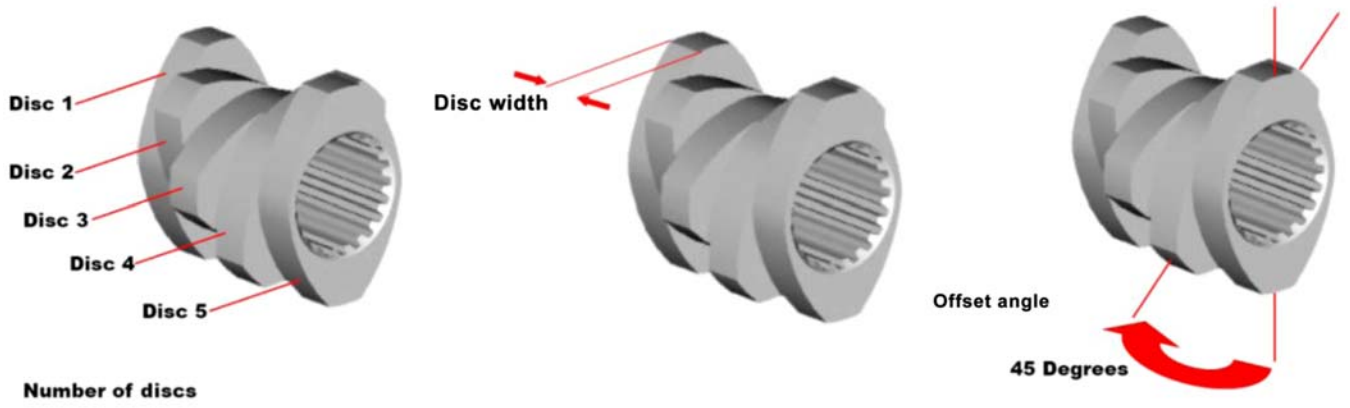

FIGURE 31.10 Geometry of a kneading block.[118]

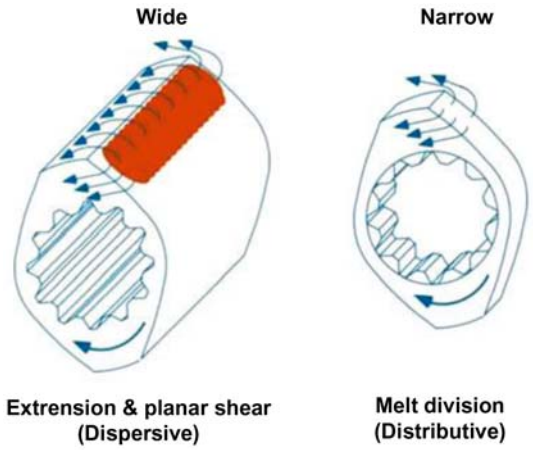

FIGURE 31.11 Material flowing around and over a kneading block.[14]

characteristics for kneading blocks. The geometry of kneading block elements is presented in Fig. 31.10. Depending on the design, kneading blocks create various shear intensities, and they can be used for either distributive or dispersive mixing. Narrow kneading disks provides good distributive mixing as more material is forced to flow in and around blocks instead of between the block and barrel wall. Wider kneading disks are mainly used for dispersive mixing because material tends to go over the top of the discs. Material flow around and over kneading disks is illustrated in Fig. 31.11.[14]

The kneading block could be configured as forward (or right-handed), neutral, and reverse (or left-handed) kneading elements (as shown in Fig. 31.12) based on the stagger angle. Since the stagger angle between disks causes an axial displacement flow, both forward- and reverse-kneading blocks also have conveying capability. However, this type of conveying, as it is related to the stagger pressure profile, is different from the drag flow observed with conveying screw elements. The conveying direction of the forward kneading elements is the same as the direction of the product flow in the extruder. It allows back-mixing of material through the gaps formed by the staggering angle. The conveying direction of the reverse kneading elements is contrary to the direction of the product flow in the extruder. Thus, the aim of incorporating reverse element in screw configuration is to produce back pressure and increase upstream degree of fill. Neutral kneading blocks have no conveying capability. Table 31.4 summarizes a simplified characteristic comparison among different kneading block elements.

In addition to kneading blocks, many other special mixing elements could be considered for improving mixing. A few examples are illustrated in Fig. 31.13.[15] Special distributive mixing elements (DMEs) utilize interrupted screw flights to allow higher material exchange between adjacent screw channels, thus enhancing back-mixing. As the opening on the screw flights causes increased leakage flow, the conveying efficiency of the screw is reduced. However, a higher fill factor and longer residence time are expected. Mixing gears or toothed mixing elements (eg, Tooth Block, ZME) offer the maximum amount of distributive mixing with minimal energy input by creating flow splitting and reorientation. Mixing gears consist of a series of cams, which divide the material flow and form multiple layers by the swirling action. The interfacial area is thereby increased. The material layers are then wiped between the cam tips and barrel, resulting in enhanced distributive mixing. The mixing efficiency of mixing gears is impacted by the number of gears and cams per gear. The degree of homogenization increases with increasing the number of mixing gears and/or the number of cams per gear. Barrier screws

FIGURE 31.12 Forward and reverse kneading blocks.

TABLE 31.4 Characteristics of Kneading Blocks[118]

	 Forward	 Reverse	 Neutral	 Forward	 Reverse	 Neutral
Conveying efficiency	+++	−−−	None	+	−	None
Distributive mixing	+++	++++	++++	+	++	++
Dispersive mixing	+	++	+++	++++	++++	+++++
Shear input	+	++	++	+++	++++	+++

FIGURE 31.13 Examples of special mixing elements.[119]

are believed to provide gentle dispersive mixing by passing particles through a defined barrier gap and exposing them to a low and well-defined shear stress. For HME, the compression and decompression of the material lead to a complex elongation flow and, therefore, lead to an optimal dispersive mixing effect. Kessler et al. demonstrated the suitability of applying barrier screw elements for manufacturing ASD by promoting mixing at relatively low temperature.[16]

The ratio between screw length and screw diameters (L/D) is an important characteristic to consider, as it impacts the material residence time and the length assigned to each process operations. This ratio, to a large extent, is determined by the extruder design. The typical L/D range for intermeshing TSEs is from 20:1 to 40:1, with a potential for up to 60:1. Higher L/D ratios offer more flexibility in terms of screw design to meet specific process requirements; however, it should balance with the consideration of residence time and torque. For pharmaceutical applications, the pilot scale screws have diameters ranging between 18 to 30 mm, whereas the screw diameter for production scale could exceed 50 mm. In advanced extrusion equipment, the screw dimensions can change over the length of the barrel and extend proportional to the length of barrel.[17–20] Morott et al. (2015) demonstrated the impact of L/D ratio along the screw design on taste-masking of sildenafil citrate.[21] A shorter screw design

with one mixing zone enhanced the perseveration of the API crystalline nature.

31.2.1.3 Dies

The main function of an extrusion die is to shape the pressurized molten material to the desired shape and desired dimensions by passing it though a predefined cross-section.[1,22,23] The die is attached to the end of the extruder and provides a passage for the material exiting from the circular extruder barrel to a more complex and often much thinner and wider die exit. A die is generally not required for extrusion granulation. Extrusion dies may vary dramatically in shape and complexity to meet the demands of the product being manufactured. For melt extrusion, an ideal die should be able to (1) balance melt flow to provide acceptable die pressure drop and (2) keep melt homogeneity without causing stagnated flow. The stagnation area could lead to thermal degradation, as the melt is being exposed to high heat for an extended period of time. Strict geometric shaping may not be required if the extrudate will be milled into fine powder for further downstream processing. However, for melt extrusion, the material could spend a significant portion of its residence time in the die under thermal stress, thus, the proper design of an extrusion die is important and requires the understanding of material characteristics, knowledge of mass and heat transfer, and extensive experience with extrusion processing. A die with a large open cross-section is believed to minimize die pressure while maintaining appropriate melt linear velocity and is thus recommended for general use.

Materials' rheological properties should be carefully evaluated when designing a melt-extrusion die, as these properties could significantly impact product quality. For example, die swelling (also known as extrudate swelling or the Barus effect), as a result of velocity relaxation of melt flow and viscoelastic relaxation of strained polymer molecules, could cause a change in the melt flow velocity profile exiting from the die and result in a stagnant region.[23–25] Giles described the four zones of the extruder die.[1] The parallel zone, where the melt acquires the final characteristics and shape prior to exiting from the die, is believed to mainly control the die swell, back pressure, and flow uniformity. To compensate for material and process variability, appropriate die adjustments, such as mandrels, choker bars, die lips, and localized temperature control, could be required to maintain a robust and stable process. Depending on the final application, slit dies (for film and sheet), strand dies (for simple geometric shapes, such as circles, squares, or triangles), and annular dies (for pipe and tubing) are commonly used dies in the pharmaceutical industry. Historically, extrusion die design is more an art than a science. However, it has been improved with recent advancements in powerful computation tools such as finite element analysis (FEA) for modeling of complex flow and heat transfer processes.

31.2.1.4 Auxiliary systems

A wide range of auxiliary systems, including feeders and various downstream equipment, are generally used with the extruder to complete the extrusion process. The selection of feeder and downstream processing equipment depends upon many factors such as desired dosage form, material characters, and processing speed. Feeders with precise and controllable discharge rates are employed to accurately meter materials into the extruder. Preblend materials can be added via a single hopper or, alternatively, multiple feeders can simultaneously add different ingredients in the correct ratios. The feed rate can be controlled either by volume (volumetric feeder) or by weight (gravimetric feeder). Volumetric feeders are designed based on some form of displacement principle, such as a rotary feeder or rotating screw. It is an open-loop device and cannot directly measure material throughput to compensate for dosing variation. The dosing accuracy of volumetric feeders is within 1–3%. In contrast, gravimetric feeders control material feed by weight and improve the dosing accuracy to 0.5–1% by adding a weigh system and closed-loop control scheme. Based on the actual discharging weight over time, the system makes necessary feeder speed adjustments to maintain the desired mass feed rate. Gravimetric feeding is the most preferable for pharmaceutical applications primarily due to better dosing accuracy. However, material properties, such as density, flowability, particle size, frication, and compressibility, play a critical role in feeder selection. For example, a crammer feeder may be a viable option when dealing with materials that have a low bulk density. If necessary, liquid additives can also be introduced to a TSE through an injection port with a typical a gravimetric or loss-in-weight liquid feed pump.

Downstream auxiliary equipment is utilized to achieve the desired dosage form. There are a wide variety of downstream systems available to extrude an infinite array of shapes. Fig. 31.14 presents different dosages that could be produced by an extrusion process.[26]

For melt extrusion, direct shaping can be achieved by either extruding melt direct to a mold with specific dimension by calendaring.[27] During calendaring, the molten strand leaving the extruder is shaped to the desired dimensions between two counterrotating calendar rollers. If applicable, direct shaping could be a cost-effective route for dosage manufacturing, mainly due to its continuous manufacturing nature. The suitability of the direct-shaping process could be highly

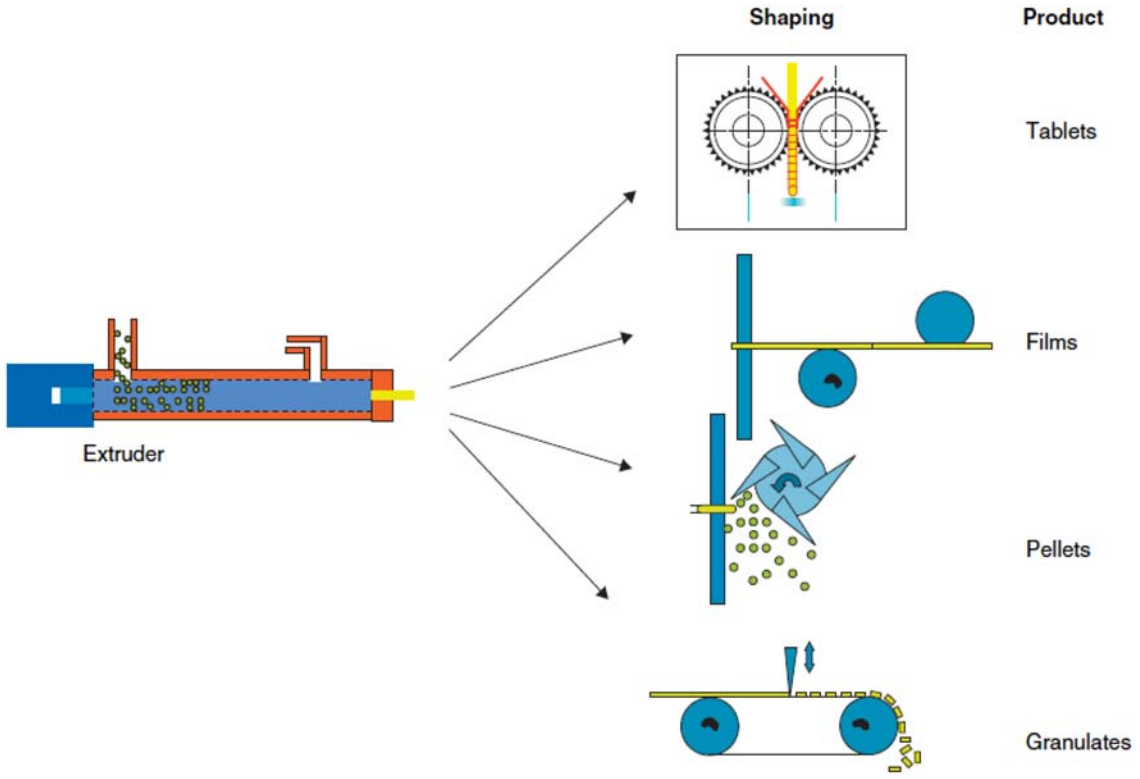

FIGURE 31.14 Different extrudate shapes produced using a twin-screw extruder.[26]

formulation dependent. One example of direct shaping is Egalet, a novel erosion based controlled-release delivery system, which is manufactured via injection molding.[28,29] Roth et al. also reported directly shaping an abuse-resistant, melt-extruded formulation into elongated tablets.[30] They believed that direct shaping increased the tablet strength by eliminating the sharp features that result from the extrudate grinding step. However, DiNunzio et al. claimed that direct-shaped dosages could suffer from a reduced erosion rate due to the low surface area and near-zero porosity; thus, it is rarely employed.[31]

As a post extrusion milling operation is often required for extrudate to manufacture the final dosage, tight dimensional control of extrudate is generally not required. Pellets are one of the most commonly used shapes and can be formed through either calendaring or pelletization.[23,32] Producing sheets of pellets by calendaring is straightforward. During calendaring, the melt is forced to distribute between two roller faces. Depending on the design of the roller surface (smooth surface vs surface with cavities), either films or sheets of pellets can be obtained. The shape and size of the pellets are determined by the roller surface cavities. The temperature of the roll surface is maintained by liquid circulation through internal channels. The calendaring conditions could play an important role in determining the physical properties and appearance of the film/sheets. When the calendar temperature is too low, the melt is difficult to stretch; when the calendar temperature is too high, the material could stick to the roller. In addition, the gap between calendaring rollers could also influence the film shape. Pelletization is a process to form extrudate pellets with typical size between 0.5 and 5.0 mm. Strand pelletization and die-face pelletization are two common pelletization methods. They distinguish themselves in terms of material temperature where the cutting takes place.[33,34] In strand pelletization, spaghetti-like melt strands are pulled by a pelletizer feeder while cooled and pushed to a cutting assembly to size to the required length. Thus, the material is generally cut at a temperature below its softening point, and pellets are more cylindrical-shaped. The diameter of the final pellet is controlled by the diameter of die orifice and pulling speed of the feeder roller, with a typical size of ≤ 3 mm for pharmaceutical applications. Die-face pelletization forms the pellets by direct cutting the melt at the die face and then cooled, most likely by air. Spherical pellets can be obtained through this process due to surface tension related deformation. Die-face pelletization offers major advantages in terms of process simplicity and spatial flexibility; therefore, if amenable, it is often preferred over the

strand system. However, since the material is cut while in its viscous state, this process could be limited in range of applicable formulations mainly due to stickiness.[35]

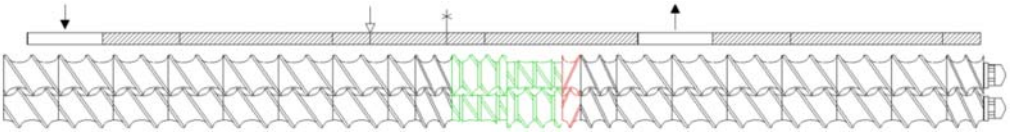
31.2.2 Extrusion process design

Extrusion is an integrated unit operation composed of several function zones. Process parameters play a key role in determining the properties of the extruded product. The complexity of the material and energy properties in different functional zones throughout the extruder is illustrated in Table 31.5. To clearly understand the overall impact of different types of parameters associated with the process on product quality attributes, analytical descriptions of the extrusion unit operation have been reported in the literature as shown in Fig. 31.15.[36] Based on this analysis, the product quality is controlled directly by key system parameters including specific energy, melt temperature, residence time, and pressure, while the common adjustable equipment and process parameters impact the product quality indirectly. In this section, the key process considerations based on the adjustable parameters (eg, feed rate, screw speed, temperature profiles) will be discussed to provide an overview of how the process variables may affect the properties of extrudate.

31.2.2.1 Feed rate

Feed rate is one of the most important adjustable process parameters. During operation, the extruder can be force-fed or starve-fed. When operated under force-fed mode, material is positively displaced into the extruder. When operated under starved-fed mode, the extruder is fed at a rate below the conveying

TABLE 31.5 Material and Energy Properties Throughout Extruder



Function zone	Solid feed	Solid convey	Melting	Mixing	Melt convey	Discharge
Material sate	Solid	Solid	Solid/Melt	Melt	Melt	Melt
Pressure (Bar)	1	1	1	>1	>>1	>>1
Conductive energy	Out of material	In and out of material	Out of material	Out of material	Out of material	Out of material
Energy conversion	None	None	PED/FED	VED	VED	VED

PED, plastic energy dissipation; FED, frictional energy dissipation; VED, viscous energy dissipation.

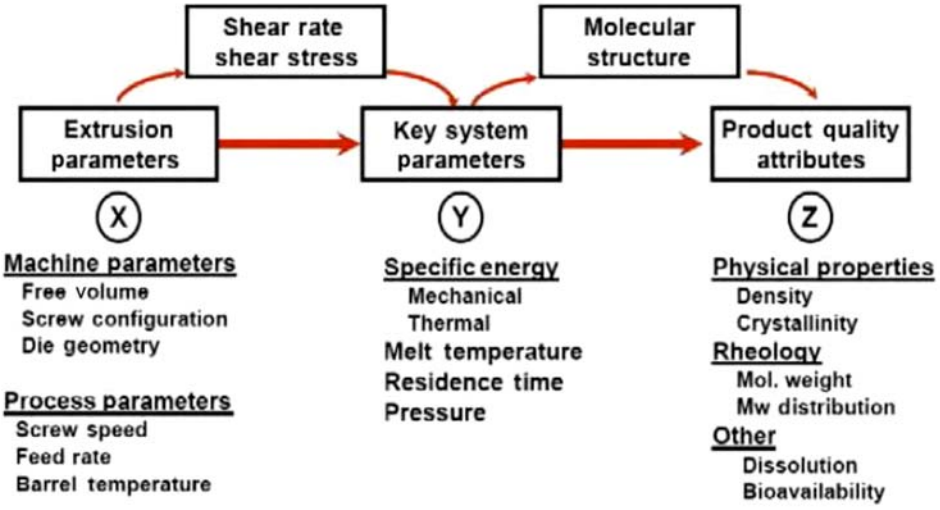


FIGURE 31.15 Analytical description of extrusion unit operation.[36]

capacity of the extruder, and thus a few of the functional zones will not be completely filled. In a starved-fed machine, the mass flow rate at the feed zone is equal to the mass exiting the barrel and accumulation in the barrel is negligible; thus, extrusion throughput is mainly determined by the feed rate but not the screw speed.

TSEs are normally run starve-fed to improve mixing and melting efficiency. The feed rate impacts the extrudate quality by affecting residence time and/or degree of fill during extrusion. Residence time represents the time that materials remain in the extruder. A short residence time leads to inhomogeneity, while long residence time can impact the degradation profile of thermally labile compounds. For melt extrusion, increasing the feed rate with an equivalent increase in the die opening generally reduces the material residence time in an extruder, which results in lower specific energy input as well as higher melt viscosity and extrudate density.[37,38] Gao et al. (2012) proved this claim experimentally.[39] Degree of fill is defined as the ratio of the volume occupied by the material to the free channel volume. An approximation of the degree of fill for conveying screw is given in Eq. (31.2).[10]

$$f = \frac{Q}{Q_d} \tag{31.2}$$

where f is the degree of fill, Q is feed rate, and Q_d is drag flow. It is clear that, under constant throughput, the degree of fill is inversely proportional to screw conveying capacity. Since reverse elements convey material in the opposite direction of material flow in the extruder, the degree of fill increases to approximately 100% immediately upstream of a reverse-pitch element due to limited drag flow.[40] This results in a buildup of localized pressure and facilitates melting; the length of this section (ie, melt section or restriction section) is insensitive to feed rate. Thus, increasing the feed rate does not linearly increase the total melt length; a decrease in specific energy input to material is then expected. However, when using a screw configuration composed of a large portion of forward elements, an increased feed rate could cause choking at the small pitch screws. Under such situations, the specific energy input to the material can increase with feed rate. Fig. 31.16 illustrates a conceptual design space of throughput versus energy input to the formulation.[41]

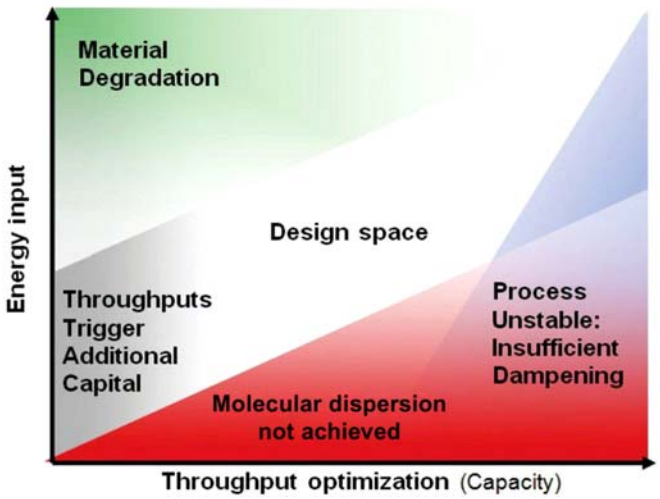

FIGURE 31.16 Conceptual representation of melt extrusion design space.[41]

31.2.2.2 Screw speed

The screw speed in a starve-fed extruder is a critical process parameter for the mixing and melting processes in extrusion. Higher screw speeds increase shear rate, shear stress, and specific mechanical energy (SME) input in all the melt-filled sections. It also reduces the length of the melt pumping section, thus leading to lower motor torque, higher melt temperature, lower die pressure, and higher product expansion.

Shear rate is defined as the velocity gradient between two moving surfaces at different speeds. The peak shear rate can be calculated according to Eq. (31.3).[14]

$$\textit{Peak share rate} = (\pi \times D \times n)/(h \times 60) \tag{31.3}$$

where D is the screw diameter, n is the screw speed in rpm, and h is the overflight gap. When considering mixing of solid particles with molten carriers, shear stress, which is related to the degree of deagglomeration, can then be estimated based on shear rate and viscosity (as in Eq. 31.4).[120] Based on Eq. (31.3), higher screw speeds lead to higher peak shear rates and better deagglomeration/mixing.

$$\textit{Peak shear stress} = \textit{Peak shear rate} \times \textit{Viscosity} \tag{31.4}$$

In addition, shearing of the polymer melt generates viscous energy dissipation. In this process, the mechanical energy from shearing is transformed into thermal energy. The rate of heat generation per unit volume due to viscous heat dissipation follows Eq. (31.5), in which m is a constant, and n is the power law constant.[20]

$$E = m \times \textit{Shear rate}^{n+1} \tag{31.5}$$

Heat in an extruder converted through viscous dissipation can also be expressed as SME. SME describes the mechanical energy input to the extrusion system

per unit mass in the form of work from the motor. Obtaining an accurate SME is difficult due to many uncertainties during measurement. One of the most straightforward calculations is presented in Eq. (31.6).[38,42]

$$SME = \frac{Power}{Throughput} = \frac{P \times \tau \times N}{m \times N_{\max}} \tag{31.6}$$

where P is the motor power or maximum available power in kW. N and N_{max} are the actual screw speed and the maximal screw speed for a giving system, respectively; τ is the torque or motor load expressed as a percentage of the rated (or maximal) power; and m is the real throughput of the process, which equals to the feeding rate in a starved-feeding system. The representative τ of the process should not include the torque level when the extruder is running empty. Assuming the heat capacity of the extrudate is known, the temperature rise can then be calculated using SME. Increasing the heat generated via viscous dissipation favors the crystalline-to-amorphous transition by increasing API dissolution in the matrix polymer and enables the production of hot-melt extruded ASD. However, a high degree of viscous heat dissipation may also induce degradation of drug substances and polymers.

Screw speed has a more significant influence on screw configurations with more restricted elements, as those configurations generally contain a greater portion of reverse paddles/screw elements. Although the degree of fill in restricted and nonforward flow sections does not change with screw speed, the degree of fill with low-conveying-capability screw elements and paddles may rise significantly with screw speed to a certain threshold level.

The impact of screw speed was evaluated on various formulations. Henrist and Remon investigated the manufacturing process for starch-based extrudates.[43] Screw speed and feed rate were found to impact physical and chemical proprieties of the extrudates. The combination of a high screw speed and a high feed rate lead to a large extrudate with low mechanical strength as well as a slow dissolution rate. However, Verhoeven et al. reported that, within the process condition range studied, screw speed had limited impact on the drug release of hot-melt extruded metoprolol tartrate-ethyl cellulose mini-matrices.[44] Shibata et al. suggested that screw speed influences the preparation of solid dispersion of indomethacin−crospovidone mainly by impacting the residence time. However, in the study, they also claimed that the X-ray diffraction (XRD) peak of indomethacin decreased with decreasing screw speed, which is contradictory to the theory that reducing screw rotation speed decreases mechanical shear.[45]

31.2.2.3 *Barrel temperature*

Since heat conduction from the barrel contributes to the melting process, barrel temperature could be critical to control the extrusion process, optimize throughput, and minimize degradation. An optimized temperature profile should be designed based on the understanding of raw material properties and the finish product requirements. Since extrusion is an integrated process, the selection of the temperature profile should also take into consideration of the screw configuration employed and other process parameters chosen.

In general, for melt extrusion, a progressive temperature profile is utilized, that is, the temperature set points increase continually from the feeder to die. In such temperature profiles, the feeding section is water cooled without heating to provide uniform flow without premature melting. The material is preheated and compressed in the solid convey zone. As rule of thumb, the temperature in the solid convey zone should be set 11−17°C below the melt temperature for both semicrystalline and amorphous polymers. The desired melt temperature should be reached at the melting zone and maintained in the remaining barrels. Certain minimum temperatures are required in the HME process to reduce the torque needed to rotate the screw. Typically, the temperature of the melting zone is set 15−60°C above the melting point of semicrystalline polymers or the glass transition temperature of amorphous polymers.[46,47] If additional dispersive and/or distributive mixing is required, the barrel temperature may need to be decreased to remove the excessive heat generated by shear. When devolatilization is needed, a constant temperature during venting is desired to facilitate the removal of volatiles. The temperature of the melt convey and discharge zone should be set to ensure good flowability into the die and acceptable melt strength.

To some extent, barrel temperature manages melt viscosity, which greatly affects the mixing between molten polymer and API. As the Weber number describes in Eq. (31.7), the viscosity of molten carriers plays an important role in the mixing of dispersed phase (ie, molten drug substance) within a continuous phase (ie, molten carrier).[120] Increased melt viscosity favors mixing.

$$W_e = \frac{\gamma \times d_0 \times \eta_c}{2\sigma} \tag{31.7}$$

in which W_e is Weber number, γ represents shear rate, d_0 is the diameter of the molten drug substance before mixing, η_c is the viscosity of the molten carrier, and σ is the interfacial tension between drug substance and carrier.

The impact of barrel temperature on products made by HME has been reported in several studies. Henrist

et al. found that only the highest barrel temperature influenced the characteristics of the starch-based extrudates.[43] Low temperatures caused a rough surface, while high temperatures induced foaming, with a temperature of 100°C being considered as optimum. When extruded at high temperature, Shibata et al. observed the shift of indomethacin absorption peaks in indomethacin-crospovidone solid dispersions, which contributed to the molecular interaction changes.[45] They also claimed that high extrusion temperature could enhance the dissolution rate of the formulation by inducing drug supersaturation.

The melt viscosity is highly dependent on both the glass transition temperature (T_g) of the carrier polymer and the processing temperature, as shown in the WLF Eq. (31.8).[121]

$$log\left(\frac{\eta}{\eta_{T_g}}\right) = \frac{-C_1(T-T_g)}{C_2+(T-T_g)} \tag{31.8}$$

in which η and η_c are the melt viscosity at a processing temperature and the glass transition temperature, respectively; C_1 and C_2 are constants; and T_g is glass transition temperature. Based on the equation, the processing temperature may have to be set relatively high to achieve a desired melt viscosity. However, the high extrusion temperature may cause the degradation of drug substances and/or polymers. Therefore, formulation and process are closely related and must be considered together when selecting a barrel temperature. Verreck et al. explored the possibility of employing supercritical carbon dioxide as a transient plasticizer for itraconazole-copovidone and p-aminosalicylic acid (p-ASA)-ethyl cellulose systems. The suitability of supercritical carbon dioxide was demonstrated by successfully manufacturing both materials with the minimal required extrusion temperature decreased by 5−20°C.[48,49]

For extrusion granulation, the temperature profile might not be as critical. A simple temperature profile, such as straight temperature profile (ie, all barrels are set at the same temperature) can be considered. However, since the frication factor between the material and barrel wall/liner is influenced by barrel temperature, the conveying efficiency could be negatively impacted by the selected temperature. Usually, the hotter the surface, the lower the friction factor is. Thus, this factor should be evaluated as part of process development to ensure the desired throughput and product quality.

31.3 HOT-MELT EXTRUSION

Interest in HME to prepare ASD of poorly water-soluble drugs began in the 1980s. Since the 1990s, use of HME to manufacture ASDs for improving drug absorption (eg, increase bioavailability and minimize food effect) has increased significantly. This is reflected by the drastic increase in research publications on ASD and the corresponding process technologies since the late 1990s, including chapters in two recently published books.[50,51] It also coincides with the increasing number of BCS class 2 and 4 drugs in new drug pipelines of the pharmaceutical companies.

Amorphous solid dispersions of poorly water-soluble drugs typically consist of an active ingredient, a thermoplastic polymer, a surfactant, and processing aids such as a plasticizer and an antioxidant. Drug loading of ASDs prepared using HME typically is below 40%. In most cases, the carrier polymer is the major component in the formulation. Both a thermoplastic polymer and a surfactant are used to maintain supersaturation and control the precipitation of drug in the aqueous environment. The carrier polymer also prevents the drug from crystallizing during the storage. Processing aids are used to improve the physical and chemical stability of the drug and the polymer during the extrusion process. Depending on their properties and functionalities, individual components in the formulations can be introduced into the extruder at different processing sections. Crystalline drugs and amorphous polymeric carriers are introduced either as a single powder blend or separately into the extruder hopper using loss-in-weight feeders. Liquid additives such as liquid plasticizers and surfactants are added through the liquid injection port. Inside the extruder, the formulation is transformed into a homogenous amorphous material under the intensive mixing of rotating screws at elevated temperatures. After exiting the die, the molten extrudate is air cooled and cut into pellets or cooled with a chill roller and broken into flakes. The pellets and flakes are further milled prior to being incorporated into the final dosage forms.

31.3.1 Formation mechanisms of ASD

During HME, the formulation in the form of a powder blend is transformed to a single-phase homogenous melt under the intensive mixing of the rotating screws and elevated temperature inside the barrel. When the extrudate is cooled quickly to ambient temperature outside the extruder, the solubilized drug is locked in a high-energy state. Even though amorphous API is thermodynamically unstable, a rationally designed ASD can be rendered sufficiently kinetically stability throughout the product shelf life when protected from moisture using an appropriate packaging configuration. The energy needed to form the melt is predominately from the motor and is transmitted by the gear box and

screw elements to the formulation via viscous heat dissipation.

The term *hot melt* does not necessarily imply that the API is always melted during the extrusion process. In fact, depending on the API properties and its interaction with the carrier polymer, HME can be carried out below and above its melting point. When the melting point of an API is below the typical HME process temperatures (< about 200°C) at which the majority of polymers are stable, homogenous dispersion of the API in the molten polymer matrix can be achieved either by API dissolution or due to primarily entropy-driven API-polymer miscibility at high temperature. When the HME processes are conducted above the melting point of the drug substance, homogeneous dispersion can be achieved by mixing the liquid drug melt and the liquid polymer melt.[52]

The intensity of mixing is a function of both the machine parameters (eg, screw geometry) and processing parameters (eg, screw rotation speed, feed rate).[14] The most intense mixing occurs at the sections containing mixing screws. As a result, solubilization of crystalline drugs takes place primarily in those sections. As discussed in the previous section, there are two main types of mixing: distributive mixing and dispersive mixing (see Fig. 31.9). Distributive mixing involves melt division and recombination, while dispersive mixing involves planar and elongational shear. The intensity of mixing also depends on the location of the material relative to the rotating screw and barrel. As shown in Fig. 31.17, material is bounded between screw flights and barrel wall, and separated into small melt pools by screw flights and barrel wall, which provide superior mixing by forming many small mass continuous mixers as compared to the large mass batch mixer. For a bilobal TSE, the high-shear regions, including overflight/tip region, lobal pool, apex, and intermesh, ensure sufficient mixing.

31.3.2 ASD formulation consideration

As fundamental principles and R&D aspects of amorphous API and ASD systems can be found in chapters "Crystalline and Amorphous Solids," "Solid-State Characterization and Techniques," "Oral Formulations for Preclinical Studies: Principle, Design, and Development Considerations," and "Rational Design for Amorphous Solid Dispersions," this section will focus the discussion on polymers and plasticizers (surfactants) selection consideration.

31.3.2.1 Polymer selection consideration

As polymers typically account for the highest percentage of ASD formulations, their selection is critical. The reason that HME can be conducted below the melting point of a drug is that the melting point of a drug is depressed when there is a strong interaction between the drug and the polymer. Intermolecular interaction between drug and polymer is also important for the physical stability of ASDs. Interaction parameter, a term used to describe the interaction between a drug and a polymer, can be determined experimentally using the melting-point depression method. Good miscibility between drug and polymer manifests itself as the depression of drug melting point in the presence of a polymer. At the depressed melting point (T_M^{mix}), the Gibbs free energy of the crystalline drug must be equal to the Gibbs free energy of the dissolved drug in its saturated solution in polymer melt. Since the Gibbs free energy is a state function, in a sense it only depends on the current state of the system and is independent of how that state has been prepared. We could use a hypothesized liquid drug substance at T_M^{mix} as a reference state. The difference in Gibbs free energy between the reference state and the drug dissolved in polymer melt at T_M^{mix} can be derived from Flory–Huggins equation. The difference in Gibbs free energy between the reference state and the crystalline drug at T_M^{mix}can be derived using thermodynamic parameters of pure drug substance. Therefore, the following equation is derived to describe the relationship between the depressed melting point of a drug substance and the interaction parameter between a drug and a polymer.[53]

$$\frac{1}{T_M^{mix}} - \frac{1}{T_M^{Pure}} = -\frac{R}{\Delta H_{fusion}} \left[Ln\varnothing_{drug} + \left(1 - \frac{1}{m}\right)\varnothing_{polymer} + \chi\phi_{polymer}^2 \right] \tag{31.9}$$

T_M^{mix} is the depressed melting point of drug in the presence of polymer. T_M^{Pure} is the melting point of pure

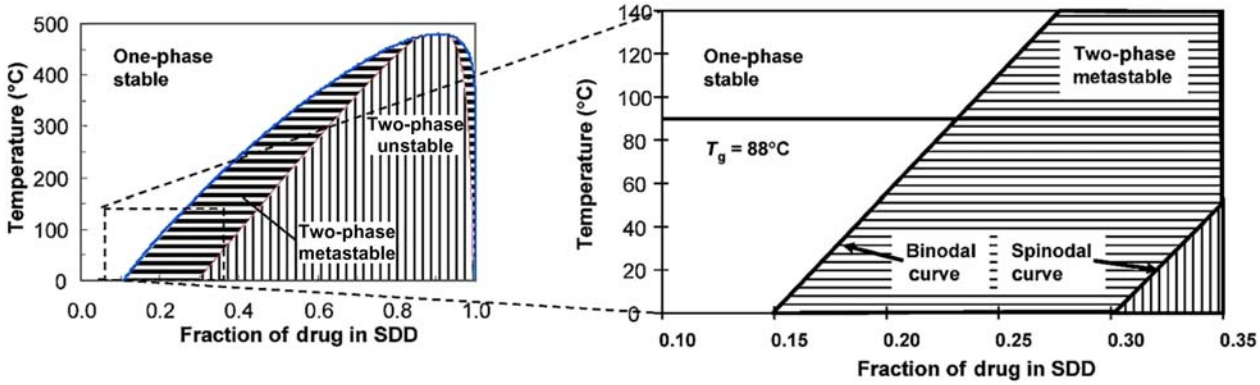

FIGURE 31.18 Phase diagram of drug substance-polymer solid dispersions.[56]

drug substance. ΔH_{fusion} is the melting enthalpy of pure drug substance, ϕ is the volume fraction, m is the polymer-to-drug molar volume ratio, and χ is the drug-polymer interaction parameter.

Once the solubility parameter becomes available, the drug-polymer phase diagram can be readily constructed using the Flory–Huggins equation. An example phase diagram is presented in Fig. 31.18.[56] The phase boundary where $\Delta G_{mix} = 0$ is defined as the binodal curve. A drug solution in polymer is thermodynamically stable outside the bimodal curve. As drug concentration is further increased, the spinodal curve is reached. The spinodal curve is defined as the line on which the second derivative of Gibbs free energy of mixing is zero. Composition between the spinodal and bimodal curves is metastable because large fluctuations are required for the system to phase separate into drug-rich and polymer-rich phases. Within the region surrounded by the spinodal curve, the composition is the least stable, and even a small fluctuation leads to phase separation (spinodal decomposition). The polymer must be thermoplastic so that it could be processed using HME. During the early stage of formulation development, selection of the polymer is based on its ability to maintain supersaturation and control the precipitation of drug in aqueous medium and to maintain physical stability of ASDs during the storage. It is important to realize that the melt extrusion process conditions are dictated to a great extent by the properties of polymers.

In most cases, there are specific interactions such as hydrophobic and dipole interactions and entropy-driven miscibility at high temperature between drug and polymer. Therefore, it is challenging to theoretically calculate the interaction parameters between drug and polymer in ASD systems. Instead, a common practice is to measure the melting point depression and then fit the data to derive the interaction parameters using Eq. (31.9).[54,55] As drug concentration is further increased, the spinodal curve is reached. Spinodal curve is defined as the line where the second derivative of Gibbs free energy of mixing is zero. Composition between the spinodal and bimodal curves is metastable because large fluctuations are required for the system to phase separate into a drug-rich and a polymer-rich phases. Within the region surrounded by the spinodal curve, the composition is the least stable, and even small fluctuation leads to phase separation (spinodal decomposition). A sample drug-polymer phase diagram of an ASD is presented as Fig. 31.18.

The degradation temperature and viscoelastic properties of polymers are the two most critical attributes that influence the extrusion conditions. Degradation of the polymer can be characterized using thermogravimetric analysis, and it can be divided into main-chain reaction and side-chain reaction. The main-chain reaction comprises the chain scission and cross-linking, while the side-chain reaction comprises the side-chain elimination and cyclization. The viscoelastic properties of the polymer must be investigated in terms of the torque limitations of extrusion processing.[57] The viscoelastic properties of a polymer can be described in terms of its storage modulus (G′, how elastic or solid-like the polymer is) and its loss modulus (G″, how viscous or liquid-like the polymer is). The loss tangent is the ratio of the loss modulus to the storage modulus (G″/G′), and a value of 1 represents the transition point from solid-like to liquid-like properties. The sum of the storage modulus and loss modulus is the complex modulus, which represents the overall resistance to deformation.

Pharmaceutical polymers commonly used in melt-extruded ASDs could be categorized into three different groups: polyvinyl-based polymers, cellulose-based polymers, and polymethacrylate-based polymers. These polymers are summarized in Table 31.6. Most of

TABLE 31.6 Common Polymers for Amorphous Solid Dispersions Prepared Using Hot-Melt Extrusion

Polymer	T_g (°C)	Grades	Notes
Hypromellose	170–180	Methocel E5	Nonthermoplastic API must plasticize Excellent nucleation inhibition Difficult to mill
Hypromellose acetate succinate	120–135	AQOAT-L AQOAT-M AQOAT-H AquaSolve-L AquaSolve-M AquaSolve-H	Easily extruded without plasticizer Process temperatures >140°C Ionic polymer soluble above pH 5.5 depending on grade Excellent concentration enhancing polymer Stable to 190°C depending on processing conditions
Modified hypromellose	117–128	Affinisol 15cp, 100cp, and 4 M	Designed for melt extrusion Broad processing window API plasticization not required Excellent nucleation inhibition
Vinylpyrrolidone	168	Povidone K30	API must plasticize Potential for H-bonding Hygroscopic Residual peroxides Easily milled
Vinylpyrrolidone-vinylacetate copolymer	106	Kollidon VA 64	Easily processed by melt extrusion No API plasticization required Less hygroscopic than povidone Processed around 130–180°C
Polyethylene glycol, vinyl acetate, vinyl caprolactam graft copolymer	70	Soluplus	Designed for melt-extruded dispersions Easily process by melt extrusion Low T_g can limit stability Not of compendial status Stable up to 180°C
Polymethacrylates	130	Eudragit L100-55 Eudragit L100	Not easily extruded without plasticizer Degradation onset is 155°C Ionic polymer soluble above pH 5.5

these materials were originally developed as binder or coating materials in conventional manufacturing processes. In recent years, novel excipients have been developed specifically for the melt-extrusion process. They typically have a wider temperature window for extrusion and are more chemically stable during the extrusion. For instance, BASF became the first company to engineer a polymer for the melt-extrusion process when Soluplus was introduced in 2009.[58] Soluplus is an amphiphilic polyvinyl caprolactam-polyvinyl acetate-polyethylene glycol graft copolymer. Dow Chemical recently introduced Affinisol, a new grade of hypromellose specifically designed for the melt-extrusion process. While conventional hypromellose E5 has been difficult to extrude due to high T_g and low thermoplasticity, the new line of Affinisol was developed with a lower melt viscosity, reduced discoloration at elevated temperatures, and wider processing window.[59] SE Tylose has developed a new grade of hypromellose acetate succinate (HPMCAS) with a lower glass transition temperature of 100°C. By comparison, the current commercial grade of hypromellose acetate succinate has a glass transition temperature of 120–135°C and must be processed at a temperature above 160°C.

31.3.2.2 *Plasticizer and surfactant selection considerations*

The addition of a plasticizer to facilitate the melt-extrusion process is well established in the plastics and pharmaceutical industries. Plasticizers are able to lower the glass transition temperature and the melt viscosity of polymer. For example, 5–10% triethyl citrate was required in the formulation to minimize degradation of troglitazone when Resulin was developed. Surfactants such as sorbitan monolaurate and vitamin E TPGS are present in ASDs of several commercial products. These surfactants are present to modify the precipitation and crystallization behavior of ASDs in aqueous environment. These surfactants have demonstrated plasticizing effects.

The major concern with using the traditional plasticizers is that the ASDs' physical stability might be compromised during the storage because of the lower glass transition temperature. This problem may be addressed by using transient plasticizers.[48,49] A transient plasticizer is intimately mixed with the polymer melt inside the twin-screw extruder and subsequently removed completely from the extruded product upon exiting the die. Supercritical CO_2, a blowing agent commonly used in plastics industry, is an ideal transient plasticizer for pharmaceutical melt extrusion. A schematic of a supercritical injection system coupled with a twin-screw extruder is shown in Fig. 31.19. The chiller and pump assist in maintaining CO_2 in the supercritical fluid. Studies conducted at Merck have demonstrated that the supercritical CO_2 can lower the processing temperature by as much as 20°C.

31.3.3 HME process consideration

As mentioned earlier, extrusion is an integrated unit operation. HME typically consists of several functional zones: (1) feeding, (2) solid conveying, (3) mixing/melting, (4) devolatilization, (5) melt conveying, and (6) melt discharge. Individual process parameters, including feed rate, screw speed, barrel temperature profile, and vacuum, are adjusted independently to meet product quality requirements. Refer to Section 31.2.2 for the general guidance on process design. As mentioned in prior sections, screw configuration should also be properly designed to achieve product requirements. Common screw elements that can be used for extrusion have been discussed in Section 31.2.1.2. A screw configuration, which is achieved by strategically placing different screw elements at different functional zone, ensures the desired mixing and pressure profile. The pressure gradient along an example screw in a starve-fed TSE is shown in Fig. 31.20. As discussed in Section 31.2.1.2, different screws typically serve different functions. An example screw design is presented in Fig. 31.21. In this case, conveying screws are used to convey solid and melt. Mixing or solubilization of drug in polymer melt is enabled using kneading elements, and mixing screws are used to create melt seal before devolatilization (Fig. 31.22).

One of the most challenging aspects in developing an HME process for manufacturing ASD is to achieve a balance between obtaining uniform ASD formulation by providing sufficient mixing while minimizing degradation of drug and/or polymer. In process design, proper selection of screw design and process

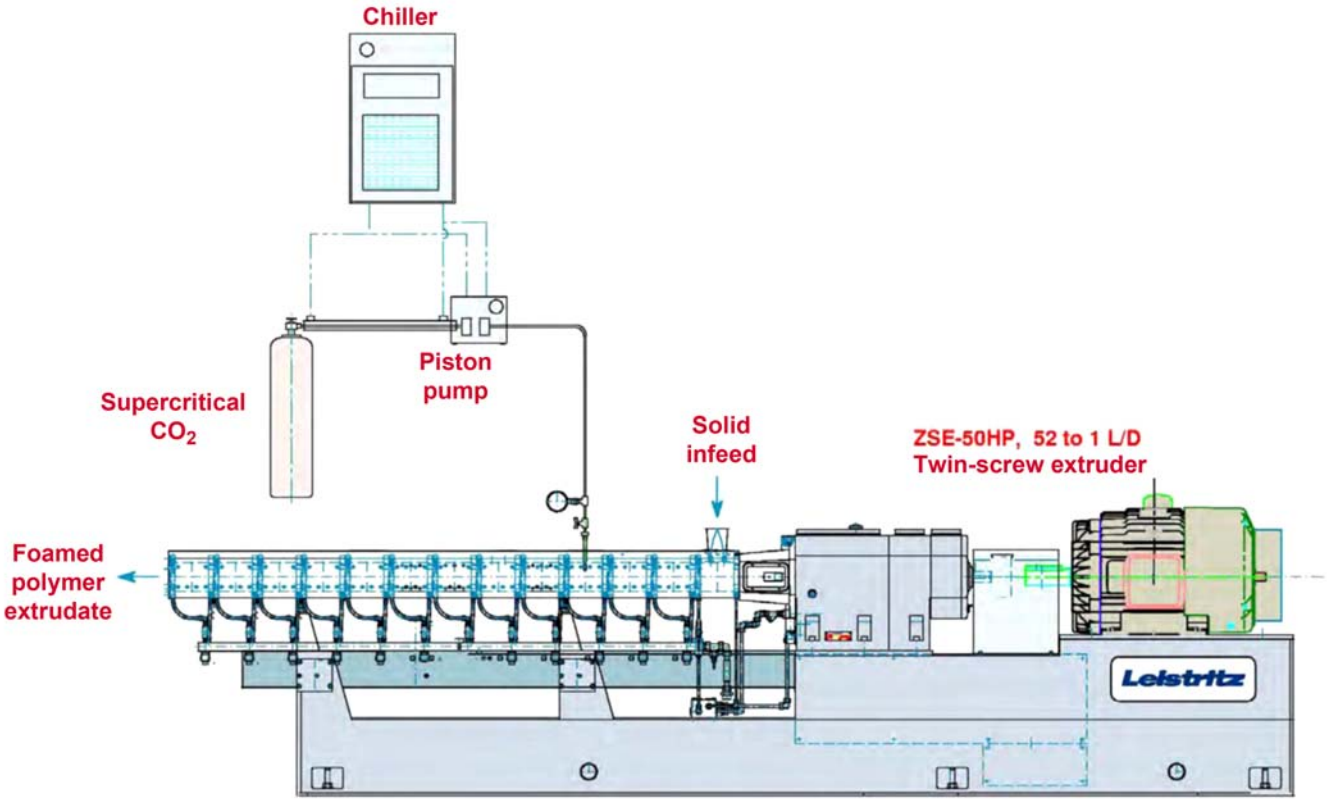

FIGURE 31.19 Schematic diagram of injection of supercritical CO_2 during extrusion process. *Courtesy of Leistriz.*

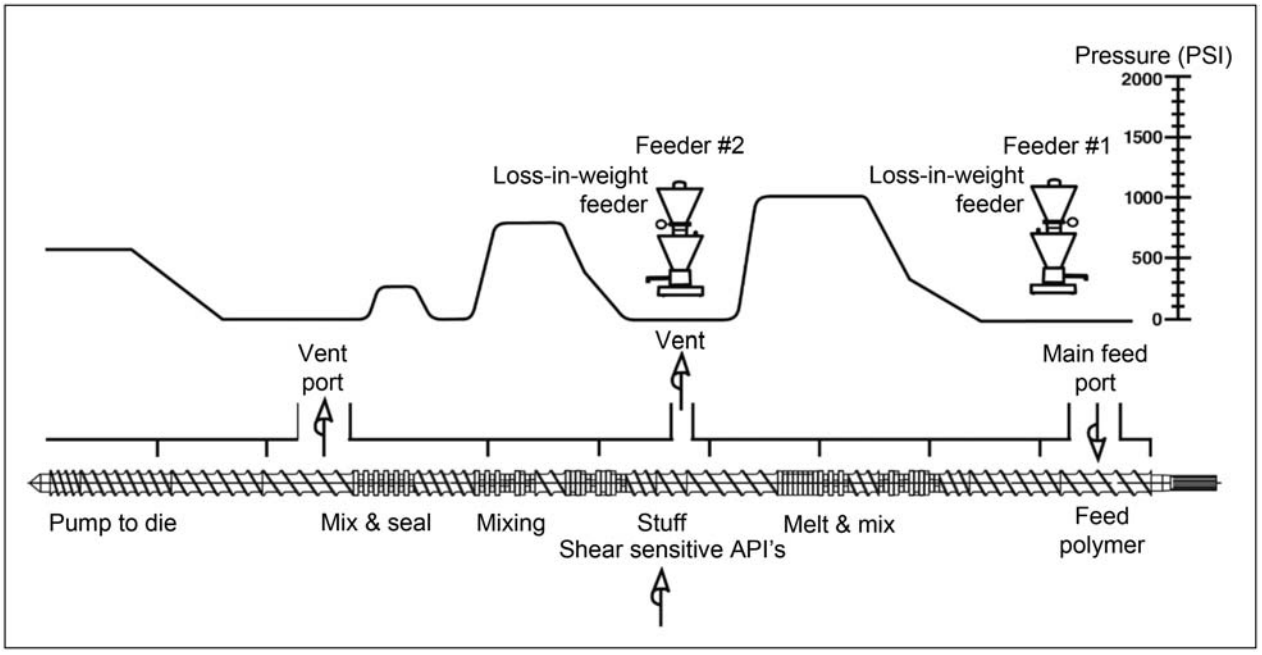

FIGURE 31.20 Pressure gradient in a starve-fed TSE process. *Courtesy of Leistriz.*

FIGURE 31.22 Different screw designs used to evaluate indomethicin-eudragit E ASD.[61]

parameters including barrel temperature profile, feed rate, and screw speed is critical, as these extrusion variables control the key systems parameters (eg, shear rate, degree of fill, residence time, residence time distribution, and melt temperature) and thus affect product quality, as shown in Fig. 31.15. The impact of each process parameter is discussed in Sections 31.2.1.2 and 31.2.2. For compounds prone to thermal and/or shear degradation, the degradation occurs primarily at the mixing/melting zones, where the formulation is exposed to the highest shear and thermal stress. In these zones, the local melt

temperature is predominately controlled by the viscous dissipation as the result of the shearing effect by the rotating screw.

Screw configuration is an important parameter for HME. Altering the screw configuration allows for the modification of the shear stress and residence time. Different screw elements can be optimized to suit particular applications. A right screw design should be able to provide sufficient mixing capacity with the proper shear stress. Generally, one kneading zone positioned at the two-third or at the end of the barrel is adequate to create sufficient mixing at the molecular level for generating ASDs. Caution should be taken when considering modifying the kneading elements, as varying kneading elements could significantly affect the product quality due to a change in residence time and shear stress. Nakamichi et al. concluded that at least one mixing zone-containing kneading element was needed to obtain homogeneous extrudates of nifedipine (NP) and hydroxypropyl methylcellulose phthalate (HPMCP).[5] Gosh et al. demonstrated that the position of the kneading block is critical for processing of thermally labile compounds. Higher drug degradation was observed when the kneading block was close to the feed zone. When kneading block is moved closer to the end of the barrel, API stability improved due to delayed melting and shorter melt residence time.[60] Liu et al. evaluated the effects of four screw configurations on miscibility behavior of indomethacin (IND) in Eudragit EPO. They concluded that IND could not be dissolved into the Eudragit EPO matrix efficiently using screw configuration A (ie, without mixing/kneading zone). They also indicated that the first kneading zone accelerated the dissolution of IND into Eudragit EPO, while the subsequent second kneading zone was superfluous.[61]

Material properties (T_g, T_m, miscibility/solubility regime) should be taken into account when selecting barrel temperature as it would affect the melting process. The heat conducted from the barrel usually assists the melting process at the beginning of the process. However, it might not play a significant role in melting materials at steady-state of the extrusion process. In fact, when additional dispersive and/or distributive mixing is present, the melt temperature is often much higher than the barrel temperature. Under such circumstance, the heated barrels actually act as a chiller to remove the excessive heat generated by shear. Even if conductive heating is not critical to material melting, it still affects the melt viscosity. Increasing the barrel temperature decreases the melt viscosity and thus decreases shear stress (as shown in Eq. 31.4), which might reduce thermal degradation. When the melt temperature is higher than the barrel temperature, increasing the barrel temperature lead to high melt temperature and thermal stress due to decreased barrel cooling capacity. In this situation, degradation formation is ultimately determined by the combined effects from both variables. If the increase in thermal stress is greater than the reduction of shear stress, the degradation could be accelerated with increasing barrel temperature. Jijun et al. have shown that maintaining barrel temperatures above 130°C is required for producing 15% nimodipine amorphous dispersion in copovidone.[62] When the barrel temperature rises above 160°C, degradation of nimodipine was observed with a color change of the extrudate from gold to brown. Thus, it is important to note that the melt temperature is consequently the most critical determining factor in the product quality, and it might be very different from the barrel temperature. In some cases, the barrel temperature might have little influence on product quality. Lyons et al. demonstrated that barrel temperature does not affect either the inclusion of API in the polymer matrix or in-vitro drug release from carvedilol and polyethylene glycol-*co*-polycaprolactone (PEO−PCL) matrices within a temperature range of 95−120°C.[63]

For a given screw design, increasing screw speed increases shear stress and specific energy input to the materials while decreasing residence time. A minimum screw speed is required to ensure sufficient specific energy and residence time required for solubilizing the drug in the polymer melt. The mean residence time for HME process is typically less than 60 seconds. However, excess shear/specific energy resulted from higher screw speed or extended residence time resulting from lower screw speed could negatively affect chemical stability. Thus, when defining a screw speed range, all of these factors should be evaluated carefully. Crowley et al. found that when processing PEO with chlorpheniramine, a low screw speed with a longer residence time induced polymer degradation due to prolonged exposure of PEO to the extrusion temperature. Increasing screw speed led to reduced melt viscosity and identification of the optimal processing condition. However, polymer degradation occurred with further increase in the screw speed due to the heat generated by the mechanical energy of the screws.[64] Gosh et al. reported similar results on processing a thermally labile API. A low screw speed induced thermal degradation due to a longer residence time, while a high screw speed caused degradation due to increased mechanical energy.[60] For a starve-fed extruder, feed rate also impacts residence time and shear stress input to the materials by affecting degree of fill. To maintain a constant melt flow, a balance needs to be identified between the screw speed and the feeding rate. Under constant screw speed, higher feed rate results in shorter residence time. Dependent

on the selected screw configuration, specific energy might increase or decrease with increasing feeder rate. Therefore, HME process design should focus on the understanding of the key system parameters (ie, the combination effects) rather than individual process parameters.

The stability of an ASD formulation could also be impacted by the temperature rise resulted from the pressure generation in the extruder front-end. The more restrictive the front-end, the higher the melt pressure and temperature, which may adversely affect the product quality. The temperature rise can be estimated by Eq. (31.10).

$$\Delta T\ (^{\circ}\mathrm{C}) = \frac{\Delta P\ (bar)}{2} \tag{31.10}$$

ΔT is the change in temperature as the result of melt pressure buildup. ΔP is the melt pressure (1 bar = 14.503 psi).

It should be pointed out that use of an HME process for manufacturing ASD is not without limitations despite its many advantages. For ASD-containing drug substances with a high melting point (eg, >220°C), limited miscibility with the carrier polymer matrix, or both, formation of an ASD can be more challenging, and low drug loading is often observed when compared with other processing technologies, such as spray-drying. Therefore, rational design and development of ASD formulation and HME process requires integrated consideration of the basic properties of the individual API, polymers, surfactants, processes and their interplays as well as the required dose. There is no one-size-fits-all formulation or processing technology for developing and manufacturing ASD products.

31.4 CONTINUOUS GRANULATION USING A TWIN-SCREW EXTRUDER

Granulation is a process in which small particles are combined to form larger permanent particles. The granulation process is widely used in the pharmaceutical industry to improve the flow, density, uniformity, and compressibility of the material for downstream processing. Granulation methods can be categorized into wet granulation, dry granulation, and melt granulation. Wet granulation utilizes liquid to bind the primary particles. High- and low-shear mixers and fluidized bed granulators are typically used in a traditional batch process for the wet-granulation process. Dry granulation does not require the addition of any liquid and solely depends on mechanical stress to bind the particles together. Roller compactors and sluggers are typically used. Both methods are operating in a continuous mode. In the melt-granulation process, granules are formed through the softening or melting of binders. High-shear or fluid-bed granulators are traditionally used for melt granulation in a batch mode.

With increasing interest in continuous manufacturing, the feasibility of continuous wet and melt granulation is revisited by researchers from academia and industry. The advantages of continuous granulation over conventional batch granulation include: (1) reduced cost, resources, and time related to scale-up for product launch; (2) less material handling; (3) more streamlined and efficient process; and (4) more robust process and consistent product quality.

Extrusion, fluid-bed agglomeration, instant agglomeration, and spray drying have been used as the techniques for continuous granulation.[65] Among these techniques, extrusion has been the most popular for pharmaceutical applications. Gamlen and Eardey (1986) first reported using a twin-screw extruder for a granulation process in 1986.[66] This technique attracted more attention after a patent for twin-screw granulation for application in a single-pass, continuous pharmaceutical granulation process in 2002.[122]

Continuous granulation via a twin-screw extruder can be used to replace the traditional granulator in a bin-to-bin manufacturing setup, or it can be integrated into a continuous manufacturing line as demonstrated in GEA's ConsiGma system. For a conventional tablet manufacturing process using a wet granulation step, it contains the following unit operations: blending of the raw materials, granulation, drying, milling, blending of extragranulate, and tableting. Using a twin-screw extruder can potentially eliminate the blending of intergranulate by feeding the ingredients using loss-weight feeders directly to the extruder. With proper screw design and process setup, unimodal particle size distribution (PSD) of granules might be achieved without a milling process for some formulations, which can significantly streamline the process. The more efficient mixing in the twin-screw extruder also requires less binder solution for wet granulation, allowing the drying time to be reduced. For melt granulation using a twin-screw extruder, high efficiency of mixing with more consistent temperature control and significantly lower residence time allows a wider range of process temperature than a normal batch melt granulation process.

As discussed in Section 31.2, a twin-screw extruder consists of two intermeshed screws enclosed in a barrel that rotate in the same direction in most of the applications. The extruder used in HME described in Section 31.3 is often utilized for continuous wet or melt granulation with modified equipment and process parameters, such as screw configuration and temperature profile. A schematic drawing of the standard

layout is shown in Fig. 31.23. Multiple loss-in-weight feeders can be used to feed different ingredients at the same time as needed. Liquid (solvent, water, binder solution, or molten binder) can be fed through a liquid injection system into the extruder. Different liquid feeding positions can be explored depending on different formulations, and the barrel temperature can be controlled. In wet granulation applications, the barrel is normally maintained at room temperature. In melt granulation applications, the barrel can be heated to maintain the temperature required to keep the binder at molten state. The modular design of the screw elements provides the flexibility to meet the product design and processing requirements.

31.4.1 Continuous wet granulation

31.4.1.1 Granulation mechanism inside extruder

For the continuous wet granulation process using a twin-screw extruder, as shown in Fig. 31.23, a powder blend is fed into the beginning of the extruder. Binders can be fed individually using a loss-in-weight feeder, in a powder blend with other ingredients, or as a predissolved solution or foam. There are multiple positions for liquid injection along the extruder. Process parameters, such as feed rate, screw speed, liquid-to-solid ratio (L/S ratio), and screw configurations, together with the formulation design determine the granulation properties. A fundamental understanding of the granulation mechanism inside the extruder helps determine the combination of different process parameters and formulation variables, therefore, enabling the efficient design of a continuous granulation process to achieve the desired product properties.

Different from the granulation process in a high-shear or fluid-bed granulator, wetting, nucleation, agglomeration, and breakage may happen in sequence along the extruder in a much shorter time within a twin-screw extruder.[67] Nucleation happens when the binder solution reaches the powder bed during a granulation process. The method by which the binder solution is applied (by spraying vs dropwise addition) can change the droplet size of the binder solution and, therefore, determines the mechanism of granulation. When the binder solution is fed as liquid drops into the extruder through a liquid nozzle, the droplet size is usually much larger than the powder particle. The immersion mechanism dominates, transforming the powder particles into big, wet, loose lumps.[68] In most cases, this nucleation phase takes place in the conveying screw element region. When the agglomerates reach the kneading elements, they are sheared, compressed, deformed, and fractured. The binder solution is redistributed in this region (eg, being squeezed to the particle surface).[69] Consolidation of granules occurs, and the granules become denser and stronger. Some large granules might even be fractured into smaller granules.

Granulation liquid mixing and distribution during continuous granulation can be visualized by NIR chemical imaging.[70] The distribution of the granulation liquid in the granule was used as an indicator to the granulation formation. The distribution of granulation liquid was more homogeneous at higher L/S ratio. However, when moisture homogeneity is dramatically increased, the PSD of granule remained bimodal. This finding suggested that the typically observed wide and bimodal PSD from a TSE granulation is inherent to the process rather than caused by the insufficient mixing of powder and liquid. Though milling can be used to alter and control the particle size and its distribution for tableting, more fines could be generated during milling, increasing the segregation tendency during subsequent material handling and transfer for downstream processing. Therefore, efforts have been taken to use the modular design of the extruder to produce granules with the desired properties. The kneading block, conveying, mixing, and tooth-mixing elements can be added or combined to the design as modules. There are studies that have shown unimodal

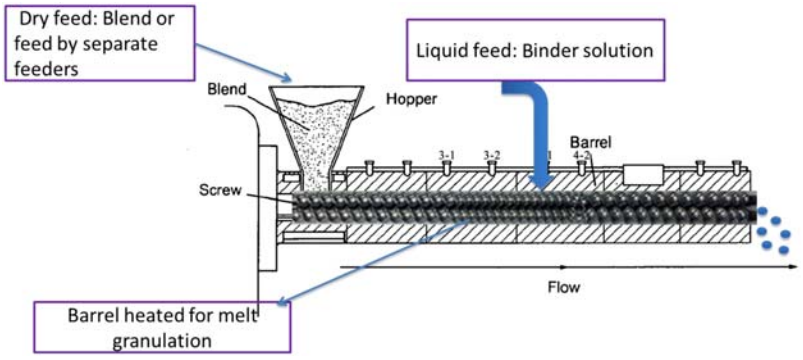

FIGURE 31.23 Schematic drawing of a twin-screw extruder used in continuous granulation.

distribution of granule particle size under certain conditions.[68,71] To help further understand the granulation process using TSE, the effect of screw design and process parameters is discussed in the following sections.

31.4.1.2 *Effect of screw design on granulation*

Three basic types of screw elements used for granulation include conveying screw, kneading, and DMEs. Detailed description of these screw elements can be found in Section 31.2.1.2. The modular design of screw elements provides flexibility in the process design. However, it can make the process development challenging due to the extensive number of available combinations and permutations. Thus, understanding the basic working principles of different types of screw elements and their impact on granulation can help with rational selection of the screw elements to aid the development of a TSE granulation process.

31.4.1.2.1 Conveying

Granule formation in conveying element is mainly due to particle collision. The granule formed is weak and can be fractured into fines easily through the friction force against the barrel wall or towards the flight of the screw. As a result, a significant amount fines are often observed. Thompson and Sun studied the evolution of agglomerates inside the extruder with only conveying elements.[4] The fraction of fines decreased along the length of the screw and mostly over the latter half of the screw. More fines were generated at a low-fill level compared with a high-fill level due to more frequent collisions between particles to facilitate granule growth and smaller portion of particles that are subject to the high-shear force at the barrel walls. Granules are mostly oblong shaped.

Conveying elements are normally used in combination with a kneading element to form stronger granules. The impact of a conveying element before and after a kneading element on granule properties can be very different.[72] Liu et al. (2015) studied the impact of the conveying screw element before and after the kneading zone on granule properties using a ZSE-HP 27 mm extruder. Three values of flight pitch (P/D = 0.67, 1 or 1.33) before and after a kneading block and two different degrees of fill level were evaluated using a microcrystalline cellulose/ lactose system and a system with the addition of ibuprofen. Only the conveying element after the kneading zone had a significant impact on granule properties.[72,73] The screw pullout picture shown in Fig. 31.24 reveals the changes in the granule characteristics across the different zones when the materials were extruded with different screw configurations at a feed rate at 15 kg/hour. The circled region is where the particles exit from the kneading block. Three different screw configurations are

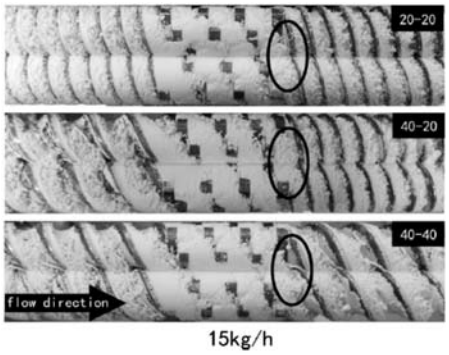

FIGURE 31.24 Screw pullouts for three screw configurations showing the granulation progress along the screws in the region of the kneading block (feed rate = 15 kg/h).[72]

demonstrated. The one on the top uses conveying elements with a flight pitch of 20 mm before and after the kneading block. The one in the middle uses a conveying element with a 40-mm flight pitch before the kneading block and conveying elements with a 20 mm flight pitch after the kneading block. The one at the bottom uses conveying elements with a flight pitch of 40 mm before and after the kneading block.

In general, collision-dominated agglomeration occured in the upstream conveying zone. The binder distribution varied considerably among the different particle sizes due to the complex velocity profiles in the conveying zone. Granule size at this conveying zone increased with the increase of the flight pitch. Velocity of particles conveyed forward increased with the increase of flight pitch, which led to more particle agglomeration. Increasing flow rate reduced the size and shape variation of the granule. This was due to a relatively reduced frequency of collisions in a wider channel. Porosity and strength of the granules were not impacted by flight pitch and flow rate. A downstream conveying element contributed to the fragmentation of compacted particles exiting the kneading block. After the kneading block, the compacted particles were extruded towards the flight of the downstream conveying element. The impact of downstream conveying element on the granule particle size was smaller when a wider flight pitch conveying element was used due to the larger angle between the obstructing planar walls. Larger, more elongated, and fragile granules were observed in the larger pitch conveying element.

31.4.1.2.2 Kneading element

Granule size and strength are mainly determined by the kneading element. Granule agglomeration and breakage occur simultaneously in this region. A kneading block comprises a number of discs, each offset by an angle from the next. The offset angle is the main variable varying the drag/pressure flow capacity of

a kneading block without changing the available volume. The disk thickness changes the volume of material flow in the kneading block. At a lower offset angle, drag flow dominates over pressure-driven flow. With increasing offset angle, the pressure-driven flow increases until only pressure-driven flow occurs at a 90° offset angle. At high screw speed (low-fill level in the conveying zone), the offset angle does not seem to affect the granule particle size. The PSD of the granules only changes with more large agglomerate at low screw speed when a 90° offset angle kneading block is used.[4] This phenomenon is very different from the HME process, in which the offset angle of a kneading block can significantly influence the extensional flow as a fluid is squeezed through the gaps of the offset disks. For cohesive granule flow, granule development appears to occur in the intermeshing region, and the offset angle of the kneading disks plays only a minor role in the compressive stress in that zone. The granules from the kneading block presents plate or ribbon-like granules due to the calendaring action when the granule is compressed through the adjacent rotating kneading disks in the intermeshing region. For example, a long reverse-flighted kneading block has been reported to cause blocking during granulation.[74]

31.4.1.2.3 DMEs

Broad bimodal size distribution, with the presence of lumps and ungranulated fines, are observed for the granulation using a twin-screw extruder in many cases. Drying uniformity of these granules is often difficult to control. To address this issue, a DME has been explored to alter the granule size distribution.[71] A picture of a DME is shown in Fig. 31.25. The angularly cut blades are perpendicular to an annulus portion of each DME. The annulus portion is thicker than the blade, as shown in the side view. The portion extending out the blade is known as the spacer. A DME can be mounted in two ways depending on the position of the spacer (see Fig. 31.26). If the spacer is placed facing upstream, it is called the *forward configuration*. If the spacer is placed facing downstream, it is called the *reverse configuration*.

A DME allows the mixing and collision of granule particles through cutting and recombination. Like the kneading block section, the DME section is also a mainly pressure-driven flow section.[4] The forwarding comb element has similar performance as the kneading block, which produced coarse granules, but a considerable amount of fines is still observed, which is likely due to the angular cuts by the mixing element. However, the granule particle shape generated is different from a kneading block. Round-to-oblong shaped granules are formed using the comb mixing element instead of elongated plate-like granules generated using

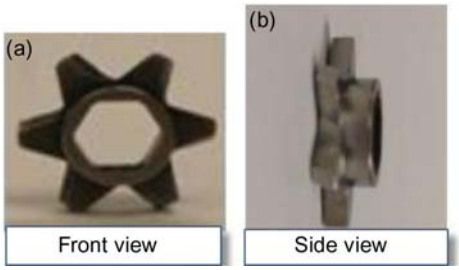

FIGURE 31.25 Pictures of a DME.[71]

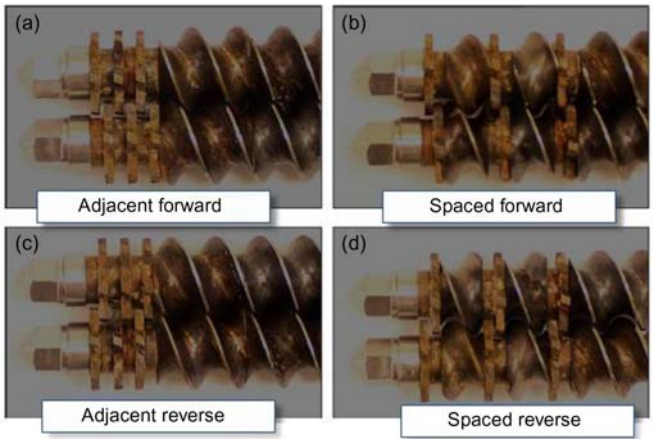

FIGURE 31.26 DME configurations.[71]

the kneading element. The particles are packed intensively in the annular region between adjacent rings. When the packaged granules pass the intermeshing region, they are chopped by the segmented rings of the adjacent comb mixing element. Granule formation can also occur in the gaps of the rings. A reverse-comb element produces complete agglomeration, which often leads to blockage, and is not recommended.

Sayin et al. studied four different configurations (see Fig. 31.26) of DMEs using a 16-mm Eurolab twin-screw extruder. Breakage and layering are the main mechanisms of granule formation when a DME is used. Large agglomerates from the convey section were broken by the rotating blade of a DME followed by layering of ungranulated fines on the newly exposed wet surfaces. Granule particle size was more significantly impacted by the orientation (spacer facing upstream or downstream) of the DME than the placement (regardless the presence of the conveying element between DME). The reverse configuration resulted in narrow PSD and more uniform liquid distribution compared to the forward configuration. In the forward DME configuration, the bimodal distribution of granule particle size often persisted until the liquid-to-solid ratio was very high, where agglomeration of the fines could take place more easily. In the

reverse DME configuration, unimodal distribution of granule particle size could be achieved at much lower liquid-to-solid ratio. The granule property difference observed was due to the difference in the spacer position in the forward DME and reverse DME. In the forward DME configuration, the spacer was between the blade of DME and helix of the conveying element. Materials were staggered between this space and carried over along the internal barrel wall without being chopped by the blade; therefore, the material flow was homogeneous and continuous. In the reverse DME configuration, the material flowed to the blade directly and was chopped.

The impact of the number of DMEs on granulation was studied by Vercruysse et al. (2015)[75] When a DME was used, the amount of fines was significantly reduced compared to the conveying-only configuration. An increase in the number of narrow DMEs (thinner blade, Fig. 31.27) did not further reduce the amount of fines; however, the additional DMEs could reduce the amount of larger granules. The addition of a third narrow DME did not have any impact on the particle size. Due to nonforwarding characteristic of the DMEs, the use of more than one wide DME (wider blade, see Fig. 31.27) is not recommended because it resulted in high and unstable torque.

FIGURE 31.27 Pictures of wide DME and narrow DME.[75]

31.4.1.2.4 Screw mixing element

The screw mixing element, as shown in Fig. 31.28, can cause more backflow, resulting in longer residence time compared with traditional conveying elements.[75] Screw mixing elements do not generate high-shear regions as the kneading element due to their higher transport capability. The granule PSD obtained using a screw mixing element is very similar to the one from conveying elements, with a high percentage of fines and a large portion of extremely large agglomerates. Comparing with screw configuration consisting only of conveying elements, a screw mixing element can slightly reduce the amount of fines. More screw mixing elements are usually required to decrease or avoid extremely large agglomerates.

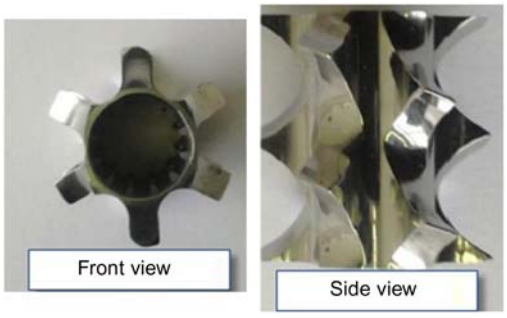

FIGURE 31.28 Pictures of a screw mixing element.[75]

31.4.1.2.5 Screw configuration

The screw configurations for the wet granulation process should always start with conveying elements, followed by kneading or DMEs. In the conveying zone, the fill level is low, and particle densification and mixing are typically very limited. Granules are formed through powder layering on the liquid droplet. There is no redistribution of the liquid in the granules; therefore, the uniformity of the liquid distribution is very poor. Multimodal PSD with a high amount of fines and a small portion of agglomerates are often obtained. Only at high L/S ratios can more agglomeration take place, resulting in fewer fines and more agglomerates. When the large agglomerates formed in the conveying zone reach the kneading zone where the fill level is significantly increased, shearing, compressing, and deformation occur, leading to densification of the material, significant reduction in the amount of fines, and an increase in the agglomerates. At a high L/S ratio, unimodal PSD can be achieved; however, the granule particle size is normally too big to be used directly for tableting. Similar results were observed when using a DME.[71] When two kneading zones were used, the second kneading zone broke down the big agglomerates formed in the first kneading zone by shearing the overwetted mass between the tips of the kneading element and the barrel wall. At the same time, the fines were exposed to the newly formed wet surface of the broken agglomerate. Therefore, when two kneading zones

were used, the portion of fines and the extreme big granules were reduced, and the median particle size was increased. When the number of kneading segments is increased, more large agglomerates were formed. The liquid distribution in the kneading zone was much better compared to the conveying zone due to the dispersive mixing. Improved uniformity was achieved with a longer kneading zone. In the case of two kneading zones, a homogenous distribution can be achieved.[4] Alternatively, DMEs can be used to replace the kneading elements or can be combined with additional kneading elements to control the granule particle properties. The screw elements at the exit are important as well.[75] When two narrow kneading elements (length = D/6 for each element) at a 30° angle were used, no change was observed in granule PSD compared with the use of the convey elements. When a wide kneading element (length = D/4 for each element) was used, further agglomeration takes place. Particles were forced into the gap of the kneading element and the barrel wall. Increasing the number of wide kneading elements used resulted in more agglomeration. However, when the offset angle was 60° or 90°, no difference in granule PSD was observed compared to the conveying element, due to the larger axial opening between the kneading disks. The use of cutter elements (see Fig. 31.29) led to more oversized agglomerates. In addition, it increased the pressure at the end of the screw chamber, giving rise to high and variable torque profiles. When a single narrow DME was used, a reduction of particles larger than 1000 micron was observed. An additional DME further reduced the large agglomerate, but it introduced more fines. It was found that the combination of one kneading block and a DME at the end seemed to optimize the PSD. More DMEs at the end reduced the median particle size.

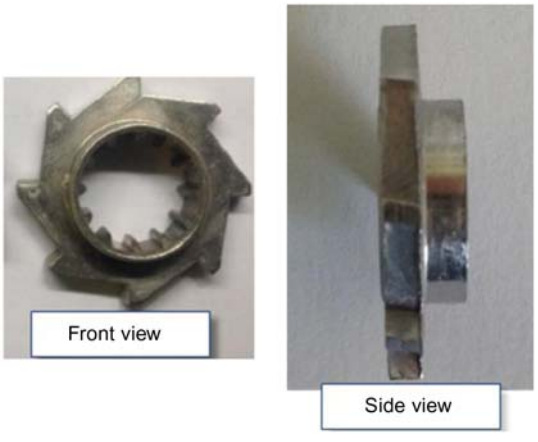

FIGURE 31.29 Pictures of cutter.[75]

31.4.1.3 *Effect of extrusion process parameters on granulation*

In addition to screw elements, feed rates (solid/liquid ratio), screw speed, and liquid injection position are other parameters that can be adjusted to change the granule properties. The effects of these process parameters on granulation also depend on formulation compositions. Some materials or formulations are more robust, and the resulting granule properties do not vary significantly with the change in process parameters. In other cases, the granule properties can change dramatically with a change in the process parameters. For example, lactose is not as sensitive to shear and over-wetting during granulation when compared to dicalcium phosphate.[76,77] In this section, the influence of process parameters on the granulation process will be discussed in relation to material and formulation characteristics to provide some general guidelines for process development.

Liquid-to-solid ratio (L/S ratio) has been found in the study of various formulations to be the most significant factor that affects the granule properties.[67,68] L/S ratio changes the friction force between the mixture and the inner wall of the barrel. A higher L/S ratio generates more agglomeration with less fracture due to a higher fill level and increased torque.[78] As a result, larger and denser granules can be produced.

The screw speed has an impact on the fill level. With a higher fill level in the barrel, higher friction force as well as higher torque are often observed. Increased screw speed and lower L/S ratio led to a shorter mean residence time and narrower residence time distribution. At high screw speeds, material flow inside the extruder is more plug flow as indicated by the narrow residence time distribution. Tu et al. studied a microcrystalline cellulose/polyethylene glycol 6000 formulation and found larger and more uniform granules were achieved with addition of more binder, a higher screw speed, and sufficient mixing.[78] However, changing the filling degree by varying the screw speed and feed rate did not significantly impact the PSD of granules with a lactose formulation.[70] In studying lactose granulation, Vercruysse found that the liquid addition method, pump orientation, pump type including peristaltic and piston pumps, tubing configuration (independent vs split tubing), nozzle diameters, liquid addition zones, and barrel-filling degree had no impact on mixing efficiency. More kneading zones and higher liquid feed rates were the only two factors that affected the mixing efficiency.

Nozzle design can influence the liquid dosing accuracy and consistency. Normally, the binder solution is injected right before the kneading block, which is also the place where pressure can build up due to the significantly increased fill level. The pressure

buildup can easily cause nuzzle clogging. To overcome this problem, a standard liquid nozzle can be modified to improve uniformity of the liquid feed rate. As demonstrated in Fig. 31.30, a tapered-tip nozzle design reduced the dead volume and the amount of material in front of the nozzle.[125] The Teflon capillary insert reduced the diameter nozzle and increased the liquid injection pressure. These designs reduced the clogging and led to a more consistent liquid feed. As discussed previously, the droplet size can affect the granule size. Addition of liquid to ungranulated powders in the dripping mode typically gives the broadest size distribution with un-granulated fines and a high percentage of lumps compared with addition using the spraying mode. Changing the nozzle diameter can change the droplet size. However, in the study of the lactose granulation by Vercruysse, the change in the nozzle diameter did not impact the moisture uniformity or the PSD of the granule.[70]

Binders can also be added in the form of foam. Thompson et al. successfully fed the foam binder using a side stuffer when the normal liquid injection device could not be used (see Fig. 31.31).[123] In foam granulation, the binder foam can rapidly spread over a large area of the powder during wetting; therefore, a lower amount of binder solution is needed compared to liquid injection. The granule properties from the foam granulation are comparable with the granules made using liquid injection.[123,124]

Different granulation behaviors have also been compared using dual-port granulation liquid injection and single-port granulation liquid injection. Dual-port granulation liquid injection facilitated the distribution of the granulation liquid and resulted in a lower and more stable torque during granulation. Changing the proportion of injection at the first injection port and second injection port did not have much impact on the torque.[79] Further improvement in moisture uniformity was not achieved by adding liquid injection zones.[70]

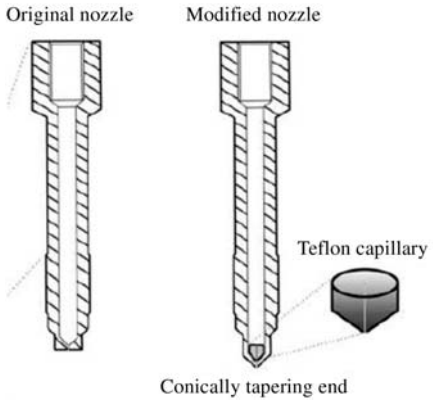

FIGURE 31.30 Liquid injection nozzle.[125]

Different binder concentrations in the binder solution also impact the granulation. Binder viscosity increases with increasing concentration. Although increased torque can be associated with higher binder viscosity during the TSE granulation process, the use of binder solution with higher viscosity can reduce fraction of the fines and, thus, facilitate generation of granules with unimodal distribution of particle size. In addition, it can also result in increased granulation strength and mean residence time and wider residence time distribution.[67] Furthermore, the binder is more effective when it is added as predissolved binder solution.[70]

In most cases, wet granulation via TSE is carried out at room temperature. At a higher barrel temperature, the powder mixture may dissolve faster in the granulation liquid compared to room temperature and lead to different granulation behavior. Vercruysse et al. reported that higher barrel temperatures led to fewer fines and stronger granules in theophylline/lactose/PVP formulation. The tablets made with granules granulated at a higher temperature had lower friability.[80]

Besides the process parameters and screw element design, attention should also be paid to the extruder geometry during process scale-up or transfer from one type of extruder to the other. Djuric et al. (2009) compared an APV Baker extruder with a Leistritz Micro extruder. A higher densification level was achieved for the extruder with a lower free chamber volume (Leistritz) in the granulation zone, which resulted in coarser granules and lower amount of fines. At the same screw speed, a higher tip speed was obtained for the extruder (Leistritz) with a larger screw diameter, which led to higher mechanical stress, resulting in coarser and stronger granules during process scale-up. Froude number, which takes into account the centrifugal force to the gravitational force, was used to determine the dynamic similarity of both extruders. The Leistritz extruder has a

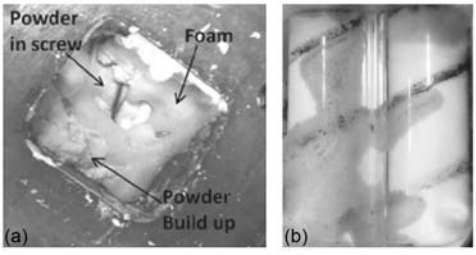

FIGURE 31.31 Different foam binder addition configurations. Image (a) shows the foam suspended above the moving screws when added directly to the open zone and powder buildup occurring on the barrel zone walls. Image (b) shows successful incorporation of the foam from a side-stuffer (as seen from a transparent viewing port above the screws while the foam entered out of view from the left-hand side). The direction of conveying for lactose was toward the top of the view in image (b).[123]

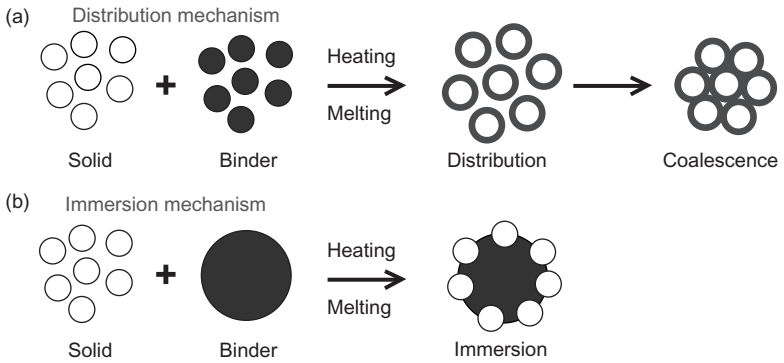

FIGURE 31.32 Agglomerate formation mechanisms in melt agglomeration. (a) Distribution mechanism; (b) immersion mechanism.[126]

higher Froude number, indicating higher centrifugal forces during granulation. When the free chamber volume is high, the feed rate can be increased without significant impact on the granule particle size.[76]

31.4.2 Continuous melt granulation

In the melt granulation, enlargement of the particles is achieved through the binding of solid particles with a molten binder. The binder used in the melt-granulation process is normally in a solid state at room temperature for ease of handling and melts or softens at elevated temperatures during the process. For continuous-melt granulation using a twin-screw extruder, the binder can either be preblended with other ingredients or subsequently fed into the extruder in a powder form, or it can be pre-melted and added continuously during granulation through a liquid injection nozzle. Melt granulation is more suitable for moisture-sensitive compounds and also has the benefit of avoiding a drying unit operation after granulation, which can increase the manufacturing efficiency.

In traditional melt granulation, binders are limited to a few choices with a melting point between 55°C and 85°C. There are generally two types of meltable binders: hydrophilic and hydrophobic. The former is often used in preparing IR dosage forms and is often limited to polyethylene glycols and poloxamers. The latter is mainly utilized in manufacturing ER products and may also serve as the rate-controlling materials. Examples include glyceryl behenate, carnauba wax, stearic acid, and glycerol monostearate. In continuous granulation using a twin-screw extruder, the more efficient mixing, heat transfer, and significantly less residence time allows a higher granulation temperature compared to a high-shear mixer. Therefore, a much lower amount and wider range of binders can be used, especially for producing IR products. In addition to the binders listed above, polymers such as polyvinylpyrrolidone (PVP), poly lactide-*co*-glycolide (PLGA), polyvinyl alcohol, and hydroxypropyl cellulose (HPC) can all be potentially used as the binder to facilitate granulation.[127,128] In certain cases, a thermally stable API with a relatively low melting point (eg, <120°C) can also serve as a binder for TSE process.

In the melt granulation process, the mechanism of granule nucleation and granule growth has been described as either immersion and layering or distribution and coalescence, as illustrated in Fig. 31.32.[81,126] When melted binder particles are smaller than powder particles or the viscosity of the binder is low, the liquid binder spreads over the surface of primary particles, and the wetted solids coalesce to form larger nuclei. When the melted binder particles are larger than the surrounding powder particles or the viscosity of the binder is high, the powder particles adhere to the surface of the droplet of the liquid binder. The granule grows as one layer of particles adheres to another layer of particles when the binder immerses out to the surface.[134] There is a strong correspondence between binder particle size and final granule size in the case of immersion and layering.

Mu and Thompson (2012) studied the mechanism of melt granulation using a twin-screw extruder.[81] In the study, two different grades of polyethylene glycol (PEG) were used as the binder, representing a binder with high and low viscosity. PEG was preblended with lactose and fed into the extruder in solid form. Inside the extruder, the heat transfer is mainly through convection and conduction. Because thermal conductivity of PEG is low, lactose powder would first be captured onto the softened PEG particle (as in the immersion model) rather than liquid PEG particle spreading around the lactose particle (as the distribution model). In a later stage, when the PEG particle is fully melted, its distribution to the outer surface of the particle by spreading would be more readily, especially in the mixing zone; therefore, granules could

grow through both mechanisms. The data indicated a strong correlation between PEG particle size with the granule particle size, which led the authors to conclude immersion mechanism was dominating. No study has been performed to study the mechanism when the binder is pre-melted and fed through a liquid injection nozzle. In this case, it is very likely that distribution and coalescence mechanisms will dominate the granulate formation and growth.

Continuous-melt granulation has been used to enhance the tableting properties of poorly compactible high-dose drugs, [82] reduce dose dumping for controlled-release drugs,[83] and reduce the tablet size for high-dose, modified-release formulation [84]. Lakshman et al. (2011) studied the tablet properties of a tablet containing 90% metformin HCl and 10% hydroxypropyl cellulose (HPC). Three granulation methods, melt granulation using a twin-screw extruder, and wet and solvent granulation using a high-shear granulator, were used in the study, and the results were compared. Due to the high water solubility of metformin HCl (about 1000 mg/mL), a small amount of moisture can dissolve a significant amount of the drug, which leads to poor powder flow, sticking, and picking during compression. Compared to the tablets made from wet granulation and solvent granulation, the tablets made from the continuous melt granulation process have higher hardness and lower friability when compressed under same compression conditions. In addition, the process is less sensitive to humidity changes in the manufacturing facility or moisture content in the granule compared to the wet and solvent granulation process. More detailed discussion of this study is available in Section 31.6.2. Keen et al. (2015) utilized a twin-screw extruder to make tramadol HCl extended-release formulation using glyceryl behenate as the binder, which is resistant to alcohol-induced dose dumping.[83] Different barrel temperature profiles, throughput rates, and lipid binder sizes were explored in the study and were found to have an impact on granule particle size. Vasanthavada et al. used the twin-screw extruder melt granulation to develop an imatinib mesylate modified-release formulation with a drug load of approximately 90%. In this study, melt granulation was compared with wet granulation. Tablets from the melt granulation process demonstrated higher tablet hardness, better friability, and slower drug release compared to the tablets prepared by a wet granulation process. The process robustness was also evaluated. None of the parameters, feed rate, process temperature, and screw speed, were found to significantly impact the final blend particle size and the drug release, demonstrating a robust granulation process.

31.4.3 Scale-up/scale-down considerations

Compared to a batch granulation process, the continuous granulation process has the benefit of avoiding scale-up by simply extending the granulation time and or operating on multiple extruders. Continuous granulation using a twin-screw extruder reaches steady-state quickly, normally after the duration of few residence times. After reaching the steady-state, granules can be consistently manufactured for days to meet the supply demand required. Keleb et al. reported successful continuous manufacturing of 8 hours of a hydrochlorothiazide /lactose/PVP formulation.[129] No significant differences in granule and tablet properties were observed over the entire granulation period.

In cases where the pilot-scale extruder cannot meet the commercial supply demand for a high-volume product, a scale-up to a commercial-scale extruder is needed. Scale-up of the extrusion process is introduced in Section 31.5. These scale-up methods are readily applicable to continuous granulation using a twin-screw extruder. Geometric similarity should be maintained between the different scales of the extruders. Most of the continuous wet/melt granulation processes are still operated under starve-fed conditions; therefore, a scale-up approach based on power or heat transfer may be more suitable compared with a volumetric scale-up method. For both continuous wet and melt granulation, the shear energy generated is much lower compared to a HME process due to different screw configurations and the absence of a flow-restricting die block. The power assumption is normally lower than 10%. Therefore, API degradation due to heat/shear energy is less of a concern compared to a HME process.

Unlike a batch granulation process in which the materials are preweighed and discharged into a batch, the solid powder and liquid binders are continuously fed into the extruder for granulation in a continuous granulation system. The feeding accuracy and consistency directly impact the final composition of the product, which makes the control of the powder and liquid feeding system critical during scale-up and scale-down. One major objective of granulation is to improve the API flow properties; therefore, the API in a granulation formulation may have poor flow and high variability in physical properties. This makes the feeding challenging, especially when the API is directly fed into the extruder without preblending with other excipients. Cartwright et al. studied different loss-in-weight (LIW) feeding systems for a poorly flowing API.[130] Three different screw designs (see Fig. 31.33) of K-tron feeders were studied for the K-tron rigid frame design. Fine concave screws and

FIGURE 31.33 Transport screws used in K-Tron LIW feeder.[130]

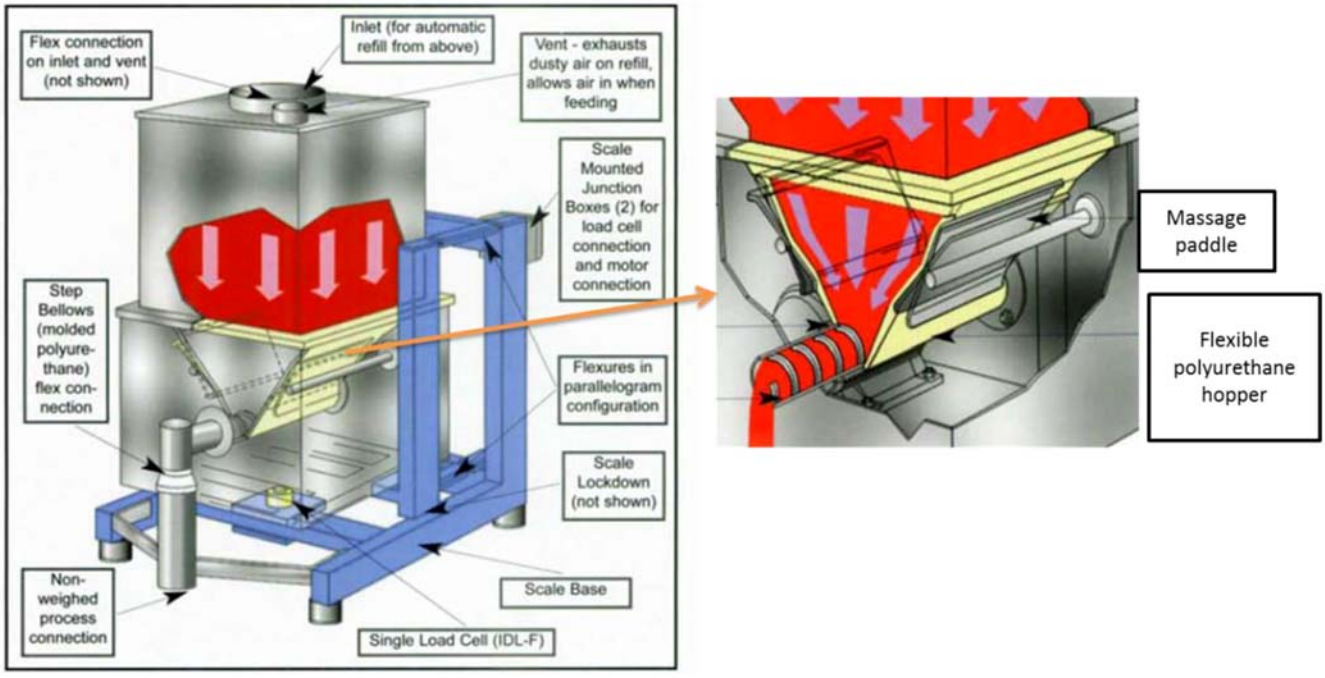

FIGURE 31.34 Brabender flexwall feeder.[131]

flighted auger screws could be used for free-flowing and dense materials. However, it caused powder compaction within the screw and between the screw and the feeder barrel wall for low bulk density and poor flow material. A core and spiral screw conveyed the poor flow material more effectively than the fine concave and flighted auger screw, but the feed speed was limited. In addition, frequent powder bridging was observed in the powder hopper due to the scimitar blade. Material compaction against the hopper walls and the widest arc of the scimitar blade was also noticed. The flexible frame loss in weight feeder (see Fig. 31.34) has hopper walls made from polyurethane or silica and massage paddle to agitate powder through. It can eliminate bridging and avoid powder compaction. Cartwright et al. used the flexible frame loss-in-weight feeder and achieved more consistent flow compared to the K-tron feeders.[130]

31.4.4 Modeling of continuous granulation

Ideally, a simulation model of the twin-screw granulator can provide insights on improving process knowledge and performing qualitative study, thus reducing the amount of experiments needed. For example, DEM and CFD models can provide particle tracking information, which can be used to construct

the residence time distribution along the spatial domain for a continuous corotating screw granulator.

However, first principle simulations of the flow in corotating intermeshing twin-screw extruders are highly challenging due to the complex geometry of the rotating screw and free surface flow in partially filled conveyed sections. On the other hand, the calibration and validation of simulation models are crucial steps in assessing their value in granulation process modeling. Typically, adjustments or tuning in model parameters through calibration are necessary to improve model accuracy and obtain reliable models. However, many of these parameters are difficult to measure in the field, creating additional challenge for simulation. Most of the modeling approaches to date were carried out using default parameter values or best-guessed values to describe the rate of nucleation, growth, and breakage. Some modeling techniques are computationally challenging. In the case of the discrete element method (DEM), it can be very computationally costly to simulate a large number of particles with small integration time steps.

A comprehensive review by Kumar et al. on applying population balance and discrete element modeling to high-shear wet granulation (HSWG) provides a good foundation for modeling of a continuous granulation process.[85] Bouffard et al. and Barrasso et al. implemented a bidirectional coupling of population balance model (PBM) and DEM using a commercially available software.[86,87] To avoid the challenges in the DEM approach, Eitzlmayr et al. have employed the smoothed particle hydrodynamics (SPH) method on a Newtonian, temperature-independent flow, taking advantages of SPH's meshless nature and the inherent capability to simulate free surface flows.[88]

To develop a microscale model such as DEM, the incorporation of microscale material properties such as wet granulate yield strength, Young's modulus, and asperity size are required. Accurately measuring these properties are important but challenging in some cases, especially the granule yield strength at different wetness levels. Table 31.7 shows the interdependencies of particle scale parameters and system parameters.[85] The combination of PBM (system level) and DEM (particle level) is the most promising approach for modeling of the continuous granulation process. These models at different scales should be linked using multiscale integration framework. This approach has been summarized by Kumar.[85]

So far, the model validation has been qualitative and focuses on model fitting of the endpoint of

TABLE 31.7 Size Changing Mechanisms Occurring in HSWG[85]

Mechanism	Particle formation	Characteristics	Equations
Wetting and nucleation		**(a)** Pendular—looks like bridge, but particles not immersed in liquid **(b)** Funicular—thicker bridges but not completely filled **(c)** Capillary—particles at edge of cluster not completely wetted by liquid **(d)** Droplet—all particles completely wet	$\tau_{wetting} = \frac{2V_0^2}{\pi^2\varepsilon_s^2 r_d^4 R_{pone}} \frac{\mu}{\gamma_{IV}\cos\theta}$ $\frac{\partial n}{\partial t} = B^0\delta(l - l_0)$
Growth-aggregation		• When dealing with systems that exhibit aggregation, it is more convenient to use particle volume rather than particle size, since volume is conserved • The success of collisions, ie, aggregation can be a function of particle size, liquid content and powder properties and operational factors such as bed height, powder velocity and shear	$B_{agg}(x) = \frac{1}{2}\int_0^x \beta(x-y,y)n(x-y,t)n(y,t)dy$ $D_{agg}(x) = n(x,t)\int_0^\infty \beta(x,y)\,n(y,t)dy$
Growth-layering		• It is more convenient to use particle size as the internal coordinate when describing layering or growth	$\frac{\partial n}{\partial t} = \frac{\partial}{\partial x}\left[n\frac{dx}{dt}\right](x,t)$
Breakage		• The complexity of breakage models extends from binary breakage models to full particle distributions represented by breakage and selection functions or empirical models	$\frac{\partial n(u)}{\partial t} = \int_0^\infty K_{break}(y, x-y)\xi_{break}(y)n(y,t)dy - \xi_{break}(x)n(x,t)$

granulation outcomes, such as granulate size distribution and their physical properties. Barrasso et al. have demonstrated the parameter estimation and validation for a multidimensional PBM used for a twin-screw granulation process.[89] As the measurements techniques for endpoint determination progress, more vigorous and complex models can be calibrated and validated utilizing the available experimental data.

31.5 PROCESS SCALE-UP

To consistently produce the extrudate with a predefined quality, it is essential to evaluate and understand both the formulation and the manufacturing process using a systematic approach. To scale-up a manufacturing process, a good starting point can be an Ishikawa (Fishbone) diagram, which provides a comprehensive overview of all variables involved. Fig. 31.35 is an example fishbone diagram for the HME process.[24] As discussed in the previous sections, a unique aspect of the extrusion process is that it consists of several processing zones. As shown in Table 31.5, HME can typically divided into the: (1) feeding zone, (2) solid conveying zone, (3) melting zone, (4) mixing zone, (5) melt conveying zone, and (6) the discharging/shaping zone with an optional devolatilization/venting zone. Thus, in successfully scaling up an extrusion process, the requirements for individual zones and the overall process need to be considered simultaneously.

31.5.1 Extrusion process scale-up

The ultimate goal of extrusion process scale-up is to generate a large quantity of extrudate while maintaining critical quality attributes. As illustrated in Fig. 31.15, the extrudate quality is determined by scale independent key system parameters, including specific energy, residence time distribution, product temperature, and potentially pressure. Therefore, those parameters should be maintained constant during scaling. In the most straightforward and simple scaling, the extrusion batch size increases by increasing the extrusion time or duplicating the same extruder used in the small scale. Under such a scenario, the extrusion process remains the same, and the process parameters should be kept unchanged. However, when scaling requires an equipment change, the scaling could become challenging as the key system parameters are not directly adjustable and, in some cases, even difficult to measure accurately. A number of publications proposed scale-up theories of HME. Nakatani reported a successful extrusion scaling by introducing an adiabatic index aimed at keeping the melt temperature constant.[90] The suitability of a one-dimensional computational extrusion simulation was demonstrated for process scale-up and transfer.[91,92] In this section, a few classical scale-up strategies will be discussed. Although these strategies provide a starting point of the scaling process, further refinement and optimization of extrudate parameters (free volume, screw configuration, die geometry) and process parameters (screw speed, feed rate, and barrel temperature)

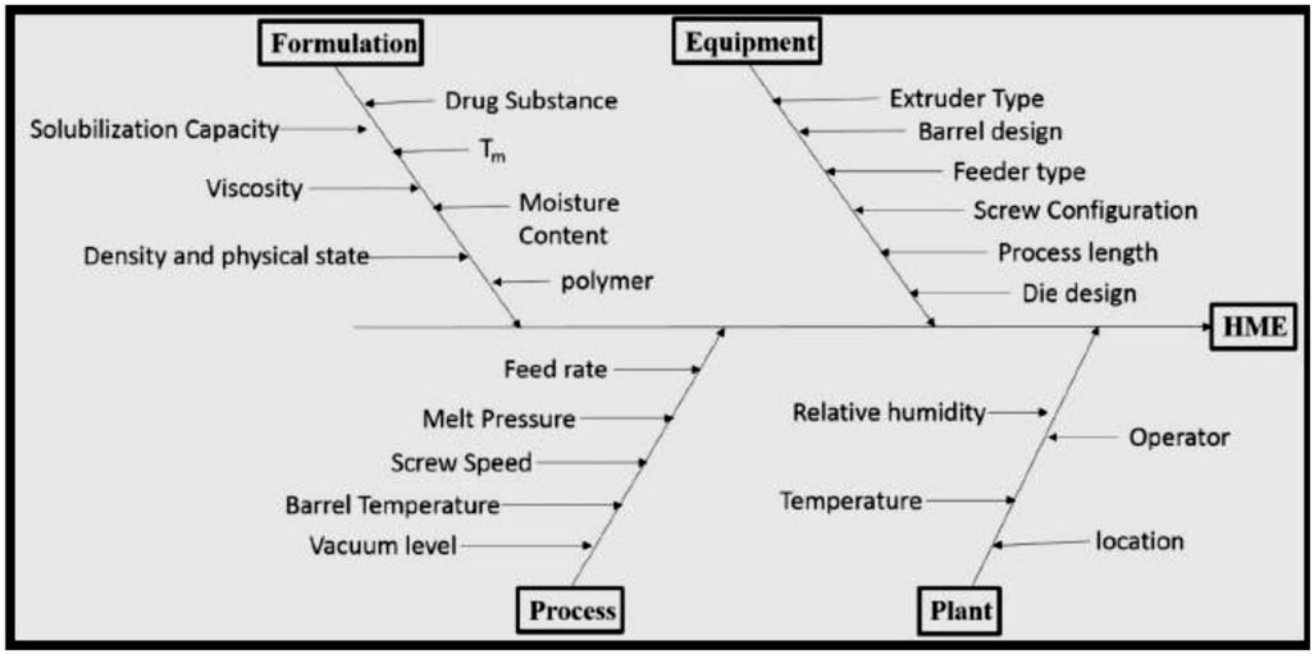

FIGURE 31.35 Ishikawa diagram of hot-melt extrusion process.[24]

are often required to identify the proper operating conditions.

31.5.1.1 Geometric similarity

Similar to scaling for all other unit operations, geometric similarity between extruders should be maintained during scaling. It is recommended to adhere to the same design of extruder and ideally remain with the same equipment manufacturer. To achieving geometric similarity, the following three extruder and screw dimensional characteristics should be examined and kept as constant is possible:

1. Length/diameter (L/D): The ratio between screw/barrel length and screw diameters (L/D) and the length of each processing zone are important for accomplishing desired processing tasks such as conveying, melting, and mixing. This ratio, to a great extent, is determined by the extruder design.
2. Screw diameter ratio (D_o/D_i): The ratio between D_i and D_o impacts free volume, shearing rate, and mixing capability. Most twin-screw extruders today are manufactured with diameter ratios between 1.45 and 1.75.
3. Screw design: The screw plays an important role in determining product quality, with conveying and mixing elements configured in a specific sequence to accomplish the desired task in each processing zone by controlling the residence time distribution and energy input. The sections of a screw configuration and their relative positions can be scaled using extruder outer diameter D_o as a scaling factor.[93] For conveying sections, both pitch and section length are calculated as a ratio to D_o, and those ratios should be maintained constant between scales. The same method applies to scaling of the kneading section length (see Fig. 31.36). However, the number of disks and offset angles should be kept constant if possible. Since an exact scale-up of each screw element for all machine sizes may not be available, the screw configuration and zone position may be changed, and, as a result, the adjustment of process parameters would likely be necessary.

31.5.1.2 Classic scale-up strategies

The classic scale-up strategies focus on the process limiting factors, including feed capacity (volumetric scale-up), motor power (power scale-up), and heat input (heat transfer scale-up).

31.5.1.2.1 Volumetric scale-up

Volumetric scale-up of the extrusion process focuses on maintaining a constant mean residence time. The volumetric scale-up strategy applies when free volume limits the throughput, that is, the extruder is operating at its volumetric limits. This occurs when the feed zone is full as a result of low material density and/or conveying capacity; increasing the screw speed increases the throughput.

When two extruders are considered geometrically similar, the degree of fill and average shear rate are also expected to be reproduced. For an extruder with the same screw diameter ratio, the same shear rate is expected when operating at the same screw tip speed. The anticipated scale-up volumetric throughput is believed to follow a cubic law and can be estimated according to Eq. (31.11).[132]

$$Q_2 = Q_1 \times \left(\frac{D_2}{D_1}\right)^3 \tag{31.11}$$

Where Q_2 is anticipated throughput of extruder with diameter D_2; Q_1 is measured throughput of the extrudate with diameter D_1.

However, when the screw diameter ratio between extruders is different, but similar screw geometries with similar screw tip speed are used, Eq. (31.11) can be modified as Eq. (31.12):

$$Q_2 = Q_1 \times \left(\frac{FreeVolume_2}{FreeVolume_1}\right) \tag{31.12}$$

Eq. (31.11) is also modified to accommodate the situation in which the screw rotation speed, expressed as N, is different between scales (Eq. 31.13).[132]

$$Q_2 = Q_1 \times \left(\frac{D_2}{D_1}\right)^3 \times \frac{N_2}{N_1} \tag{31.13}$$

As the residence time depicts mass flow patterns in an extruder and plays a critical role in determining product characteristics, it is recommended to obtain this information, particularly in the case of scaling-up and transferring processes to a different extruder with differing geometries. Comparing to other key system parameters, the residence time distribution is fairly easy to measure using a pulse stimulus response technique [94–96]. Fig. 31.37 shows a typical set-up for residence time distribution measurement.[97] During the measurement, a tracer is added into the feeding section at $T_{0,}$ and the concentration of the tracer is measured at the exit of extruder over the time. The concentration of the tracer can be measured using either an offline or online method (eg, NIR or Raman).

31.5.1.2.2 Power scale-up

Power scale-up is based on constant SME, which means constant energy per unit mass. Maintaining constant SME during scaling is critical, particularly for the manufacture of ASD systems, because the energy input is essential to achieve the desired product

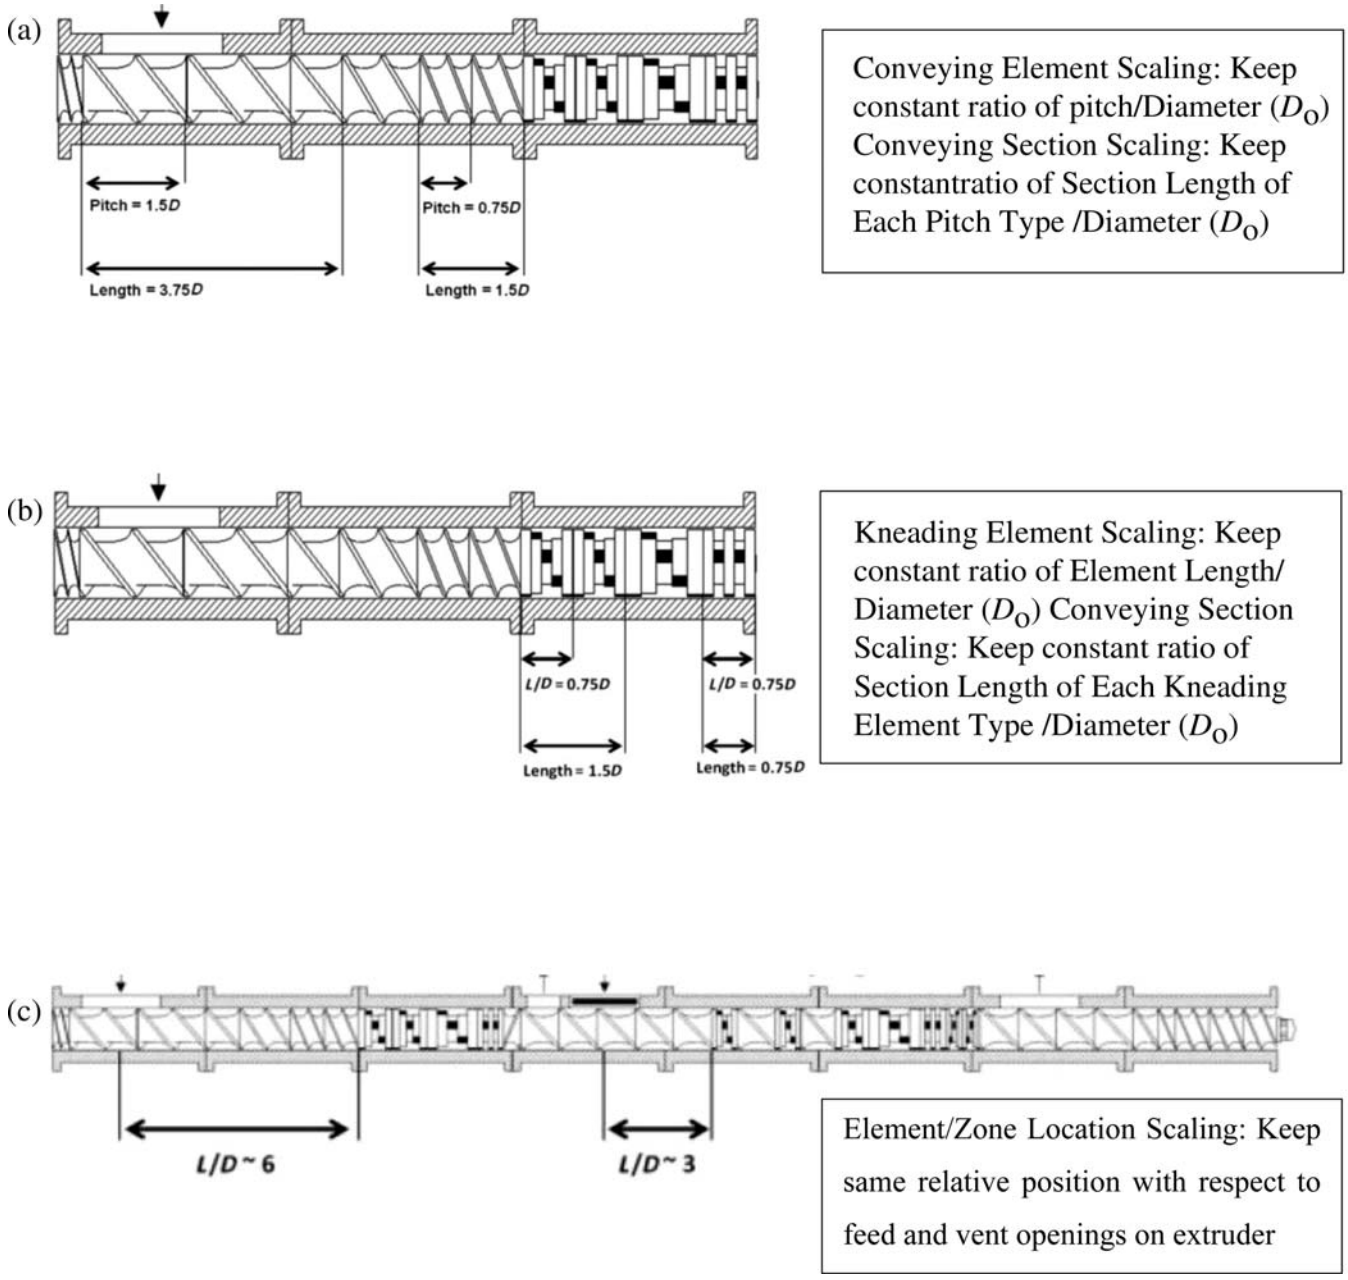

FIGURE 31.36 Scale-up of screw design. (a) Conveying section scale-up; (b) kneading section scale-up; (c) screw element/zone location scale-up. Modified from Ref. [93].

attributes when processing in the solubilization regime. SE is the sum of SME and specific thermal energy (STE). STE input is governed by heat conduction from barrel to material. This section will focus on the scale-up strategy based on SME.

One of the most straightforward SME calculations is shown in Eq. (31.6). The premise of applying this calculation during scaling is similar screw geometry, same percentage of fill, and equivalent screw speed as measured by tip velocity. The maximum throughput can be calculated with a given SME for the small extruder and available power for the large extruder. When comparing this throughput to the one calculated using the volumetric scale-up strategy, a disparity may be observed. This could be due to the torque density difference among extruders. Torque density (see Eq. 31.14) describes the relationship between power and free volume. When scaling to an extruder with lower torque density using the power scale-up strategy without considering torque density, the

FIGURE 31.37 Residence time distribution measurement setup.[97]

calculated throughput is less than the one obtained through the volumetric scale-up strategy. This may result in the process operating at lower degree of fill, higher shear rate, and longer residence time. Thus, the torque density should be assessed prior to the application of the power scale-up strategy.

$$Torque\ density = \frac{Torque}{Centerline\ Distance^3} \tag{31.14}$$

SME is a function of torque, screw speed, and throughput in which screw speed and throughput are adjustable process parameters, while torque is a response variable. Thus, this strategy can also be used to evaluate the relationship between power (as function of torque and screw speed) and screw speed. In general, if an increase in throughput is desired, screw speed should be increased congruent to maintaining constant SME.

31.5.1.2.3 Heat transfer scale-up

The heat transfer scale-up strategy can be adopted when the extrusion process is limited by heat transfer, and the desired melt temperature may not be achieved. Thermal heat transfer in TSE is dependent on the degree of fill, barrel surface area, temperature gradient between product and barrel, and residence time. Direct scale-up for heat transfer is based on the heat transfer area, that is, a square law (Eq. 31.15). Based on this strategy, the heat transfer coefficients should be constant among scales to maintain the same melt temperature. As with other scale-up assumptions, the degree of fill and screw diameter ratio must be the same.

$$Q_2 = Q_1 \times \left(\frac{D_2}{D_1}\right)^2 \tag{31.15}$$

For extruders with different screw diameter ratios, Eq. (31.15) should be modified based on the true value of the inner barrel surface area.

A heat transfer limit is not common in pharmaceutical applications, as product temperature is mainly dependent on the viscous dissipation generated by converting SME rather than barrel heating or cooling. In general, the same barrel temperature profile can be employed initially during scaling. However, due to the circular geometry of the extruder inner barrel surface, we should realize that increasing the extruder size results in the decreased thermal heat transfer per unit mass. Thus, when scaling with this strategy, a large extruder could be operated at lower degree of fill as compared to the small-scale machine due to increased melt temperature. Lower fill at a constant screw speed also increases the average shear rate and residence time. Scaling based on heat transfer limitation is a complex process; therefore, caution should be taken when using this strategy. Additional experiments and modeling might be required to yield proper scaling results.

31.5.1.2.4 Simulation-assisted scale-up strategies

Extrusion simulation allows for process scale-up with high confidence and in a cost-efficient manner. Simulation-assisted scale-up is particularly useful when geometric similarity and the requirement for classic scale-up strategies cannot be met. The ultimate goal of simulation tools is to produce a glass extruder so that the process is fully understood, and all properties are visible. Kohlgrüber summarized the possibilities and limitations of extrusion modeling.[98] Based on the number of spatial model dimensions, modeling approaches can be categorized into: (1) zero-dimensional models (0-D), which focus on the balance of the complete extruder or an individual section; (2) one-dimensional models (1-D), which focus on the process along the extruder axis; and (3) two- or three-dimensional models (2-D, 3-D), which consider the cross-section and require defined the boundary condition to better reflect the process.[98]

The 3-D models, typically based on complete numerical solutions of motion equations using FEA or similar techniques, provide an accurate and detailed picture of the flow field during the extrusion process. Polyflow is a commercially available 3-D simulation software. This model assumes a fully filled extruder under nonisothermal conditions and can track the simulated trajectories of particles. The software output is a 3-D description of flow in an extruder, including distributions of temperature, pressure, shear rate, and other responses. Additionally, the software can quantify dispersive and distributive mixing as well as predict stagnation areas. However, since this model can only simulate the viscous fluid-filled zone, it is not possible to model an entire extrusion process along the length of the screw.[99]

Alternatively, 1-D models are typically based on lumped-parameter methods, in which the equations of motion are integrated throughout the cross-section. By trading off the resolution, 1-D models offer the desired information within a shorter period of time with

simpler inputs requirement (eg, material properties not understood at the molecular level are sufficient). The commercially available 1-D models are summarized in several published articles.[99,100] Akro-Co-Twin Screw is one of the earliest marketed models, while Ludovic is the most widely used in the pharmaceutical industry.[99,100] Although different 1-D models can be developed based different theories and/or calculation methods, the common simulation outputs include temperature, pressure, fill ratio, viscosity, shear rate, energy consumption, and residence time distribution. The sample outputs from Sigma and Ludovic are shown Fig. 31.38 and Fig. 31.39.[98,101] The emphasis on the change along the screw axially for particularly difficult to measure system parameters (ie, energy distribution, residence time distribution, and material temperature) enables thorough process understanding and easy process scale-up. It was reported that computational extrusion process simulation using Loduvi could identify high-energy intake locations and allow optimization of screw design to ensure scalability.[102] It is also demonstrated that the WinTXS software package can be tuned to match simulation results with experimental data by using proper inputs, including material properties and process information. A correlation can be established between product quality and simulation output, which assisted an appropriate scaling.[92]

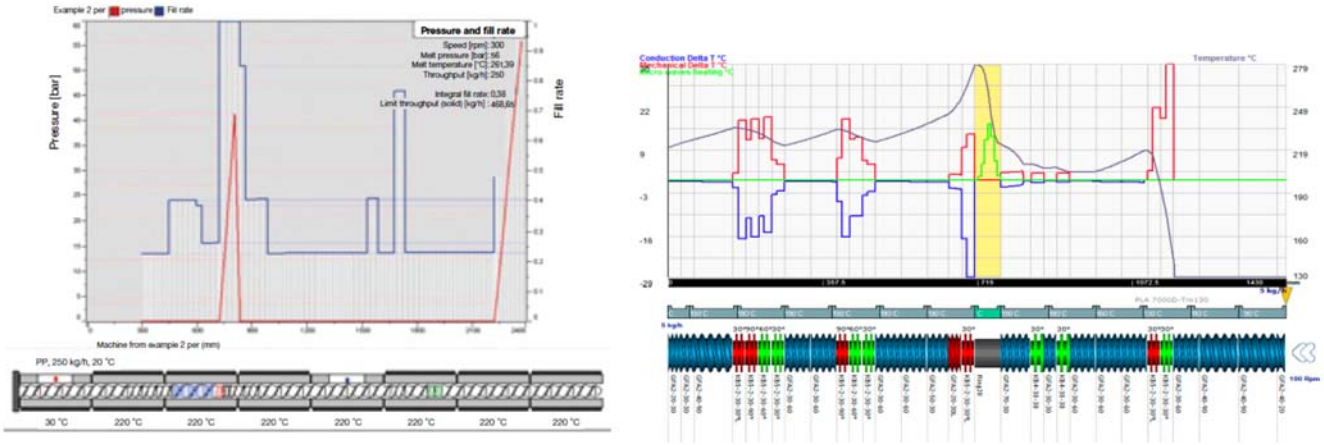

FIGURE 31.38 Sample output using sigma and Lodovic program.[98]

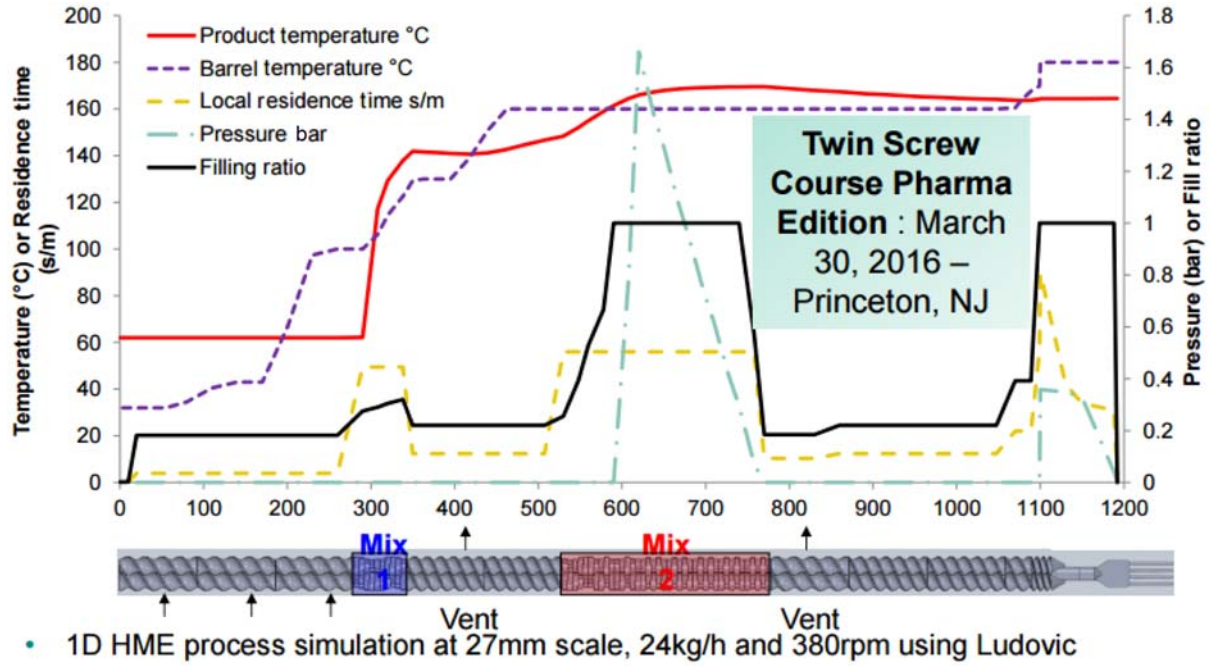

FIGURE 31.39 Modeling of HME via SCC's Ludovic.[101]

31.5.2 Product and process understanding, control strategy, and PAT

Quality by design (QbD) promotes a thorough understanding of the product and manufacturing process via a systematic approach. The developmental activities as per QbD expectations as shown in Fig. 31.40 are part of the quality risk-management process. In the context of extrusion, once the quality target product profile (QTPP) linked directly to safety and efficacy has been identified, the development focus should follow a series of structured risk assessments. A comprehensive formulation and process evaluation based on critical quality attributes (CQAs) should be performed at the initial risk assessment. The results from this risk assessment help prioritize the development activities. For instance, minimizing SME input while maintaining sufficient mixing is the study focus when developing an ASD with a material prone to thermal degradation. However, when developing an extrusion granulation process with a similar material, understanding the impact of degree of fill and residence time distribution might take precedent over the efforts of reducing SME input. Design space, as one of the important elements of a QbD approach, offers operational flexibility. The expectation for design space is that the process understanding should be achieved at a multivariate level. That is, the interdependence between the product quality and individual process parameters and the additive influence from multiple parameters are clearly identified and understood. As the extrudate quality is directly driven by key system parameters, as shown in Fig. 31.15, the deployment of those scale-independent process responses is an ideal way to bridge the gap between quality attributes and process independent parameters. Developing the design space around the key system parameters provides manufacturing flexibility and seamless scale-up. As the sources of variability and their impacts are understood, a control strategy span to raw material, in process control (IPC), and process design must be developed to ensure CQAs are consistently met. Multiple control strategies for the same process are possible, as long as they can be justified through a rigorous quality risk-management process.

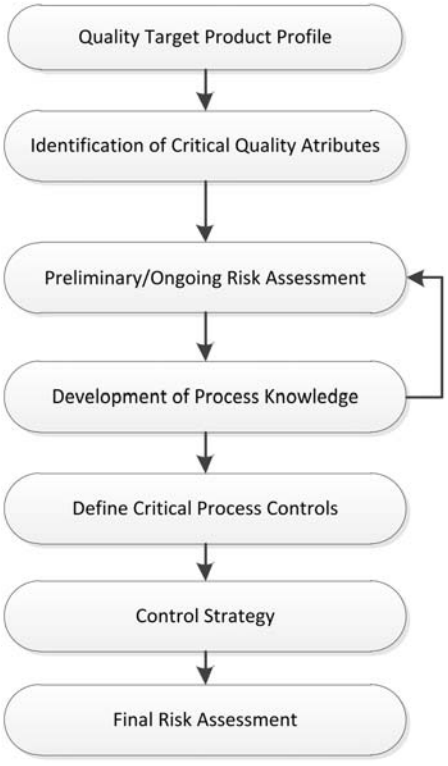

FIGURE 31.40 Product and process development following QbD approach.

One of the other important components of QbD is process analytical technology (PAT). PAT encompasses online, in-line, or at-line measurement for enhanced process understanding and improved control for product quality. The implementation of PAT yields many manufacturing advantages. Two specific advantages to the extrusion process are noted here: (1) PAT enables continuous manufacturing of quality extrudate by monitoring and identifying deviations in real-time,[103] and (2) PAT improves manufacturing efficiency by eliminating time consuming offline analysis, and this is particularly true for hot-melt polymer matrix formulation as the extraction of drug substance from the matrix can be complicated.

PAT tools have long been used by the plastics and food industries for monitoring, analyzing, and characterizing the extrusion process and product in-line. The schematic of PAT integration into the melt extrusion process is illustrated in Fig. 31.41.[104] Raman and near-infrared (NIR) are two widely studied spectroscopy-based analytical techniques for in-line or online monitoring of the melt extrusion process.[105–107] Saerens et al. reported using Raman to monitor the API solid state change from crystalline to amorphous. When combined with principal component analysis (PCA) and partial least squares analysis (PLA), they also demonstrated that Raman is able to simultaneously quantify the API concentrations in process samples.[103] The suitability of Raman for PAT application was also presented by Tumuluri et al. for clotrimazole and ketoprofen formulations.[107] Similar to Raman spectroscopy, NIR can provide both quantitative and qualitative information on melt and/or extrudate. It can be used to monitor the content uniformity and verify the extrusion performance in terms of residence time distribution. Islam et al.

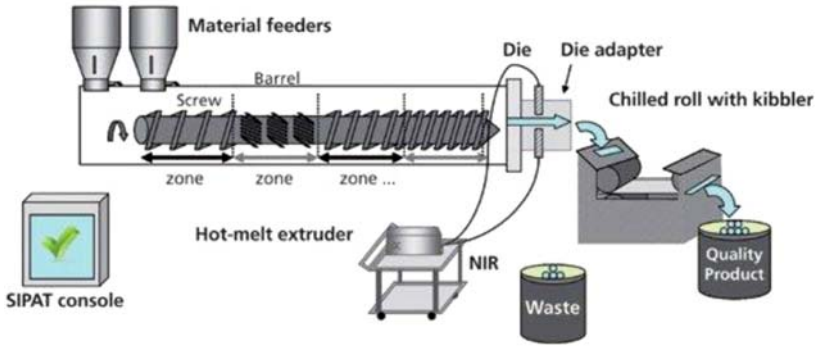

FIGURE 31.41 Schematic of PAT integration into melt extrusion.[104]

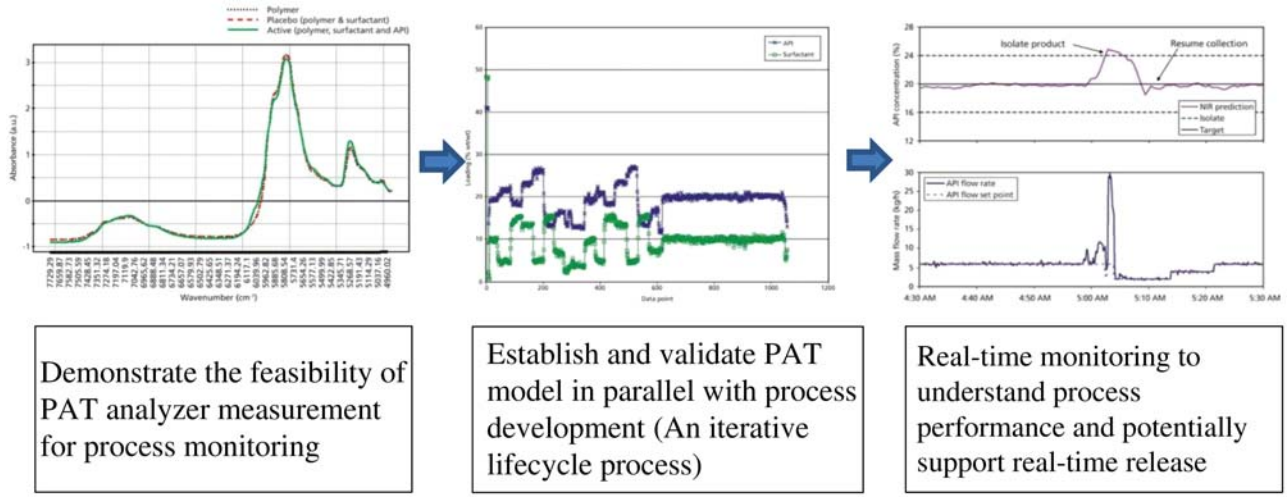

FIGURE 31.42 Establish PAT model for process monitoring. Modified from Ref. [104].

utilized in-line NIR spectroscopy to assess the effect of the process critical parameters and identify the critical quality attributes (CQA).[108] Saerens et al. suggest that in-line NIR spectroscopy could be a potential PAT tool for monitoring polymer–drug solid-state behavior while determining API concentration.[108] Additionally, other tools, including ultrasound and UV–vis spectroscopy have also been reported in the literature for in-line characterization of extrusion processes.[109–111]

Implementing PAT for real-time quality assurance requires a validated model to correlate the CQAs with process analyzer measurements. Mathematical transformation is typically needed when process analytical data is in the format of spectra or chemical images. Validating a PAT model is an iterative process that can last throughout the product lifecycle. The process map of establishing a PAT model for melt extrusion process monitoring is shown in Fig. 31.42.[104,133] Once the feasibility of a PAT analyzer measurement for the formulation is demonstrated, developing a calibration model is initiated. The model is then challenged and validated in parallel with development and ready to be implemented for routine commercial production once proven it is robust to all foreseen variability. A properly developed PAT model should be able to monitor the process performance based on the CQAs of interest and quickly identify any deviations from predetermined acceptance criteria. If a problem is identified, the suspect extrudate can be diverted into waste, and the product collection will resume when the process fault is resolved. Thus, the real-time quality assurance is achieved with PAT, that is, a deviation or process fault can be detected immediately upon occurring and lead to accurately isolating this product portion without impacting the entire batch. In addition, PAT eases the demand between process monitoring and manufacturing support by simplifying the multivariate nature of the process into a single data stream representing product quality.

31.6 CASE STUDIES

Over the last decade, many new products have been developed utilizing the TSE process to achieve the desired drug product profile. This section provides several examples of product developmental using TSE to enable or improve process, product quality and performance.

31.6.1 Improving oral absorption of BCS class II drugs

Utilizing HME to manufacture ASD formulations to improve oral absorption of insoluble drugs offers many advantages when feasible. Various fundamental aspects of product development are addressed in the relevant chapters of this book. Two examples discussed in this section illustrate the importance of understanding API, product, and process when using HME.

Rezulin is the first commercial product containing ASD manufactured using HME process. Troglitazone, the active component of Rezulin, is a BCS class II drug with low and highly variable bioavailability. At the time of the product approval in the 1990s, Park-Davis/Warner-Lambert had already developed an organic solvent-based spray-drying process to prepare a povidone-based ASD of troglitazone with enhanced bioavailability. Forecasting a large commercial volume for Rezulin, concerns arose about the cost, environment, health, and safety impact associated with the anticipated increasing use of large quantity of organic solvents during production. A concerted effort to identify an alternative solvent-free manufacturing process led to the HME process using a twin-screw extruder. The TSE process initially developed using a Leistritz 18 mm intermeshing corotating twin-screw extruder was successfully scaled up to a Leistritz 50 mm extruder for the commercial production. The extrusion processing time is less than 1 minute for the batch size of 5000 kg.

Noxafil delayed-release tablets contains a melt-extruded ASD of posaconazole, a weakly basic triazole antifungal drug. Posaconazole exhibits pH-dependent solubility. It dissolves in acid conditions but rapidly precipitates in the upper small intestine. The first generation Noxafil, a suspension of crystalline form, exhibits highly variable bioavailability with a substantial food effect. The melt-extruded formulation was compared to the suspension at a 100 mg dose in a crossover study in healthy volunteers examining fed-state and fasted-state plasma profiles. The results, presented in Fig. 31.43, show substantial oral bioavailability improvements with reduced food effect.[112] However, Posaconazole undergoes significant degradation at temperatures above its melting point of 170°C, presenting a challenge for commercial scale extrusion. To overcome this problem, a formulation was designed in which the molten polymer (HPMCAS) was used to solubilize posaconazole below its melting point. This allows for production of the material at reduced temperatures to improve the stability of the drug.

31.6.2 Improving processing characteristics through modification of API surface

Metformin is a biguanide antihyperglycemic agent most widely prescribed for the treatment of type 2 diabetes. Its hydrochloride salt is freely soluble in water

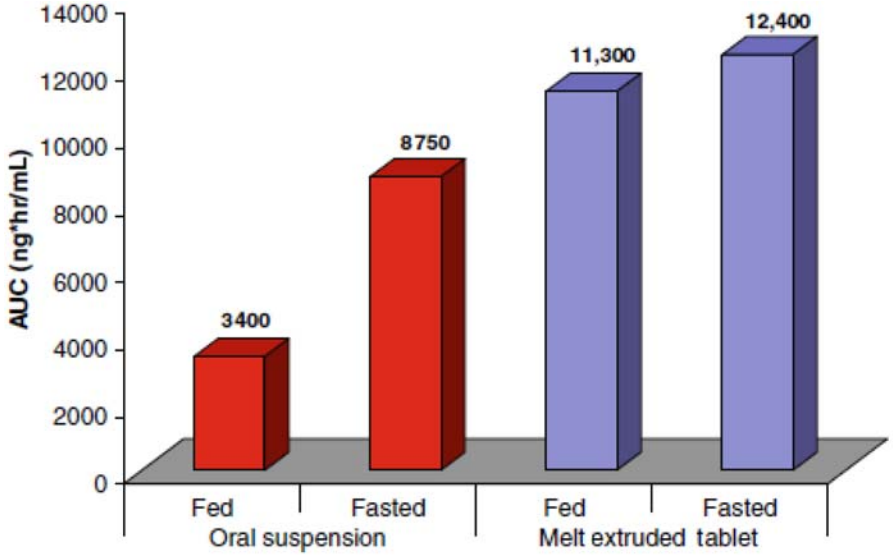

FIGURE 31.43 Posaconazole oral bioavailability: suspension containing crystalline drug vs tablets containing amorphous solid dispersion.

with a pK_a of 12.4 and melting point of 223–226°C. Due to its high daily dose up to a total of 2000 mg, the common strengths of metformin tablets include 500 mg, 850 mg, or 1000 mg, which indicate that (1) high drug loading is required, especially when developed as a fixed-dose combination or ER dosage form and (2) formulation processing behaviors will be dominated by the API properties. Because of high solubility (about 300 mg/mL)[113] metformin HCl dissolved in moisture can form solid bridges upon moisture desorption.[82] In worst cases, extensive formation of solid bridges could transform free-flowing powder into a solid block overnight. As a result, variable bulk and tablet properties of metformin HCl made using wet granulation have been observed, including granulation flowability, density, compactability, and the hardness, disintegration, and dissolution of the tablet. To overcome these problems, Lakshman et al. (2011) investigated melt granulation (MG) of metformin HCl with hydroxypropyl cellulose (HPC) as the meltable binder using a 16 mm Thermo Prism twin-screw extruder to poorly compactible high-dose API. A high (90%) drug-load tablet formulation containing 1025 mg of metformin was melt granulated at a temperature above the glass transition of HPC but below the melting point of metformin HCl (see Table 31.8). It was found that good compressibility can be achieved using MG process depending on process conditions (Fig. 31.44). When compared to the aqueous and solvent wet granulation (WG) processes, significantly improved hardness and friability results were obtained for tablets made with the MG process. Tablet hardness of MG tablets was also found to be less sensitive to changes in moisture content during compression and subsequent storage. The low-moisture contents of the granules (about 0.2% w/w) is believed to be conducive to averting moisture-induced physical transformations in metformin HCl tablets, thus avoiding change of tablet hardness with time, variable powder flow behavior, and problems with dissolution stability. In addition, the study also shows that the TSE granulation process can decrease the need for relatively large amounts of excipients often required for overcoming processing challenges posed by API physicochemical and mechanical properties, thus reducing tablet sizes of high-dose drugs.

The significantly enhanced compactibility of metformin HCl tablets can be attributed to the effective modification of the API surface properties through highly efficient and more consistent coating of the binder (HPC) through the melt-extrusion process. This is indicated by the rank-order improvement in tablet bonding among the three processes studied by the authors.[82] Based on the principle of the granulation process, the coating efficiency by HPC is expected to be lower with aqueous-based WG process when compared with solvent-based WG process (ethanol/isopropanol, 95:5, v/v) because both the API and HPC are dissolved in the granulation fluid during the mixing process, while solubility of the API in alcohol is much lower. Since the API is not miscible with the molten HPC, the highest coating efficiency is achieved with the TSE process, resulting in most effectual modification of the API surface properties. This is consistent with the study findings in our laboratory using a poorly compressible API as a model drug to manufacture extended-release hydrophobic matrix tablets. A powder blend consisting of about 90% API and about 6% rate-controlling polymer and other excipients were granulation using an 18 mm twin-screw extruder equipped with six barrels and with the die block removed from the end barrel (Coperion ZSK laboratory extruder). Solid materials were fed into the extruder at a feed rate of 1 kg/hour

TABLE 31.8 Melt-Granulation Process Parameters Evaluated for Metformin Tablets[82]

Process parameter	Set point	Variation ± set point or fixed
HPC level	9%	5–15%
Feed rate	30–35 g/min	± 10 g/min
Screw speed	210 rpm	± 90 rpm
Extrusion temperature	160°C	140–180°C

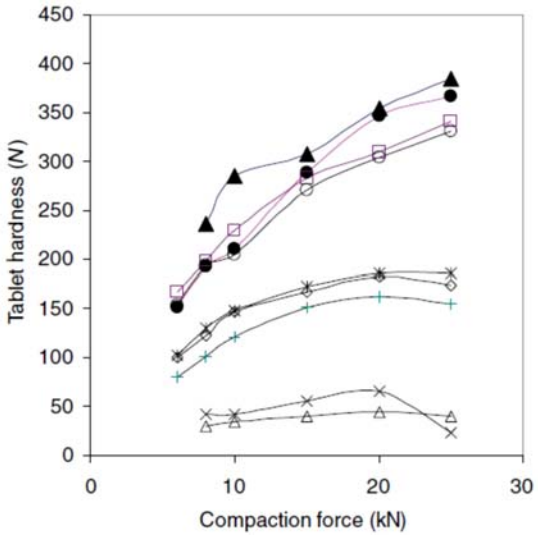

FIGURE 31.44 Compaction profile of metformin Hcl melt granulations.[82] The feed rate, screw speed, highest processing zone temperature, and magnesium stearate level were, respectively: •: 40 g/min, 120 rpm, 140°C and 0.75%; +: 20 g/min, 300 rpm, 180°C and 0.75%; ○: 40 g/min 120 rpm, 140°C and 1.25%; □: 40 g/min, 120 rpm, 180°C and 1.25%; *: 30 g/min, 210 rpm, 160°C and 1.00%; ×: 20 g/min, 300 rpm, 140°C and 1.25%; ◇: 30 g/min, 210 rpm, 160°C and 1.00%; ▲: 40 g/min, 120 rpm, 180°C and 0.75%; and △: 20 g/min, 300 rpm, 140°C and 0.75%.

using a K-Tron twin-screw volumetric feeder followed by granulation using conveying elements at a screw speed of 120 rpm and a barrel temperature of 150°C. Because the melting point of the API (770°C) is significantly higher than the glass transition temperature (T_g) of the polymer (41°C) and because there is no API-polymer miscibility, the surface of the API is modified effectively by the polymer through the extrusion process, enabling tablet compression. Tablets of the same formulation were also prepared with a solvent-based high-shear WG process using polymer solution in ethanol as the granulation fluid followed by drying, sieving, and compression. Because the API is insoluble in ethanol, the granulation-drying process also facilitated similarly effective coating of the API surface. As a result, tablets made using both processes exhibited similar compactability and dissolution. Vasanthavada et al. (2011) also studied the high-dose ER formulations of imatinib mesylate with a drug load of 89% by melt granulation using a 16 mm Thermo Prism twin-screw extruder (ie, a 1074-mg tablet containing 956 mg API).[84] The process temperature of 185°C is below the melting point of the API (212°C) but above the T_g values of polymers, which included HPC, ethyl cellulose (EC), and hydroxypropyl methylcellulose (HPMC). A factorial design of experiment (DOE) designed to investigate the effects of process variables, such as feed rate, process temperature, and screw speed, over a wide range demonstrated robust performance with respect to granulation and tablet characteristics as well as drug release. Acceptable compressibility and tablet hardness can be obtained using as little as 5% polymer for melt granulation. In addition, tablets produced using the MG process exhibited higher hardness and lower friability when compared with those made with the WG process, consistent with the findings from MG study of metformin tablets previously discussed. Evaluation of the tablets using confocal Raman microscopy revealed that the API remained as unmelted crystals, and polymers were finely distributed (coated) on the surface and in between API particles, confirming the importance of effective coating of the polymer in improving API processibility by modifying its surface properties.

31.6.3 Continuous granulation for manufacturing extended-release tablets using a twin-screw extruder

Clarithromycin is a macrolide antibiotic used to treat many different types of bacterial infections. It is a weak base with pKa = 8.7 and pH-dependent solubility. Biaxin XL is the extended-release hydrophilic matrix tablets of clarithromycin. It was a high-volume product manufactured using wet granulation in a high-shear granulator followed by fluid-bed drying, milling, compression, and film coating. In Zu et al.,[114] Biaxin XL tablet is used as a model drug product to investigate the feasibility of continuous wet granulation using a twin-screw extruder.

Granulation was performed by feeding the preblended formulation of the commercial tablets[115] consisting of 50% API, 20% HPMC, and other excipients into an 18 mm corotating twin-screw extruder (Coperion ZSK laboratory extruder) equipped with six barrels without a die. Granulation fluid (water) was added through liquid injection into a designated barrel. Process variables studied over a wide range include liquid feed rate, screw configuration and speed, liquid-to-solid ratio, and position of liquid injection using an experimental design provided in Table 31.9.

TABLE 31.9 Study Design of Granulation Process Parameters for Clarithromycin Extended-Release Tablets Using TSE

Run	Screw configuration	Liquid feed rate (kg/h)	Screw speed (rpm)	Injection position	L/S ratio

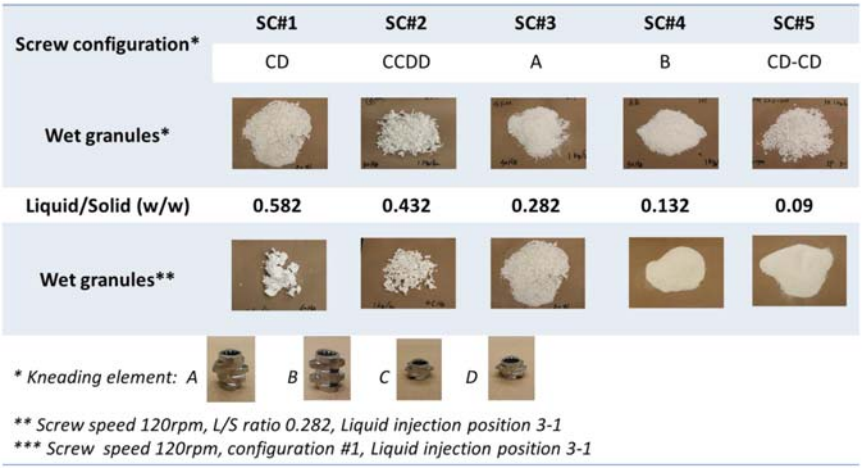

FIGURE 31.45 Influence of screw configuration and percentage liquid on granulation characteristics of clarithromycin ER tablets.

The influence of these process parameters on characteristics of the resulting granules (particle size, strength, and density), milled granules (PSD, strength, and density) and tablets (solid fraction, hardness, and dissolution) was evaluated. Among the process parameters investigated, liquid-to-solid ratio, screw speed, and screw configuration showed the most significant effect on the granule properties (Fig. 31.45). For example, increasing the percentage of liquid or the liquid-to-solid ratio results in larger and wetter granules and higher granule strength. Granules are smaller when a less aggressive kneading zone is used. The granule size decreases with an increase of screw speed. However, these large differences in granulation properties can be mostly equalized by controlling the milling process of the dried granulation (eg, using a 840 μm band and Fitzmill with impact forward, 3000 rpm). The only factor that affects the milled granule particle size is the liquid-to-solid ratio. Other process parameters including screw configuration do not have a significant impact on the milled granule properties. Tablet hardness, porosity, and dissolution are also comparable within a wide range of percentage of liquid of 9−28.2% when compared with the tablets manufactured using high-shear granulation. Increased porosity and faster dissolution were observed for tablets made with >43% liquid, using commercial tablets as a reference, though tablet strength remains essentially unchanged. When compared to the high-shear granulation process, TSE not only renders significantly more homogeneous admixture of the formulation composition, as indicated by the nearly uniform potency values across different granulation sieve cuts, but it also requires a considerably reduced amount of liquid to achieve effective granulation. For example, approximately 35% of liquid is typically added using the high-shear granulator, while liquid levels as low as 9% have been shown to be sufficient to produce tablets with the same quality when using the TSE process. As a result, a drastically reduced drying cycle is expected due to a lower moisture content and homogeneity of the resulting wet granules.

To evaluate the applicability of the study findings to other products, Depakote ER tablet was investigated as a second-model drug product using a similar but reduced study design by focusing on the effects of liquid-to-solid ratio while keeping the other process parameters constant. Depakote ER is also an extended-release tablet based on a hydrophilic matrix system that provides approximately 20 hours of in-vivo absorption[116]. It was also a high-volume product manufactured using wet granulation in a high-shear granulator followed by fluid-bed drying, milling, compression, and film coating. The active ingredient, divalproex sodium, is a stable and permeable compound with an acidic pKa of 4.8. It is freely soluble in the intestinal pH where most of the dose is released. In contrast to Biaxin XL, Depakote ER tablets contain high loading of high-solubility API and high level of high-viscosity-grade HPMC. Nevertheless, the study results were found to be similar to those of Biaxin XL. For instance, similar dissolution was observed with tablets manufactured using percentage of liquid ranging from 9% to 23% using the high-shear granulated product (about 14% liquid) as a reference. However, accelerated dissolution was observed with tablets made from considerably overgranulated and much larger granulation, which was milled using a 1000-μm band and Fitzmill with impact forward, 3000 rpm (see Fig. 31.46). It should be noted that an increase in the dissolution rate does not take place until approximately 40−50% of drug release. Hence, the change can be most likely be attributed to the gradual loss of matrix integrity during dissolution, because large particle size combined with low porosity of the granules made

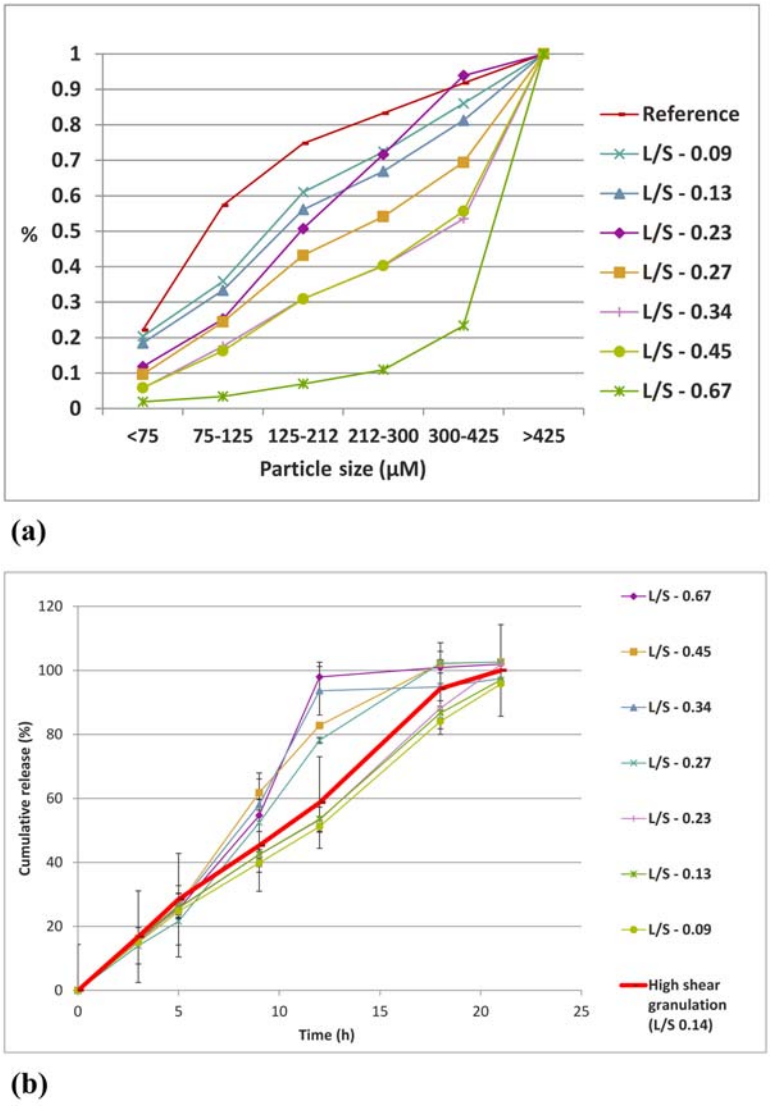

FIGURE 31.46 Influence of percentage liquid on (a) particle size distribution and (b) dissolution of divalproex sodium ER tablets.

with high-percentage liquid can alter water penetration and gel structure of the matrix. It is found that the impact is more pronounced with the ER formulation of divalproex sodium containing high-viscosity-grade HPMC when compared with clarithromycin ER formulation that contains low-viscosity-grade polymer, since the former usually results in larger particle size and higher density. In principle, this type of dissolution problem can be resolved by controlling PSD through modifying the milling condition.

31.6.4 Extended-release opioid tablets with abuse-deterrent properties

The abuse of prescription opioid drug products has been a growing problem in the United States. One of the successful formulation strategies to deter this abuse is to prepare a dosage form with high physical strength to prevent crush and extraction. Both Opana ER extended-release oxymorphone hydrochloride tablets and Nucynta ER extended-release tapentadol hydrochloride tablets are manufactured using INTACT, a proprietary technology developed at Grünenthal GmbH. Poly(ethylene oxide) is used as the drug-release retardant and matrix former. The manufacturing process consists of blending, extrusion, cooling, cutting, forming, and coating. During the melt extrusion, the poly(ethylene oxide) based matrix formulation is melted and pressurized. As a result, the melt-extruded matrix possesses strong physical strength in comparison to the tablets prepared using a conventional tableting process. The resulting PEO matrix tablet exhibits a breaking strength of greater than 500 N. As shown in Fig. 31.47, the melt-extruded formulation could not be crushed by a mortar and pestle.[117]

31.7 SUMMARY

The rapid adoption, implementation, and expanded applications of the extrusion technology in the pharmaceutical industry resemble what occurred in the food and plastics industry five decades ago. In the early 1960s, the food and plastics industries began to abandon batch mixers and embrace extrusion technology in order to more efficiently produce products of more consistent quality and at a lower cost. The batch mixer is a large-volume discontinuous mixer. In comparison, a twin-screw extruder is a small-volume continuous mixer. Valuable knowledge, technical know-how, and manufacturing experience gained in these industries have allowed expeditious adoption and implementation of this established processing technology to enable formulation development of challenging drug molecules and efficient pharmaceutical manufacturing.

TSE is being adopted by the pharmaceutical industry at very rapid pace. Pharmaceutical companies are not only actively utilizing the TSE process for manufacturing novel drug-delivery systems but are also replacing less efficient and less robust batch processes with TSE extrusion. At the same time, twin-screw extruder suppliers have downsized and redesigned equipment for production in the GMP environments. Additional efforts have also been made to design TSE systems for testing early development materials available only in limited quantities. Excipient companies are engineering novel materials suitable for extrusion process. At the same time, regulatory agencies are encouraging the pharmaceutical industry to adapt flexible, robust, and efficient continuous manufacturing process in order to build product quality into process design.

32.1 INTRODUCTION

Roller compaction is the preferred method for dry granulation in the pharmaceutical industry. It is a continuous manufacturing technique introduced in the second half of the 19th century in the coal industry to compact powdered coal into briquettes.[1] The technology was later adopted by metallurgists for roll pressing of metal powders before finally being introduced into the food, agricultural, and pharmaceutical industries.[2] The pharmaceutical industry has traditionally been very good at adopting technologies from other industries and learning from the prior knowledge. However, the behavior of metals and organic materials differ dramatically, so significant efforts have been made, and are still ongoing, to adapt the process for pharmaceutical applications.

Good powder flow is particularly important when manufacturing tablets, the most common solid oral dosage form, because rapid and accurate filling of the tablet die is essential to achieve consistent tablet weights, and thus, consistent drug dose. When active pharmaceutical ingredients (API) possess desirable flow characteristics and demonstrate minimal tendencies toward segregation, direct compression processes, which involve the compaction of ungranulated powders into tablets, are feasible. However, API powders typically possess poor flow characteristics, which present handling challenges during the manufacturing process and are a potential source for segregation in powder blends. Pharmaceutical manufacturing processes utilize roller compaction operations to mitigate these challenges caused by poorly behaving API by improving flow and content uniformity of powder blends. The roller compaction technique densifies powder blends to produce granules with particle sizes larger than that of the input material, and thus improved flow characteristics compared with ungranulated material. In addition, the granulation process reduces the potential for API segregation, which can result in poor API content uniformity. Fig. 32.1 demonstrates where the roller compaction operation would fit into a typical manufacturing process for tablet dosage forms. Since tablets are the most common oral solid dosage form, the remainder of the chapter assumes tablets as the final dosage form, unless otherwise noted.

Compared with direct compression processes, roller compaction operations are better suited to handle powders with the following attributes: (1) small particle sizes and/or challenging morphologies (eg, high aspect ratio particles), (2) low bulk density, (3) poor flow properties, and (4) high risk for API segregation. Consequently, roller compaction workflows are more capable of accommodating variability in API properties compared with direct compression processes. Roller compaction is a dry process; therefore it is more suitable for moisture- and heat-sensitive material, which is an advantage over wet granulation. Furthermore, roller compaction is a continuous process, enabling a single instrument configuration able to accommodate a greater range of batch sizes compared with wet granulation.

Developing Solid Oral Dosage Forms
DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00032-7

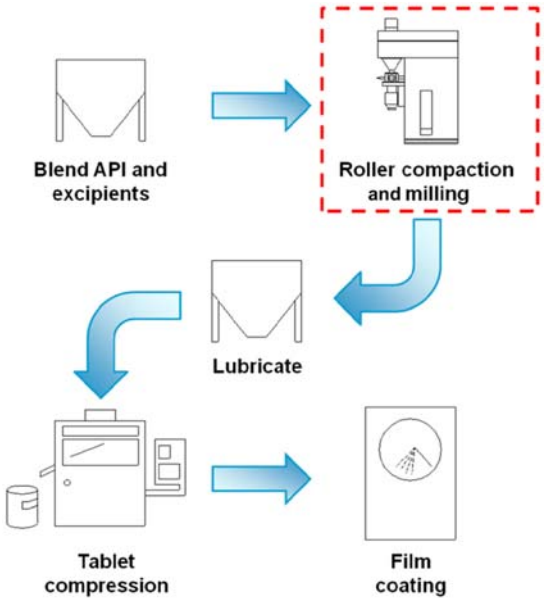

FIGURE 32.1 Schematic showing where roller compaction fits into the manufacture process for tablet dosage forms.

Benefits of the roller compaction process include

- *Improved flow*—larger granules typically flow better than fine powders, resulting in improved powder transfer, flow in hopper, and die-filling during tabletting
- *Increased bulk density*—faster bulk transfer; reduced dust generation; smaller bins can be used during post-granulation blending; reduced in-die fill volume during tabletting, facilitating manufacture of large tablets
- *Improved blend uniformity*—contents of blend "trapped" into granules, facilitating uniform distribution of materials throughout the entire blend and reducing potential for materials to segregate; this is particularly pertinent to API distribution and subsequent dose uniformity
- *Continuous process*—enables manufacture of larger batch sizes by simply increasing operating times, which allows a single roller compaction unit to support a wide range of batch sizes (eg, a typical pilot scale roller compactor can manufacture batch sizes of 1–200 kg)
- *Improved dust control*—consolidation and densification of powder into granules reduces the amount of fines and discrete API particles, reducing dust generation during tablet manufacture and exposure risk to operators
- *Improved tablet disintegration and dispersal*—granules readily absorb water, enabling faster disintegration compared with tablets made by direct compression; immediate release tablets: disintegrate to granules, which disperse and disintegrate themselves; capsules: granules improve dispersion and mitigate plug formation

This chapter will provide an overview of roller compaction and discuss key elements of the operation, including equipment design, simulation, and characterization tools that facilitate efficient execution of roller compaction operations, trouble-shooting methods, scale-up considerations, as well as review current modeling techniques that simulate the roller compaction process and improve mechanistic understanding of the process. Case studies will be used throughout the chapter to highlight discussions in the text.

32.1.1 Overview of roller compaction materials and operation

The overarching goal of the roller compaction process is to transform poorly flowing, fine powders into granules of a desired particle size range and distribution with appropriate flow and compactability. Optimal particle size distribution also facilitates good granule flow, which is important for efficient transfer of material into hoppers and powder feed systems to ensure accurate and reproducible metering of doses (ie, capsule or sachet filling, and filling of tablet dies on a high-speed rotary press). Achieving optimal particle size distribution is important with respect to tablet weight uniformity, especially for low-weight tablets that may be susceptible to significant weight variation if granules are too large. Granule compactability is essential for the manufacture of tablets, which must be of sufficient hardness and tensile strength to prevent damage during film coating, packaging and shipping.

A basic overview of the roller compaction process is depicted in Fig. 32.2. Briefly, loose powder is fed into the roller compactor from a feed system, which typically sits atop the instrument. The feed system is often comprised of an agitator within the hopper and one or more feed screws that convey the powder from the hopper to the rolls, and also facilitates particle and air removal from the powder bed. An integrated vacuum deaeration system, consisting of a sintered metal filter or mesh screen, may be incorporated into the feed system to better remove air from the powder bed (deaeration). This deaeration helps to reduce the friability of the compacted ribbon edges and leads to denser ribbons.[3,4] The powder is passed from the feed system between the two counter-rotating rolls of the roller compactor. The rolls apply a compressive force to the powder, compressing the material to form a densified compact, typically in the form of a ribbon (sheet). These compacts then typically undergo a size reduction process (milling) to produce free-flowing granules that are amenable for

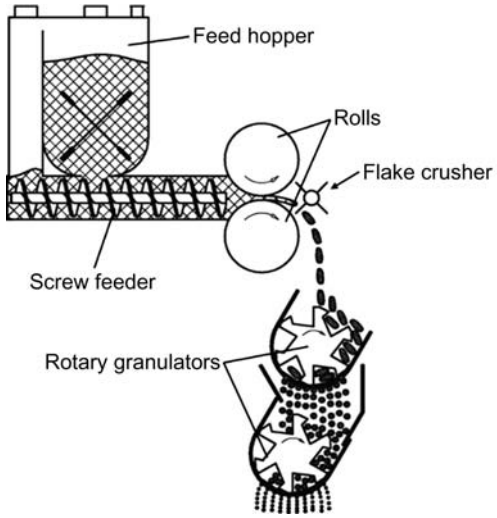

FIGURE 32.2 Schematic illustrating a typical roller compaction process. *Source: Courtesy from Alexanderwerk AG.*

downstream processing, such as capsules or tablets.[5] Ultimately, the success of a roller compaction process is assessed on the properties of the milled granules and the final dosage form, such as tablets.[6,7]

It should be noted, however, that designs differ between manufacturers and models, which will be addressed in more detail later in the chapter. In Fig. 32.2, the feed screw is oriented horizontally with vertically aligned rolls; however, alternate configurations include a horizontal or angled roll orientation, depending on the manufacturer and instrument model. Furthermore, a number of different roll surfaces are commercially available, including smooth, knurled, ribbed, and serrated. For larger scale roller compactors that include an integrated mill system, the milling apparatus is located immediately after the rolls, and may include a flake crusher followed by a one- or two-stage mill, which is typically a screen and an impeller operating in a rotary or oscillating motion. Smaller lab-scale instruments do not usually include mills, and thus the ribbons must be milled using a separate unit.

In today's quality by design (QbD) paradigm, it is important to establish a robust design space of process parameters and material properties. QbD strategies facilitate a more comprehensive understanding of how material and process attributes impact product quality and performance, as well as providing insight into potential interactions between the two.[8]

32.1.1.1 Material considerations

A typical roller compaction formulation consists of API, filler (eg, microcrystalline cellulose (MCC) and/or lactose), disintegrant (eg, croscarmellose sodium, crospovidone), lubricant (eg, magnesium stearate, stearic acid), and often times a glidant (eg, silicon dioxide) to reduce potential friction with the rolls and facilitate flow of powder. Formulations possessing drug loadings <60% wt are generally found to be amenable for roller compaction. Higher drug loading formulations generally have a higher tendency for material adhesion to the rolls, which adversely impacts ribbon quality and material throughput, thus presenting challenges to maintaining a consistent flow of powder to the rolls. One way to mitigate material-related challenges typically associated with API powder properties is through the appropriate selection of excipients. Specific grades of excipients, such as lactose and MCC, are available that possess optimized physical properties in terms of flow and compactability, and thus can be used to improve the overall powder properties of an active blend. A proposed list of desirable properties for blends intended for roller compaction is detailed in Table 32.1.[9]

32.1.1.2 Key operating parameters and product attributes

A list of key operating parameters and product attributes for the roller compaction process are given in Table 32.2.

The key parameters typically monitored during roller compaction operations are roll gap, feed screw speed, and roll pressure because they most impact ribbon/granulation quality. In most pilot-scale and larger roller compactors, a floating roll is utilized to minimize fluctuations in ribbon solid fraction caused by variations in powder flow, and may include a closed feedback loop to modify the feed screw speed in response to inconsistencies in powder flow. Therefore, roll gap and feed screw speed often fluctuate continuously throughout the roller compaction operation due to variations in powder flow and a feedback loop controlling feed screw speed, although the average of these values should remain consistent once the operation has reached steady state. For example, when roll pressure and roll-gap targets are defined, then feed screw speed is varied in response to changes in roll gap (due to variation in powder flow) to ensure that sufficient powder is delivered to the rolls to maintain the target gap. Roller compactors with two fixed rolls, as opposed to a floating roll design, tend to show greater variability in granule properties as a result of powder flow variation. Additional process parameters, such as roll speed and mill screen size may also impact ribbon/granule properties, but are generally considered to be "fixed" parameters for a given run because they do not fluctuate during the roller compaction operation. Roll speed selection is often based on throughput considerations. Changes in roll speed may change ribbon tensile strength for a given roll pressure, because the dwell time (ie, the duration that pressure is applied to the powder by the rolls) is impacted. Mill screen size will influence granule particle size, flow, and

TABLE 32.1 Properties of an Ideal Roller Compaction Material

Property	Value	Target value
Compactability	At 0.7 solid fraction	>1 MPa
Loss of compactability[a]	At <0.9 solid fraction	>1.7 MPa
Bulk density	At >0.14 solid fraction	>0.2 g/mL[b]
Wall friction	Angle of wall friction	<20 degrees[c]
Flow assessment	Flow function coefficient	>4[c]
	Carr's Index	<35%
Solid-state properties	Melting point	>90°C
	Glass transition (T_g)	>90°C
	Loss of crystallinity during compaction	None
Particle size for content uniformity	Blend potency	Meets Rohr's criteria[10]
Stability with excipients	Acceptable stability	>2 years at room temp[11]
Material adhesion	Not yet determined	Not yet determined

TABLE 32.2 Key Product and Operating Parameters Typically Associated With Roller Compaction

Key operating parameters	Ribbon attributes	Granule attributes
Roll pressure	Solid fraction/ porosity	Particle size distribution
Feed pressure (ie, feed screw speed)	Tensile strength	Compactability
Roll speed	Thickness	Flow
Roll gap		

compactability, and a change of mill screen size may necessitate changes to other process parameters. Thus, appropriate selection of these "fixed" parameters should be conducted early in the development process.

Key product attributes typically monitored during the roller compaction operation focus on ribbon properties because they provide a good indication of the resultant granule properties. Generally, from batch to batch, ribbons possessing similar solid fraction, tensile strength, and thickness will yield granules of comparable particle size distribution, flow, and compactability properties.

32.1.1.2.1 Ribbon solid fraction

Ribbon solid fraction is commonly used as an in-process target because it provides a strong indication of granule properties. Solid fraction, which describes the extent of compaction of a material, is defined as the ratio of a material's envelope density to its true density (ρ/ρ_{true}). Porosity is the inverse of solid fraction; therefore a solid fraction of 1 indicates that the compact has zero porosity. Solid fraction is proportional to the force applied to the powder, and is independent of ribbon thickness. There is a positive correlation between solid fraction and tensile strength, with ribbons of greater solid fraction having a greater tensile strength. If the solid fraction (or tensile strength) of ribbon is too low, then the ribbon will break up to fine powder rather than granules when milled, resulting in a poorly flowing product. Ribbons of adequate solid fraction typically produce larger, better-flowing granules; however, overly compacted granules exhibit poor compactability during tablet manufacture. Therefore, the correct balance between fines content generated during roller compaction is necessary to achieve granules with both proper flow and compactability characteristics (Fig. 32.3). The optimal ribbon solid fraction range will be product specific to a certain extent, but the ideal solid fraction for ribbon is generally in the range of 60–80%. Fig. 32.4 illustrates typical solid fractions ranges for ribbons, with respect to that for loose powders and tablets.

Granule compactability is not a major concern when manufacturing granules for filling into capsules or sachets, therefore it may be more desirable to produce granule of a higher solid fraction, in the range 75–85%, to achieve improved granule flow.

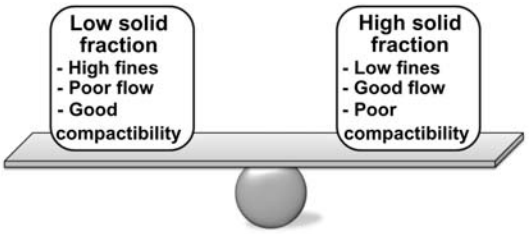

FIGURE 32.3 Getting the balance right—ribbon solid fraction impacts granule particle size distribution, flow, and compactability.

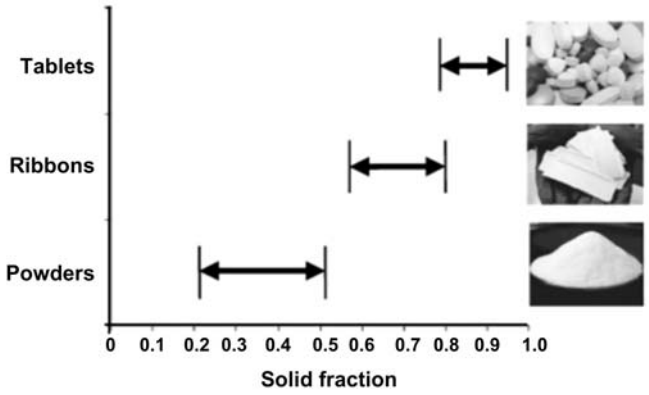

FIGURE 32.4 Typical solid fractions of pharmaceutical materials.[26] *Source: ©2004 with permission from Elsevier.*

In this instance, the target ribbon solid fraction range should also be assessed in relation to dissolution performance.

32.1.1.2.2 Ribbon tensile strength

Ribbon tensile strength is derived from the breaking force and thickness of the ribbon, and has a positive correlation with solid fraction. Greater ribbon tensile strengths can be achieved by increasing roll pressure and, to a lesser extent, slowing the roll speed (ie, increase the dwell time). Ribbon tensile strength may be characterized using a three-point bend test (details discussed in Section 32.2) to measure the ribbon breaking force, which can then be translated into a tensile strength. Low tensile-strength ribbons more readily reduce to fine powder during milling, which may have a negative effect on subsequent blend flow and negates the advantages borne from granulation. However, over-compressed ribbons typically produce tablets of lower tensile strength, which is attributed to reduced inherent compaction potential after granulation.[12] Recommended tensile strengths for roller compaction ribbons are >1 MPa at 0.7 solid fraction[9] to ensure that robust granules are produced. Ribbon of higher tensile strength may be preferred if the granule will not be subsequently recompacted, as in the case of granules intended for capsules.

32.1.1.2.3 Roll gap and ribbon thickness

Roll gap at the point of maximum compaction essentially dictates ribbon thickness (although material relaxation after the ribbon is released from the rolls will cause a slight increase in ribbon thickness compared with roll gap values). Fluctuations in powder flow may affect in-process variation of roll gap and ribbon thickness due to changes in the mass of powder passing between the rolls. Roller compactors that utilize a floating roll will respond to changes in powder flow by dynamically altering roll gap to maintain a constant solid fraction. Changes in roll gap should not impact ribbon tensile strength if powder density is uniform throughout the sample, because tensile strength should increase proportionally with increasing ribbon thickness. However, there is evidence to suggest that density is not uniform through the thickness of the ribbon, especially for thicker ribbons, with material being more compacted at the upper and lower surfaces and less compacted in the center. Thus, thicker ribbons may present a higher tensile strength, but result in a higher proportion of fines.[13–17] Therefore, ribbon thickness may influence granule particle size distribution, flow, and compactability, especially when using a larger roll gap.

32.1.1.3 Operating principles

Plastically deforming materials undergo a finite amount of compaction and deformation, and there is a limit to the degree of fracturing a brittle material will incur under typical pressures applied during roller compaction and tablet manufacture.[18] To relate the limits of a material's compaction and deformation to measurable tablet properties, the effect of recompression (subjecting a material to multiple compression steps, ie, roller compaction followed by tablet manufacture) on the compactability of a material has been well documented. Recompression generally causes a reduction in tablet strength, and this reduction is more significant when the initial compaction is carried out at a higher pressure,[19–25] as demonstrated in Fig. 32.5. This loss in tablet strength is often referred to as a "loss of compactability" or "reduction in strength" and has been attributed to: (1) work hardening of granules and (2) granule size enlargement.[24,25] The concept of "work hardening" was proposed as an empirical method to describe the magnitude of the reduction in compactability; it can be defined as the irreversible plastic deformation of particles that introduces defects that "harden particles."[23] For the latter cause, larger particles (formed from the first compaction step) are hypothesized to reduce compact strengths because they possess lower surface areas, thus reducing packing efficiency and availability for bonding.[24]

Farber et al. presented a relationship correlating roller compaction conditions and tablet strength, in which compaction is assumed to be cumulative throughout the lifetime of a material.[19] This theory, coined as the "unified compaction curve model," postulates that compact strength (ribbon and tablet) is generated irreversibly, as if strength is primarily controlled by plastic deformation of primary particles. Therefore, the tensile strength of compacts manufactured from granules is dependent on the inherent compactability remaining after granulation. As such, if a relatively large amount of particle bonding and tensile strength is generated during roller compaction, then there is less potential for gaining tensile strength during tablet compaction, resulting in weaker tablets. When the total compaction history is accounted for, the compaction behavior of uncompacted blends and roller-compacted granules ultimately adheres to a single master compaction curve, or unified compaction curve. The concept of the unified compaction curve is illustrated in Fig. 32.6. Application of the unified compaction curve model to an MCC/lactose system is demonstrated in Fig. 32.7. It should be noted that the model is generally more applicable to systems containing a significant proportion of plastically deforming material, such as MCC and starch.

32.1.1.4 Roller compaction equipment design

There are many different roller compactor designs in the market today, and examples of the various designs are given next (Fig. 32.8). The main differences between the roller compactor designs are the roll orientations, feed screw systems, roll surfaces, and mill types.[14,27,28] The rolls may be configured in parallel, perpendicular, or at 45 degree to the horizontal, in addition to related differences in the feed system orientation. Feed systems may vary by the feed screw orientation and number of feed screws (Fig. 32.9). Possible orientations for feed systems, based on current commercially available units

include: (1) vertical gravity or vertical feed screw (Freund-Vector (Marion, IA), (2) horizontal feed screws (Alexanderwerk (Remscheid, Germany)), (3) a horizontal conveying screw followed by a vertical tamping screw (Fitzpatrick (Elmhurst, IL)), and (4) horizontal feed screw followed by an angled tamping screw (Gerteis (Jona, Switzerland)). The specific arrangement can influence compaction behavior within the roller compactor, such as feed pressures. Roller compactors with a horizontal feed screw and vertically stacked rolls typically come equipped with either a single or double feed screw to convey the powder to the rolls. The use of single- or double-feed screws is dependent upon equipment scale and roll width. For example, the pilot plant scale Alexanderwerk WP120 roller compactor uses a single-feed screw, due to the narrow roll width of 40 mm, versus the use of a double-feed screw on the production scale WP200, which uses 75 mm wide rolls. Consistent delivery of powder to the entire roll width is key; so for larger roll widths, the use of a single feed screw is not common because the periodicity of a single-feed screw can be observed in the widthwise density distribution of the roller compacted ribbon.[29] The use of a double-feed screw can help reduce this widthwise density variability by moving the maximum density achieved for each feed screw closer to the edge of the roll.[30]

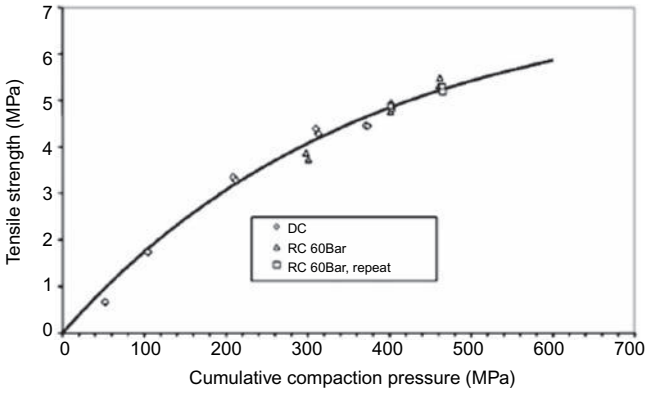

FIGURE 32.7 Unified compaction curve for a 1:1 MCC:Lactose blend (solid line). Direct compression (*DC*) compaction and roller compaction (*RC*) experimental data points denoted for indicated conditions.[19] *Source: ©2008 with permission from Elsevier.*

Deaeration of incoming uncompacted feed powder is a common component of the feed screw system. The powder being fed to the rolls has an apparent density equivalent to the powder's bulk density. Therefore, air is entrapped within the powder mass being conveyed to the rolls. Entrapped air increases the propensity of roller compacted ribbons to laminate once the compressive force from the rolls is removed. Removal of entrapped air within the feed powder improves the powder's compactability. The air can be removed via gravity, a tamping screw, or a

vacuum depending on the design of the roller compactor. Vacuum deaeration is most effective way and is accomplished through the use of sintered metal filters and a vacuum pump. The filter is typically incorporated into the walls of the feed screw system and allows the powder to flow across the inner surface of the filter. The vacuum pump is then connected to the outer surface and pulls air out of the powder. This increases the density of the powder and prepares the material for compaction at the rolls.

A variety of roll surfaces are available for the various roller compactors; the surfaces can vary from polished smooth (flat) rolls to textured rolls with knurling, as shown in Fig. 32.10.[31] Materials with a tendency to stick to surfaces may benefit from testing with different types of roll surfaces. In addition to assessing the impact of roll surface, these cases may require further exploration of lubrication levels and types of lubricant (ie, magnesium stearate vs stearic acid, sodium stearyl fumarate), as well as benefit from the use of external lubrication units to mitigate sticking challenges.[32]

Some rolls are interlocking punch-and-die while others are pocketed to create briquettes.[33] The different roll surfaces are used to alter the amount of friction between the powder particles and roll to facilitate the powder being pulled through the rolls to create a ribbon. A punch-and-die roll arrangement consists of one roll that fits inside the other, which removes the need for side seals to contain the powder during roller compaction. This arrangement is commonly associated with the use of Gerteis roller compactors, but the concept can be adapted to other equipment designs as this roll configuration yields significantly different ribbon density distributions compared with more traditional roll configurations, producing ribbon in which the density is highest at the edges of the ribbon and lowest in the center. In more traditional roll configurations that utilize a static side seal, frictional drag effects between the powder and side seal minimize powder accumulation at the edges of the roller compacted ribbon, yielding lower density edges with a higher density center. Although the density distribution within the ribbon may be different, the same average ribbon density can be achieved for both arrangements by adjusting compression force applied by the rolls. It is important to note, however, that the resultant milled particle size distribution is a function of the density of the ribbon coming off the rolls; thus, there may be a shift in the amount of fines and coarse particles depending on the proportion of low- and high-density regions within the ribbon.

The manner in which ribbons are milled is important because ribbons are not the final dosage form.[34] The mill design is the final differentiation among roller compactor equipment manufacturers. Some manufacturers use an integrated mill with the roller compactor, which consists of a single (Gerteis (Jona, Switzerland)) or double (Alexanderwerk (Remscheid, Germany)) set of screens with rotating impellers. The other option is an external mill (Fitzpatrick (Elmhurst, IL)) if the roller compactor does not have an integrated mill. The choice of mill screen size, rotor speed, and rotor-to-screen clearance will impact the final granule particle size distribution. Optimization of the milling operation to ensure proper granule flow and particle size distribution for blend uniformity should be performed as part of process development.

Roller compactor equipment design can have significant impacts on the ribbon products. For example, roller compactor design elements, such as roll design and feed system, have been shown to cause roller compacted ribbons to exhibit a three-dimensional density distribution. The density distribution of roller compacted ribbons has been characterized in previous

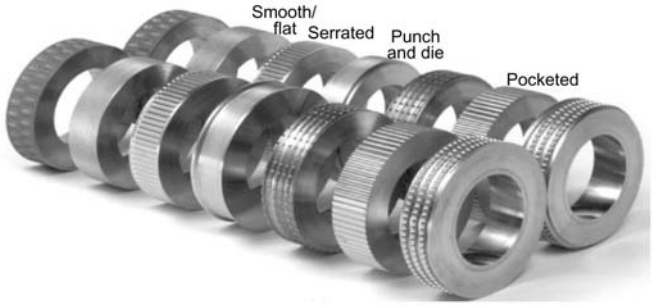

FIGURE 32.10 Roll design options.[12] *Source: Copyright © 2012 by John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.*

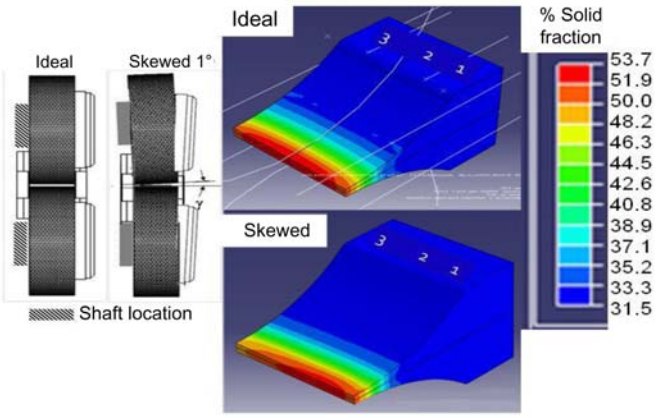

FIGURE 32.11 Finite element modeling explains observed anisotropic density distribution in ribbons.[38]

studies both experimentally and computationally for metals and organic materials.[14,30,35–37] These studies have shown that ribbons coming off of a roller compactor generally exhibit a parabolic widthwise density distribution, where the edges possessed a lower density than the center of the ribbon for rolls equipped with fixed side walls.[30,35] The lower density edges of the roller compacted ribbons were attributed to frictional effects between the powder and fixed side walls.[35] The lengthwise density variation was shown to manifest itself as a sinusoidal wave of higher density running throughout the ribbon's length.[14,37] Therefore, ribbons with the same average density do not necessarily perform the same in downstream processes. In support of these studies, McCann[38] used near infrared (NIR) spectroscopy to map the density distribution of ribbons and found that the ribbon edge closer to the machine body had a slightly higher density than the outer ribbon edge, in addition to the observation that the maximum ribbon density was offset from the center line. Finite element computational modeling was used to show how the cantilevered design of the roller compactor used in the study contributed to the anisometric ribbon density. The upper roll drive shaft was found to have deflected from parallel, which can cause the outer edge of the roll to deviate at a small angle away from being parallel with the bottom roll. In the computational model, a 1 degree deviation from parallel was simulated. This small deviation from parallel showed that the applied pressure was anisotropic with the inner ribbon edge, experiencing higher pressure than the outer edge, as shown by the skewed orientation in Fig. 32.11.

32.2 IN-PROCESS ANALYTICAL CHARACTERIZATION TOOLS

Several tools, listed in Table 32.3, have been used to improve process understanding of the roller compaction operation, as well as to facilitate accurate characterization of product qualities. In the table, bench-top roller compactors are mentioned because they have the potential to serve as a material-sparing option during the design and optimization of roller compaction operations. Commercially available bench-top roller compactors include the TFC-LAB micro-roll compactor (Freund-Vector), Fitzpatrick IR 220 Chilsonator (Fitzpatrick), BT120 (Alexanderwerk), and the Miniroll roller compactor (Riva (Hampshire, UK)). Input requirements for these bench-top units can be as low as 5 g of material. However, due to the absence of peer-reviewed literature at this time regarding the contribution of these units to the general mechanistic or scale-up knowledge for roller compaction, the bench-top units will not be discussed in this chapter.

TABLE 32.3 List of Tools and Tests Used to Characterize the Roller Compaction Operation

Tool/test	Application
PROCESS DEVELOPMENT/UNDERSTANDING	
Instrumented roll	Modeling
	Mechanistic understanding
Compaction simulator	Roller compaction simulation
Bench-top roller compactors	Roller compaction simulation

Three-point bending flexural test	Ribbon strength
Arc punch	Ribbon density
Laser profilometer	Ribbon density
Process analytical technology tools	Ribbon density, tensile strength, moisture content, API content, granule size

32.2.1 Instrumented roll

The current pharmaceutical industry standard roller compactors include operator interfaces that allow for online monitoring of operating conditions, including roll pressure. However, the roll pressure readings do not accurately reflect the actual compaction pressures experienced by the powder because they include equipment effects. To address this gap, the instrumented roll has been developed as a means to monitor the compaction pressure of powders in-situ during the roller compaction process.[35,39–43] This technology has been adapted from the metallurgy field, where measurements of normal forces, or pressures, on materials compacted during a rolling process have been reported as early as 1933.[44–46] Fig. 32.12 shows a roller compactor roll that has been instrumented with three sensors, positioned along the full width of the roll. Pressure sensors embedded on the surface of the roll of a roller compactor are used to measure the pressure exerted by the rolls onto powder during the roller compaction process. Thus, for this particular instrumented roll, pressure readings may be recorded along the width of the roll for every rotation, enabling measurements at the roll center and the sides, where edge effects have been reported. It should be noted that instrumented roll data reported in literature are not collected in a uniform manner because the instrumented roll is not a standardized tool and is often specially assembled in-house. Variability in instrumented roll specifications exists in terms of sensor placement, type (eg, strain gauge load cells[35,41–43,47] or piezoelectric transducers[17,39,40,48–50]), and number of sensors.

The ability of the instrumented roll to monitor normal and shear stresses in-situ has provided scientists with an in-depth look into the roller compaction operation, enabling a greater mechanistic understanding of the process and facilitating the development of predictive models through the establishment of empirical relationships and compaction theories. The basic function of this tool is to map the evolution of roll pressure and stress profiles during the roller compaction process, from which greater knowledge evolves through the quantification and prioritization of relationships between operating conditions and product quality.[35,50] Data collected from instrumented rolls are in the form of pressure and stress profiles, as shown in Fig. 32.13. From these plots, maximum compaction pressures (P_{max}) and shear stresses are extracted to provide insight into relationships between operating conditions and experimental parameters, including formulation, process, and equipment considerations, to compaction quality.[17,35,43,49,51]

32.2.1.1 *Mechanistic understanding*

One of the key drivers behind the use of instrumented roll technology was to increase the mechanistic understanding of the roller compaction operation by providing information on the actual pressure that imparts powder compression, allowing for deconvolution of ribbon quality from equipment and material influences. Instrumented roll data have substantiated strong correlations between ribbon solid fraction (γ_R) and P_{max} and have demonstrated the independence of this relationship from equipment factors (ie, roller compactor type/scale), processing conditions, or material selection.[19,26,52–54] In Reynolds et al.,[52] P_{max}- γ_R profiles for an active blend, where drug load exceeded 30%, lie virtually along the same curve despite varying

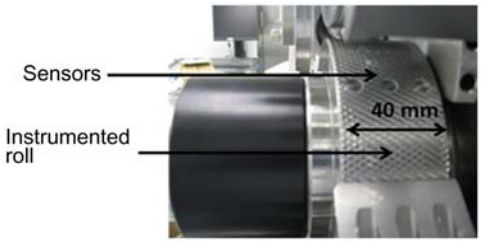

FIGURE 32.12 Roller compactor roll that has been instrumented with three pressure (strain gauge load cell) sensors.[42] *Source: ©2012, with permission from Elsevier.*

operating parameters, operating scale, and even slight changes to the formulation (Fig. 32.14). Hydraulic roll pressure, screw speed, and roll speed were varied between 20 and 60 bar, 35 and 75 rpm, and 5 and 10 rpm, respectively, in this study. Intragranular lubricant levels were also adjusted between 0.25% and 0.75%, by weight.[52] However, regardless of the wide range of input conditions examined in this work, the resultant P_{max} ultimately dictated γ_R.

Given the importance of P_{max} to product quality, numerous studies have been conducted to elicit trends regarding the impact of different operating parameters, such as roll gap, roll speed, and feeding conditions (ie, feed screw speed) on compaction pressure (Fig. 32.15). This information is highly valuable because it enables a more thorough understanding of the design space for the roller compaction operation and imparts process robustness, providing confidence in product quality in the event that operating conditions drift during manufacture. It is important to note that that these trends are unique to each system and therefore must be re-established for each material/equipment combination. Guigon et al. used the instrumented roll to determine that a constant P_{max} was achieved during the roller compaction of hydragilitte (SH100), lactose, and sodium chloride powders through the maintenance of a constant roll gap (Fig. 32.15a).[14] Constant roll gap was achieved by controlling feed screw and roll speeds, although feed-screw speeds played a more dominant role in impacting roll gap, and thus P_{max}. Yu et al. demonstrated that P_{max} was relatively independent of roll speed when roller compacting MCC, but was highly dependent for a dibasic calcium phosphate dihydrate (DCPD) system (Fig. 32.15b).[50] Yusof et al. reported a sizeable dependency of P_{max} on feed rate when roller compacting maize powder (Fig. 32.15c).[55] However, roll gap and roll speed were found to have a larger influence on P_{max} than feed screw rate. Ingelbrecht et al. also found that feed screw rate had minimal effect on P_{max} relative to roll speed and hydraulic roll pressure for a maize starch system.[39] However, maintenance of a constant roll/feed screw speed ratio enabled optimal operating conditions. After reviewing numerous studies, it is apparent that there is no clear "dominant input factor" that governs the roller compaction operation, as the impact of different input factors on product quality is highly dependent upon the material and equipment being used.

One input factor that is consistently assessed in roller compaction studies is the impact of feeding conditions, such as feed rates and feed design, on compaction force (or pressure). This topic of feeding conditions remains of particular interest because of its significant manifestation

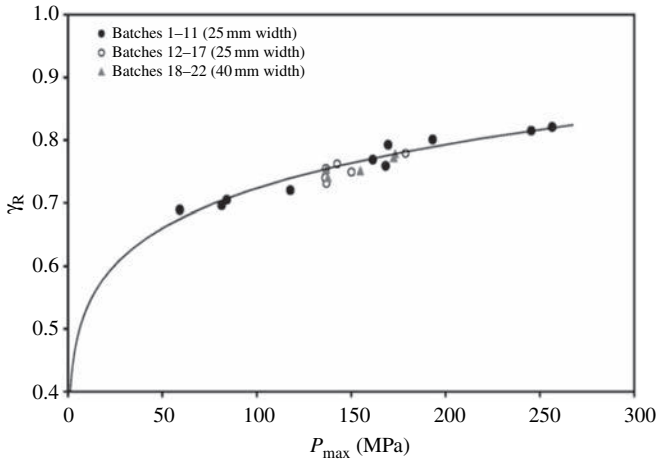

FIGURE 32.14 Ribbon solid fraction (γ_R) as a function of maximum pressure (P_{max}). Roller compacted material is an active blend (>30% drug load) with MCC and dibasic calcium phosphate dihydrate (DCPD) as primary excipients compacted over a wide range of operating conditions and two roller width configurations. Multiple lubricant levels were also explored.[52] *Source: ©2010, with permission from Elsevier.*

on ribbon density. Simon et al. reported heterogeneity in stress patterns along the width of a roller compactor roll and matched its period with that of the single screw feeder in the roller compactor unit. In this work, sodium chloride (NaCl) was roller compacted and the stress experienced by the powder was measured directly using an instrumented roll and the density profiles across the resultant ribbons were quantified using a light transmission technique. The stress exerted on the compact demonstrated a periodical heterogeneity in stress distribution, with patterns matching that of the single feed screw.[17] This phenomenon was also captured for alumina and lactose[17] and was reported by Cunningham when studying stress patterns of roller-compacted MCC.[35] Roller compaction operations that utilize a piston-feeding device, where a uniform pressure delivers powder to the rolls as opposed to the periodical pressure from a rotating screw, did not display periodical stress patterns in the ribbon. Alternatively, Lecompte et al.[15] did not observe periodical stress patterns in roller compacted material even when using a single-screw feed design. In Lecompte et al.'s experimental set-up,[15] the feed screw was positioned further away from the rolls than the unit described in Simon et al.[17] This extra distance between the feed screw and the rolls dampened the screw's ability to impart stress heterogeneously to the ribbon, providing further indication that heterogeneous stress distributions are tied to feeding conditions (ie, screw geometry and position). Along this same principle, stress variations on the powder were shown to be minimized by using a dual-feed screw design in combination with vacuum deaeration.[56] Additional findings from Lecompte et al.'s study found that operating parameters that maximize the amount of powder fed to the rolls (ie, high feed screw speeds, low roll speeds, and narrow gap settings) also serve to promote uniform stress distribution across the roll width.

Interest in understanding heterogeneities in ribbon densities extends beyond a general academic pursuit. Stress heterogeneities in the ribbon can lead to large variations in ribbon densities, which can then impact granule quality in terms of wide particle size distributions and potentially high fines content if the ribbon densities in some regions are especially low. As alluded to previously, multiple studies have reported the existence of pressure gradients across the ribbon width, regardless of feeder type.[16,17,42,57] In Fig. 32.16a, 3D images depict the stress distribution across the width of a ribbon manufactured under varying hydraulic roll pressures. At select operating conditions, where the hydraulic roll pressure was low, there were significant variations in the stress at the center of the ribbon versus the edges of the ribbon, in line with that observed in Fig. 32.16b. As the hydraulic roll pressure was increased, the stress distribution over the width of the ribbon became more homogenous.[15] These stress variations were correlated with density variations across the ribbon width. Ribbon density, as a function of width, was mapped using three different characterization techniques: micro-indentation, X-ray micro-computed tomography, and segmentation. The results from all three techniques were in alignment with instrumented roll data, showing that maximum compaction stress tends to occur near the center of the ribbon.[16] The reason for this density pattern is attributed to frictional resistance on the sides of the rolls, which reduces powder flow to the edges. These stress/density

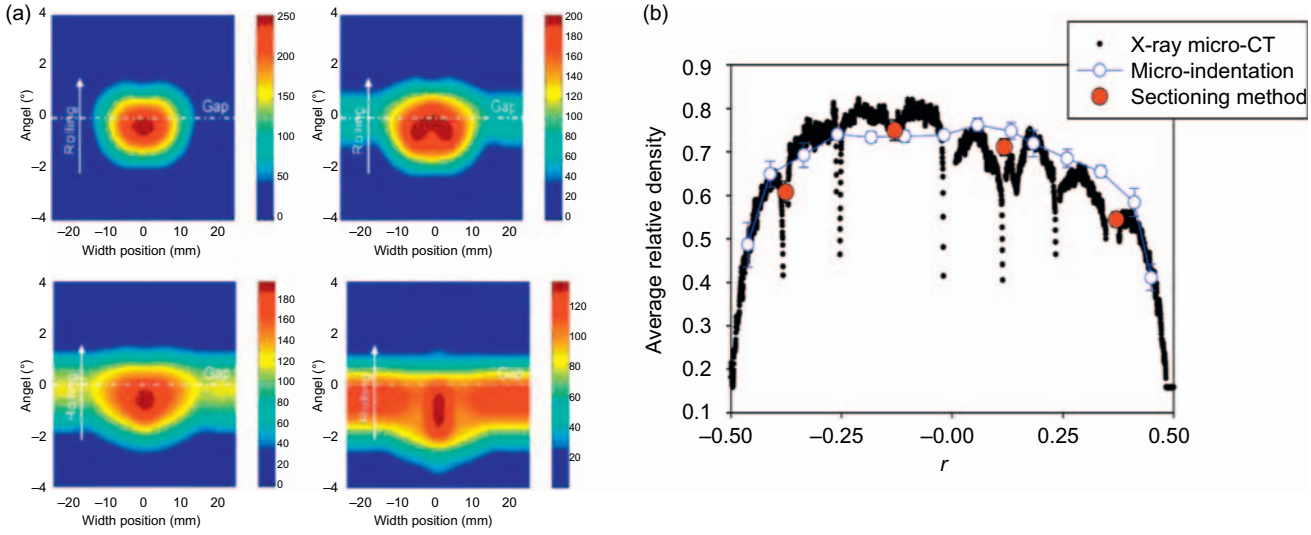

FIGURE 32.16 (a) Stress distributions (MPa) for different compaction forces as a function of rolling angle and roll width position where an increase in hydraulic roll pressure favors more homogenous stress distributions across the roll width,[15] (b) density profile along the ribbon width, where densities have been measured using multiple characterization techniques.[16] *Source: ©2005, ©2009 with permission from Elsevier.*

variations can be minimized by implementing side seals to minimize leakage and imposing a vacuum to facilitate deaeration of the powder.[12,42,56,57] Miguelez-Moran et al. used an instrumented roll to demonstrate that density variations across the ribbon were minimized when roller compactors were run at lower roll speeds, smaller gaps, and when using powders that slipped along the seal surfaces more readily. Lubrication of sealing plates and/or sufficient lubrication of feed powders minimized ribbon density variations, especially those consisting of lower edge densities and higher densities at the ribbon centers, through the reduction of frictional effects between the powder and the sealing plates.[48]

As indicated by Miguelez-Moran et al.,[16] formulation choices can also have significant effects on roller compaction operations. Instrumented roll technology has also been used to explore the impact of formulation considerations, such as filler, binder, and lubricant selections, on roller compaction performance, and more specifically, on ribbon and granule quality. The majority of these studies have focused on the behavior of a specific excipient, or class of excipients, to provide insight into guiding the selection of appropriate materials for roller compaction. In a few cases, a model active ingredient has been added to investigate the impact of the active on excipient behavior. Several studies have examined the role of roller compacting a more plastically deforming material, such as MCC, versus a more brittle, fragmenting material, such as lactose or DCPD. Yu et al. found that a lower P_{max} was required for DCPD to achieve the same solid fraction as MCC when roller compacted under the same conditions.[50] Inghelbrecht et al. conducted extensive studies to understand how roller compaction operating parameters needed to be adjusted to achieve similar quality granules when roller compacting different lactose grades (α-lactose monohydrate 200M, α-lactose monohydrate 90M, anhydrous β-lactose, and spray-dried α-lactose)[58] and different MCC grades (Avicels PH-101, PH-105, PH-302, RC-581, CE-15).[59] The authors concluded that more brittle materials (ie, lactose) required lower feed screw speeds than plastic-deforming materials (ie, MCC) in order to achieve similar quality granules, in terms of friability and granule size. In the MCC study,[59] ibuprofen was added to the blends, up to 75% by weight, and found to disrupt the binding capacity of MCC. For ibuprofen loadings between 25% and 50%, higher compaction pressures (ie, P_{max}) were needed to achieve the same granule quality as pure MCC. However, at 75% ibuprofen content, the brittle nature of the ibuprofen dominated the material's behavior and the target granule quality was attained using lower P_{max} conditions, in line with the earlier observations regarding roller compaction of more brittle excipients (lactose) compared with more plastic excipients (MCC). Interestingly, the extent of the impact of ibuprofen content on granule quality varied for the different MCC grades, which was attributed to differences in particle size and density. The impact of different binder selections, including different grades of copovidones, crospovidones, and celluloses,[60] as well as lubrication levels,[35,48,61] on granule quality have also been reported. As seen in Fig. 32.17, Yu et al. found that the addition of magnesium stearate (MgSt) as a lubricant influenced MCC and DCPD very differently, where increasing levels of MgSt reduced shear stress for DCPD, but MgSt had no effect on MCC. Boundary lubricants, such as MgSt, possess low coefficients of friction, typically ~0.1,[62] and thus provide a weak interfacial layer for materials. Organic materials, such

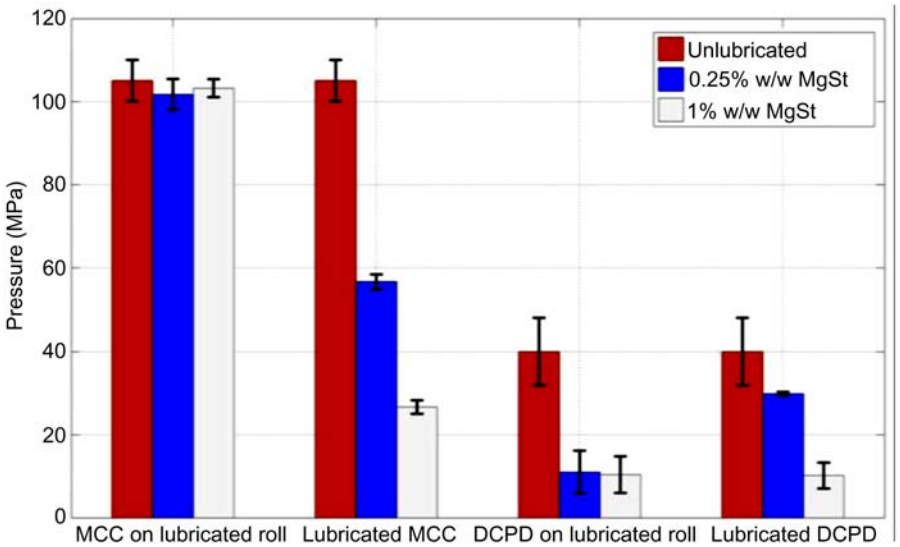

FIGURE 32.17 Impact of lubrication on pressure for MCC and DCPD.[61] *Source: ©2013 with permission from Elsevier.*

as MCC, can be difficult to boundary lubricate because they already possess low interfacial shear strengths, similar to that of boundary lubricants. However, the coefficients of friction for nonorganic materials, such as DCPD, are typically higher than that of organic materials (~0.5 for DCPD), making them amenable to the effects of a boundary lubricant. Wu et al. studied the impact of moisture content of the feed powder on ribbon quality.[63] Results showed that MCC powders containing more than 10% water content were more susceptible to nonhomogenous stress distributions in the ribbon. As the moisture content in MCC powders was increased, the powder became more cohesive and flowability of the moist powders decreased. Consequently, feeding conditions in the roller compactor unit were impacted by nonuniform flow of powders into the compaction zone and exacerbated by increased frictional effects between the powder and side cheek plates. These conditions resulted in P_{max} and density distribution profiles across the ribbon where the values at the center of the ribbon were significantly higher than values at the edges, with higher moisture contents of the feed powder leading to more pronounced differences between center and edge values. Interestingly, ribbons made with powders with high moisture content also possessed different hydration states across the ribbon. In all of these cases, the authors found that optimized roller compaction parameters varied significantly depending on the feed's material properties. Differences in roller compaction behavior were observed when materials possessed different particle sizes, shapes, morphologies, moisture content, and plastic/elastic properties. Overarching conclusions could not be extracted from these studies because many of the identified trends related primarily to excipients, and thus their application to realistic drug formulations has not been fully established.

To summarize, none of the empirical correlations discussed in this section could have been made without the use of an instrumented roll because marketed commercial roller compactors do not have the capability to monitor the actual compaction pressure experienced by the powders. The ability to separate equipment-induced pressure effects from the actual pressure that is directed toward powder compaction is vital for gaining in-depth understanding of the roller compaction process. While ribbon densities are typically monitored to track the adequacy of different roller compaction settings, literature has clearly shown that ribbon densities are influenced by numerous parameters, ranging from material characteristics to process parameters and equipment considerations, and thus, knowledge of actual pressure profiles has been essential to improving the mechanistic understanding of roller compaction behavior. While the instrumented roll has been useful in gaining additional insight into the roller compaction process, it has also revealed the significant complexities of this operation.

32.2.1.2 *Modeling contributions using instrumented roll*

Instrumented roll technology has been a useful tool to support the development of roller compaction models. Schonert et al. used the instrumented roll to substantiate the existence of slip and nonslip compaction regions, a key aspect that serves as the foundation for the majority of roller compaction models.[43] Instrumented roll data has been used to collect input for finite element (FEM)-based models to describe feed stresses induced by the feeder, roll surface pressures, and roll shear stresses at different locations across the roll width.[35,64,65] A more detailed discussion on the use of instrumented rolls for modelling purposes is presented in Section 32.3.

32.2.2 Uniaxial compaction to simulate roller compaction

Uniaxial compaction, using both a compaction simulator and a rotary tablet press, has been used to simulate ribbon manufacture on a roller compactor.[26,49,66,67] Current approaches to feasibility and development, as well as scale-up, of roller compaction operations require significant amounts of material for experimentation. Technical transfer of roller compaction processes from one machine to another, in addition to scale-up challenges, depends on equipment parameters that are prone to bias through equipment type and instrumentation. For example, the accurate translation of maximum compression force exerted by the rolls on the powder requires knowledge regarding powder behavior (eg, flow and compressibility) and knowledge of equipment properties (eg, roll configuration, how force is applied to the rolls, and energy losses due to equipment design). Successful transfer of roller compaction processes typically cannot be confidently assessed until the ribbons have been manufactured and characterized.

A material-sparing approach to the roller compaction process, in which compression events during roller compaction are simulated using uniaxial compaction, has been used to increase the development efficiency of roller compacted products (Fig. 32.18). Limited amounts of material may be used for uniaxial compaction compared with roller compaction (~10× reduction), and characterization of the simulated compacts enables more rapid screening during development.[26] Key process parameters of maximum compaction pressure, roll gap, and material mass can be accurately simulated and controlled; however, it should be

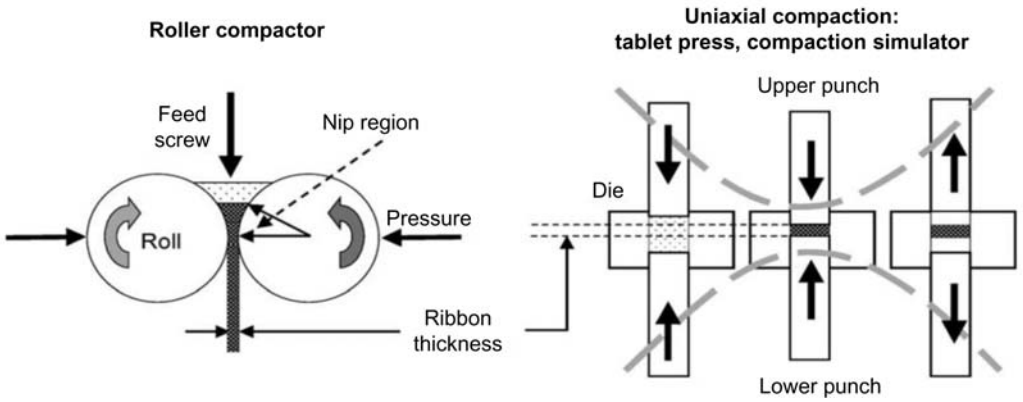

FIGURE 32.18 Simulating a roller compactor using uniaxial compaction.[26] *Source: ©2004 with permission from Elsevier.*

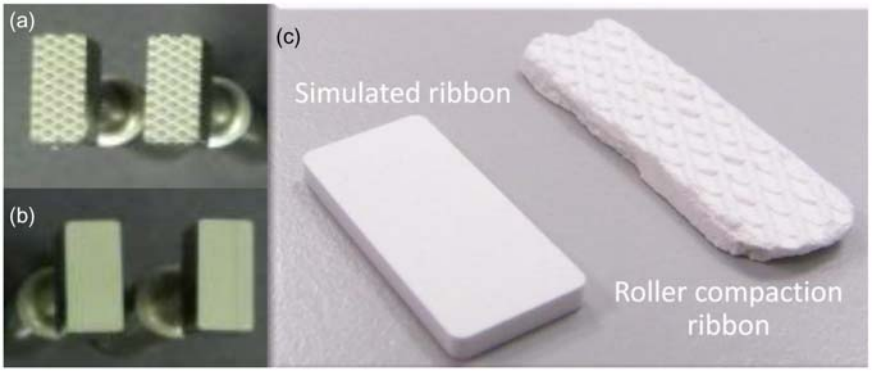

FIGURE 32.19 Rectangular tooling used for roller compaction simulation: (a) smooth surface, (b) knurled surface, (c) photographs of simulated and actual ribbons. *Source: Photographs from unpublished data.*

noted that the simulation approach does not account for variables associated with feed mechanisms and the shear behavior experienced by the powder between the rolls. Ribbon solid fraction is typically used as the primary indicator of product quality for comparison between the simulation using uniaxial compaction and the actual roller compaction process. Uniaxial compaction for roller compaction simulation has been conducted using rectangular-shaped, flat-face tooling in an attempt to mimic the roll surface and to facilitate tensile strength measurements using the three-point bend test (Fig. 32.19), although good correlations between simulated and actual roller compaction processes have been achieved using round flat-faced tablet tooling. In summary, this simulation approach may be used to efficiently determine target ribbon qualities and, if appropriate correlations are developed between compaction pressures and roll pressures, optimal roller compaction operating parameters.

Hein et al.[21] used uniaxial compaction to analyze the suitability of materials for roller compaction. Crystalline α-lactose monohydrate, anhydrous β-lactose, spray-dried lactose, and MCC compacts were assessed to determine which of the diluents would be most suitable for roller compaction. The materials were compacted using an eccentric tablet press equipped with round, flat-faced tooling, milled to form granules using a rotary granulator, and then recompacted on the eccentric press to form tablets. Characterization of resultant tablets (ie, elastic recovery, tensile strength) was compared with previously published studies in which those same materials were roller compacted. The measured properties for these tablets prepared using the simulated roller compaction process compared well with the results found in the literature for tablets manufactured by an actual roller compaction process. Of the materials assessed in this study, anhydrous lactose was found to be the most suitable material for roller compaction, which was in agreement with previous reports.[27,58,59]

Few studies have reported direct comparisons between actual roller compaction experiments and those simulated by uniaxial compaction.[26,48,66,67] Gereg et al.[66] correlated data generated for lactose

monohydrate on a manual hydraulic press (Carver press model C, Carver Inc.) to a production-scale roller compactor (Fitzpatrick, model IR-520), using a roll pressure equivalent to the compaction pressure used on the Carver press, and found that granules (assessed for particle size, flow, and density) and final tablets (characterized by friability, density, and hardness) manufactured by both methods possessed exceptionally similar characteristics. However, ribbon qualities were not assessed in the study. Miguelez-Moran et al.[48] reported that similar pressure-density relationships were obtained for MCC regardless of the method of compaction, uniaxial or roller compaction, and even roll speed, as long as the tablet and the ribbon possessed the same thickness (Fig. 32.20). By keeping the thickness of the compacts constant, the degree of deformation and wall friction effects were similar.

Zinchuk et al.[26] used a custom-built compaction simulator and rectangular-shaped tooling to simulate roller compaction. Unlike experiments using manual hydraulic presses or rotary presses, the compaction simulator was programmed to more closely emulate the roller compaction profile, enabling movement of both top and bottom punches and the ability to program the exact profile of a particular roller compactor machine. In addition, both smooth and serrated punch surfaces were also assessed because the surfaces of rolls are often patterned to facilitate powder uptake in the feed zone. Actual and simulated ribbons of MCC exhibited similar compression behavior (compactability) and mechanical properties (tensile strength), regardless of roll surface pattern, as long as the ribbons were compacted to the same solid fraction (Fig. 32.21). Minor discrepancies that were observed between simulated and actual ribbons were insignificant compared with the variability in the measurement of the actual ribbon attributes, given the nonhomogeneity of densities and strengths across the ribbon width.[17] The extent of these discrepancies between actual and simulated ribbons may depend on material properties. Larger standard deviations were observed for ribbons manufactured at higher compaction pressures and were attributed to differences in micro-crack formation in the compacts at such high pressure conditions. By focusing efforts on maintaining consistent ribbon solid fraction, rather than equipment-dependent factors like compaction pressure, ribbon quality was deconvoluted from instrument type and parameters, and should facilitate consistent process scale-up or transfer between instruments. It was assumed that simulated and actual ribbons possessing equivalent material properties would result in equivalent granulations.

Hilden et al. went one step further and developed a correlation between compaction stresses achieved during uniaxial compaction to that during roller compaction. Based on phenomenological observations, a relationship between peak ribbon stress, σ_{Equiv}, and applied roll force, F, was developed:

$$\sigma_{\text{Equiv}} = 9.1\frac{F}{Rw} \tag{32.1}$$

where R and w are roll radius and width, respectively. This relationship was applied to six different case studies, examining formulations ranging from placebos to active formulations, up to 37% drug load, and multiple roller compactor units (Fitzpatrick IR 22 and IR520, Gerteis Mini-Pactor 250/25). In all cases, the solid fractions of compacts manufactured by

uniaxial compaction were comparable to those of actual roller-compacted ribbons when subjected to an equivalent compaction stress. In one example, an active formulation (31% drug load) was roller compacted under multiple conditions to yield ribbons of varying solid fraction. Fig. 32.22 shows how the compaction profiles of different batches of tablets, prepared using the granules of varying solid fractions, lie essentially along the same curve. In addition, the compaction profiles of the roller-compacted ribbons, which did not undergo a tabletting operation, also collapsed upon this same curve. Not only does this data further support the concept of using uniaxial compaction to simulate roller compaction, but it also provides further evidence supporting the concept of a unified compaction curve (described in the introduction section). The value of the relationship between applied roll force and equivalent compaction stress is its ability to provide information regarding intensive material properties and not be convoluted by extensive process or tablet properties.

32.2.3 Density characterization tools

Envelope density is the density used to determine the solid fraction of roller compaction ribbons. Envelope density is defined as the mass of an object

divided by its volume, where the volume includes that of its pores and small cavities. Due to the irregular shape of roller compaction ribbons, determining the envelope densities of the ribbons requires specialized tools, a few of which are listed next.

32.2.3.1 Envelope density analyzer

Envelope density analyzers utilize a displacement technique in which the volume of a solid object, such as roller compaction ribbon, is determined by the displacement of a solid medium. A brief description of the technique is as follows: a sample holder is filled with a dry, solid medium and a plunger compresses the powder until a specified compression force is achieved. This preliminary compaction, containing only the displacement medium, establishes an initial baseline for the volume in the sample holder. Next, the test run is conducted. In the test run, the object is placed in the sample holder containing the medium and the compaction process is repeated. The difference in the distance traveled by the plunger between the preliminary and test run is used to calculate the displacement volume, which can be attributed to the volume of the object. This process, illustrated in Fig. 32.23,[68] is able to accurately capture geometries of patterned ribbons.

The solid medium should be composed of small, rigid spheres that possess a narrow size distribution, good flow properties, and achieve close packing around the object under analysis. The particles of the medium should be sufficiently small such that they conform closely to the object's surface during consolidation, yet do not invade any pore space. The most commonly used commercial envelope density analyzer is the Micromeritics's GeoPyc Model 1360, in conjunction with DryFlo as the medium.

32.2.3.2 Arc punch

An arc punch is utilized in the same manner as a cookie cutter. The punch is pressed upon a ribbon in order to cut out a sample of a known geometry. The mass and thickness of the ribbon sample is measured, thus enabling the calculation of the sample volume. This method does not account for patterned surfaces of ribbons.

32.2.3.3 Laser profilometer

A laser profilometer with dual laser distance sensors (custom designed by Custom Lab Software Systems) was used to determine the density of roller compaction ribbons. The profilometer scans ribbon samples with low intensity laser beams that integrate the sample thickness across the ribbon surface and then quantitate the apparent volume. The use of the laser profilometer method to determine ribbon density was compared with more traditional methods of volume displacement (ie, GeoPyc) and manual measurements using calipers. Fig. 32.24 shows how ribbon density measurements by the laser profilometer compared well with measurements by volume displacement. Advantages of using the laser profilometer over the volume displacement method are more rapid turn-around times and better capability to handle friable ribbons. Both of these methods are significantly more accurate than measurement by calipers.

32.2.4 Ribbon strength characterization

32.2.4.1 Three-point bending flexural test

Tensile strength of roller compaction ribbons may be assessed using a three-point bending flexural test. This technique has been widely used to test mechanical properties of ceramics, polymeric, and metallic materials, and more recently for pharmaceutical powders.[26,70,71] A rectangular sample is stressed by applying a force to the center of the sample until the sample fails (Fig. 32.25). The tensile strength, σ_T, of the compact is determined using the following relationship:

$$\sigma_T = \frac{3}{2}\frac{FS}{Wt^2} \tag{32.2}$$

where F is the load applied to the fracture, W is the sample width, S is the distance between supports holding up the sample, and t is the sample thickness. This relationship assumes that linear elastic behavior

occurs[72] and that stress varies linearly across compact thickness, from maximum tensile stress at the lower face of the compact through zero to equivalent compressive stress on the upper surface of the compact. Tensile strength values were found to be independent of loading rate.[73] To facilitate the direct comparison between samples, compacts tested should optimally possess the same dimensions. Three-point bend tests may be performed using a dynamic mechanical analyzer, universal testing machines, such as an Instron testing system (Instron, High Wycombe, UK), or a texture analyzer.

32.2.5 Process analytical technology tools

Process analytical technology (PAT) tools enable nondestructive, online monitoring of critical process variables, thus facilitating the ability to make real-time adjustments to process operations in order to consistently manufacture products with the desired qualities. PAT tools pave the way for real-time release of products, eliminating the need for extensive offline laboratory testing, and promote the adoption of continuous manufacturing systems. Critical quality attributes (CQAs) for roller compaction include ribbon (density, moisture content, tensile strength) and granule (density, moisture content, tensile strength, particle size) characteristics and content uniformity.[74] Ideally, the objective of implementing PAT tools into the roller compaction operation is to be able to develop and utilize statistical, predictive cause–effect relationship models to implement system controls and feedback loops to automate operations. Fig. 32.26 provides a schematic of how PAT may be used to monitor a roller compaction system.[75] The data collected from PAT tools, in conjunction with multivariate analysis approaches, can be used to elucidate relationships between input parameters and CQAs.

The first form of online monitoring applied to roller compaction was acoustic emission, where the signal produced during powder compression was recorded with a microphone and transformed into a frequency spectrum. Changes to the acoustic emission bands correlated to different compression forces and were

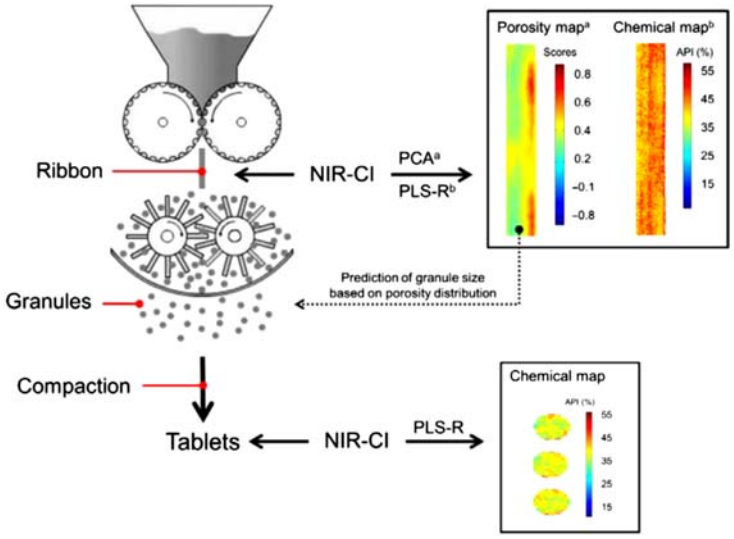

FIGURE 32.26 Overview of process monitoring of roll compaction and tabletting: the implementation of NIR-CI to gain information related to the physical or chemical properties of intermediate or final product.[75] *Source: ©2015 with permission from Elsevier.*

especially apparent when capping occurred. More recently, Akseli et al.[76] demonstrated the use of acoustic wave forms in the ultrasonic spectrum, along with X-ray micro-computed tomography to quantify density variations in ribbons. Heterogeneities in ribbon densities were correlated to tablet mechanical properties to provide insight into how lubrication levels and processing conditions at the roller compaction step impacted subsequent tablet properties.

NIR probes have also been successfully used to monitor ribbon properties, including density,[77–84] moisture content,[78–80] tensile strength,[78,79,83] Young's modulus,[78,79] API concentration,[79,83] and granule properties, including particle size.[77,82,84] NIR data, in conjunction with data analysis methods, have been used to develop models to predict these ribbon and granule properties. Gupta et al.[77] proposed a model to predict ribbon tensile strength based on the slope of the best-fit line through the NIR spectra. Predictive models have also been developed in conjunction with partial least squares (PLS) regression to predict ribbon density, moisture content, tensile strength, and Young's modulus.[78,79] Soh et al.[84] presented a predictive model for granule and ribbon properties that considered not only NIR spectral data, but also raw material properties, operating parameters, and roll gap. Acevedo et al.[81] developed a system to monitor ribbon density in real-time, using not only spectral baseline shifts, but both principal component analysis (PCA) for qualitative analysis and PLS for quantitative analysis. PCA was found to be a more suitable method for monitoring ribbon density because it was a less time-consuming method than PLS. It should be noted that, for the development of NIR-based models, it is important to conduct calibration experiments and subsequent product analysis under similar conditions. Gupta et al. reported large discrepancies between predicted and experimental data when the models were developed using calibration data sets with samples that were stored for 24 hours prior to analysis, whereas experimental data was measured directly from the press.[78] In addition, the selection of optimal probe size and measuring distance (between the probe and the sample) has the potential to yield higher accuracy results.[83]

More recently, microwave resonance tools[80,85] have demonstrated feasibility in monitoring moisture content and envelope density of roller compaction ribbons. Microwave resonance is an attractive option because it does not require sophisticated chemometric software and needs fewer calibration standards than NIR, thus facilitating transfer between measurements of different formulations.[85] These two techniques possess different penetration, being a few millimeters for NIR and several centimeters for microwave; thus microwave signals can penetrate the full thickness of the ribbon. Furthermore, microwave resonance is quite sensitive to water.[74] Consequently, microwave resonance sensors were found to produce more accurate results, compared with NIR (with approximately half of the root mean square error), for both density and moisture determination.[80] However, whereas microwave resonance does not provide chemical information, NIR does.[74]

Near-infrared chemical imaging (NIR-CI), an emerging technique for pharmaceutical applications that is capable of simultaneously collecting large amounts of spectral and spatial information, has recently been applied to develop predictive models for ribbon density, API content, and granule particle size, and can map the density distribution across all ribbon dimensions.[75,86] Using this technique, an NIR spectrum is recorded in each pixel of a sample image, resulting in a

hyperspectral data cube that can be used to visualize the distribution of physical or chemical properties within the sample matrix. Souihi et al. used NIR-CI to effectively determine ribbon density and its distribution across both the width and length of the ribbon, as well as determining the spatial distribution of the compaction pressures on the surface of the ribbon. Results from this study revealed that low roll forces during the roller compaction operation contributed to heterogeneous API distributions in the ribbon. Khorasani et al.[75] used NIR-CI along with PCA to map ribbon density distributions and develop a predictive model for granule particle size distribution. In addition, PLS regression was used to predict API distribution and content within the ribbons. The technology has demonstrated strong potential as a quality control measure for roller compaction operations.

32.3 ROLLER COMPACTION MODELS

Several models have been developed to describe the roller compaction process,[65] such as Johanson's rolling theory for granular solids,[51] the slab method,[4,35,87,88] and modeling by finite element method (FEM)[41,64,89] and discrete element method (DEM).[90,91] The development of these models has not been trivial because numerous complex behaviors must be taken into account[35]:

- Nonlinear behaviors related to the contact or frictional conditions at the roll surface
- Adequate quantification of the constitutive behavior of a deforming powder that undergoes significant evolution of its mechanical properties as a function of density
- Lack of experimental inputs that adequately represent relevant process conditions (eg, frictional coefficient of roll/powder under stress states encountered during roller compaction)
- Experimental difficulties and/or high cost of evaluating the actual process and boundary conditions (ie, feed stress, friction, initial conditions, and density of the powder in the feed region)
- Numerous interrelated parameters associated with equipment design, material properties, and process settings that complicate model verification because many of these parameters can have similar effects on the overall behavior (ie, roll force or density of compact)
- Behavior variability across multiple aspects (ie, rolling direction, across roll width, and even across ribbon thickness) requires two- and three-dimensional effects to be captured, which complicates solution techniques

These process models, in conjunction with experimental studies, have provided important insight into the roller compaction process, enabling a rational scientific framework to probe the underlying mechanisms that drive the operation. This enhanced knowledge has improved our understanding of the relative importance of multiple input factors, including material, equipment, and process considerations, and their impact on product quality. As such, these models play an important role in shaping QbD strategies for the efficient development of roller compacted products and have been used to help establish critical process parameters (CPPs), control strategies, and facilitate scale-up operations. Through the incorporation of models in the QbD approach, a physics-based understanding of the operation is used to predict CPPs, which facilitates a deeper understanding of the compaction profiles experienced by the powder during the roller compaction process that can be used to inform on technical transfer and scale-up activities. For instance, model outputs can be used to identify input parameters necessary to match compaction profiles across the ribbon for different roller compaction units. It should be emphasized, however, that the roller compaction models presented here have been tested only under limited conditions and require additional testing for universal applicability. A summary of process models that have been developed for roller compaction are listed in Table 32.4. To date, roller compaction models have focused primarily on establishing a relationship between input variables (material properties, process conditions) and ribbon properties (solid fraction, ribbon strength). It is commonly assumed that similar ribbon properties lead to comparable granule properties (compactability, flow), which are of interest in downstream operations.

32.3.1 Johanson's rolling theory for granular solids

Johanson's theory is a one-dimensional, continuum-level approach to model the roller compaction process that has been widely used since the 1960s because it has yielded relatively good correlation with experimental data. This theory assumes that powders are isotropic, frictional, cohesive, compressible, and behave in accordance with the effective yield functions proposed by Jenike and Shield.[51,106] As such, the plane strain condition between the rolls can be represented as in Fig. 32.27.[51] Johanson's theory centers upon the existence of three regions of material behavior: a slip, nip, and release region. A detailed description of each of these compaction regions is given in the legend to Fig. 32.28. Briefly, in the slip region, the powder experiences "slipping" at the roll surface and the roll moves

faster than the powder. At this stage, the material does not undergo significant compaction and the particles rearrange as the rolls "slip" past the material, adhering the Jenike–Shield yield criterion. In the nip region, the material becomes increasingly trapped between the rolls, moving at the same speed as the roll, and undergoes significant compaction. As such, the powder no longer follows the Jenike–Shield yield criterion and behaves according to a powder bulk density-hydrostatic pressure relationship. The nip angle, α, is defined as the point at which the material transitions from the slip (a slip boundary condition) to the nip (no-slip boundary condition) region. By convention, an angle of 0 degree corresponds to the point at which the roll gap is at its minimum. A schematic of the roller compaction process is illustrated in Fig. 32.28.

The pressure gradient ($\partial\sigma/\partial x$) in the slip region is described by the following equation:

$$\frac{1}{\sigma}\left(\frac{\partial\sigma}{\partial x}\right)_{\text{slip}} = \frac{4\left[\frac{\pi}{2}-\theta-\upsilon\right]\tan(\delta)}{\frac{D}{2}\left(1+\frac{S}{D}-\cos\theta\right)(\cot(A-\mu)-\cot(A+\mu))} \tag{32.3}$$

where δ is the feed material's effective internal angle of friction, D is the roll diameter, S is the roll gap, φ_w is the angle of friction between the roll face and the feed material, μ is the coefficient of friction between the powder and roll surface, and A is defined as:

$$A = \frac{1}{2}\left(\theta+\upsilon+\frac{\pi}{2}\right)$$

$$\upsilon = \frac{1}{2}\left[\pi-\sin^{-1}\left(\frac{\sin\varphi_w}{\sin\delta}\right)-\varphi_w\right]$$

The pressure gradient in the nip region is described by:

$$\frac{1}{\sigma}\left(\frac{\partial\sigma}{\partial x}\right)_{\text{nip}} = \frac{K\left[2\cos\theta-1-\frac{S}{D}\right]\tan\theta}{\frac{D}{2}\left(1+\frac{S}{D}-\cos\theta\right)\cos\theta} \tag{32.4}$$

where K is the compressibility constant of the feed material.

A summary of the input parameters required by Johanson's theory, as well as output obtained, is listed in Table 32.5.

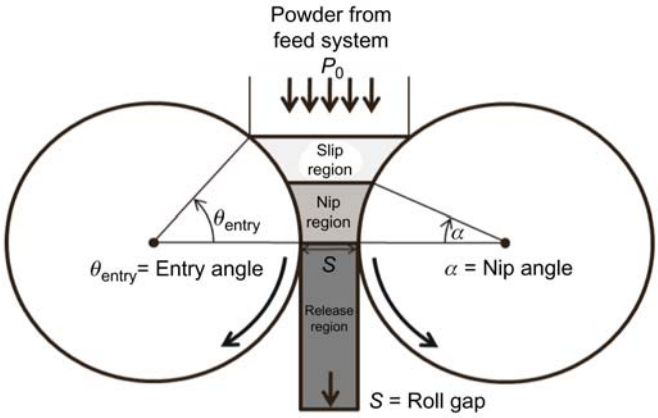

FIGURE 32.28 Schematic of the roller compaction system, where P_0 is the feed pressure, θ_0 is the angle at which P_0 is applied, α is the nip angle, and S is the roll gap.
Slip Region—Powder enters into the area between the rolls by the forward velocity generated by the feeding mechanism (screw feeder pictured in Fig. 32.2). The slip region begins at the point where the rolls begin to impact powder behavior, the boundary of which is defined by the entry angle (θ_{entry}) and the feed pressure (P_0). In this region, the roll surface moves faster than the powder; therefore the powder "slips" on the surface of the roll and compaction forces are very weak. Particle rearrangement in this region is prevalent, facilitating deaeration of the powder. The transition point from the slip region to the subsequent nip region is influenced by a number of factors, including the coefficient of friction between the powder and roll surface, the internal friction coefficient of the powder, design of the roll surface (eg, smooth or knurled), and roll diameter. Powders with low bulk density benefit from longer residence times in the slip region, which can be achieved by lower feed rates and roll speeds, because it enables more time for deaeration and powder densification.
Nip Region—(compaction region) Powder moves at the same speed as the roll surface and is drawn into the roll gap. The boundary between the slip and nip regions is defined as the nip angle (α). Compaction of the powder occurs in the nip region, with the maximum pressure applied just before the point that the roll gap (S) is smallest. Increased residence time in the nip region, due to a large nip angle or a slow roll speed, allows for prolonged application of pressure to the powder. High residence times in the nip region tend to lead to greater particle deformation, breakage, and bond formation, thus producing a compact of greater tensile strength.
Release Region—(extrusion region) Following the nip region, the powder, now in the form of a ribbon, separates from the rolls and transitions into the release region. Elastic recovery and expansion occurs. *Source: Adapted from Rowe JM, et al. Mechanistic insights into the scale-up of the roller compaction process: a practical and dimensionless approach. J Pharm Sci, 2013;102(10):3586–95.*

TABLE 32.5 Input Parameters Required by Johanson's Roller Compaction Model and Output Generated

Input parameter	Experimental measurement technique	Output
MATERIAL PROPERTIES		
Effective angle of internal friction (δ)	Shear test	Normal stress distribution
Wall friction angle (φ_w)	Shear test	Roll force
Compressibility factor of material (K)	Uniaxial compaction	Roll torque
Roll diameter (D) and width (W)	Equipment specification	Nip angle
Feed pressure (P_0)	Roll instrumented with pressure sensors	Ribbon density at $\theta = 0$ degree

At the nip angle, the pressure gradients in the slip and nip regions were proposed to be equal, which allows for the determination of the nip angle by equating Eqs. (32.3) and (32.4). Once the nip angle has been established, the pressure, or stress, profiles of the rolls can be determined if the initial condition is known (P_0). Following a simple power law relationship, the resultant ribbon density (γ) can be related to pressure (σ) as follows:

$$\frac{\sigma_1}{\sigma_2} = \left(\frac{\gamma_1}{\gamma_2}\right)^K \tag{32.5}$$

As such, output from Johanson's model enables an estimation for ribbon density for a specific material/processing condition combination. Alternatively, once the model is established, it can be used to reverse-calculate necessary input parameters to achieve target ribbon densities.

Criticisms of Johanson's theory concern the little attention given to feeding conditions, which are known to impact compaction properties, not accounting for throughput rates (ie, feed screw speed, roll speed), as well as key assumptions regarding the model's stress calculations.[107] However, its simplicity and ability to be solved analytically provides a good basis for modeling efforts, and reasonable agreement between predicted and experimentally measured roll pressures have been demonstrated in studies with MCC (Avicel PH102)[40] and maize powder[55] under limited conditions. In both studies, the predicted results were found to be sensitive to

model input parameters, especially those relating to the feed powder, specifically friction coefficients (δ and φ_w) and feed pressure (P_0).

Difficulties in determining accurate values for the friction coefficients and feed pressure have limited the practical application of Johanson's theory. The shear test is a common experimental method used to determine the friction coefficients required by Johanson's model. However, the accuracy of using such tests has been disputed because the actual frictional behavior of powders (and thus the coefficients) changes significantly over the course of powder densification. Rowe et al. determined the friction coefficient values using a shear tester (Freeman Technology FT4) with varying operating conditions, using consolidation pressures between 9 and 75 kPa. Relatively little change (<20%, ±5 degree) in δ and φ_w values was observed over this range of consolidation pressures.[53] The sensitivity of a modified Johanson-based model was tested over these ranges of δ and φ_w values and was found to have only a minor impact on predicted outputs, which is in agreement with the more exhaustive study conducted by Reynolds et al.[52] using a ring shear tester that examined φ_w changes over a 20 degree^o span and δ changes over a 50 degree span with minimal impact to modeling results. The primary hurdle, however, to the ubiquitous application of Johanson's theory is most likely due to the difficulty in determining P_0 without sophisticated pressure sensor-instrumented rolls (which will be further discussed in this section). P_0 encompasses several important factors, including the extent of material densification in the feeding zone, prior to the slip region, and how efficiently the material passes through the rolls (eg, material jamming prior to the rolls, side leakage). Thus, the value of P_0 significantly impacts modeling results, and has essentially served as a calibration factor that requires adjustment for each feed material-equipment combination. To date, the use of instrumented rolls is the only way to experimentally determine P_0.

The instrumented roll has also been an especially useful tool to address controversies over the proper determination of nip angle. Some have estimated nip angle by determining the angular position at which compaction pressures just begin to increase, but before P_{max} is achieved. Bindhumadhaven et al. estimated nip angle values directly from instrumented roll data through the determination of the intersection of two tangents drawn through the pressure profile, as illustrated in Fig. 32.29a.[40] Feed pressure values were estimated from instrumented roll data. Others have preferred to estimate nip angle using Johanson's model (described in further detail in the next section). For example, instrumented roll data has been used to fit Johanson's stress gradient equations (Eq. (32.3) and (32.4)) to solve for nip angle.[50] Friction angle and compressibility factor parameters (δ, φ_w, K) were determined by multivariate fitting, thus eliminating the uncertainty surrounding the accuracy of offline

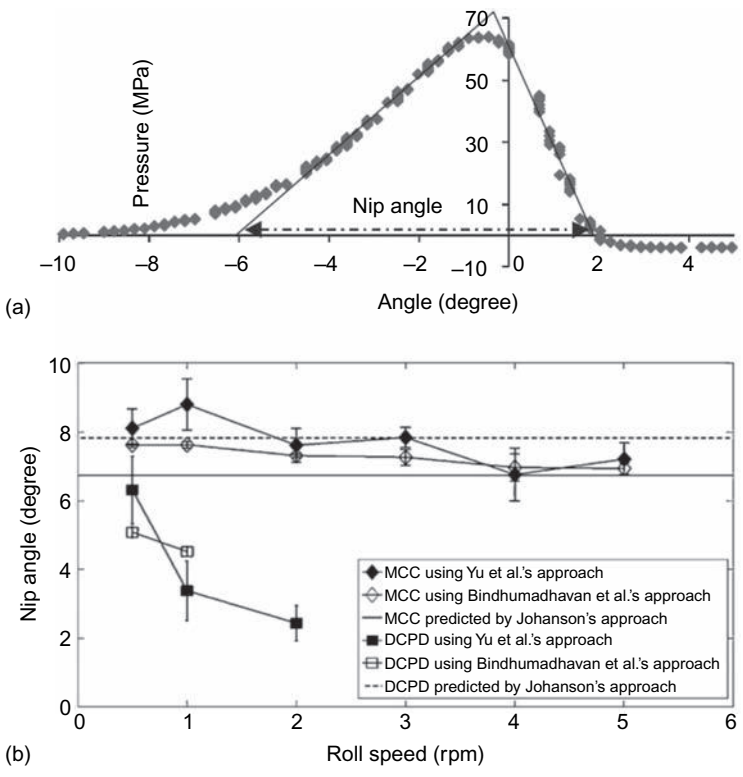

FIGURE 32.29 (a) Nip angle determination from instrumented roll data,[40] (b) variation of nip angle with roll speed for MCC (Avicel PH 102) and DCPD.[50] *Source: ©2005, ©2012, with permission from Elsevier.*

techniques typically used to measure these parameters. Fig. 32.29b compares nip angle determination by multiple approaches.[40,50,51] Predicted nip angle values for plastic-behaving MCC were comparable for all approaches, although Johanson's model clearly did not account for roll speed. However, in the case of DCPD, for which nip angle was more sensitive to roll speed, Johanson's model significantly overestimated nip angle. The discrepancies between Johanson's model and the other two models, especially at high roll speeds, were attributed to inaccuracies in the proper determination of feed pressure values, especially as the feed pressures for poorly flowing materials are often impacted by roll speed and subsequent air entrapment influences. In addition, Johanson's model assumes sufficiently dense packing of powders in the slip zone that facilitates flow of feed powder to the rolls, which is not necessarily representative behavior for poorly flowing materials and may lead to inaccurate estimations of frictional behavior. Bindhumadhaven et al.[40] and Yu et al.'s[50] approaches to nip angle determination again produced comparable results, even for DCPD. Advantages to Yu et al.'s[50] approach is its applicability to low roll speed/small P_{max} regimes, for which Bindhumadhaven et al.'s[40] method is limited, and the elimination of direct measurements of friction angle and compressibility factor parameters, which are intrinsically difficult to measure under appropriate conditions.

Nesarikar et al.[42] has also used instrumented roll data to fit Johanson's roll force equations[51] to estimate nip angles directly from experimental pressure profile data, circumventing the need for input feed pressure values. One of the key features of this model was that wall friction angle values, φ_w, were also estimated indirectly from instrumented roll data, enabling a more accurate representation of frictional behavior between the powder and rolls. Johanson's model, used in conjunction with optimal normal stress profiles for a placebo calibration data set, was found to successfully predict ribbon densities of several active formulations. In addition, by matching the normal stress profiles across two scales of operation, the model was shown to adequately predict scale-up parameters from a pilot (roll diameter: 120 mm, roll width 40 mm) to a commercial-scale (roll diameter: 200 mm, roll width 75 mm) roller compactor. In a separate study, Nesarikar et al.[57] further leveraged instrumented roll data to develop a statistical model, built upon normal stress data collected using instrumented roll technology, that predicted ribbon densities for roller compaction processes. By correlating normal stress data of new materials to that of a previously measured calibration set (based on placebo data), an expression for ribbon density as a function of P_{max} and roll gap was developed. Even though the model was built using placebo data, predicted ribbon densities for placebo and active formulations (up to 17% drug load) compared well with experimentally measured density values. The model was found to be sensitive to varying formulation (lubrication, active drug loadings) and process (roll speed, screw speed, vacuum level, and associated deaeration) conditions. When using statistical models, caution should be taken if using the model outside of the conditions from which the model was built. In this study by Nesarikar et al., %RSD of the prediction increased with increasing drug load.

32.3.2 Modified approaches to Johanson's theory

In 2010, Reynolds et al. presented a modified approach to Johanson's theory that incorporated additional processing parameters to account for material behavior, such as potential precompression of the powder in the feed and slip region, and material throughput during roller compaction.[52] The preconsolidation relative density, γ_0, may be obtained using the following relationship, generated from a material's compaction profile:

$$\log(\gamma_R) = \frac{1}{K}\log(\sigma) + \log(\gamma_0) \tag{32.6}$$

where γ_R is the relative density of the ribbon, K is the compressibility factor, and σ is the pressure. This preconsolidation factor provides additional information regarding a material's compressibility, specifically under low amounts of compaction pressure.

An additional modification to Johanson's theory includes the incorporation of the feed screw speed, N_s, as many roller compactor designs utilize a screw conveyor to transport the material from the feed hopper to the rolls. Typically, a roller compaction operation maintains either a constant roll gap (gap-control) or a constant feed screw speed (screw-control), depending on the formulation. Johanson's original theory only accounts for roll gap. In order to incorporate N_s into Johanson's theory, a mass balance was set up around the nip region, equating the material being fed into the rolls to that exiting the rolls as a ribbon, assuming a steady-state condition with negligible side-seal leakage. A depiction of the mass balance around the nip region is illustrated in Fig. 32.30. The mass flow rate of material entering the rolls is assumed to be proportional to N_s and the material exiting the rolls is a function of the roll speed (N_R) and the solid fraction of the ribbons, γ_R. Based on the mass balance around the nip region, S may be related to N_s and N_R using the following expression:

$$\frac{S}{D} = \frac{c_s}{\pi\rho_{true}\gamma_R D^2 W}\frac{N_S}{N_R} \tag{32.7}$$

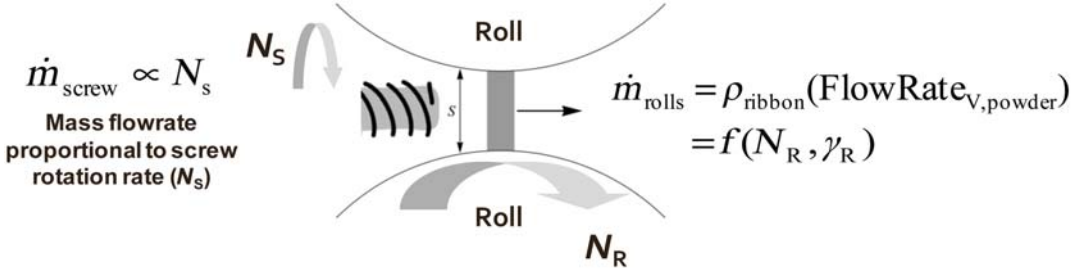

FIGURE 32.30 Schematic of the compaction zone of a roller compactor, where a mass balance is applied to the nip region of the roller compaction process.[53] *Source: ©2013 by John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.*

where c_s is the screw speed constant, ρ_{true} is the true density of the powder, and W is the roll width. The factor c_s is determined using a set of calibration roller compaction experiments and is used to infer how efficiently the feed screw transfers material into the rolls. This expression for S/D, presented in terms of N_S/N_R, may then be substituted into the equations of Johanson's theory (Eqs. (32.3)–(32.4)) to yield the following expression for the ribbon solid fraction, γ_R

$$\gamma_R = \gamma_0(2R_f)^{1/K}\left\{ WD\int_{\theta=0}^{\theta=\alpha} \times\left[\frac{c_S N_S}{\pi\rho_{true}\gamma_R D^2 W N_R\left(1+\frac{c_S N_S}{\pi\rho_{true}\gamma_R D^2 W N_R}-\cos\theta\right)\cos\theta}\right]^K \cos\theta\partial\theta\right\}^{-1/K} \tag{32.8}$$

where R_f is the roll separating force originally defined by Johanson.[51] The incorporation of γ_0 into the calculation of γ_R was achieved by correlating the final ribbon density to the material's preconsolidated state through the power-law relationship presented by Johanson's theory in Eq. (32.5).

$$P_{max} = \left(\frac{\gamma_R}{\gamma_0}\right)^K \tag{32.9}$$

Reynolds et al.[52] demonstrated good agreement between predicted and experimentally measured ribbon densities across two different scales of roller compactor (25- and 40-mm roll widths), while adjusting common operating factors such as N_S, N_R, S, and hydraulic roll pressure. A key advantage of the approach by Reynolds et al.[52] is the limited amount of material required to build the model, about 1–2 kg, which is used to determine the c_s value. A summary of the input parameters required by Reynolds et al., which are in addition to those required by Johanson's theory (except for P_0), is listed in Table 32.6. The material assessed in this work was an active blend with a drug load greater than 30% wt with primary excipients being MCC and DCPD.

TABLE 32.6 Input Parameters Required by Reynolds et al. That Are Additional to Those Required by Johanson's Theory, Which Are Listed in Table 32.5[52]

Input parameter	Measurement technique
Preconsolidation relative density (γ_0)	Uniaxial compaction (same from K determination)
True density (ρ_{true})	Helium pycnometry
Screw speed constant (c_s)	4–5 roller compaction batches, varying N_s/N_R, and envelope density analyzer to measure ribbon densities

Rowe et al.[53] elaborated upon the work reported by Reynolds et al.[52] to develop a roller compaction model more accessible to formulators and to present a dimensionless approach to modeling the roller compaction process. As mentioned previously, one of the primary deterrents to the universal application of Johanson's model is the difficulty in accurately determining P_0 values without the use of specialized equipment.[51] Reynolds et al.[52] did not discuss the determination of P_0 because roll force values (R_f) were obtained using an experimentally determined calibration factor to relate hydraulic roll pressure to R_f. This calibration factor is not always known, drifts over the lifetime of the equipment, and does not translate between roller compactor units. Rowe et al.[53] proposed an iterative algorithm to determine P_0, for which a series of equations are solved to determine the P_0 value that satisfies both Johanson's theory[51] and Reynolds's modifications,[52] thus eliminating the need to experimentally determine P_0 values. Like the Reynolds's method,[52] the proposed method requires only standard, routinely measured parameters as inputs and minimal amounts of material (~1–2 kg) to establish critical relationships between material input and process parameters. Good correlations between

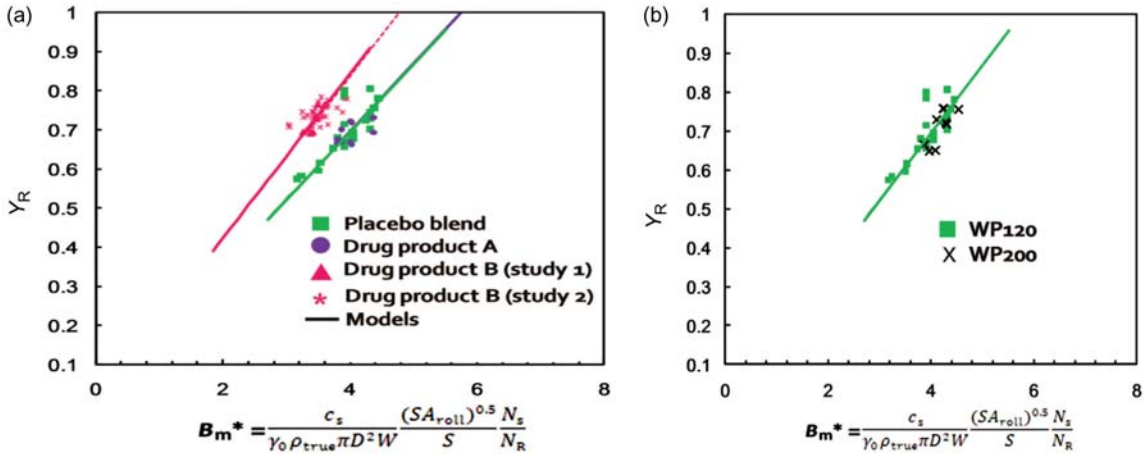

FIGURE 32.31 Solid fractions (experimental data = points, model = line) of ribbons prepared by roller compaction, as a function of a modified Bingham number, B_m^*: (a) ribbons manufactured using an Alexanderwerk WP120 roller compactor, (b) comparison of placebo ribbons prepared on an Alexanderwerk WP120 and WP200.[53] *Source: ©2013 by John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.*

predicted and experimental results were demonstrated for placebo and active blends (up to 22% wt drug load).

In addition to facilitating the mainstream use of Johanson's model, a dimensionless relationship between key process parameters and final compact properties was elucidated to improve the mechanistic understanding of the roller compaction process. This dimensionless parameter, referred to as the modified-Bingham number (B_m^*), relates yield-to-viscous stresses during roller compaction and delineates how operating conditions impact ribbon properties. Yield and shear stresses essentially drive the roller compaction process. Too large of a yield stress can adversely impact the efficiency of material flow through the rolls and will produce a very hard, brittle ribbon that may not recompress well into tablets. Too large of a viscous stress indicates that the material is flowing well through the rolls, but experiencing too little powder densification, producing very soft ribbons that result in poor granules. B_m^* was derived from the fundamental definition of shear stress, and is described as

$$B_m^* = \frac{c_s}{\gamma_0 \rho_{true} \pi D^2 W} \frac{(SA_{roll})^{0.5}}{S} \frac{N_s}{N_R} \tag{32.10}$$

where, c_s is the screw speed constant, SA_{roll} is the surface area of the roll, N_s is feed screw speed, γ_0 is the preconsolidation factor, ρ_{true} is the true density of the powder, D is the roll diameter, W is the roll width, S is the roll gap, and N_R is the roll speed. A linear relationship between γ_R and B_m^* was observed for all of the materials studied, demonstrating the significant correlation between the dimensionless parameter relating yield and viscous stresses to the roller compactor product (Fig. 32.31). The study showed that a constant ratio of yield-to-viscous stresses, as indicated by a constant B_m^*, enabled the manufacture of products with consistent attributes, even at two scales of operation. B_m^* was shown to provide guidance toward determining the design space for formulation development, as well as to facilitate scale-up development.

As mentioned in previous sections, permeating air in the powder bed is known to have a negative impact on the roller compaction process, as the feed powder can be destabilized by the flow of escaping air. Esnault et al.[92] proposed a model to capture these effects, using Johanson's theory to capture solid stress and deformation and Darcy's law for fluid transport. The Kozeny–Carman law was used to describe permeability as a function of porosity and particle size. For this model, the effect of air pressure on the solid was considered to be negligible between rolls and airflow through the gap was ignored. The model predictions were not validated experimentally.

32.3.2.1 Johanson's model comparisons with experimental data (instrumented roll)

A few studies have attempted to quantify Johanson's model predictions against experimental data, which has been enabled by the use of instrumented roll technology. Yusof et al. demonstrated reasonable agreement between measured roll force and roll torque values (using instrumented roll data) and those predicted by Johanson's model for the roller compaction of maize flour as long as roll gap was less than 0.15 mm. Discrepancies between experimental and predicted results for larger roll gaps were attributed to the high sensitivity of Johanson's model to input parameters, especially regarding accurate characterization of frictional behavior. Bindhumadhaven

et al.[40] found that while the Johanson model predicted P_{max} value well for low roll speeds, discrepancies surfaced when roller compaction was conducted at higher roll speeds (Fig. 32.32a). The inconsistencies between experimental and predicted values at higher roll speeds were attributed to the inability of the model to capture the decreasing nip pressures and greater entrainment of air at higher roll speeds. Studies have also shown weaknesses in Johanson's model when material behaviors were not ideal. In Yu et al.,[50] Johanson's theory was shown to overestimate nip angles for DCPD and DCPC-MCC mixtures with <50% MCC due to poor flowability of the feed powders (Fig. 32.32b). To mitigate these gaps in Johanson's theory, instrumented roll data may be used to fit input parameters to Johanson's equations, thus using experimental roller compaction runs to empirically determine the appropriate values for input parameters (ie, P_0 and friction coefficients). Once the appropriate input values have been defined, Johanson's model can be used to describe future roller compaction behavior of the material. Excellent correlation between experimental and predicted results has been achieved by this method.[42,57] In fact, by fitting roller compaction data to Johanson's equation using experimentally determined P_0 values, the pressure profiles of the roller compaction process are elucidated and have been shown to facilitate scale-up activities.[42,57]

Curves indicate simulated results, as determined from Johanson's theory.[40] (b) Comparison of measured and predicted nip angles for MCC-DCPD mixtures, as a function of MCC content.[50] *Source: ©2005, ©2012, with permission from Elsevier.*

32.3.3 Slab analysis

One of the most fundamental approaches used to model the roller compaction process is the slab method. The slab method considers equilibrium force and mass balance equations on one-dimensional elements, or "slabs," that represent deforming powder, providing information about two principal stresses during compaction, as opposed to Johanson's model which only provides the mean stress. In addition, it allows users to incorporate complex powder qualities to the model, such as cohesion and global friction between particles, making it an attractive modeling option compared with Johanson's approach.

In the slab method, the compaction zone is segmented into differentially small slices, or slabs, and a one-dimensional analysis of the stresses acting on each of these slabs is used to simulate a single element passing through the rolls of a roller compactor (Fig. 32.33). The shape of the slab is bounded by the roll surfaces and, due to the small width (dx) of the slab relative to its height (dh), the boundaries may be represented by straight lines tangent to the roll's contours. Inertial forces acting on the material are considered to be negligible and thus, only the normal and shear stresses acting on the four sides of the trapezoidal slab are assessed. Shear stresses in the system originate from the frictional forces existing between the material and roll surface and the dissection of these stresses into their direct and tangential components enable the calculation of the forces acting on the slab. Equilibration of the forces acting on the roll (along the x direction) can be described by the following equation, which is referred to as the von Karman equation of rolling, and is independent of material properties[108]:

$$\frac{\partial(\sigma_x h)}{\partial\theta} + R(P\sin\theta \pm \tau\cos\theta) = 0 \qquad (32.11)$$

where R is the roll radius, h is the thickness, or height, of the slab, and "+" is applied when $\theta > \theta_{neutral}$ and "−" is applied when $\theta < \theta_{neutral}$. The neutral angle lies between the nip angle and 0 degree, which is the point at which the direction of the frictional force on the roll reverses direction. For instance, when $\theta > \theta_{neutral}$, frictional forces direct powder toward the gap. When $\theta > \theta_{neutral}$, the frictional forces direct powder away from the gap.

The mass conservation and momentum relationships are linked to one another using empirically determined stress-strain constitutive relationships, resulting in a system of equations that describes the normal roll

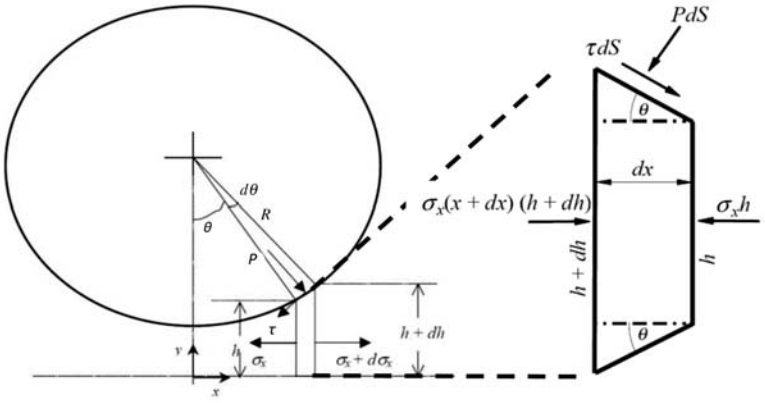

FIGURE 32.33 Force balance on a slab element during roller compaction and free-body diagram of slab. The stresses acting on the slab are described such that the roll pressure, P, and roll shear stress τ, act at the roll surface, which is defined by the angular increment, $d\theta$, and the slab surface in contact with the roll, dS. *Source: Adapted from Cunninghham JC. Experimental studies and modeling of the roller compaction of pharmaceutical powders. In:* Materials engineering. *Philadelphia, PA: Drexel University; 2005. p. 267. and Balicki M. Numerical methods for predicting roll press powder compaction parameters. Albi: Ecole Des mines D'Albi-Carmaux; 2003.*[109]

stress distributions and ribbon densities throughout the different positions in the roller compaction process. The primary assumptions applied in slab analysis are listed in Table 32.7.[35] Slab analysis has been commonly used in the metals industry to study rolling and extrusion for decades, making it an obvious avenue to pursue for roller compaction due to the similar nature of the processes.[88,108] In slab analysis, a plane stress and the existence of a slip region is assumed. However, the point at which different models diverge is the selection of the yield criterion, which defines the transition of elastic to plastic deformation in the material. It is also important to emphasize that models based on slab analysis require the nip angle as input, which may be experimentally determined or estimated using Johanson's model, and the powder density at the nip angle. Similar to Johanson's model, slab model results enable the prediction of ribbon densities for a set of input conditions (ie, material and process conditions), as well as provide a means to reverse-calculate necessary input conditions to achieve a target output (ie, ribbon density).

TABLE 32.7 Assumptions for Slab Method Models for Roller Compaction

Slab method assumptions
One-dimensional variation in field quantities (eg, stress and strain constant through slab thickness)
Deformation is considered plane strain (ie, strain in the roll width direction is zero)
Homogeneous deformation state exists in the slab element
Constant friction coefficient following Coulomb's friction law
Constant circular arc of contact
Negligible elastic deformation
Constitutive model is porous plasticity
Body forces can be ignored (eg, gravity)
Inertial effects are ignored

Katashinskii[93] proposed a yield strength, which was met by the difference of the principle stresses. Lee and Schwartz[96] introduced the Coulombian criterion and assumed that the yield stress and the cohesion in the Coulombian criterion were dependent on the state of material compaction, and thus, a function of the rolling angle. The slip region of the strip element was proposed to impart tangential forces to both rollers, which were set to be equal to the coefficient of the external friction multiplied by the normal force acting on the strip, enabling completion of the force balance. Katashinskii and Shtern[94,95] modified Katashinskii's[93] original approach to develop an equilibrium equation based on roll friction, normal stress acting in the rolling direction, and the roll pressure to describe the stress–strain behavior of a slab element experiencing shear deformation and densification. The continuity equation was used to account for powder compressibility. Roll friction was based on Coulomb's law and allowed to vary with rolling angle and assumed to be zero at the neutral angle; although it should be noted that there is no physical justification for such an assumption.[65] Input parameters such as initial feed stress acting in the rolling direction, rolling angle, neutral angle, coefficient of friction, initial relative density of the powder, gap and roll diameter are required from the user. Musikuin[97] developed a model for roller compaction that mirrored an approach commonly used for cold rolling of continuous metals, in which particle deformation was assumed to occur only in the nip

region. It was assumed that material "slips" at all angular positions except the neutral angle, θ_0, and once it entered the nip region, the particulate material behaved as a porous solid. The roll shear stress was defined by the limiting (slipping) condition and adhered to Coulomb's law. Musikuin then employed a simple, constitutive model for the material based on the difference between maximum and minimum stresses, which was the primary modification to similar models used for continuous metals. The principal stress was assumed to be zero at the bite angle and at the centerline of the rolls. Input parameters supplied to the model include the tapped density, which was the assumed material density at the bite angle, and the material density at the centerline of the rolls (ie, ribbon density). The shape of the roll pressure profile resulted in a combination of monotonic concave curves that met at sharp points at the neutral position. In order for the model to match maximum roll pressure data reported in literature, additional manipulations to model parameters were necessary. Thus, the primary limitations to Musikuin's model were the neglect of tangential stresses, assumptions that slippage only occurred at the roll surface, leading to a pressure profile shape that did not match that of experimentally measured profiles, and its reliance on manipulation of multiple model parameters to match experimental data. Dec et al.[65,99,100] introduced a slab model for roller compaction that utilized a yield criterion for metal powders that was originally proposed by Kuhn and Downey,[4] which is based on the relationship between Poisson's ratio and density. The nip angle value and the position of the neutral plane were determined from experimental data. The density profile for each compaction step was determined from compression test data for a corresponding mean stress. The predictive capabilities of this model were severely limited due to its heavy reliance on experimentally measured values as model inputs and the forced matching with the output density. More recently, Schonert et al.[43] applied the slab method to roller compaction by utilizing a normal-to-shear stress relation (ie, transmission coefficient) in a powder as a substitute for a yield criterion by representing the relative amount of pressure transmitted from σ_x to σ_y.

Shima and Yamada pursued an alternate route that incorporated principles applied in the mechanics of powder compaction and utilized an energy-based continuum model, in which the upper bound theorem was used to analyze the roller compaction of metal powders. The upper bound theorem is based on determining a probable velocity field for the material that minimizes energy dissipation attributed to both powder densification and friction at the roll/powder interface. The authors used a yield criterion that was originally introduced by Shima and Oyane,[87,98] in which a constant friction law dictated that frictional shear stress was constant and independent of normal stress. Initial assumptions for the values of gripping angle and velocity field were needed for the model input and then these values were refined through an iterative process, in which the rate of energy dissipation was minimized and the continuity equation was satisfied. The resultant density and strain rate distributions for the slab could then be calculated and used to determine stress distributions. Primary findings from this model were: (1) powder/roll frictional conditions had minimal impact on density distributions and, (2) gripping angle values significantly affected density distributions. Within this work, the authors presented seven case studies and identified rather significant discrepancies in several of the cases, with the specific causes for these discrepancies not discussed.

Numerous approaches have been used to apply slab analysis to the roller compaction operation with varying degrees of success, while demonstrating advantages and disadvantages of each approach. However, a primary drawback for all of the models built upon slab analysis is their dependence on experimental inputs, including the positions of the nip and neutral angles, as well as initial feed stresses, and thus limiting their predictive capabilities. As mentioned previously, these values are difficult to obtain experimentally, requiring specialized instrumented equipment. Such obstacles produce an additional limitation to the widespread use of the slab method.

32.3.3.1 Slab model comparisons with experimental data (instrumented roll)

Patel et al.[49] predicted MCC pressure distributions in a roller compaction process using a slab model, where nip angle was estimated using Johanson's theory. The model, which used input parameters generated from uniaxial compaction data, underestimated compaction pressure values by a factor of 1.5–2.5, although the predicted trends matched experimental data (Fig. 32.34). The discrepancy between the predicted and experimental results was attributed to (1) using an instrumented roll with a single load cell in the center of the roll, which did not account for pressure variation across the roll width, and it has been shown that roller compaction of MCC tends to produce nonhomogeneous pressure distribution profiles where pressures at the center of the ribbon are higher than those at the edges.[35,41,64,102] Therefore experimental pressure readings taken from the center of the roll would be expected to be higher than that predicted by a model that assumes uniform distribution of stresses across the ribbon width; (2) Nonuniform flow of powder in the nip region and through the rolls, yielding shear forces that do not occur during uniaxial compression; (3) The neutral angle, and maximum pressure, was assumed to be coincident with

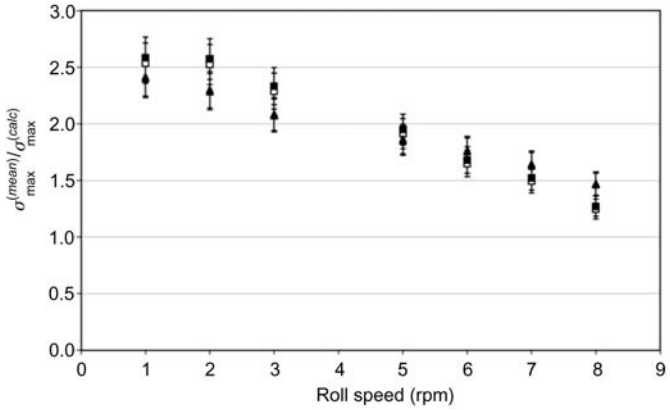

FIGURE 32.34 Ratio of the maximum measured pressure to predicted pressures, as a function of roll speed at roll gaps of □ 0.9 mm and ■ 1.6 mm.[49] *Source: ©2010, with permission from Elsevier.*

the minimum roll gap in Johanson's model, however, maximum pressure is known to occur before the centerline between the rolls (i.e., the minimum roll gap).[35] Overall, Patel et al.[49] found uniaxial compaction to provide a suitable first-order representation for roller compaction operations, although the authors warn that the model cannot accurately simulate nonhomogenous ribbon properties and shear effects that are present during real-life operation.

32.3.4 Finite element method

FEM is a numerical technique used to approximate the solutions of complex equations through the subdivision of a whole problem domain into simpler parts, or finite elements. Solutions are achieved by minimizing associated error functions for the collection of elements. To better visualize the concept of FEM, one can see how the connection of many tiny lines can be used to approximate a circle. FEM incorporates methods for connecting many simple element equations over many small sub-domains, the finite elements, to approximate a more complex equation over a larger domain.[110] FEM is an ideal resource for problems with complicated geometries, loadings, and complex material properties and has been found to be well-suited for systems of dense solids, where the material behaves in an elastic or elasto-plastic manner.[111] With respect to the roller compaction process, the deforming powder region is divided into a number of continuously distributed elements, or meshes. The mechanisms driving motion and deformation (ie, strain) of each of the elements are computed numerically according to a user-defined stress-strain constitutive relationship. The use of FEM to model tablet compaction had been reported in several studies, and thus many of the concepts that were applied in these previous works were translated to

TABLE 32.8 Assumptions for FEM-Based Models for Roller Compaction

FEM roller compaction model assumptions
Effect of interstitial air is ignored
Roll deformation due to roll pressure is ignored
Coulomb friction is the dominant frictional interaction at the powder/roll interface
Gravity and inertia are ignored
Screw feeder effect is approximated by stress at the entry angle

modeling of the roller compaction process.[18,112–114] Typical assumptions of FEM-based models for roller compaction are listed in Table 32.8.

FEM-based roller compaction models two-dimensional (2D)[35,41,64,65,89,101] and three-dimensional (3D)[64,102,103]) have enabled further insight into the stress and displacement fields that are typically generated during the unit operation, compared with Johanson's- and slab-based models, because they can account for through-the-thickness variation, more accurate representation of material behavior (typically using the Drucker–Prager/cap (DP/C) model[18,64,112–114]), frictional considerations, and feeder system effects. While friction for the roll/material is typically assumed to follow Coulomb's friction law with a constant friction coefficient, specific frictional considerations (ie, slip versus stick) can be directly evaluated in order to satisfy both equilibrium and compatibility and are not restricted by an upper bound argument. In addition, the effect of the feed system can be studied by varying the feed stress (constant[41,64,65,89] and oscillatory[35,64]) applied to the mesh in the rolling direction at the in-flow boundary. Early simulation attempts observed severe mesh distortions when implicit Lagrangian simulations were utilized.[35] Thus, the Arbitrary Lagrangian-Eulerian (ALE) method has since been used for its adaptive meshing capabilities. As an example, a schematic of a mesh designed for roller compaction analysis is shown in Fig. 32.35.[64] The mass and densities of the roll and material mesh were optimized to minimize both the inertial effects for the quasi-static deformation problem and computational time.

FEM simulations have been found to accurately reflect trends that had been previously observed experimentally, and thus confirm well-known empirical correlations. Typical simulation outputs include roll pressure, roll torque, roll shear stress, nip and neutral angles, and densification values. As expected, maximum roll pressures and exit densities were found to be significantly impacted by both feed stress and frictional coefficient values. Roll force, roll torque, and consequently, exit densities, all increased with increasing feed stress and frictional coefficients. However, in addition to verifying

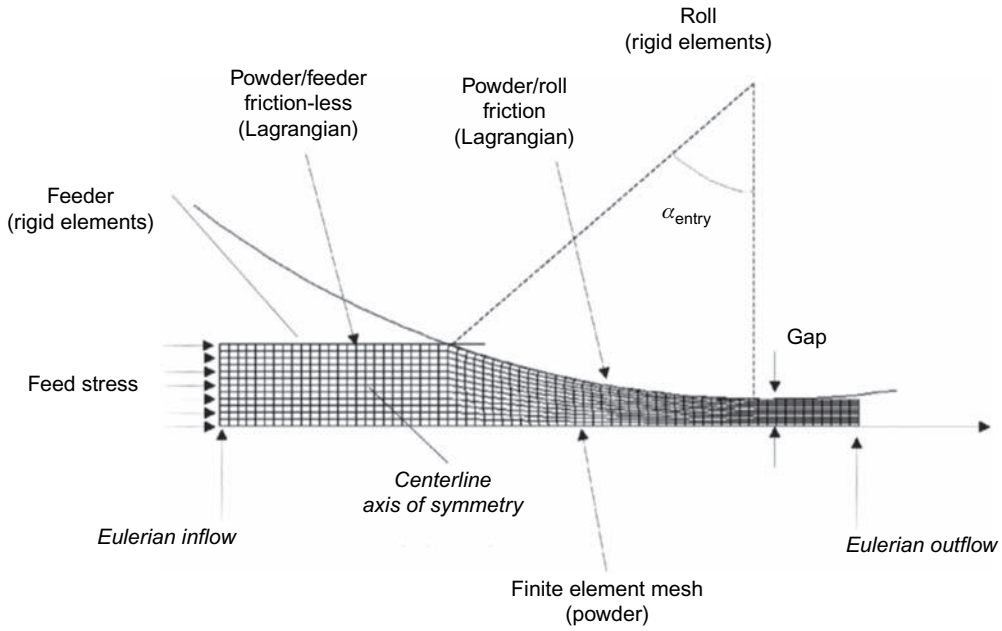

FIGURE 32.35 Schematic of finite element mesh for roller compaction with notation of axis of symmetry, Eulerian in-flow and out-flow, Lagrangian roll and feeder boundaries, and rigid bodies for the roll and feeder.[64] *Source: ©2010, with permission from Elsevier.*

known empirical correlations, FEM models have elucidated higher level principles regarding roller compaction mechanisms. For instance, the existence of slip and nip regions in the compaction zone was verified, as delineated by a marked increase in roll pressure and shear for rolling angles near the minimum roll separation. In addition, maximum pressures were predicted to occur 0.5–1.1 degree before the centerline between the rolls (0 degree),[64,65] in line with experimental observations.[35] FEM simulations also highlighted the probability of nonuniform velocity fields across the ribbon width, a result that the 1D-Johanson model cannot capture.[64,102] These nonuniform velocity fields were correlated back to nonconstant feed conditions, as well as potential frictional effects. To further probe this finding, the application of oscillating feed stress conditions (a common occurrence in screw feeders) has been shown to produce periodic variations in roll pressures and exit densities,[64] in line with experimental observations.[14,41] Simulations have also indicated that powders possessing larger friction coefficients, for a given feed stress, yield higher maximum roll pressures and maximum relative densities. Such findings can be physically explained because powders possessing higher friction coefficients grip the powder sooner in the roller compaction operation and thus undergo densification sooner, although there appears to be a limit to the impact of the friction coefficient on roll pressure, above which its effect becomes limited.[64]

To better understand the role of frictional effects on roller compacted products, Cunningham et al.[64] employed a 3D model to account for the presence of side seals on roller compaction units. In roller compaction operations, side seals are used to minimize leaking of powder to the roll edges in an attempt to reduce the amount of ungranulated material (ie, fines) in the final granulation. The side seals were found to induce frictional effects that resulted in lower roll pressure and densities near the edges, compared with the ribbon center. Material selection that increased side seal friction resulted in higher density variations throughout the transverse direction of the compact, in agreement with experimental observations. The model was also used to assess the impact of variable in-flow of material (another common experimental observation for screw feeders) along the roll width on roll pressure. Simulation results showed that both the side seal friction and nonuniform feeding to the rolls contribute to nonuniformity in roll pressure and density across the roll width and provided rationale behind experimental observations.

While qualitative comparisons have been made between FEM simulation results and experimental observations, few studies have quantitatively assessed the accuracy of FEM predictions. Cunningham[35] reported good correlations between predicted and experimentally determined nip angles for an MCC system. However, predicted ribbon densities, as a function of roll pressure, were found to overestimate experimental values by 15–20%. These discrepancies were attributed primarily to post-gap expansion of the MCC, which was not accurately captured by the simulation. Determination of typical expansion values for MCC and accounting for the

excessive expansion accordingly brought the predicted values much closer to the experimental values. Muliadi et al. went on to quantitatively compare the results of a 3D FEM simulation with experimental data.[103] Roller compaction experiments were performed using an air-powered piston feeder, as opposed to a more traditional screw feeder, in an attempt to apply a uniform feed stress to the powder. MCC was also used as the representative compound for this study. Similar modeling conditions and parameters to those used by Cunningham et al.[64] and Michrafy et al.[102] were applied (ie, ALE scheme, modified DP/C model for the material stress-strain constitutive behavior, and Coulomb friction to approximate powder/roll interactions). In this case, however, the inlet stress location was determined by monitoring the point at which the feed piston stroke reached its maximum. The roll gap corresponding to the maximum piston stroke was established using a laser distance sensor. Thus, no parameter-fitting was used in this method, making this FEM-based model truly predictive. By meticulously ensuring that the input parameters to the simulation were as accurate as possible, excellent correlations between the simulation and experimental results were achieved. Fig. 32.36 demonstrates the accuracy of predicted ribbon densities, as a function of ribbon position, to experimentally measured values for multiple-feed stress conditions. These results are also in alignment with predicted trends reported by the previously discussed 3D FEM models, demonstrating that ribbon density is highest in the middle of the ribbon and lower at the edges.[64,102] However, it should be noted that the sensitivity of the FEM results to the friction coefficient was highlighted as one of the primary weaknesses of FEM models. FEM simulations rely heavily on the user's experimental input. Therefore, appropriate parameters for feeding conditions and friction models (because processing energy is transmitted throughout the roll-material contact) and powder properties are imperative if these simulations are to be truly predictive.[101] An additional drawback to the proliferation of these FEM-based models is the requirement of expensive computer resources and expertise. However, once expertise in this technique is established, FEM-based analysis has demonstrated a promising ability to provide mechanistic insight into rolling compaction, and as a result, enable improvements in process and equipment optimization that may outweigh the costs of initial investment.

32.3.4.1 Comparison of FEM to Johanson's theory

Given the widespread use of Johanson's theory to model the roller compaction process, Muliadi et al.[89] quantitatively compared the results obtained from Johanson's theory with those simulated by a 2D FEM approach. MCC was selected as the model compound. Predicted nip angle, maximum normal stress, and maximum relative density values were compared for the two models. The predicted impact of select input values, such as roll powder friction coefficient and inlet normal stress (feed stress), on the model output is shown in Fig. 32.37. Nip angle predictions by both approaches followed similar trends and were within ~25% of each other. However, the relative densities and maximum normal stresses predicted by Johanson's model were consistently higher than those predicted by FEM. Interestingly, Johanson's theory predicted relative density values greater than 1 for all of the conditions assessed in this study. These physically unattainable values were attributed to the fact that Johanson's theory, as a 1D model, was unable to capture the 2D velocity gradient experienced by the powder as it moved through the rolls. This 2D velocity field is also believed to enable some portions of the material to remain in a condition of "slip" even in the nip region. The inability

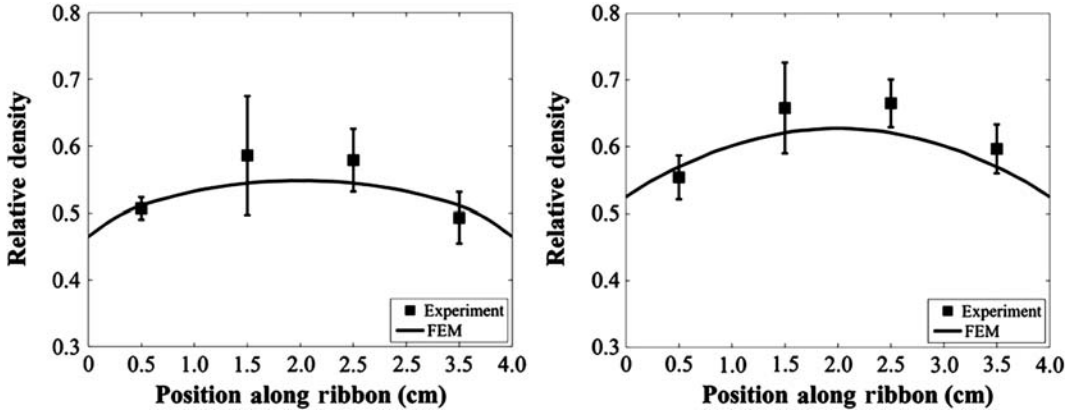

FIGURE 32.36 Comparison of FEM-predicted and experimentally measured ribbon density distributions for a feed stress of 132 kPa. Left and right plots correspond to a hydraulic roll force of 5.5 and 9.2 kN, respectively. A ribbon position of zero is farthest away from the compactor roll shaft support and a ribbon position of 4 cm is closest.[103] *Source: ©2013, with permission from Elsevier.*

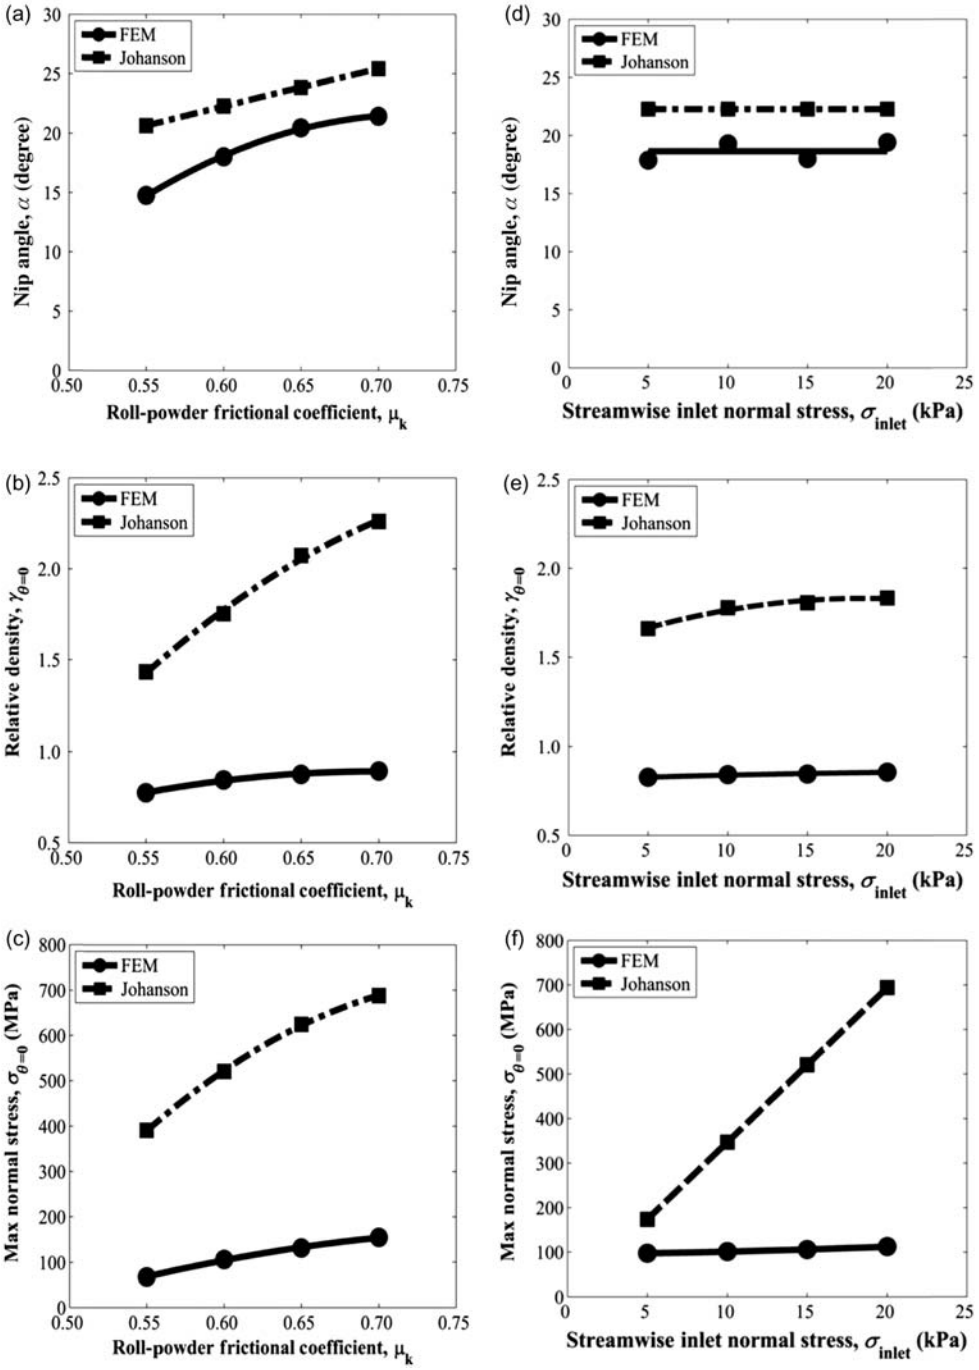

FIGURE 32.37 FEM-predicted (a) nip angle, (b) maximum relative density, and (c) maximum normal stress values as a function of roll-powder friction coefficient. FEM-predicted (d) nip angle, (e) maximum relative density, and (f) maximum normal stress values as a function of inlet normal stress. Additional parameters were σ_{inlet}, roll gap, roll diameter, and inlet height were 15 kPa, 2, 120, and 15 mm, respectively.[89] *Source: ©2012, with permission from Elsevier.*

of Johanson's theory to capture the 2D velocity gradient led to an overprediction of mass flow rate of material into the nip region. Such a phenomenon would be exaggerated for highly compactable materials, such as MCC. In terms of maximum normal stress, Johanson's theory predicted stresses larger than those by FEM. However, agreement between the two approaches improved for powders that were more compressible, possessed smaller effective friction angles, larger roll powder friction coefficients, and lower feed stresses.

DEM modeling of the roller compaction process will not be discussed in this chapter because the few

attempts that have been reported have not been as successful as FEM models.[111] Odagi et al.[91] modeled the roller compaction operation using DEM, but reported pressures in the nip region to be several orders of magnitude smaller than experimentally obtained values. In general, it appears that a continuum approach, as opposed to a discrete approach, may be better suited to roller compaction conditions, especially where large pressures are generated, such as in the nip region.

32.3.5 Neural networks and other artificial intelligence approaches

Pharmaceutical applications of neural networks, a form of artificial intelligence, have included direct compression of tablets and fluid bed granulation, in addition to roller compaction. These artificial intelligence approaches center on establishing cause and effect relationships within data sets and then using those relationships in "reverse" order to determine the process conditions necessary to achieve user-specified outputs. Such techniques are useful when gaps exist in experimental measurements of important process parameters or when complexities in both physical process geometry and mechanical behavior of powders impede process modeling efforts. However, it should be noted that these results are not founded upon physical or mechanistic principles of the system, but empirical correlations gleaned from the provided data sets. For this reason, the largest disadvantage of these models is their limited predictive capabilities to the training set conditions. Predictions for conditions outside of the training sets must be approached with caution.

For roller compaction systems, neural net models have been used to predict how process parameters[39] and formulation selection[104] can impact downstream operations. For instance, roller-compacted ribbons possessing higher densities tend to yield stronger, harder granules, with lower granule friability. While strong granules are desirable for their attractive flow properties, excessively strong granules may not readily disintegrate and may not compact well, adversely affecting dissolution and tablet strength, respectively. Optimization of formulation and process input variables, with respect to granule friability, tablet strength, and disintegration, is not trivial because these target values move in opposite directions of each other. Such complicated relationships would be difficult to balance using a mechanistic model, thus making these scenarios ideal for a neural network. Inghelbrecht et al.[39] used a neural net model to accurately predict granule friability and particle size of maize starch based on user-specified processing conditions (feed screw speed, roll pressure, and roll speed). Turkoglu et al.[104] utilized a neural network to guide formulation decisions for an acetaminophen tablet, for which binder grade and concentration, extra-granular material consideration, and number of roller compaction passes were optimized to yield granules of acceptable friability and tablets possessing adequate strength and disintegration properties. More recently, Mansa et al.[105] demonstrated the ability of a commercial software package that utilized neural network, genetic algorithms, and fuzzy logic to successfully predict ribbon densities from user-specified process conditions (roll speed, roll gap, and hydraulic roll pressure) and formulation considerations (material type, particle size distribution, powder densities, compressibility, tensile strength, friction angles, and flow function). The true value of the model, however, was demonstrated not in its ability to predict process outputs from user-specified inputs, but the ability of the model to outline the necessary inputs (process and formulation conditions) to achieved target outputs (ribbon density). Model-predicted conditions were successfully verified experimentally.

32.4 APPROACHES TO DEVELOPING A ROLLER COMPACTION PROCESS

A suggested approach to developing a robust roller compaction process, in accordance with QbD principles, is summarized in Fig. 32.38 and described in further detail below. The establishment of appropriate critical material attributes, CPPs, and quality attributes for both the ribbons and granules early on in the process enables an efficient and robust assessment of the operation and lends the process well to future technical transfer and scale-up activities.

32.4.1 Material assessment: appropriateness for roller compaction

When selecting roller compaction as the granulation approach for a project, consideration should first be given to the appropriateness of the formulation for manufacture using roller compaction. As previously described, blends with drug loadings <60% are amenable for roller compaction. Material characterization of the feed powder should be assessed in to provide insight into potential manufacturing challenges (Refer to Table 32.1). For instance, blends with low bulk density or poor flow properties may not efficiently pass through the rolls. Insufficient compactability may indicate a potential for poor tablet compactability of resultant granules. The propensity for a material to adhere to surfaces (ie, roll surface) is another important trait to consider. Material adhesion challenges, typically

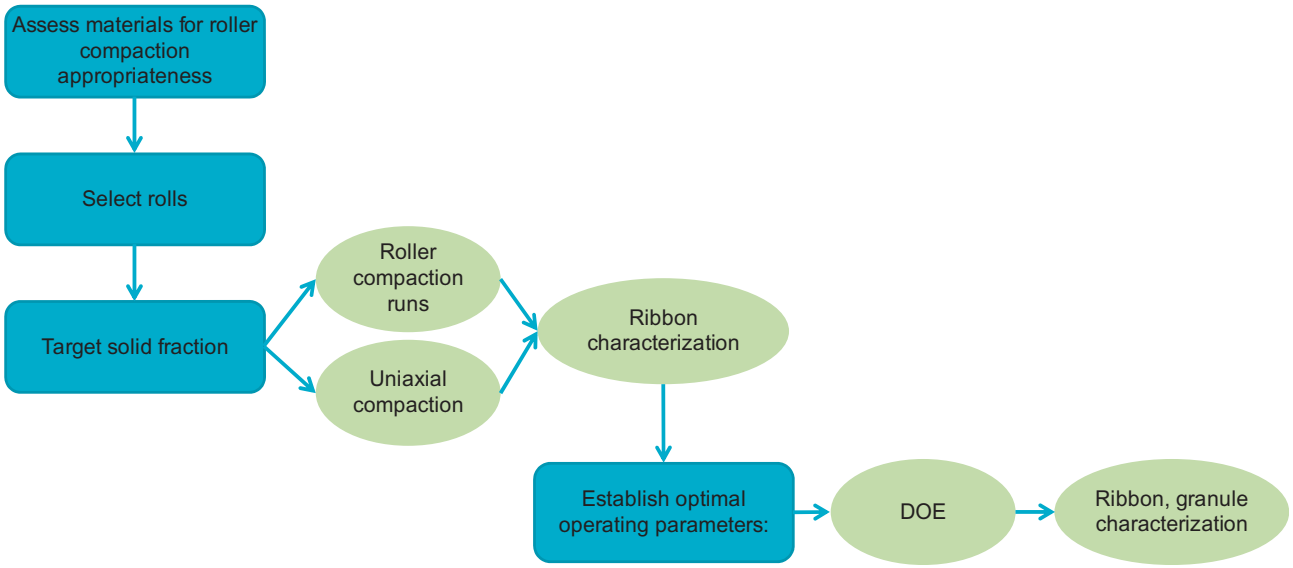

FIGURE 32.38 Flow diagram describing suggested approach to roller compaction process development.

associated with APIs rather than excipients, are difficult to assess because a robust characterization method has not been established. When material is observed to adhere to surfaces during early development work, proper excipient selection is often the first-line strategy to mitigate adhesion challenges, which typically includes modification of lubricant selection or level; however, in cases where acceptable mitigation is not achieved, changes to API form, particle size or particle morphology may be considered. If powder adhesion still cannot be properly rectified, alternative granulation techniques, such as wet granulation methods, are suggested.

32.4.1.1 Roll selection

As mentioned in the previous section, roll surface design is known to impact powder flow through the roller compactor. Patterned roll surfaces (ie, knurled, serrated) assist in "grabbing" powder and facilitating powder flow between the rolls. Roll surface design may also be a critical factor with powders that have a high tendency to stick or adhere to surfaces. The finish of the roll surface can affect roller compaction properties, such as the nip and entry angles during compaction, and thus the cumulative pressure applied to the powder. Therefore, it is advantageous to select the rolls at an early stage to provide consistency throughout the development process. Different roll designs and combinations (ie, smooth upper and lower rolls vs smooth upper/knurled lower roll) should be evaluated. When conducting preliminary experiments, typical roll gaps (2.0–3.0 mm) and 3–4 different roll pressure values should be evaluated. Feed screw performance can be a good indicator of powder flow performance; for example, if powder is not effectively drawn through the rolls and a back pressure is being created, then the load (ie, torque) on the feed screw may increase, and if using a closed feedback loop between the roll gap and the feed system (ie, gap control), then the feed screw speed will be significantly increased as the instrument attempts to feed more material between the rolls to open the roll gap.

32.4.1.2 Optimizing roller compaction parameters: targeting a ribbon solid fraction

The next objective is to identify the target range for ribbon solid fraction, which will relate to key roller compaction process parameters and the remaining compactability of the granule, which is important for subsequent tablet manufacture. It is recommended to produce ribbon or compacts at three or four different solid fraction values within the range 0.6 and 0.8 (refer to Fig. 32.6). The lower end of the range should be defined by the lowest solid fraction ribbon that can be milled to produce desirable granules, without a significant increase in fines content. Historically, a target ribbon thickness is selected (within the range 2.0–3.0 mm is typically acceptable) and the feed rate and roll pressure are manipulated to achieve acceptable solid fractions (0.6–0.8) while maintaining the target ribbon thickness. Sample analysis should include solid fraction and tensile strength measurements. Subsequently, the ribbons are milled to produce granules, which should

be assessed for compactability to determine suitability for tablet manufacture. Additional granule characterization includes particle size and powder flow analysis. Generally, ribbons of lower solid fraction result in granules comprising smaller particles that retain good compactability but may display poor powder flow; whereas higher solid fraction ribbons result in larger particles with relatively less compactability that are likely to possess desirable flow properties. Ribbons of suitable solid fraction produce granules that result in sufficiently strong tablets that can be manufactured on a high-speed tablet press while maintaining good tablet weight control. Ideally, a tablet of 0.85 solid fraction should have a tensile strength of greater than 1.7 MPa[115] and surpass tablet friability standards as defined by USP <1216>; and tablet weight should generally be maintained within 95–105% of the target weight throughout the manufacturing run.

More recently, small-scale compaction techniques have been used to predict target ribbon solid fractions before conducting any work on a roller compactor. When material or development time is scarce, the use of a uniaxial compaction method to simulate roller compaction (technique described in detail in Section 32.2) is a useful tool for producing compacts over a range of solid fractions. Simulated roller compaction ribbons may be prepared on a compaction simulator; these compacts may then be tested using characterization methods identical to those used for actual roller compaction ribbons. The simulated compacts may also be milled to yield granules, to emulate those prepared by roller compaction. The use of this small-scale simulation method provides >70% reduction in material resources compared with traditional development approaches.

32.4.1.3 Optimizing roller compaction parameters: establishing the design space

Once the target solid fraction has been identified, the acceptable solid fraction range should now be determined. The necessary operating parameters required to achieve the target solid fraction may be estimated using one of the roller compaction models described in the previous section. In lieu of modeling results, a design of experiment (DOE) should be conducted based upon knowledge from previous products. If modeling results are available, the DOE should be designed around the predicted edges of failure.

Key product attributes for the roller compaction ribbon are solid fraction, thickness, and tensile strength (see Section 32.1 for more detail). However, it should be noted that ribbon tensile strength is not commonly monitored during the commercial manufacturing process: ribbon solid fraction and thickness, which relate to tensile strength, are more easily measured attributes and thus more amenable to commercial manufacturing. Granule properties (eg, particle size distribution, flow) may also be measured offline to provide an indication of the roller compaction process. Key process parameters that impact ribbon and granule quality are roll pressure, feed pressure, and roll gap. Feed pressure is primarily dictated by feed screw speed and is typically controlled via an internal feedback loop rather than being adjusted by the operator. As such, the DOE is often built around targeted roll pressure and roll gap values and the feed pressure is allowed to float. A two-factor, three-level DOE (2^3) investigating roll pressure and roll gap is generally considered to be sufficient, especially as a first-pass assessment of the operation. During this DOE, throughput requirements (at commercial manufacturing levels) should be considered when selecting roll speed values. The parameters from the initial study, which was used to identify a suitable target solid fraction, may be used as the center points, plus upper and lower range values. Upper and lower roll pressure range limits might be based on those from the initial study, or an arbitrary range can be used, such as ±10 bar from center. The operating range for roll gap should be at least ±0.2 mm from target; thus a minimum operating range would span 0.4 mm. Ribbon samples should be analyzed to determine solid fraction and, if capabilities allow, tensile strength.

32.4.1.4 Output characterization

Ribbon quality is considered to be an indicator of granule quality. However, it is ultimately granule quality that is most critical for downstream operations. Thus, ribbon samples should be milled to produce granules and subsequently assessed for compactability and flow. Particle size distribution data is also valuable, and can typically be related to granule flow performance. When milling ribbons, especially throughout a DOE investigation, it is recommended to use a single mill screen aperture size to avoid confounding effects from changes to process parameters. Recommended screen mesh sizes are in the range of 0.8–1.2 mm to break up loose aggregates without reducing the granules back to fines. It is also recommended to test the impact of different screen sizes on granule quality to demonstrate process robustness once the working ranges for roll pressure and gap have been determined. Process robustness against milling conditions has late-stage development and scale-up implications because many commercial roller compactors are integrated with a mill system, and thus milling conditions may not be exactly translated.

32.5 ILLUSTRATIVE EXAMPLE DETAILING THE TYPICAL DRUG PRODUCT DEVELOPMENT PROCESS FOR A ROLLER COMPACTED PRODUCT

Formulation A, comprising 35% active drug (Tables 32.9), required the development of a dry granulation method using an Alexanderwerk WP120 roller compactor. Selection of target processing parameters for the manufacture is detailed below. While not detailed in this example, similar studies may be executed to understand the impact of API and excipient material attributes, in addition to process parameters, on product performance.[8]

32.5.1 Selection of rolls

32.5.1.1 *Experimental set-up*

Smooth/Smooth and Smooth/Knurled upper/lower roll configurations were evaluated to assess the impact on roller compaction performance. The operating conditions for roller compaction manufacture are detailed in Table 32.10.

32.5.1.2 *Outcome*

When manufacturing using two smooth rolls and gap-controlled operations, feed screw speeds and load readings reached 100% capacity; whereas the smooth/knurled roll configuration resulted in acceptable and stable feed screw loads of approximately 60% capacity, while maintaining a consistent roll gap. Therefore, the smooth/knurled roll configuration was selected because it better facilitated good powder flow through the roller compactor compared with the smooth/smooth roll configuration.

TABLE 32.9 Composition of Formulation A

Formulation composition		
	Role	Wt %
Intra-granular		
Active drug	API	35.0
Lactose monohydrate	Filler	30.0
Microcrystalline cellulose	Filler	30.0
Silicon dioxide	Glidant	1.0
Croscarmellose sodium	Disintegrant	2.0
Magnesium stearate	Lubricant	0.5
Extra-granular		Wt %
Croscarmellose sodium	Disintegrant	1.0
Magnesium stearate	Lubricant	0.5

TABLE 32.10 Roller Compactor Operating Conditions

Property	Target values
Hydraulic roll pressure (bar)	35, 70
Roll gap (mm)	2.2
Operating method	Gap-control

32.5.2 Selection of operating parameters

32.5.2.1 *Experimental set-up*

- Small (~1–2 kg) batches were manufactured on the roller compactor to manufacture ribbons at varying solid fractions (0.65, 0.70, 0.75, and 0.80) with a target ribbon thickness of 2.2 mm. Subsequent ribbons were milled using the in-line mills of the Alexanderwerk roller compactor. Ribbon manufacture could also be executed using a compaction simulator, in the event that material is limited.
- Granules were compacted into tablets using a compaction simulator
- Two-factor, three-level DOE was conducted to optimize acceptable roll pressure and roll gap ranges (Table 32.11).

32.5.2.2 *Outcome*

- Roller-compacted ribbons of 0.65 solid fraction were weak, possessing tensile strengths of 0.7 MPa, and resultant granules of the 0.65 solid fraction ribbons possessed a higher fines content compared with the other lots. Ribbons of 0.70 solid fraction possessed tensile strength of 1.8 MPa, exceeding the recommended target of >1.0 MPa at 0.7 solid fraction (Figs. 32.39 and 32.40).
- Tablets manufactured from 0.80 solid fraction ribbons were weaker than those manufactured from the other three lots of granules (Fig. 32.41). Granules from 0.65, 0.70, and 0.75 solid fraction ribbons displayed satisfactory compactability; however, the higher solid fraction granules displayed better mass flow in the tablet press hopper, which is attributed

TABLE 32.11 Experimental Plan for Two-Factor, Three-Level DOE to Investigate Roll Pressure and Roll Gap Range

Run	Hydraulic roll pressure level	Roll gap level	Hydraulic roll pressure (bar)	Roll gap (mm)
1	High	Low	74	2.0
2	Low	High	54	2.4
3	Center	Center	64	2.2
4	Low	Low	54	2.0
5	High	High	74	2.4

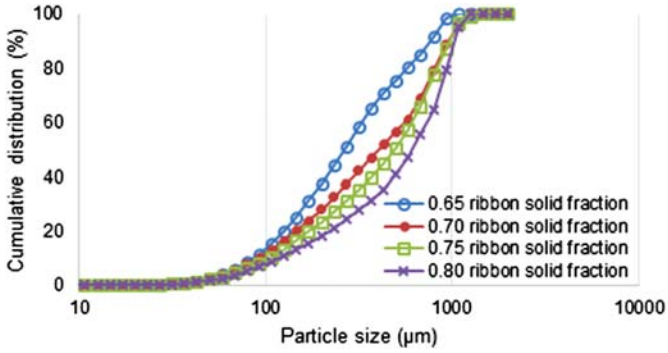

FIGURE 32.40 Cumulative particle size distribution for granules from ribbon of 0.65, 0.70, 0.75, and 0.80 solid fraction. Analysis performed using a Sympatec GmbH QicPic Particle Size Analyzer.

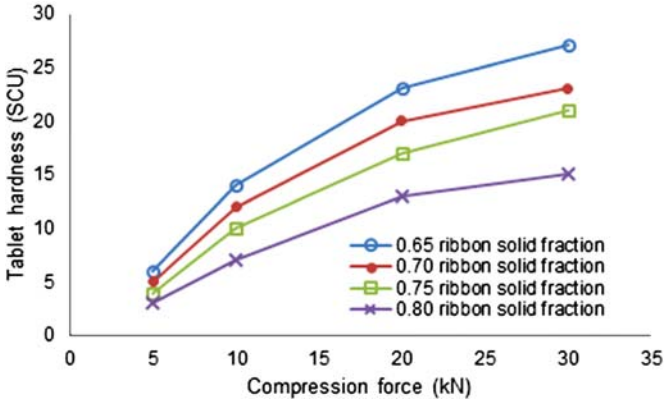

FIGURE 32.41 Compaction profiles generated using granules from ribbons of 0.65, 0.70, 0.75, and 0.80 solid fraction. Tablets manufactured using a Medel'Pharm Stylcam 100R press replicator with 9.00 mm round, biconcave tooling.

to differences in particle size distribution. During this evaluation, a hydraulic roll pressure of 64 bar was used to produce ribbon of approximately 0.75 solid fraction, therefore this roll pressure was set as the target for further work.

- A DOE was executed, in which a hydraulic roll pressure of 64 bar and roll gap of 2.2 mm were selected as center points and expected to yield ribbons of ~0.75 solid fraction based on data generated in the previous stage of work. The operating space was investigated by testing above and below the center points for roll pressure and roll gap, investigating high/high, low/low, high/low, and low/high combinations.
- Experimental results are listed in Table 32.12. Highlights from the results include:
  - Ribbons manufactured using center-point parameters averaged 0.74 solid fraction, comparable with the target of 0.75 solid fraction. The combination of low roll pressure/high roll gap resulted in the lowest solid fraction of 0.71 and the combination of high roll pressure/low roll gap resulted in the highest solid fraction of 0.77.
  - Based on granule flow characterization, ribbons of higher solid fraction produced better-flowing granules.
  - Higher solid-fraction ribbons produced less compactable granules, which resulted in tablets of lower hardness compared with those from ribbons of lower solid fraction.
  - All tablets exhibited less than 1% weight loss after 100 revolutions in the friabulator, which is acceptable.
  - All tablets achieved the dissolution target of Q80 release within 30 minutes.

Final conclusions: Small-scale batches enabled the establishment of:

- Target quality attribute for the ribbon: solid fraction of 0.75; and
- Target process parameters were set to the following: target hydraulic roll pressure was set at 64 bar with an operating range of 54–74 bar; and the target roll gap was 2.2 mm with an operating range of 2.0–2.4 mm.

32.6 SCALE-UP CONSIDERATIONS OF ROLLER COMPACTION

Pharmaceutical scale-up is commonly thought of as the process by which batch size is increased. This can be accomplished by enlarging the physical dimensions from lab- to pilot- to plant-scale or by increasing the output from a certain piece of equipment.[116] Roller compaction is a unit operation that readily lends[6,7] itself to scale-up by either method. Through the use of continuous processing, larger amounts of powders can be compacted using the same piece of equipment used

TABLE 32.12 Results of Two-Factor, Three-Level DOE Investigating Roll Pressure and Roll Gap Range; Solid Fraction Was Measured Using a Micromeritics GeoPyc 1360 Pycnometer; Granule Flow Was Measured Using an Erweka Powder Flow Tester; Tablet Friability Was Assessed at 100 Revolutions Using Apparatus Compliant With USP <1216>; and Dissolution Testing Was Performed Using USP Type 2 Apparatus at 50 rpm.

Run	Roll pressure/gap (center/low/high)	Ribbon solid fraction	Granule flow (g/s)	Tablet hardness (SCU)	Tablet friability (% weight loss)	Tablet dissolution
1	H/L	0.77	4.5	17	<1	Q80 @ 30 min
2	L/H	0.71	3.2	22	<1	Q80 @ 30 min
3	C/C	0.74	3.8	20	<1	Q80 @ 30 min
4	L/L	0.73	3.6	21	<1	Q80 @ 30 min
5	H/H	0.76	4.2	18	<1	Q80 @ 30 min

for smaller scale batches by running for a longer period of time. The two main advantages of continuous processes are that ease of scale-up for larger batches and a 24-hour automatic production line is possible.[117] For example, a roller compaction process could be scaled-up from a 40 kg batch to a 400 kg batch by simply increasing the batch run time from 1 to 10 hours.

Ideally, when scaling up by enlarging the physical dimensions of the roller compactor from one production scale to another, the equipment should be similar geometrically, dynamically, and kinematically.[117] The geometric condition is fulfilled when the ratio of physical dimensions between the small-scale and the scaled-up version are constant. Dynamic similarity is seen when the ratio of forces exerted between matching points in the two roller compactors are equal. Finally, kinematic similarity is met when the ratio of velocities between matching points in both systems are equal.[117] In reality, the scale-up process is more complicated because the equipment ratios between different scales may not match exactly. During scale-up consideration, regulatory guidance on manufacturing changes/similarity must be taken into account. Scale-up to larger roller compactor equipment is typically considered a "level 1 equipment change," according to the Food and Drug Administration's (FDA) Scale-Up and Post Approval Changes guidance document for immediate-release solid oral dosage forms (SUPAC-IR)[118–120] because roller compactors operate on the same operating principles and have the same design. Batch size increases must also be considered, since a level 1 change occurs when the production batch is up to 10-times larger than the pilot batch size. A level 2 batch size change occurs when the scaled-up batch size is greater than 10-fold for equipment operating on the same operating principles and design.[119,120]

Apart from the regulatory requirements, it is important to understand the effects of scale-up on the compacted ribbon and subsequently, the final dosage form. As discussed in previous sections of this chapter, the material attributes of interest from a roller compaction process are typically ribbon solid fraction, ribbon tensile strength, granule particle size distribution, and granule bulk density. During scale-up, it is generally accepted that if ribbon thickness and ribbon solid fraction are translated across scales, then granule attributes, and thus performance, will also be comparable. Ribbon and granule attributes are generally evaluated offline for confirmation of scale-up success. Ribbon density can be determined offline using an arc punch or GeoPyc or online using a PAT application, such as NIR spectroscopy as discussed in previous sections. Granule properties, such as particle size distribution, can be measured offline using a sieve method, light scattering technique (static or dynamic light scattering), or image analysis technique (QICPIC, Morphologi G3). Online particle size options include focused beam reflectance measurements or optical systems.[121,122] Scale-up focuses on the process parameters of roll pressure, roll gap, and roll speed because these parameters can have an effect on ribbon and granule attributes. The mill speed should also be considered as this can influence the milled particle size distribution. Once the development design space has been mapped to the commercial scale design space, the need to continue to measure these product attributes will be dependent upon the process control strategy.

The large-scale design space may be established by a few different methods, as listed in Table 32.13. The first option is to use historical experience to identify process parameters that are likely to produce ribbons and granules of acceptable quality. The issue with this approach is that it requires large amounts of material to perform a full DOE to translate the small-scale design space to the large scale. The rapid pace of pharmaceutical development and the rising costs of new active ingredients make this approach unattractive for most product scale-ups. The second approach is to use a surrogate formulation, typically a placebo formulation, to execute an experimental design to map the design space of the

TABLE 32.13 Scale-Up Approaches

	Historical experience	Surrogate mapping	Modeling

How it works	Trial and error approach, using historically known conditions as a starting point	• Execute DOE at commercial scale using surrogate material, often placebo
		• Apply DOE results to active blend
			• Execute experiments to collect model input
			  ◦ Limited roller compaction runs at small-scale
			  ◦ Material characterization
			• Using modeling results to predict roller compaction design space
			• Spot-check predictions at large-scale to verify modeling predictions

Considerations	Requires large amounts of material, as an entire DOE executed commercial scale	Results most accurate for low drug load formulations and when placebo blend is highly similar to active blend	• Requires extra effort initially, compared with previous scale-up methods, but overall uses significantly less material, resource • Ensure modeling assumptions are well understood

small- and large-scale roller compactors. The use of a common placebo formulation is an acceptable practice because the information gathered can be extrapolated to an active containing formulation. This approach saves the cost of running large-scale batches with active ingredient and, when paired with historical knowledge from previous successful scale-ups, can be used to define the large-scale design space. When considering the placebo formulation it is important to remember that the closer the placebo is to the real product's formulation the more accurate the scaled-up parameters will be for the commercial process. It is recommended to spot check the design space at center point and the extremes to ensure ribbon and granule properties align with product properties produced by the small-scale design space.

The third approach utilizes modeling techniques outlined in the previous section of this chapter. In this approach, a material characterization measurements are required up front to supply the inputs for the model and a limited number of experimental runs on small-scale equipment are required to validate the model. One of the key model inputs, which should be understood on both scales, is the relationship between hydraulic pressure and applied roll force. This relationship can be measured by the use of an instrumented roll or force cradle. Once the limitations/assumptions of the model are understood, it can be modified to generate a design space for the large scale. It is recommended to spot check the design space predicted by the model at center point and the extremes to ensure ribbon and granule properties align with product properties produced by the small-scale design space. This approach requires more up-front work, but requires less material and resources to be successful. In addition, the model can then be confidently applied to subsequent product scale-up activities.

32.7 ILLUSTRATIVE EXAMPLE DETAILING A POSSIBLE APPROACH TO SCALING-UP A ROLLER COMPACTION PROCESS

A combination of scale-up approaches was used to determine appropriate roller compaction conditions when scaling up from a roller compactor fitted with 120-mm-diameter rolls to a roller compactor fitted with 200-mm-diameter rolls.

32.7.1 Experimental design

1. Selection of material to be used for scale-up study
   a. To minimize API costs, a surrogate roller compaction placebo formulation was used to mimic a formulation with 4% wt drug load.
   b. Composition of the placebo was 1/1 MCC/lactose (anhydrous) and contained relevant amounts of disintegrant, glidant, and lubricant
2. Selection of target ribbon solid fraction
   a. A target ribbon solid fraction of 65–77% was selected, based on results obtained from a small-scale roller compaction simulation (manufacture of compacts using a uniaxial compaction simulator).
   b. The selected ribbon solid fraction range is in line with previously documented experience; thus, resultant granules were expected to possess sufficient compactablility for tabletting.
3. Selection of design space
   a. 12-run DOE devised to characterize the design space for both roller compactors (Table 32.14). The experiments were designed such that three separate analyses could be performed:
      i. Two-factorial design (runs 1–8) used to establish the impact of roll gap and roll

TABLE 32.14 Design of Experiments for Roller Compaction Runs

Run	Roll speed (mm)	Hydraulic roll pressure (bar)	Roll gap (mm)	Mill speed (rpm)
1	Center	Center	Center	Center
2	Center	Low	Low	Center
3	Center	Low	High	Center
4	Center	High	Low	Center
5	Center	High	High	Center
6	Center	Center	Low	Center
7	Center	Center	High	Center
8	Center	Center	Center	Center

10	High	Center	Center	Center
11	Center	Center	Center	Low
12	Center	Center	Center	High

pressure, which is typically found to be main factors to effecting ribbon density or tensile strength.

ii. Runs 1, 8, 9, and 10 to assess the impact of roll speed on ribbon density and granule properties.

iii. Runs 1, 8, 11, and 12 to assess the impact of mill speed on granule properties.

iv. Runs 1 and 8 at center point for all parameters to assess the reproducibility of the impact of process parameters on ribbon and granule properties.

b. Roll speed range determined by commercial throughput considerations

c. Milling parameters selected based upon historical experience

d. Ribbon density and granule particle size distribution were selected as the material attributes of interest.

32.7.2 Results

The DOE was executed using the surrogate placebo blend on both the pilot scale (120-mm rolls) and commercial scale (200-mm rolls) roller compactor.

- Ribbon density data showed that the commercial roller compactor required higher hydraulic pressure set points to generate a ribbon with a comparable density with that of the pilot-scale unit. This was expected since the rolls of the commercial unit were wider, and thus, a higher force was required to maintain the same compressive force per cm of roll width. The design space for ribbon density is given in Fig. 32.42.
- Particle size distributions for the two roller compactors were equivalent, as seen in Fig. 32.43. The data from all 12 conditions were averaged together and plotted along with the minimum and maximum observed results. As shown, the distributions completely overlap. In addition, both roller compactors exhibited the same relationships for changes in roll speed and mill speed. Statistical analysis of the results showed that neither roller compactor exhibited a relationship for roll speed on ribbon density or had a significant relationship for particle size with regards to changes in mill speed.
- Granule bulk and tapped density values were similar for all DOE conditions.

Overall, this scale-up approach was shown to be successful for providing suitable process parameters to

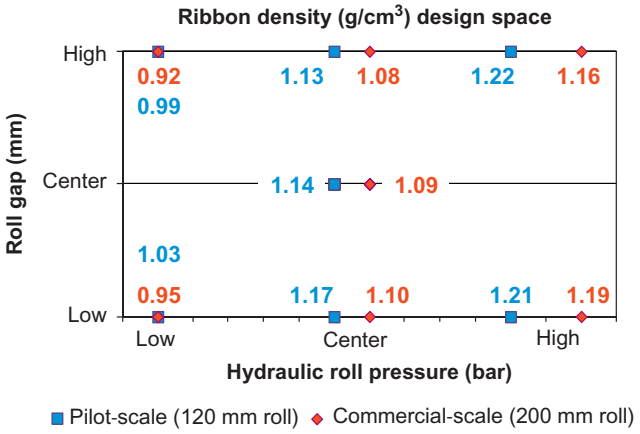

FIGURE 32.42 Ribbon density design space map.

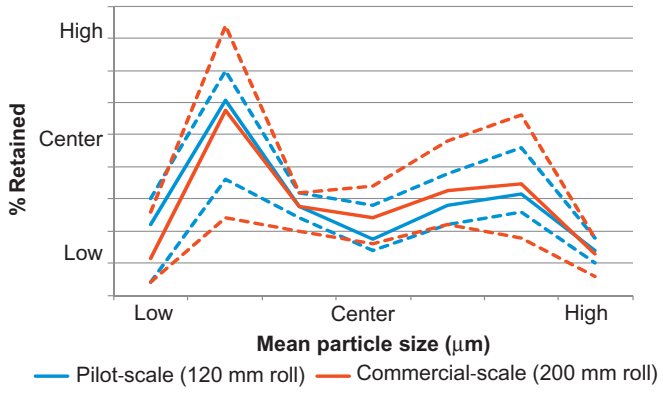

FIGURE 32.43 Granule particle size distribution. Dashed lines indicate minimum and maximum observed results and solid line is average.

TABLE 32.15 Common Roller Compaction Challenges and Mitigation Approaches

Problem	Possible cause	Remedies
Sticking to compaction rolls	Insufficient lubricant level	Add lubricant; typically 0.2–0.5%; external lubrication a possibility
	Excessive moisture	Reduce moisture content; Dehumidify environment
	Poor scraper adjustment	Decrease clearance between rolls and scrapers; Replace worn scrapers
	Excessive force	Decrease roll force
	Melting of product	Cool rolls to decrease temperature; use water, nitrogen
	Improper roll configuration	Use smooth or grooved rolls
Soft compact/friable granulation	Improper formulation	Increase compressible binder; Decrease lubricant level
	Compaction force too low	Increase compaction force
	Compaction (dwell) time too short	Decrease roll speed
	Excess blend time for powder and lubricant	Decrease blend time
	Raw material variation	Monitor key raw material specifications
Excessive fines	Air entrapment	Use deaeration system
	Leakage of powder	Tighten seals (top/side); replace worn seals
	Poor powder compressibility	Increase compressible binder; screen/sieve product to desired particle size
	Improper granulation/mill screen	Use coarser screen for milling compacts
	Improper granulation/mill speed	Decrease mill speed
	Low compaction force	Increase roll force
Low bulk/tap density	Compaction force too low	Increase roll force
	Particle size too large	Use finer screen/plate to mill the compacts
	Challenging material	May need to pass material through roller compactor several times
Poor flow characteristics	High fines content	See remedies for "excessive fines"
	Particle size too small	Use coarser screen/plate to mill the compacts
Poor granule dissolution	Compaction force too high	Decrease roll force
	Improper formulation	Add a disintegrant (ie, starch, MCC)
Drug release profile—too slow	Poor formulation-slow release	Increase %hydrophilic polymer; use polymer with lower MW; Decrease %lubricant
Drug release profile—too fast	Poor formulation-fast release	Increase hydrophilic polymer (ie, HPMC); use polymer with higher MW
Low throughput/production rate	Feed rate too slow	Increase screw/roll speed ratio
	Improper screw design	Use alternate screw (double flight)
	Air entrapment	Use a deaeration system
Poor product stability/discoloration	Heat generation during compaction or milling	Decrease compaction force; use water-cooled rolls; use nitrogen cooling
Improper ribbon thickness	Poor scalability of the screw/roll speed ratio	Increase screw/roll speed ratio to increase thickness; decrease screw/roll speed ratio to decrease thickness
	Improper roll gap setting	Adjust roll gap to desired thickness

(*Continued*)

TABLE 32.15 (Continued)

Problem	Possible cause	Remedies
Compaction in hopper/top seal	Improper screw/roll speed ratio	Increase roll speed; decrease screw speed
	Improper screw/hopper clearance	Increase clearance between the screw feeder and side walls of the hopper
Mottled tablet appearance	Over-compaction of powder	Decrease compaction force
	Material sticking to rolls	See remedies for "sticking to compaction rolls"

scale-up or scale-down a process. The data generated could be used to justify process parameters for an active formulation by taking into account how the active formulation's mechanical and physical properties differ from the placebo. In addition, this approach can be utilized to confer equivalence between equipment of the same scale. This type of assessment would be important when commercial production occurs on multiple roller compactors to ensure recipe set points are properly defined to ensure equivalent ribbon and granule properties.

32.8 TROUBLE-SHOOTING

A compilation of common roller compaction challenges and potential mitigation strategies are given in Table 32.15.

32.9 CONCLUSIONS

The roller compaction process is an effective and efficient means of enhancing powder behavior, in terms of flow and compactability, for downstream pharmaceutical processes. Over the past couple decades, roller compaction has become the predominant granulation method due to its many advantageous characteristics (eg, it does not require heat, solvents) and its popularity continues to increase, especially as the industry moves toward continuous production processes. This chapter has highlighted the benefits of roller compaction processes over alternate processing techniques, essential aspects of equipment, formulation, and process design, and critical considerations for scale-up, as well as reviewed both traditional and novel characterization tools, techniques, and models to facilitate efficient process development methods. Another important trend featured in this chapter was the growing use of small-scale tools and methods to simulate the roller compaction process, many of which can be conducted at bench-scale to enable efficient execution of roller compaction development processes, even at early stages of drug product development.

33.1 INTRODUCTION

Compressing pharmaceutical tablets is one of the most efficient processes for producing a single dose of medication. Tablets are accepted and trusted by professionals and consumers alike; they are easily administered and simple to dose.

Compressing powders into a solid form dates back thousands of years. It wasn't until the early 1800s that tablet compression was automated in the sense that the hand crank was replaced by a leather belt and a steam-driven power bar. Early single-station tablet presses produced an average of 100 tablets per minute (TPM), while maintaining uniformity requirements for tablet hardness, thickness, and weight. Soon after, single-station presses were fading and making room for new technology: the rotary tablet press. Introduced in the mid-1800s, the rotary tablet press boasted speeds capable of compressing 640 TPM compared with high-speed presses today, capable of compressing up to 24,000 TPM. Although tablet presses have evolved through the years, the same principles apply (Fig. 33.1).

33.2 OPERATION PRINCIPLES OF COMPRESSION BY ROTARY PRESS

Modern rotary press usually include the following components:

Name of component	Function(s)
Hopper	Containing powder
Feeder	Distribute power into die cavity
Gravity, forced, centrifugal/die feed	Provide additional mixing
Turret	Position and progress the punch and die
Punch, lower and higher	Accept powder from feeder
	Contain powder until compression occurs
	Densify and compress the powder
	Eject the compressed tablet
Feed cam	Lower the lower punch to allow powder to come in
Compression cam, upper/lower	Force upper and lower punch to compress
Ejection cam	Lift the lower punch and push tablet above the turret
Ejection plate	Remove tablet off turret
Hydraulic	Provide hydraulic pressure
Instrumentation	Monitor force, speed, distance, etc.
Air handling	Provide exhaust

33.3 TOOL DESIGN

Good granulation is important for compressing quality tablets. If the granulation is poor, so will the long-term results. A proper tablet granulation will have good flow, compressibility, and release properties. Tablet compression tooling is equally responsible for the success of a tableting program. Tooling must

Developing Solid Oral Dosage Forms

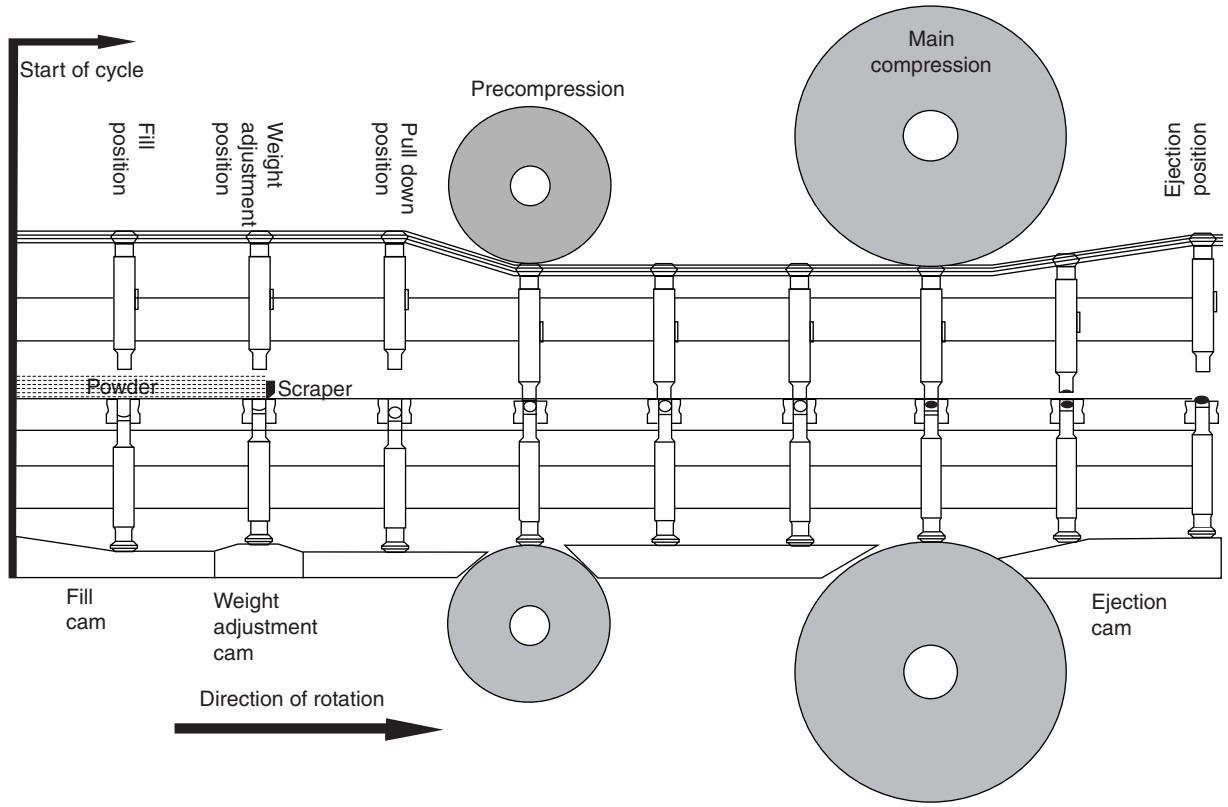

FIGURE 33.1 Rotary tablet press cycle.

be engineered to withstand the stresses associated with tablet compression, provide satisfactory service life, and maintain physical tablet uniformity. Proper tablet design is also critical. Pharmaceutical marketing departments feverishly attempt to design unique tablets, anticipating the design will quickly become branded and trusted in the eye of the consumer. A proper tool design is essential for placing that innovative design into the consumer's view.

The basic knowledge of tablet compression tooling and tablet design can save literally millions of dollars, prevent product loss, and reduce unnecessary equipment downtime. Understanding the basic physics of tablet compression will greatly enhance the ability to compress quality tablets more efficiently and provide better knowledge to troubleshoot and identify potential pitfalls before they happen (and they do!).

Communication is important with any tableting campaign. Marketing, research and design (R&D), engineering, production, and the tooling supplier must be in accordance and communicate new product-design and production requirements. The ideas and responsibilities of these departments may vary, but they share the common goal of manufacturing a quality tablet efficiently and productively.

33.3.1 Terminology

To communicate properly and understand the following material, it is important to have a basic understanding of the terminology used in this industry. Although these terms are most common and accepted, some terms may vary slightly between countries. This article deals with the terminology and general information related to the most common tablet shapes and rotary press tooling, the "TSM," "B," "D," and "Euronorm" 19- and 21-mm configurations (Tables 33.1 and 33.2 and Fig. 33.2).

33.3.2 Common tooling standards

There are two internationally recognized standards for tablet compression tooling, the "TSM" and the "EU" standards. Both "TSM" and "EU" standards identify the physical tool configuration for "B" and "D" type tablet compression tools, their critical dimensions, and associated tolerances assuring tablet quality and an efficient tablet press operation.

The "TSM" tooling standard is recognized in the Americas and is considered exclusive in the United States. "TSM" stands for the *Tablet Specification Manual*

TABLE 33.1 Common Tooling Terminology

Term	Definition
Tooling set	A complete set of punches and dies to accommodate all stations in a tablet press
Tooling station	The upper punch, lower punch, and die, which accommodate one station in a tablet press
Head	The largest diameter of a common punch that contacts the machines cams and accepts the pressure from the pressure rollers
Head flat	The flat portion of the head, which makes contact with the pressure rollers and determines the maximum dwell time for compression
Top head angle	Angle from the outside head diameter to the top head radius; it allows for sufficient head thickness and smoother camming
Top head radius	The radius on the top of the head, which blends the top head angle to the head flat. Some head configurations may consist of only the head radius without the head angle. This radius makes the initial contact with the pressure roll and allows a smoother transition into the compression cycle
Head back angle	Sometimes referred to as the inside head angle; located underneath the top head angle or the top head radius, which contacts the machine camming for vertical movement of the punch within the punch guides
Neck	Located below the head and provides clearance as the punch cycles through the machine cams
Barrel or shank	The vertical bearing surface of a punch, which makes contact with the punch guides in the machine turret for vertical guidance
Barrel chamfer	Chamfers at the ends of the punch barrel, eliminate outside corners
Barrel-to-stem radius	The radius that blends the punch barrel to the stem
Stem	The area from the barrel to the edge of the punch tip
Tip length	The straight portion of the punch stem
Tip straight	The section of the tip that extends from the tip relief to the end of the punch tip; it maintains the punch tip size tolerance
Land	The area between the edge of the punch cup and the outside diameter of the punch tip; this adds strength to the tip to reduce punch-tip fracturing
Tip face or cup	The portion of the punch tip that determines the contour of the tablet face; it includes the tablet embossing
Cup depth	The depth of the cup from the highest point of the tip edge to the lowest point of the cavity
Tip relief	The portion of the punch stem, which is undercut or made smaller than the punch tip straight; most common for lower punches to aid in reducing friction from the punch tip and die wall as the punch travels through the compression cycle; the area where the punch tip and relief meet must be sharp to scrape product from the die wall as the lower punch travels down for the fill cycle
Key	A projection normally made of mild steel, which protrudes above the surface of the punch barrel. It maintains alignment of the upper punch for reentry into the die; mandatory on upper punches with multiple tips and all tablet shapes other than round; commonly used with embossed round tablet shapes when rotation of the punch causes a condition known as double impression
Key position	The radial and height position of a key on the punch barrel; not found in all presses
Punch overall length	The total length of a punch, other than flat-face tablet configurations, that is normally a reference dimension, which consists of a combination of the working length and the cup depth dimensions
Working length	The dimension from the head flat to the lowest measurable point of the tip face, responsible for the consistency of the tablet's overall thickness
Anneal	A heat-treating process used on fragile punch tips to decrease the hardness of the punch cups reducing punch-tip fracturing
Bakelite tip relief	An undercut groove between the lower punch tip straight and the relief; it assures a sharp corner to assist in scraping product adhering to the die wall; normally a purchased option for lower punches
Major axis	The largest dimension of a shaped tablet
Minor axis	The smallest dimension of a shaped tablet
End radius	The radius on either end of a capsule or oval-shaped tablet
Side radius	The radius on either side of an oval- or modified-shaped tablet
Band	The center section of a tablet between the cup profiles: it is governed by a direct relationship of the die cavity profile
Compound cup	A cup profile which consist of two or more radii
Embossed	The raised identification on a tablet or a punch face; an embossed punch tip results in a debossed tablet
Debossed	The depressed identification on a tablet or a punch face; a debossed punch tip results in an embossed tablet

TABLE 33.2 Tablet Terminology

Term	Definition
Major axis	The largest dimension of a shaped tablet
Minor axis	The smallest dimension of a shaped tablet
End radius	The radius on either end of a capsule or oval-shaped tablet
Side radius	The radius on either side of an oval- or modified-shaped tablet
Band	The center section of tablet between the cup profiles: it is governed by a direct relationship of the die cavity profile
Compound cup	A cup profile which consist of two or more radii
Embossed	The raised identification on a tablet or a punch face: an embossed punch tip results in a debossed tablet
Debossed	The depressed identification on a tablet or a punch face: a debossed punch tip results in an embossed tablet

and is published, revised, and distributed by the American Pharmacist Association in Washington, DC. The "TSM" standards, once known as the "IPT" standards, were originally developed in 1968 by a committee consisting of major US pharmaceutical companies. Their motivation was an attempt to maintain standardization for "B" and "D" tablet compression tooling, which provides interchangeability between tablet presses. The "TSM" provides engineered drawings that are a valuable reference for troubleshooting and tool inspection. Today, the "TSM" committee consists of professionals from the tablet press, tooling, and tablet manufacturing industries. The "TSM" also includes useful information such as standard cup configurations for round tablets and a reference to common bisects for breaking tablets into multiple uniform dosages.

The "EU" tooling standard is internationally recognized and is more widely used than its counterpart, the "TSM" standard. "EU," which is the acronym for "Eurostandard" and "Euronorm," is considered the European standard for interchangeable "B" and "D" type compression tools. The "EU" standards were created by Trevor Higgins in an attempt to establish a tooling "norm" that provides tool interchangeability with the most common "B" and "D" type European tablet presses. The "EU" standard is printed and distributed by I Holland Ltd, Nottingham, UK.

33.3.3 EU, TSM, B, and D type punches

The "TSM" and "EU" standards manuals provide mechanical drawings and technical information for "B" and "D" type tools, which constitutes a majority of the tool configurations used today. The "B" type configuration has a nominal punch barrel diameter of 0.750″/19 mm. The "B" type has two different die sizes. The larger "B" dies have a diameter of 1.1875″ (30.16 mm) and the smaller "BB" dies have a 0.945″ (24 mm) diameter. The "D" type has a larger nominal barrel diameter of 1″ (25.4 mm) and a die diameter of 1.500″ (38.10 mm.). The "B" and "D" tool designation identifies the physical tooling size and was coined by engineer Frank J. Stokes in the late 1800s.

Stokes resided in Philadelphia, PA when he developed the first commercially available rotary tablet in the United States—the Stokes B1 Rotary. The B1 rotary press was extremely successful and most in demand by pharmaceutical companies nationwide. Mr Stokes, realizing the need for compressing larger and heavier tablets, developed the Stokes D3 rotary tablet press. The D3 tablet press uses slightly larger punches and dies, increasing the overall capacity to compress larger and heavier tablets.

During the second industrial revolution, Stokes expanded manufacturing capabilities and operated a facility in England for international distribution. Stokes soon became the world's leading tablet press manufacture and sold tablet presses and tooling in nearly every industrialized country. The designation "B" and "D" quickly became the international standard for identifying a tablet press capacity and a tool configuration, as it remains today.

At the brink of World War II, Stokes left England and focused all manufacturing activities in Pennsylvania. Stokes left behind trained engineers and qualified manufacturing personnel who soon realized the potential of the tablet press market and began manufacturing tablet presses and tooling under the name "Manesty." As a marketing strategy, Manesty reengineered the punches and tablet press cams to enhance tooling life and provide better performance. The Manesty punch is similar to the original Stokes design, but is exclusive to Manesty presses and not interchangeable with the more popular Stokes tablet presses. Manesty called their tablet presses the "Manesty B3B" and the larger "Manesty D3a"

Manesty soon became a major supplier in the compression equipment industry and successfully competed against Stokes in the global market. In the mid 1980s, the tablet press industry exploded and press manufactures were competing with tablet press output and innovation. Accommodating newer and high-speed tablet presses, the original Manesty tooling standard was refined to provide better interchangeability with the most common "B" and "D" tablet presses, identified by the "Eurostandard," often referred to as the "EU" standard and the "EU" norm.

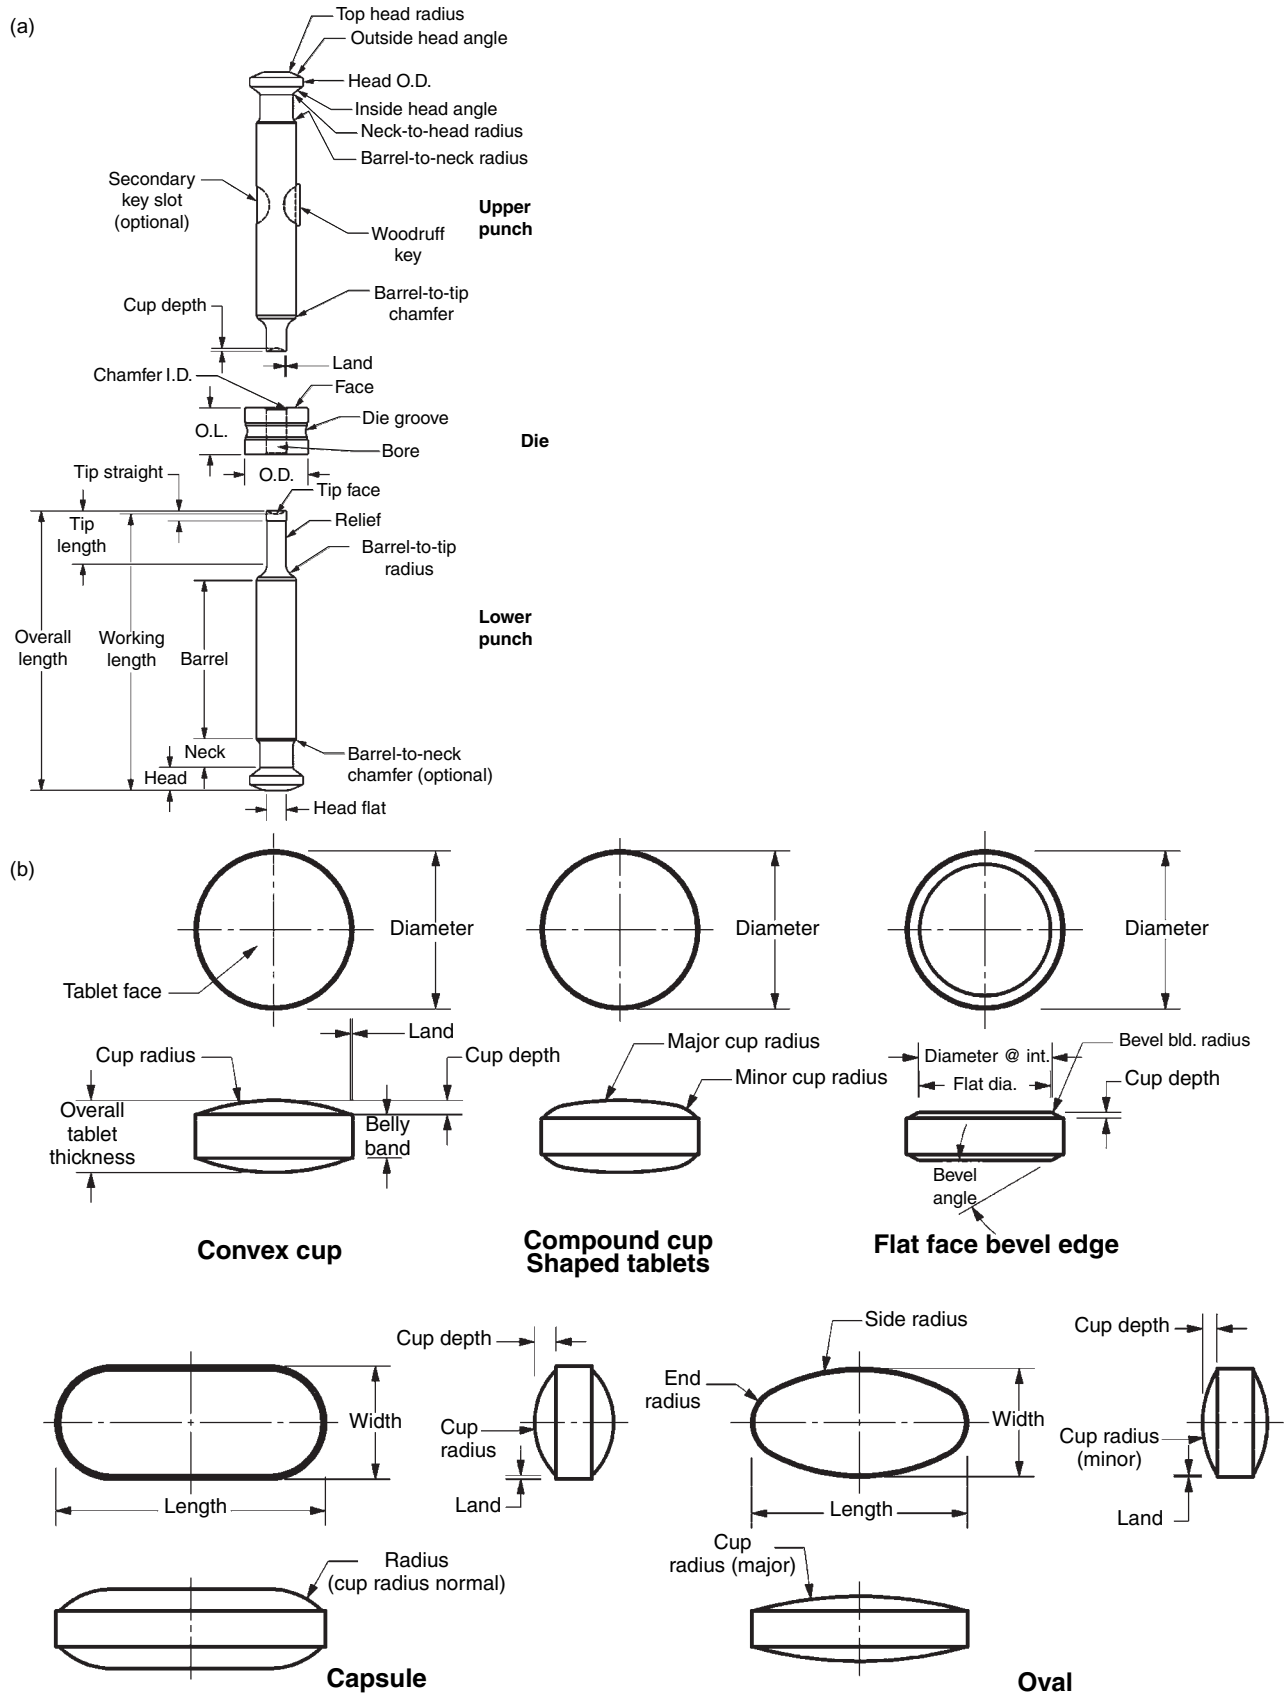

FIGURE 33.2 Punch and die terminology.

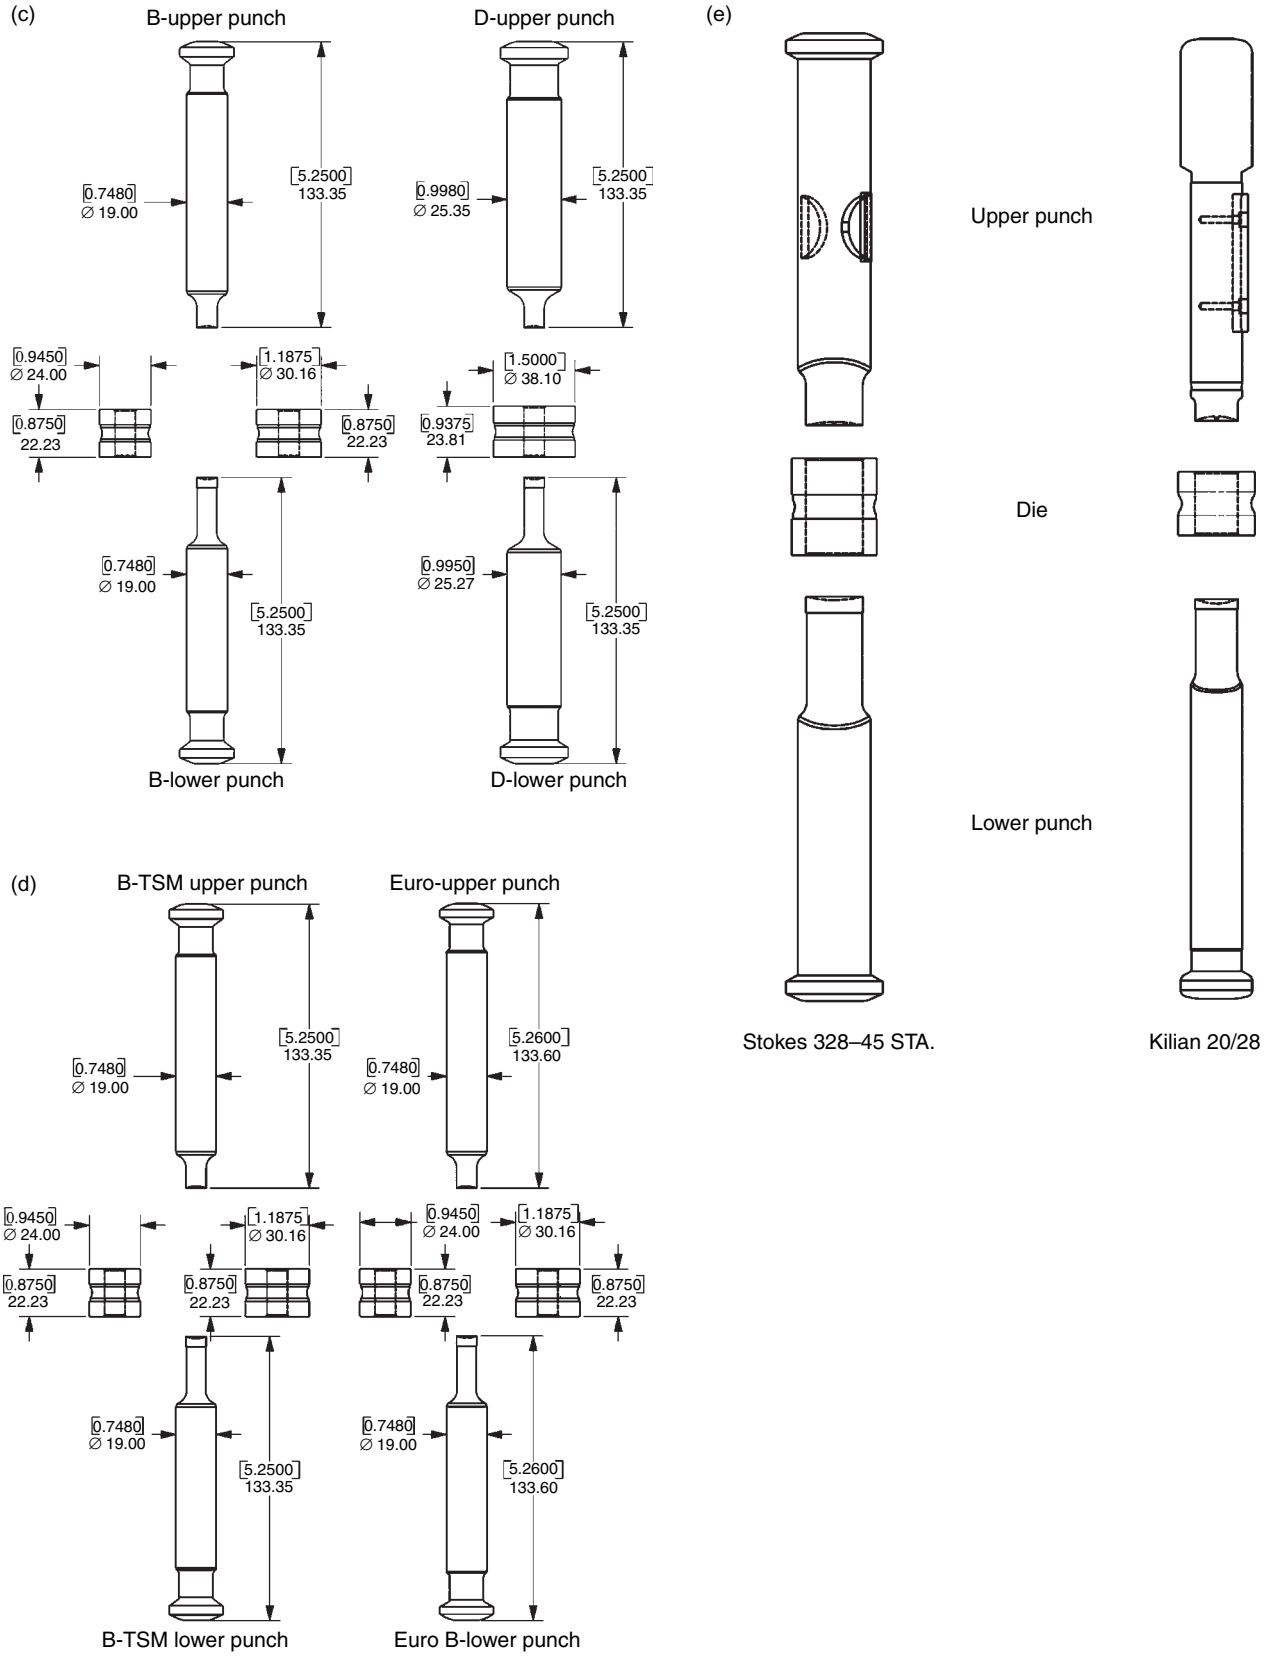

FIGURE 33.2 (Continued)

There are various models of tablet presses that do not conform to the standard "B" and "D" tool configurations and are engineered to be exclusive to a particular make and model of tablet press. Some of the more common configurations were designed in the early 1900s and are still used on tablet presses today. These unique tablet presses are generally larger and engineered to compress larger tablets more effectively. Kilian Gmbh, a division of IMA in Milan, Italy, is a major European manufacturer of tablet presses using the most common unique tool configuration. The Kilian-style upper punch does not use the common punch head configuration to guide the punches through the press cams; instead, the upper punch is guided by a machined cam angle located on the side of the upper barrel. The Kilian design provides a larger head flat, therefore, increasing the compression dwell time over the more popular "B" and "D" type tools.

33.3.4 Recent innovations

New technology continues to introduce innovative tool configurations in the effort to provide better efficiency of tablet press speed, product yield, cleaning, and safety.

In 1997, Ima introduced a line of unique tablet presses called the Ima Comprima. The Ima Comprima models use an innovative approach with tool design and granulation delivery. Unlike traditional tablet presses using a gravity-feed frame or force-feeding mechanism to fill the die with granulation, the Ima Comprima feeds the granulation through the die table, taking advantage of the centrifugal force created by the rotating turret for a rapid and uniform die fill. Unlike traditional presses, the Ima Comprima ejects the compressed tablet through the bottom of the die and uses gravity to eject the tablet from the press. Traditional tablet presses eject the tablet at the top of the die, requiring a mechanical stop or a take-off bar to physically contact and knock the tablet from the lower punch face. The Ima Comprima press is engineered to improve product yield, while providing a dust free environment for a more clean operation and a safer environment for the operator (Fig. 33.3).

The most recent innovation with tablet press and tooling technology is developed by Fette GmbH, located in Schwarzenbek, Germany. The new technology was introduced in 2005 and is favored by high-volume tablet manufactures. The technology does not use traditional compression dies, instead Fette developed die segments. Die segments provide an advantage over traditional dies by combining the tablet press turret die table and dies into three or five integral segments. Die segments are much easier and quicker to install than individual dies and die locks, reducing tablet press set-up time dramatically. More space is available around the turret circumference to increase the number of punches because the concept does not require the use of dies, which results in more tablets compressed per revolution than traditional presses of the same size.

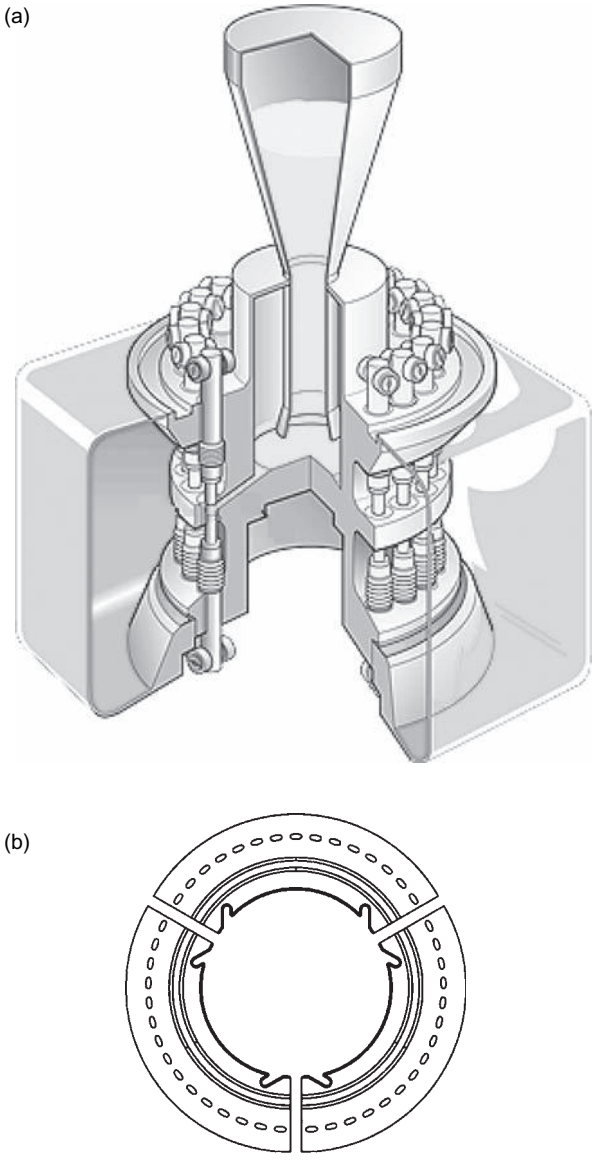

FIGURE 33.3 (a) IMA press and tools. (b) Fette 2090 die segments.

Tablet press technology has recently brought attention to the steel used for punches and dies with "wash in place" tablet presses. "Wash in place" tablet presses are becoming more common and are available

from most major tablet press suppliers. To reduce the possibilities of tool discoloration and corrosion, it is important that the tools are immediately removed and dried if the tools cannot be confirmed dry in the tablet press turret.

33.3.5 Cup depth, overall length, and working length

These are the most critical dimensions in any tooling program that relate directly to final tablet thickness, weight, and hardness. The overall length (O.L.), is a reference dimension and, therefore, does not have a specified tolerance. A reference dimension is defined by the Machinery Handbook (2) as

> A dimension, usually without a tolerance and used for information purpose only. It is considered auxiliary information and does not govern production or inspection operations. A reference dimension is the repeat of a dimension or is derived from other values shown on the drawing or on related drawings.

The two dimensions comprising the punch overall lengths are the working length and the cup depth, with the exception of flat-face tip configuration, which does not have a cup and is used to compress a wafer-type tablet. The two dimensions are the working length dimension, with a tolerance of plus or minus 0.001″, and the cup depth, with a tolerance plus or minus 0.003″. Combining the two tolerances that affect the O.L. of a punch, the calculated tolerance would be plus or minus 0.004″. The major concern with these dimensions is to maintain consistency within a set of punches in order to maintain tablet weight, hardness, and thickness. The more critical of the two dimensions is the working length (W.L.). The W.L. needs to be inspected as a single dimension and preferably for consistency within the given working-length tolerance, and not for a number formulated from the cup depth subtracted from the overall length. A set of punches should be separated into uppers and lowers and inspected for variances as such. For example, all of the upper punches are checked for length consistency, and then all of the lower punches are checked as a separate unit. As long as both upper and lower punches fall within the desired tolerance range, tablet thickness, hardness, and weight will be consistent.

Although the cup depth is not responsible for tablet thickness, it should be confirmed within the given tolerance to maintain tablet overall consistency, and it too should be inspected as single dimension (Fig. 33.4).

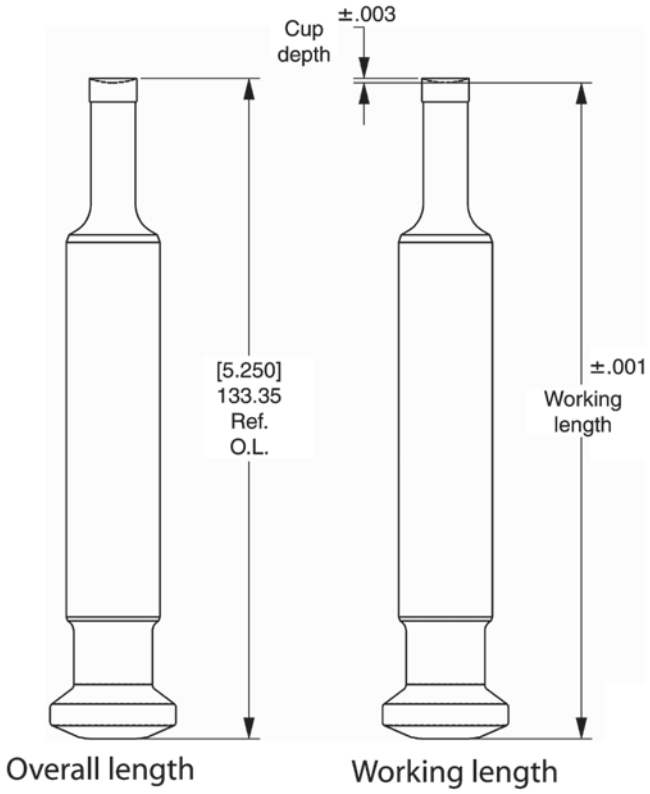

FIGURE 33.4 Overall and working lengths.

33.3.6 Tooling options

During the 1980s, the tablet compression industry was introduced to higher speed and more automated tablet presses that assured interchangeability with the "TSM" standard tool configurations. Although the standard tool configuration may be compatible, in some cases, it was not optimal and required minor modification to achieve expected performance. In addition, the standard tool configuration may not be desirable for compressing certain products. All products are different and have unique characteristics, and therefore, may require slight tooling modifications. Tablet manufactures need to be informed of available options to achieve the best possible performance from the tablet press and tooling. The next section provides a description of tooling options that can be a benefit on both high-speed and standard presses.

33.3.6.1 Common tooling options

33.3.6.1.1 Domed heads

The domed head configuration is adaptable to both the upper and lower punch, and maintains the identical top head radius and head flat as the "Eurostandard." It is an option only for the "TSM" head configuration and is compatible with the American "TSM" cams, and

should be considered for all high-speed tablet presses. As the speed of the tablet press continues to increase, tablet manufactures are coming to realize the advantage of the domed-style head with the larger top radius. The domed head style has several advantages over the standard "TSM" head profile. The larger 5/8″ radius on the domed head reduces the enormous stress that is more common with the smaller 5/16″ radius on a standard head when the punch makes initial contact with the pressure roller. This stress can cause a condition called head pitting, which is identified by voids on the head flat. The impact of the pressure roller and head radius at high speeds and heavy forces can cause a work-hardening effect, contributing to the pitting of the head flat. This form of pitting is detrimental to the life of the punches and pressure rollers. The domed head configuration provides a smoother transition into the compression cycle of the tablet press, reducing stress and premature wear of the pressure rollers (Fig. 33.5).

33.3.6.1.2 Punch head flats

The punch head flat is located at the opposite end of the punch tip. It is usually the flat on top of the largest diameter of the punch. The head flat provides dwell in the cycle of compression. Dwell as related to tablet compression can be defined as "time spent in the same position." "Time spent in the same position" refers to the time the punch is held vertically in-between the pressure rollers; this time is generally measured in milliseconds.

Dwell time is dictated by the rotational speed and pitch diameter of the turret and the size or diameter of the punch head flat. The punch head flat is an "important" dimension, but is not considered a critical dimension of the punch. As with all important dimensions of the punch, it is essential to maintain a dimensional consistency within the entire set. In general, the majority of powders or granulate formulated for compression will produce quality tablets that meet all requirements, even if the punch head flat diameter is spread and using the entire tolerance range. A discrepancy related to physical tablet specifications, which may be correlated with the inconsistency of the head flat, is typically uncommon. If maintaining tablet consistency becomes challenging, knowing and understanding the importance of the head flat becomes essential.

For products requiring longer dwell time, the punch option commonly referred to as the "extended head flat" is an attractive alternative to the standard head flat (Fig. 33.6a). The extended head flat option maximizes the flat area by reducing punch head top radii, thus resulting in a larger flat diameter. The extended head flat will increase the dwell time, or the time under full compression between the pressure rollers. The extended dwell time can aid in reducing tablet defects, such as low hardness, laminating, and even capping. The extended head flat option can also help to reach the maximum press speed, yielding optimal production for powders difficult to compress.

However, the extended head flat option does increase the physical head flat diameter to a dimension critically close to the punch neck diameter. If the maximum compression force or dwell initiates at a point on the top of the punch head, which is outside the neck diameter below, it can create dangerous stresses in in

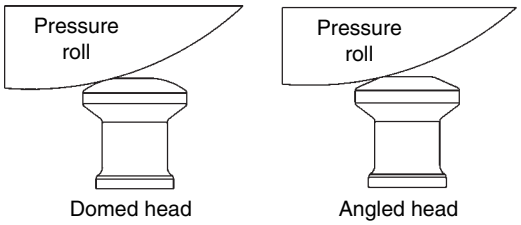

FIGURE 33.5 Note: Differences between TSM and TSM domed.

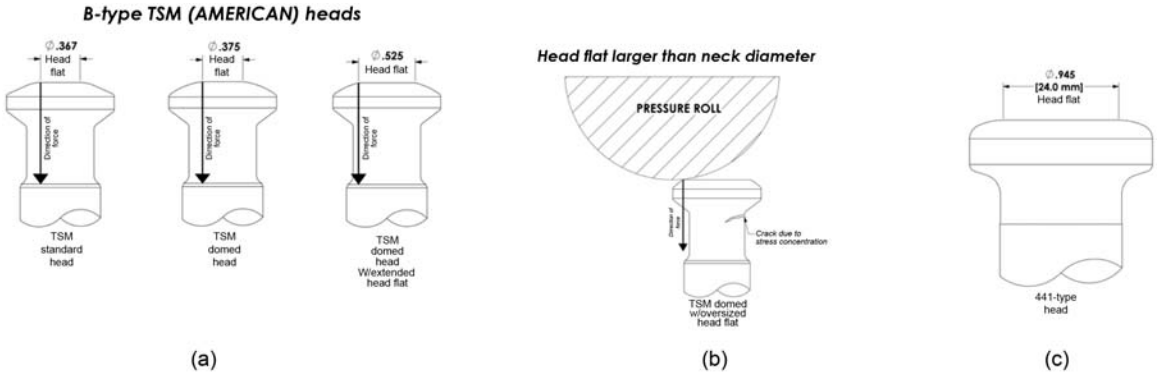

FIGURE 33.6 Dwell time.

the steel that are prone to fracture the punch head or even the punch neck, which may result in extensive machine damage (Fig. 33.6b).

Some tablet press manufactures provide an option to substantially increase the punch head flat dimension by using special cams and neckless style punches. This configuration is sometimes referred as the Neckless 441 design and is an option only for "D" type punches (Fig. 33.6c).

The procedure of reworking the punch head is common and is performed to reduce the rolling fatigue or pitting generally caused from excessive pressure, improper lubricants, and insufficient lubrication, contamination from airborne powders and improperly wearing and/or aligned machine parts. The procedure of reworking the head should only be performed by a trained technician in order to maintain the proper dimensions.

Introducing a new and unused spare punch into a well-worn set of punches should be done with caution because the new punch head flat may be inconsistent with the worn punch. It is advisable to check the critical working length and compare it with the worn punch to assure compatibility before adding it to the set.

33.3.6.1.3 Rotating heads

The rotating punch head is a two-part punch configuration, the head is separate from the punch barrel and tip, allowing the head to be removed and replaced as the head wears. When compressing round tablets, the punches will rotate as they are pulled around the cam track through the various stages of the tablet compression. As the punches rotate, the wear and stresses on the back angle of the head are distributed around the entire back angle-bearing surface. When compressing tablet shapes other than round, the punches do not rotate, causing the wear to be concentrated at a single point, which results in premature head wear. The wear is distributed along the entire surface of the back angle because the rotating head configuration allows the head to rotate when compressing nonround tablet shapes. This helps to decrease head wear and prolong the life of the punches (Fig. 33.7a).

33.3.6.1.4 Mirror-finished heads

Some high-speed tablet presses use heavy metal cams, such as bronze and bronze alloys. This material is good for eliminating premature head wear and prolonging tool life, but it has a negative effect because it contaminates the lubrication and turns it a black, dark-green color. The typical finish of a punch head is done with fine emery or fine abrasive pads. This finish leaves fine radial lines on the contact surfaces of the heads and has a filing effect on the softer cams,

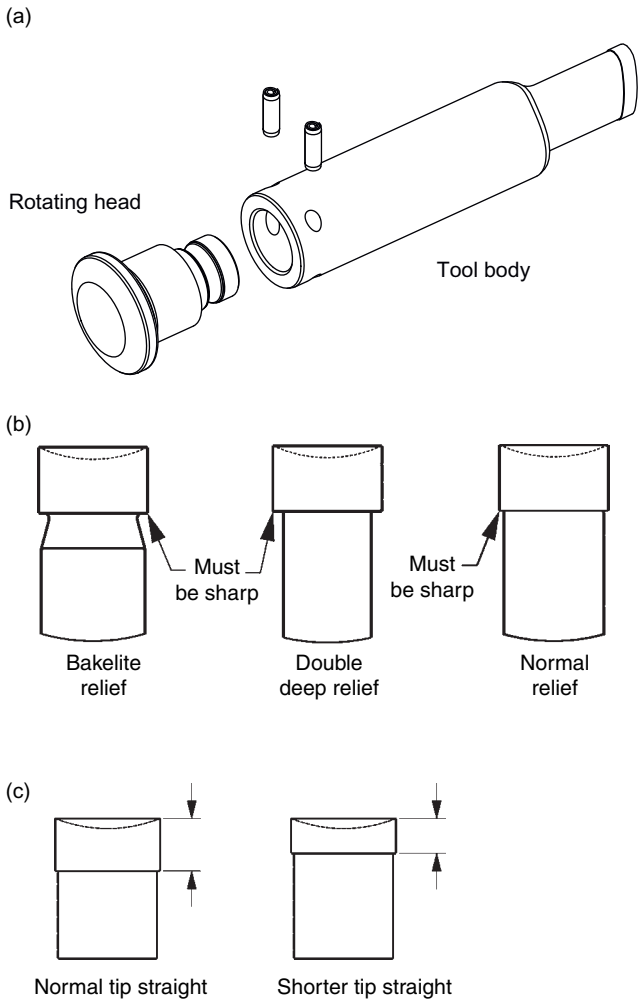

FIGURE 33.7 (a) Rotating head. (b) Punch tip reliefs. (c) Punch tip straights.

causing discoloration of the lubrication and premature cam wear. Polishing the punch heads with a soft cotton wheel and fine polishing compound to a mirror finish helps keep the lubrication cleaner and prolongs cam life.

33.3.6.1.5 Bakelite relief and double-deep relief

It is important to maintain a sharp edge around the lower punch tip relief. A sharp edge assists with the pull-down cycle of the lower punch after tablet ejection. If residual product is adhered to the die wall, the sharp lower punch tip relief will help scrape the die clean as well as cutting through the product to reduce the possibility of product wedged and re-compressed between the punch tip and die wall. Product wedged between the punch tip and die wall may cause excessive heat and thermal expansion of the punch tip. This could result in punch binding and/or seizure, premature head wear, tablet

discoloration, or burning and dark specs contaminating the tablet. A bakelite relief assures a sharp edge to assist with removing product adhered to the die wall, allowing the punch tip to move freely in the die. A "double deep relief" increases the depth of the lower punch relief and provides the same results as the bakelite relief; both designs assure a sharp edge at the punch tip. The bakelite relief is an added-cost option for punches, whereas the double-deep relief is generally a no charge option (Fig. 33.7b).

33.3.6.1.6 Short lower punch tip straight

The lower punch tip creates a tremendous amount of friction because it travels the full length of the die through the various stages of tablet compression. When compressing sticky products or products with a low melting point, the friction created by the lower punch tip can cause lower punch binding. Reducing the bearing surface of the lower punch tip will reduce friction, allowing the punch to travel easier in the die and reduce operating temperatures.

33.3.6.1.7 Punch-barrel chamfers

Punch-barrel chamfers are required on punches used with presses fitted with rubber or plastic guide seals. The barrel chamfer has an advantage over the common break edge for these press models. The absence of a chamfer on the tip end of the punch can create difficulties while installing punches. Forcing the punch past the seal can damage to the seals, resulting in seepage of lubrication from the upper-punch guides, inherently causing product contamination. Damaged lower guide seals can allow product seepage into the lower-punch guides as well as mixing with the lubrication, causing tight punches and possibly press seizure. A barrel chamfer on the head end of the punch can reduce wear of the punch guides caused by the punches being cocked from the torque of rotation as the punch travels vertically in the guides (Fig. 33.8).

33.3.6.1.8 Key types and positions

Punch barrel keys are mandatory for upper punches when compressing nonround tablets. The upper punch key maintains alignment of the tip for reentry into the die for compression. Keys are not generally required for lower punches because the lowers do not leave the die during the compression cycle, so maintaining alignment is not required. Keys may also be required when compressing round tablets with embossing to eliminate the punch from spinning after compression, causing damage to the embossed tablet and reducing the likelihood of a "double impression" on the tablet face. The punches may also require keys when the orientation of embossing for the top and bottom of the tablet is required to be constant.

Keys fitted to the upper punches are available in two configurations: (1) the standard Woodruff key, sometimes referred to as the pressed-in key and (2) the feather or flat key, often referred as the European key.

The Woodruff key, often referred to as the half-moon key because of its shape, is available in two styles, standard and the Hi-Pro. The Hi-Pro key has a tab on each side of the exposed top section and rests on the barrel. The taps keep the key secure by eliminating the rocking action common to the standard Woodruff. To obtain maximum security for high-speed presses, the Woodruff key is fastened into the barrel using screws. The Woodruff key can swell the barrel at the position of the key slot as is pressed into position, causing excessive drag and sometimes galling of the upper punch and punch guide.

The feather key is a longer, flat key, and comes in a variety of lengths, depending on the tablet press. Unlike the pressed in Woodruff key, the feather key fits into a milled slot and is secured into position using machine screws.

The height and radial position of a key is critical to obtain maximum press performance. Unfortunately, no standard has been established due to the particular requirements of the many styles of tablet presses. If the key is placed too low or is too long, it can interfere with the upper punch guide seal and cause damage and/or seepage of lubrication, resulting in product contamination. If the key is too high, it can travel out of the key slot at the top of the punch guide, resulting in severe damage to the punches and press (Fig. 33.9).

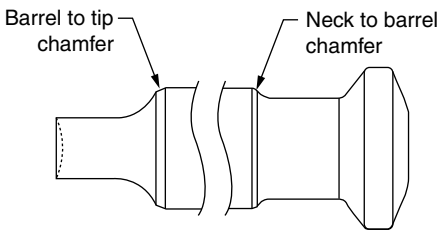

FIGURE 33.8 Punch and barrel chamfers.

33.3.7 Tool configuration for small and micro tablets

It is common to experience difficulties maintaining tablet hardness, thickness, and weight while compressing small and micro tablets. Compression force is sensitive and will generally require minimum forces. In some cases, the tablet is compressed by the weight of

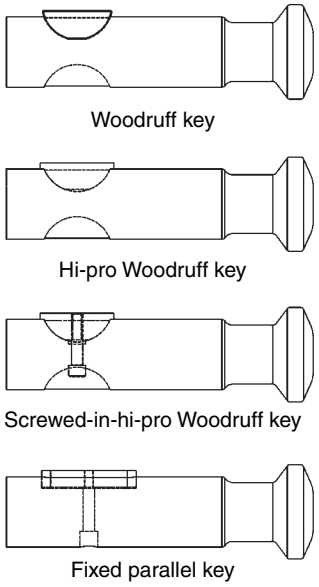

FIGURE 33.9 Key types.

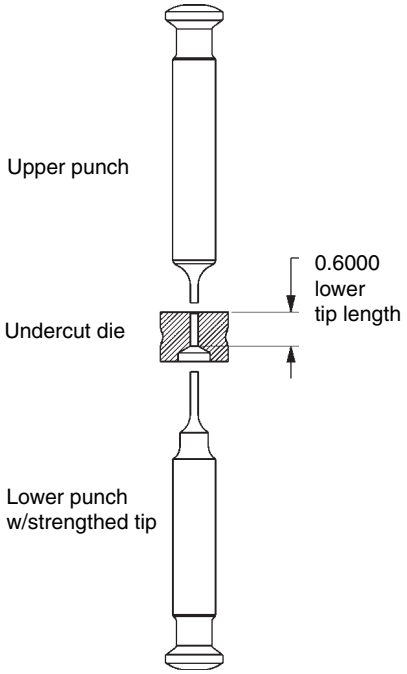

FIGURE 33.10 Tool configuration and micro tablets.

the punch. Excessive tonnage can distort the punch tip and alter the critical working length, making tablet consistency virtually impossible. Tip breakage is also frequent and can damage additional punches and the tablet press, most commonly the feed frame. A special tool configuration is recommended for compressing tablets smaller than 0.125″ (3 mm). This configuration modifies the punches and dies and is used in conjunction with a shallow fill cam that is fitted on the press to minimize lower punch travel in the die. The punch modification involves shortening the punch tips and eliminating the lower punch relief. Shortening the tip straights to their minimum length will strengthen the tip, considerably increasing the maximum compression force. The lower punch tip relief is removed to reduce the clearance between the tip stem and the die bore, providing additional support to the tip stem, thus decreasing distortion. Reducing the tip length increases the barrel length; therefore the bottom of the die is undercut to accept the longer barrel for tablet ejection (Fig. 33.10).

33.3.8 Tapered dies

A tapered die has numerous advantages. A die can be tapered on one side or on both sides, with the advantage of turning the die over and doubling its life. The biggest advantage of a tapered die is to exhaust trapped air in the product as the upper punch enters the die at the beginning of the compression cycle. This is especially helpful for deep-cup punches, fluffy granulation, and high-speed presses. A tapered die provides the ability to compress a harder tablet with the same amount of pressure required with a straight die. It is helpful in reducing capping and laminating. Taper will allow the tablet to expand at a slower rate because it is being ejected from the die, reducing stress that can cause lamination and capping. Taper decreases the ejection force, prolonging the life of the lower punch heads and ejection cam, thus reducing friction and allowing the press to operate at a lower temperature. Tapered dies help align the upper-punch tip upon entering the die, eliminating premature tip wear—this is especially helpful for presses with worn upper-punch guides. A standard taper on a “BB” or “D” die is 0.003″ by 3/16″ deep. Die taper can be tailored to meet special requirements. Although there are numerous advantages with using taper, there are also disadvantages. The upper punch can wedge in-between the punch tip and die wall as it’s pressed into the die because the taper is conical with the largest area at the top. Excess product can migrate between the punch tip and die bore due to the additional punch tip to die bore clearance as a result of the taper. If the upper punch is wedged and sticks in the die, it will be evident by spotty tablets and/or premature wear at the back angle of the upper punch (Fig. 33.11).

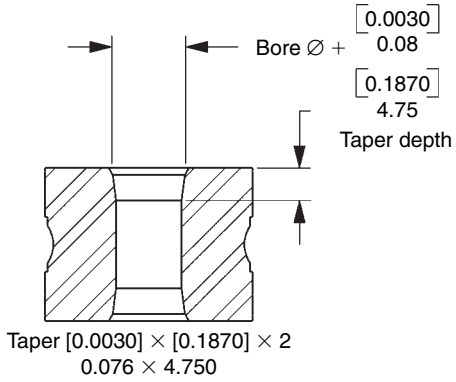

FIGURE 33.11 Tapered die.

33.4 TABLET DESIGNS

Proper punch face contour is essential for tooling life and tablet quality. The compression force should be determined during the R&D phase of a new product. If heavy compaction forces are required, a shallow- or standard-cup configuration should be considered to assure satisfactory tooling life and tablet quality. If the compaction force is to remain light to standard, a variety of configurations may be considered. Compression force has a lateral force that can expand the sides of the punch cup outward toward the die wall.

Excessive pressure can permanently distort and cause premature failure of the punch tip. For a high compaction force the cup may be strengthened by:

1. Increasing the land area on the punch tip to provide additional strength
2. Reducing the hardness of the punch tip, allowing the tip to flex without breaking
3. Increasing the cup radius or decreasing the cup depth to eliminate the damaging effect of flexing and abrasion to the inside of the cup

The flat-face bevel edge (FFBE) tablet configuration is subjected to the same lateral force. These edges can be strengthened by steps 1 and 2 and by increasing the radius between the flat and the bevel, which is normally 0.010–0.015″. The flat-face radius-edge (FFRE) configuration provides a stronger punch tip than the FFBE and can eliminate edge chipping by reducing sharp corners on the tablet face. Another common cup configuration is the compound cup. The compound cup has two radii, which makes the tablet roll better during the coating process, eliminating tablet-edge erosion. The compound cup design generally has more cup volume and is the optimum tablet design for heavy tablets because it generally reduces the tablet band, giving the tablet a thinner appearance. However, the compound cup is one of the weakest tablet designs

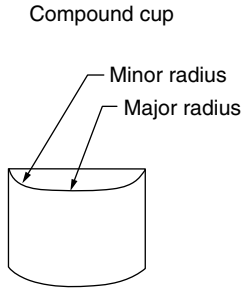

FIGURE 33.12 Compound cup.

due to the stresses created at the intersection of the two cup radii and the steep cup, which causes excessive abrasion during compression, shortening the tool life (Fig. 33.12).

Elaborate three-dimensional cup configurations are becoming more common in the candy and vitamin industry. It is critical that compaction forces are determined during the R&D phase and results provided to the tooling manufacture because of the high- and low-cup designs.

The concavity standards for round punch tips are published in the TSM. These standards (Table 33.3) include cup depths for shallow, standard, deep, extra deep, modified ball, FFBE, and FFRE. For radius cup designs, the "TSM" identifies the cup by the cup depth, whereas the European tableting industry identifies the cup by the cup radius (Fig. 33.13).

33.4.1 Tablet shapes

There are as many tablet shapes as there are applications, which are endless. Tablets are used in automobile airbags, batteries, soaps, fertilizers, desiccants, and buttons, just to name a few. Historically, round tablets were the most common, uncomplicated, and easy to set-up and maintain. Special-shape tablets are tablet shapes other than round, and include shapes such as capsule, oval, square, triangle, etc. Exotic shape tablets are more unique than round or special shapes. Exotic-shaped tablets include animal and heart-shaped tablets and other unique tablet shapes that require an internal radii or angle (Fig. 33.14).

A unique tablet shape will provide better tablet identification, which helps maintain consumer interest and loyalty.

The most common special shapes in the pharmaceutical industry are the capsule, modified capsule, and oval shapes. These shapes typically accommodate more volume and are more unique than standard rounds. A film-coated tablet is better to use with a modified capsule, rather than a capsule shape, to eliminate twinning during the coating process. A modified

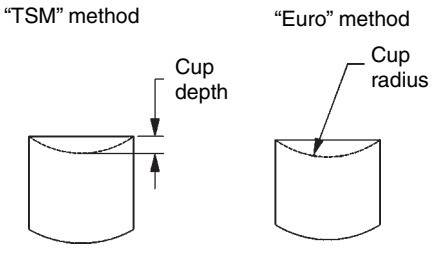

FIGURE 33.13 For radius cup designs, the TSM identifies the cup by the cup depth, whereas the European tableting industry identifies the cup by the cup radius.

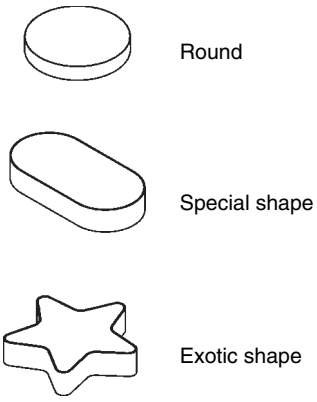

FIGURE 33.14 Basic tablet shapes.

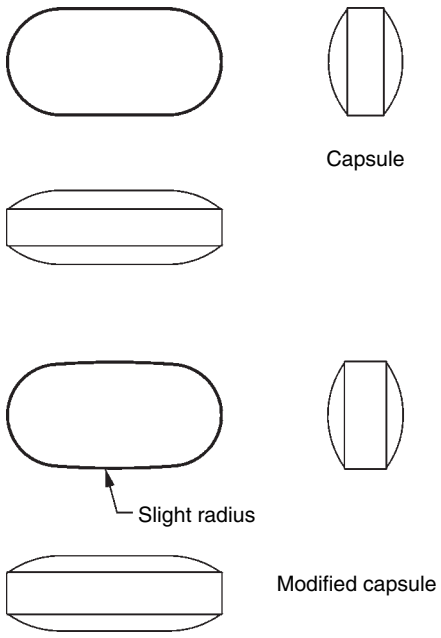

FIGURE 33.15 Capsule and modified capsule shapes.

capsule shape can be designed to have the appearance of a capsule shape with the advantage of a radius on the major axis, reducing the contact surface area during the coating process (Fig. 33.15).

33.4.2 Tablet face configurations

Tablet shapes are virtually infinite, as are tablet face configurations. The tablet face configuration is commonly referred to as the "cup" of the punch. The cup is the area at the tip end of the punch that is responsible for the configuration of the top and bottom of a tablet. The "TSM" provides cup depth standards for the six most common cup configurations for round tablets.

The "TSM" defines the cup depth of single radius tablet configurations by the depth of the concavity and differs from the "EU" configurations, which use the cup radius value. The cup radius is more difficult to check and to set internal limits for reworking.

A single radius cup is the strongest cup configuration and is the most common configuration for round tablets. Adding another radius to the cup changes the cup configuration to a compound or a dual-radius cup. The compound cup has the advantage of having more volume than the single radius cup. Increased volume to the cup will reduce the size of the "belly band," making the tablet appear thinner and easier to swallow. The configuration of compound cup is better for film coating. The rounded edges tend to roll better in the coating pan, reducing the possibilities of edge erosion. There are several disadvantages to using the compound cup design. The intersection of the two cup radii becomes a high-stress point, which is prone to failure under extreme loading, and therefore has a much lower maximum compression force rating than the single radius shallow and standard cup. Extreme loading is not uncommon with the compound cup configuration. The compound cup has more volume; therefore as the upper punch cup enters the die, it fills the die with air, and then must be extracted before compression. For this reason, the compound cup commonly requires slower press speeds or higher compression force than a single radius shallow or standard cup. The compound cup sidewall is steep and receives high abrasion as the tablet is compressed, wearing the tip and weakening the cup. The tip land is critical to the punch tip strength and should be checked often for wear. If the land wears thin, it will cause a condition known as "J hook," which is a common cause of capping and laminating. The land is easily refurbished using 400-grit sharpening stones and a large cotton buff wheel. The compound cup design has a smaller window or available space for engraving and printing than the single radius shallow and standard cup.

Three-dimensional cup configurations are common with vitamins and candies. The three-dimensional cup configuration provides raised features on the tablet surface, providing the opportunity to sculpt features and character details.

33.4.3 Undesirable shapes

A tablet shape too close to round may cause a condition known as punch-to-die binding or self-locking. These shapes must be avoided in order to provide maximum tablet output and satisfactory tool life (Figs. 33.16 and 33.17).

The corner radius of a special shape, such as a square and triangle, is critical for maintaining the strength and integrity of the die. A corner radius less than 0.032″ can cause excessive stress and failure as the die is locked into position with the die lock and subjected to the shock of tablet compression.

33.4.4 Tablet identification

There are two basic methods for identifying a tablet—printing and engraving, with the latter being the most common. There are two styles of engraving—embossed and debossed. With debossing, the identification is raised on the cup face and engraved into the tablet, while embossed identification is cut into the cup face and raised on the tablet (Fig. 33.18). These two styles can be used in conjunction with each other.

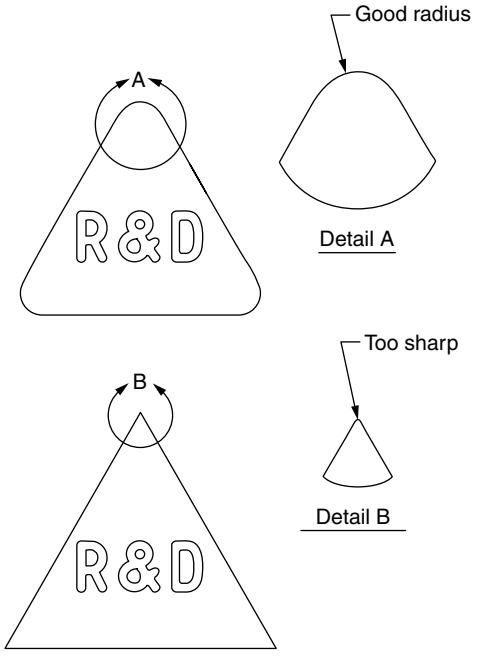

FIGURE 33.16 TSM versus euro method to identify cup radius.

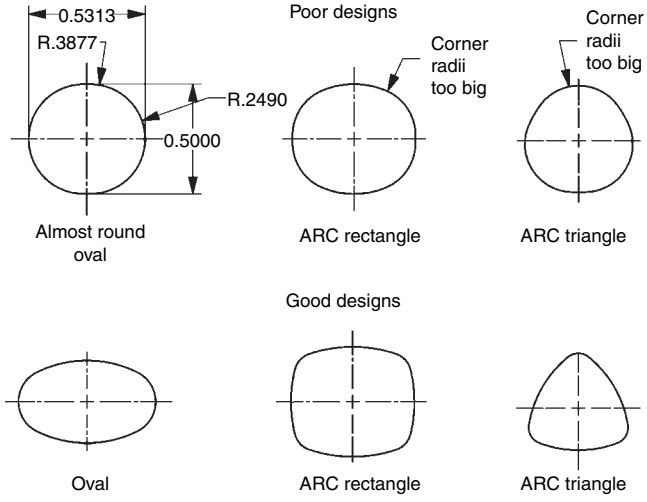

FIGURE 33.17 Good designs versus poor designs.

FIGURE 33.18 Raised embossing in panels.

To ensure product identification, many companies engrave their corporate logos on their product line. As tablet size decreases, the legibility of the identification tends to diminish, eventually reaching the point at which it is no longer legible. For this reason, tablet manufacturers should consider the entire range of tablet sizes when considering the format of a logo for better legibility. As a tablet decreases in size, the logo and drug code are subject to picking (product sticking in or around the identification). Formulation data and product history, if available, should be provided to the tooling manufacturer so that they may engineer an engraving style and format to help minimize picking and sticking because some products are more prone to picking than others.

A company that engraves or embosses most or all of their tablets should consider maintaining a character font. The font should be designed to eliminate sharp corners whenever possible and opening the closed-in areas of a character as much as possible (Fig. 33.19).

For sticky products, the engraving style can be designed to pre-pick the islands of a character, for example, filling in the centers of the "B," "R," "0," "8," etc. The pre-pick character can be difficult to film coat and is prone to fill in and bridging, and therefore the characters can be partially pre-picked for film coated tablets. A partial pre-pick is generally preferred and only removes a percentage of the island instead of removing the island completely. A ramped engraving style, also referred to as a tapered peninsula, provides the same advantage as a pre-picked style and, when used at the outside corners, opens areas of a character. It provides a lower depth of these areas and then tapers the tablet surface (Fig. 33.20).

The radius at the top of an engraving cut at the tablet surface can be a main contributor to picking and tablet erosion. A general guide for the value of the radius is approximately one-third of the engraving cut depth. For example, if the engraving cut depth is .012″, then the radius at the top of the engraving should be 0.003″/0.004″.

FIGURE 33.19 Poor font choice versus good font choice.

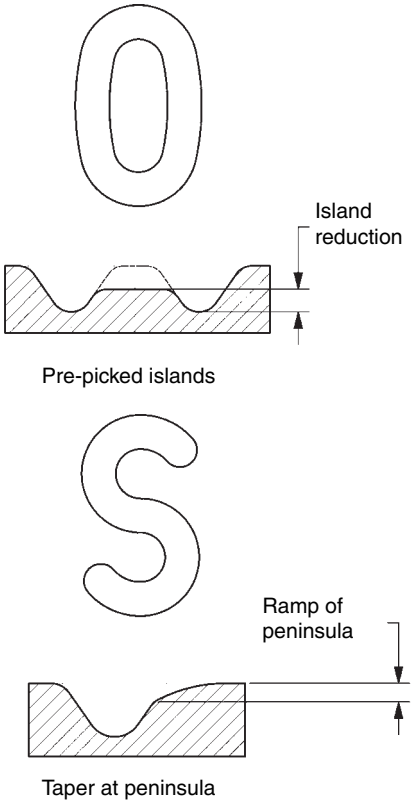

FIGURE 33.20 Partial pre-pick and tapered peninsula.

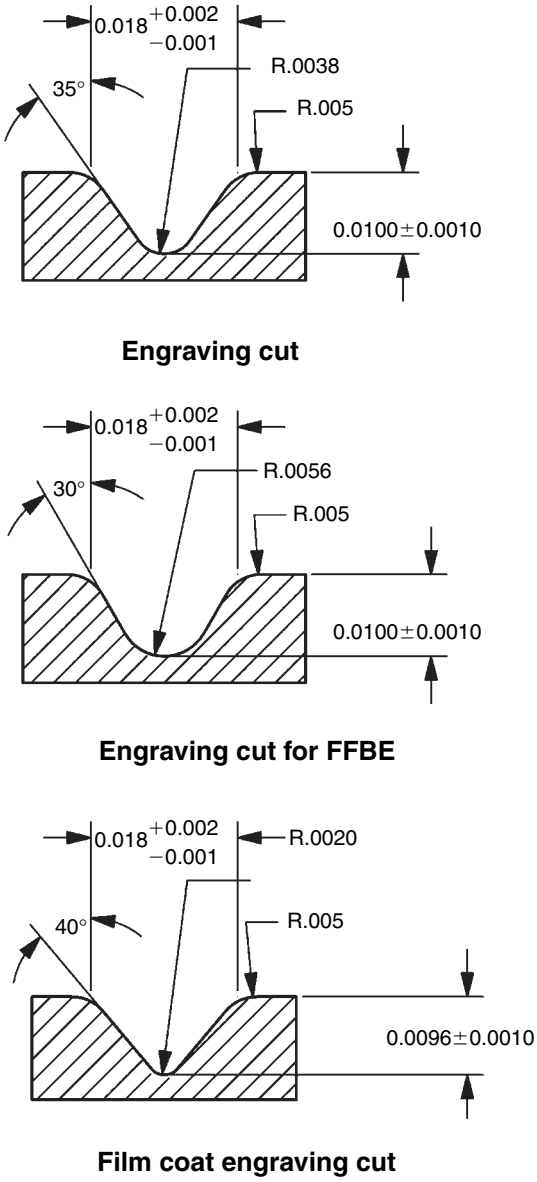

FIGURE 33.21 Engraving cut angles.

The angle of a standard engraving cut for a noncoated tablet is 30 degree. If sticking occurs, it is recommended to increase the angle to 35−40 degree, which is the angle recommended for film-coated tablets. The wider engraving angle may diminish legibility of the engraving cut by allowing more light into the bottom of the cut, but has a better draft angle that provides improved product release (Fig. 33.21).

Incorrectly placing an engraving cut too close to the tablet edge or to the secondary radius for compound cups can result in punch-tip fracturing. Although tooling manufacturers generally maintain certain guidelines for the layout and configuration of the engraving, they must consider the amount of engraving in relation to the tablet size, tablet configuration, and product characteristics before releasing the final tablet design for approval.

33.4.5 Bisects

Bisects, commonly known as a score or break line, are available in a variety of styles.

The purpose of a bisect is to break the tablet into a predetermined dosage, most commonly two equal parts. Breaking a tablet into prescribed dosages should give the consumer a certain degree of confidence that they are receiving the proper dosage. Bisects should be placed on the upper punch whenever possible. Placing the bisect on the lower punch can create problems when the take-off bar removes the tablet from the lower punch. The depth of the bisect is generally deeper than the engraving cut, therefore making it difficult to slide the tablet across the punch face at the ejection cycle.

The standard "TSM" bisect has two different configurations for concave tablets: protruding and cut flush. The protruding bisect style follows the curvature of the cup and extends past the tip edge of the punch. This style helps break the tablet into equal parts because the extended bisect is pressed into the tablet band. The problem with this style is that the protruding bisect may run into the tip edge of the lower punch

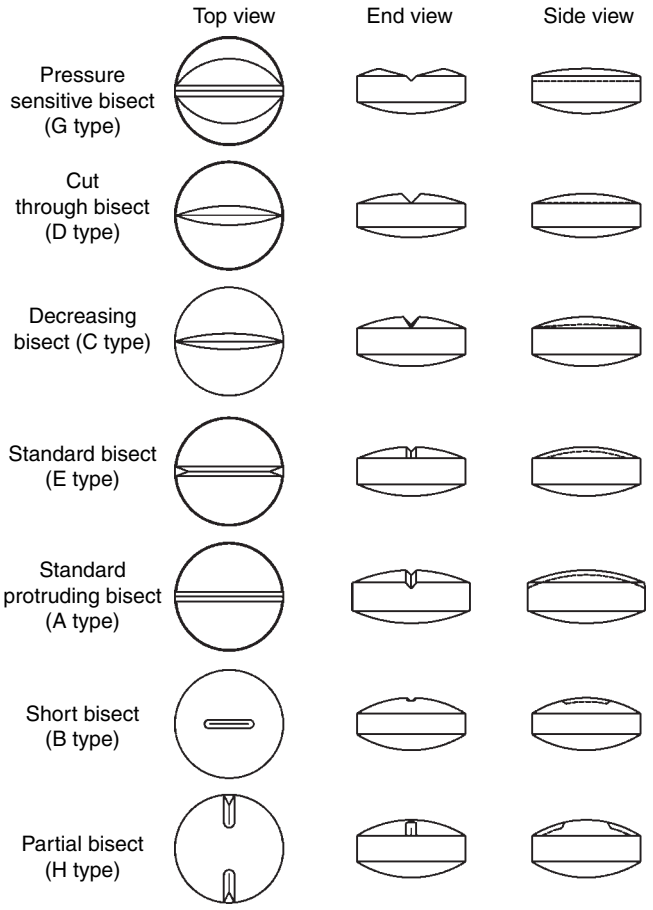

FIGURE 33.22 Bisect types.

if they become too close during tablet press set-up or if the tablet press continues to cycle after the hopper has been emptied. Hitting the bisect into the lower punch edge will leave deep impressions while smashing and swelling the protrusion of the bisect on the upper punch. Standard cut-flush bisect has become more popular for this reason (Fig. 33.22).

A cut-through bisect, also known as a European-style bisect, can only be used on radius cup designs. It has an advantage over the standard bisect by allowing the consumer to easily break the tablet into equal dosages. The cut-through bisect is wider at the center of the tablet than the standard bisect, which reduces the available engraving space on the tablet face. The height of the cut-through bisect is generally the same as the cup depth.

33.4.6 Steel types

Choosing a steel type is generally left up to the tooling manufacturer, unless a specific type has been requested. The criteria for selecting a steel type includes the quantity of tablets to be produced, the abrasiveness or corrosiveness of the granulation, the pressure required for compression, and the cup configuration.

There are two basic categories of steel common in the tablet-tooling industry that are standard and premium. Although the categories may imply that one is superior in quality to the other, this is not the case. Standard steel is the most commonly used grade, whereas the premium grades are used generally for abrasive products and special applications. The cost is generally higher for premium steels due to the quantity of material purchased by the tool manufacturer and the steel composition. Premium steels tend to be harder and more difficult to machine. Premium steels are harder, so they can also be more brittle and prone to fracturing under excessive pressure. Commonly used standard steel grades are: S-5, S-7, S-1, and 408, and premium steel grades D-2, D-3, 440-C stainless steel, and 0–1. Table 33.4 shows the maximum compression.

TABLE 33.4 Maximum Compression

Punch tip diameter	Max compression force by cup depth (kilonewtons)						
	Shallow concave	Standard concave	Deep concave	Extra-deep concave	Modified ball	FFBE	FFRE
1/8	12.5	4.4	2.7	1.8	1.0	3.7	4.9

1	770.0	552.0	445.0	185.0	63.0	119.0	311.0

33.4.7 Inserted dies

Dies are normally manufactured from D-3 premium steel. D-3 steel is superior for wear, but due to its high carbon and high chromium content, does not provide toughness. Dies are not subjected to the same stresses or shock as the punches and, therefore, can be manufactured from harder and better-wearing steels.

The most common die for compressing abrasive granulation is the carbide-lined die. The carbide-lined die has a carbide insert that is inserted into a steel sleeve, which provides a cushion to reduce the possibility of chipping and fracturing the carbide insert. Carbide dies are more expensive than steel dies and are easily justified with the extended die life because die life is easily increased by 10 times in most cases. Carbide die is more brittle and subject to fracturing under excessively heavy compression forces because it is much harder.

If the carbide insert is too thin at its narrowest point due to the tablet size, the carbide insert can fracture due to die-lock pressure and stresses of tablet compression. This is also true for the steel sleeve. The tooling manufacturer should be consulted to determine if a tablet size is acceptable for a carbide liner.

Ceramic-lined dies are becoming more widely used as tougher grades become available. The most common ceramic grade used for compression dies is currently partially stabilized zirconia (PSZ). Dies lined with PSZ have the same general wear characteristics and require the same precautions as carbide-lined dies, but have an advantage in reducing the friction coefficient during the fill and ejection cycles.

When inserting carbide or ceramic dies into the die pocket, a die-driving rod fitted with a nylon tip should be used to prevent carbide fracturing. Die-lock pressure should also be reduced by 10%.

33.4.8 Multitip tooling

Normally, one punch compresses one tablet, with the exception occurring when using multitip tooling. Multitip tools are more common in Europe and have only recently been accepted in the United States. The multitip tool configuration is engineered to compress more than one tablet at a time with the total number of tablets per punch dictated by the punch size and tablet size.

There is a tremendous advantage for using multitip tooling when considering production, operating efficiency, and overall capacity. Increasing production by the multiple of punch tips can be achieved, but typically should not be expected. Using the formula, tablets currently produced $\times$ number of punch tips $\times 0.9 =$ number of tablets expected, will provide a more accurate estimate of the TPM rate.

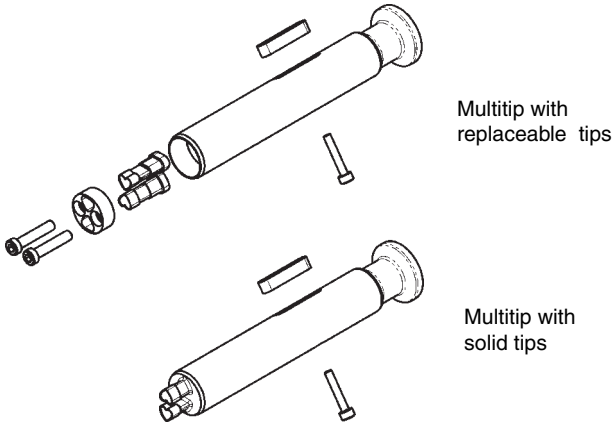

FIGURE 33.23 Multitip tools with replaceable tips and solid tips.

Multitip punches are available in two configurations: a solid punch or an assembly with multiple parts. The solid punch design is easier to clean because it does not have multiple parts, unfortunately, however, if only one tip is damaged the entire punch is unusable and discarded. The multiple part punch design separates the punch tips from the punch body, The punch tips are fixed in place using a cap and/or set screws. If a punch tip is damaged, it can be simply removed and replaced, putting the punch back into service. To properly clean the multiple part design, the tool is required to be disassembled, cleaned, and dried thoroughly before reassembly. This procedure can require substantial labor.

Tablet compression and ejection force most likely will increase, as will the operating temperature. To reduce the potential of product sticking in the punch face, it is suggested to monitor the tablet press and tooling operating temperature. If the compression and/or ejection force becomes too great, the punches may show premature wear on the head flats and back angles and excessive wear on the tablet-press cams.

It is recommended to use the rotating head option for the lower punch. The rotating head will reduce punch in die friction by allowing the punch head to spin freely as it takes the pressure away from the punch tips in the die. The lower punch will be able to move more easily through the cycles of tablet compression (Fig. 33.23).

33.4.9 Punch-tip pressure guide

Punch-tip pressure is calculated by tablet press manufactures and is dictated by the tablet configuration

and steel type. With the assistance of computer-aided designing and finite element analysis (FEA) software, tooling manufactures have become more accurate with the maximum tonnage for round and shaped tablet designs.

Table 33.4 provides the cup configurations with the corresponding maximum tonnage force for round punch tips. This guide has been calculated from the computer-generated procedure "Finite Element Analysis" and is the most accurate guide available.

Calculating the maximum compression force for shaped tablets (ie, capsule oval etc.) can be difficult and confusing. It is recommended to contact the tooling supplier and request these values. The maximum tonnage for round and shaped tablets should be provided on the engineered tablet drawing provided by the tooling supplier, along with the cup volume and surface area. It is important that these values have a strong presence with R&D and are used when formulating a new product. The tonnage requirement should be acceptable before the product reaches the production phase. If tool failure is experienced at the R&D phase, the tablet can be redesigned to accept the required tonnage.

33.5 CARE OF PUNCHES AND DIES

Great care must be taken when cleaning, transporting, and storing punches and dies because they are precision instruments and can damage easily. Upon receiving punches, they should be cleaned and dried thoroughly prior to use. If standard operating procedures require incoming inspection, then the tools should be inspected immediately and any concerns or discrepancies should be reported to the supplier before the tools are used and/or put into storage for future use. Following inspection, the tooling should be lightly oiled, packed in a protective container, and stored in a dry place.

When tooling is required to be shipped, they should not be shipped in storage containers. Most storage containers are not designed to support the weight of the tooling through the handling practices of commercial freight companies. Tooling should be returned in their original individual plastic or cardboard shipping containers and packed tightly to avoid movement. Punch tips are extremely fragile and should be protected at all times from hitting each other or other hard surfaces. A dent or nick on a punch tip can keep the punch from fitting properly into the die. To avoid damage to the die during tablet press set-up, a proper driving rod should be used when inserting the die in the die table. A mild steel rod with the same diameter as the punch guide fitted with a nylon tip is recommended. To prevent damage to the die, die table, and die lock, the die lock pressures indicated by the tablet press manufacturer's operating manual should be observed. Excessive die-lock pressure can distort the die bore and cause punch tightness, fracture the die, and even crack the die table, which would cost thousands of dollars to repair.

33.6 TOOLING INSPECTION

Tooling inspection programs are becoming more common and are performed as a precautionary measure to reassure critical dimensions and embossing details. Confirming critical dimensions will also confirm clearances between the punch and mating parts of the tablet press. Most tooling suppliers will provide a detailed inspection report or a certificate of conformance to assure tablet manufacturers that a specific set of tooling is within the specified tolerance and is capable of producing consistent and quality tablets. The inspection area should be a atmospheric-controlled environment, well-lit for visual inspection, and equipped with calibrated measuring equipment instruments and gauges.

The tooling inspection program should be divided into two sections: incoming inspection and in-process inspection.

The incoming inspection program is for new tools and confirms adherence of critical dimensions. Tools that are supplied with a detailed inspection report should be verified by checking a small percentage of tooling to qualify the supplier's inspection report. A confirmation of the checked dimensions should be recorded and maintained for future reference.

The in-process inspection procedures are recommended for determining wear subjected on critical dimensions responsible for tablet quality and press operation. The most important dimension affecting tablet hardness, weight, and thickness consistency is the working length of the punches. It is not critical to inspect the working length for a calculated dimension, but to instead inspect for consistency within the set. During the inspection process, it is good practice to determine if the punches and dies are in need of polishing and/or light reworking.

The outer dimensions of the punch tip are also critical for inspection and examination. Unfortunately, the worn punch tip is difficult or nearly impossible to inspect using traditional measuring instruments, such as a micrometer or an indicator. The punch tip wears at the edge of the cup and can only be measured accurately using an optical comparator. Dies should be visually checked for wear rings in the compression

zone, and replaced if worn. The severity of a die-wear ring can be checked with an expanding indicator. The expanding indicator will not provide the actual die size, only the depth of the wear ring. The expanding indicator is also capable of measuring the amount and depth of the die taper.

The results of the working length inspection should be documented in addition to noting tool wear and polishing or reworking, if performed. When tooling wear exceeds the new tool specification, it is not generally considered unusable or out of new punch specification.

33.7 TOOLING REWORKING

If considerable reconditioning of the punches and dies is necessary, the tools should be returned to the manufacturer for evaluation. Extensive reworking of the tooling should be performed only by skilled personnel to assure conformance to strict tolerances, providing tablet consistency and proper press operation.

Polishing the cup is the most common procedure of punch maintenance performed by the tablet manufacturer and can be easily performed with proper training. Improper or excessive polishing can reduce the cup depth and diminish the height of the embossing, thus reducing legibility and the ability to film coat. There are three common procedures of polishing the cup: (1) large soft cotton wheel fitted to a bench grinder motor; (2) a dremel tool using nylon brushes and polishing paste; and (3) drag finishing, a process that drags the punch through a fine media of walnut shells or plastic pellets infused with polishing compound. The most effective methods is using the large cotton wheel. Polishing the cup with a large soft cotton wheel is the only method that polishes the cup and restores the critical land at the same time. Restoring the land can increase tool life, strengthen the punch tip, and reduce the likelihood of capping and laminating. Polishing the punch cups with nylon brushes or using a drag finisher is the simplest method of polishing, but will not restore the tip edge or refurbish the tip land, which removes the hooked edge commonly referred to as a "J hook" that is common in capping and laminating. It is not advised to polish or restore the punch head flat because this can alter the critical working length, resulting in inconstant tablet hardness, thickness, and/or weight.

33.8 PRESS WEAR

Tablet press wear can sometimes be the reason for tooling failure and is often overlooked. As the tolerances of punches and dies are constantly monitored, so should the critical tolerances of a tablet press. For example, if tablet overall thickness is inconsistent, the working length of the punches should be checked first; in most cases this dimension is the easiest to check. If the working length of the punches is acceptable, the tools are usually put back into service to frequently experience a reoccurrence of the initial problem. If the pressure roller is out of round, out of concentricity, or worn with severe pitting or flat spots, the result will be inconsistent tablet thickness, which would be expected with improper punch working lengths.

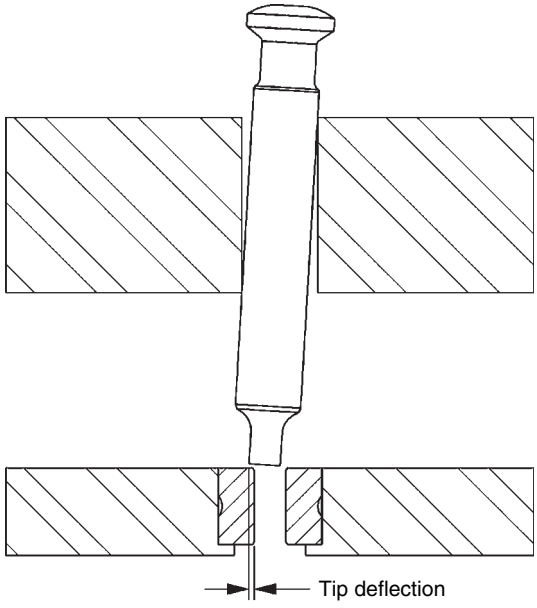

FIGURE 33.24 Deflection of punches indicates excessive wear in turret guides.

Fig. 33.24 shows the correct way to check the turret guide for wear. A new turret may have approximately 0.003″ tip deflection. A turret guide considered worn has a tip deflection of 0.012−0.014″ and should be sleeved or replaced.

Problems in tableting often have a domino effect. It is important to identify and remedy a problem before it affects other areas of the press, the tooling, and the tablet quality.

33.9 PURCHASING TABLET COMPRESSION TOOLING

Considering all the available tooling options and steel types, it can be confusing and complicated to purchase tablet tooling. Before making the final purchase, it is advisable to request a tool and tablet drawing for

approval. Most tooling manufactures can submit a sample tablet made of copper or a special grade of plastic for further approval. The following list is a guideline for information that is needed by the tooling manufacture to properly custom-manufacture tooling that meets the requirements of the product and tablet press:

- The size, shape, and cup depth of the tablet to be compressed (a sample tablet or sample tools would be sufficient if this information is not available)
- Drawing number of the tablet if a drawing exists, if not, request a drawing for future reference
- Hob number, if the order is a replacement
- Press type, model number, and number of stations required
- Steel type if other than standard
- Historical data referencing tablet problems such as capping, sticking, picking, high ejection forces, etc.
- If the tablet is a core and will be coated
- Special options such as tapered dies, domed heads, key type, etc.
- Special shipping instructions

33.10 CONSIDERATION OF TOOLING

Choosing the proper tooling options is critical for a smooth operation. It is recommended to utilize all available industry resources, such as tablet press and tooling manufacturers, for assistance with these choices. It is likely that they have resolved similar difficulties for other customers and have the expertise to recommend the correct options. Recording and maintaining tableting problems are important and should be communicated to the tooling manufacture. Without the knowledge of common tableting problems, the tooling manufacturer can only continue to supply standard tooling.

33.11 APPLICATION OF QUALITY BY DESIGN AND TOOLS (CASE STUDY)

33.11.1 Objective

To develop the compression process parameters and control space for a bi-layer tablet by applying right-first-time (RFT)/six sigma approach.

33.11.2 Methods

The overall approach following the RFT/six sigma is shown in Fig. 33.25. The applied RFT/six sigma tools include failure mode and effects analysis (FMEA), process mapping, critical quality attribute (CQA), critical process parameters (CPPs), cause-and-effect analysis, design of experiment (DOE), control plan, etc.

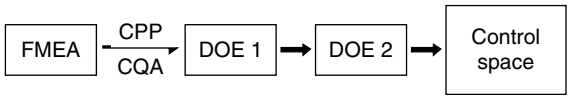

FIGURE 33.25 The overall approach following the RFT/six sigma.

A bi-layer tablet is used for this development. The key ingredient of the formulation includes a water-soluble active pharmaceutical ingredient (API), compressible sugars, flavors, flow-aid, lubricant, and other ingredients. The manufacturing process includes blending, milling and compression using an instrumented rotary press.

FMEA is used to identify CPPs. The CPP's include compression force at first station (precompression), compression force at second station (main compression), and turret speed. The CQAs include potency, content uniformity, and lamination.

Two DOEs are used to understand the knowledge space and identify control space and operation parameters.

33.11.3 DOE design

Study I

Goal: Establish the preliminary compression parameters
Design: Three factors at two levels (3×2)
Factor 1: Main compression
Factor 2: Precompression
Factor 3: Speed

Study II

Goal: Identified optimal process parameters
Design: Two factors at three levels (2×3)
Factor 1: Main Compression
Factor 2: Speed

(Sampling plan: Physician quality reporting initiative-driven)

33.11.4 Results

Lamination is shown in Figs. 33.26 and 33.27.

Based on these results, the operation ranges for compression are optimized as: (1) precompression 0.15–0.3 Kp, (2) main compression 6–7 Kp, and (3) turret speed at 18–20 rpm.

33.11.5 Conclusions

Optimization of compressing of a bi-layer tablet could be difficult due to: (1) the confounding

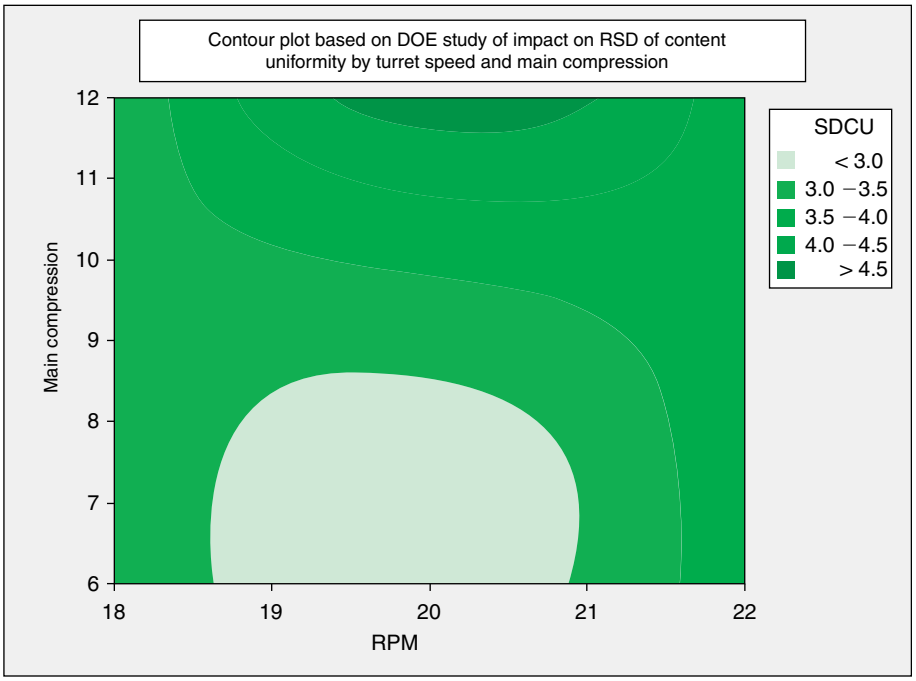

FIGURE 33.26 Impact on RSD of content uniformity by turret speed and main compression force.

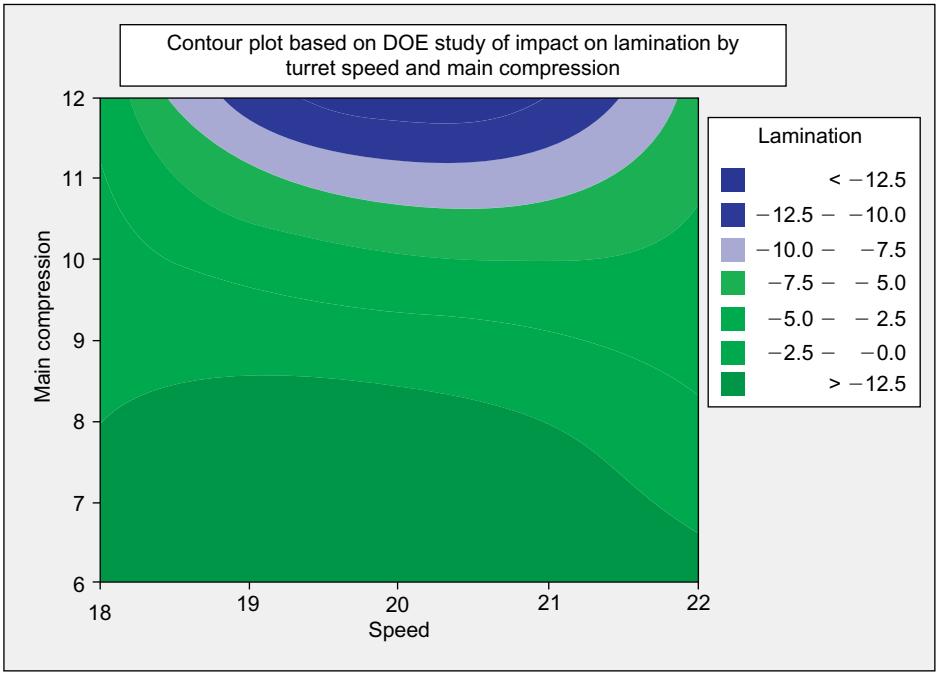

FIGURE 33.27 Impact on lamination by turret speed and main compression force.

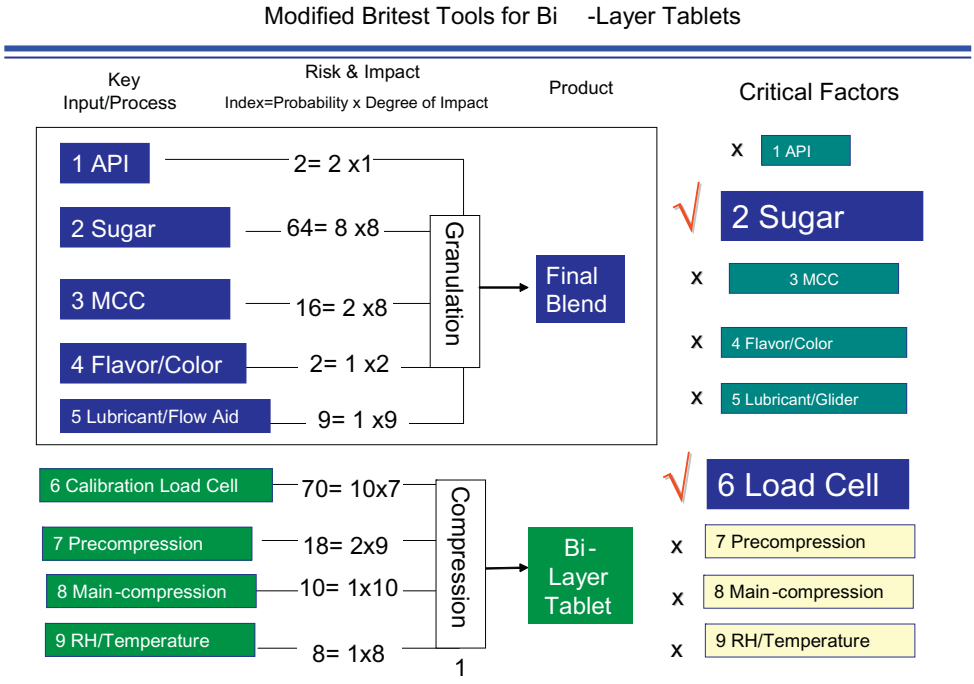
Note: Lamination index > 0 = meets requirement

interaction of powder-filling of two layers that may have different flowability, (2) competition of compression force between two layers, and (3) separation/lamination of two layers.

However, by applying the RFT/six sigma approach and utilization of these process characteristic tools, the optimal process parameters and control space can be effectively identified.

33.11.6 Application of britest tool in troubleshooting



33.12 SCALE-UP OF COMPRESSION

In this chapter we will examine press speed as a major factor in tableting, and review measures and functions of tableting speed, such as dwell time, contact time, consolidation time, and decompression (relaxation) time.

The importance of dwell time in compaction has been a subject of discussion for the past 30 years, and yet there is still confusion about how to measure or even define it. Moreover, other important time segments of the compaction event have been mostly neglected because they depend on press geometry and are difficult to quantify.

We have taken a comprehensive approach to calculations of such time events, and found press efficiency factors as by-product. In order to evaluate press or tableting efficiency, we need to consider such important factors as feed time, ejection time, and total tableting time.

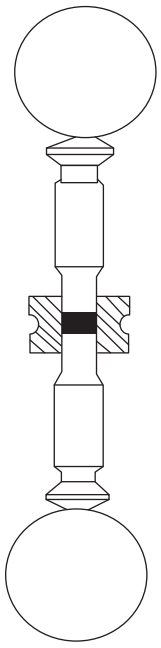


FIGURE 33.28 Punch and die set.

33.12.1 Compaction and compression

Tablets are made of powder compressed in a die by punches. On a rotary tablet press, the die table along with many punches rotates and pushes each set of upper and lower punch between compression rollers (Fig. 33.28). This causes the punches to move inside the die and compress the powder.

Two processes take place when the tablet is made: compaction and compression. During tableting, both processes occur simultaneously (Fig. 33.29).

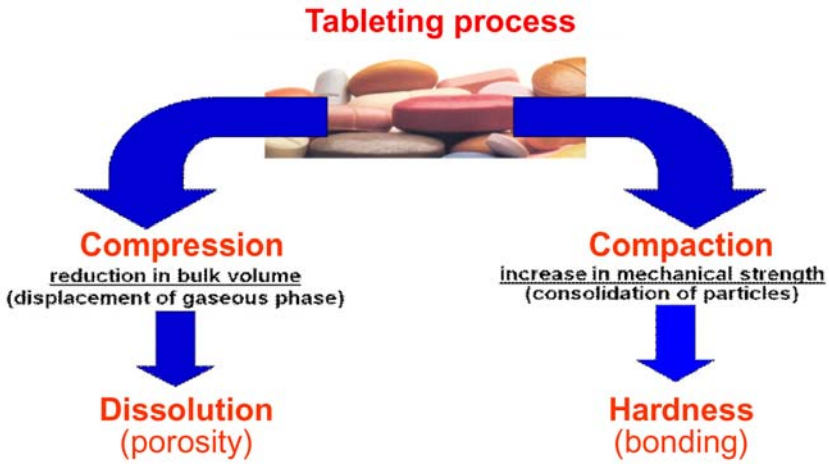

FIGURE 33.29 Compression and compaction as two simultaneous processes in tableting.

By definition, compaction is the increase in mechanical strength of powder under force due to consolidation of particles. Thus, compaction is related to particle consolidation and bonding, which has a direct effect on the tablet hardness and friability.

Compression, on the other hand, is defined as a reduction in bulk volume of the powder under force due to displacement of air between particles. Compression results in a reduction of void space between solid particles, which means a decrease in porosity of a tablet. It is a known fact that porosity, along with the pore size and distribution, affects total surface area, disintegration, and dissolution time.

Several variables are useful in describing the compaction process. Tablet hardness, or breaking force, of a cylindrical tablet can be converted into tensile strength $\sigma = 2 \cdot F/(\pi \cdot d \cdot h)$, where F is the crushing force, d is tablet diameter, and h is tablet thickness (tensile strength is better than hardness because it is normalized with respect to tooling size and shape). A quantity known as "solid fraction", or relative density, is defined as $SF = w/(\rho \cdot v)$, where w is tablet weight, ρ is true density, and v is tablet volume.

Three types of graphs are required to adequately represent and characterize compaction: tabletability (tensile strength vs applied compaction pressure), compressibility (solid fraction vs applied pressure), and compactibility (tensile strength vs solid fraction). If the graphs coincide for any two lots, then formulations are essentially identical with respect to the compaction process. This information can be extremely useful in scale-up.

There are three major mechanisms of particle consolidation: elastic, plastic, and brittle fracture (Table 33.5). Any deformation of elastic materials under stress is temporary; it disappears when the pressure is removed (rubber may provide a typical example). Plastic materials, such as avicel, are deformed permanently even at small pressures. For some materials (such as emcompress), powder particles undergo fragmentation under applied pressure. Such deformation is called "brittle fracture."

TABLE 33.5 Particle Consolidation Mechanisms

Material	Reversible	Time dependent
Elastic (rubber)	Yes	No
Plastic (avicel)	No	Yes
Brittle (emcompress)	No	No
Viscoelastic (starch)	Partly	Yes
Brittle-plastic (lactose)	Partly	Yes

No material deforms by a single mechanism. There is always a combination of either elastic and plastic or brittle and plastic behavior and usually one of the mechanisms predominates. The so-called "viscoelastic" materials deform elastically at low pressures, but as the pressure increases, at some point (yield point) the deformation becomes irreversible. Likewise, there are materials, such as lactose, which initially show some fragmentation, but then may exhibit plastic flow under increased pressure. Plastic flow is time-dependent and decreases as pressure goes up (due to decrease in porosity). Thus, plastic and viscoelastic materials exhibit what is called "strain rate sensitivity," which means they are sensitive to speed of tableting.

As powder particles consolidate, they go through several stages of consolidation (shown in Fig. 33.30 for plastically deforming material). The main events are: reduction in the volume of air between solid particles, particle rearrangement, particle deformation, plastic flow into the interparticulate voids, and formation of interpariculate bonds due to plastic deformation.

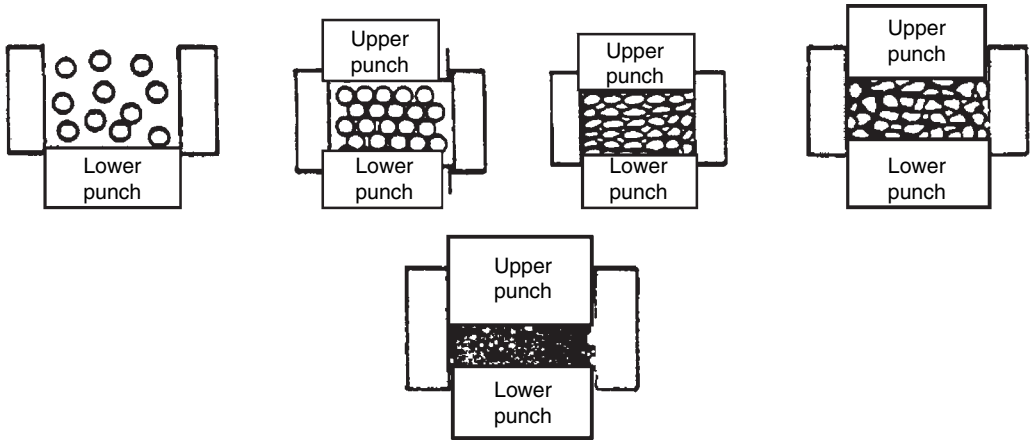

FIGURE 33.30 Consolidation stages with plastic flow.

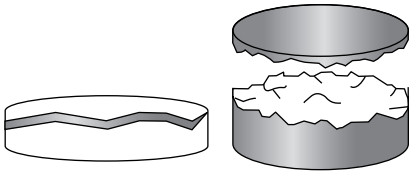

FIGURE 33.31 Tablet capping.

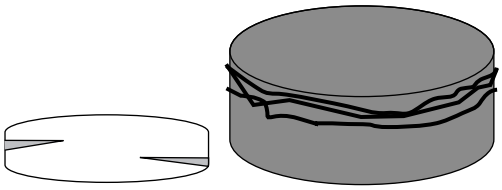

FIGURE 33.32 Lamination.

33.12.2 Tableting failure

Most scale-up problems in tableting are speed-related because the product is moved from a relatively slow R&D press to high-speed production machines. Such problems are: capping, lamination, cracks, picking, and chipping. Other general problems relate to flowability of powders (feeding issues), underlubrication (may cause sticking), and temperature sensitivity (some powders, such as ibuprofen formulations may even melt in the die during long batches as the in-die temperature increases).

Capping is a stratification phenomenon that results in a horizontal dislocation of a tablet layer (Fig. 33.31).

Capping tendency increases with compression force and tableting speed,[1–4] with precompression force,[5] and with punch penetration depth and tablet thickness.[6] Capping occurs due to increase of elastic energy under high-speed compaction compared with a lesser increase of plastic energy. It may also be a result of the expansion of air trapped in pores of the tablet, although this assumption has been disputed in the literature. Press speed is a major factor contributing to capping due to slow process of stress relaxation.

Lamination (Fig. 33.32) occurs when the tablet splits apart in single or multiple layers. Lamination is often blamed on overcompressing—too much compression force flattens out the granules, and they no longer lock together. Lamination can also occur when groups of fine and light particles do not lock together.

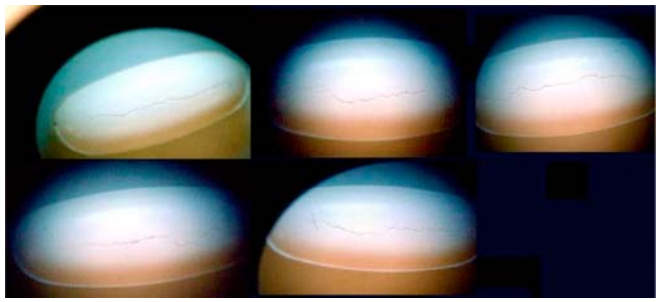

FIGURE 33.33 Crack on the upper side of tablets due to stress relaxation.

Tendency of tablets to laminate increases with speed, compression force, and precompression force.[5,7]

It is a fact that the consolidation part of the compaction cycle (during the "rise time" of the force-time profile) is 6–15 times more important than the decompression part as a factor contributing to capping and lamination.[8,9]

Elastic recovery during decompression can cause stress cracking due to elastic recovery during ejection (Fig. 33.33). This is clearly a strain rate (speed) related phenomenon.

Chipping may be caused by inadequate (brittle) formulation, take-off misalignment, sticking, while picking/sticking to punch faces is formulation-dependent (Fig. 33.34).

33.12.3 Main factors of tableting

The major factors of a tableting process are force and speed of compaction.

The compression force is the dominant factor of the tableting process. As the compression force increases, tensile strength (hardness) of tablets increases, and then may level into plateau or even decrease, as evidenced by numerous studies. Increased force may cause lamination and capping. Friability, disintegration times, and dissolution profile are also affected.

As the punch speed increases, so does the porosity of tablets[10] and their propensity toward capping and lamination. The tensile strength of compacts tends to decrease with faster speeds, especially for plastic and viscoelastic materials, such as starch, lactose, avicel, ibuprofen, or paracetamol; more information can be found in numerous studies.[2,11–20]

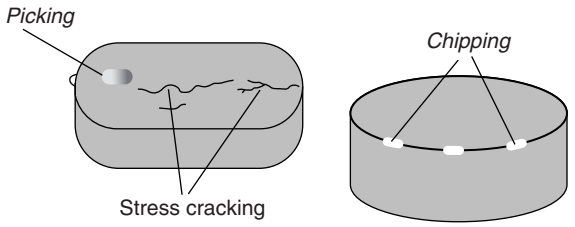

FIGURE 33.34 Picking, chipping, and stress cracking.

Speed also affects the compact temperature in the die, and its mechanical integrity. With increase in porosity, one should expect a drop in disintegration and dissolution times, but the interplay of the force-speed relationship may confound the effect. Although the energy absorbed by the tablet may not change, the power expended in the compaction process may differ greatly with speed, and this, in turn, may have an effect on tablet properties.

The third important factor is force profile, which is directly related to the diameter of compression roll. Larger rolls will provide larger contact times, and with all other factors being equal, this may translate into an increase in tablet hardness (Fig. 33.35 and Table 33.6).

Numerous other factors may affect the scale-up process. Among them is the quality of the measurements, variation in tooling, powder properties, and tablet weight.

TABLE 33.6 Larger Hardness for Larger Roll Diameter at Approximately the Same Dwell Time (Linear Speed)

MATERIAL: AVICEL PH101		
Press:	Betapress	Fette 2090
Stations	16	36

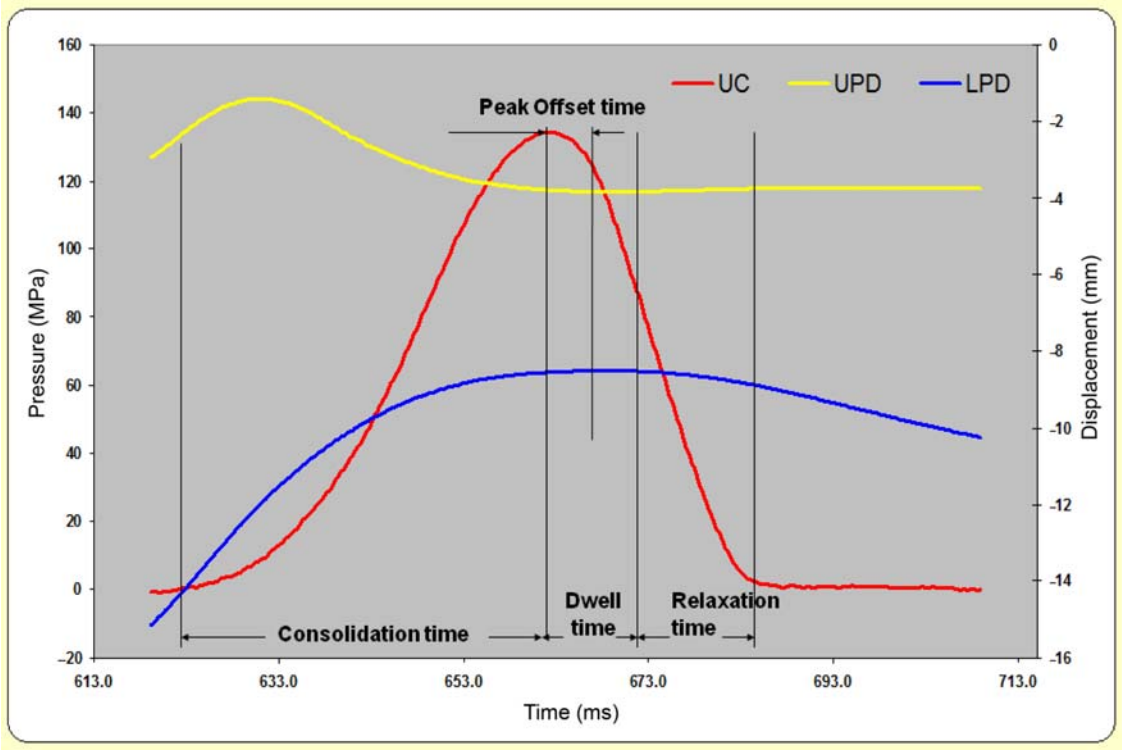

FIGURE 33.36 A compaction event. Legend: *UC*, upper compression; *UPD*, upper punch displacement; *LPD*, lower punch displacement.

33.12.4 Compaction event

A typical compaction event is represented in Fig. 33.36 in terms of pressure (force divided by punch tip area) versus time. The event can be broken into three parts: consolidation, dwell, and relaxation times. We can see that compression reaches its peak well before the punches are vertically aligned with the center of the compression roll (middle of dwell time). The time between the peak of compression and the middle of dwell time is called peak offset time.[21,22] This phenomenon is due to plastic flow in the material being compressed and this flow relieves the pressure, causing the force decrease. Thus, the shape of compression-time form depends on the plasticity of powder.

33.12.5 Tableting time definitions

Let us informally define all discernable time events of the compaction cycle that can be calculated on the basis of geometrical parameters.

- Feeding time, T_f: time when the die is fed with powder
- Contact time, T_c: Time when both punches are moving, having their tips in contact with the material that is being compacted, and their heads are in contact with the pressure rolls.
  $T_c = T_s + T_d + T_r$
- Consolidation (solidification) time, T_s: The portion of contact time, T_c, when punches are changing their vertical position in reference to the rolls, decreasing the distance between the punch tips
- Dwell time, T_d: The portion of Contact Time T_c when punches are not changing their vertical position in reference to the rolls.
- Decompression (relaxation) time, T_r: The portion of contact time, T_c, when punches are changing their vertical position in reference to the rolls, increasing the distance between the punch tips before losing contact with the rolls.
- Compression time, T_p: The portion of contact time, T_c, before the decompression period begins,
  $T_p = T_s + T_d$
- Ejection time, T_e: Time when the tablet is being ejected from the die
- Total time, T_t: time required to produce one tablet on a press (including time between tablets)

Note that all times are defined by punch position relative to the compression roll.

Thus, all calculations can be done on the basis of press geometry, without any reference to product

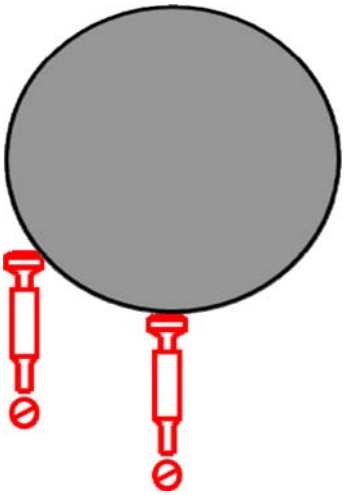

FIGURE 33.37 Geometry of contact time and dwell time.

properties or punch displacement measurements. Once the optimal processing parameters have been established on a research press, the scale-up can be optimized with the help of relatively simple calculations by matching the most important time events.

33.12.6 Dwell time and contact time

As we already know from the stated definition, contact time is the time when the punch head is in contact with the compression roll, while dwell time is when the flat portion of punch head is in touch with the compression roll (Fig. 33.37).

Dwell time is defined as a portion of the contact time when punches are not changing their vertical position with respect to the rolls, that is, when a flat portion of the punch head is in contact with the rolls. Note that dwell time (unlike contact time) as defined does not depend on the roll diameter.

The notion of dwell time is largely misused or misunderstood. In fact, it should be used as a yardstick, a measure of linear (ie, tangential or angular) velocity and therefore will depend on the punch head geometry. The speed comparisons based on the dwell time assume that the punch has a flat head. The velocity then is the length of that flat portion divided by the dwell time. For the same linear velocity, the smaller the punch head flat, the smaller the dwell time. Surprisingly, dwell time for dome-shaped punch heads is practically zero by definition, regardless of press linear velocity or RPM. That is why, compared with dwell time, linear velocity is a better measure of press speed.

Any attempt to calculate dwell time from compression-time traces (eg, as a duration of 90% of the peak) is doomed to failure because such a curve depends on the material properties of the powder being compressed. Plastic flow and elastic recovery distort the "ideal" shape of the force-time profile.

A "classic" simple formula of dwell time does not take into account trajectory curvature:

$$DT(\text{ms}) = (L \cdot NS \cdot 3,600,000) \,/(\pi \cdot PCD \cdot TPH)$$

Where L = Length of a flat portion of the punch head (mm)

NS = Number of stations
π = 3.14159265
PCD = Pitch circle diameter of the turret (mm)
TPH = press speed in terms of tablets per hour

Dwell time is historically used as a sort of "yardstick" to measure compaction speed (Fig. 33.38).

As you can see, Manesty Betapress is ideally positioned within the range of production speeds for the fast-speed presses. That is likely why this press is often used for R&D work. On the other hand, small presses, such as Korsch PH106 or Piccola, do not even come close to benchmark production speeds of 6–15 ms in terms of dwell time.

In fact, dwell time as defined depends on tooling geometry (it is zero for a punch with round head, for example). A linear (tangential) speed of the turret is a better way to represent press speed independently from punch head geometry (Fig. 33.39).

In what follows, we will present the comprehensive set of formulas that represent all tableting events that can be derived from press and tooling geometry.

33.12.7 Tableting geometry

Press speed is a major factor in tableting, and yet the commonly used measures of press speed (such as RPM, tablets per hour, dwell time, linear speed, etc.) do not take into account significant differences in press and tooling geometry, press deformation, tablet thickness, or depth of fill.

Let us introduce a tableting notation that will enable us to generate formulas for exact calculation of the compaction time events (Table 33.7).

In order to visualize some of the variables with respect to press geometry, let us look at Fig. 33.40.

Based on the previous considerations, the following formulas can be derived (Table 33.8).

The previous algorithms and formulas are based on extensive list of published papers and on our own investigations into the geometry and dynamics of tableting.

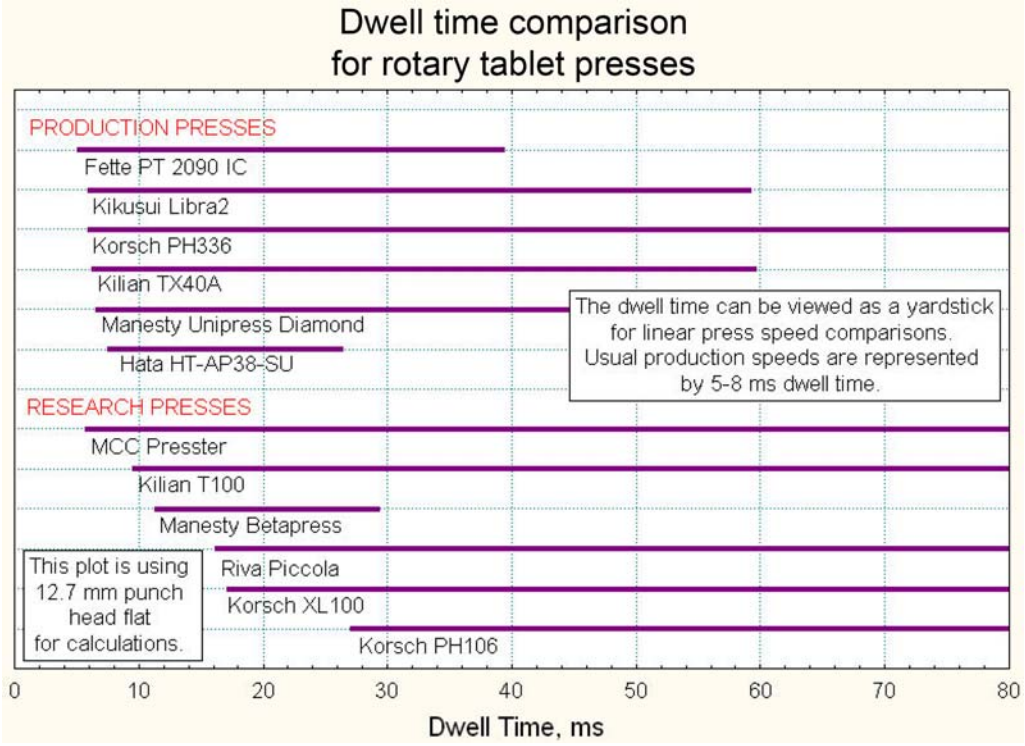

FIGURE 33.38 Dwell time ranges for rotary tablet presses.

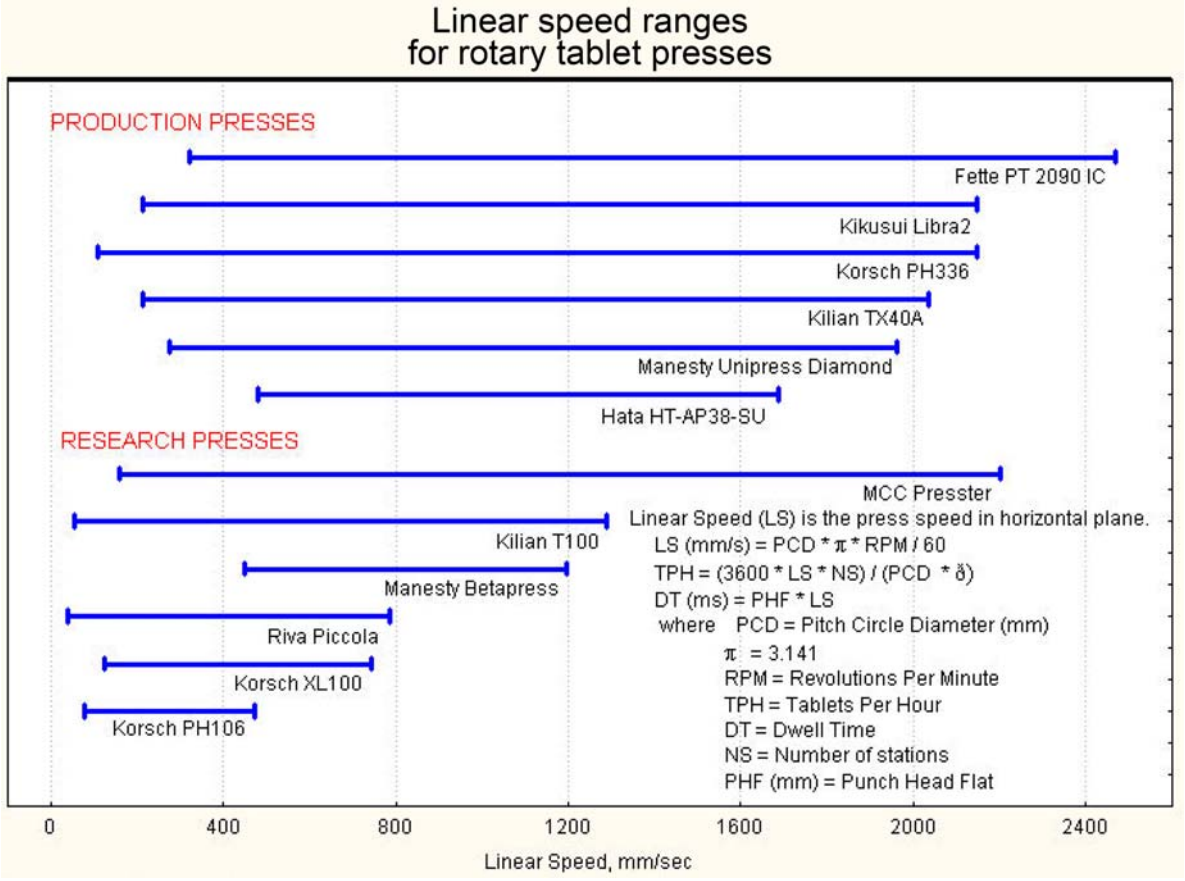

FIGURE 33.39 Linear speed ranges for rotary tablet presses.

TABLE 33.7 Notation Used in Formal Calculations of Compaction Time Events

A	Angular displacement of punch axis from vertical plane through roll axis (rad.)
A_e°	Angle of slope of ejection ramp (deg.)
A_f°	Central angle of turret occupied with feed frame (deg.)
d	Rate of total press deformation (mm/kN)
E_e	Ejection efficiency factor; $E_e = T_e/T_t$
E_f	Feeding efficiency factor; $E_f = T_f/T_t$
E_s	Consolidation efficiency factor; $E_s = T_s/T_t$
F	Compression force (kN)
H_f	Depth of fill (mm)
H_i	In-die tablet thickness (mm)
H_t	Out-of-die tablet thickness (mm)
L_f	Length of feed frame on pitch circle (mm)
N_s	Number of stations
R1	Radius of compression roll (mm)
R2	Radius of punch head curvature (mm)
R3	Radius of punch head flat (mm)
R4	Radius of turret pitch circle (mm)
r	Frequency of turret rotations (1/min)
T1	Time of turret rotation by angle A1 (ms)
T2	time of turret rotation by angle A2 (ms)
T_c	Contact time (ms); $T_c = T_s + T_d + T_r$
T_d	Dwell time (ms)
T_e	Tablet ejection time (ms)
T_f	Die-feeding time (ms)
T_r	Decompression, or relaxation, time (ms)
T_s	Consolidation time (ms)
T_t	Time to produce one tablet on a press (ms)
V_a	Angular velocity of press turret (rad/s)
V_h	Linear horizontal speed of compaction
V_v	Average vertical speed of compaction during consolidation time (compaction rate combined for both punches) (mm/s)
Xs	Horizontal travel of punch during consolidation time (mm) (in direction perpendicular to vertical plane through roll axis)
X1	Horizontal distance of punch axis from vertical plane through roll axis (mm)
Z	Vertical displacement of upper punch from axis of pressure roll (mm)
Zr	Vertical travel of punch during relaxation time (mm); Zr = $[H_t - H_i)/2$
Zs	vertical travel of punch during consolidation time (mm)
Zu	Upper punch penetration (mm)

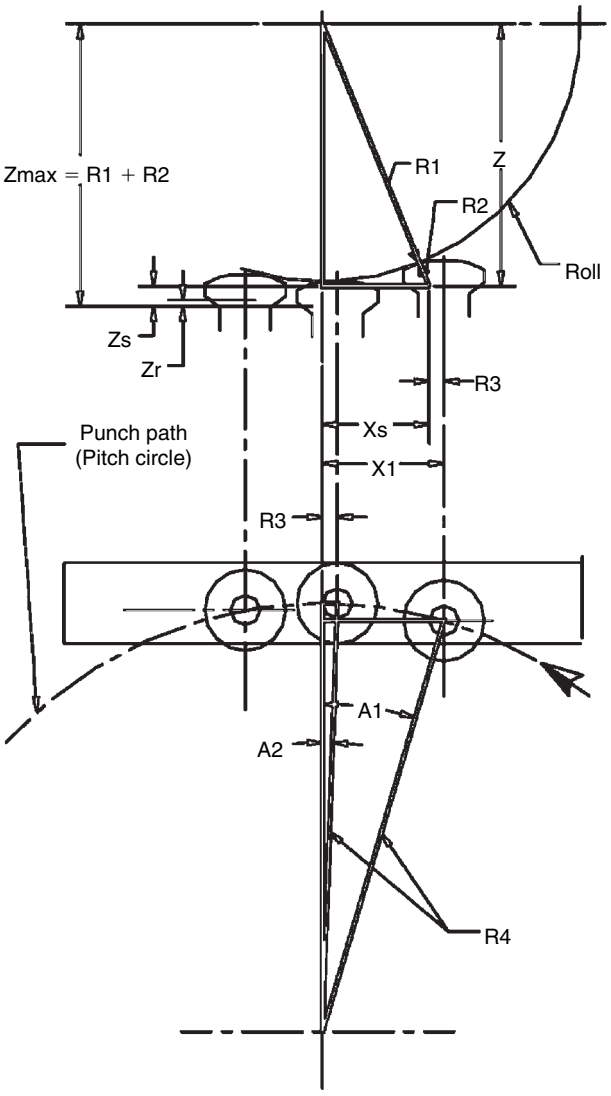

FIGURE 33.40 Graphic representation of variables used in calculation of compaction time events.

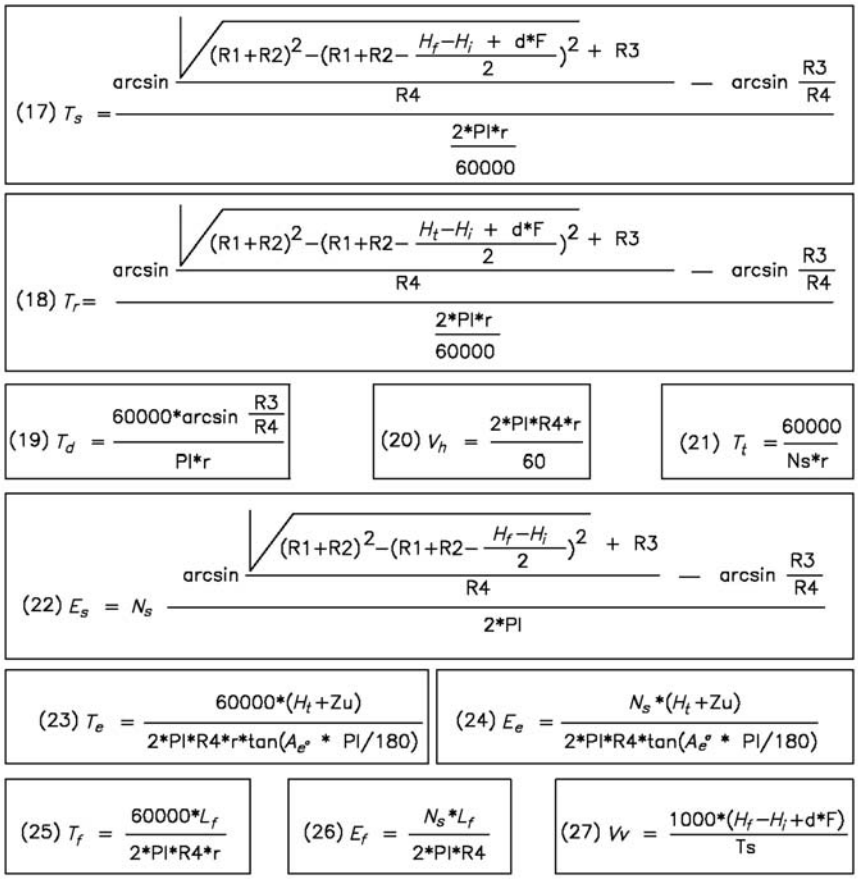
Consolidation time, T_s, calculation is based on geometrical parameters such as roll diameter, pitch circle diameter, punch geometry, depth of fill, and in-die tablet thickness. Calculation of T_s takes into account a correction for press deformation if the rate of deformation is known. Other calculation formulas are based on the analysis of Rippie and Danielson[23] and represent an extension of the work by Muñoz-Ruiz et al.[24] Calculation of vertical punch displacement, Zs, during consolidation time is based on depth of fill, H_f, and in-die thickness, H_i. A new, more accurate expression for dwell time, T_d, calculation takes into account the rotational motion of the punches. A proper formula to calculate decompression (relaxation) time, T_r, is used for estimation of all periods of the compaction events and the entire contact time T_c.

TABLE 33.8 Formulas for Tableting times, Velocities, and Press Efficiencies



33.12.8 Tableting scale-up

In order to adequately replicate any process on a different scale, one has to make sure that the processes are similar on both scales. There are three similarity principles in the general theory of modeling: matching geometric, kinematic, and dynamic ratios of characteristic variables. Geometric considerations in simulating compression on a rotary press would require matching die and punch set and compression rolls.

Unlike many other pharmaceutical unit operations, scale-up of tableting process from R&D to production does not involve increase of volume: the die size does not increase. Moreover, it is easy to match the compression force. The most critical factor of tableting scale-up is the rate of compaction (ie, punch speed).

A new class of single-station tablet presses, generally called "compaction simulators," was introduced in 1980s. They were designed to simulate punch movement on a rotary press at high speed to enable making one tablet at a time for formulation development. The classic hydraulic simulator uses a theoretical equation for punch movement, as developed by Rippie and Danielson.[23] Another type of machine, called Presster, is using the principles of similarity to replicate the actual process of making tablets on a rotary press (Fig. 33.41). Yet another product, called Parcus, introduced recently as a material sparing device, can also be used to make single tablets at high production speeds with the goal of eliminating scale-up problems. Useful information on practical use of compaction simulators and their applicability to scale-up can be found in numerous publications (see, eg, Refs. 25–30).

Scale-up of tableting process involves shorter die feeding times (can affect tablet weight), smaller consolidation times (may lower compactibility), and faster ejection (can create cracks or lamination).

At the same production rate, duration of tableting events depends on roll diameter, pitch circle diameter, number of stations, punch geometry, length of feed frame, and the angle of ejection ramp. On the other hand, the speed of various tableting events becomes a limiting factor in press productivity.

However, matching consolidation time T_s, or a sum of T_s and T_d, will, most probably, ensure the same tablet quality, or, at least, bring the process to a close proximity of the target.

FIGURE 33.41 Presster—rotary tablet press replicator. *Source: Photo courtesy of MCC—Metropolitan Computing Corporation, East Hanover, NJ.*

To properly scale-up a formulation based on consolidation time, one should:

1. Evaluate the minimum consolidation time, T_s (or $T_s + T_d$), at which tablets of a satisfactory quality can be produced (ie, the maximum compaction speed) during formulation development. If possible, use a compaction simulator, Presster or a high-speed rotary press equipped with Parcus to establish optimal T_s, or $T_s + T_d$ to match those in production.
2. Calculate at what speed (RPM) different production presses can offer the established minimum satisfactory consolidation time, and what tablet output can be expected from different presses at that speed.

Now that we know how to calculate time events, we can apply this information to practical problems of scale-up. In the following example, we will try to scale-up "a perfect formulation" by matching consolidation time, T_s, and dwell time, T_d.

Let us say that we have a wet granulation of a low dose of brittle API, mixed with Avicel PH102 and 0.5% Magnesium Stearate. On all presses we will use TSM B 3/8″ round flat tooling, with 10-mm depth of fill and 300-mg target tablet weight, out-of-die target thickness of 5 mm, corresponding with 10 kN of compression force. Let us further assume that tablets were made in R&D on a 16-station Manesty Betapress at 50 RPM. Our objective is to move this product to production, where we have a choice of 36-station Korsch PH336, 36-station Kikusui Pegasus 1036, or 37-station Fette P3000 tablet presses.

Calculation of T_s and T_d yields the following results (Table 33.9):

Both the Korsch and Kikusui press can match the $T_s + T_d = 57.6$ ms, but Fette cannot, even at the slowest speed of 30 RPM. If, however, we increase the Betapress speed to 60 RPM, we are able to match $T_s + T_d = 48.1$ for all presses under consideration (Table 33.10). Given the choice, Fette P3000 is preferred because of its high consolidation efficiency factor ($E_s = 1.36$).

Another example involves scale-up of a formulation from 10-station Riva Piccola tabletop R&D press to 14-

TABLE 33.9 Consolidation Time T_s and Dwell Time T_d for Production Tablet Presses Matching Betapress Run at 50 RPM (E_s is the Consolidation Efficiency Factor as Defined Previously)

Korsch PH336	36	33.4	72,169	44.6	13.0	57.6	0.89
Kikusui Pegasus 1036	36	34.8	75,230	42.6	15.0	57.6	0.89
Fette P3000	37	30.0	133,200	36.7	11.7	48.4	1.36

TABLE 33.10 Matching $T_s + T_d$ for Manesty Betapress, Korsch PH336, Kikusui Pegasus 1036, and Fette 3090

Tablet press	Stations	RPM	TPH	T_s (ms)	T_d (ms)	$T_s + T_d$ (ms)	E_s
Manesty Betapress	16	60.0	57,600	35.1	13.0	48.1	0.56
Korsch PH336	36	40.1	86,603	37.2	10.8	48.0	0.89
Kikusui Pegasus 1036	36	41.8	90,277	35.5	12.5	48.0	0.89
Fette P3000	37	30.2	134,112	36.4	11.6	48.0	1.36

TABLE 33.11 T_s and T_d for Riva Piccola Run at 50 RPM

Tablet press	Stations	RPM	TPH	T_s (ms)	T_d (ms)	$T_s + T_d$ (ms)	E_s
Riva Piccola	10	50.0	30,000	54.1	24.0	78.1	0.80

TABLE 33.12 Matching $T_s + T_d = 69.6$ ms for Riva Compacta, Riva Piccola, Kikusui Libra 2, and Fette PT3090 Rotary Tablet Presses

Tablet press	Stations	RPM	TPH	T_s (ms)	T_d (ms)	$T_s + T_d$ (ms)	E_s
Riva Compacta	18	40.0	43,200	50.0	19.6	69.6	0.60
Riva Piccola	10	56.0	33,612	48.3	21.4	69.7	0.80
Kikusui Libra 2	36	23.9	51,664	51.3	18.3	69.6	0.74
Fette PT3090	61	15.6	114,000	52.7	17.0	69.7	1.67

station Riva Compacta, 36-station Kikusui Libra 2, or 61-station Fette PT3090. Let us assume all formulation, tooling, and processing parameters are the same as in the previous example.

TABLE 33.13 Comparison of $T_s + T_d$ for Fette PT3090 at 60 RPM, Kikusui Libra 2 at 92.2 RPM and Riva Presses at Maximum Speed

Tablet press	Stations	RPM	TPH	T_s (ms)	T_d (ms)	$T_s + T_d$ (ms)	E_s
Fette PT3090	61	60.0	439,400	13.7	4.4	18.1	1.67
Kikusui Libra 2	36	92.2	199,120	13.3	4.8	18.1	0.74
Riva Compacta	18	100.0	108,000	20.0	7.9	27.9	0.60
Riva Piccola	10	100.0	60,000	27.0	12.0	39.0	0.80

For 50 RPM, Riva Piccola achieves $T_s + T_d = 78.1$ ms (Table 33.11). It is too slow for the other three presses to match. Piccola has to be run at least 56 RPM (Table 33.12) to be matched with the other presses at slow speeds (eg, Fette has to be run at a mere 15.6 RPM).

If the production manager and the marketing considerations demand that the product be run on the Fette press (because of its high efficiency and production rate), then we can do the analysis backward to see if the research press can match $T_s + T_d$ of Fette at, say, a mid-range speed of 60 RPM. Table 33.13 shows that while Kikusui Libra can match that target speed, Riva presses cannot.

34.1 INTRODUCTION

In today's pharmaceutical industry, film coating is generally referred to as a process by which a thin, continuous, solid polymer layer is applied to the surface of a dosage form (typically tablets, capsules, and multiparticulates). The purpose of film coating includes esthetic enhancement, increased shelf life, taste masking, moderating the release profile of active pharmaceutical ingredient (API), trade-marking, and protection of intellectual property.

The thickness of the film is generally less than 100 μm. The composition of the film may include a mixture of excipients (polymers, plasticizers, colorants) as well as an API.

34.1.1 The basis of film coating

Film coatings can be applied by different methods, such as spraying a liquid, dipping into a liquid, precipitating from supercritical fluids, or depositing a powder using an electrostatic technique[1].

Spraying a liquid is the most widely used process for film coating and typically includes three basic steps:

1. Spraying an atomized liquid on the target surface that is in continuous movement
2. Maintaining a controlled balance between spray application and evaporation rates by applying heated process air onto the target surface
3. Continuing the process until the desired amount of coating is applied[2]

34.1.2 Evolution of pharmaceutical-coating technology development

Application of coatings to medicinal products can be traced back to the middle ages. However, a uniform and consistent film-coating process that meets the minimum requirements imposed by today's regulatory requirements has only been available for the past few decades.

The earliest process, sugar coating, is performed in a solid wall, smooth bowl-shaped container, employs an external heat source, and is a multistage process that can take several days to complete. Film coating emerged as an alternative to the sugar-coating process to reduce process time.

The evolution in design of coating process equipment has progressed from an open system to one that is completely enclosed and self-contained. Liquid delivery and air-handling systems have also improved as demand for precision and accuracy became more of a regulatory requirement.

The efficiency of heat exchange in film-coating processes has been dramatically improved with the introduction of side-vented (perforated) coating pans that allow the process air to pass completely through the tablet bed, while use of various types of sensors facilitates the monitoring of key process parameters (KPP).

By the end of the 20th century, film coating had evolved to such a degree that it was unrecognizable from processes carried out just 50 years earlier.

Other key developments involve the implementation of process analytical technology, whereby the continual

DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00034-0

assessment of critical process parameters (CPP) that impact critical product quality attributes allows the process to be controlled within a well-defined design space, often obviating the need for routine finished product testing.

Finally, continued process improvements have led to the introduction of innovative coating processes, most notably those involving continuous processing.

34.1.3 Coating equipment introduction

Based on a variety of pan designs, coating pans can typically be classified as solid-wall pans (Fig. 34.1), and fully- or partially-perforated pans (Figs. 34.2 and 34.3).

Based on the type of process, the coating pan can be classified as batch process-coating pan, continuous-coating pan, or off-press continuous coating pan (Fig. 34.4). While early continuous coating pans were designed to coat large batches of tablets (500–2000 kg/hour) where the desire is for large volume throughput at low manufacturing costs, recent designs have focused on slower throughput rates (approximately 50 kg/hour) to match up with the output of a typical production speed tablet press.

FIGURE 34.1 A solid coating pan fitted with immersion sword air-flow enhancement.

34.2 FILM-COATING FORMULATIONS

34.2.1 Overview of types of film-coating formulations

Film-coating systems are usually defined by the way the coating materials are formulated into a liquid coating system, and typically take the form of:

- Polymers applied as organic-solvent-based solutions (typically reserved for modified-release applications today)[3]
- Polymers applied as aqueous solutions (most commonly used for immediate-release film coatings)
- Polymers applied as aqueous dispersions (mainly used for modified-release applications)
- Various materials applied as hot melts (typically used for modified-release and taste-masking applications)

The transition to aqueous processes has been driven by a genuine desire to avoid the hazards associated with using both flammable and potentially toxic solvents, and the added costs of dealing with environmental issues.

Water is not, however, a panacea, and use of aqueous-coating formulations is often associated with challenges that need to be addressed, such as:

- The possibility that processing times will be increased; this issue can, however, be minimized by using high solids aqueous-coating systems[4,5].
- The potentially negative impact on drug stability if water is not effectively removed during processing; however, modern processing techniques coupled with use of higher-solids-coating systems now effectively eliminates this issue.
- The increased likelihood that the harsher process conditions used may affect drug dissolution characteristics; this problem is now minimized by the use of specialized coating formulations that allow processing temperatures to be minimized.

Aqueous-coating formulations can take two forms, namely, aqueous solutions of polymers, which are typically reserved for immediate-release coating applications, and aqueous dispersions (latexes) of polymers, which are frequently used in modified-release coating applications.

When it comes to forming coatings from polymer solutions, the process involves the conversion of a viscous liquid into a visco-elastic solid through a process of continual solvent evaporation, through several stages: (1) Rapid evaporation of solvent

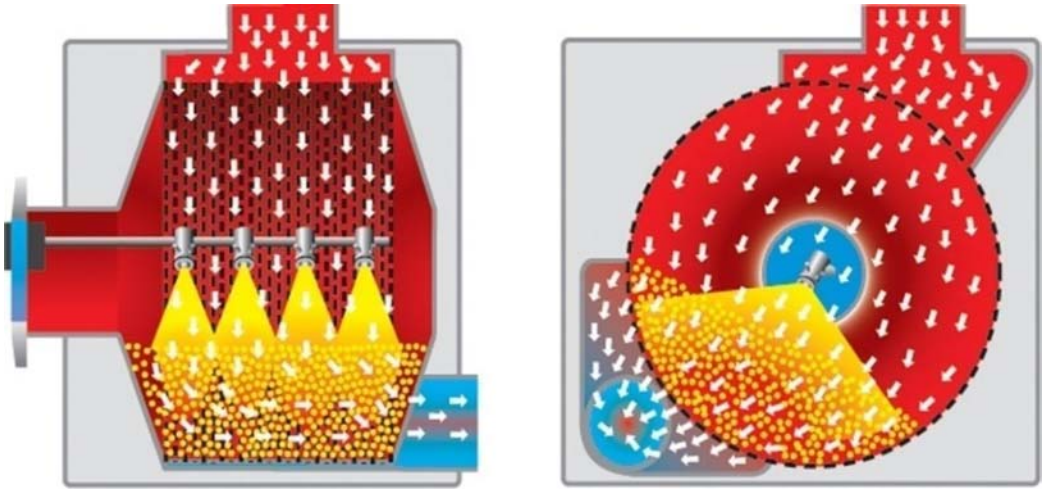

FIGURE 34.2 Schematic of a fully-perforated coating pan. *Source: Courtesy of Vector.*

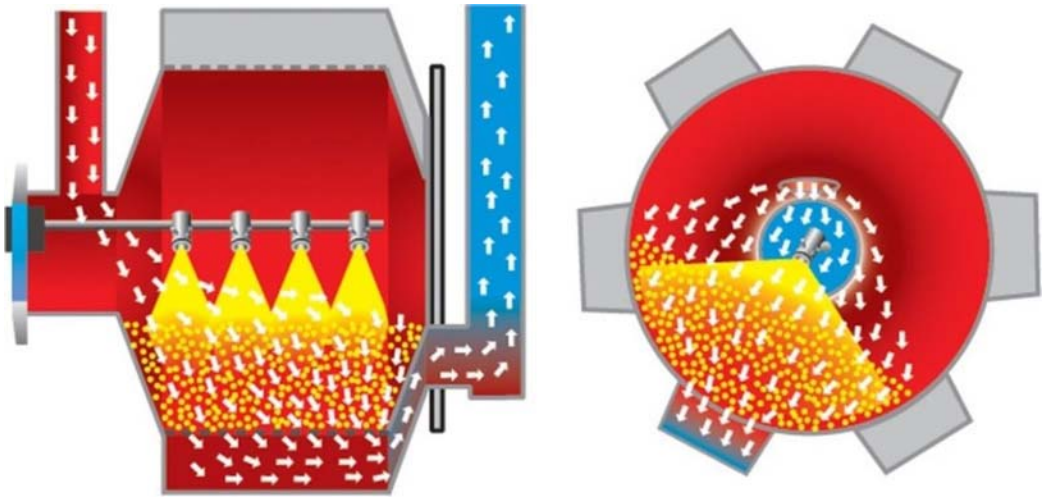

FIGURE 34.3 Schematic of a partially-perforated coating pan. *Source: Courtesy of Vector*[6].

FIGURE 34.4 Example of a continuous coating pan. *Source: Courtesy of O'Hara Inc.*

from finely-atomized droplets of solution, which are deposited onto the surface of the substrate to begin the process of build-up of coating material; (2) Continued solvent evaporation (now at a slower rate) from the coating that is forming on the substrate surface; (3) Immobilization of polymer molecules (at the so-called "solidification point"), such that continued solvent loss now leads to the development of shrinkage stresses within the coating; and (4) Continuation of solvent loss (usually throughout the life of the product) at extremely slow rates.

In contrast, the formation of coatings from aqueous polymer dispersions (Fig. 34.5), while still involving a process of evaporation, is radically different.

Polymer dispersions must undergo a process of "coalescence," where the dispersed polymer particles

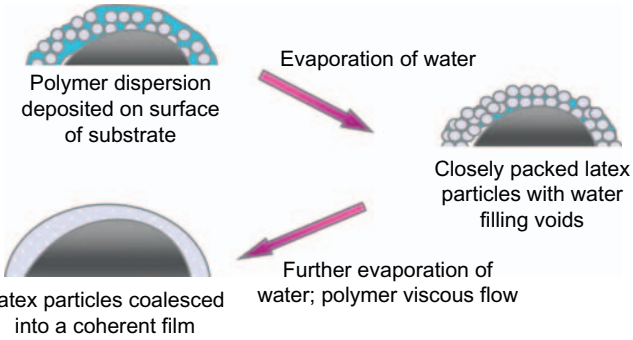

FIGURE 34.5 Schematic of film formation from aqueous polymer dispersions.

must flow together. For this process to occur, pressure develops within the film structure, while the particles of polymer soften under the influence of process heat; as a result, the polymer particles tend to flow together. Pressure development results from evaporation of water; as the porosity of the membrane is reduced during the evaporative process, a capillary network is formed within the structure of the coating, resulting in the development of capillary forces that squeeze the particles together. The ability of the polymer particles to soften sufficiently is dependent on these factors:

- Heat provided by the coating process
- The glass transition temperature of the coating system (dictated by the properties of the polymer, and the properties and concentration of the plasticizer, where needed), which determines the minimum film-forming temperature (MFFT) of the system. The product temperature within the coating pan must exceed the MFFT for film coalescence to occur.

While it is common for many coating formulations to contain a plasticizer (see later discussion), polymer dispersions may require the presence of a plasticizer to facilitate film formation. Generally, it is necessary to use plasticizers with polymer dispersions either when the polymer on which the dispersion is based has a high glass transition temperature (such as ethyl cellulose), so that the MFFT of the system exceeds the product temperatures experienced in the process, or if the flexibility of the resultant film coating needs to be improved.

Unnecessary, or excessive, use of plasticizers should always be avoided, otherwise excessive tackiness will be experienced.

Common ingredients used in many film-coating formulations are: (1) polymer, (2) plasticizer, (3) colorants, and (4) solvent/vehicle.

When designing coating formulations, there are several important issues to consider. These generally involve the need to optimize:

- The visual characteristics of the final product
- The functional characteristics of the coating
- The "processibility" of the coating system (eg, issues relating to preparation and application of the coating liquid, as well as those associated with processing time and costs)

Film coatings are applied to pharmaceutical solid oral dosage forms for a number of purposes, often leading to coatings being categorized on the basis of their intent with regard to influencing drug release, namely immediate-release coatings, which although often used for esthetic purposes, may also be used to improve product stability, facilitate product identification, and achieve an improvement in product organoleptic characteristics (such as taste and odor). Modified-release coatings, which can be subdivided into two sub-categories, namely delayed-release (enteric) coatings, and extended-release (sustained- or controlled-release) coatings.

34.2.2 Overview of types of materials used in film-coating formulations

34.2.2.1 Polymers

Polymers are the essential building block of coating formulations, providing the main characteristics for the final coating formulation[7,8], and are usually characterized in terms of:

- Chemistry, which will mainly influence:
  - Solubility of coating system,
  - Rheology of coating liquid,
  - Mechanical properties of coating, and
  - Permeability characteristics of coating.
- Molecular weight (or molecular weight distribution), which is likely to influence:
  - Mechanical properties of coating and
  - Rheology of coating liquid.

Unlike that of inorganic materials, the molecular weight of a polymer is much more difficult to define because a sample of polymer will consist of a broad distribution of molecular weights.

In order to characterize the molecular weight of a polymer, we usually measure this molecular weight distribution (using techniques such as "gel permeation chromatography"), and then express the molecular weight in terms of one of two statistically defined averages (as shown in Fig. 34.6), namely, weight average molecular weight, M_w, and number average molecular weight, M_n.

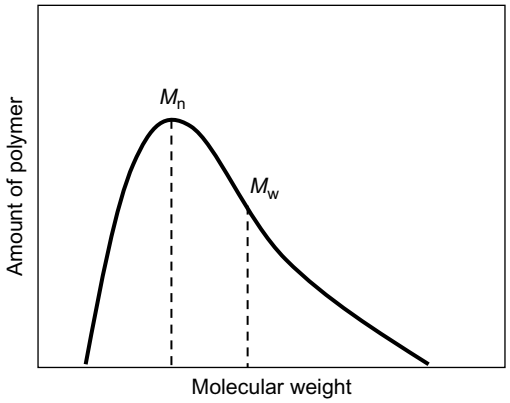

FIGURE 34.6 Typical molecular weight profile for a polymer.

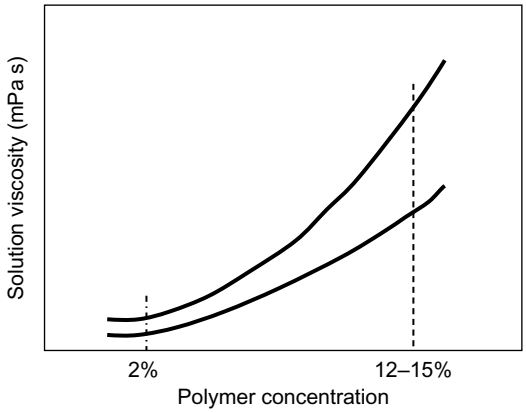

FIGURE 34.8 Effect of polymer concentration on the viscosity of aqueous polymer solutions.

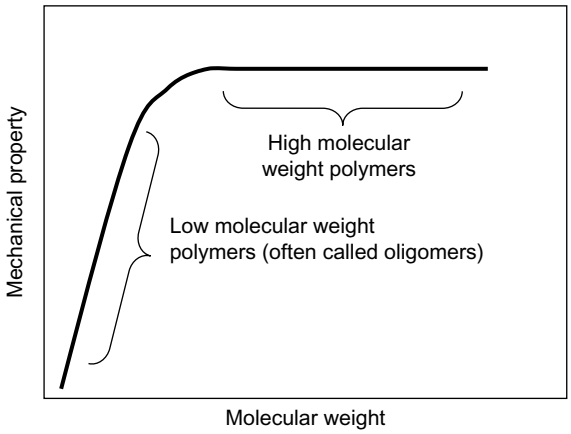

FIGURE 34.7 Effect of molecular weight on the mechanical properties of polymers.

A derived parameter that is often useful is the polydispersity function, which is defined as:

$$\text{Polydispersity} = M_w/M_n$$

The influence of molecular weight on the mechanical properties of polymers is shown in Fig. 34.7, where generally as molecular weight increases, tensile strength and elastic modulus also increase, and adhesion decreases.

Polymer molecular weight can, as stated previously, affect coating solution viscosity. In absolute terms, the relationship between polymer molecular weight and solution viscosity is governed by the Mark–Houwink equation:

$$[\mu] = k\,M^{\alpha}$$

Where $[\mu]$ is the intrinsic viscosity of the polymer, M is its molecular weight, and k and α are constants relating to the solvent system used and the solution temperature.

For more pragmatic reasons, we often prefer to use the term nominal viscosity, where:

$$\text{Molecular weight} = k(\text{nominal viscosity})^{n}$$

Nominal viscosity is usually measured, in water at 25°C, using a solution containing 2% w/w polymer.

Not only does polymer molecular weight influence solution viscosity, but so does polymer concentration, as illustrated in Fig. 34.8. As stated previously, nominal viscosity is measured for dilute solutions of polymer. No particular batch of polymer will conform exactly to the nominal viscosity value for that grade. Thus, the manufacturers (and usually the compendia as well) will set a specification range. As seen in Fig. 34.8, at the 2% solids concentration (usually used for setting the nominal viscosity specification), the batch-wise variation in solution viscosity is usually quite small (often only ±2 cP, or m Pa s). However, as we increase the solids content of the solution, not only does the viscosity increase exponentially, but the difference in solution viscosity from batch-to-batch can increase dramatically, so that the batch-wise variation in coating solution viscosity (depending on the solids contents of our coating solutions) may be as much as 100–200 cP.

34.2.2.2 *Plasticizers*

Plasticizers are another common ingredient added to coating formulations. They are typically used to reduce the *glass transition temperature*, T_g (see Fig. 34.9), and increase coating flexibility.

Most polymers that we use in film coating are essentially amorphous materials, and as such, exhibit a reasonably well-defined glass transition temperature (a fundamental characteristic of polymers that has a profound effect on polymer properties that can also influence film formation, especially when using aqueous polymer dispersions). This transition does not represent a change in state (as we see with melting

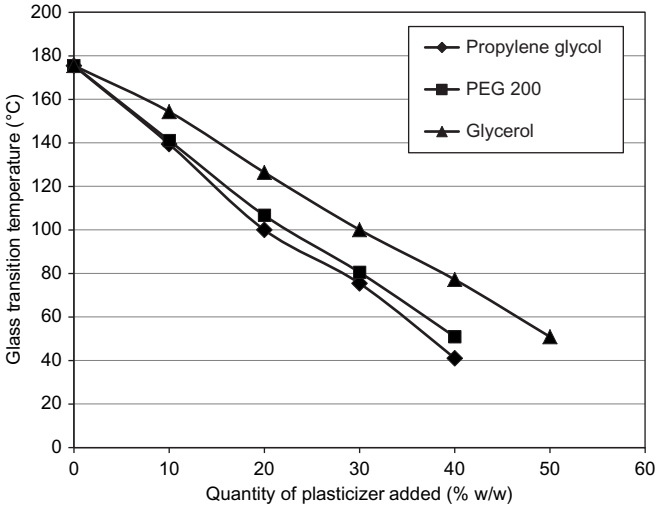

FIGURE 34.9 Effects of plasticizers on the glass transition temperature of HPMC.

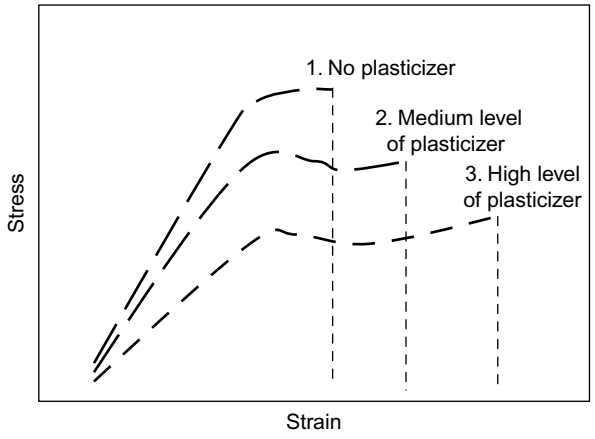

FIGURE 34.10 Effects of plasticizers on the mechanical properties of film coatings.

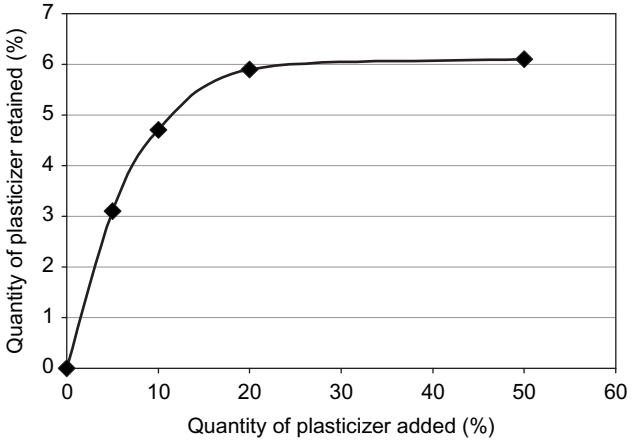

FIGURE 34.11 Lack of plasticizer permanence (for propylene glycol in HPMC films).

TABLE 34.1 Examples of Common Plasticizers Used in Film Coating Formulations

Class	Examples
Polyhydric Alcohols	Propylene glycol. Glycerol. Polyethylene glycols.
Acetate Esters	Glyceryl triacetate (Triacetin). Triethyl citrate. Acetyl triethyl citrate.
Phthalate Esters	Diethyl phthalate
Glycerides	Acetylated monoglycerides.
Oils	Castor oil. Mineral oil.

point), but rather is indicative of a point where there is a dramatic increase in molecular mobility. At this point, the polymer changes from a tough, rigid, inflexible, and brittle material into one that is softer and more pliable. These latter properties are of great value in film coating, and thus it is beneficial to match the glass transition temperature of the final coating system to the coating conditions that will be used.

For most coating systems, it is desirable that the glass transition temperature of that system be optimized for the coating process conditions used. For aqueous polymer dispersions (or latexes), it is critical that such optimization is achieved, otherwise appropriate coalescence of the coating will not occur.

A list of common plasticizers used in coating formulations is shown in Table 34.1, and their comment effects on film mechanical properties are shown in Fig. 34.10.

When it comes to selecting a suitable plasticizer for a coating formulation, some key issues to consider are: efficiency, which defines how much plasticizer must be added to produce the desired effect; compatibility, which indicates how effectively the plasticizer interacts with the polymer, and the level up to which that interaction occurs; and permanence, which relates to both plasticizer-polymer compatibility and plasticizer volatility (see Fig. 34.11 for an example of poor plasticizer permanence).

The common general effects of plasticizers used in film-coating formulations are shown in Table 34.2.

34.2.2.3 *Colorants*

See Table 34.3 for common types of colorant used in film-coating formulations.

Colorants are generally used in film-coating formulations to improve product appearance, aid in product identification, and potentially improve product stability.

While it is possible to use either water-soluble colorants (dyes) or water-insoluble colorants (pigments),

TABLE 34.2 Summary of Common Effects of Plasticizers

Property	Effect of increased plasticizer concentration
Tensile strength	Reduced
Elastic modulus	Reduced
Film adhesion	Variable, but increased under optimal-use conditions
Viscosity of coating liquid	Usually increased, with effect being greater as plasticizer molecular weight is increased
Film permeability	Variable, depending on physicochemical properties of plasticizer
Glass transition temperature (T_g) of film	Reduced, with magnitude of effect being influenced by compatibility with polymer

TABLE 34.3 Common Types of Colorant Used in Film-Coating Formulations

Type	Examples
Water-soluble dyes	• FD&C Yellow #5 • FD&C Blue #2
FD&C lakes	• FD&C Yellow #5 Lake • FD&C Blue #2 Lake
D&C lakes	• D&C Yellow #10 Lake • D&C red #30 Lake
Inorganic pigments	• Titanium dioxide • Iron oxides
"Natural" colorants	• Riboflavin • Beta-carotene • Carmine lake

TABLE 34.4 Contrast Ratio Values for Coatings Colored With Selected Pigments

Pigment	Contrast ratio
None	33.3
Titanium dioxide	91.6
Red iron oxide	99.5
Yellow iron oxide	98.4
Indigo carmine lake	99.5
Tartrazine lake	66.7

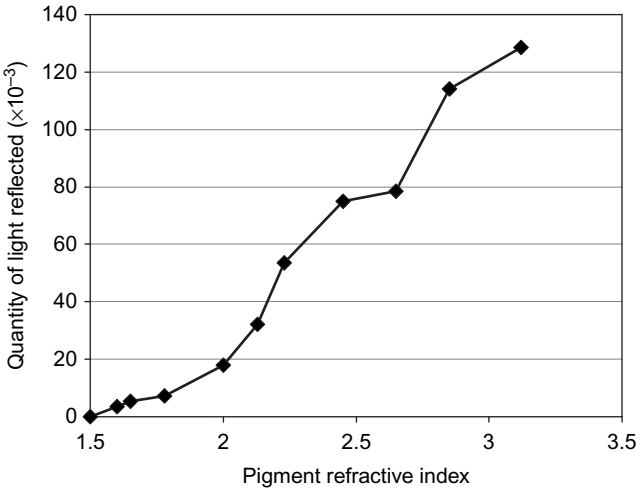

FIGURE 34.12 Hiding power and influence of pigment refractive index.

as shown in Table 34.3, the use of pigments has several advantages because they:

- Replace some of the polymer, thus allowing the solids content of film-coating liquid to be increased while still maintaining a sprayable viscosity;
- Act as a solid inclusion in the final dried coating, often improving the moisture barrier properties of the coating;
- Exhibit better light stability than water-soluble colorants;
- Are less prone to color migration as the coatings dry; and
- Exhibit light excluding behavior, thus improving the stability of photo-labile drug substances

In order to exert these properties effectively, it is desirable that the colored film coating is able to completely mask the substrate. The ability to achieve this goal is usually expressed as the hiding power (or contrast ratio) of the coating. The consequences of poor hiding power include the fact that higher coating levels will have to be employed to achieve uniform appearance from tablet to tablet, and from batch to batch, and if the tablets are intagliated (ie, have a logo), higher levels of coating can cause increased risk of logo bridging.

The contrast ratios of film coatings colored with selected pigments are shown in Table 34.4.

Generally, the main factors that can influence the hiding power of a particular film coating are:

- The quantity of light reflected at the polymer–pigment interface (which, in turn, is influenced by the refractive index of the colorant, see Fig. 34.12)
- The wave length of light absorbed by the colorant
- The amount of light absorbed
- The concentration of the colorant in the coating (see Fig. 34.13)
- The thickness of the coating (see Fig. 34.13)

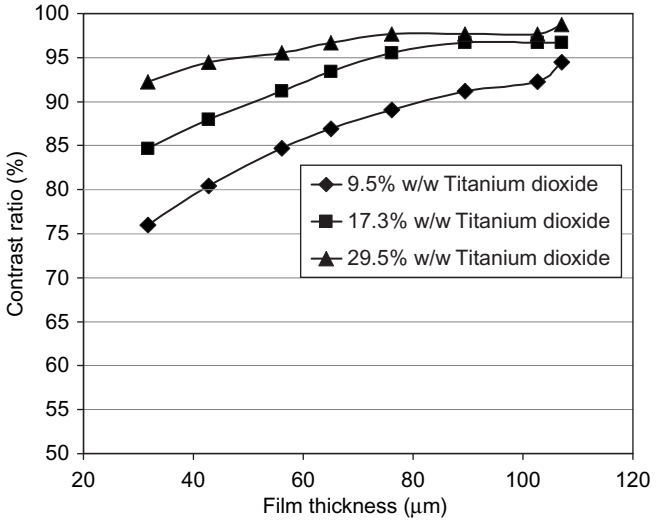

FIGURE 34.13 Effects of pigment concentration and coating thickness on the contrast ratios of colored film coatings.

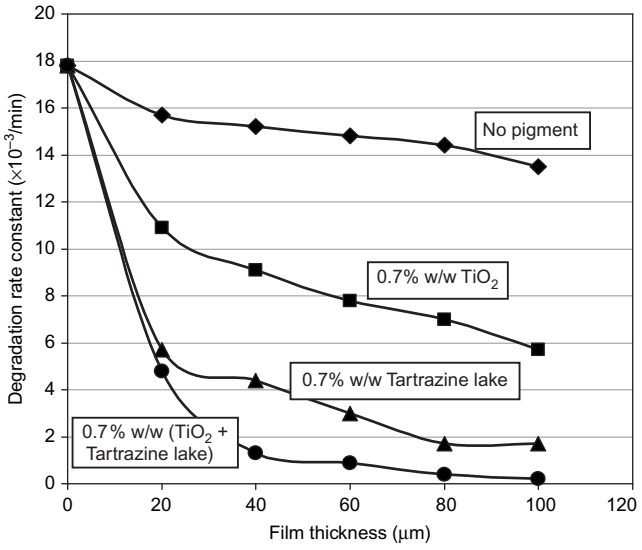

FIGURE 34.14 Photostabilization of nifedipine using pigmented film coatings.

The ability of film coatings to improve product stability is generally related to:

- The influence of pigments on coating permeability (generally, as pigment concentration is increased, up to a critical level called the critical pigment volume concentration, film permeability to environmental gases such as water vapor and/or oxygen are reduced); decreased permeability can lead to improved product stability
- The ability of the coating to exclude light, an important issue when coating products containing photolabile APIs (such as Nifedipine, as shown in Fig. 34.14)

In summary, the general effects of pigments on the properties of film coatings are shown in Table 34.5.

TABLE 34.5 General Effects of Pigments in Film Coatings

Property	Effect of increased pigment concentration in film
Tensile strength	Reduced (but effect may be minimized by effective pigment dispersion in film)
Elastic modulus	Increased
Film adhesion	Generally, little effect
Viscosity of coating liquid	Increased, but usually not substantially
Film permeability	Reduced, unless critical pigment volume concentration (CPVC) is exceeded
Hiding power	Increased, but effect is dependent on refractive index and light absorption characteristics, of pigment

TABLE 34.6 Examples of Common Solvents Used in Film-Coating Formulations

Class	Examples
Water	–
Alcohols	• Methanol • Ethanol • Isopropanol
Esters	• Ethyl acetate • Ethyl lactate
Ketones	• Acetone
Chlorinated hydrocarbons	• Methylene chloride • 1:1:1 Trichloroethane • Chloroform

34.2.2.4 *Other additives*

While polymers, plasticizers, and colorants constitute the major ingredients in film-coating formulations, other materials that might be used for a variety of reasons include:

- Antiadhesive agents, especially when the polymer is somewhat tacky;
- Flavoring agents (typically in nutraceutical applications);
- Surfactants (to facilitate the wetting of insoluble materials dispersed in the coating formulation);
- Pore-forming agents (especially in extended-release film-coating formulations).

34.2.2.5 *Solvents/vehicles*

Currently, most coating formulations that are applied to solid oral dosage forms are liquids. Thus, the key additive that is used to render the coating formulation a liquid is a solvent (the term vehicle is used to describe the situation where an aqueous polymer formulation is preferred).

A list of common solvents used in coating formulations is given in Table 34.6.

Quite clearly, in modern film-coating practices, water is often the preferred solvent[9]. Nonetheless, water is a compromise solvent for these reasons:

- Water has higher latent heat of vaporization (see Table 34.7), thus requiring more energy input to the coating process to assure that effective drying takes place (thus often precluding the use of conventional coating equipment).
- Aqueous coating systems have higher surface tensions than their organic-solvent-based counterparts (see Table 34.8), thus impacting wetting and adhesion (see Table 34.9) on many types of pharmaceutical tablets (eg, vitamins).
- Aqueous coating systems are more viscous than organic solvent-based systems (see Table 34.10), thus having some impact on pumping and atomization efficiency.

TABLE 34.7 Latent Heats of Vaporization of Common Solvents

Solvent	Latent heat of vaporization (kJ/kg)
Methylene chloride	556.7
Methanol	1967.1
Water	2260.4

TABLE 34.8 Surface Tension Values of Common Solvents

Solvent	Surface tension (mN/m) at 20°C
Acetone	23.7
Chloroform	27.1
Ethyl alcohol	22.8
Methyl alcohol	22.6
Water	72.8

TABLE 34.9 Adhesion Values of HPC Coatings Deposited From Various Solvents

Solvent system	Adhesion value (kPa)
Methylene chloride:methanol (9:1)	29.8
Ethanol:water (95:5)	23.9
Acetone:water (9:1)	20.2
Chloroform	14.4
Water	7.1

TABLE 34.10 Influence of Solvents on the Viscosity of HPMC-Based Coating Solutions

Solvent	Polymer concentration (% w/w)	Solution viscosity (m Pa s) (cP)
60:40 methylene chloride–methanol	5.0	40
80:20 ethanol–water	5.0	70
Water	10.0	450

In some cases, use of organic solvents has continued, especially when:

- The coating process will not accommodate the use of water (ie, drying is poor);
- The adhesion achieved with aqueous systems is unacceptable;
- Certain critical ingredients (eg, polymer) are neither water-soluble nor available as a latex system; and
- Exposure to an aqueous process would cause stability problems for the product being coated.

34.2.3 Film-coating formulations used for immediate-release applications

34.2.3.1 Characteristics of polymers used

- Generally water soluble;
- Able to form strong, flexible films;
- Adhere strongly to tablet surfaces;
- Form elegant films;
- Facilitate ease of processing (pumping, spraying, atomization, and lack of tackiness); and
- Permit rapid drug release from dosage form.

A typical dissolution profile for a product coated with an immediate-release film coating is shown in Fig. 34.15.

34.2.3.2 Examples of types of polymers used

Common polymers used in immediate-release coating formulations are listed in Table 34.11.

34.2.3.2.1 Cellulosic polymers

Cellulosic polymers, especially hydroxypropylmethylcellulose (HPMC), have long been the mainstay of film-coating formulations, with a popularity that stems from their common usage from the early days of film coating when organic solvents were always used; global regulatory acceptance; ready availability from a number of vendors; and ability to form coatings generally having acceptable properties (such as good film strength and aqueous solubility).

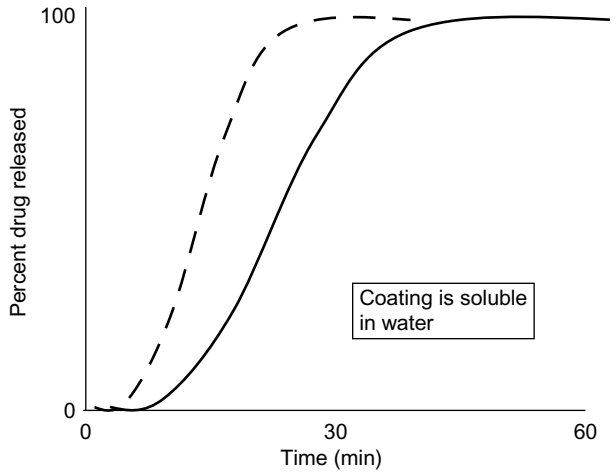

FIGURE 34.15 Typical drug release profile for products coated with immediate-release coatings.

TABLE 34.11 Examples of Common Polymers Used in Immediate-Release Coating Formulations

Polymer class	Examples
Cellulosic	• Hydroxypropylmethylcellulose • Hydroxypropylcellulose • Hydroxyethylcellulose
Vinyl	• Poly (vinyl pyrrolidone) • Poly (vinyl alcohol) • Poly (vinyl pyrrolidone)−poly (vinyl acetate) copolymers • Poly (vinyl alcohol)−poly (ethylene glycol) copolymers
Glycols	• Poly (ethylene glycol)
Acrylics	• Amino alkyl methacrylate copolymers
Other carbohydrates	• Maltodextrin • Polydextrose

34.2.3.2.2 Vinyl pyrrolidone polymers

The most common vinyl polymer used in the pharmaceutical industry today is poly (vinyl pyrrolidone). While this polymer has been primarily used as a wet binder in granulation processes, it has certain utility in film coatings (due to its potentially high film-adhesion characteristics), although uses are somewhat limited because it generally forms extremely tacky films (both during application of the coating and on final coated product), and produces coatings that tend to be somewhat brittle.

In contrast, poly (vinyl pyrrolidone)-poly (vinyl acetate) copolymer potentially has greater utility because it is less tacky than the homopolymer, produces films that exhibit good adhesion characteristics, and generates coating solutions with low viscosities.

34.2.3.2.3 Vinyl alcohol polymers

Poly (vinyl alcohol) has gained popularity recently because of its good film properties, and the relatively low viscosity of its coating solutions. Typical characteristics of coatings made with this polymer include the fact that coating solutions that can be somewhat tacky, while subsequent dry films tend to exhibit good adhesion properties (to tablet surfaces) and excellent barrier properties (to environmental gases such as oxygen and water vapor); however, applied coatings may, under certain circumstances, slightly retard tablet dissolution behavior.

To obviate some of the problems of the homopolymer (especially tackiness), poly (vinyl alcohol)-poly (ethylene glycol) is a copolymer designed with certain improvements in mind.

34.2.3.2.4 Acrylic polymers

The acrylic polymers that are typically used in film-coating applications are:

- Generally not water soluble, per se (the polymer tends to dissolve readily at low pH);
- Traditionally used to create film coatings with improved taste-masking capabilities because the pH in the mouth is usually alkaline (ie, above that where the coating will dissolve in water); and
- Usually applied as solutions in organic solvents, although special polymer grades that allow aqueous polymer suspensions to be prepared are now available.

34.2.3.3 Formulation strategies used

Immediate-release film coatings have traditionally utilized relatively simple formulation strategies, typically combining a single polymer in combination with other ingredients, such as plasticizers and colorants. The introduction of aqueous coatings created a major challenge for formulators, especially with regard to managing the viscosity of the coating formulation and achieving acceptable adhesion of the coating to the surface of the tablets being coated.

Such challenges have typically been met, over the course of time, by utilizing polymer mixtures, such as blends of:

- Different molecular weight grades of the same polymer (such as a mixture of HPMC 6 cP and HPMC 3 cP),
- Similar polymers (such as HPMC + HPC), and
- Cellulosic polymers with other carbohydrate materials (such as HPMC with maltodextrin, polydextrose, or lactose).

The properties of some typical polymer blends are shown in Table 34.12.

TABLE 34.12 Film Properties of Various Polymer Blends

Polymer	Tensile strength, σ (MPa)	Elastic modulus, E (GPa)	σ/E value ($\times 10^{-2}$)	Film adhesion (kPa)
HPMC blend	31.74	2.25	1.41	250.5
HPMC/HPC blend	17.68	0.99	1.79	253.5
HPMC/lactose blend	13.53	2.34	0.58	500.6

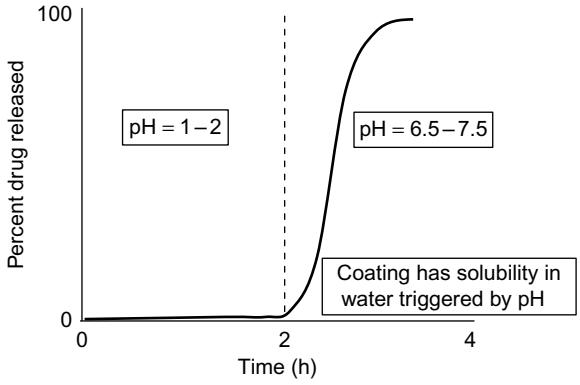

FIGURE 34.17 Typical drug release profile from products coated with enteric coatings.

34.2.4 Film coatings used for modified-release applications

As described previously, film coatings used for modified-release applications can be subdivided into two main categories, namely delayed-release (or enteric) coatings, and extended-release coatings.

34.2.4.1 Delayed-release (enteric) coatings

Enteric coatings are primarily used for the purpose of:

- Maintaining the stability of APIs that are unstable when exposed to the acidic conditions of the gastric milieu. Such API's include erythromycin, pancreatin, and the class of proton pump inhibitors, such as omeprazole.
- Minimizing the side effects (eg, nausea, and gastric irritation and bleeding) that can occur with APIs such aspirin and certain nonsteroidal inflammatory compounds.
- Creating opportunities for "night-time dosing" strategies, where the intent is to allow the dosage form to be consumed at bed-time, and permit effective blood levels of the API to be attained just prior to waking.
- Facilitating colonic drug delivery.

The functionality of enteric coatings is, for the most part, mediated by a change in pH of the environment to which the enteric-coated product is exposed. Enteric polymers remain unionized (and thus, insoluble) at low pH values, and begin to dissolve at a pH value of approximately 5.0–5.5. In addition, the functionality of enteric coatings can be greatly affected by many other factors, such as:

- The nature of the API contained in the dosage form; this is especially true when that API is ionic in nature.
- The quantity of coating applied; insufficient coating can result in ineffective gastric resistance, while too much applied coating can seriously delay drug release when the dosage form passes into the small intestine.
- The presence of imperfections in the coating (eg, cracks, "pick marks," etc.) that can also lead to reduced gastric resistance.
- The chemistry of the polymer used (especially dissolution pH and dissolution rate at a given pH).
- The influence of the in-vitro test conditions used (such as pH and ionic strength of the test medium; as well as the agitation rate used in the test).

Enteric film-coating polymers are essentially polyacids (see Fig. 34.16), and typically only dissolve in water above pH = 5.0–6.0; these polymers are selected for their ability not only to form robust coatings that adhere strongly to tablet surfaces, but also to permit rapid drug release from dosage form once it passes from the stomach into the small intestine (see Fig. 34.17).

A list of commonly used enteric-coating polymers is given in Table 34.13, and these form the basis of enteric coating formulations used in either organic-solvent-based or aqueous-coating formulations. A breakdown of coating systems specially designed for aqueous-coating applications is shown in Table 34.14.

TABLE 34.13 Examples of Common Polymers Used in Enteric Coating Formulations

Polymer	Comments
Cellulose acetate phthalate	Hydrolysis potential—high[a]
Cellulose acetate trimellitate	Hydrolysis potential—medium[a]
Polyvinyl acetate phthalate	Hydrolysis potential—low[a]
Hydroxypropylmethylcellulose phthalate	Hydrolysis potential—medium[a]
Hydroxypropylmethylcellulose acetate succinate	Hydrolysis potential—low[a]
Poly (MA-EA) 1:1	–
Poly (MA-MMA) 1:1	Relatively high dissolution pH
Poly (MA-MMA) 1:2	Relatively high dissolution pH

MA, Methacrylic acid; EA, Ethyl acrylate.

While enteric-coated products have conventionally taken the form of tablets, recently a preference has been shown for coating multiparticulates because of their more consistent gastrointestinal transit characteristics. Enteric-coated capsules (especially one-piece softgels, containing garlic or fish oils used in nutraceutical applications) have also become quite commonplace.

34.2.4.2 *Extended-release coatings*

Extended-release coatings are typically completely insoluble in water, and permit the release of the API by means of diffusion through an intact coating membrane. Polymer selection, and the general formulation strategies employed in this category will very much depend on a number of factors, including a desire to create a specific type of drug-release characteristic, minimize the risk of dose-dumping, utilize processing methodologies that already exist within the company, and prepare a unique dosage form that enables the manufacturer to take a proprietary position with respect to dosage-form presentation.

In order to meet these requirements, critical objectives include the need to:

- Achieve the target drug-release characteristics in a reproducible manner;
- Ensure that drug-release characteristics are insensitive to expected variations in raw materials and coating-process conditions;
- Confirm that the coating formulations (and associated coating processes) are essentially uncomplicated, and facilitate scale-up from the laboratory into production; and
- Ensure that the final product is stable and does not exhibit time-dependent changes in drug-release characteristics.

When it comes to designing extended-release products, these may take a number of forms, namely tablets, prepared as film-coated tablets, film-coated mini-tablets, or compacted, film-coated particulates, as well as capsules, prepared as encapsulated, film-coated particulates, or film-coated capsules.

Coated multiparticulates often form the basis for extended-release products when an applied coating is the main mediator of drug release because of the desire to minimize dose dumping, and facilitate more consistent gastro-intestinal transit times. Such coated multiparticulates (see Fig. 34.18) can take the form of drug-loaded pellets (nonpareils), granules (irregularly shaped granules or granules that have been spheronized), drug crystals, and finally drug/ion-exchange-resin complexes.

In terms of designing extended-release coating formulations, the types of polymers used are often selected for their ability to exhibit similar robustness characteristics as those described for enteric coatings, but also for their permeability characteristics that allow the drug to be released at a controlled rate that is consistent with the biological requirements for that API (see Fig. 34.19).

A list of common polymers used for extended-release coating applications is shown in Table 34.15, while examples of aqueous-coating systems are shown in Table 34.16.

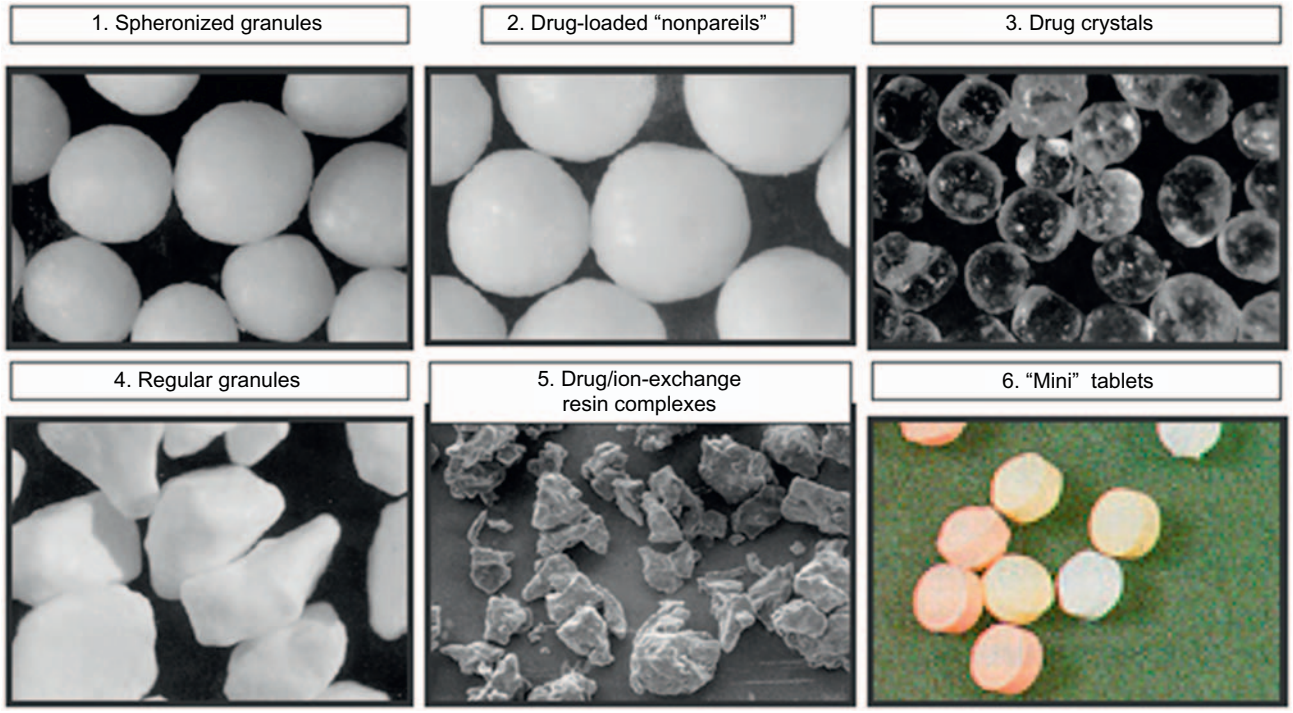

FIGURE 34.18 Examples of multiparticulates.

TABLE 34.15 Examples of Common Materials Used in Extended-Release Coating Formulations

Coating material	Membrane characteristics
Fats and waxes (beeswax; carnauba wax; cetyl alcohol; cetostearyl alcohol)	• Permeable and erodible • Permeable and soluble (at high pH)
Shellac	• Permeable and soluble (at high pH)
Zein	• Permeable and water-insoluble
Ethylcellulose	• Semi-permeable and water-insoluble
Cellulose esters (eg, acetate)	• Permeable and water-insoluble
Acrylic ester copolymers	

TABLE 34.16 Examples of Aqueous Extended-Release Coating Systems

Product	Polymer used	Comments
Surelease	Ethylcellulose	Plasticized aqueous polymer dispersion, addition of lake colorants should be avoided
Aquacoat	Ethylcellulose	Pseudo latex dispersion, plasticizer must be added to facilitate film formation
Eudragit NE 30D[a]	Acrylic copolymer	Latex dispersion; no plasticizer needed unless it is necessary to improve film flexibility
Eudragit RL 30D[a]	Acrylic copolymer	Aqueous polymer dispersion; no plasticizer needed unless it is necessary to improve film flexibility
Eudragit RS 30D[a]	Acrylic copolymer	Aqueous polymer dispersion; no plasticizer needed unless it is necessary to improve film flexibility

[a]*Also available as Kollicoat Systems.*

The performance of extended-release coating formulations is often defined by:

- The nature of polymer used, especially in terms of its chemistry (which can greatly influence coating permeability) and molecular weight (which has a significant effect on coating robustness).

- Presence of additives, such as:
  - Plasticizers (which can greatly influence coating robustness, as well as the extent of film formation when using aqueous polymer dispersions);
  - Anti-adhesive agents (which are often used to reduce agglomeration in the case of multiparticulates, as well as reduce imperfections in the coating caused by picking and sticking);
  - Colorants which, although used for identification purposes, can influence film permeability; and
  - Water-soluble pore-forming agents, which are typically added to the formulation as a deliberate strategy to modify the permeability characteristics of the applied coating.
- Coating thickness which is, in turn, influenced by the:
  - Surface area to be covered,
  - Quantity of coating applied,
  - Uniformity of distribution of coating, and
  - Coating process efficiency.

While extended-release coating formulations have typically been designed as polymer solutions in organic solvents, there has been significant interest over the past 20 years in using aqueous-coating systems. Irrespective of the formulation approach used, it is critical that the formulation of the coating enables the appropriate drug-release characteristics to be achieved in a consistent manner, the membrane obtained should be structurally sound, the coating systems are readily adaptable to existing coating-process technology, and the coating formulation and processes are sufficiently optimized to prevent the occurrence of time-dependent changes in drug-release characteristics.

Meeting these objectives can be more challenging when using aqueous polymer dispersions because it is necessary to ensure that coalescence of the coating during film formation proceeds to an endpoint where membrane porosity is eliminated, this completeness of coalescence is either achieved during the coating process, or by means of a short curing step performed at the conclusion of that process, and further gradual coalescence, over an extended period of time, is avoided.

Thus the coating formulation used must be suitably optimized in terms of its ability to achieve completeness of film coalescence in the particular coating process to be employed. This usually means that the MFFT (which is closely related to the glass-transition temperature of the polymer employed, either in its natural state, or as modified by the presence of a plasticizer) is matched to the typical temperature conditions used in the process. In addition, the coating process conditions employed must also be optimized to ensure that they enable the correct temperature conditions to be achieved (to facilitate film coalescence).

34.3 DESIGN AND DEVELOPMENT OF FILM-COATING PROCESSES

34.3.1 General introduction to coating processes and equipment

34.3.1.1 Overview

A film coating is usually applied onto tablets until they reach a targeted weight range, often expressed as a percentage weight gain. A typical weight gain for an esthetic coating is 2–4%, whereas, for clear coatings, the weight gain may be as little as 0.5–1.0%. For controlled-release applications, the quantity of the coating required is directly related to its thickness. A thickness of 30–50 μm (this translates to 4–6 mg polymer/cm^2 of tablet surface) is usually sufficient to provide a satisfactory enteric coating. It will require a greater weight gain to achieve a controlled release film of a suitable thickness because a batch of smaller tablets contains a greater total tablet surface area.

The reasons for selecting a specific film-coating process are essentially the same, regardless of whether the process is performed in a perforated coating pan or a fluid-bed coating process. In general, the major criterion for deciding between either a coating pan or a fluid-bed process is often related to the size and shape of the product to be coated. A rule of thumb is that if the product is approximately 6 mm or less in diameter, then the preferred equipment for applying the coating is the fluid-bed coater, mainly because when attempting to coat small particles in a perforated coating pan (where process air is drawn down through the tablet bed under a negative pressure) the pressure drop across the product bed can drastically reduce the process air volume, a factor which will reduce the evaporative capacity of the pan. This, coupled with the close contact of the product in the spray zone (increasing the risk of agglomeration), makes the coating of small particles in the coating pan less desirable. When attempting to coat larger size products (such as tablets) in a fluid-bed process, often the capacity of the fan is insufficient to fluidize such a product, and even when successful fluidization is achieved, product attrition may be excessive.

34.3.2 Batch coating systems

Batch coating of solid oral dosage forms requires a process where the equipment involved not only acts as a container, but also provides constant motion and facilitates the evaporation of the coating solvent. In a pan-coating process, the container will typically be cylindrical and will rotate on a horizontal axis. The coating formulation will be sprayed onto the surface of the constantly moving product in a finely atomized

state, typically achieved using a spray gun. Droplets from the spray gun are composed of a solution (or suspension), which is a mixture of a liquid carrier and solids. The principle of this type of coating is to apply the solution in such a manner that a droplet from the spray gun will land on the product and spread. The temperature of the product will then rapidly evaporate the liquid from the suspension, leaving only the dried solids. The coating solution/suspension viscosity must be such that any evaporation that occurs between emergence of droplets from the spray nozzles until the time they impact the surface of the product being coated, these droplets will retain sufficient fluidity to enable them to spread into a uniform coating before solvent evaporation is essentially completed. This will leave a dry coating, consisting of the solids that were in the solution, on the surface of the product.

In order to produce a uniform coating, each tablet must have an equal probability of passing through the spray zone throughout the course of the coating process. In order to facilitate such uniform distribution of the coating, coating pans typically have some type of mixing baffle that not only facilitates the tumbling action of the product being coated, but ensures that product is moved back and across the coating pan. Finally, in order to promote efficient drying within the process, the coating pan must not only facilitate the application of process air across the surface of the tablet bed, but also ensure that this process air can pass through the tablet bed to complete the drying process.

Coating pans described in this section are typically considered to be closed systems, where the environment outside of the coating pan is completely separated from that within the coating pan, so that material is contained within the process and drying efficiency is maximized.

Overall, the challenge in film coating is to ensure that the coating is uniformly applied across the surface of the product to be coated, and that process thermodynamics (which defines the balance between the rate at which the coating liquid is applied and the rate at which the coating solvent is removed) are controlled in such a manner that prevents both tablets from being overwetted, such that they stick together, and that overall process efficiency (the relationship between the amount of coating material delivered into the process and that which actually ends up on the tablets) is maximized.

34.3.3 Continuous-coating systems

A continuous-coating system differs from a batch system in that tablets are continually fed into the process, pass through the spray zone in a short period of time (typically 15–20 minutes), and then are continually emptied from the process in the former. In a batch process, the tablets reside inside the coating pan for the duration of the coating process (potentially 1–4 hours depending on batch size), and only emerge once the entire process is completed. Despite these differences, the coating principles, as well as process thermodynamics, are essentially similar. A typical batch coating process is shown in Fig. 34.20, while a continuous process is exemplified in Fig. 34.21.

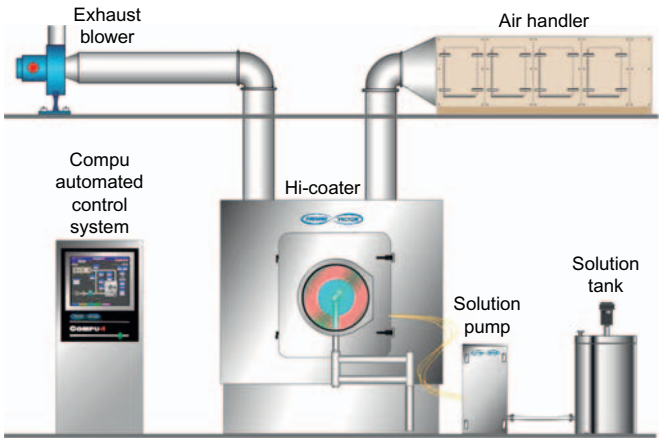

FIGURE 34.20 Example of a coating system for batch processing.

34.3.4 System components

The peripheral equipment for a coating system for either the batch system or the continuous-coating system will be very similar. Figs. 34.20 and 34.21 show equipment components typically used with both batch- and continuous-coating systems.

34.3.4.1 Overview

Process air is drawn in through an air handler where it will be heated, dehumidified (or humidified, depending upon requirements), and filtered before going to the coating pan. The process air enters the coating pan and is exhausted via a plenum located below the tablet bed, to a dust collector and a blower. Finally, the exhaust air is discharged into the environment (when organic solvent-based coating systems are used, the exhaust air will pass through a solvent recovery unit or an incinerator before being discharged). Some organic solvent systems may use a closed-loop system where solvent is condensed from the air stream before being fed back into the inlet process air stream. A closed-loop system has the advantage of using process air, which is conditioned to suit the operating parameters required for the process, thus requiring less energy input for the operation.

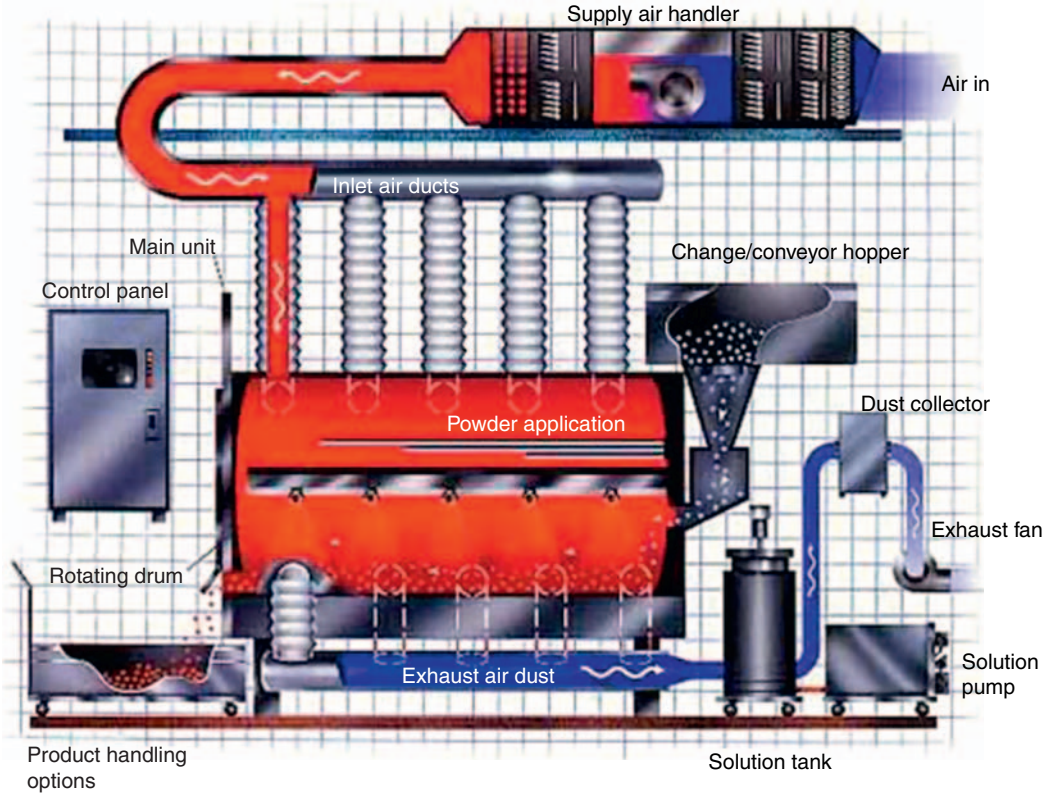

FIGURE 34.21 Example of a coating system for continuous process.

34.3.4.2 *Pan units*

34.3.4.2.1 Comparison of batch-type coating pans

The coating pan can be either fully or partially perforated around the cylindrical surface of the drum, which allows process air to be drawn through the tablet bed, ensuring more effective drying. An example of a partially perforated coating drum is shown in Figs. 34.22 and 34.23, and displays an integrated exhaust plenum on the outside of the drum. A fully perforated coating pan is shown in Figs. 34.24 and 34.25.

As the coating drum rotates, the product being coated (eg, tablets) tumbles in the drum, always remaining near the bottom of the pan (as indicated in Figs. 34.23 and 34.25). Partially perforated coating pans are constructed with exhaust plenums welded to the outside of the pan. Process air enters the coating pan through a mouth ring at the front opening of the pan, or through the back of the pan, and is drawn out through the exhaust plenums built onto the exterior of the cylindrical portion of the drum, see Fig. 34.23. The perforations in the coating pan are located over these plenums. This arrangement forces all of the process air to pass through the tablet bed. There is greater

FIGURE 34.22 Exhaust plenum on the exterior of a partially perforated coating drum.

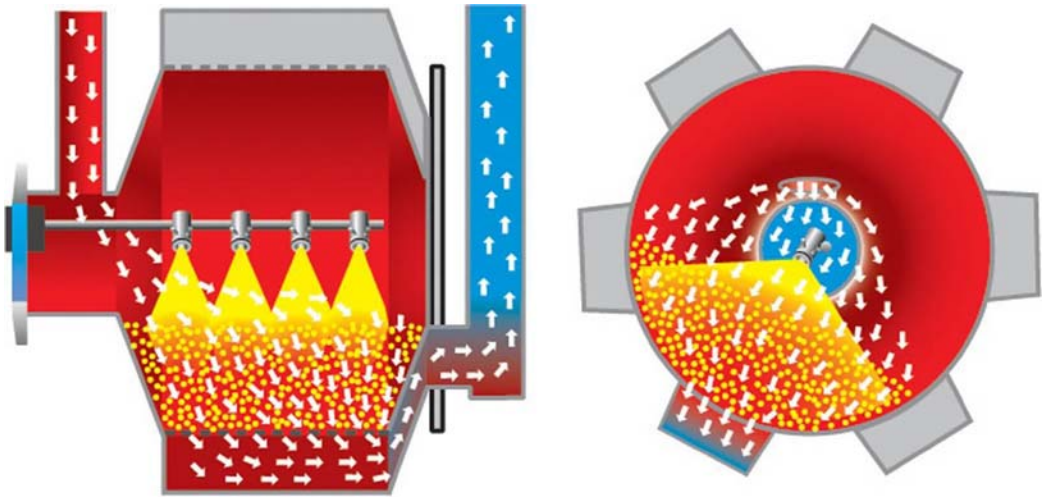

FIGURE 34.23 Air-flow diagram and chamber design of a partially perforated pan.

FIGURE 34.24 Exterior of the fully perforated coating drum.

pressure drop in the path of the process air (compared with the fully perforated pan) because of the plenum system and the tablets. The path of the process air through the fully perforated pan is shown in Fig. 34.25.

Coating can be performed with any of these pans if the auxiliary equipment (blowers, heater, filters, etc.) is configured and specified properly for the physical layout. Some coating-pan equipment includes auto discharge. The mixing baffles can be configured in these pans such that when the pan is rotated in a reverse direction, the product will be discharged out of the door. Some coating pans have a trap door on the product drum so that the product can be discharged into product trays placed under the units. Several of the manufacturers will also supply product-loading totes, fitted with chutes, that will allow the product to be loaded from above the coating pan instead of through the drum opening.

Coating pan capacities for laboratory size units range from 0.5 to 110 L. Capacities for production-size coating pans range from 90 to 1300 L. The laboratory size units are used to perform feasibility studies and for the purposes of product and process development. An example of laboratory-size units is shown in Fig. 34.26. In general, each manufacturer makes sizes of coating pans that are comparable, although the trend now is to provide lab-scale coating equipment with multiple pan-size inserts.

Each manufacturer will provide specifications for general operation of their coating pans. Typically, they will recommend and/or furnish the peripheral equipment required to complete a system.

34.3.4.2.2 Comparison of continuous-coating equipment

An example of a continuous-coating unit is shown in Fig. 34.27. The product is moved through a drum (that represents a stretched version of a batch-coating pan) at a rate that allows the tablets to be completely coated as they pass through the coating pan. Mixing baffles may be present to help move product from one end of the coating unit to the other end. The application of coating material within a continuous coating pan is essentially the same as that in a batch side-vented coating pan. Continuous coating pans are available from Thomas Engineering, O'Hara Technologies, Driam, Bohle, and GEA.

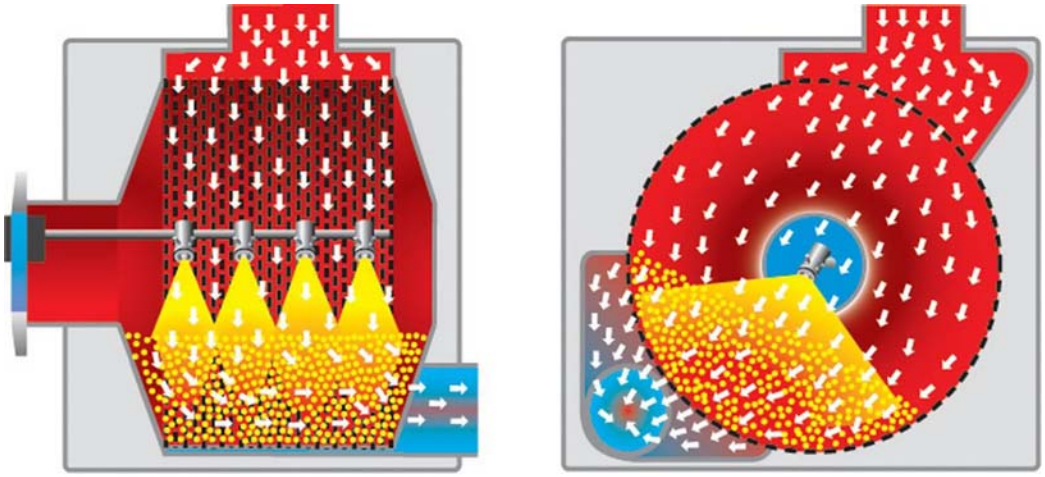

FIGURE 34.25 Air-flow diagram and chamber design of a fully perforated pan.

FIGURE 34.26 An example of a laboratory-size coating pan.

FIGURE 34.27 Example of a continuous-coating pan.

34.3.4.3 *Process air equipment*

All coating-pan equipment, including continuous-coating process equipment, requires conditioned-process air to enable solvents (aqueous or organic) to evaporate quickly. The process air generally should be dehumidified, cleaned, and heated. An air handler is used to perform these functions. A typical air handler is made up of different functional sections as shown in Fig. 34.28.

The first section will generally be composed of two filters: a bird screen followed by a prefilter. The prefilter is typically rated for 30% efficiency. The next section of the air handler is a preheat unit, followed by a dehumidification unit. The preheat section is placed before the dehumidification unit to protect any chilled water coil (or refrigeration coil) from freezing. Three methods of dehumidification are used: chilled water, refrigeration, or a desiccant dryer. The desiccant dryer is generally used to obtain the lower dew points. If humidification is required (ie, during winter when the air is very dry), this is accomplished by injecting steam into the process air stream. A heating coil is required to heat the process air.

The air handler shown in Fig. 34.28 is a face and bypass unit, which allows heated and room-temperature

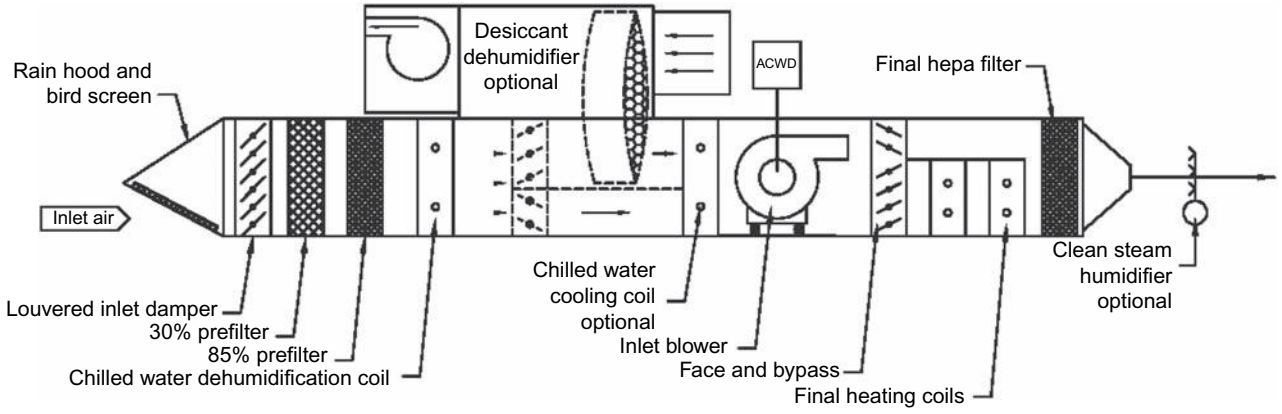

FIGURE 34.28 Example of an air-handling system.

air streams to be blended to achieve the required set-point temperature, as well as to allow temperature changes to be made quickly and facilitate better control of temperature. A conventional (nonbypass type) air handler will require some time to cool down because the heater coils remain in the process air stream after the heat has been stopped. In addition, as heat (either electric or steam) is provided, there tends to be a greater risk of oscillations in temperature occurring.

The finished product is normally cooled before being removed from the coating pan after spray application of the coating is completed. The face and bypass unit can achieve a shorter production time because a heating coil does not have to cool down before cooling the product. The air handler comprises a fan (blower), which must be rated for the proper quantity of process air to facilitate heat transfer to the product. The final stage of an air handler should be a high-efficiency particulate air (HEPA) filter to provide clean air with 99.97% efficiency.

The schematic shown in Fig. 34.28 illustrates the typical components of an air-handling system. The duct work between the HEPA filter and the coating pan should be stainless steel to preserve the integrity of the clean, process air. The quantity of process air is generally recommended by the equipment manufacturer for the size of the equipment. It is desirable to use the maximum amount of process air possible to achieve the maximum heat transfer and drying efficiency. However, caution must be exercised when increasing the air flow within the system because pressure drop increases exponentially and turbulence can be generated that will affect the spray patterns inside the coating pan. The inlet blower should be capable of providing sufficient air pressure at the desired quantity of air to bring the pressure in the coating pan to atmospheric pressure or slightly negative (up to −100 mm of water column), when the exhaust blower is operating and product is loaded in the pan. The exhaust blower must provide a vacuum pressure at the required air flow that will overcome the losses created by the different components between the coating pan and the exhaust blower.

The outlet process air duct should be connected to a dust collector to collect solids that did not adhere to the product or dust that is generated when product is loaded into the coating pan. The duct work before and after the dust collector, and the dust collector itself, must be able to withstand the amount of vacuum that will be created by the exhaust blower. The dust collector also must be designed with an explosion vent that will relieve the pressure in case of a dust explosion. When film coating is performed using an organic solvent, the entire system must be designed either to contain an explosion, or allow the explosion to be safely vented. Typically, the equipment manufacturer will recommend a system that will satisfy the requirements for a specific type of solvent.

As mentioned previously, the partially perforated coating pan generally creates greater pressure drop, thus requiring a high-pressure blower; whereas a fully perforated coating pan produces a lower pressure drop, but requires a larger quantity of process air. Finally, the exhaust blower should be capable of generating the recommended air flow for heat transfer and producing a vacuum of 25−100 mm of water column inside the coating pan. In areas where the noise of the blower cannot be tolerated, especially on the systems that require a high pressure blower, a silencer should be used after the exhaust blower. Most manufacturers of coating pans will provide the above peripheral equipment as part of a turnkey system. Some systems will have a bypass section that allows the process air to bypass the coating pan, typically being used where the coating pan door must be opened for several minutes, thus allowing cool air to enter the coating pan. If the temperature probe, which is used for the control loop,

is in the exhaust duct work, the control loop will call for a higher temperature. When the coating pan door is closed, the inlet process air temperature will be considerably higher, which in turn can cause the product temperature to exceed the set limits. The bypass allows the process air temperature to remain constant. The bypass also must have a pressure drop to prevent the air flow from increasing, thus causing a temperature change during bypass conditions. Utilizing the bypass will then allow the temperature control loop to hold the process air at a constant temperature during the time the airflow is not passing through the coating pan.

34.3.4.4 Spray systems

The design and operation of the spray-application system is a critical element of the coating process. In general, two types of spray systems are used, an open-loop system or a recirculation-loop arrangement. An open-loop arrangement is typically used with both hydraulic spray guns (atomization is generated through a high liquid-line pressure) and pneumatic spray guns (atomization is generated by a compressed air stream that impinges on the liquid stream as it emerges from the nozzle), while a recirculation loop is typically used only with pneumatic spray guns. Generally, a recirculation loop provides more flexibility, but requires more equipment and tubing to configure. When the spray is off, the coating formulation is recirculated back to the solution tank, providing mixing in the tubing to prevent precipitation of solids out of solution. A separate agitator in the solution tank should be employed for coating formulations prone to precipitation. To use the recirculation loop, a valve in the spray gun and a valve in the recirculation loop must be provided to change from spray to recirculation. A flow-measuring device is not needed for a positive displacement pump, but is desirable. A separate pump can be provided for each spray gun or a single pump connected through a manifold can feed all spray guns. The manifold can create different pressures at each gun due to the pressure drops in the manifold tubing, which in turn will cause different droplet sizes and distributions at each gun; a manifold system also has the additional disadvantage of causing extra liquid to be fed to the remaining spray guns should one or more nozzles become blocked. Many spray systems use a multiple pump configuration to prevent the pressure drop problem.

34.3.4.4.1 Comparison of different spray guns

Two types of spray guns are typically used for coating: either pneumatic or hydraulic. A third type is an ultrasonic, which has had limited success for coating processes. For most circumstances, the use of pneumatic spray guns dominates the industry today because of the preference for using aqueous-coating systems.

34.3.4.4.2 Pneumatic spray guns

The pneumatic gun sprays liquid out through an orifice, which is then subjected to a stream of compressed air that breaks the spray into droplets. The size of the droplets, the distribution of droplets, and the type of pattern is determined by the quantity of compressed air flow and the physical configuration of the spray gun. An illustration of a pneumatic spray gun is provided in Fig. 34.29, and shows the different ports for the compressed air supply and solution feed.

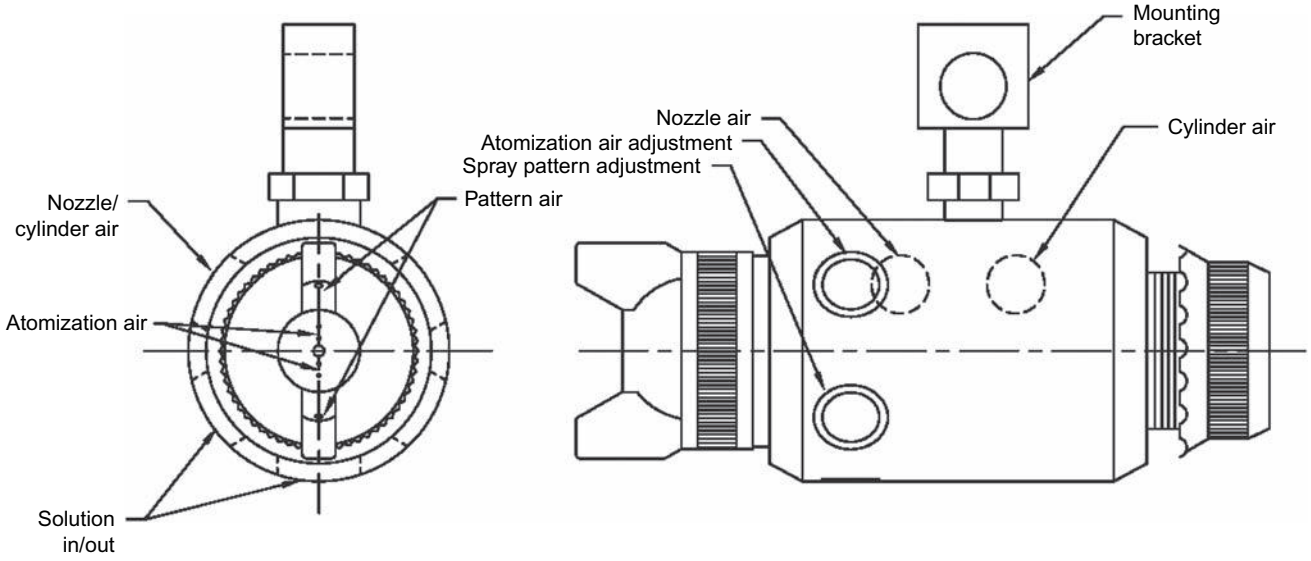

FIGURE 34.29 Example of a pneumatic spray gun with separate adjustments for atomization air and pattern air.

TABLE 34.17 Common Spray Gun Manufacturers

Manufacturer	Address	Trade name	Types of spray guns
Binks Sames Corporation	Geneseo, IL 61254	Binks Guns	Pneumatic
Freund (Vector Corp.)	Marion, IA 52302	Vector or Freund Guns	Pneumatic
Schlick	Coburg, GERMANY 96540	Schlick Guns	Pneumatic Hydraulic
Spraying Systems Co.	Wheaton, IL 60189	Spraying Systems	Pneumatic Hydraulic

Table 34.17 provides manufacturers of spray guns.

Solution and air orifice sizes on the spray guns may need to be changed for different types of coating suspensions but, in general, a single orifice size will suffice for most commonly used coating suspensions.

34.3.4.4.3 Hydraulic spray guns

A hydraulic spray gun uses pressure on the liquid feed lines to force the coating liquid through an orifice where, under the influence of the pressure drop created at the nozzle, the liquid is sheared into droplets. The orifice must be changed for different types of spray patterns and spray distributions. Hydraulic spray guns have limited use in coating pans because the spray distribution is considerably wider than for pneumatic spray guns. The typical pressures required to maintain effective atomization also often result in spray rates being too high for aqueous applications; however, this type of nozzle can be very beneficial when using organic solvent-based coating formulations.

In all types of spray guns, as the spray rate is changed, the pattern, droplet size, droplet distribution, and droplet velocity will also change. The pneumatic gun provides more flexibility because the atomizing air can be varied to obtain the desired spray droplet characteristics without changing the nozzle. Ultrasonic spray guns produce relatively small droplet size over the wide range of spray rates, and have the advantage in that the larger orifices they employ result in less plugging of the nozzle. Both the hydraulic and pneumatic spray guns are subject to plugging, causing disruption of the droplet size distribution and the spray pattern. The hydraulic gun is more prone to plugging than the pneumatic gun because the orifice openings are smaller.

34.3.4.4.4 Solution delivery pump

The open-loop arrangement described previously for the spray-application system is generally used with pumps, such as a gear pumps, a lobe pump, or peristaltic pumps. These pumps are capable of supplying pressures of 1–7 bar gage pressure to the spray nozzles. Peristaltic pumps are most commonly used because of the ease of cleaning and lower cost. Centrifugal pumps are normally not used because of pressure requirements and the need for a flow measurement service due to the characteristics of the pump.

The selection of the pump is determined by the type of spray guns used. The hydraulic spray guns will require 2–4 bar of solution pressure at the desired flow rates. The pneumatic spray guns will require 0.05–1.0 bar at the desired flow rate. The ultrasonic spray guns require only pressure to supply the solution to the spray head (typically less than 0.7 bar). Normally, pumps that operate at lower pressures create fewer problems relative to pump wear and sealing of connections to the pump and spray guns. To ensure that proper flow and pressure is provided to each spray gun, many of the spray systems incorporate a separate pump (or pump head driven from a common drive system) for each spray gun. A single pump or a single tubing distribution system, through a manifold to the spray guns will result in different pressures and flow rates at the spray guns. When selecting a pump, the location from which the coating solution is being drawn must be considered. Some coating formulations may require additional pump pressure due to a high vacuum pressure on the inlet side of the pump. When using more than one pump, the inlet tubing must be sized for the total number of pumps and the vacuum loss due to the size of the inlet tubing.

The connections for the spray system are very critical and must be installed with care. If there is a leak in the tubing on the inlet side of the pump, air bubbles are created in the suspension which travel to the spray heads and cause distortion of the spray pattern and droplet size distribution. Any leaks in the tubing, piping, or connections will result in dripping onto the product because all spray guns are mounted inside the coating pan over the product; causing twinning (tablets stuck together) or picking (tablets stuck together and separated).

34.3.4.4.5 Delivery control

The application of the coating liquid onto the tablets can only be consistent if the rate at which the liquid is being delivered to each spray nozzle is also consistent. For this reason, effective control of the flow of coating suspension must be exercised. In the past, assumptions have been made that if a positive displacement pump is used, then the rotational speed of the pump shaft (rpm) can be used to determine the flow rate. However, variations in the spray gun outputs can

occur because of pressure changes in the system and systems where more than one pump is used. Therefore it is advisable that some form of measurement and control be used for the suspension flow. The most common form of measurement is a mass-flow meter. Spray systems that use a manifold for the spray guns can be configured to use a single pump, but a mass-flow meter should be used at the outlet of the pump. Spray systems that use multiple pumps feeding individual guns should incorporate a mass flow meter in the common-source, line-feeding the pumps. There are several types of mass-flow meters that have been used including vortex-flow meters, Coriolis mass-flow meters, and turbines. Turbines are not typically used because they cannot be cleaned properly without removing them from the coating suspension line. Differential pressure is not used because this requires an orifice plate which generates more pressure drop for the spray system, thus increasing the work load for the pump. These flow devices will normally have to measure mass flow over a range of 100−1000 mL/minute. An alternative means to measure the application of the coating is to use a weight-loss system, which involves putting the solution tank on load cells (weight measuring sensors) and then, knowing the density of the suspension, the amount of material applied can be determined as a reduction in the tank weight. This weighing system must be capable of having the tare weight set to zero before starting application of the coating liquid.

34.3.4.4.6 System controls

System controls may take one of several forms and should be chosen based on the tolerance required for the product, the operator's technical knowledge level, and the extent of control desired. There are basically three types of systems:

- Manual: All functions are selected and controlled by an operator;
- Semiautomatic: These systems use a combination of manual and automatic systems; and
- Automatic: This system requires minimal operator input during the coating process.

Typically, the design of a coating process is based on the equipment used, and the process conditions that are deemed critical to the overall success of that process. Ideally, for any given process, these conditions should be held constant:

- Process air flow
- Inlet process air temperature
- Average static pressure in the coating pan
- Humidity (or dew-point) in the process air going into the coating pan
- Coating pan speed
- Spray rate of the coating solution

All three control systems mentioned previously will require certain parameters to be measured in order to make any coating system operate with consistent results. The manual system will have only instruments that provide local readouts, which are used by the operator to adjust the controls. Both types of automation will require outputs that can be input into a programmable logic controller (PLC) or computer.

These measurements represent the minimum required for any of the coating systems to provide a consistent coating operation:

- Inlet process air temperature
- Exhaust process air temperature from the coating pan
- Process air flow volume or flow rate in the inlet duct to the coating pan
- Pump speed or suspension spray rate.
- Coating pan rotation (RPM)

These controls are required for each of the systems:

- Power to the system
- Temperature controller
- Air-flow control (manual or motorized dampers, or blower motor speed control)
- Solution volume or rate control (mechanical or pump motor speed control)
- Coating pan rotational speed (mechanical or pan motor speed control)

Each of these items for either measurement or control will be analog in nature, either by an analog meter or an analog signal to a PLC or computer.

Other measurements that may be included with a coating pan system are:

- Process air temperature after the preheater
- Dew-point temperature after the dehumidification or humidification
- Differential pressure across the inlet filter to the air handler
- Differential pressure across the HEPA filters in the inlet air duct
- Differential pressure across the coating pan
- Static pressure in the coating pan
- Differential pressure across the dust collector
- Static pressure after the air handler
- Static pressure at the inlet of the exhaust blower
- Product temperature
- Main compressed-air pressure
- Solution tank weighing system
- Solution pressure
- Solution mass-flow meter
- Compressed air flow rate to pneumatic spray guns

34.3.5 General characteristics of the pharmaceutical coating process

34.3.5.1 Typical process steps

If this is the first time that a particular product has been coated, it is generally necessary to estimate the approximate batch size to use. Coating pans are usually rated for a specific brim volume capacity. Brim volume can be defined as volume capacity, if loaded to the very bottom of the pan opening. The initial pan load is usually somewhat less than brim volume in order to prevent product from spilling out of the pan opening should the product volume increase during the coating process or if the product movement should change. As a starting point, the brim volume capacity should be multiplied by 95% in order to estimate the starting fill volume; this estimated volume can then be multiplied by the product's bulk density (in g/mL) to determine the approximate maximum batch capacity. Product bulk density can be approximated by determining the weight of a 1-L volume of tablets. Batches of 70–75% of the maximum can usually be coated without a problem. For smaller batch sizes, it is necessary to examine product movement to verify that it is adequate, and also determine that the exhaust air plenums (in a fully perforated pan) are completely covered. Reduced height baffles can be used to improve product movement with smaller pan loading. In cases where the exhaust plenum is not completely covered, it may also be necessary to use a restrictor plate to reduce the exhaust opening, thus preventing air from being drawn around the tablet bed rather than through it.

For continuous coating pan systems, the throughput is controlled by a combination of the pan drum angle, pan speed (rpm), and tablet input rate. A higher throughput is achieved by increasing one or more of these factors. Either one of these changes causes the product to flow more rapidly through the pan, thus increasing the potential production rate.

34.3.5.1.1 Coating pan set-up

The typical coating process consists of several different steps. The first step is to verify proper operation of the spray delivery system, which must be calibrated to deliver a consistent gun-to-gun delivery of the coating solution, especially when manifold systems are used. Calibration can be accomplished by individually collecting and weighing the solution from each spray gun for a set interval of time. The calibration procedure should determine if the overall delivery of solution is accurate (if it matches the theoretical rate) and also confirm that the variation in solution flow between guns is minimized. If there is an unacceptable variation (usually $> \pm 5.0\%$), then the system will need to be adjusted so that the pressure drop between guns is the same. Most spray guns are equipped with a needle valve-adjustment cap that controls the clearance between the spray needle and the liquid nozzle. Adjustment of the position of the needle valve will in turn facilitate adjustment of the fluid delivery rate through a particular spray gun. After making an adjustment to the spray guns, the solution collection should be repeated. When uniform solution delivery has been achieved, it is necessary to calibrate the nozzle air volume to the spray guns. Some spray guns have a common line for providing atomization air and pattern air. For these systems, the air volume is achieved by setting the desired nozzle air pressure. Other guns have separate controls for the atomization and pattern air, and a mist checker or flow meter for display of the actual air volume. For these systems, a needle valve (located on the spray gun body) is usually adjusted to set the atomization air volume. Once the atomization air volume has been set for all of the guns, a second needle valve is adjusted to the desired volume for pattern air. After these air volumes have been set, it is possible to verify the approximate dimensions of the spray pattern by passing a hand through the air stream. This spray pattern should be checked at a distance that is equal to the distance between the tablet bed and the spray guns.

34.3.5.1.2 Loading/charging

After proper set-up of the pan and spray equipment has been confirmed, the pan can be loaded with product either through the front of the pan (pan mouth ring) or through a discharge door located on the flat of the pan (if it is so equipped). During the loading of the pan, the exhaust air is usually turned on to eliminate or minimize exposure to irritating and potentially hazardous dusts. It is a good idea to minimize the distance that the product is allowed to drop during charging because this will minimize or eliminate tablet breakage. It is usually recommended that the pan be jogged occasionally during loading to move product towards the back of the pan.

34.3.5.1.3 Preheat/de-dusting

After loading, the next step is to preheat the product to the desired process temperature. While the product is being preheated, it is also de-dusted by the process airflow. This is a good time to circulate coating solution through the spray guns (if a recirculation system is used). Verification that the spray guns are positioned correctly can be accomplished at this time, checking both the angle to and distance from the tablet bed. During the preheat step, the product can either be rotated continuously at a very slow speed (preferred)

or jogged intermittently. This will minimize attrition while ensuring that the product is uniformly heated. For heat-sensitive products, it will be necessary to jog on a more frequent basis to prevent overheating the upper surface of the tablet bed. Tablets are generally preheated to a specific product or exhaust temperature. The product and exhaust temperatures are typically not the same, though they tend be fairly close during the coating process. Once the exhaust air or product has been heated to the desired starting temperature, application of the coating liquid can be initiated.

34.3.5.1.4 Application of a seal/barrier coat

In a few rare cases, it may be necessary to apply a barrier-coating after the application of the primary film coating. The need for a barrier/seal coat typically occurs when there is an interaction between the film polymer and the product substrate (eg, interaction between an enteric polymer and tablets containing an alkaline drug, or interaction between an acid labile drug and an enteric polymer, which is acidic). In such cases, a seal coat of an inert film polymer, such as HPMC prior to the enteric polymer coating, may be used. A second example occurs when there is an interaction between the coating solvent and the product (ie, an aqueous coating and an effervescent product). To remedy this type of problem, a seal coating with an alternative solvent may be used. It is possible to coat, for example, some effervescent products with aqueous solutions if the spray rate for the initial phase of the coating is reduced, process temperatures are substantially increased, and the solids content of the coating suspension is high (approximately 20% w/w).

34.3.5.1.5 Application of the film coating

Prior to commencing the spray cycle, the pan should be set to the desired rotational speed. If a frequency drive is used, it is important to allow approximately 5 seconds for the pan to achieve the rpm set-point. Once the product has reached the required speed, the spray can be started. The initiation of the spray will cause the product and exhaust temperatures to drop slightly due to evaporative cooling. If these temperatures drop below the desired range, the inlet temperature will need to be increased. If the coating system has an inlet air handler with some type of humidity control, there will be a very consistent batch to batch correlation between the inlet temperature necessary to achieve the desired exhaust and/or product temperatures. Some systems automatically control the inlet temperature to maintain the required exhaust temperature. The time required for the coating cycle is determined by a number of factors that include: desired coating weight gain, coating process efficiency, coating solution solids level, spray rate, and the size of the spray zone. The end of the spray cycle is usually controlled by either time or the application of a set quantity of coating solution because these factors tend to be constant for a particular product. If the spray cycle is controlled by solution quantity, this can be accomplished through the use of either a mass-flow meter or a mass balance. Either of these methods will provide a totalization of the solution applied.

34.3.5.1.6 Gloss coat

After the primary coating has been completed, a dilute over-coating may be applied to prevent the tablets from blocking or sticking (such as with some of the aqueous dispersions that are thermoplastic) or to provide a higher film gloss. If the purpose is to provide a higher gloss, a dilute HPMC solution may be used. The process temperatures may be reduced slightly to reduce the amount of spray drying that occurs.

For some of the aqueous coating dispersions, it is recommended that the product be maintained at a slightly elevated temperature to fully cure the coating and provide a stable release profile. After coating, the product should be cooled prior to the application of a powdered wax (if one is to be applied to improve tablet flow and gloss). Cooling the product after coating also minimizes potential problems due to heat instability of the active (since product temperature will rise after the spray is turned off due to loss of the evaporative cooling effect. A product is typically cooled to an exhaust or product temperature of 25–30°C before discharging from the pan.

34.3.5.1.7 Wax addition

After cool-down of the product, a powdered wax may be used to provide a higher tablet gloss. The waxes typically used are either a carnauba wax, a combination of carnauba and beeswax, or rice wax. A small quantity of wax (5–10 g per 100 kg of tablets) is applied to the rotating tablet bed. The tablets are allowed to rotate for approximately 5 minutes with no process air. After 5 minutes, the tablets are rotated for an additional 5 minutes with the process air on. This allows any excess wax to be exhausted. A canvas-lined pan is not necessary for the wax application, although it may provide a slightly higher gloss.

34.3.5.1.8 Product discharge

At the conclusion of the cool-down period, the product is ready for discharge. Depending on the type of pan used, the product will be discharged through a "trap-door" on the flat of the pan or through the front

pan door (either by manual scooping, or using one of the many emptying scoop devices supplied by the equipment vendor). In some systems, the pan may be rotated backward or counter-clockwise to aid in discharging the product, in which case the baffles are designed to direct the product out the front door. Discharge of the entire batch usually will be achieved in 2–10 minutes, depending on the pan size and type of discharge method employed. For most cases, the coated product should not be allowed to drop more than 60–90 cm, otherwise tablet breakage may be experienced.

34.3.6 Understanding process thermodynamics

34.3.6.1 Adequate evaporative rate

The theoretical evaporative rate for aqueous film coating can be determined using the following equation:

$$\text{Rate} = \frac{\text{CMH} \times C_P \times \ell \times [(T_{IN} - T_{OUT}) - 0.10(T_{IN} - T_{OUT})]}{\text{LHV}}$$

where:

Rate = Evaporative rate of water per hour (kg)
CMH = Actual process airflow in cubic meters per hour
C_P = Specific heat capacity of the air (kcal/kg °C)
ℓ = Density of the air stream (kg/m^3)
T_{IN} = Inlet process temperature (°C)
T_{OUT} = Exhaust process temperature (°C)
H_L = Heat loss of the coating system (%)
LHV = Latent heat of vaporization (kcal/kg °C)

This equation will determine the approximate quantity of water (in kg/hour) that can be evaporated in a coating-pan system. However, this may not be the optimal rate necessary to achieve a high-quality coated product. The quality level, as stated previously, depends on many other factors. If all of these other critical factors are examined and optimized, this equation can be used as a tool to determine the approximate spray rate.

Example:
Assumptions:
Ambient air conditions = 21.1°C/50% RH
Air flow = 2166 m^3/hour
Specific heat capacity of air = 0.241 (kcal/kg °C)
Density of the air stream = 1.015 (kg/m^3)
Inlet air temperature = 70°C (167°F)
Exhaust air temperature = 40.5°C (105°F)
Coating solution solids = 12%
Number of spray guns = 4
Heat loss = 10%
Latent heat of vaporization = 577 (kcal/kg)

$$\text{Rate} = \frac{2166 \times 0.241 \times 1.015 \times [(70.0 - 40.5^\circ\text{C}) - 0.10(70.0 - 40.5^\circ\text{C})]}{577}$$

$$= 28.51 \text{ kg/hour or } 475 \text{ g/minute of water evaporated}$$

For a 12% w/w solids coating liquid, this equals 540 g/minute per total or ~135 g/minute per gun.

34.3.6.2 Process air

34.3.6.2.1 Volume

In all coating pans, elevated temperatures are used in conjunction with airflow to convert the solvent in the coating solution into a vapor and carry it away from the tablets being coated. In general, the amount of water vapor that can be removed is directly proportional to the air volume that passes through the coating pan and is limited by the saturation of the air stream. Therefore, if maximum evaporative capacity is the rate limiting factor with respect to the spray rate, it would be advantageous to use as high an airflow as possible without creating spray turbulence or air leakage. Manufacturers of the coating pans will usually specify the maximum airflow that can be used while still maintaining an acceptable level of turbulence. As the process air stream is heated, its capacity to hold water vapor increases. Again, if maximum evaporative capacity is the rate limiting factor, the inlet air temperature should be as high as possible. However, spray rates (per spray gun) are frequently limited not by evaporative capacities, but rather by the diminishing quality of the spray as the spray rate is increased. The total spray rate is usually limited by the number of spray guns, but more accurately, the size of the spray zone available. Therefore, the airflow capacity between pans of different sizes should be in direct proportion to the spray zone. For example, if a coating process is developed in a pan with two spray guns (each gun possessing a 20-cm spray pattern) and a process airflow of 1000 CMH (cubic meters per hour); scale-up to a larger pan with four spray guns should have an airflow of approximately 2000 CMH. Using an airflow in direct proportion to the spray rate will also allow a closer correlation between the process temperatures in different size pans.

34.3.6.2.2 Humidity

The process air used in a coating pan is either conditioned or unconditioned. In either case, there are day-to-day variations in the moisture present in the air stream. Humidity in the inlet air stream is usually determined by the dew-point temperature. Dew-point temperature provides a direct indication of humidity

in the air. Relative humidity can be used; however, the temperature of the air must also be known to determine the level of moisture. In the case of conditioned air, variations are less (especially when the process has the capability to dehumidify and rehumidify the air stream). With unconditioned air, these variations are great and can cause coating problems. If the air is unconditioned, the spray rate must be selected such that in the most humid condition that might occur, the film coating would still dry at a rate that would not result in overwetting or stability problems with the product. Some level of spray-drying would occur since most batches would be coated at lower humidities. The severity of the spray-drying would be directly related to the variation in the ambient humidity. Therefore, the growing trend is to dehumidify the process air stream. Dehumidification not only provides the coating process with more consistent coating conditions, but also provides for greater evaporative capacity. This allows the system to evaporate more moisture at a given airflow and temperature than an airflow of a higher humidity. With the advent of sustained release coating, some companies have opted for a combination of dehumidification/humidification. Such a system allows the process to be conducted at a consistent inlet dew-point temperature, regardless of the ambient conditions. A system that conditions the inlet air stream to a consistent dew point allows the coating process to operate at a reproducible drying rate regardless of fluctuations in ambient conditions.

34.3.6.2.3 Temperatures

As stated previously, the coating process can be successfully controlled by the inlet, exhaust, or product temperatures. Process control based on inlet air temperature control is most common. Control based on exhaust or product temperatures will often react slower because of the heat sink effect of the tablet bed (such control will also require fluctuations in inlet temperature, spray rate, and process air volume to occur, with spray rate fluctuations being the least desirable). With inlet temperature control, the exhaust temperature will drop slightly after the spray is started. This temperature drop is due to evaporative cooling. This will not occur with exhaust temperature control because the inlet temperature will be controlled to maintain the desired set-point. In any event, control via any of these methods will yield the same approximate temperatures. All of these temperatures are equally important because the moisture from the spray droplets is dried by both convection (due to the process air) and conduction (due to the product temperature). The desired exhaust temperature is dependent on several factors, such as:

1. Coating solution characteristics

   The tackier the coating as it dries, the higher the exhaust or product temperatures must be to prevent overwetting defects during the coating process. If the film polymer is thermoplastic, the product must be kept below the temperature at which the polymer begins to soften to prevent the tablets from blocking or sticking together.
2. Product temperature limits

   If a product exhibits instability problems at elevated temperatures, the product must be kept below these limits. This is most critical during preheating of the tablet bed since evaporative cooling of the bed is not occurring and the product may not be uniformly heated if the pan is not being continuously rotated. The product temperature will begin to rise immediately after the spray is stopped due to the loss of the evaporative cooling effect. Therefore, it may be necessary to begin a cool-down cycle immediately after the spray cycle.

   The inlet temperature required to achieve the desired exhaust temperature will be affected by the spray rate, the percentage of solids in the coating solution, the heat loss across the pan, and the condition of the drying air.
3. Pan speed

   To effectively optimize film-coating quality, the tablets must be mixed such that each tablet has the same probability of being in the spray zone for an equal duration of time. Therefore, it is essential that the product be examined to ensure that mixing is uniform. Mixing problems that occur include: sliding of tablets (usually seen with large capsules or oval-shaped tablets), “dead-spots” or sluggish product movement (this can be an extremely serious problem if it occurs while the tablets are in the spray zone), or product thrown into the spray zone by the mixing baffles.

   If product movement is not uniform, the first course of action should be to evaluate the product flow at different pan speeds. The pan speed selected should be the lowest speed that produces a rapid and continuous product flow through the spray zone. This will allow for the uniform application of a film coating while subjecting the tablets to a minimal amount of attrition. In general, if tablet friability is less than 0.1%, tablet attrition will not be a problem. A smaller tablet can be slightly softer since these tablets produce a less abusive tumbling

action. Product flow can be evaluated either subjectively or through mixing studies using tablets of various colors. Tablets of different colors can be placed in different zones (eg, front, middle, and back) of the pan. Tablet samples are taken at set time intervals to determine the length of time required to achieve a homogeneous mixture. A more sophisticated means of evaluation includes the use of radioactively marked tablets and a counter mounted on the spray bar to record the number of passes through the spray zone per unit time. The product speed is generally assumed to be traveling at the same linear velocity as the inside circumference of the coating pan.

In a continuous-coating pan system the product flow is from the charge port to the discharge port. Depending on the coating level, the product may pass through multiple drums (these drums may be located end-to-end or stacked horizontally). One continuous-coating pan system currently available contains five spray guns for a 1.5 m coating-drum length.

34.3.7 Understanding spray dynamics

34.3.7.1 Spray rate

The selection of the proper spray rate is dependent on more than just the thermodynamic considerations. If this were not so, the ultimate coating system would offer unlimited airflow and temperature. The spray rate (per spray gun) is also dependent on the ability of each spray gun to produce a consistent droplet size distribution. It has been shown that the droplet size will increase as the spray rate is increased (unless a compensating change is made in the atomizing air). Other factors that must be considered when determining the spray rate are:

- Solution viscosity—As solution viscosity is increased, the spray gun's ability to produce an acceptable droplet size distribution is diminished. Therefore, viscosity will limit the maximum spray rate that can be used and still produce acceptable film quality.
- Spray pattern width—If the spray pattern width is set-up properly, the spray pattern will essentially be the same as the spray gun spacing. The typical gun-to-gun spacing is 12–20 cm. At spacing greater than 20 cm, the uniformity of the spray across the pattern begins to deteriorate. Spacing of less than 12 cm is an ineffective use of spray guns and tends to add more expense for added spray guns, solution lines, and pumps. There is a limit to how much spray can be applied to a tablet per pass through the coating zone before the tablet begins to exhibit coating defects. Therefore, the wider the spray pattern width (without overlapping adjacent spray patterns), the greater the spray rate per gun.
- Product movement—The more consistent and fast the product flow through the spray zone, the higher the spray rate that can be delivered and still achieve an acceptable level of film-coating uniformity. Product movement is often dictated by the pan speed, baffle design, tablet size and shape, and tablet robustness (particularly friability).

34.3.7.2 Droplet size distribution

One of the most critical aspects of coating concerns is the manner in which solution is applied onto the tablet. The spray droplets can be almost any size if the size distribution is sufficiently narrow. If the system is set up to operate such that smaller droplets dry properly, then larger droplets will stay wet and picking or twinning will occur. If the system is set up to dry larger droplets properly, small droplets will be dry and not spread properly on the tablet, thus causing "orange-peeling" and a dull, rough film appearance will result. Most spray guns used in the industry today have a limited range over which the spray can be varied and still retain a uniform distribution. Examples of some typical droplet size distributions are shown in Fig. 34.30. These droplet size distributions were produced using a coating solution with a viscosity of 130 cP. Ideally, a spray gun that produces a narrow droplet size distribution should be used. This distribution can vary with changes in solution viscosity, spray rate, or a change in solution solids; therefore, the manufacturers of the spray guns will generally not provide information concerning these parameters. A simple method of examining this distribution can be performed by quickly passing a sheet of paper through the spray and subjectively

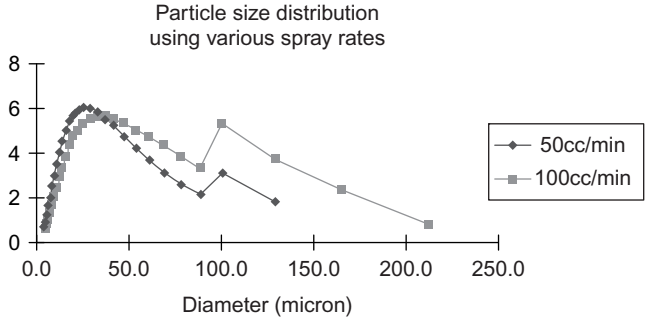

FIGURE 34.30 Examples of droplet size distributions obtained at different spray application rates.

analyzing the droplet size. A typical droplet distribution usually ranges from 5 to 250 μm. In general, if droplets vary in size from 5 to 1600 μm, it will be difficult to optimize the film-coating quality.

34.3.7.3 Coating zone/pattern

As mentioned previously, the larger the spray zone per spray gun, the higher the maximum spray rate that can be used per spray gun. Therefore, if the gun spacing or the spray pattern is reduced, the spray rate should be reduced proportionally. Applying more spray per unit area of the tablet bed beyond a certain point will change the film-coating appearance. If the spray rate is increased above this maximum, either overwetting or spray drying will occur, depending on whether the process is run dry or wet.

A recent trend in coating is to achieve greater production through the use of elongated or "stretch" coating pans. Lengthening the coating pan not only increases its capacity but, more importantly, the spray zone. This allows more spray guns to be used thereby increasing the overall spray rate. An increase in pan volume achieved by increasing bed depth with no increase in spray zone does nothing to allow an increase in overall spray rate. Therefore, one means of scaling up the process time for coating can be achieved by using the following calculations:

$$\text{Spray time (large pan)} = \text{Spray time (small pan)} \times \frac{\text{Batch size (large pan)}}{\text{Batch size (small pan)}} \times \frac{\text{Spray zone (small pan)}}{\text{Spray zone (large pan)}}$$

These calculations assume that the coating zones for each of the pans are used efficiently.

A number of factors have an effect on the spray pattern width. As the pattern air volume for the spray gun is increased, the spray pattern widens. An increase in the atomization air will cause a reduction in the pattern width. This is logical because the increased volume of atomization air would make it more difficult to flatten or widen the pattern. Lastly, as the spray rate is increased, the spray pattern is widened. Therefore, if the atomization air volume or spray rates are adjusted, it then is important to reexamine the spray pattern width to ensure that the spray zone is effectively utilized. Balancing the atomizing and pattern air correctly is critical to maximizing the size of the spray zone while avoiding undesirable effects, such as creating a dumbbell-shaped spray pattern.

34.3.7.4 Coating analysis

These are some characteristics of a typical film coating process:

Product specification:	Tablet	8.0 mm diameter
	Weight	250.0 mg/tablet
	Density	0.73 g/mL
Coating solution specifications:	Solids	12% w/w
	Density	1.0 g/mL
	Quantity	62.5 kg
Equipment specifications:	Pan diameter	170 cm
	Pan volume	550 L
	Pan speed	5 RPM
	Four spray guns	
Coating conditions:	Spray tate	125 g/min per gun
	Total spray rate	500 g/min
	Spray time	125 min

- Assumptions:
  - Spray zone:

Per spray gun = Spray width × Spray pattern length = 7.5 cm × 20.0 cm = 150 cm^2

Total spray zone = Number of spray guns × Spray zone per gun = 4 × 150 cm^2 = 600 cm^2

Tablets per coating zone = Total spray zone × Number of tablets/cm^2

Assume 3.5 tablets/cm^2 in spray zone = 600 cm^2 × 3.5 tablets/cm^2 = 2100 tablets/coating zone

Total spray length = Spray pattern width × Number of spray guns = 20 cm × 4 = 80 cm

Tablet bed velocity (same as the peripheral pan velocity) = Pan circumference × Pan speed
= 3.14 × 170 cm × 5.0 RPM = 2669 cm/minute

- Tablets per minute in the spray zone:

$$\begin{aligned}\text{Coating zone/minute} &= \text{Tablet bed velocity} \times \text{Total spray length}\\ &= 2669\ \text{cm/minute} \times 80\ \text{cm} = 213,520\ \text{cm/minute}\\ \text{Tablets/minute in the spray zone} &= \text{coating zone/minute} \times \text{Number of tablets/in}^2\\ &= 213,520\ \text{cm/minute} \times 3.5\ \text{tablets/cm}^2\\ &= 747,320\ \text{tablets/minute}\end{aligned}$$

- Coating solution per pass through the spray zone:

$$\text{Coating per pass through the spray zone} = \frac{\text{Total spray rate}}{\text{Tablets per minute/spray zone}}$$

$$\begin{aligned}\text{Coating per pass through the spray zone} &= \frac{500\ \text{g/minute}}{747,320\ \text{tablets/minute}}\\ &= 0.669\ \text{mg/tablet}\ (0.080\ \text{mg solids})\end{aligned}$$

- Passes through the spray zone:

$$\text{Total passes through the spray zone} = \frac{\text{Tablets per minute/spray zone}}{\text{Total number of tablets}} \times \text{Spray time}$$

$$\text{Total passes through the spray zone} = \frac{747,320\ \text{tablets/minute}}{1,700,000\ \text{total tablets}} \times 125\ \text{minutes} = 55.0\ \text{passes}$$

- Weight gain:

$$\text{Weight gain/tablet} = \text{Coating per pass through the spray zone} \times \text{Number of passes}$$
$$\text{Weight gain/tablet} = 0.080\ \text{mg solids/pass} \times 55.0\ \text{passes} = 4.40\ \text{mg}$$

$$\text{Total weight gain} \approx \frac{\text{Weight gain/tablet}}{\text{Tablet weight}}$$

$$\text{Total weight gain} \approx \frac{4.40\ \text{mg}}{225\ \text{mg/tablet}} \approx 2.0\%$$

In this analysis, each tablet would be within the spray zone approximately 55 times over the course of a 125-minute coating trial. In actuality, many of these tablets would be in the spray zone either more or less frequently, depending on the uniformity of the product movement. In addition, failure to optimize the gun-to-gun delivery or spray distribution will have an adverse effect on the coating uniformity. Therefore, this factor should be examined to ensure a consistently high-quality film coating.

34.3.8 Controlling coating processes—critical factors

Once all formulation requirements have been fulfilled, these factors can be examined to optimize the coating quality and system performance, and can generally be grouped into three areas: uniformity of spray application, uniformity of product movement, and achieving an adequate evaporative rate. These factors must all be examined and optimized in order to optimize the coating process.

34.3.8.1 Uniformity of the spray application

34.3.8.1.1 Spray gun design

There are a variety of spray gun manufacturers. Some of the more common suppliers include Binks, Freund, Schlick, and Spraying Systems. The most common type of gun used is air atomizing or pneumatic. This type of gun allows for the use of variable spray rates. In the past, hydraulic gun systems were used; however, they did not allow flexibility in spray rates. The solution nozzle orifice must be sized to match the desired spray rate. In order to change the spray rate, a change in the fluid nozzle may be necessary. In addition, the use of smaller nozzle orifices can

increase susceptibility to plugging of the gun tip. With some types of spray guns, the air cap and spray-nozzle configuration produce a predetermined ratio of atomization to pattern air at a given supply pressure. In other guns there are separate controls for adjusting the volumes of the atomization and pattern air. This allows the separate adjustment of either atomization or pattern without having to change the air cap and/or the solution nozzle. For example, the width of the spray pattern can be changed without changing the spray droplet size. The atomization air breaks the solution stream into a fine droplet size while the pattern air serves to flatten the spray into a fan-shaped pattern. The volume of atomization controls the mean droplet size of the spray. The pattern air volume controls the overall width of the spray.

34.3.8.1.2 Number of spray guns

The number of spray guns needs to be adequate to provide uniform coverage of the entire product bed. To maximize the uniformity and application of the coating, the spray zone should cover from the front edge to the back edge of the tablet bed. Adding more spray guns will not automatically guarantee that the overall spray rate can be increased. The use of additional guns is only justified if the existing number of guns is insufficient to cover the tablet bed from the front to back of the pan. The objective is to produce a uniform "curtain" of spray that the tablets pass through. Spray guns are usually capable of developing pattern widths of 12–20 cm without adversely affecting the spray droplet distribution. At greater pattern widths, the volume of pattern air needed to fan out the spray can lead to a distortion of the droplet size distribution due to recombination of spray droplets. The spray guns should be set up such that adjacent spray patterns are as wide as possible without overlapping. Overlapping of spray patterns can lead to localized overwetting of the tablet bed.

34.3.8.1.3 Uniform gun-to-gun solution delivery

It would seem obvious that to achieve uniformity of solution application, all spray guns must be set up to deliver the same quantity of coating solution. A recent trend in coating systems is the use of a single-pump manifold for multiple spray guns. For these types of systems, it is mandatory that calibration be performed on a regular basis to ensure that all spray guns are delivering the same quantity of solution. Furthermore, the calibration must be performed with the coating solution to be used. Calibration with water will not be satisfactory because its viscosity is much lower than that of the coating liquid and it will not be as sensitive to differences in pressure drop between the spray guns. Calibration is also recommended when using peristaltic pumps because the tubing is subject to fatigue. Calibration is usually accomplished by adjusting a knob that controls the restriction of the spray nozzle by the spray needle.

34.3.8.1.4 Atomization air volume/droplet size

As stated previously, the atomization air volume can be adjusted to control the mean droplet size of the spray. An increase in the atomization air volume can reduce the mean or average droplet size. An increase in either spray rate or solution viscosity will cause an increase in not only the droplet size distribution, but also the mean droplet size. Therefore, the droplet size should be evaluated at the exact spray rate that will be used for the coating trial. The quality of the spray in terms of droplet size and distribution should be evaluated at several different settings.

34.3.8.1.5 Spray gun angle

Ideally, the spray gun should be directed at the middle (midway between the leading and trailing edges of the tablet bed) and at a 90 degree angle to the moving tablet bed. If the spray guns are directed higher toward the leading edge of the tablet bed, it is possible that spray could be applied to the pan or onto mixing baffles as they begin to emerge from the tablet bed. Conversely, if the spray guns are directed too low on the tablet bed, spray applied to the tablets may not have sufficient time to dry. This could result in the transfer of film from the tablets to the pan surface. If the spray guns are not directed at a 90 degree angle to the tablet bed then, the spray as it exits the solution nozzle has a tendency to build up on the wings of the air cap.

34.3.8.2 Uniformity of product movement

34.3.8.2.1 Pan speed

This area was covered in an earlier section (see Process Parameters-Pan Speed). Product movement must be uniform if a uniform application of the coating solution is to be achieved and the minimum pan speed necessary to achieve this objective is recommended. Once the pan speed has been determined, it can be scaled up by duplicating the peripheral edge speed. This is done by taking the ratio of the small pan to large pan diameter multiplied by the small pan speed.

One final note is that the product movement should be continually evaluated and adjusted as necessary during the coating cycle. Frequently, the product movement will change as a coating is applied to the tablet surface and the degree of slip of the tablets increases.

34.3.8.2.2 Tablet size and shape

Different tablet sizes and shapes will exhibit very different flow characteristics. In general, smaller tablets will flow better than larger tablets. Longer, less round shapes, such as capsule and oval shaped tablets will tend to slide and flow more poorly (more sliding) than other shapes. If the tablet shape or size is changed, the product flow properties must be reexamined. In addition, if the size is too small, it will require a fine mesh to cover the perforations in the pan to prevent the exhaust of product. One other consideration is that if the product is fine (~1 mm or less) and the airflow is exhausted down through the product bed, then there will be a considerable pressure drop across the bed. This pressure drop will cause a reduction in the process airflow.

34.3.8.2.3 Baffle type/size/number

The primary function of the mixing baffles is to transfer the product between the front and back of the coating pan. A variety of different baffle shapes and sizes exist. Coating pans are usually equipped with a standard baffle design that works well for the majority of different products. However, it may be necessary to use a different baffle design for unusual shapes and sizes. Coating pans can also be fitted with anti-slide bars. These bars are positioned on the flat of the coating pan and perpendicular to the product flow. They are used to prevent tablets with large flat surfaces from sliding inside the pan. With most coating pans, it is necessary to use a reduced baffle size when working with smaller batch sizes.

Standard-size baffles used with a small batch will result in sluggish product movement and/or excessive variation in the spray gun-to-product distance. As the baffle passes through the product, it will temporarily carry a portion of the tablets up out of the tablet bed, thus causing a brief increase in the gun-to-bed distance. As these tablets cascade off the baffle, the tablet bed height rises and the gun-to-bed distance decreases. A minimum variation in the gun-to-bed distance is desired so that the spray always travels a consistent distance and spray droplets striking the tablets have a constant moisture level. The typical variation in gun-to-bed distance is from 2.5 to 5.0 cm. A reduced or small-batch baffle is generally recommended whenever the batch size is less than 75% of the rated pan brim volume.

34.3.8.2.4 Batch size

As previously mentioned, the batch size/baffle combinations are critical to obtain an acceptable product movement. An acceptable batch size range for film coating is usually 50–95% of the rated brim volume. By using only 95% instead of 100% of the rated volume, one can eliminate the spillage from the pan mouth ring during coating. Occasionally, what appears to be an acceptable pan load initially may turn out to be excessive for those products that exhibit a change in product movement as a film is applied or with coatings of an extremely high weight gain. A problem in working with smaller batches (~50%) in a perforated coating pan is that, unless part of the exhaust plenum is blocked off, the process air will preferentially pass around the tablet bed due to less restriction or pressure drop. Batches of this size potentially can be coated successfully, however, the drying efficiency will be reduced.

34.3.8.3 Adequate evaporative capacity

34.3.8.3.1 Process air volume

The process air stream should be adjusted to the maximum volume that yields a laminar, nonturbulent air flow. A turbulent airflow will distort the spray patterns and lead to lower coating efficiency due to spray drying of the coating. It is important to periodically inspect the coating pan to ensure that all process air passes through the tablet bed. Any air that passes around the product will result in a reduced evaporative efficiency. The inlet air volume is more important than the exhaust air volume as an indicator of the evaporative capacity because it is this air that passes through the tablet bed and vaporizes the water from the coating and then conveys it away from the tablets. The exhaust air volume will typically be slightly greater than that of the inlet due to the addition of atomizing air from the spray guns, also due to slight leakage that may exist, and by the addition of water vapor to the exhaust air stream. If there is a large difference between the inlet and exhaust air volumes due to leakage, this can be a problem, because this air can artificially depress the exhaust temperature.

34.3.8.3.2 Spray rate

The initial spray rate that is selected may be based on previous coating trials that have yielded successful results. This is an acceptable approach if the coating solution and product being coated are very similar. However, it is important to remember that changes in these factors can drastically affect the spray rate and other parameters selected. Another method for determining an initial spray rate is to evaluate the quality of the droplet size distribution. Spray rates for aqueous film coating vary from 6 to 30 g/minute for a small 2.0 L pan to 80–250 g/minute per gun in a large production-scale pan. The key factors that limit the maximum spray rate per gun are the viscosity of the coating solution, the type of spray gun used,

and ultimately the level of film quality that a Pharmaceutical company deems acceptable.

34.3.8.3.3 Spray gun-to-tablet-bed distance

For small-scale coating systems, the gun-to-bed distance can be as little as 2.5–5.0 cm. The typical gun-to-bed distance is 20–25 cm for a production-sized coating pan. This distance usually provides an economical tradeoff between the cost of the number of guns needed to adequately cover the spray zone and the desired quality of spray. If the gun-to-bed distance is less than 20 cm, then either the spray rate must be reduced or the inlet temperature and product temperature increased to compensate for the shortened evaporation time. If this distance is greater than 20 cm, the inlet process temperature should be reduced otherwise more spray drying is likely to occur.

34.3.8.3.4 Product/exhaust temperature

Typically, aqueous film-coating processes are set up to achieve an exhaust temperature of 38–44°C. Based on the desired spray rate, an inlet temperature is determined that allows an exhaust temperature in the target range to be maintained. Coatings that develop greater tackiness will require exhaust temperatures to be adjusted to prevent overwetting defects, or excessive heat when working with thermoplastic coatings that become tacky when getting too hot (for these coatings, a typical exhaust temperature range might be 30–38°C).

The exhaust temperature is slightly lower (~1–5°C) than that of the product bed due to heat loss between the measurement points. Usually, the greater the distance between the exhaust and product temperature probes, the greater the differential. The only time when these temperatures will vary more is during preheating and cool-down. A product temperature probe will display an average of the entire tablet bed. The product temperature can be determined through the use of either a probe that extends into the tablet bed or through the use of an infrared temperature probe directed at the zone just above the spray zone. Tablets in the spray zone are at a slightly lower temperature due to evaporative cooling and are not representative of the average product temperature.

34.3.8.3.5 Dew-point temperature

The dew-point temperature is directly related to the moisture contained in the process airstream. Dew-point temperatures can be measured using either a capacitance or a chilled mirror-type dew-point sensor. To accurately reproduce the drying rate from trial to trial, it is recommended to maintain the dew point within a controlled range. The more critical the coating (ie, sustained release coatings), the tighter the range. High dew-point temperatures can be reduced through the use of a dehumidification system employing either chilled water coils or desiccant dehumidification. Chilled water systems are usually specified to control the dew point at 10–12°C (50–53°F) or an absolute moisture content of 7.5–8.5 g/kg of air. With a desiccant dehumidification system, the dew point can routinely be controlled to a temperature as low as −6°C (21°F). Low dew-point temperatures can be adjusted by humidifying the air via the injection of clean steam into the process air. If no attempt is made to limit the variation of the inlet dew point, then fluctuations in ambient air conditions can lead to reduced coating efficiency (spray drying), longer processing times, or film defects due to overwetting.

34.3.9 Scale-up

34.3.9.1 Batch size

The most accurate method of determining batch size is to load the coating pan to within 2.5–5.0 cm of the pan opening and then rotate the pan at the desired rpm to ensure that the pan is not overfilled. However, there are two different methods for approximating the batch size. The first method is to multiply the rated brim volume times 95%, and then multiply the resultant volume by the bulk density of the product. A second method for determining the pan load size is to multiply a known ratio of batch size to pan volume for a small-scale pan times the volume of the pan being scaled to. For example:

$$\text{Large pan batch size} \approx \frac{\text{Small pan batch size}}{\text{Small pan volume}} \times \text{Large pan volume}$$

$$\text{Large pan batch size} \approx \frac{65.0\ \text{kg}}{90.0\ \text{L}} \times 550.0\ \text{L} \approx 397.0\ \text{kg}$$

However, on the production scale, pan fill weights are often determined by compression batch weight rather than desired pan fill capacity, so coating on this scale may use pan loadings that are less than ideal.

34.3.9.2 Pan speed (angular pan velocity)

When scaling up a coating process, it is critical that the tablet speed through the spray zone in the larger pan is comparable to that used in the smaller pan. In other words, the pan angular velocity must be the same for both coating pans. Pan velocity can be duplicated by multiplying a ratio of the small pan diameter

to large pan diameter times the pan speed used for the smaller coating pan. For example:

$$\text{Pan speed for large pan} = \frac{\text{Small pan diameter}}{\text{Large pan diameter}} \times \text{Pan speed for small pan}$$

$$\text{Pan speed for large pan} = \frac{100\ \text{cm pan}}{170\ \text{cm pan}} \times 9\ \text{rpm} = 5.3\ \text{rpm}$$

This equation will yield a close estimate of the pan speed. However, subtle differences in the baffle design between coating pans may require a slight adjustment from this calculated pan speed.

34.3.9.3 Available coating zone

To scale up the coating process with any degree of confidence, the spray rate must be determined using the same gun-to-bed distance used in the larger coating pan. Any change in the gun-to-bed distance will change the drying time for the spray droplets and thus alter the quality of the coating. The same spray rate used in the small-scale pan can also be used in the production-scale pan, assuming that the same spray gun spacing and spray pattern widths are used. Typically, the use of more spray guns without increasing the size of the overall spray zone will not allow an increase in either the total or the per gun sprays. Increasing the total number of spray guns will only be of value if the existing spray zone is inadequately covered with fewer spray guns. If the spray pattern width used in the larger coating pan is narrower than that used in the small pan then the spray rate per gun should be reduced in proportion to the reduction of the spray zone width. This will allow the same density of film coating to be applied per unit area of the tablet bed surface. Otherwise, the quantity of coating applied on the tablets per pass through the spray zone would increase. This would most likely change the quality of the coating and could lead to overwetting or logo bridging defects. Here is an example of scale-up using a ratio of total spray zone utilized:

	Pan #1	Pan #2
Pan volumes	90.0 L	850.0 L
Batch size	60.0 kg	566.0 kg
Coating solution	2 kg	113 kg
Number of spray guns	2	10
Spray pattern width (per gun)	20 cm	15 cm
Spray rate (per gun)	150 g/min	To be determined
Spray rate (total)	300 g/min	To be determined
Spray time	40 min	To be determined

$$\text{Spray rate for large pan} = \frac{\text{Pattern width for pan \#2}}{\text{Pattern width for pan \#1}} \times \text{Spray rate (per gun) for pan \#1}$$

$$\text{Spray rate for large pan} = \frac{15\ \text{cm spray pattern}}{20\ \text{cm spray pattern}} \times 150\ \text{g/minute per gun} = 113\ \text{g/minute per gun}$$

$$\text{Total spray rate for pan \#2} = \text{per gun spray rate (pan \#2)} \times \text{number of spray guns (pan \#2)}$$
$$\text{Total spray rate for pan \#2} = 113\ \text{g/minute per gun} \times 10\ \text{spray guns} = 1,130\ \text{g/minute/total}$$

$$\text{Spray time} \approx \frac{\text{Quantity of solution to apply}}{\text{Total spray rate}}$$

$$\text{Spray time} \approx \frac{113\ \text{kg}}{1.33\ \text{kg/minute}} \approx 85\ \text{minute}$$

34.3.9.4 Spray-rate-to-pan-speed ratio

One factor that is quite commonly overlooked is the ratio of the spray rate to the pan speed. The ratio of spray rate to pan speed has serious implications in both the amount of film coating applied onto the individual tablets per pass through the spray zone and on the overall uniformity of the film coating itself. Therefore, with any increase in the spray rate, one should evaluate the need for an increase in the pan speed. In some instances, the tablets may be able to withstand a greater application per pass through the spray zone without any adverse effects on film quality or the uniformity of the coating. Whenever the spray rate and pan speed are both increased, the tablets should be evaluated for signs of overwetting or increased tablet attrition. One problem that may result if the pan speed and spray rates are too high relative to the evaporative rate is that wet film coating from the tablets may be transferred to the pan surface.

34.3.9.5 Airflow-to-spray ratio

When scaling-up the film coating process, it is recommended that the airflow used in the larger coating pan be proportional to the increase in the spray rate. If the airflow is increased in the same ratio as the increase in spray rate and if the spray rate per unit area of the bed surface is the same, the same inlet and exhaust temperatures can be maintained. The inlet temperature must be increased to maintain the same evaporative rate if the airflow is not increased in the same proportion as the spray rate. If the spray rate per gun and the gun-to-bed distance are the same for both pans, the airflow can be scaled up in direct proportion to the increase in spray guns. For example:

	Pan #1	Pan #2
Spray rate (per gun)	125 g/min	125 g/min
Number of spray guns	2	4
Total spray rate	250 g/min	500 g/min
Inlet airflow	1000 CMH	To be determined

$$\text{Airflow for pan \#2} = \frac{\text{Total spray rate for pan \#2}}{\text{Total spray rate for pan \#1}} \times \text{Airflow for pan \#1}$$

$$\text{Airflow for pan \#2} = \frac{500\ \text{g/minute}}{250\ \text{g/minute}} \times 1000\ \text{CMH} = 2000\ \text{CMH}$$

34.4 TROUBLESHOOTING

34.4.1 Introduction to troubleshooting

Troubleshooting is basically a "reactive" process because it deals with something that has already gone wrong. A coating problem will usually manifest in one or more of these ways:

- Those affecting visual coated-product quality,
- Those affecting coated-product functionality,
- Those affecting coated-product stability, and
- Those affecting processing efficiencies and costs.

When dealing with an existing, marketed product, the troubleshooting process is constrained by many regulatory issues. These problems are the most troublesome in that the proper corrective action may require refiling with the FDA. Therefore, other less suitable remedies may be taken, which may lessen the symptoms rather than correct the actual cause of the problem. Of course, application of a suitable quality by design (QbD) program, as mandated by regulatory agencies, should essentially help eliminate problems in film-coating processes, with the possible exception of those due to equipment failure.

Identifying appearance-related problems is relatively easy because visual feedback is immediate. The magnitude of the problem is also often immediate. Identifying nonappearance related problems (such as those associated with chemical stability or drug release) is more difficult because:

- The existence of the problem is often not readily apparent,
- Determination is often on the basis of some analytical procedure that evaluates only a small sample (relative to the batch size in question) of tablets, and
- Sampling, and the relevance of the samples selected to the characteristics of the whole batch, becomes a critical issue.

34.4.2 Up-front approaches to avoid troubleshooting issues

The best solution to "fixing problems" is to avoid them in the first place. One way in which many coating problems can be avoided is through the proper formulation of the product substrate and the film-coating solution. Before the coating process can be developed or scaled-up, the product must be evaluated to ensure that it meets the formulation requirements for film coating. Often, problems arise because the tablet core formulation is not sufficiently robust to withstand the rigors of film coating.

The core must be formulated such that minimal attrition occurs during the film-coating process. The deeper the product bed, the more abuse the tablets must withstand. For smaller tablets (less than 100 mg), 5–6 kp tablet-breaking force (hardness) may be sufficient. For medium-sized tablets, 12–16 kp may be sufficient. For larger capsule-shaped tablet, such as a 1 g capsule-shape, a hardness of more than 20 kp may be necessary. A better measure of a product's suitability for coating is friability. In general, a product with a friability of 0.1% or lower should be sufficient to avoid attritional problems during the coating process. Other core formulation issues that should be addressed prior to developing the coating process include:

- Product stability: All core ingredients must be stable at the temperatures required for the evaporative process (typically 40–45°C for aqueous-based coatings)
- Product shape: The use of large flat product surfaces must be avoided to prevent the tendency for "twinning" of product cores

- Logo design: The core logo should be designed such that attrition and bridging of the logo do not occur
- Resistance to dimensional changes (avoiding ingredients that undergo thermal expansion, or expand through excessive moisture absorption)
- Film adhesion: The core should be sufficiently porous to allow the film to adhere properly to the surface
- Chemical/functional robustness:
  - Role of amorphous, hydrophilic materials
  - Low melting-point ingredients
- Mixing potential: Small, more round products will tend to flow well. Large or longer tablet shapes will tend to exhibit "sluggish" movement.

Another issue that must be addressed before the coating process can be developed is the film-coating formulation, which must be extensively evaluated to ensure that it meets the requirements for intended coating process. Some of the issues that must be addressed include providing:

- Sufficient film mechanical strength to prevent cracking or edge wear;
- Sufficient plasticizer to prevent the formation of a brittle film;
- Sufficient pigment to mask the color of the tablet core;
- Appropriate solids level that allows a coating to be applied quickly to protect the core from attritional effects;
- Sufficient adhesion between the coating and the core surface;
- A solution viscosity that is low enough to allow the production of a uniformly atomized spray; and
- Sufficient coating suspension stability, including absence of growth of microorganisms and prevention of sedimentation of suspended coating solids.

34.5 CONSIDERATION OF PRODUCT SUBSTRATE

To effectively develop the coating process, the product must be evaluated to ensure that it meets the necessary criteria for a substrate.

34.5.1 Hardness/friability

The tablet core must be capable of withstanding the rigors of tumbling in the coating pan. In a larger diameter coating pan, the bed depth will be greater and therefore, subject the tablets to greater stress. So, an acceptable tablet hardness or friability for a small coating pan may not be sufficient for a larger pan. A tablet hardness tester is used to determine the edge-to-edge (diametral) tablet hardness. Typical hardness measurement units include: kiloponds (kp), Strong Cobb Units (SCU), and Newtons (N). The kilopond is defined as the force exerted by a kilogram mass upon its support in a gravitational field of $g = 9.80665$ m/second^2. One kilopond is equal to 9.807 N units or 1.4 SCU. Tablet hardness has traditionally been the measure of a tablet's suitability for coating. However, in many cases, the tablet may be of substantial hardness but still exhibit unacceptable capping tendencies or show excessive wear on the tablet edges or logo. Therefore, a better means of determining a tablet's ability to withstand tumbling is friability. This is usually determined by tumbling a certain number or weight of tablets for a set number of rotations (usually 100 revolutions) inside a cylinder. The tablets are weighed before and after tumbling and weight loss is expressed as the percent friability. A recent innovation to the friability test is to line the inside of the friability cylinder with a mesh screen. This has been shown to provide a better correlation between the friability test and actual suitability for subjecting to a coating process.

34.5.2 Weight variation

Tablet cores are usually produced to a particular weight range specification. However, sometimes these ranges are not sufficiently narrow. This usually occurs when the tablet granulation exhibits flow problems. A wide tablet weight variation will make it difficult or impossible to accurately determine the actual tablet weight gain due to the application of the film coating, since the weight variation in the uncoated cores can be greater than the weight of the film to be applied. In addition, wide variations in tablet weight can be accompanied by variations in tablet hardness.

34.5.3 Stability

The tablets must be stable under the conditions required for coating. The product must be able to withstand the temperature and humidity of the process airflow. Product temperature is significantly less than that of the inlet air during the coating process due to evaporative cooling. However, during the preheat phase, the product temperature may approach that of the inlet air if the tablets are not jogged frequently enough. Tablets should be able to handle the usual product temperature of 35–50°C. As mentioned previously, it may be necessary to use drier conditions during the initial phase of the coating process to

prevent stability problems with moisture-sensitive products, such as effervescent tablets.

34.5.4 Compatibility

The compatibility of the tablet core with the excipients in the film-coating solution must be verified. In some instances, certain actives have exhibited an interaction with the plasticizer in the coating solution.

34.5.5 Shape

If possible, certain tablet shapes should be avoided for film coating. Tablets with sharp edges may exhibit a greater tendency for edge wear. Cores with large, flat tablet faces may result in poor product movement due to sliding. Tablets with large flat surfaces (such as deep walled capsule shaped tablets) will also show a much greater tendency to exhibit twinning during coating. Adding a slight concavity (0.1−0.2 mm) to the tablet faces or tablet edges reduces the likelihood of agglomeration or twinning.

34.5.6 Logo design

Sharp corners or small islands on the tablet logo can lead to logo attrition problems. If the logo is too fine or contains too much detail, the film coating may bridge or cover the logo. A draft angle of 35 degree is recommended for film-coated tablets. Tooling manufacturers are usually aware of the tool design specifications for tablets to be film coated. Finally, placement of a logo on the crown of a tablet may lead to more crown erosion.

34.5.7 Core porosity

The tablet core must be formulated so that there is good adhesion between the film coating and the tablet surface. If the core porosity is low, poor adhesion will result, and picking and/or peeling of the film will occur. Core porosity can be a problem with wax matrix tablets due to poor adhesion between the tablet surface and film-coating droplets. To remedy this, more adhesive film polymers (ie, hydroxypropylcellulose, copovidone, or polyvinyl alcohol) may be used.

34.5.8 Disintegration/dissolution

The disintegration of the tablet core must be sufficiently rapid when tested prior to the addition of the film coating. If the core does not dissolve quickly prior to coating, the addition of film coating may only provide a further delay. However, in most instances, a change in dissolution after film coating is often caused by exposure of the tablet core to the coating process conditions (such as heat) rather than as a result of a direct effect of the applied film coating.

34.6 COATING FORMULATION

34.6.1 Film mechanical strength

The film-coating formulation must be optimized such that the resultant film has adequate mechanical strength. The reasons for this are twofold; first, the film must be strong enough to protect the tablet from excessive attrition while tumbling during the coating process and, second, the applied coating must be sufficiently durable to resist the erosion of the film itself. A weak film will usually exhibit wear or erosion at the tablet edges, or may crack as a result of being subjected to mechanical stress (tumbling) or excessive heat. The addition of too many nonfilm-forming excipients (such as pigments and detackifying agents like talc) will decrease the strength of the film. Such reduced film strength may also occur if a drug is added to the coating solution.

34.6.2 Plasticizer level

The function of a plasticizer is to reduce the glass transition temperature (T_g) of the film or, in other words, to produce a film that is not brittle under normal process and storage conditions. If the film is inadequately plasticized, the film will be too brittle and more prone to cracking. If a film-coating formulation has an excessive level of plasticizer, the mechanical strength of the film will be reduced, and excessive tackiness may be observed.

34.6.3 Pigment level

If the coating solution contains insufficient pigment, it will be impossible to develop the desired color intensity. In addition, low pigment levels can make it difficult to minimize color variation due to poor opacity of the applied coating. On the other hand, excessively high pigment levels can, as stated previously, reduce the mechanical strength of the coating.

34.6.4 Film solution solids

A low solids level in the coating solution can not only needlessly increase the process time, but can also increase the time required to provide a protective film coating, thus resulting in increased tablet attrition. High solution-solids levels coupled with a low

addition level can make it difficult to achieve acceptable film-coating uniformity. High solids levels can also be a problem if they result in a high solution viscosity. If a high solids level does not create an excessively viscous solution, it provides an excellent opportunity to reduce the amount of coating solution required and, thus, the coating time. Aqueous polymer dispersions available on the market provide high solids solution at an extremely low viscosity.

34.6.5 Solution viscosity

Solution viscosity, as stated previously, is closely tied to the solution solids level. As solution viscosity is increased (above $\sim$200–250 cP) the droplet size distribution produced by the spray guns becomes increasingly wider due to an increase in larger droplets. Slight increases in viscosity can be compensated for by increasing the volume of atomization air. However, at higher viscosities (greater than $\sim$350 cP) it is difficult to eliminate all of the larger droplets. To compensate for the presence of larger droplets, the operator will usually increase the inlet temperature to prevent the larger droplets from overwetting the product. This will result in an increase in the amount of spray drying due to premature evaporation of water from the finer droplets. The net result is a lower coating efficiency and a rougher film surface.

34.6.6 Stability

The coating solution must be stable for the duration of the coating time. This includes both chemical and physical stability. The most typical instability problem encountered is settling-out of solution solids. This occurs with solutions that contain an excessive percentage of solids or when the coating has insufficient suspending capacity (due to low polymer content and/or low viscosity). Settling of solids can lead to blockage of the solution lines or the spray guns. For coating liquids where settling of insoluble components (such as pigments) is a problem, use of a recirculating spray system and/or using a suitable tank mixer can help.

34.6.7 Compatibility

This refers not only to the compatibility of the coating materials, but also to the compatibility between the film coating and the tablet core. For example, the addition of color concentrates that contain ethanol has led to precipitation of some of the polymer used in aqueous dispersions. As a remedy, a propylene glycol-based color was used. In another product there was an interaction between the plasticizer and the active ingredient used in the tablet core. It was necessary to reformulate the coating solution using an alternative plasticizer. Finally, when applying ionic coatings, such as enteric coatings, interaction with ionic materials in the core must be considered, as does potential interaction with core ingredients that are acid unstable (such as proton pump inhibitor APIs like omeprazole, lansoprazole, etc.)

34.6.8 Processing issues as they relate to troubleshooting

34.6.8.1 Equipment maintenance issues

Many coating problems can occur as a result of poor equipment maintenance, and these can be avoided through implementation of a routine equipment maintenance program. This program must involve the periodic calibration of all analog and digital instrumentation. Poor maintenance of process-monitoring equipment results in decisions being made on the basis of inaccurate information. The maintenance program should also involve the inspection of all wear items. The equipment manufacturer should be able to provide a listing of these parts with a recommendation for the frequency of inspection.

34.6.8.2 Process adjustment as a troubleshooting initiative

The dynamics associated with the spray application of the coating liquid represent perhaps one of the most underappreciated areas of the whole film-coating process.

Key issues to be aware of include:

- Fluid flow rate through the nozzle, interaction with the driving forces for effective atomization, and the ultimate size of droplets formed
- Droplet velocity
- The interaction of atomized droplets with the surrounding drying environment, and the relative state of the droplets as they arrive at the tablet surface

While the importance of many operating parameters (air flows, temperatures, spray rates, etc.) is relatively well understood, the ultimate impact of other parameters on the issue of troubleshooting is often overlooked, such as:

- Mixing effectiveness in the pan, and the impact of, for example, baffle design;
- Pan loading, and its impact on process efficiencies and product quality; and
- The potential change in tablet roll dynamics as coating is applied.

Another approach to troubleshooting involves the systematic evaluation of the film-coating process. Film-coating processing issues can be classified into these categories, namely achieving:

1. Good uniformity of the spray droplet size and application,
2. Effective uniformity of product movement through the spray zone, and
3. Proper solvent evaporation rates for the coating process.

There are a number of issues that must be addressed with regard to each of these objectives. This is a partial listing of some of the factors to be considered:

Issues that affect the uniformity of spray droplet size and application:

- Can an acceptable spray droplet size distribution be produced at the desired spray rate?
- Can an acceptable spray droplet size distribution be produced using the coating solution viscosity?
- Is there adequate compressed air volume for the atomization of the coating liquid?
- Are the number and type of spray guns suitable to provide uniform coverage of the product bed?
- Are the spray guns located at the proper spacing?
- Is the spray pattern width sufficient to maximize the size of the spray zone without overlap adjacent spray patterns?
- Is the spray-gun-to-product-bed distance correct?
- Is the solution delivery rate the same for all spray guns?

Issues that affect the uniformity of product movement:

- Is the batch volume sufficient for the pan being used?
- Is the correct pan speed being used?
- Does the pan contain the proper baffle type and are they in the correct position?
- Are tablets being "thrown" into the spray zone by baffles or baffle mounts?
- Is the product size and/or shape conducive to good product movement?

Issues that affect the solvent evaporation rate of the coating process:

- Is the proper process air volume being used?
- Is the incoming air stream controlled to a consistent dew point?
- Are the inlet, exhaust, and product temperatures correct for the tablets being coated?
- Is the proper spray rate being used?

It is important that the objectives be examined in the order listed to effectively troubleshoot the film-coating process. One should first deal with issues affecting uniformity of spray application, then issues that affect product movement, and lastly, issues dealing with the evaporative rate of the coating process.

For example, let's assume that the product is exhibiting signs of picking, which is an over-wetting defect. Let's also assume the root cause of this defect is due to poor product movement, which causes the product to stop in the spray zone. Now it might be possible to eliminate this problem by increasing the process temperatures (evaporative rate factor). However, the product movement through the spray zone would still be poor and coating uniformity would be less than optimal. A better remedy would be a corrective action that results in improved product movement (2nd Objective).

A second example might assume the same defect (picking), however in this case, the cause of the defect is due to nonuniformity of the solution delivery through the spray guns. One of the spray guns is delivering significantly more solution than the others. One could probably reduce the spray rate to eliminate the over-wetting problem; however this would not be the appropriate remedy. If this were done, then the coating uniformity would still be less than optimal and the corrective action would have lengthened the necessary coating-process time. A more appropriate remedy would be a corrective action which results in an improved spray application (1st Objective).

34.6.9 Troubleshooting: summary

Overall, problems often have more than one cause, and problem resolution is likely to be complex. Problem resolution may encompass minor changes that have little regulatory impact, or they may require intervention by making significant (from the regulatory standpoint) changes to either formulations or processes.

The simplest approach to problem resolution is problem avoidance.

34.6.10 Film-coating defects/ troubleshooting—summary

The information shown in Table 34.18 contains a brief definition of common tablet-coating defects together with typical causes and suggested remedies.

TABLE 34.18 Tablet Coating Defects and Suggested Corrective Actions

1. Overwetting/picking: This condition occurs when part of the film coating is pulled off one tablet and is deposited on another. If detected early in the process, it can be covered. If detected late in the process the coating will likely be unacceptable.

Possible cause	*Remedies*
Insufficient drying rate	Increase the inlet and exhaust temperatures
	Increase the process air volume
	Decrease the spray rate
Inadequate atomization	Increase the nozzle air pressure or the atomization air volume
	Decrease film coating viscosity
Poor product movement	Increase pan speed
	Switch to an alternative baffle design
	Adjust batch size (volume)
Poor distribution of spray	Check the uniformity of solution delivery through the spray guns (calibration)
Insufficient drying rate	Increase the inlet, exhaust, and product temperatures
	Increase process air volume
	Reduce the spray rate
Excessive variation in Process Air Humidity	Dehumidify and/or humidify process air to maintain a constant inlet air dew point

2. Twinning: Twinning is a form of overwetting whereby two or more of the tablet cores are stuck together.

Possible cause	*Remedies*
May be due to any of the possible causes for overwetting	
Poor tablet core design	Change tablet design to eliminate large flat surfaces

3. Orange peel**:** Appears as a roughened film due to spray drying. This condition relates to the level of evaporation that occurs as the spray droplets travel from the gun to the tablet bed. If there is excessive evaporation, the droplets do not have the ability to spread and form a smooth coating. A narrow droplet size distribution is important to ensure that the majority of droplets dry at the same rate.

Possible cause	*Remedies*
Excessive evaporative rate	Reduce the inlet and exhaust air temperatures
	Reduce the gun-to-bed distance
Excessive atomization of the spray	Reduce the nozzle air pressure or atomization air volume
Large droplet size variation	Reduce the solution viscosity
	Reduce the spray rate

4. Bridging: Bridging is a condition in which the film coating lifts up out of the tablet logo[10].

Possible cause	*Remedies*
Poor film adhesion	Reformulate the film coating solution to improve adhesion
	Reformulate the core formulation to increase porosity
Poor logo design	Redesign logo to incorporate shallower angles

5. Cracking: May occur due to internal stresses in the film[10].

Possible cause	*Remedies*
Brittle film coating	Increase the addition level of the plasticizer
	Use a different plasticizer
	Use a polymer with a greater mechanical strength
Poor film adhesion	Dilute the film-coating solution
	Reduce the quantity of insoluble film coating additives

(*Continued*)

TABLE 34.18 (Continued)

6. Poor coating uniformity: Poor coating uniformity can manifest itself in either a visible variation in color from tablet to tablet, or in the form of an unacceptable release profile for tablets.

Possible cause	*Remedies*
Insufficient coating	Apply a coating of 1.5−3.0% (for clear coating as little as 0.5%) weight gain to attain uniformity, requires higher levels if the color of the tablets and the film are of very different colors
Poor color masking	Reformulate the film coating to a darker color and/or increase the quantity of opacifier
Poor uniformity of solution application	Increase the pan speed
	Reduce the spray rate/increase the coating time
	Increase the spray pattern width
	Increase the number of spray guns
	Check the uniformity of solution delivery through the spray guns (calibration)

7. Tablet attrition/erosion: Attrition is exhibited when some portion of the product substrate exhibits a high level of friability. This typically occurs at the tablet edge or face. Often signs of attrition will be minimal or nonexistent in smaller diameter coating pans. However, when the coating process is scaled-up to a production-sized pan, this problem can become more severe due to the increased batch weight and bed friction[11].

Possible cause	*Remedies*
Insufficient tablet friability	Reformulate the tablet core to a friability of no more than 0.1% friability
Poor film-coating formulation	Reformulate to provide coating with greater mechanical strength
Excessive pan speed	Reduce the pan speed to the minimum required to achieve a smooth and continuous bed movement
Insufficient spray rate	Increase the spray rate to provide a protective film coating in a shorter time, this may require an adjustment in the inlet air temperature

8. Core erosion: Core erosion is another type of attrition due specifically to overwetting of the tablet core. With this type of defect, excessive overwetting may cause a partial disintegration of the core surface.

Possible cause	*Remedies*
Surface overwetting	Reduce the spray rate
	Increase the inlet and exhaust air temperatures
	Increase the spray pattern width
	Reduce the spray droplet size/increase the atomization air volume
	Reformulate the core with less water sensitive excipients
	Improve tablet bed movement
	Increase the bed to gun distance

9. Peeling: Peeling occurs when large pieces or flakes of the film coating fall off the tablet core.

Possible cause	*Remedies*
Poor adhesion	Reduce the amount of insoluble additives in the coating solution
	Increase the level of film former in the coating solution
	Reformulate to incorporate a film polymer with greater adhesion
	Reformulate the tablet core to increase porosity
Brittle film coating	Increase and/or switch to an alternative plasticizer

10. Loss of logo definition: This defect occurs when the tablet logo is no longer clearly legible. It may be due to one or more of the defects previously covered: core erosion, tablet attrition, or bridging. Loss of definition can also occur when the logo is filled in with spray dried film.

Possible cause	*Remedies*
Core erosion	Reduce the spray rate
	Increase the inlet and exhaust air temperatures
	Increase the spray pattern width
	Reduce the spray droplet size/increase the atomization air volume
	Reformulate the core with less water-sensitive excipients
	Improve tablet bed movement

(*Continued*)

TABLE 34.18 (Continued)

Excessive film-coating level	Reduce the film-coating weight gain
	Improve the uniformity of the coating distribution
Tablet attrition	Reformulate the tablet core to a friability of no more than 0.1%
	Reduce the pan speed to the minimum required to achieve a smooth and continuous bed movement
	Increase the spray rate to provide a protective film coating in a shorter time; this may require an adjustment in the inlet air temperature
Bridging	Reformulate the coating solution to improve the film adhesion
	Reformulate the core formulation to increase porosity
	Redesign logo to incorporate shallower angles
Excessive drying rate	Reduce the inlet and exhaust air temperatures
	Reduce the gun-to-bed distance
	Reduce the nozzle air pressure or atomization air volume

11. Core stability issues**:** These problems may manifest as discoloration of the core or degradation of the core active.

Possible cause	*Remedies*
Moisture sensitivity	Explore the remedies for overwetting defects
	Reformulate the core with less water-sensitive excipients
Heat sensitivity	Decrease the inlet and/or product temperature
Tablet component incompatibility	Investigate the compatibility of the tablet core with the coating formulation
	Determine the compatibility of the core ingredients

12. Tablet marking: Usually evident as the presence of black marking on the face of the tablets.

Possible cause	*Remedies*
Abrasion of oxide from the coating pan surface	Change to a tablet shape that tumbles rather than slides (ie, round rather than oval/capsule)
	Reduce the level of titanium oxide in the coating
	Add baffles to reduce the sliding of tablets
	Coat the pan with coating solution to act as a barrier
	Increase the spray rate or reduce the pan speed

34.7 APPLICATION OF SYSTEMATIC AND STATISTICAL TOOLS FOR TROUBLE SHOOTING AND PROCESS OPTIMIZATION

As we move firmly into the 21st century, the QbD, physician quality reporting initiative (PQRI), and risk management are introduced to allow the manufacturer and the regulator to better design, monitor, and control the quality of the product in United States, Europe, Japan, and other countries.

These are some key initiatives:

Concept of design space
QbD
Risk assessment
DOE
Knowledge space/control space
ICH Q8 (development)
ICH Q9 (risk management)
ICH Q10 (quality system)
KPP/CPP
Key quality attribute/critical quality attribute

To meet these challenges, many systematic and statistical tools are being used in a sequential manner to

- Identify root cause(s);
- Understand the KPP/CPP and knowledge space/control space;
- Optimize the process; and
- Establish the control plan, which should be one for continuous improvement.

Many pharmaceutical companies employ a variety of systematic and statistical tools and define the procedures of their approach. These tools include

six-sigma/DMAIC, DOE, Kepner Tregoe analysis (KT), Brightest, Pareto Analysis, Gauge RR, Lean sigma, risk assessment, and other tools.

Case Study: Using Systematic and Statistical Tools by Right-First-Time Approach to Address Film Coating Issues.

DEFINE : Poor Color Uniformity and Uneven Surface of Film Coating for Product XXXXXX.

The film coating of Product XXXXXX shows a poor colour uniformity and rough surface when transfer from Site A to Site B.

MEASURE

Observation:

1) Site A:
Material: a commercial blue film coating material
Coating Pan: fully perforated
Pan Load: 45 kg
Inlet Air Temperature: 60-65°C
Bed Temperature: 40-42°C
Exhaust Temperature: 45°C
Pan Speed: 7 rpm
Number of Gun: 2
Gun to Bed Distance: 25 cm
Spray Rate: 120 g/min total

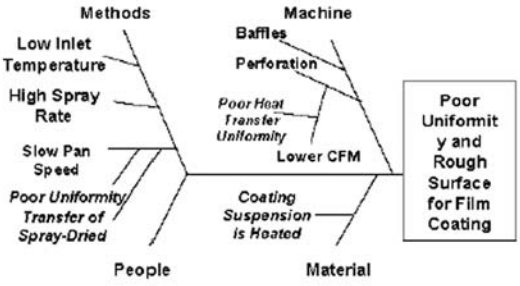
2) Site B
Material: same as Site A
Coating Pan: solid pan
Pan Load: 95 kg
Inlet Air Temperature: 45-50°C
Bed Temperature: 34-36°C
Exhaust Temperature: 40°C
Pan Speed: 10-12 rpm
Number of Gun: 3
Gun to Bed Distance: 30 cm
Spray Rate: 150-250 g/min total

The resulting tablets did not meet the Appearance Quality Limits. About 20% of coated tablets show significant lighter shade. The rough surface appearance show some solids deposits about 500-2000 µ.

ANALYSE

Cause & Effect Analysis (Fish-Bone Analysis)

Cause and Effect Analysis



.

Based on the shape and size of surface defects, some coating materials are detached and transferred onto other tablets. This could due to the imbalance of heat exchange, pan speed, and spray rate,

IMPROVE

DOE Coating Study
.3X3 Full factorial design
Factor 1: Bed Temperature
Factor 2: Pan Speed
Factor 3: Spray Rate/Atomization

The knowledge space is identified and better understood. The optimized parameters are identified and successful full-scale batches are manufactured.

The final parameters for Site B are listed below:

Material: same as Site A
Coating Pan: solid pan
Pan Load: 95 kg
Inlet Air Temperature: 50-55°C
Bed Temperature: 40-42°C
Exhaust Temperature: 42-45°C
Pan Speed: 12 rpm
Number of Gun: 3
Gun to Bed Distance: 25 cm
Spray Rate: 180-250 g/min total

CONTROL

The control plan is established for future manufacture.

Development, Optimization, and Scale-Up of Process Parameters: Wurster Coating

D. Jones[1,†] *and E. Godek*[2]

[1]Glatt Air Techniques Inc., Ramsey, NJ, United States [2]OWI-Consulting, Inc., Coatesville, PA, United States

35.1 INTRODUCTION

In 1959, Dr Dale Wurster, then at the University of Wisconsin, introduced an air suspension coating technique now known as the Wurster system. The Wurster process enjoys widespread use in the pharmaceutical industry for layering and film-coating of particles and pellets, as well as the emerging controlled-release tablet dosage forms. Product containers typically range in size from 3.5″ (100–500-g batch sizes) to 55″ (up to approximately 1100 kg). The Wurster process is used commercially for coating particles from less than 100 μm to tablets, and for layering to produce core materials.

35.2 BASIC DESIGN

The basic design components of a commercially available Wurster system are shown in Figs. 35.1 and 35.2. The coating chamber is typically slightly conical, and houses a cylindrical partition (open on both ends) that is approximately half the diameter of the bottom of the coating chamber (in up to 18″ Wurster coaters). At the base of the chamber is an orifice plate that is divided into two regions. The open area of the plate under the partition is very permeable. This permits a high volume and velocity of air to pneumatically transport the substrate vertically through the partition. As they accelerate upward, particles pass a spray nozzle that is mounted in the center of this up-bed orifice plate. The nozzle is referred to as a two-fluid or binary type, where liquid is delivered to the nozzle port at low pressure and is atomized by air at a preselected pressure and volume. The spray pattern is generally a solid cone of droplets, with a spray angle ranging from approximately 30–50 degree (Fig. 35.3). The so-called "coating zone," which is formed is a narrow ellipse, and varies in volume depending on the size of the substrate being sprayed and the pattern density in the partition.

The diagram in Fig. 35.4 illustrates the regions of flow in the Wurster process. The region outside of the partition is referred to as the down bed. The configuration of the orifice plate in this area depends on the size and density of the material to be processed. The purpose of the airflow in the down bed region is to keep the substrate in near-weightless suspension, irrespective of its distance to either the wall of the product container or the partition. The goal is to have it travel rapidly downward (to minimize cycling time), and then be drawn horizontally toward, and ultimately into the gap at the base of the partition. In general, larger substrates, like tablets, require significantly more air to produce this condition than smaller substrates, like pellets or fine particles. The orifice plate must be selected accordingly (no single down-bed plate can achieve good fluidization properties for all substrates). As mentioned previously, the material flow inside of the partition is controlled by the up-bed or partition plate. In general, this plate is considerably more permeable than the down-bed plate. In pilot- and production-scale Wurster systems, the up-bed plates are removable so that one or the other may be changed to fine-tune the behavior in these individual regions (see Fig. 35.5).

A second key process variable in Wurster coating is the height that the partition sits above the orifice plate, which controls the rate of substrate flow horizontally

into the coating zone. Typically, the smaller the particles to be coated, the smaller the gap will be. When the Wurster coating chamber is assembled properly, the resulting flow pattern should be relatively smooth and rapid in the down bed, and very dense and homogeneous in the up-bed (or partition) region.

The substrate exits the partition at a high rate of speed, requiring a region to decelerate. Above the product container is the expansion area (or freeboard, in traditional fluidized bed terms), which is typically conical to allow for decreasing air and particle velocity. Wurster machines designed for pellets and small particles employ elongated expansion chambers to essentially enhance deceleration in the air space rather than by high velocity impact against machine components in the filter housing. By contrast, tablets do not need much expansion height, and in fact, attrition may be a severe problem if they travel too high into the expansion area. The orifice plate and partition height should be optimized so that the tablets travel upward only a very short distance out of the partition before beginning their descent. As a result, a mesh bonnet can be used in the expansion chamber, just above the product container, to keep the tablets from colliding with the expansion chamber. The coarse mesh is intended to allow the fines from the cores or some spray-dried

coating to exit the process area, avoiding incorporation in the layers of film. A conventional Wurster machine is typically not used extensively for tablet coating because of the comparatively high stress to which the tablets may be exposed. However, it is recommended when the film quality (minimal defects) or active component distribution uniformity are very important, especially for modified-release tablets. The films applied by Wurster systems are high quality due to the concurrent spray and high-drying efficiency of this air suspension process. There have been modifications to the Wurster process specifically for tablet coating. These include spray nozzle surrounds, partition geometry, and airflow adjustability at the interface between the wall of the product container and the down-bed orifice plate (to be described in more detail later in this chapter).

Pellets and small particles are layered or coated extensively via the Wurster process using water, organic solvents, or even by spraying molten materials. All fluidized-bed techniques are known for high rates of heat and mass transfer, and the Wurster process is very effective in this regard. Highly water-soluble materials can be coated using water-based applications without concern for core penetration. Droplets applied to the surface spread to form a continuous film or layer, and then quickly give up their moisture to the warm, dry air. After a thin film has been applied, spray rates can be increased because the soluble core has been isolated. Films applied with volatile organic solvents are also high in quality because the formed droplets impinge on the substrate very quickly, minimizing the potential for spray drying of the film.

35.3 HS WURSTER CONSIDERATIONS

HS Wurster technology, shown in Figs. 35.4 and 35.6, is a product of Glatt Air Techniques, Inc., in Ramsey, NJ, and involves the use of a proprietary device to influence the behavior of the substrate in proximity to the coating zone. Unfortunately, the liquid spray-application rate is not controlled by the drying capacity of the fluidization air, but by the nature of the coating material (tackiness) or by the region immediately surrounding the spray nozzle (the first area of focus is this region). In all Wurster inserts, the high velocity of air rushing through the partition relative to the lower velocity in the down bed creates suction at the partition gap according to Bernoulli's Principle. As a consequence, particles entering the partition through the gap have a horizontal component to their flow. Some travel toward the spray nozzle instead of simply making the transition from horizontal to vertical flow. The atomizing air has a very high velocity (it is likely supersonic), and creates another area where Bernoulli's Principle applies, which draws the substrate to the base of the developing spray pattern. In a standard Wurster machine, the nozzle is elevated above the orifice plate at a position just below the confluence of fluidizing substrate particles. A portion of the developing up-bed stream of product can pass the nozzle tip, either closely or at a further distance. The zone directly above the nozzle tip is where the coating liquid and the atomizing air mix, and droplets begin to form. Particles that are very close to this zone tend to be strongly overwetted, and if they contact other particles, agglomerates are formed. To control what could otherwise be severe agglomeration, a typical response is to reduce the spray rate. This leaves a large amount of the drying capacity unused. Other commonly used agglomeration control techniques include raising the inlet (and product) temperature to increase the drying rate or raising the atomizing air pressure to shrink droplet size—options which are in conflict with producing high-

quality films. Even using these corrective measures, a quantity of agglomeration in traditional Wurster systems is almost inevitable.

The HS modification for the Wurster process was conceived to keep particles away from the spray nozzle until the spray pattern is fully developed. As a result, more of the excess drying capacity can be used, and the application rate increased substantially (more than doubled in many pilot-scale experiments). Agglomeration is also substantially diminished or eliminated because the particles are kept away from the wettest portion of the pattern (Fig. 35.6). An additional benefit is that the high-atomizing air velocities necessary to produce very small droplets for coating of particles smaller than 100 μm may be useable without pulverizing the substrate. The velocity of this air diminishes dramatically with distance from the nozzle, and even a few centimeters are significant. Therefore, keeping the product away from the nozzle tip allows the atomization air velocity to decrease significantly before contacting the substrate, reducing the likelihood of attrition, especially during the early stages of coating.

Coating of substrates smaller than 100 μm has been achieved more frequently using the HS Wurster coater. Success depends on many factors, both process- and product-related. Product considerations, such as flow properties of the substrate (generally poor in this size range, which must be improved), as well as the liquid, which must be amenable to atomizing to droplets well below 10 μm, must be addressed. The tremendous surface area of such fine particles also requires very high coating quantities, and consequently, a low potency of the final-coated product (often less than 50%).

35.4 COATING AND PROCESS CHARACTERISTICS

The coating liquid is sprayed in the direction of motion of the fluidizing particles. In general, the fluidization is orderly, with very rapid, dilute-phase pneumatic transport in the up bed, and relatively smooth and rapid transport in the down-bed region (outside of the partition). Droplet travel distance is minimized because the liquid is sprayed into a well-organized pattern of substrate moving relatively close to the nozzle. In this manner, droplets reach the substrate prior to any appreciable evaporation. By retaining their low viscosity they are able to spread on contact, and the resultant films are excellent, even when using organic solvents as an application medium. The drying efficiency of the fluidized-bed also minimizes the potential for core penetration, and the sample shown in Fig. 35.7 clearly shows a well-defined boundary layer between the substrate and the coating material; in this case a film applied using an aqueous dispersion.

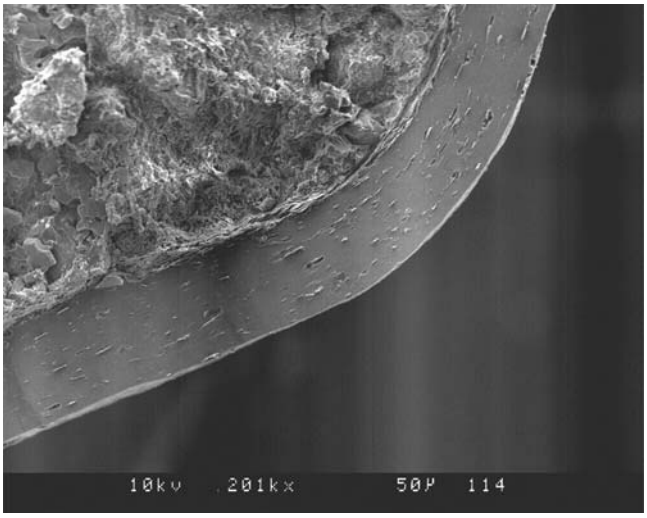

FIGURE 35.7 Cross-section showing boundary layer between coating and core material (200× magnification).

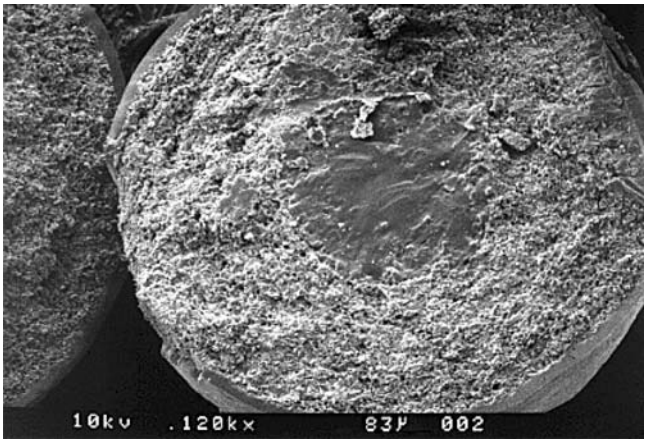

FIGURE 35.8 Cross-section of drug-layered, film-coated pellet (120× magnification).

35.5 PROCESSING EXAMPLES

The Wurster process is used commercially for coating and layering (high solids build up onto a type of core material). Substrates include particles smaller than 100 μm, crystals, granules, pellets, and tablets. As mentioned previously, films may be applied using water-based solutions, aqueous dispersions, or organic solvents.

The first example of a material layered and coated using the Wurster process is shown in cross-section in Fig. 35.8. The starting material is a very small, nonpareil sugar seed, and it is layered to a high potency using a suspension of drug in a dilute-binder solution. Release of the drug is controlled by a film subsequently applied. All three components are clearly identifiable.

The example shown in Fig. 35.9 is a tablet, film-coated (for sustained release) and layered with an additional dose of active material prior to drilling with a laser. Immersed in liquid, drug solute exits the laser hole in this type of dosage form. The Wurster process was selected for this product due to its abilities in film and drug distribution uniformity.

The product in Fig. 35.10 is coated with a moisture barrier. The substrate contains a significant quantity of material smaller than 5 μm. Agglomeration of fine particles does occur, as seen in the scanning electron micrograph (SEM). However, the average particle size of the finished product is still less than 50 μm. The film is applied from a volatile organic solvent solution, and is typically very tacky, hence the agglomeration "crater" where another particle has detached.

A water-soluble core, coated with a soft, heat-sensitive polymer system is shown in Fig. 35.11. The cross-section shows the deformable nature of the film, and these particles may be filled into capsules or compressed into tablets to be delivered. Although the product must be processed at low temperatures, core penetration was not a problem due to the process parameters used and the drying capability of the Wurster process.

Often the economics of coating very small particles dictate whether a product ever reaches the marketplace. When coated in a standard Wurster system, the drug particles shown in Fig. 35.12 proved too costly to produce. However, when the HS components were fitted to the pilot-scale 18″ Wurster machine, the process time was reduced by more than 50%, and the product is now commercially produced. The SEM shows very good morphological properties for the core, in that the particles are nearly spherical, and are not porous. In laboratory trials, this substrate was found to be very robust—attrition of the cores early in the coating process (before they were sufficiently coated to have improved surface strength) was essentially nonexistent.

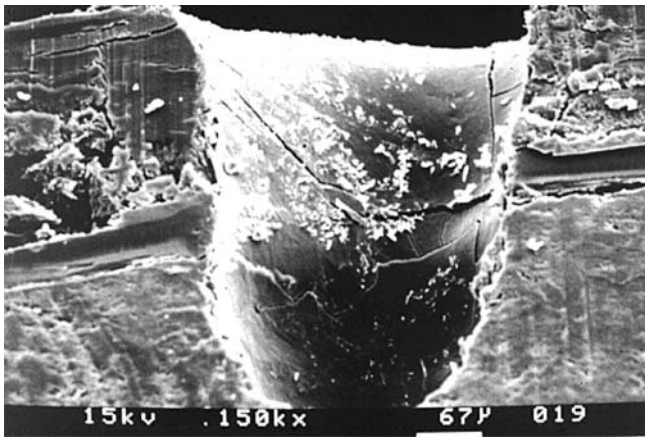

FIGURE 35.9 Cross-section of a tablet coated using the Wurster process (150× magnification).

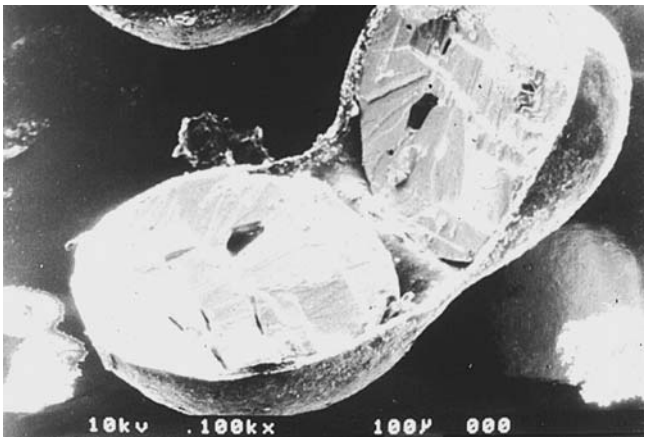

FIGURE 35.11 Water-soluble crystal coated for sustained release (100× magnification).

35.6 PROCESS VARIABLES

35.6.1 Batch size

The working capacity for a Wurster insert of a particular size is generally defined as the volume outside of the partition, with the partition at rest on the orifice plate. Loading of product only in the area outside of the partition helps to ensure that the nozzle remains clear at the beginning of the process. This is especially important for fine particle or pellet coating. For tablet coating, up to half of the volume inside the partition can also be used. As the bed becomes fluidized, the dense phase or surface of the down bed will drop, indicating that there is room for the batch to expand as coating is applied. In some cases, it may appear that there is more than enough, and that batch size could easily be increased. The danger is that the level of the bed is dynamic—varying in depth in response to the behavior of the up bed and surface properties of the substrate during spraying. Should the substrate begin to drop down into the partition against the desired flow, the up bed would be seriously disturbed, agglomeration would be likely, and the batch might be lost.

The minimum batch size is approximately 20–25% of working capacity. It is critical that there be sufficient material in the up-bed region to accumulate all or most of the coating material being sprayed or "efficiency" (actual yield vs expected) will suffer. The down bed acts as a material reservoir, "feeding" the base of the partition (entrance to the coating zone), and if its depth is insufficient, the up bed will be too sparse, favoring spray drying. In a more extreme case, coating of the inner wall of the partition may be experienced (this is more common in very small laboratory-scale inserts). Use of such a small volume of the product container is recommended only if the final batch size is significantly larger than the starting volume (eg, layering). Early in the process, the coating efficiency is compromised. This inefficiency diminishes as the batch size increases, improving mass flow through the coating zone. When approximately half of the down bed working capacity is occupied, the efficiency will be at or near its maximum for the formulation being executed. Ultimately, the inefficiency seen at the beginning of the process should be of little or no consequence to the finished batch.

After the layering step, it is strongly recommended that the minimum batch size be increased to approximately 50% of the working volume if a thin film is to be applied. For film-coating, inefficiency will likely impact the resultant dissolution behavior. Some amount of spray drying may result in unexpectedly rapid release of drug, particularly for a sustained-release coating.

35.6.2 Fluidization pattern

Irrespective of the amount of substrate in the Wurster insert, the fluidization pattern is controlled by the orifice plate configuration, the partition height, and the fluidization air volume. As mentioned previously, the goal is to have a rapid and relatively smooth down bed. This is not always possible, depending somewhat on particle size (small particles are difficult, if not impossible, to fluidize without bubbling), but to a greater extent on the tackiness of the product during spraying. Some coating materials are inherently tacky or move sluggishly due to temperature sensitivity. If this is the case, it is more important to keep the entire bed moving and involved by marginally over-fluidizing (turbulence or bubbling in the down bed), rather than attempting to achieve a smooth flow. This can be accomplished by raising the partition somewhat or using a more permeable down-bed plate, to allow extra air to percolate through the descending product. The risk in not doing this is that, as the process progresses, the bed may stall in some region on the orifice plate, and a portion of the batch may not receive all of the desired coating. Typically, this happens in the back portion of the product container, usually out of sight from the operator. The reason for this is that, in most installations, the process air enters the inlet plenum via a duct behind the machine. More air enters the product bowl in the front, due to momentum because the air has mass and needs to make a sharp turn upwards. This can be minimized by increasing the pressure drop across the bottom plate using a retention screen with a lower porosity.

In general, tablets require a large air volume in the down bed to keep it well-aerated. The partition region of the plate is also selected to allow only sufficient air flow to minimize the distance tablets travel out of partition to avoid attrition. By contrast, the orifice plates for pellet coating may differ significantly. The plate is permeable inside of the partition, and the down-bed section is only perforated to the extent that the product flows downward in near-weightless suspension. Achieving this condition typically requires only about a one-fourth of the open area needed for tablet coating. Finally, plates designed for powders are even less permeable in the down-bed region (and boiling may be impossible to control, due to the flow properties of fine materials).

Another critical process variable in the fluidization pattern for Wurster processing is the height of the partition above the orifice plate. The height is also substrate-dependent. For instance, tablets, a comparatively large substrate, would require a substantial partition height, such that a sufficient number of them could pass through the gap per unit time to accept the

TABLE 35.1 Partition Height as a Function of Substrate and Wurster Coating-Insert Size

Substrate	Partition height
Tablets	25–50 mm in small machines
	50–100 mm in 18″ Wursters and larger
Pellets	Approximately 15–25 mm small machines
	Approximately 35–60 mm in 18″ Wursters and larger
Powders	Approximately 25–50 mm in all machines

maximum amount of coating being sprayed into the partition area. Pellets and intermediate particles do not need as high a partition height as tablets, and fine particles and powders need only a small gap to result in an ideal fluidization pattern. Table 35.1 profiles suggested conditions for partition height as a function of substrate and Wurster coating-chamber size.

35.6.3 Atomizing air pressure and volume

Droplet size should be small, relative to the particle size of product to be coated. For example, coating of tablets may need less than 2 bar (30 psi) pressure. Higher pressure and air volume will result in a higher atomization air velocity, increasing kinetic energy at the interface between the spray pattern and slower-moving substrate. The potential for causing attrition of the tablets by accelerating them into machine components is also enhanced. Finally, the high atomizing air velocity may distort the fluidization pattern.

When coating small particles, a somewhat higher atomization air pressure may be necessary, to achieve small droplet size and thereby avoid agglomeration. There is some risk, however, that the high shear associated with pressures in the 3–6 bar (45–90 psi) range, depending on the type and size of the spray nozzle, may cause breakage of fragile core material. The Gustav Schlick Company in Coburg, Germany, is a supplier of spray nozzles in widespread use in Wurster processing. The 970 series nozzle is found in small (3.5″, 4″, 6″, 7″, and 9″) Wurster bottom-spray coaters. With water-like materials, it is useable in a spray-rate range of approximately 0–100 g/minute. Fig. 35.13 shows the influence of atomization air pressure on mean droplet size for water sprayed at 25 g/minute (data by Schlick). Interestingly, increasing the pressure beyond 2 bar does little to decrease the droplet size. This is, in part, due to the fact that 25 g/minute is well within the nozzle's ability to atomize. What should be noted is that, if a process is being run in which agglomeration is a minor problem and increasing the atomization air pressure seems to improve the situation, it is likely a consequence of the increased air velocity and kinetic energy, not a smaller droplet size.

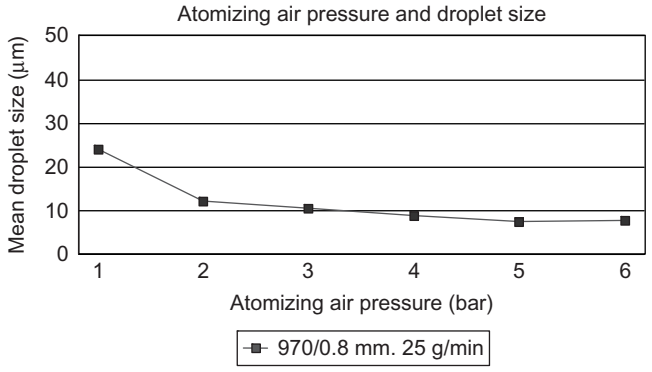

FIGURE 35.13 The relationship between atomizing air pressure and droplet size for a Schlick 970 series nozzle spraying water.

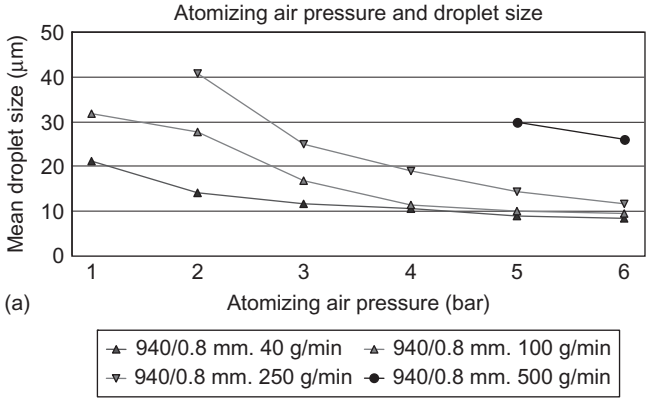

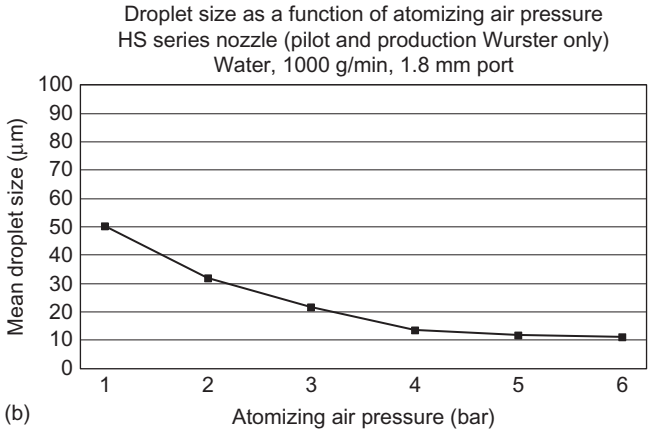

FIGURE 35.14 (a) The relationship between atomizing air pressure and droplet size for a Schlick 940 series nozzle at various spray rates using water. (b) The relationship between atomizing air pressure and droplet size for a Schlick HS Wurster nozzle at 1000 g/min spraying water.

Looking at the performance envelope of the Schlick 940 series nozzle (Fig. 35.14), which is used in older style 12″, 18″, 24″, 32″, 46″, and 55″ Wurster coaters, it can be seen that droplet size increases with faster spray

rates (at a constant atomization air pressure). In cases where the spray rate is 250 g/minute or less, it is possible to increase atomization air pressure/volume/velocity to achieve droplets smaller than 20 μm. However, the data shown for the 500 g/minute rate demonstrates that even at the highest practical atomization air pressure (6 bar), it is not possible to produce 20 μm droplets (spraying water). This is an important consideration in larger capacity equipment, where there may be significant drying capacity, and the rate-limiting factor is the inability of the nozzle to atomize liquid (to a satisfactory droplet size) at the rate at which the process air may remove the resultant water vapor. The only possibility for taking advantage of the increased drying capacity is to enlarge the nozzle (use more compressed air at the same pressure).

The 940 series nozzle is unable to produce droplets smaller than 20 μm at 500 g/minute using water, even at very high atomization air pressures. A process that has excessive drying capacity, but is limited by droplet size (eg, fine particle coating), will result in unnecessarily hindered productivity. Upgrading to the HS nozzle, which uses substantially more compressed air at the same atomization air pressures (approximately three times the volume of the 940 series nozzle), will result in a dramatic improvement in drying capacity utilization. The graph in Fig. 35.14b depicts a droplet profile that is similar to the 940 series nozzle spraying at 250 g/minute, with the exception that the HS data is for 1000 g/minute, a spray rate four times that of the 940 series nozzle. This permits the HS nozzle to be operated at low atomizing air volumes and pressures, limiting the potential for attrition due to high kinetic energy.

35.6.4 Nozzle port size

Droplet size is rarely influenced by nozzle port size. At a fixed volumetric spray rate, the velocity of the liquid into the atomization air is controlled by the nozzle port size. The lower the velocity, the more complete the atomization of the liquid will be, and the smaller the mean droplet size; Fig. 35.15 illustrates this data for a 940 series nozzle for two different spray rates. For 100 g/minute, the mean droplet size is nearly the same for all data points, with the exception of the values at 2 bar. However, this appears to be an anomaly because the mean droplet size is the same for both port sizes at the lower pressure of 1 bar. At the higher spray rate of 250 g/minute, the mean droplet sizes are the same at 3 bar and higher. Only at 2 bar is there an appreciable difference, owing to the lower liquid velocity, and longer dwell time for the liquid in the atomizing air stream. In addition, factors such as liquid viscosity and surface tension influence this behavior; and it is preferable that they both be low to avoid the need for high atomization air pressure, regardless of the size of the substrate. If viscosity is an issue (high), nozzle port size should be selected to accommodate it (to minimize back pressure in the spray pump).

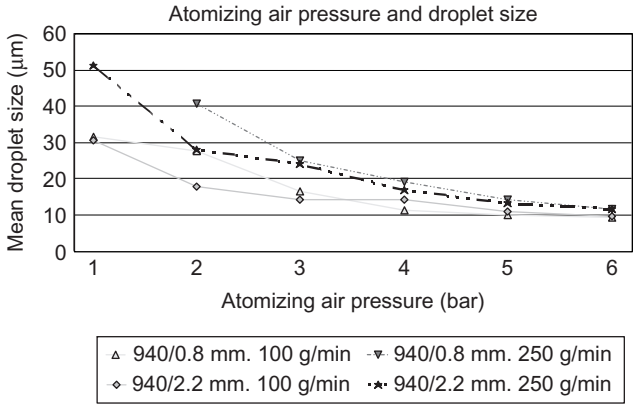

FIGURE 35.15 The relationship between atomizing air pressure and droplet size for a Schlick 940 series nozzle at 100 and 250 g/min (water) using 0.8 and 2.2 mm nozzle port sizes.

35.6.5 Evaporation rate

Evaporation rate or drying capacity is controlled by fluidization air volume, temperature, and its absolute humidity (dew point). The temperature of the fluidization air is generally adjusted to maintain a constant product temperature. The product temperature, in turn, is influenced by spray rate and humidity of the incoming air. First, to take advantage of excess drying capacity, inlet temperature must be raised to keep the product temperature from dropping, due to the increase in evaporative cooling as spray rate is increased within a given batch. Secondly, if the dew point of the incoming air is not controlled, the drying conditions to which the product is exposed will not be reproducible. The dew point changes seasonally, especially in northern climates, and may range from below 0°C during winter to more than 20°C in summer. These normal variations in weather conditions may result in some notable influences in processing.

In cold weather, static electricity during fluidization may be a problem, and in summer, high humidity conditions may result in substantially slower spray rates, due to erosion of drying capacity, especially for aqueous coatings. This phenomenon is, of course, more pronounced when product temperatures of 30°C and less are desired (thermally sensitive substrates or coating materials). Allowing the process air dew point to vary will result in a variation in the residual moisture in the applied film. This can lead to a change in the glass transition temperature for some coatings.

For latex materials, residual moisture may result in "aging" effects—changes in dissolution with time (product instability). For most products, a dew-point range of approximately 10−20°C throughout the year is recommended, to minimize this so-called "weather effect." If the product is very sensitive to moisture in the process air or even thermally sensitive, a desiccant dryer is suggested, which will produce dew points well below 0°C. In any case, process air dewpoint control is recommended in the system's air handling unit.

35.6.6 Product temperature

All air suspension processes are noted for their high heat and mass transfer capability. A wide range of product temperatures may be used. Values below 30°C may be used for heat-sensitive materials. Values exceeding 50°C may actually be used with little or no spray drying of the applied coating. High product temperatures are especially attractive for water-based spray liquids. The rate-limiting step for most processes is related to the physical properties of the liquid being applied. The use of psychrometry is effective in determining the threshold at which moisture applied to the surface of the substrate begins to remain in the applied layer, rather than to leave with the process air. This inflection point is where agglomeration begins to take place. The surface tackiness promotes the sticking together of substrate particles. This so-called exit air relative humidity threshold is related to the product temperature. For example, for an exit humidity threshold of 60%, the water removal rate for a product temperature of 40°C is approximately 100% higher than for a product temperature of 30°C. Water content in air is an exponential function—for high product temperatures, the water removal rate is dramatically increased without fear of agglomeration.

35.7 CASE STUDIES FOR LAYERING AND FINE PARTICLE COATING

With an understanding of the range of application of the Wurster process, plus the process and product variables that influence its performance, it is interesting to look at some case studies. The first involves the use of an 18″ HS Wurster coater for solution layering (refer to Figs. 35.16 and 35.17 for in-process data). A water-based drug solution was made, using a high solids concentration. The goal of the trial was to find the maximum possible spray and production rates, avoiding agglomeration as much as possible. The starting material is very fine, initially requiring a reduced spray rate (400 g/minute). However, as the particles grow larger, the spray rate can be elevated as the surface area of individual particles increase. The finished particle size is less than 200 μm, and the potential for productivity using the Wurster process is clearly evident here. The majority of the spray liquid is applied at 900 g/minute. Heat and mass-transfer rates are very high. The inlet air temperature is more than 90°C, the product temperature is approximately 35°C, and the

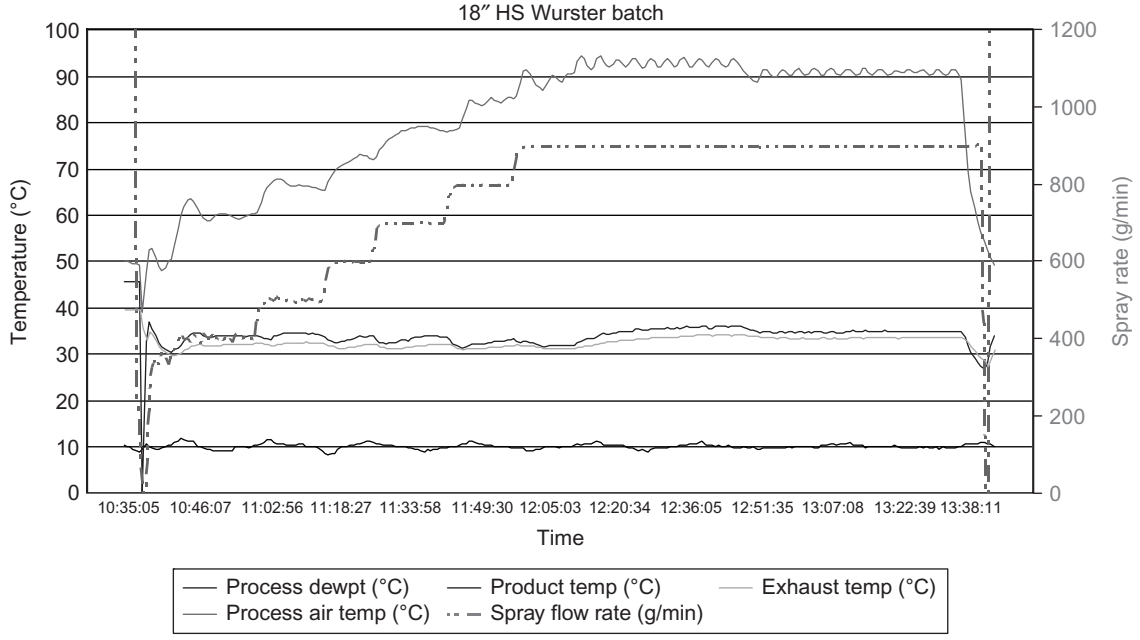

FIGURE 35.16 In-process data (temperatures and spray rate) for an 18″ HS Wurster solution layering process.

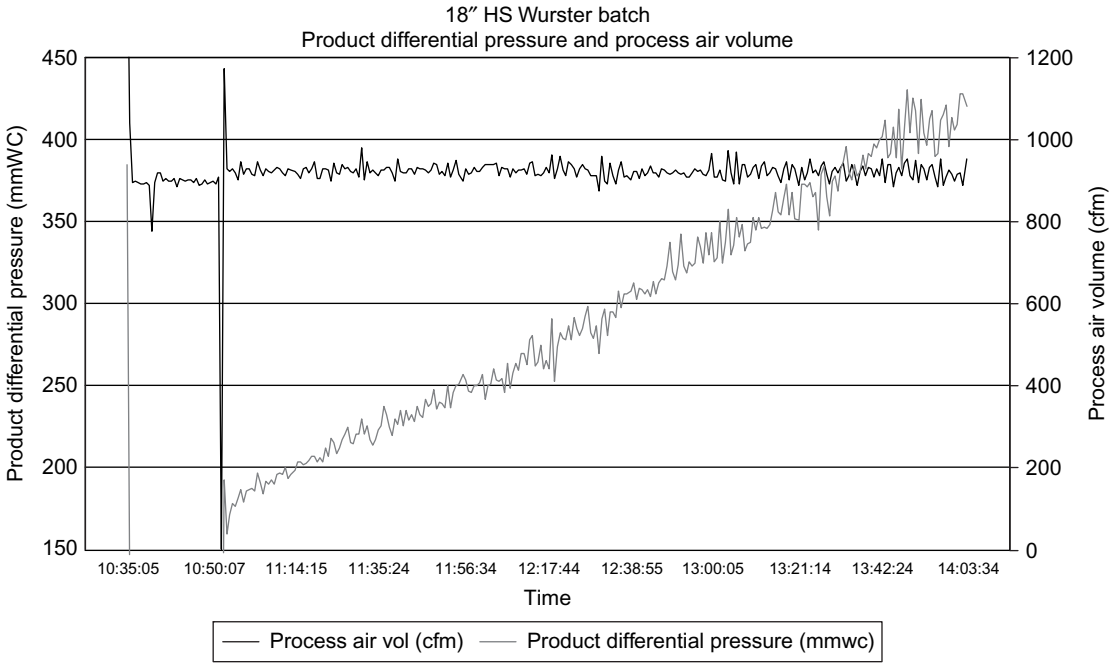

FIGURE 35.17 In-process data (process air volume and product differential pressure) for solution layering in an 18″ HS Wurster coater.

process air volume is 900 cfm. Using psychrometry software, the exit air humidity is found to be at 85% relative humidity, indicating that the vast majority of available drying capacity is being used. An interesting tracing is that of the product differential pressure, shown in Fig. 35.17, as the starting batch size is approximately one-quarter of the finished product weight. As bed depth increases in the down bed, the particles react differently to the up bed process air flow. There is a near-absence of oscillation in the early readings because the down bed is shallow, and there is minimal coalescence of air bubbles as they enter and pass through the bed. However, as batch size increases, the down bed deepens. Small air bubbles, entering through the orifice plate and product retention screen, coalesce into larger bubbles. Back-flow or turbulence in the down bed becomes evident. The escalating peak-to-trough values indicate bubbling air flow in the down bed. This is of no consequence to the process, provided that the down-bed cycling time remains rapid, so that the mass flow in the "coating zone" continues to be high in density and velocity. A consequence of adverse fluidization properties would be agglomeration, however, in this particular pilot-scale trial, this was essentially nonexistent.

The second case study involved coating fine granular acetaminophen particles for sustained release. The uncoated crystals, shown in Figs. 35.18 and 35.19, illustrate a good substrate for coating. They are uniform in size distribution, and do not contain an appreciable amount of fines. What is not seen by SEM, however, is

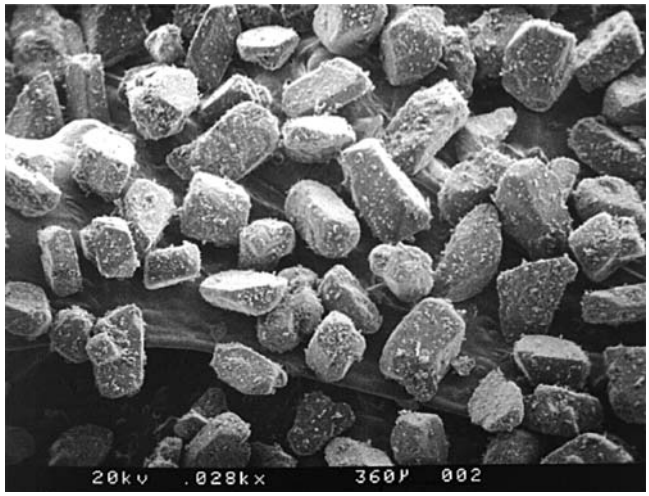

FIGURE 35.18 Uncoated acetaminophen (APAP) crystals (28× magnification).

their fragility. As the particle size data shown in Tables 35.2 and 35.3 reveals, the material is very prone to fracture. Within a few minutes of product warm-up (prior to spraying), the content of material smaller than the 80 mesh screen (180 μm) escalates from nothing to more than 3%, and continues to climb early in the spraying process until sufficient coating has been applied to improve the strength of the primary core material. It is important that the fines that exist in the initial product, in addition to those generated during the early stages of coating, are treated in one of two

ways. First, using a comparatively high spray rate initially, they may be incorporated in the lower layers of film, such that the majority of the remaining film governs the coated-product release properties. Second, an outlet filter media can be selected such that fines are permitted to exit the processor (to be collected in a remote dust collector). If attrition is serious or if fines are continually incorporated in the developing film, as was the case using the conventional 18″ Wurster coater, the release properties of the film will be affected, and in all likelihood, challenging to reproduce. In Figs. 35.20 and 35.21, the acetaminophen crystals have been coated to a 28% coating level (final potency of 78.1%) with AquaCoat (FMC), a pseudolatex of ethylcellulose. The standard version 18″ Wurster equipment was used in a Glatt model GPCG-60 fluid-bed processor, using the HS nozzle, but no HS nozzle surround, and a (then) contemporary version of an up-bed plate referred to as "high mass flow." This plate may be described as having a gradient of holes (and permeability) from the outer perimeter to the spray nozzle. The highest permeability is in close proximity to the nozzle. The intent of this design was to enhance the pressure gradient at the partition gap and increase the flow of material into the coating zone. What became apparent during these trials was that this resulted in a high concentration of substrate close to the tip of the nozzle and the developing spray

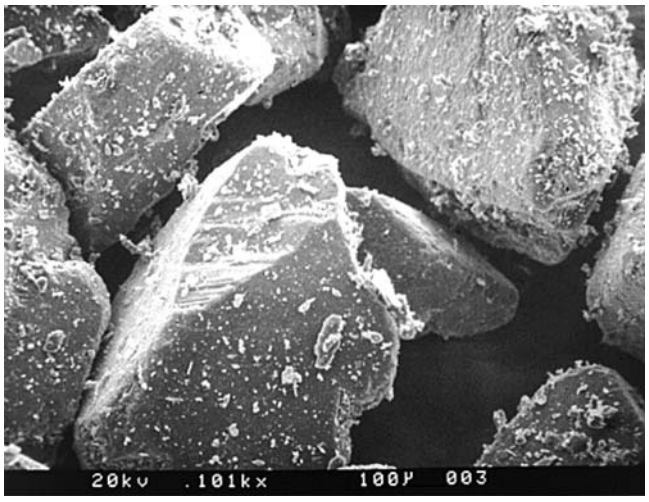

FIGURE 35.19 Uncoated acetaminophen crystals (100× magnification).

pattern. Recall that this region is high in liquid content and atomizing air velocity, which can lead to attrition of fragile substrates.

The HS nozzle, for high-capacity spray rates, was used so that the influence of the perforated plates and HS nozzle surround could be seen independently of a key variable, such as nozzle type. In the SEMs, at both the low and higher magnifications, the fines generated early in the spray process due to the high velocity atomization air are readily seen embedded in the film. They are present to the extent that the final particle size is substantially larger than the starting material (see Table 35.2). The resultant porous nature resulted in a faster drug-release rate (Fig. 35.22). This occurs in spite of the fact that the total surface area per unit mass is expected to be lower, due to the increased particle size. This type of problem should be resolved or batch-to-batch reproducibility (dissolution) will be difficult to achieve. In this example, the atomizing air pressure had to be reduced to as low as 2.2 bar to slow the generation of fines, which ultimately became embedded in the film.

In Figs. 35.23 and 35.24, the partition plate was replaced with a more uniformly permeable type "G," and the HS nozzle surround was installed. The surround acts to keep the particles away from the highest velocity and densest droplet region of the spray pattern, as described previously. The result is that the atomization air pressure could be maintained at 3.5 bar throughout the spraying process, with only minimal

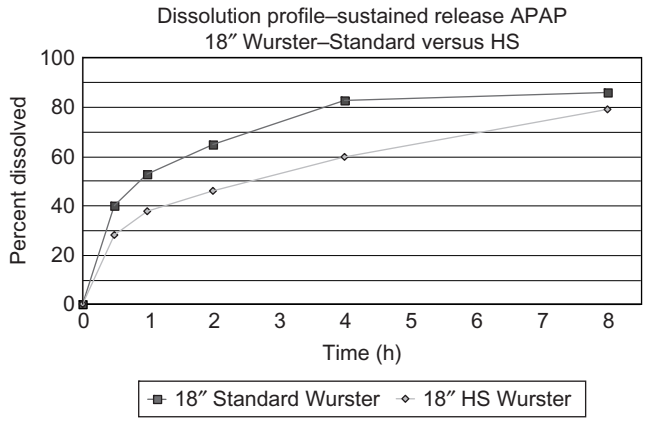

FIGURE 35.22 Dissolution profile for fine granular acetaminophen batches coated in 18″ standard and HS Wursters with 28% w/w coating of AquaCoat ECD (FMC BioPolymer).

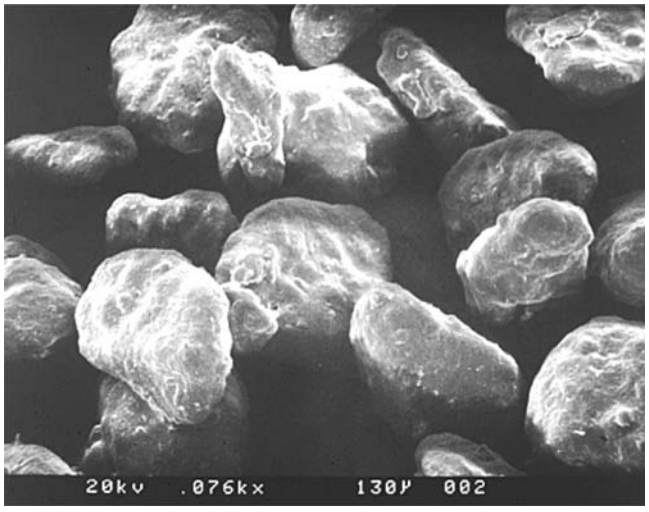

FIGURE 35.23 Acetaminophen—28% coating using 18″ HS Wurster coater (76× magnification).

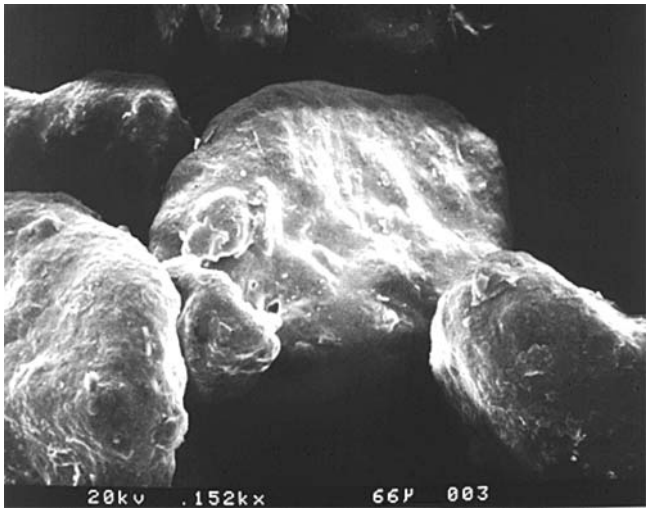

FIGURE 35.24 Acetaminophen—28% coating using 18″ HS Wurster coater (152× magnification).

generation of fines, as evident in the SEMs. The average particle size after coating was smaller than when using the standard Wurster configuration because fewer fines were generated and embedded. This resulted in a less porous film, and slower drug release, as seen in the accompanying dissolution profile shown in Fig. 35.22. An additional benefit was a reduction in process time, due to the ability to apply the coating at a higher spray rate (approximately one-third faster).

For the experiment involving the standard Wurster system, the total process time of 3 hours and 39 minutes is not unreasonable for production. However, in the sieve analysis, the coarsest fraction disappears early in the process, and well into spraying the fraction of material defined as "fines" continues to increase to nearly 20%. Ultimately, these fines are agglomerated to the main fraction of material, and their final content is marginal. However, the average particle size shifts to the coarse side, with more than 40% retained on the 40 mesh screen compared with only 18% found in the batch coated using the HS components.

The process time using the HS components was reduced by 48 minutes or approximately 30%. In addition, the near absence of fines seen in the SEMs will lead to improved batch-to-batch reproducibility in the dissolution profile.

35.8 SCALE-UP OF WURSTER PROCESSING

"Is the process scalable?" is a reasonable and common question. The answer typically begins "yes, but . . ." The ability to scale a process successfully depends on the magnitude of difference between the small and larger-sized batches. In the laboratory, development may take place with a batch size smaller than 1 kg. This size of equipment should be considered to be for screening purposes, without expecting that the formulation developed on the small scale will behave identically in pilot or production equipment. The batch size is small, the particle trajectory is comparatively short, the bed depth is shallow, and the spray nozzle does not use much compressed air to produce droplets. The mass of the batch is likely to be insufficient to manifest problems with attrition due to fragility of the substrate. Mass flow inside of the partition during spraying, cannot match that of larger equipment, so the amount of coating or layer applied to the substrate will not be in the same proportion as in larger equipment.

Experience has shown that the biggest hurdles in scale-up occur when moving from a 6″ Wurster coater (or smaller) to a 7″, 9″, 12″, or 18″ Wurster coater. Usable working volumes (courtesy of Glatt Air Techniques, Inc., Ramsey, NJ) are 3.6 L (6″ Wurster

coater), 8.3 L (7″), 13.6 L (9″), 37 L (12″), and 102 L (18″). In addition to the increase in volumetric capacity, the partition length increases, the partition diameter increases, bed depth and mass effects increase, particle trajectory increases, and the spray-nozzle dimensions increase (in size and consumption of atomizing air volume) to accommodate the increased spray rate. High kinetic energy from the combination of high atomizing air velocity and volume may be a significant, and in many cases unpredictable, factor in scale-up.

What should be evident is that scaling from any of the laboratory-sized Wurster systems to the pilot-scale 18″ Wurster coater is the true "scale-up," presenting the most significant challenges. Thereafter, production equipment typically incorporates multiples of the partitions and spray nozzles used in the 18″ Wurster. In reality, this "scale-up" should be referenced as "scale-out." Parameters such as process air volume, atomizing air pressure (and volume), spray rate, and temperatures derived for the 18″ Wurster are typically replicated on a "per partition" basis in the production equipment. Hardware components are also duplicated—the spray nozzle, partition diameter, and orifice plate configurations (permeability in both the up- and down-bed regions) are the same in both scales of equipment. Partition length is nominally longer, therefore the increase in bed depth is usually inconsequential provided that the 18″ Wurster coater is used at or near its working capacity. Examples of the pilot-scale 18″, and production scale 32″ HS Wurster coaters are shown in Figs. 35.2 and 35.25.

Successful scale-up in Wurster processing depends on a number of factors. At a minimum, development scientists should have a good understanding of the robustness of the process in laboratory equipment. Experiments bracketing the operating ranges of key parameters should be conducted, preferably on batch sizes exceeding 5 kg. Smaller batch sizes may be used, and the relationship of the process variables may be seen, but very small batches may not be indicative of what is seen on a somewhat larger scale. Ideally, design of experiments should be employed to quantify the magnitude of impact for the key variables.

FIGURE 35.25 Inside view of 32″ HS Wurster coater. *Source: Photograph courtesy from Glatt Air Techniques, Inc.*

As in any process, there is a multitude of variables to consider, including batch size, spray rate, atomizing air pressure/volume, process air volume, and temperatures (product, process air, and dew point). There are also equipment considerations—down-bed and up-bed orifice plate configuration, partition height above the plate, and the spray nozzle type, as mentioned previously.

Some concerns are not readily apparent. Equipment may increase in size and batch capacity, but not all components increase proportionally. For example, outlet air filter surface area actually decreases in proportion to batch size. This is problematic for products using layering or coating materials that cause filter media to blind. When a filter becomes occluded, process air volume is affected, particularly during shaking. The Wurster process requires process air flow to be continuous—it is not interrupted to shake fines back into the bed. As a consequence, when it is time to shake the filter, air flow is stopped, but only through the filter segment to be shaken. In contemporary machines, this means that the totality of the process air volume must now pass through the remaining half of the filter media. If the differential pressure across the filter is high, there will be a precipitous drop in process air volume. A consequence is that the velocity of substrate inside of the partition will momentarily drop, which could cause agglomeration. In an extreme case, with multiple partition production-scale Wurster systems, a severe drop in total process air volume may cause one of the partitions to stop "spouting." Under this circumstance, this partition may be filled from the top by the remaining spouting partitions. Even after shaking stops, and the process air volume returns to its set point, the filled partition may not evacuate. Atomizing air from the spray nozzle inside of the partition will create a small void, into which the liquid continues to be sprayed. However, the material surrounding this void is static, and is quickly over-wetted. Eventually, agglomerates and wet mass will make their way outside of the partition, and sampling will reveal a severe problem. By this time, the batch is essentially lost. Ultimately, if laboratory experimentation has shown that the spray material has a propensity to cause filter blinding, even to a comparatively limited extent, filter media must be a strong consideration during scale-up activities.

Relative to the environment in which spraying takes place (the coating zone), the particle size of the substrate is becoming smaller in scale-up. This may result

in a higher coating efficiency (coating material applied with respect to the theoretical or expected yield) in pilot and production equipment versus the laboratory scale. If the product is coated on a weight basis, the higher coating efficiency may lead to a change in dissolution (for sustained release coatings, it would decrease).

35.8.1 Batch size

As mentioned previously, the maximum batch size for a Wurster process is identified as that which occupies all of the volume outside of the partitions with them at rest on the orifice plate. There is some flexibility in batch size—the process will still work when using less than the maximum working capacity. However, it has been seen in scale-up that batch size, within a given insert size, may impact finished product properties. Therefore, it is recommended that the proposed finished batch size be close to the working capacity of the larger Wurster (approximately 75−100% based on the finished product density).

35.8.2 Spray rate

The spray rate for a product is typically a key variable, from several perspectives. The first is economic—long processes result in high manufacturing costs. Lengthy processes also increase the likelihood of problems during the process, particularly nozzle-port clogging (there are some hardware alterations that can be made to eliminate or at least mitigate this potential problem). Spray rate also dictates the rate of accumulation of solids by the batch, and this is important for finished dosage form performance. Coated product is nearly always stronger than uncoated core material. If the core sloughs fines, these may be incorporated into the layers of film, altering its release properties (release will be governed more by imperfection than by the intrinsic properties of the film). Consequently, it is a goal in scale-up to maximize the solids addition rate.

Drying capacity is a key component in scale-up. The starting point for estimating the spray rate is related to the increase in process air volume (at the same temperature and dew point as used in the laboratory scale), not the increased batch size. However, the rate-limiting factor may not be completely related to the increase in drying capacity offered by the larger Wurster system. Irrespective of the physical properties of the liquid, the application rate will more likely be strongly controlled by the interface between the accelerating core material, and the atomized droplets (coating zone). There may be significant benefits in using the spray nozzle surround described previously as HS Wurster equipment, which is not typically used or is of lesser benefit in small Wurster equipment. The surround prevents the flowing substrate from entering the spray pattern until it is more fully developed. This eliminates local over-wetting, preventing agglomeration in this region. A consequence is that scale-up in the Wurster process may not necessarily mean a significant increase in process time, which is a common occurrence in many types of processes.

35.8.3 Droplet size and nozzle considerations

Spray conditions represent a challenge for development personnel in scale-up. Small Wurster coaters tend to use the same size nozzle (Schlick 970 series), and as the product proceeds through small increments in batch size (from 6″ to 7″ or 9″ units with batch capacities ranging from approximately 1 to 10 kg), only atomization air pressure needs to be increased to accommodate the somewhat faster spray rate. However, when shifting to the 12″ or 18″ Wurster coater, the potential increase in spray rate forces operation of this small nozzle beyond its performance envelope, and a move to a larger nozzle, with a higher atomizing air volume, is mandated. Droplet size is principally related to the air-to-liquid mass ratio, and attempting to keep this in the same range in the scale-up efforts is recommended. However, there is a caution to its use. In some calculations, the air-to-liquid mass ratio may result in atomizing air pressure values that are outside of the nozzle's recommended operating range. The spray nozzle performs two different functions: (1) to produce droplets for the coating or layering application, and (2) to attempt to prevent the nozzle from fouling. The atomizing air at the tip of the nozzle helps to clear the tip of material forming as a result of drying that occurs between the interface of the liquid and the very dry atomizing air. If the atomizing air pressure (below approximately 1.5 bar) and volume is too low, the velocity of the atomizing air will be insufficient to remove dried film from the nozzle tip. This material could eventually grow to a size that impacts or diverts the spray pattern, causing a sudden and severe amount of agglomeration. In addition, the atomizing air velocity must be sufficient to permit shearing of the liquid to produce droplets. If the pressure and velocity are too low, agglomeration will be unavoidable.

At the other end of the spectrum, if the air-to-liquid mass ratio calculation yields an atomizing air pressure exceeding approximately 3.0 bar in the pilot-scale Wurster, attrition of the core material may be the consequence. Kinetic energy is represented as $E = 1/2\ mv^2$, where "m" is mass and "v" is velocity. Assume a scale-up from a 7″ Wurster machine (laboratory scale), with a batch size of approximately 5 kg, to a pilot-scale 18″ HS Wurster machine, with a batch size of approximately 60 kg. At 2.0 bar atomizing air pressure, the 970 series

(laboratory) nozzle uses about 2.1 cfm of compressed air. At the same pressure, the HS nozzle consumes nearly 30 cfm, or about 14 times that required for the laboratory batch. The atomizing air velocities are essentially the same—both operate at supersonic speeds at this pressure. If constant air density is assumed, the kinetic energy equation shows that the material in the pilot-scale equipment will be exposed to nearly 14 times more energy than the laboratory batch. For most applications using either water- or solvent-based materials, an atomizing air pressure of 1.8–3.0 bar is sufficient.

35.8.4 Process air volume

Process air volume is also a key factor in scale-up, providing three major functions. First, it delivers heat to the product, for evaporation and removal of the coating application medium. Second, and perhaps more significantly, it strongly affects the fluidization pattern. For scale-up, approximately the same air velocity through the partition plate for both sizes of inserts is recommended. The increase in overall air volume will then be principally related to the increase in the partition plate area through which the fluidization air will flow in the larger machine. "Scale-up" generally refers to increasing batch size and equipment geometry from small (6″, 7″, 9″, and 12″ Wurster coaters) to the pilot-scale. Partition diameter length increases, up to and including the 18″ Wurster coater. Beyond the 18″ Wurster coater the concept of "scale-out" may be more applicable, and scaling to 32″, 46″, or 55″ Wurster coaters is more direct. The larger inserts use multiples of the same diameter partition and spray nozzle found in the 18″ Wurster machine. Therefore, the increase in air flow would be a multiple of the number of partitions (700 cfm in the 18″ would lead to a target air flow of 2100 cfm in the three-partition 32″ Wurster machine).

The final manner in which the air volume impacts the process in scale-up is also related to the fluidization pattern. In multiple-partition Wurster systems (such as the 32″ and 46″ coaters), distribution of the process air across the entirety of the product container is a function of several factors. Orifice plates in both the up- and down-bed regions are selected based on the size, density, and surface properties of the materials being produced. As stated previously, the goal is to have the process air delivered to the product bed, such that the material in the down bed is in "near-weightless suspension" or behaving like a fluid. To achieve an essentially level surface requires a minimum of pressure across the down bed. This pressure is the result of several factors: core material quantity (initial batch size); partition height (the influence of the Venturi effect); orifice plate configuration; and finally, process air volume. For example, if 700 cfm were used in the 18″ Wurster coater, the target value for the three-partition 32″ Wurster coater would be 2100 cfm, as previously stated. Initial fluidization with the desired batch size may result in a tilted bed (higher in the rear of the insert than in the front) if product differential pressure was insufficient to cause the air to be uniformly distributed. Raising the partition height somewhat would increase the mass flow in the up-bed region, potentially increasing overall product differential pressure. If this change were insufficient, a second approach would be to use a less permeable down-bed plate. Both of these alternatives are preferred to increasing the process air volume. The consequent elevated spout height may enhance the potential for attrition, due to collision with the inside components of the filter housing.

For multiple partition production Wurster systems, it is prudent to optimize the fluidization pattern prior to actually producing a batch. A "mass flow study," which involves bracketing of process air volume and partition height for a set of orifice plates and batch size is recommended. The first step is to configure the Wurster insert with a set of up- and down-bed orifice plates. The initial partition height for the trial would be set at the lowest value selected for the study. Finally, the insert is positioned in the machine tower, and process air is drawn through it. The range of process air volumes to be tested should bracket the air volumes to be used for all steps of the process. At each of the selected air volumes, the product differential pressure (dP product) should be recorded. These will be the baseline contributions of the orifice plates. When the process is repeated with a batch in the insert, the difference between the total dP product and the baseline will reflect the "mass flow" in the insert. The goal is to identify the maximum product contribution, with a minimum of disruption to the fluidization pattern. An example is shown in Figs. 35.26 and 35.27. In Fig. 35.26, the air volumes tested are 1250, 1500, 1750, 2000, 2250, and 2500 cfm. At each increase in air volume, there is a slight increase in product differential.

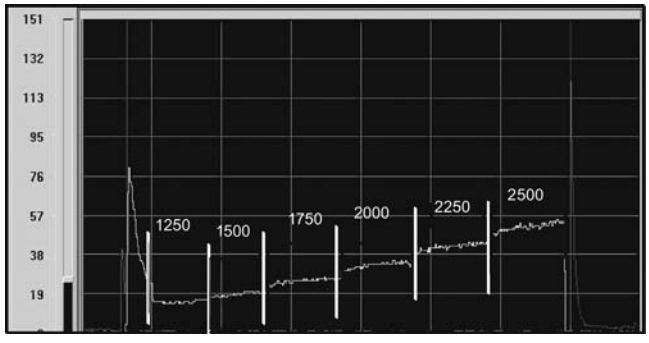

FIGURE 35.26 Product differential pressure in an empty 32″ HS Wurster coater fitted with type "B" and "G" orifice plates (air volumes displayed are in cfm).

Overall, the pressure contribution from the plates ranges from about 17 to 55 mmWC. Fig. 35.27 shows the impact of putting a large batch (approximately 250 kg) of pellets into the insert (note: it is prudent to use a very strong substrate for these trials because they will be subjected to mechanical stress for an extended period of time). With the partition height set at 50 mm, it is evident that as air volume is increased, the quantity of product in motion (mass flow) increases. The values for 1250 and 1500 cfm seem to indicate that the air volume is insufficient to fluidize the entire batch—for the bed is certainly stagnant in some region at 1250 cfm. At 1500–2000 cfm, the peak-to-trough values indicate a reasonably stable fluidization pattern. At 2250 and 2500 cfm, the enlarged peak-to-trough values reveal that some air bubble coalescence is occurring, resulting in some degree of back flow or turbulence in the down bed. This is not necessarily negative—a periodic bubble bursting through the down bed, along the wall of the product container, gives assurance that the product is not stagnant in this region. The air volume selected for this particular process was 2250 cfm. In addition to the fluidization properties, the high volume of air permits higher rates of heat and mass transfer, which translate to faster spray rates and a shorter process time.

Higher partition heights, common for pellet coating, were also tested (60 and 70 mm). Interestingly, the peak-to-trough values widen at lower air volumes with higher partition heights. It is speculated that the strength of the venturi at the base of the partition, which draws product into the up bed, is either lessened or defeated, allowing air bubbles to move only vertically in the down bed.

The previous example is effective for coating or layering materials that do not exhibit tackiness in the down bed—they have a low surface coefficient of friction. Unfortunately, there are many products that display tacky behavior, and these same processing conditions may permit stalling of the batch in some region. Some users may try to counter this behavior by increasing the overall process air volume. However, it is likely that the majority of this increase will flow through the partition, and this region is not the source of the problem. It would be desirable to divert more of the process air volume to the down-bed region. A method for achieving this would be to replace the up-bed plates with ones that are less permeable. In this manner, at the same air volume, more of the process air is diverted through the down bed, making it more vigorous or turbulent. Figs. 35.28 and 35.29 illustrate a mass flow study that is a consequence of this change. The "B" down-bed plate remains, but the "G" up-bed plates were replaced by the less permeable "H" plates. Once again, the partition height is set at 50 mm for the test. What can be seen is that the dP product contribution of the plates alone is

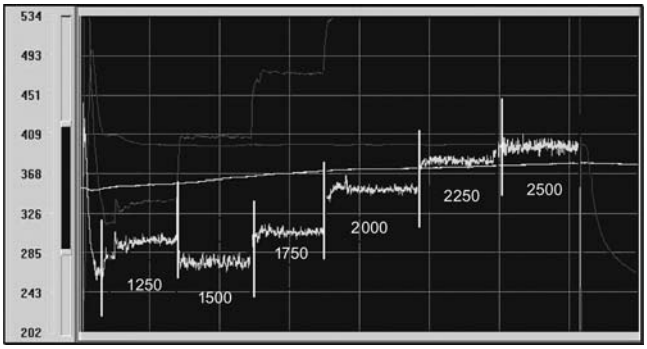

FIGURE 35.27 Product differential pressure in a 32″ HS Wurster coater fitted with type "B" and "G" orifice plates, with a batch (air volumes displayed are in cfm).

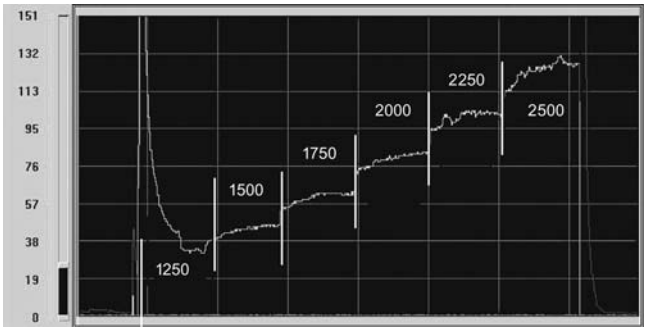

FIGURE 35.28 Product differential pressure in an empty 32″ HS Wurster coater fitted with type "B" and "H" orifice plates (air volumes displayed are in cfm).

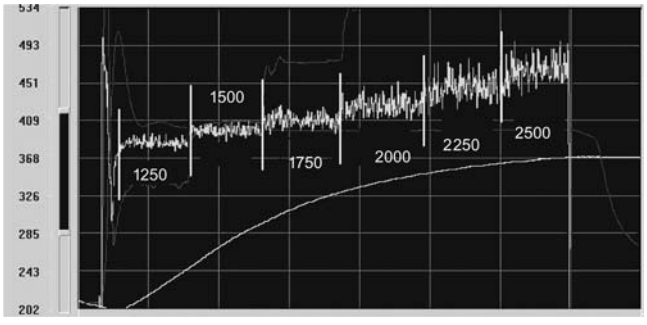

FIGURE 35.29 Product differential pressure in a 32″ HS Wurster coater fitted with type "B" and "H" orifice plates, with a batch (air volumes displayed are in cfm).

now considerably higher. In this case, the range is from approximately 30 to 125 mmWC. When the same batch weight is added, stable down-bed flow occurs at much lower air volumes—somewhere between 1250 and 1500 cfm. The peak-to-trough values for higher air volumes are very broad compared with the previous example, indicating significantly more turbulence in the down bed. The selected air volume for this trial was 2000 cfm. The turbulence was sufficient to avoid

regional bed stalling with the tacky coating material, and the relatively high air volume allowed for a reasonably high spray rate.

35.8.5 Process air and product temperatures

As is typical of the laboratory scale, the temperature of the process air is generally adjusted to maintain a constant product temperature, and as spray rate is increased, the process air temperature is adjusted upward. If laboratory trials were conducted using a conservative or low product temperature, it may be possible to explore a higher product temperature in the production-scale equipment to improve productivity. However, it is strongly recommended that this is not done if the impact of higher product temperature on finished product attributes has not been explored, particularly for latex-coating materials.

35.8.6 Mass effects

The influence of larger batch size (or mass effects, as they are referred to), is more difficult to predict. In small-scale equipment, the product must be robust—if it must be treated cautiously in laboratory equipment, scale-up to pilot and production machinery will be nearly impossible. In Wurster processing, the big step in scale-up is from laboratory equipment (6″, 7″, 9″) to the pilot-scale 18″ Wurster machine. In small machines, bed depth rarely exceeds 200 mm, and fluidization height (substrate travel out of the partition) is principally limited by machine dimensions to 1.25 m or less. In the 18″ unit, bed depth may range up to 600 mm, and fluidization spout height can approach or exceed 2 m. Product may also collide into the outlet air filters or other mechanical components of the machine. Further scale-up to the 32″ or larger Wurster coaters from the 18″ is somewhat simplified because bed depth is about the same, and the objective in fluidization is to keep particle velocity similar in larger equipment to that used in the pilot-scale machine.

35.9 SUMMARY

The Wurster system is widely used for layering and coating because of its ability to apply high-quality films to a broad range of substrates. The orifice plate configuration in combination with the partition height and process air volume, organize the substrate in close proximity to the spray nozzle. Droplets of coating liquid travel only a short distance, and are applied cocurrent with the accelerating substrate. Productivity is related to the presentation of substrate surface area per unit time with respect to this quantity of liquid. Layering and/or film coating may be conducted using solutions or suspensions of materials in liquids comprising organic solvents or water. The interaction between droplets and substrate is so rapid that materials applied using even the most volatile solvents are not subject to spray drying—they are high in quality, and their release is governed by their intrinsic properties, not by imperfections in the film. In addition, within limits, materials can be sprayed from a molten state, congealing onto the surface of the slightly cooler substrate. As a production-scale batch processor, the Wurster has a moderate batch capacity (up to approximately 600 kg), and is efficient in terms of material balance and productivity.

36.1 INTRODUCTION

Over the past several decades, the pharmaceutical industry has grown tremendously, and significant progress has been seen in improving drug product quality and reliability of pharmaceutical manufacturing process. However, the public is still facing unprecedented drug shortages and recalls in recent years. By far, the most frequently cited reasons for drug shortages relate to manufacturing and quality issues.[1,2] In addition, the pharmaceutical industry is also facing several challenges such as payer's rising expectations on lowering cost while ensuring good product quality with a reliable supply, increasing the complexity of manufacturing technology, and increasing regulatory scrutiny. Hence, the industry is increasingly focusing on better understanding and control of commercial manufacturing as it relates to the product quality. A robust commercial manufacturing process means it is capable of consistently manufacturing desired quality product that meets the needs of the patient. A robust process development starts with a systematic approach to product and process design: understanding the impact of variability in input variables (raw materials, formulation and process parameters), and defining an appropriate control strategy to mitigate potential risks to product quality and manufacturability. Robust process development also includes a demonstration of the capability of the process at commercial scale and approaches to continually monitor and identify improvement opportunities for the process over the lifecycle of the product. These activities are the key three stages of the lifecycle approach for process validation as discussed in the 2011 Food and Drug Administration (FDA) process validation guidance titled *Guidance for Industry: Process Validation: General Principles and Practices*.[3] This guidance defines the process validation as the "collection and evaluation of data, from the process design stage through commercial production, which establishes scientific evidence that a process is capable of consistently delivering quality product." This definition of process validation focuses on scientific evidence throughout the product lifecycle. Process validation should not be considered as a one-off event in producing three consecutive batches of commercial scale product and evaluating its conformance with the predefined specifications. Instead, it is a science and risk-based development paradigm that builds product quality through a three-stage lifecycle approach which links the product and process development, qualification of the commercial manufacturing process, and maintenance of the process in a state of control during commercial production. In 2014, European Medicine Agency issued a revised guidance on process validation.[4] Even though there are differences in terminology, both guidances emphasize a lifecycle approach and embrace the basic principles of science and risk-based approach put forth in ICH Q8, Q9, and Q10. Since the introduction of these guidances, much progress has been made by the pharmaceutical community to address the expectations and challenges in implementation during process development and commercial manufacturing. This chapter will discuss some of the useful approaches that can be used to achieve a robust commercial manufacturing using the three-stage lifecycle approach, implementation of science and risk-based approaches such as advanced process analytical technology (PAT) tools, and real-time release testing

Developing Solid Oral Dosage Forms
DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00036-4

(RTRT) strategies. These concepts have the potential to provide an increased assurance of product quality.

36.2 PROCESS DESIGN, UNDERSTANDING, AND CONTROL STRATEGY DEVELOPMENT

The initial stage (Stage 1) of process validation is process design, understanding, and control strategy development. It is well recognized that a rational strategy for process development is to begin with the end in mind and to focus on patient's need with regards to drug product safety and efficacy. It is also important to consider the product manufacturability which is defined as the extent to which a product can be easily and effectively manufactured at minimum cost and with maximum reliability.[5] The first step of product and process development is to establish the quality target product profile (QTPP), which is a prospective summary of the quality characteristics of a drug product that ideally will be achieved to ensure the desired quality, taking into account safety and efficacy of the drug product.[6,7] QTPP forms the basis of design for the development of the product and process. From QTPP, the critical quality attributes (CQAs) of the drug product can be identified. CQA is defined as the physical, chemical, biological, or microbiological property or characteristic that should be within an appropriate limit, range, or distribution to ensure the desired product quality.[4] Criticality of a quality attribute is primarily based on the projected severity of harm to the patient (eg, from loss of drug efficacy or causing serious adverse effect) should the product fall outside the acceptable range for that attribute. The probability of occurrence, detectability, and controllability are not relevant to the determination of the criticality of a product quality attribute.[5]

Once the QTPP and CQAs are defined and identified, the subsequent development activities focus on how to achieve the QTPP design requirements. Risk assessment tools are often used to prioritize development studies.[8] Prior knowledge of existing commercial manufacturing of similar product or manufacturing technology platform can be utilized to facilitate the risk assessment. Based on the initial risk identification, potentially high-risk material attributes, formulation variables, and process parameters are further studied to understand their impact on the identified CQAs. Based on the development study results and updated risk analysis, critical material attributes (CMAs) and critical process parameters (CPPs) can be identified, and the functional relationships between CMAs, CPPs, and drug product CQAs can then be established during development. Knowledge gained through appropriately designed development studies culminates in the establishment of a control strategy. A control strategy is a planned set of controls, derived from current product and process understanding that ensures process performance and product quality. The controls can include parameters and attributes related to drug substance and drug product materials and components, facility and equipment operating conditions, in-process controls, finished product specifications, and the associated methods and frequency of monitoring and control.[9] Yu, et al. summarizes the commonly used control strategy in three levels (Fig. 36.1).[10]

Level-3 control strategy mainly relies on extensive end-product testing and tightly constrained material attributes and process parameters. This type of control strategy leads to acceptable product quality when the input variables are controlled adequately. However, when the inputs vary beyond expected variability, the resulting product quality can be impacted. The pharmaceutical industry has recognized the limitation of the Level-3 control strategy and has been developing more advanced control strategies in the past years.

Level-2 control strategy consists of controls with reduced end-product testing and allowing variation of material attributes and process parameters within the established design space. Understanding the impact that variability has on in-process materials, downstream processing, and drug product quality provides an opportunity to shift controls upstream and to reduce the reliance on end-product testing. Among process monitoring technologies, PAT has gained attention in pharmaceutical industry since the publication of PAT guidance in September 2004.[11] In this guidance, PAT is defined as "A system for designing, analyzing, and controlling

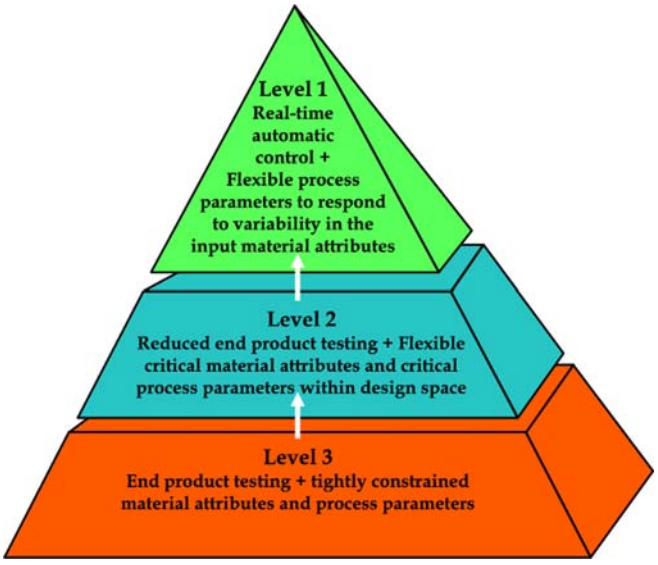

FIGURE 36.1 Control strategy implementation options. *Copied from Yu LX, Amidon G, Khan MA, Hoag SW, Polli J, Raju GK, et al. Understanding pharmaceutical quality by design. AAPS J 2014;**16**:771–83.*

manufacturing through timely measurements (ie, during processing) of critical quality and performance attributes of raw and in-process materials and processes, with the goal of ensuring final product quality." The PAT toolkit often includes process analyzers, multivariate analysis tools, process control tools, and continual improvement/knowledge management systems.

A recently published review paper on PAT discussed the advantages of PAT implementation at various stages of pharmaceutical development, and recent developments in sensor technology, followed by specific cases of PAT implementation in laboratory and pharmaceutical production.[12] Additionally, RTRT could be regarded an example of Level-2 control, as it provides the ability to evaluate and ensure the quality of final product based on in-process data, which typically include a valid combination of measured material attributes and process controls. RTRT is defined as "the ability to evaluate and ensure the acceptable quality of in-process and/or final product based on process data."[6]

Level-1 control strategy utilizes automatic engineering control to monitor the CQAs of the output materials in real time to achieve adaptive control. The key concept is to monitor input material attributes and automatically adjust the process parameters based on the enhanced process understanding to assure that CQAs consistently comply with the established acceptance criteria.[10] This includes control strategy options such as feedback or feed forward control. These are examples of dynamic control where downstream process parameters and attributes are manipulated in response to variation in upstream process parameters and attributes. A feedforward control is defined as one in which manipulations are made proactively to downstream variables in response to measurements of disturbances upstream, whereas feedback control is one where manipulations are made to upstream variables response to measurement of disturbances downstream. On-line monitoring techniques such as PAT could facilitate implementation of such dynamic control strategies.[6] It is noteworthy to mention that PAT tools and RTRT are not necessarily always implemented together. A PAT tool can be implemented for the monitoring of attributes of either in-coming materials or that of in-process materials during manufacturing. PAT tools can also be put in place for monitoring quality of finished products, without using that information for product release. On the other hand, adoption of PAT is not the only way to implement RTRT. For example, RTRT can be achieved by the use of predictive models as a surrogate for traditional release test, where the model uses traditional in-process measurements. (This is often referred to as "soft sensors.")

This chapter only provides a high-level overview of process design, understanding, and control strategy development. More in-depth discussion of each unit operation and its unique challenges and solutions can be found in other chapters of this book and related scientific literature.[6–8,13–22]

36.3 PROCESS SCALE-UP, TECHNOLOGY TRANSFER, AND PROCESS QUALIFICATION

Process scale-up and technology transfer in pharmaceutical industry involve, in general, moving a product/process from research and development stage into the production stage. More detailed discussions can be found in chapter "Product and Process Development of Solid Oral Dosage Forms," and other chapters on process development and scale-up of individual unit operations. In most cases, early development studies are often conducted using laboratory or pilot scale equipment. The potential risks associated with scaling-up the process from lab or pilot scale to production scale are assessed and mitigated via further studies. The assessment includes evaluating the impact of facility, utility, environment conditions, personnel and equipment design and operating principle changes on product quality and process performance. In some cases, a process step for example milling or compression is continuous operation in nature, the scale up can be achieved by simply extended the processing time. In some cases, the performance of a process can be predicted by fundamental engineering and scientific principles or empirical process models developed at the laboratory or pilot scale; the scale up is guided by the model prediction. While in other cases, at-scale knowledge is needed to adjust the control strategy developed at the laboratory or pilot scale. It is important to assess systematically product and process knowledge gained during the development stage and determine any residual risks within the proposed control strategy. At the end of Stage 1 (development phase), the proposed commercial control strategy is communicated to the receiving sites along with any identified residual risks which will be evaluated during the process qualification stage (ie, Stage 2 of the lifecycle approach for process validation). Several challenges regarding process qualification are discussed in the subsequent sections (36.3.1–36.3.3).

36.3.1 Design of a facility and qualification of utilities and equipment

The objective of process qualification is to evaluate the process designed and developed from Stage 1 (the initial stage of the lifecycle approach for process validation) and to determine if it is capable of

reproducible commercial manufacturing. To meet this objective, the first step is to select a suitable facility which is appropriately designed for the selected manufacturing process. For example, the facility design and environment control for an aseptic filling process for an injectable product would be considerably different from a solid oral dosage form manufacturing facility. The second step is to demonstrate that utilities and equipment are suitable for their intended use and perform properly. The qualification will include all the aspects that would traditionally fall into the installation qualification, operational qualification, and performance qualification (IQ/OQ/PQ) categorization. It is also important to ensure that the analytical methods for in-process controls and release testing are appropriately verified or validated for its intended use. Further detail information on these topics can be found in scientific literature and general guidelines developed by industry working groups.[23–26] These upfront preparation works are important to ensure the variability from the facility, utilities, and equipment, and the analytical methods are understood and controlled appropriately to support the process performance qualification (PPQ) execution.

36.3.2 Number of PPQ batches

Since the publication of the Process Validation Guidance, an often debated topic is how many PPQ batches are needed at Stage 2b to demonstrate the commercial manufacturing process performs as expected and the product manufactured at production site is ready for commercial distribution. There is no sacrosanct number of batches or approach for demonstrating a successful PPQ. Manufacturers are responsible for providing assurance that the process is adequately qualified before moving to routine commercial manufacturing in Validation Stage 3. Use of science and risk-based approach including statistical method to determine the number of PPQ batches is extensively discussed in scientific literature. Such risk-based approach combines knowledge of the capability of the process during development, fundamental scientific understanding of a particular process as well as the plan for future monitoring in Stage 3. Several example approaches reported in scientific literature are given here. For example, F. Wiles proposed using a combination of risk assessment, control charting, and capability statistics to determine how many PPQ batches are needed and when PPQ milestones have been met.[27] In this method, "an assessment of process risk is performed through application of a process failure mode, effects, and criticality analysis (PFMECA). The output of PFMECA is used to select appropriate levels of statistical confidence and coverage which, in turn, are used in capability calculations to determine when significant Stage 2 (PPQ) milestones have been met."[27] Success from the PPQ stage signals the readiness to release batches for commercial distribution, and the frequency of monitoring and testing can be adjusted during the routine commercial production stage. Individual control chart, moving range, and range/sigma control charts are used in conjunction with capability statistics to demonstrate that the commercial process is operating in a state of statistical control.

A Bayesian method was developed by H. Yang to address the question *"how many batches are needed for process validation under the new FDA Guidance."*[28] "By combining process knowledge gained from development stage with the expected outcomes of PPQ, the Bayesian method estimates the number of qualification batches that are needed to provide a high level of assurance that the process will consistently produce future batches meeting quality standards."[28] Several examples based on simulated data are presented to illustrate the use of the Bayesian method in helping manufacturers make risk-based decisions for Stage 2 PPQ. For example, a large "n" (=480) is needed for one process which has a poor history of performance during development, and small "n" (=4) for another process which shows a track record of good performance during development, and moderately large "n" (=18) for the third process which demonstrates variable performance during development.

The International Society for Pharmaceutical Engineering (ISPE) published discussion paper on potential approaches for answering the question, "How many PPQ batches are needed to demonstrate a high degree of assurance in the manufacturing process and that the control strategy is sufficiently robust to support commercial release of the product?"[29] This discussion paper describes a framework for systematically assessing the level of product knowledge and process understanding, and how well the control strategies are linked to the CQAs. Based on the residual risk identified from the risk assessment, three different approaches were proposed to estimate the number of PPQ batches and to establish the scientific evidence whether the level of between-batch variability is appropriate for commercialization:

1. Approach 1—based on scientific rationale and experience

   The paper proposed a range of number of PPQ batches based on the residual risk level. While 3 consecutive batches is sufficient for low-risk processes; more batches are needed when there is an elevated residual risk.
2. Approach 2—target product performance and target process capability

   This approach utilizes process capability index (C_{pk}) and target confidence level to determine the

number of PPQ batches based on the identified residual risk level. This is to address two questions: What is the objective measure that process will consistently produce a product that meet its requirement? and What is an acceptable high degree of assurance? The paper encouraged the manufacturer to justify the choices of the target confidence level and capability level based on the risk associated with product knowledge, understanding, and robustness of the control strategy.

3. Approach 3—expected coverage

   This approach is based on the concept of order statistics.[30] In this approach, the residual risk level is used to determine the expected "coverage" of the PPQ batches and the number of PPQ batches. The "coverage" is defined as the proportion of the expected "future" data to be contained within the acceptance limits. The lower the risk level, the lower the expected coverage from the PPQ batches alone, and the lower the number of PPQ batches needed.

Another frequently debated topic is how to select the appropriate conditions for PPQ batches. The concept of worst-case conditions for process validation was a key theme of the 1987 process validation guidance. However, attempting to cover worst-case conditions in process validation would often mean that parameters applied to validation batches bore a little resemblance to the actual variability of the process to be encountered during routine commercial manufacturing. Following the process design stage (Stage 1) where the process variability and the functional relationships between CMAs, CPPs, and the drug product CQAs are well understood and addressed, the PPQ batches should be manufactured under normal conditions by the personnel routinely expected to perform each step of each unit operation in the process. A risk-based approach is highly encouraged to select the conditions for the PPQ batches and justify it based on the enhanced understanding of the product and process and the actual variability of the CMAs and CPPs.[31] Thus, high assurance is obtained that the commercial manufacturing process is capable of consistently producing acceptable quality products within commercial manufacturing conditions.

36.3.3 Heightened level of monitoring and testing to demonstrate intra- and inter-batch consistency

As indicted in the 2011 FDA PV guidance, in most cases, PPQ will have a higher level of sampling, additional testing, and greater scrutiny of process performance than would be typical of routine commercial production.[3] The objective of the heightened level of monitoring and testing is to confirm uniform product quality throughout the batch or batches. The selection of the parameters to be monitored or tested is mainly based on their impact to product safety, efficacy and quality. In general, it can include, but is not limited to, the drug product CQAs, input material CMAs, CPPs, critical in-process controls, and other relevant parameters that are indicative of process performance. The increased level of the scrutiny and the duration of the heightened sampling and monitoring period can be adjusted based on the volume of production, process complexity, level of process understanding, and experience with similar products and process.

Yu et al. proposed a staged sampling approach when limited batches have been manufactured during the PPQ stage.[32] Fig. 36.2 represents an illustrated example using simulated assay data. The first three batches (A, B, and C), manufactured during the PPQ stage, represent a higher level of sampling within each batch. The goal of the initial higher level of sampling is to demonstrate product quality throughout each batch, establish initial estimates of within and between-batch variability, and use those estimates to generate an initial estimate of process performance. Then, sampling in subsequent batches (D, E, and F) is adjusted (in this case, lowered) to a statistically representative level that was based upon the variability estimates established in the first three batches.

Another example approach proposed by ISO 16269-6 (2014) uses statistical tolerance intervals.[33] In this approach, the coverage, defined as the proportion of the expected "future" data to be contained within the acceptance limits, is adjusted based on the risk of the product CQA. The actual number of samples required varies based on the data type (discrete or continuous) and the expected distribution (normal or unknown).[33]

Several other statistic approaches have also been proposed in a recent ISPE discussion paper including graphical exploration, variance components analysis, Monte Carlo simulation, ASTM E2709/E2810 (historically also referred to as CuDAL), statistical interval, Bayesian statistics, control charts, and process capability indices.[34] Even though this paper does not reflect a consensus position of the industry, it provides a comprehensive summary of viable approaches and options that can be used to evaluate the intrabatch and interbatch variability during process qualification stage.

When PAT and/or RTRT are used as a part of the commercial control strategy, special considerations should be given to the sampling strategy. Typically, implementation of RTRT would include in-process on-line/at-line sampling. The selected sample size is representative of the batch size and is also justified statistically. Additionally, the sampling frequency is chosen to provide assurance of consistent manufacture of

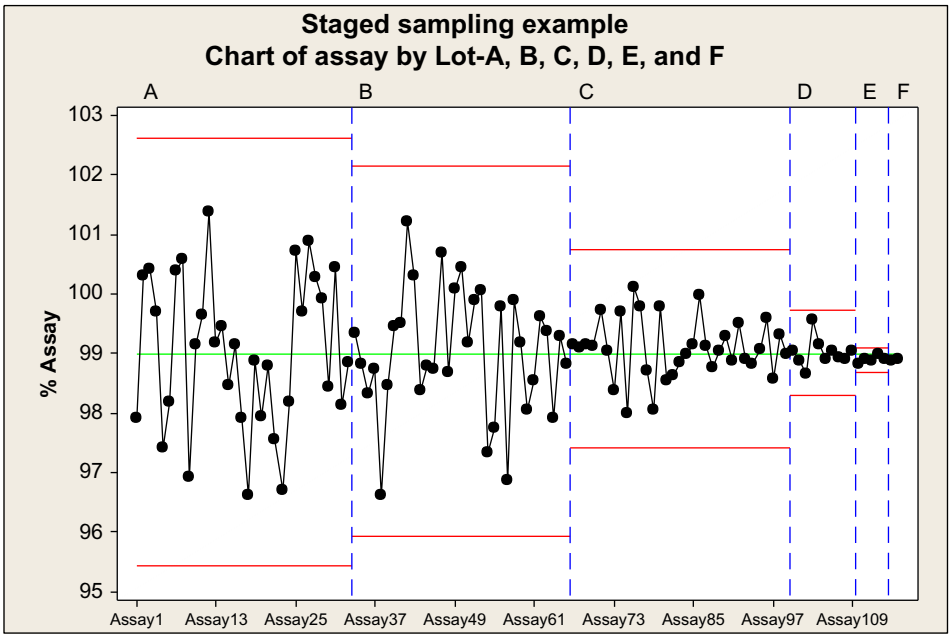

FIGURE 36.2 Theoretical example of a staged sampling approach when limited batches have been manufactured during process performance qualification (PPQ) stage.

desired quality product. In addition to sample size and sampling frequency, measurement location needs to be defined. For example, for real-time in-process identity testing for release, it is important to consider what/if any downstream processing steps are present after identification testing before final release of the finished product to prevent the inadvertent addition of any unknown materials into the process due to a system and/or human error. Furthermore, contingency plans can be in place in case of failure of the primary analytical method that is used for RTRT measurement. For example, if an NIR analytical procedure is used for tablet content uniformity to support RTRT, an alternate control strategy can be in place for an alternative mode of measurement of tablet content uniformity in case of sudden failures of the NIR instruments during routine commercial production.

36.4 CONTINUED PROCESS VERIFICATION

Often, significant sources of the variability related to commercial manufacturing have been systematically identified, and the appropriate detection, control, and/or mitigation strategies have been established during process design, scale-up technology transfer, and process qualification studies. However, during routine commercial manufacturing, a process may encounter additional sources of variation that were not previously detected or to which the process was not previously exposed. Hence, it is important to monitor the process continually and maintain the process in a state of control (the validated state) during commercial manufacture. The heightened testing and monitoring of process parameters, material attributes, and drug product quality attributes utilized during the PPQ can be continued until sufficient data are available to generate significant variability estimates. Testing and monitoring can then be adjusted to a statistically appropriate and representative level. For some cases, it is even necessary to requalify the process when the source of materials, equipment, production environment, personnel, and manufacturing procedures has been significantly changed.

36.4.1 Process monitoring program

In general, a science and risk-based approach can be applied to determine the process monitoring program, that is, what to monitor and the monitoring frequency and locations. A routine commercial manufacturing process has many input variables, process parameters, and in-process material attributes. The monitoring program focuses on the important parameters known or suspected to affect the quality, efficacy, or safety of the product. Additionally, other parameters can also be included if they are indicative of process performance and/or can provide a timely signal to assist in process controlling. Sources of information from other quality and manufacturing systems such as change control, scheduled preventive maintenance, calibration, or production interruptions; and customer complaints are also valuable inputs for monitoring. These may help explain unexpected shifts or variation in the production process and manufacturability issues.

In a recent publication, Mitchell et al.[35] provided an example of the monitoring and the review frequency for a process based on the enhanced understanding of the product and process from Stages 1 and 2 studies. In this example, high-risk parameters are monitored and reviewed more often to respond more quickly to out-of-control conditions that could risk product quality. Some medium risk process parameters and performance attributes are also included in the monitoring program since it is indicative of process performance and manufacturability. Low-risk parameters are not monitored due to their low impact on quality attributes. This example illustrates the principles that how the current understanding of the manufacturing process and the level of risk impacting product quality can be utilized to determine the parameters to be included in the monitoring program, the location and the frequency of the analysis.

36.4.2 Tools for process monitoring

Various statistical process control (SPC) tools can be used in monitoring and evaluating process variability and process capability. There are many available industry standards, books, and guides on these topics.[36–40] In the next section, two commonly used tools (control charts and process capability analysis) are briefly discussed.

36.4.2.1 Using control chart to evaluate if the process is in-control

Control charts were developed by Walter Shewhart in the early 1920s and are still widely used in many industry sectors including the pharmaceutical industry.[41–44] A control chart is a graphical display of a product quality characteristic that has been measured or computed periodically from a process at a defined frequency. The observations sampled at a particular time point constitute a subgroup. Through statistical methods, control charts can differentiate the common cause and special cause variation of a process. The common cause variation is natural or inherent to the process; while the special cause variation is not inherent to the process and may only be present at times. A process displaying only common cause variation is considered in a state of statistical control or stable while a process displaying special cause variation is not in statistical control. An illustrative example of a control chart can be seen in Fig. 36.3. In this figure, the process is monitored at a predetermined frequency, and the process output is measured and graphed sequentially. The process mean and standard deviation can be calculated. The upper SPC limit (UCL) and the lower SPC limit (LCL) are typically defined as 3 times of the standard deviation away from the process mean. The UCL and LCL establish an envelope around the process mean, where the majority of the output of a stable process should lie within. The control charts are sometimes also referred to as "the voice of the process."

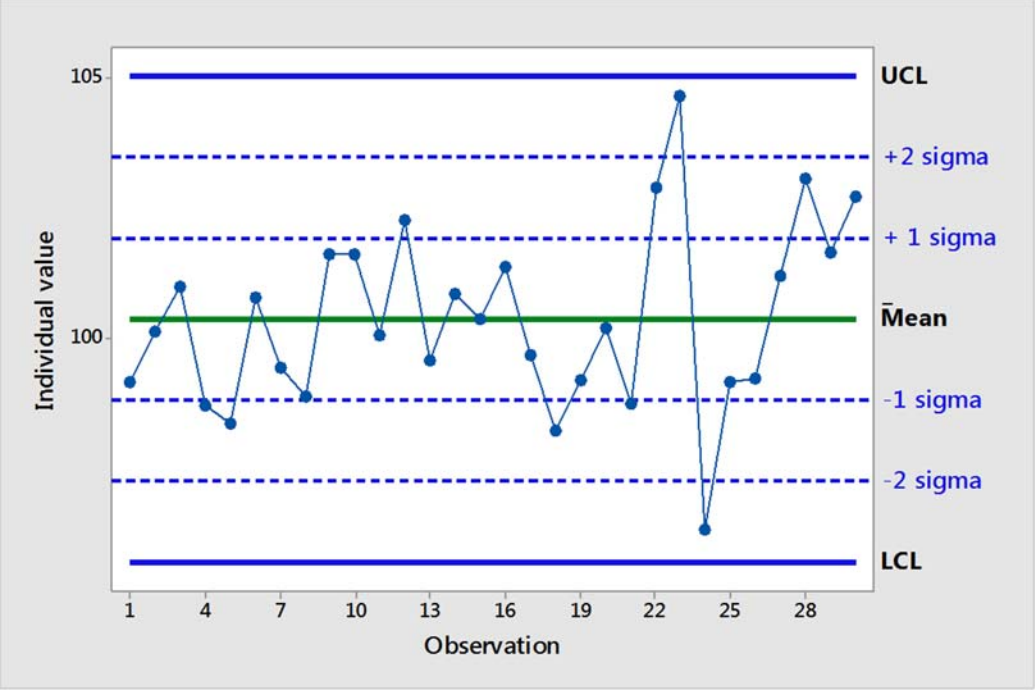

FIGURE 36.3 Schematic example of an I-chart.

To aid in the detection of special cause variations in the process, a set of decision rules are widely used along with the control charts. The set of decision rules is called the "Western Electric Rules," which was developed by the Western Electric Company, as the name implies.[45] The Western Electric Rules provided a standard way of identifying the out-of-control signals, by differentiating common cause variations from special cause variations. One frequently used Western Electric rule is "any single data point falls outside of the LCL and UCL" (the SPC limits). When a data point violates this rule, it indicates the process may have encountered special cause variations that may require further investigation. However, it is important to keep in mind the rule has a certain probability of being a "false alarm"; that is a data point from a stable process violates this rule just by chance. For example, for a normally distributed process, the probability of "false alarm" is close to 0.3%. Details of other Western Electric Rules can be found in the references.[33] It is important to establish a risk-based action plan that is based on the potential impact to product quality, when responding to the statistical signals from the control charts. Such a plan provides balance between over reaction to the signals and failure to act against unwanted variability that may impact product quality.[3]

There exist many different types of control charts, based on the characteristics of the process, the collected data set, and the underlying distribution assumptions. Fig. 36.3 is an example of a Shewhart control chart with individual measurement, called I-chart (subgroup size = 1). When subgroup size is between two and ten, an X-bar/R chart is most commonly used. When subgroup size is greater than ten, X-bar/S (standard deviation) chart becomes a more appropriate option. One key consideration of this type of charts is the rational subgrouping since the general assumption is that data in a subgroup are considered from a stable process to be used to define common cause variation. I-chart, Moving Range chart (MR-chart), X-bar/R chart and X-bar/S Chart are for continuous numeric variables. On the other hand, p-chart for the binomial distributed attributes (categorical or discrete numeric data, eg, by counting), and the u-chart for the Poisson distributed attributes are frequently used for discrete variables.[39]

These aforementioned univariate SPC charts works well if all the monitoring parameters are independent of each other. However, most pharmaceutical manufacturing process involves a large number of input material attributes, process parameters, intermediate and finished drug product CQAs, and some of these variables may be interrelated. Multivariate statistical process control (MSPC) can be a useful tool to address this challenge. MSPC refers to a set of advanced techniques for the monitoring and control of the manufacturing process (batch or continuous processes) which identifies the vital few variables (principle components) and the underlying patterns in a dataset. In addition, the functional relationships between these variables can be established (http://www.camo.com/applications/process-control.html). Furthermore, MSPC techniques can reduce the information contained within all of these variables down to two or three composite metrics through the application of principle components analysis or partial least squares. The use of MSPC in pharmaceutical industry has increased greatly in recent years.[46–49] The readers are encouraged to find further details of MSPC in the provided literature as it is beyond the scope of this chapter.

36.4.2.2 *Using process capability and process performance indices to evaluate if the process is capable*

While the control charts signify the "voice of the process," the specification limits (acceptance criteria) of the product quality attributes indicate the "voice of the customers" (based on patient's safety and efficacy needs). These two measures are compared to demonstrate if the process is capable of producing products meeting customer's requirements consistently. The comparison is often expressed in the form of a process capability index (C_p and C_{pk}). The calculation formula and description of these indices are presented in Table 36.1. The potential application of these process capability indices to enhance pharmaceutical product

TABLE 36.1 Description and Calculation of Process Capability Indices

Calculation	Description
$PC = 6\,\hat{\sigma}$	Process capability (PC): a statistical estimate of the outcome of a characteristic from a process that has been demonstrated to be in a state of statistical control
$C_p = \frac{(USL - LSL)}{6\,\hat{\sigma}}$	Process capability index (C_p): an index describing process capability in relation to specified tolerance
$C_{pkl} = \frac{Mean - LSL}{3\hat{\sigma}}$	Lower process capability index (C_{pkl}): an index describing process capability in relation to the lower specification limit
$C_{pku} = \frac{USL - Mean}{3\hat{\sigma}}$	Upper process capability index (C_{pku}): an index describing process capability in relation to the upper specification limit
$C_{pk} = \min(C_{pkl}, C_{pku})$	Minimum process capability index (C_{pk}): smaller of the upper process capability index and the lower process capability index

quality has been gaining international attentions in recent years.[32,50,51]

USL, upper specification limit; LSL, lower specification limit; $\hat{\sigma}$ represents common cause variability in a stable process

The process capability indices use the common cause variation as the variability measurement of the process. Therefore, it represents the "capability" of a stable process free of special cause variation. For a process that exhibits some special cause variations, more appropriate indices are P_p or P_{pk}, sometimes referred to as the process performance indices; where the process standard deviation estimate uses the overall standard deviation which accounts for all common cause variations and special cause variations.

It is important to point out that both the process capability and performance indices are statistical estimates of the process, and are subject to the variability of the sampling procedure. As such, the indices are less robust when the sample size is small; and become more reliable with increasing sample size. In fact, it is highly recommended that when a capability index or a performance index is reported, the lower bound of the estimate is also reported at the same time. For the process performance index P_{pk}, the approximate 100 $(1-\alpha)$% lower confidence bound of the process performance index[36] is defined as Eq. (36.1):

$$P_{pk} \geq \hat{P}_{pk} - z_{1-\alpha}\sqrt{\frac{1}{9n} + \frac{\hat{P}_{pk}^2}{2n-2}} \qquad (36.1)$$

where n is the sample size for the index estimate, and $Z_{1-\alpha}$ is the $100(1-\alpha)$ percentile of a standard normal distribution, and $\hat{P}_{pk}$ is the point estimate of the process performance index.

Fig. 36.4 shows the relationship between the lower boundary of P_{pk} and the sample size and confidence. For example, when a process demonstrates a process performance index of 1.15 with 60 data points, we can state such a process has a P_{pk} of 1.0 with about 90% confidence.

36.4.3 Continual improvement

Given the current regulatory requirement for reporting of postapproval changes according to 21 CFR 314.70, the pharmaceutical industry is dis-incentivized from making changes to an approved manufacturing process. For years, traditional pharmaceutical process development led to tightly controlled process and stringent specifications that were largely established on the basis of limited manufacturing experience. Product quality is ensured predominantly by restricting the flexibility of the manufacturing process and relying on extensive end product testing. Even though this approach has historically provided sufficient confidence that quality is suitably controlled in an unchanged process, this type of lifecycle management does not support continued assurance of quality and in the long term. It is neither efficient nor cost-effective and can result in reactive actions for both industry and regulatory authorities. There is a great need to embark the principle of "quality

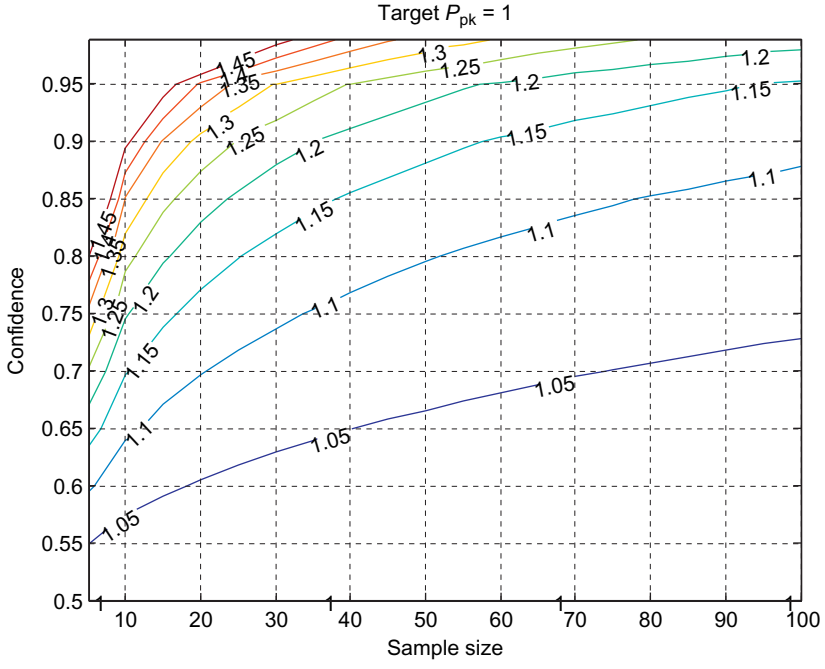

FIGURE 36.4 P_{pk} lower boundary.

excellence" whereby the pharmaceutical manufacturers and the regulatory agencies for collaborative partnerships to facilitate continual improvement efforts based on science and quality risk management.

Continual improvement is a set of activities that the manufacturer carries out to enhance its ability to achieve the desired product performance, and/or to make the process more efficient by increasing yield/reducing cost. Continual improvements typically consist of five phases- Define, Measure, Analyze, Improve, and Control (DMAIC)[52]:

- Define the problem and the specific project goals
- Measure the performance of the current process and collect relevant data
- Analyze the data to investigate and determine the cause-and-effect relationships. Seek out the root cause of the defect if any.
- Improve or optimize the current process based upon data analysis using techniques such as design experiments (DOE) to create a new state of the process.
- Control the newly established process to confirm the improvements. Implement control systems such as SPC, production dashboards, visual aids, and continued process verification (CPV) /monitoring.

36.4.4 Illustrative Example-1: monitoring key excipient material variability of an extended release tablets and continual improvement of process performance and product quality

A case study is given in this section as an example of the commercial manufacturing monitoring and continual improvement.[53] Niacin Extended Release (ER) Tablets is a hydrophilic matrix polymer based ER tablet which contains about 16% Hypromellose (HPMC) and 81% of API. A control chart (Fig. 36.5)[53] of niacin release at 20 hours (D20h) from more than 800 commercial lots indicated that the drug release was impacted by the HPMC lots, even though some variability was also apparent within the same HPMC lot, possibly due to additional variability in the manufacturing process and analytical method. Some of the tablet lots barely passed the lower specification limit of not less than 75% and a few lots failed. The apparent variability of the drug release at 20 hours of this product presented a significant challenge to maintain uninterrupted supply to patients of desired quality product.

HPMC is a cellulose derivative by introducing methoxy (MeO) and hydroxypropyl (HP) substitutions simultaneously under alkaline conditions with inherent chemical heterogeneity due to the potential chemical variability of cellulose derivatives. Initial investigation performed on HPMC lots used in the commercial manufacturing indicated that the HP content is a primary impacting factor ($p < 0.0001$) while the viscosity is of borderline significance ($p = 0.07$). Neither MeO nor particle size was found significant. A regression model based on the HP content and viscosity ($R^2 = 0.79$) predicts the D20h well in general. However, some HPMC lots deviated significantly from this model. As a part of the investigation, HPMC lots from two additional vendors (vendor B and vendor C) were also evaluated experimentally. The regression model did not predict dissolution for HPMC lots from vendor C (HP ~8.3–8.6%), although the predicted

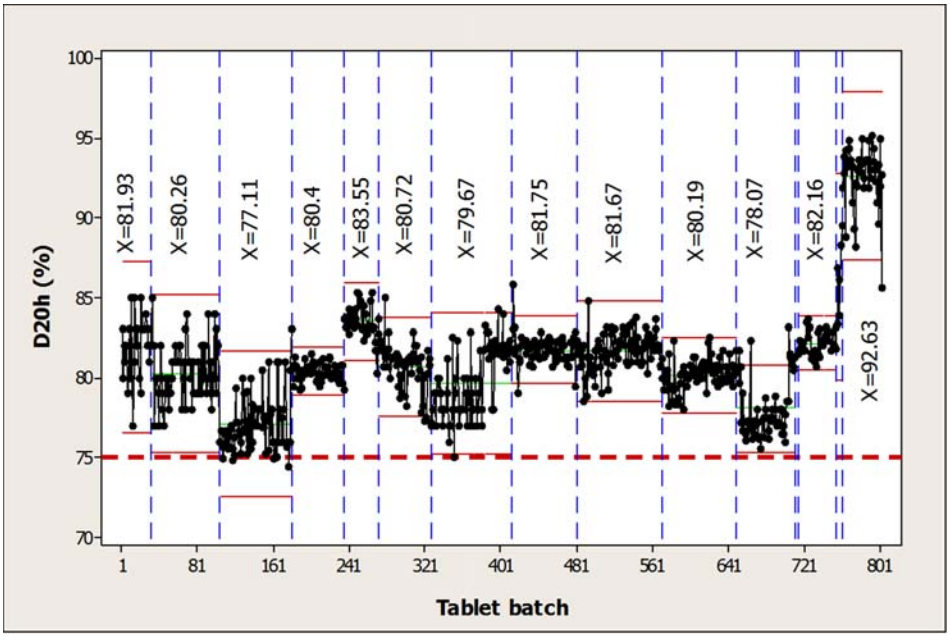

FIGURE 36.5 Run chart of niacin release at 20 hours segmented by HPMC lots.

and tested values were consistent (~90% released at 20 hours) for HPMC from vendor B (HP ~9.5–9.7%).

An investigation using a two-dimensional NMR clearly differentiated two types of hydroxypropyl substituents: one as native where the hydroxyl is free (designated as HP1) and the other is inner substitution where the hydroxyl group is further substituted by either a MeO group or another HP group (designated as HP2). The HP1/HP2 ratios were found to vary significantly among the vendors: HP1:HP2 ~ 3.3:1 for the commercial HPMC vendor, while HP1:HP2 ~ 2:1 for both vendor B and vendor C. The HP1:HP2 ratio is perceived to be important because HP2 represents a longer and larger substitution and greatly weakens the polymer/polymer interaction, thus, favoring faster drug release. Indeed, even though the overall HP contents for vendor C HPMC lots were much lower (HP ~8.3–8.6%), they produced fastest release rates (>90%) while the regression model predictions were low (<80%). It was postulated that the apparent conformance of vendor B materials to the regression model was purely a coincidence because with this highly substituted HP make up (HP1:HP2 ~ 2:1), the HP content does not need to be as high as in HPMC from the commercial vendor to release fast.

Even though the vendor-to-vendor differences were explained by the difference in the HP makeups, the fact that not all HPMC lots from the commercial vendor conformed to the regression model still warrants further investigation. It was likely that additional chemical heterogeneity such as the nonuniform distribution of the substitution along the cellulose backbone may play a role. It has been found that more heterogeneously substituted HPMC have impacted its solution properties such as cloud point[54] thus, may impact drug release from hydrophilic matrices.

Based on reviewing drug release mechanisms from hydrophilic matrices, the erosion rate of polymer was concluded to play a significant role in the drug release process. Therefore, a method was developed to measure the erosion rate of pure HPMC samples. The results confirmed that niacin release from the ER tablets correlated highly with the erosion rate of HPMC, regardless of the vendor (Fig. 36.6).

Based on the investigation, a specification was then set on this property of HPMC. With the improved control on HPMC, no further dissolution issue has surfaced. In addition to that, predicted and observed drug release has been consistent. The Niacin ER tablets drug release at 20 hours data from 311 commercial batches manufactured post the implementation of the change are presented in Fig. 36.7, and a process capability analysis plot is given in Fig. 36.8. The 95% lower confidence bound of the performance index (LB for $P_{pk} = 1.43$) indicates the additional control led to great

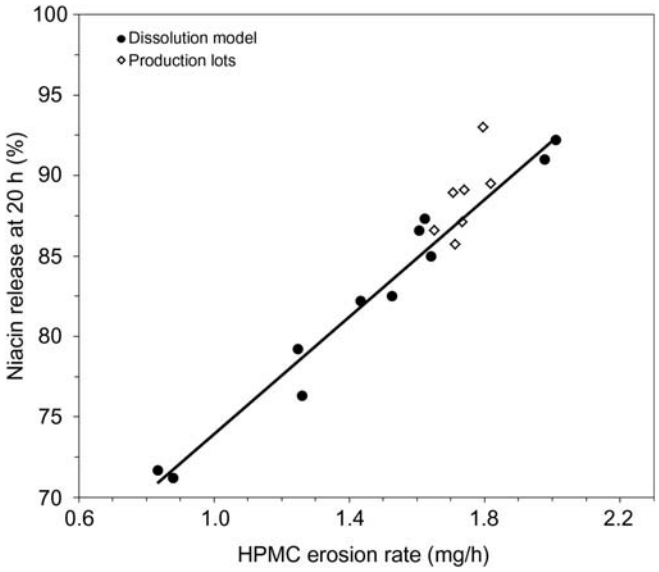

FIGURE 36.6 Correlation between niacin release at 20 hours and HPMC erosion rate.

improvement in meeting the quality requirement of drug release at 20 hours.

In the above example, the lot-to-lot and vendor-to-vendor variability of HPMC was not apparent from the typical compendia type of properties conventionally measured. In the end, a specification was developed based on measurement of an unconventional property of HPMC to control its variability. Searching beyond the compendia properties and understanding the dosage form design are necessary to understand better and control excipient variability. The case study also demonstrated that control chart can be an effective tool to detect the presence of special cause variation in the manufacturing process and to ascertain if the process has reached a state of statistical control. The control charts also serve as indicators of impending problems and allow operating personnel or process engineers to take proactive actions to prevent product quality failure from happening.

36.4.5 Illustrative Example-2: using PAT and RTRT to monitor and control traditional batch manufacturing process

CPV and PAT/RTRT can be applied independently. However, there are synergies between the two when they are applied together—for example, the ability to respond more quickly to data generated and monitored in real time (as opposed to waiting for traditional QC testing). Below is a schematic of conceptual example (Fig. 36.9) of using PAT/RTRT for monitoring and controlling a typical solid oral dosage manufacturing process using traditional batch manufacturing process.

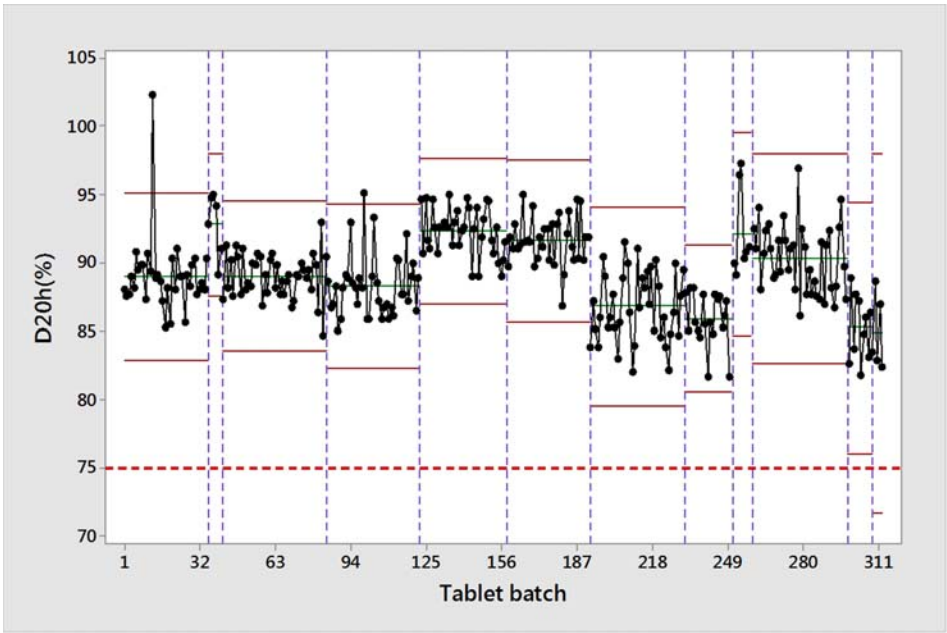

FIGURE 36.7 Run chart of niacin release at 20 hours, after the additional HPMC specification is implemented.

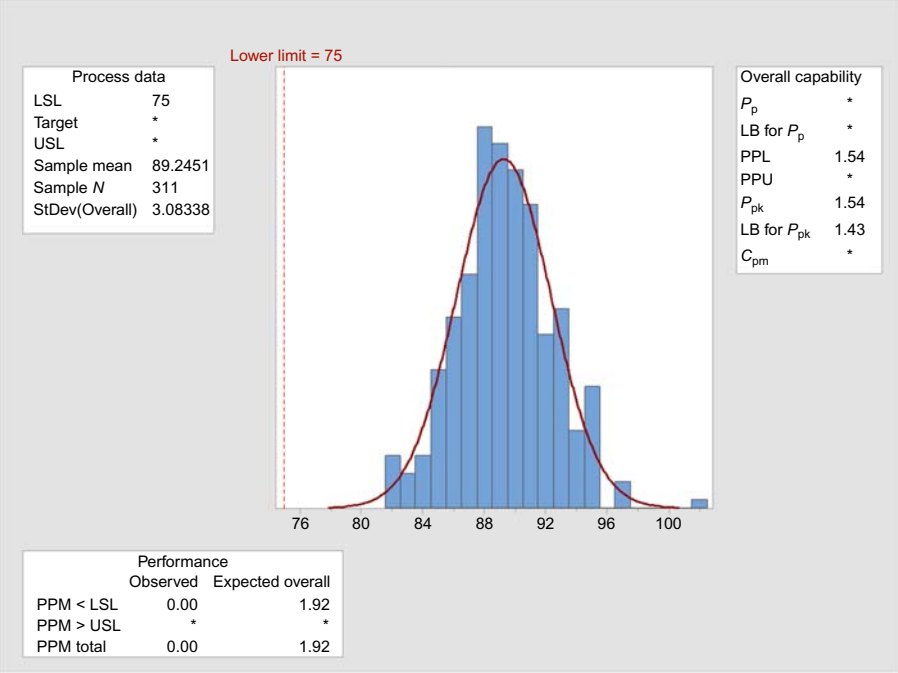

FIGURE 36.8 Process capability analysis of niacin release at 20 hours, after the additional HPMC specification was implemented.

The example is a typical solid oral dosage manufacturing process using traditional batch manufacturing process. The manufacturing steps include dispensing of raw materials, blending, milling, roller compaction, compression, and coating. Many on-line and in-line PAT tools are used including the use of in-line NIR for blend uniformity monitoring, in-line or on-line particle size monitoring by laser diffraction, and at-line monitoring of tablet active content and identity (ID) by NIR. RTRT is implemented for the following tests: assay, CU, ID, and dissolution. RTRT relies on the measurement from the PAT tools. In this example, tablet assay and CU for release are calculated based on at-line NIR measurement during compression, tablet identity for release relies on at-line ID measurement on tablet cores, multivariate mathematical model to predict dissolution for release is based on

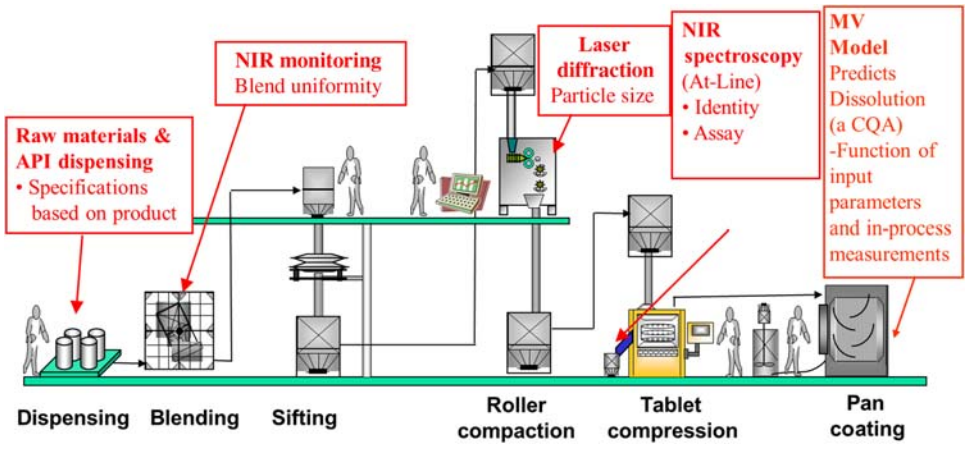

FIGURE 36.9 A schematic of conceptual example of PAT/RTRT implementation for a typical solid oral dosage manufacturing process using traditional batch manufacturing process.

TABLE 36.2 Highlights of Scientific Considerations for Implementing RTRT

Type of RTRT	Highlights of some specific questions to address during implementation
Real-time ID testing for incoming materials	• Is the ID test capable of distinguishing other raw materials available at the manufacturing location?
Real-time ID testing for finished products	• Is the ID testing capable of distinguishing between other products manufactured at the manufacturing location? • Does the product have any unique identifiers such as embossing that would interfere with the ID testing, depending upon orientation of the sample? • If the ID testing is performed on an intermediate instead of the finished product, what are the process steps after the point of ID testing that would disallow any potential human and/or system error?
Real-time measurement of core tablet content uniformity by NIR	• Is the sample size and sampling frequency for NIR measurement, representative of the batch? • Is there potential for segregation to occur in the feed hopper or feed frame after the point of measurement? • Since NIR measures active concentration in the tablet, is variation in weight of the tablet accounted for when calculating total active content in the tablet? Is the acceptance criteria proposed for content uniformity proportional to the sample size measured by NIR? • Is the RTRT method comparable to the traditional analytical method, for example, HPLC? • Is the calibration model associated with the NIR method adequately developed, validated, and maintained and is it applicable over the proposed range of operation at commercial scale?

Considerations for models serving as surrogates for release test	• Does the model include all the variables that have a potential to impact the attribute that is being modeled?
	• Is the model capable of detecting nonconforming batches?
	• Is the calibration model robust? For example:
	  ◦ Does it include possible variations in raw materials and processing conditions, that is expected to occur at commercial scale?
	  ◦ Has the model been validated using statistically approaches?

in-process measurements made during the production of material and process attributes that impact dissolution. Table 36.2 highlights some specific considerations (not exclusive) for different types of RTRT implementation for this case study in addition to the general considerations discussed in ICH Q8 (R2) and other ICH documents.[6,7]

If a model is used to support RTRT, as in the case where a model serves as a surrogate for release test, it is regarded as a high impact model, as per the criteria outlined in the "Models" section in the ICH QIWG *Points to Consider* document.[5] A model can be considered high the impact if the prediction from the model is a significant indicator of the quality of the product. Examples of such models can include multivariate models to predict dissolution for release, calibration models associated with NIR procedures that are used

for CU and assay release testing. For these cases, the ICH IWG "Points to Consider" document provides useful direction. Various examples of these models are also discussed in the paper on the role of models in pharmaceutical industry.[55–57]

36.4.6 Illustrative Example-3: using PAT and RTRT to monitor and control a continuous manufacturing process

Continuous manufacturing (CM) process refers to a manufacturing scheme where the material(s) and product are continuously charged into and discharged from the system, respectively, throughout the duration of the process.[58] CM is regarded as an innovation that has lots of potential to improve agility, flexibility, and robustness in the manufacture of pharmaceutical products. In addition, CM offers many other advantages such as smaller equipment footprint (and therefore CGMP processing area), shorter cycle times, inventory reduction, improved yields, reduced capital costs, and improved control over quality (http://www2.aaps.org/Arden/). More details regarding CM will be discussed in chapter "Emerging Technology for Modernizing Pharmaceutical Production: Continuous Manufacturing." This section focuses on the application of PAT/RTRT for monitoring and controlling CM process.

CM requires control systems that ensure continuous monitoring of quality of the intermediates and finished products, with the ability to detect and remove nonconforming batches. This leads to implementing many on-line/at-line PAT tools or models that can predict quality properties based on process data, that is, soft sensors, and information from which can then be leveraged to implement RTRT. Schematic below shows a conceptual example (Fig. 36.10) of implementing PAT/RTRT for a CM process via dry granulation for solid oral dosage form.

In this example, raw materials are added to a continuous blender via loss in weight feeders. The blended material then goes through a continuous dry granulation process such as roller compaction. Roller compacted ribbons are milled into granules which are then lubricated using a continuous blender where the lubricant is directly added to the blender using a loss in weight feeder. Lubricated granules are then compressed using a rotary tablet press and coated using a continuous film coating method. In this example, RTRT is implemented for the following tests: Assay, CU, ID, and Dissolution. RTRT for tablet assay and CU is calculated based on on-line NIR measurement during compression, tablet identity for release relies on on-line identity measurement on tablet cores, and a multivariate mathematical model is used to predict dissolution as a function of in-process measurements of active amount, tablet hardness, and granule particle size distribution. Additionally, for the continuous system, information from the in-line/on-line PAT tools can be used for process control. Data from PAT tools can be used either in feedback or feedforward mode to adjust the process parameters (as needed) to ensure that the process is operating as desired. To sum, real-time monitoring and release testing offers the advantage of continual assurance of quality during continuous manufacturing operation, however adoption of RTRT is not a requirement for CM implementation.

36.5 SUMMARY

Both the regulators and the pharmaceutical industry have been confronted with new and increasingly complex challenges, such as unprecedented drug shortages and recalls. By far, the most frequently cited reasons for drug shortages relate to manufacturing and product quality issues. Hence, a heightened focus is needed for better understanding the impact of commercial manufacturing

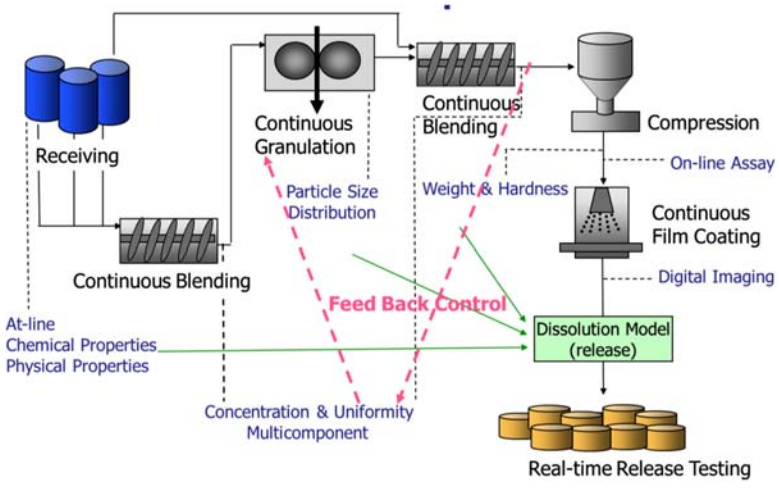

FIGURE 36.10 A schematic of conceptual example of PAT/RTRT implementation for a continuous manufacturing process.

on product quality. The topics covered in this chapter—lifecycle approach to process validation, routine commercial process monitoring, and continual improvement as well as PAT and RTRT applications—are part of the overall effort to improve pharmaceutical product quality and process performance.

Emerging Technology for Modernizing Pharmaceutical Production: Continuous Manufacturing

T. O'Connor and S. Lee

U.S. Food and Drug Administration, Washington, DC, United States

37.1 INTRODUCTION

Over the past decade, there has been progress in the adoption of systematic science and risk approaches for pharmaceutical development, which emphasize product and process understanding and control strategy. Nevertheless, available product quality data show that pharmaceutical manufacturing and its regulation, in general, are being confronted with new and increasingly complex challenges, such as the unacceptably high occurrence of product recalls and drug shortages,[1,2] globalization of drug product manufacturing that results in complex supply chains that span several countries, and lack of manufacturing flexibility for optimization and continuous improvement, resulting in an increasing number of postapproval supplements for manufacturing changes submitted to the US Food and Drug Administration (FDA) for review.

The adoption of emerging technology is one of the key mechanisms for addressing these challenges. Modernizing manufacturing technology may lead to a more robust manufacturing process with fewer interruptions in production, fewer product failures (before or after distribution), and greater assurance that the drug products manufactured in any given period of time will provide the expected clinical performance. Continuous pharmaceutical manufacturing is an emerging technology that offers potential efficiency, agility, flexibility, and quality advantages over traditional processing methods.[3] A number of technologies are available for continuous drug product manufacturing. There are inherent implementation challenges, but the extent of the challenges will depend upon the specific product and the manufacturing route selected. This chapter describes some of the current challenges facing pharmaceutical manufacturing. Next, it discusses how the adoption of emerging technology can enable the addressing these challenges, using continuous manufacturing as an example. Then technologies that enable continuous drug product manufacturing, the so-called hybrid continuous models for powder processing, are described, and finally implementation challenges are highlighted.

37.2 CHALLENGES FOR PHARMACEUTICAL MANUFACTURING

Pharmaceutical manufacturing processes are generally less efficient and understood compared with those in other chemical process industries.[4] This has resulted in product recalls and failures due to inherent defects in product and process design. The number of Class I recalls, which denotes a situation where there is a reasonable probability that exposure to a defective product will cause serious adverse health consequences or death, have increased sevenfold over the past decade.[1] Examination of the data further indicates that these recalls are typically due to failures in the implementation of manufacturing process scale-up and routine production. For example, in 2014, the chief causes of pharmaceutical recalls were the presence of particulate matter and failure to meet the product quality specifications.[5]

Developing Solid Oral Dosage Forms
DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00037-6

The lack of agility, flexibility, and robustness in the pharmaceutical manufacturing sector poses a potential public health threat because manufacturing failures may lead to poor product quality and drug shortages. Many drug shortages have been caused by the use of outdated equipment, reliance on aging facilities operating at the maximum production capacity, and lack of effective quality management systems. A 2012 FDA analysis of data collected form manufacturers determined that 66% of production disruptions leading to shortages resulted from either stoppages to address product-specific quality failures or general efforts to remediate a problematic manufacturing facility.[2]

Globalization continues to pose challenges for pharmaceutical manufacturing. Due to economic factors, supply chains for many active pharmaceutical ingredients (APIs) and final drug products span several countries and thereby contain multiple supply vulnerabilities. Under current manufacturing practices, intermediates may not be immediately processed. Instead, they are stored in containers and shipped around the world to the next manufacturing facility. This is a significant risk for APIs or intermediates that can degrade over time or are sensitive to environmental conditions, directly impacting the overall drug product quality. This trend is evident in the product recall data: 26% of drug recalls reported during 2014 to the FDA were international in nature, impacting more than one country, compared with just 4% in the beginning of 2013.[5]

For existing processes, the current regulatory framework may not help the implementation of manufacturing innovations generated from knowledge obtained during production. This effect is evidenced by the increasing number of postapproval supplements received for review over the past decade, in part owing to our current practice of "locking in" an applicant's manufacturing process before it is fully optimized. A burdensome regulatory framework causes manufacturers to submit supplements as they strive for process optimization. The large number of postapproval supplements also creates a drain on FDA resources that could otherwise be dedicated to other public health priorities. Due to the fractured global regulatory environment, the timeline between filing the first regulatory submission and final global approval for the implementation of a manufacturing improvement can be several years. Over this time period, the manufacturer must utilize different manufacturing processes in the various regions to supply patients with products. This creates supply chain and logistical challenges and vulnerabilities and slows the implementation of innovative technologies, which could improve product quality and availability.

37.3 THE ADOPTION OF EMERGING TECHNOLOGY TO ADDRESS PHARMACEUTICAL MANUFACTURING CHALLENGES

The adoption of emerging manufacturing technologies is one way to address the cited challenges. An emerging technology can be viewed as a technology that has the potential to modernize the pharmaceutical manufacturing body of knowledge to support more robust, predictable, or cost-effective processes. Examples of such elements include an innovative or novel: (1) product manufacturing technology (eg, dosage forms and delivery systems); (2) manufacturing process (eg, design, scale-up, and automation); and/or (3) testing and monitoring technology. As explained next, the adoption of emerging technologies can help drive the sector toward the vision of a maximally efficient, agile, flexible pharmaceutical manufacturing sector that reliably produces high-quality drugs without extensive regulatory oversight.[6]

Continuous manufacturing is an emerging pharmaceutical technology.[3] This manufacturing technology is not a new concept per se, since it has been extensively utilized in the petroleum, chemical, and food industries (among many others) for several decades. However, there is currently limited experience with implementing this technology within the pharmaceutical industry. Batch manufacturing is traditionally utilized for the production of pharmaceutical products. In this type of process, materials from one step are processed over a period of time set by recipe, then usually tested off-line as per the in-process controls, and finally stored before they are sent to the next processing step. If the in-process material does not meet quality expectations, it may be discarded or, under certain circumstances, reprocessed before moving to the next process step.[7] In continuous manufacturing, materials produced during each process step are sent directly and continuously to the next step for further processing. Each processing step needs to reliably produce its intermediate output material or product with acceptable characteristics. Modifying the processing rate of particular unit operation(s) (eg, synthesis, crystallization, and blending drying) to achieve the desired quality may not be possible for continuous manufacturing because it may create disruption for downstream unit operations unless buffer capacity is designed into the system.

Continuous manufacturing, compared with batch manufacturing, thus generally involves a more highly integrated level of process design and operation so as to ensure continuous control of product quality attributes. There are different types of continuous manufacturing implementation models. Fig. 37.1

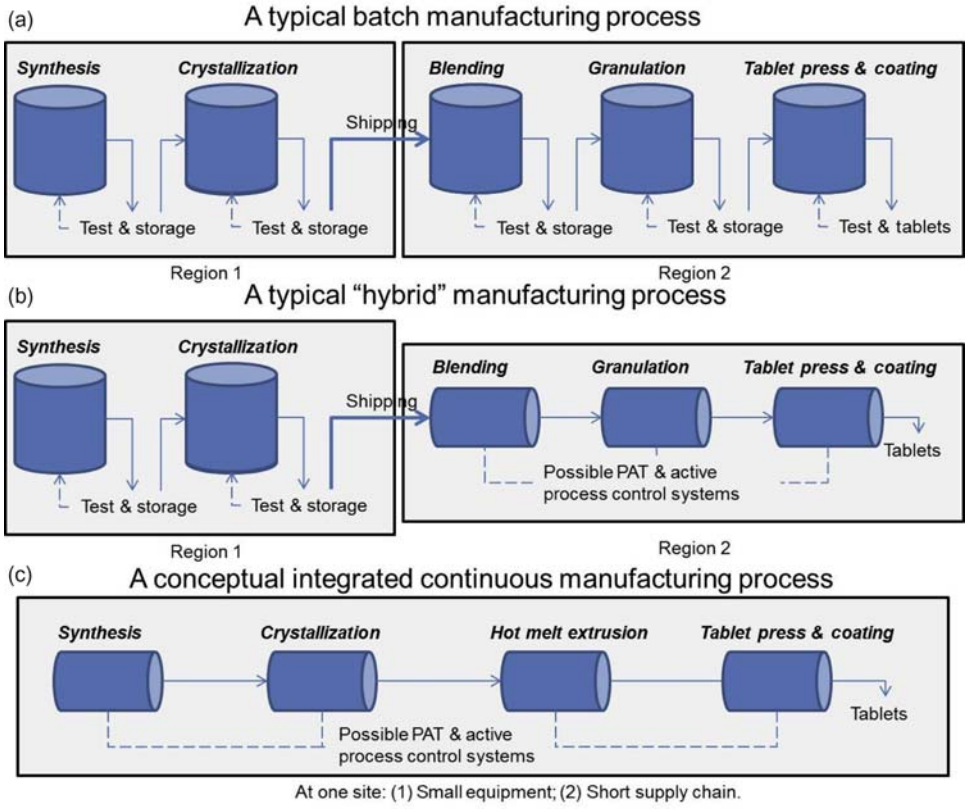

FIGURE 37.1 Conceptual examples of continuous manufacturing implementation. (a) An example of batch manufacturing process where the API and final dosage form are produced at different facilities and off-line testing is used to verify product quality between processing steps, (b) An example of a hybrid approach where the API is produced using batch technology, but the drug product starting with the API is manufactured continuously and supervised by an active control system that ensures quality, (c) An example of end-to-end continuous manufacturing process from raw materials to final dosage form. To take advantage of the unique aspects of continuous, end-to-end processes may lead to the utilization of emerging processing technologies, such as spray drying, hot melt extrusion, and printing, among others.

depicts two such implementation models (ie, hybrid and end-to-end) for continuous pharmaceutical manufacturing. Fig. 37.1b shows the drug product hybrid model where the API is produced separately using batch technology, and the drug product, starting with the API, is manufactured via an integrated continuous process. The hybrid model can also be applied to drug substance manufacturing where the API starting from raw materials is produced via an integrated continuous process, and the drug product is manufactured separately. Fig. 37.1c shows an example of end-to-end models where the continuous process starts with raw materials and produces the final dosage form. To take advantage of the unique aspects of continuous manufacturing, end-to-end processes may lead to the development and utilization of emerging process technologies. The future vision for continuous manufacturing for both models is one in which: (1) individual continuous unit operations are connected to form an integrated manufacturing process, (2) process analytical technology (PAT) systems are utilized to provide real-time data for process monitoring and control, and (3) engineering process-control systems are implemented to mitigate the impact of raw material and process variability on the quality of finished products. Compared with traditional batch manufacturing, continuous manufacturing provides several potential opportunities to improve control of product quality and thereby increase the efficiency, flexibility, and agility of manufacturing, as highlighted next.

Continuous unit operations are generally more efficient than their batch counterparts and offer much higher throughput per unit volume and per unit time, thereby often greatly reducing the size of the processing equipment. The manufacturing footprint is further reduced because the material flows from one processing step to the next, and does not need isolated suites or dedicated modules. For this reason, a substantial reduction in both capital and operating expenses for a continuous process can be achieved.[8] Furthermore, continuous processing can decrease the amount of potentially expensive API required for process development studies, greatly

reducing the material cost of process development and optimization efforts.

Continuous manufacturing may also increase process efficiency by facilitating the streamlining of the manufacturing process through the removal of corrective or work-up unit operations. One potential example of process intensification (collapsing of a multistep process into a smaller number of steps or unit operations) is reaction that telescopes drug substance manufacturing.[9] Traditional batch reactions normally include several reaction steps with isolation and purification work-up operations following each reaction step. The postreaction work-up steps can be highly time consuming and generate large volumes of waste. To avoid this lengthy process, telescoping could be an ideal alternative and well-suited for continuous flow chemistry.[10] Other examples include: (1) the potential to eliminate downstream corrective drug product unit operations, such as sizing steps (eg, granulation, milling), due to better control of the particle size distribution during crystallization, and (2) reduction in the segregation risk from continuous blending.[11,12] Continuous manufacturing may also facilitate the adoption of emerging processing technologies which are well-suited for continuous operations.[13]

Continuous manufacturing also has the potential to improve the agility and the flexibility of the pharmaceutical manufacturing sector. The pharmaceutical industry currently has a limited ability to rapidly increase production in the face of drug shortages or other emergencies, such as pandemics. Bringing up a new facility or manufacturing line in response to such emergencies may take up to several months or even years. Continuous manufacturing can potentially permit increasing production volume without the current obstacles related to scale-up, providing more response capacity. Scale-up options, such as operating the process for longer periods of time, utilizing parallel processing lines, or increasing the flow rate through the process, can be built into the process design and verification. Modularized skid-mounted continuous plants also offer the possibility of rapidly bringing additional manufacturing capacity on-line.[14] In addition, due to the small volume of materials needed to run continuous manufacturing systems, it may be possible to design and optimize a continuous system on commercial scale equipment, thus eliminating scale-up.[15,16] Eliminating scale-up bottlenecks in the path to market may facilitate rapid clinical development of breakthrough drugs.

Continuous manufacturing provides advantages to address complex supply chain issues due to globalization. Continuous manufacturing allows the production at various scales with a given process, which may facilitate regional or in-country manufacturing. Under a continuous operating mode, hold times between steps can be eliminated. This is a significant advantage for APIs or intermediates that can degrade over time or are sensitive to environmental conditions, directly improving the overall drug product quality. Furthermore, the small scale of continuous manufacturing can decrease the safety hazards associated with highly energetic or hazardous materials and potentially allow for more flexibility in the use of nonspecialized manufacturing facilities.[17]

Continuous manufacturing is strongly aligned with the FDA's support of the quality-by-design (QbD) paradigm for pharmaceutical development and offers opportunities to improve process robustness. Development of a robust process relies on utilizing product and process understanding to identify sources of variation to product quality and to design appropriate control strategies to address these risk areas. Continuous manufacturing provides an opportunity to utilize enhanced product and process understanding to adopt advanced manufacturing controls and produce uniformly high-quality products with reduced waste, resulting from the generation of out-of-specification material.[4]

37.4 TECHNOLOGIES FOR CONTINUOUS DRUG PRODUCT MANUFACTURING

The design of the manufacturing process for solid dosage forms varies from compound to compound because the properties of the API molecule play a significant role in the development of an appropriate formulation. The majority of solid oral drug products are produced using one of several manufacturing routes: direct compression, wet granulation, or dry granulation. Technologies are available to implement an integrated continuous process line for each of these design alternatives. Fig. 37.2 depicts the unit operations utilized for three continuous manufacturing routes.[18] New process technologies are also being developed or adapted to the pharmaceutical industry (eg, spray drying, hot melt extrusion (HME), casting, and 3D printing) to take advantage of continuous processing in order to combine the function of multiple steps into a single process or reduce solid handling.[13] These technologies can enable end-to-end manufacturing from raw materials to the final dosage form in a single, integrated continuous process.[16] In general, even if the drug substance and drug processes are not physically integrated, the processes should be designed as a single system, with a consistent design objective, so that downstream processes are not implemented to correct issues that could have been controlled upstream. Regardless of the manufacturing route, continuous manufacturing naturally lends itself to the adoption of

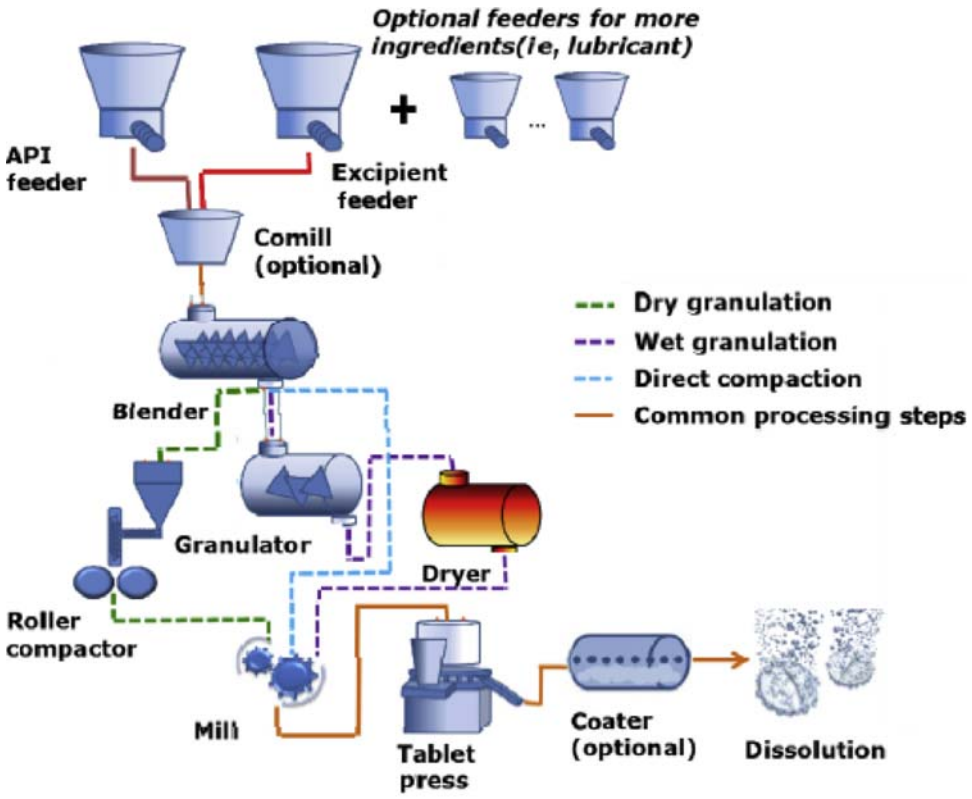

FIGURE 37.2 Continuous drug product manufacturing routes. Three manufacturing routes for the continuous production of pharmaceutical tablets are shown. Common processing steps for all three routes include feeding, blending, and tableting. The dry granulation route involves roller compaction followed by milling of the produced ribbons, while the wet granulation route involves wet granulation followed by drying and then by granule milling. In the case of direct compaction, there is no granulation step and therefore milling is not required prior to tableting.[18]

advanced approaches for real-time monitoring and process control due to the absence of isolated intermediates and the typically faster process dynamics for a continuous process that may necessitate more frequent measurements. These process monitoring and control systems are typically an essential component of the control strategy for a continuous process.

37.4.1 Feeding

The objective of the feeding operation is to supply the correct ratio of raw materials specified by the drug product formulation. In a continuous process, this requires feeding each material at a specified rate, such that the final product will have the proper composition. If the feed rate of one ingredient changes even for a brief period of time, the resulting variation in composition of the process stream can propagate downstream,[19,20] potentially leading to out-of-specification product units. The ability to feed powders consistently and continuously is typically accomplished through the use of loss-in-weight (LIW) feeders.

LIW feeders comprise a volumetric feeder mounted on top of a weighing platform that measures the mass of the feeder and its powder contents. The most common mechanism for feeding utilizes a hopper mounted on top of a positive-displacement screw element. When the screws are in motion, powder is fed from the material hopper into the process, and the total weight of the screw feeding system and the hopper decreases at a rate equivalent to the rate at which material is fed into the process. A gravimetric controller continuously monitors this LIW to adjust the screw speed so that the rate at which material enters the process remains on target. Alternatively, feeders can operate in volumetric mode, where the screw speed is kept at a constant value based on a predetermined calibration to achieve the desired feed-rate set point. Volumetric mode cannot adjust for those variations in powder density that typically occur when emptying and refilling the hopper[21]; however, when gravimetric control mode is not possible, such as during start-up and hopper refill, volumetric mode is necessary.

Even under gravimetric control, the granular nature of the materials places a limit on how accurately the

addition of material can be controlled. This is due to the fact that powders are composed of three phases: solid (ie, the particles), liquid (ie, moisture content attributed to water molecules on the surface or in between particles), and gas (ie, air between the particles); bulk powder behavior is dependent on how these three phases interact. Powders can be made to flow when energy is applied but then can hold shape when the energy is removed. This complex behavior leads to variations in the interaction between feeding screw and material, both within the screw and at the exit of the feeder, thus leading to variations in the feeding rate. The amplitude and frequency of feeding variations depends on the material properties of the powder and the feeder design and configuration.[19]

A general methodology for design of the feeding operation has been outlined based on the following steps: select potential feeders and tooling (eg, screw type and exit screen) based on the desired volumetric throughput; screen the potential tooling options for compatibility issues (eg, material adhering within the flights of the screws and clogging of screens with cohesive material); and test compatibility and monitor feed rate. During feeding trials, selection of the proper sampling interval is important because a sampling interval that is too long relative to the subsequent processing will not adequately detect transient fluctuations or disturbances.[19,20] At high feeding capacities, the discrete nature of the powder stream becomes less significant and feeding accuracy is greatly improved. The main challenge lies in feeding solid materials accurately at low-flow rates, where the variations can become large compared with the rate at which the material is being fed. Minor components (eg, lubricants and disintegrants) are thus more susceptible to feeding limitations.[13] This limitation is also generally compounded by the powder properties of these materials (eg, low density material, such as SiO_2, and material with poor-flow properties). However, precision feeders are becoming available, which can mitigate the challenges posed by low-flow rates.

37.4.2 Blending

The purpose of blending in downstream pharmaceutical applications is to reduce composition variability and thus minimize spatial and temporal composition variations in the material exiting the mixer. Convective mixers are the most common type of continuous blender, comprising a horizontal or inclined tube with a bladed impeller running down its central axis, whereby the rotating blades cause convective mixing. Design parameters for this type of blender are tube length and diameter, and blade size, shape, and configuration.[18] Material and operating parameters that can impact performance are impeller rate, flow rate, bulk density, and cohesion.[22] A well-designed continuous mixer should be able to produce evenly distributed (not segregated) blends with good control of composition over time. Achieving this objective can be described in terms of radial and axial mixing.[23] The degree of radial mixing varies as a function of distance traveled down the length of the mixer. Thus, a snapshot of a radial cross-section of the blender tube near the entrance at steady state would show two unblended powders. If the blender is properly designed and operated, a snapshot of the radial cross-section near the exit of the blender would show two powders blended together (Fig. 37.3).[12] Radial mixing is a steady state process, and can largely be considered time-invariant as opposed to a batch-mixing process, where the homogeneity of the powder blend varies as a function of time.

Axial mixing (ie, back-mixing) refers to mixing along the length of the tubular mixer. As discussed in the feeding section, the feed rate of the drug product components will vary around the desired flow rates. If a continuous feeder simply radially blended the incoming materials, then any disturbance from feeding would pass right through the blender and end up as variation in the final drug product.[23] Axial mixing can reduce the impact of component feed rate fluctuations at the exit of the mixer because it categorizes blending between powder segments that enter the mixer at different times. In a continuous process, it is critical to

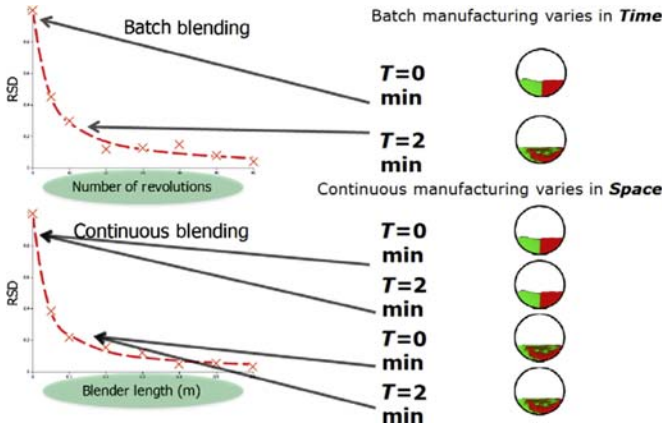

FIGURE 37.3 Comparison between batch and continuous blending. Difference in perspective for batch and continuous blending. The charts depict the relative standard deviation (RSD) for the content uniformity of a powder blend as a function of time for batch mixer and as a function of blender length for a continuous mixer. For the continuous mixer, the content uniformity does not vary as a function of time as shown by the callouts. Thus, the RSD for samples taken from the sample location in a continuous mixer should not change with time (ie, the samples taken at $T = 0$ min and $T = 2$ min are equivalent).[12]

understand that the feeding and blending systems must be designed to work together as a system. The amplitude and frequency of variations in the component feed rates must be fully understood because this leads directly to the degree of axial mixing that is required in the blending step. Impeller speed and cohesion have shown a significant interacting effect on axial mixing with cohesiveness, increasing axial mixing at high impeller rates, but having a negligible effect at lower impeller rates.[22] As a consequence of axial mixing, the particles in the powder blend will experience a distribution of processing times. This residence time distribution (RTD), a probability distribution that describes the amount of time a solid or fluid element is likely to remain in a particular unit or process, can be used to characterize a continuous mixer (eg, filterability of incoming disturbances), and the RTD will depend upon the design and operating parameters of the mixer as well as the physiochemical properties of the powder blend.[24] Process modeling, including RTD modeling, is expected to play a major role in determining the balance between axial and radial mixing that results in the desired product quality attributes, given the specific material feeding characteristics, for the drug product.[23]

Another distinguishing characteristic between a batch- and continuous-blending process is that the risk of segregation (ie, demixing) is lower in a continuous process. Segregation occurs when particles separate due to differences in their size, shape, or density. In a batch manufacturing process, the entire "batch" is present in the mixer for the entire processing time, while only a small portion of the batch is present in a continuous mixer at given moment in time. Thus, the radial length scale over which mixing occurs in the continuous process is much less, increasing mixing efficiency. Whereas in continuous processing, the steady-state material balance describes that the flux of material entering the system must equal the output flux, independent of particle size and density, otherwise there would be an accumulation of either smaller or larger particles in the blender. There is the possibility, however, that the RTD of different size particles could be different during dynamic phases of the process, such as start-up and shutdown.

37.4.3 Granulation

37.4.3.1 Wet granulation

Continuous wet granulation can be performed using a variety of techniques and equipment, with the most common including fluid-bed granulators and extrusion. The most widespread continuous fluid-bed granulators are horizontal moving-bed granulators/driers, which are mainly used in the chemical, dairy, and food industries. Although the concept of continuous moving-bed granulators can be used within the pharmaceutical industry, there are hardly any applications of them for the production of solid dosage forms, mainly because they are ideally suited for high-volume products. Another category of fluid-bed granulators is the rounded bed design, where the material is confined to an enclosed space (similar to batch fluid-bed processors), but able to continuously discharge agglomerated material through an outlet at the bottom of the screen (round-shaped). This allows the equipment to function over a greater range of production rates. A counter-current air flow through the pipe positioned at the center of the bottom plate ensures that only agglomerated particles are discharged. Only larger particles are able to overcome the air velocity, whereas the counter-current airflow carries undersized particles back into the processing chamber until they are sufficiently agglomerated. This allows the process to manufacture an essentially dust-free product, the velocity of the counter airflow determining the particle size of the end product.[25]

Extrusion is the most studied continuous granulation process for pharmaceutical application. This is due, in part, to the fact that extrusion is readily scaled-up and therefore lends itself to the pharmaceutical development process where the amount of product needed increases as it moves through the clinical development stages. Pharmaceutical granulation is often carried out in twin-screw extruders with co-rotating screws, an example of which is depicted in Fig. 37.4. In an extrusion granulation process, liquid binder is added continuously into the barrel and the moving powder is wetted and forms an extrudate. This extrudate is then broken into smaller pieces due to the shearing force that exists during the process. The material is then transported by conveying elements into mixing zones where it is mixed, compacted, and elongated by the kneading disks of the mixing zones. Mixing and agglomeration occur as the material is conveyed along the length of the barrel. A drying step is also required. In these processes, the main design parameters include the length of the barrel, the number of screws (one or two), the geometry of the screws, and the location of a point or points along the barrel where binding solution is added. Extruders used for granulation are operated in an open manner without a die at the end of the barrel. Granulation involves different rate processes, such as nucleation, coalescence, and consolidation (growth) and breakage. As opposed to batch granulation processes, where granulation rate processes may occur simultaneously, a dominant

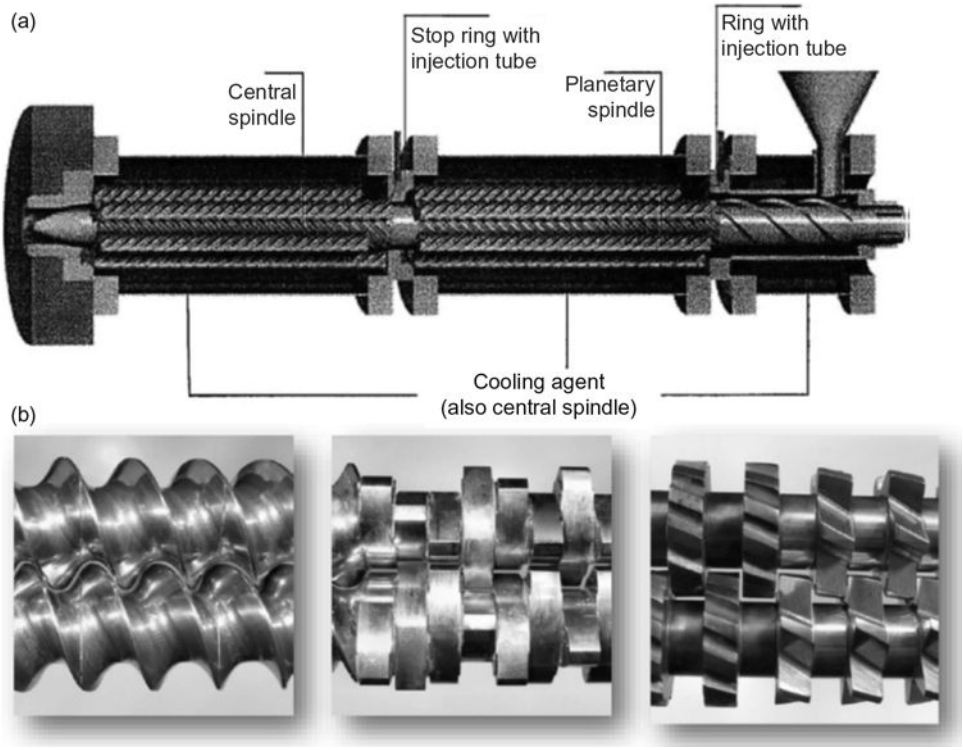

FIGURE 37.4 Twin-screw, high-shear wet granulator. (a) Twin-screw extruder, (b) Examples of co-rotating screws.[25]

granulation mechanism typically exists in each of the compartments along the length of the extruder.[26] Separating the granulation rate processes along the extruder should lead to better control of granule properties such as size and density, however, it is generally observed that extrusion tends to produce granules with a multimodal size distribution and greater porosity, usually requiring postprocessing size reduction. The broader size distributions observed are primarily due to relatively large droplet size of granulating liquid, liquid addition method, and poor liquid distribution compounded by the relatively short residence time in the granulator. Improvements in extruder design may be able to mitigate these challenges.[27]

It is important to understand the role of different screw elements (such as conveying and kneading elements) in order to describe the various rate processes in twin-screw granulator. Conveying screw elements possess axial displacement properties that are responsible for transporting the feed powder and liquid materials into the kneading section. The kneading elements provide a shear-intensive zone that allows granule formation by intimate mixing of liquid and powder; however, the granules obtained are typically characterized by a broad bimodal size distribution, with the presence of lumps and ungranulated fines.[26,28] Studies suggest that the compacted materials are also chopped by the conveying screws, which leads to the irregular and porous granules observed, and poor liquid distribution from dripping the binder liquid into the conveying section results in the observed bimodal broad granule size distribution.[28,29] Distributive mixing elements (DME) have also been studied for their use in twin-screw extrusion granulation. This type of screw element produces distributive mixing through cutting and recombination to allow collisions between in-flowing granular materials. Depending on their configuration relative to the incoming material, the DME elements produced granules with a narrower size distribution and improved liquid distribution.[30] This suggests the ability to tailor particle morphology and the potential to eliminate downstream milling operations.

Operating parameters of interest include screw speed, granulation temperature, and liquid-to-solid ratio.[31] Powder properties and binder properties, including viscosity and surface tension, have the potential to influence the process as well.[32,33] Tu et al.[34] have experimentally studied granule properties as a function of operating conditions, including screw speed and liquid-to-solid ratio. The authors developed regime maps for the process, describing the extruder geometry in terms of granulation (ie, the nucleation and growth of granules), extrusion (ie, material shaped into a continuous form, such as fiber or film), and breakage (ie, breaking of agglomerates into smaller

particles) regimes. The resulting regime maps suggest that desired granulation performance (narrow granule size distribution and large mean granule size) can be achieved with a higher liquid-to-solid ratio and a higher screw speed. However, increasing the liquid-to-solid ratio must be done with caution to avoid rapid growth and densification of granules beyond the processing ability of downstream units. The uniformity of size distribution can be improved by reprocessing and/or more aggressive mixing. Extrudates produced above a certain liquid-to-solid ratio tend to have a paste-like consistency.[34]

Granule drying is an inherent part of the wet granulation process. Drying is typically carried out utilizing a fluidized bed,[18] although other approaches, such as squeeze drying, belt drying, and drying through a screw, may be developed.[13] The fluid-bed drying process can be controlled through varying the air temperature, air velocity, product feeding rate, or the height of the powder in the bed, which can be adjusted by a weir installed at the outlet. The result of a fluid-bed drying process strongly depends on the RTD within the bed. The average residence time in the dryer significantly affects the propensity for undesired secondary agglomeration to occur during the drying process.[35] Thus, the key challenge in this operation is to achieve sufficient drying in a reasonable amount of residence time.

37.4.3.2 *Dry granulation*

Continuous granulation can also be accomplished via dry granulation through roller compaction. In the roller compaction process, powder is fed into a set of counter-rotating rolls, which compress and convey the powder forward with the motion of the rolls. Where the rolls are closest together, a compact ribbon is formed, which is continuously fed to a mill that transforms the ribbon into granules. Roller compaction can be a viable processing approach for powders with good flowability and compressibility, but may not perform well for powders with low bulk density, small particle size, or that are very cohesive. The development of a robust process can thus be challenging due to the strong dependency on raw material properties, however, because roller compaction results in the removal of the drying step, capital and operating costs are reduced and it can be used for moisture-sensitive APIs.[18]

Roller compaction equipment for a continuous process does not differ much from current batch production methods. Roller compactors vary mostly in terms of configuration. The orientation of rolls can be arranged either horizontally (with ribbons coming out parallel to the floor), vertically (with ribbons coming out perpendicular to the floor), or at some intermediate angle. In addition, the gap between the rolls can be fixed throughout the process or adjusted to account for variation in the incoming material. The roll diameter and width vary from one piece of equipment to another. The surface of the rolls can also vary from smooth to rough with grooves to pocketed designs. Finally, the powder can be fed either gravimetrically or using a screw feeder.[25] The propensity for the production of fines can be greater in roller compaction, compared with wet granulation, depending on the properties of the powder. Ribbon density and ribbon density variability can be used to evaluate the impact of process parameters (eg, feed rate, roll speed, and roll gap) on performance. If the ribbon density is too high, the process can yield tablets with both low hardness and high friability, while if the ribbon density is too low, the produced granules can possess a wide particle size distribution that results in tablets with increased weight variability.[36] The moisture content is another quality attribute of the produced granules because it affects the flowability, cohesively, and compressibility of the granules.[37] Real-time measurements of ribbon density, composition, and moisture content has been demonstrated[38] and can be used in multi-input, multi-output feedback control strategies that can assure that ribbon density is maintained.[39] The main difference when moving to continuous manufacturing is that the dry granulation process will be integrated with upstream and downstream operations, and thus the feed rate and other properties will be impacted by the upstream units and thus, must be monitored and managed via appropriately designed control strategy.

37.4.4 Particle size reduction

The most commonly used size reduction equipment in the industry is the conical-mill (ie, the co-mill). Co-mills use an impeller to push incoming material through a conical screen. The key design parameters for a co-mill include the screen mesh size, the size of the cone, the impeller shape, and the impeller-to-screen distance, which can be adjusted using spacers. In addition to achieving the desired particle size distribution, yield can also be a concern in particle size reduction operations because the production of a large quantity of fines could result in significant losses of potentially expensive API.[18]

Co-mills are inherently continuous equipment however, the manner in which they are operated will be somewhat different. In batch production, the material to be milled is loaded on top of the co-mill and the mill is run at a set speed until all of the material has

been processed. In a continuous process, it will be necessary to match the rate at which the mill processes material to the rate at which upstream units operate.[40]

37.4.5 Compression

The compaction of powder blends is typically achieved in a tablet press, which contains several components integrated as a single processing unit. A hopper conveys material into the tablet press. A feed frame is then used to distribute the powder or granular material into the die cavity that defines the tablet size and shape. A punch compresses the material within the die and then ejects the compressed tablet. The design of tablet presses can vary parameters depending on the tooling, the number of compression stations, and feeding method (ie, force feeding or suction filling).[18] The tooling includes the die and punch size, and geometry, which can be changed according to the desired tablet weight and shape. Tooling must be engineered to withstand the stresses associated with compression to provide satisfactory reliability and maintain tablet uniformity. Key operating parameters for a tablet press include the powder feed rate and the compression force applied to the tablets, as well as the feed-frame speed (ie, the rate of tablet production). Die-fill uniformity is often a limiting factor for setting the operating speed on a rotary press and impacts tablet weight and weight variability, while compression force affects tablet properties like hardness and density.[41]

Segregation during die filling that results in content uniformity issues can occur if the powder material possesses wide particle size distributions or density variability. The time required to fill the die can be impacted by low bulk density, poor compressibility, or the cohesiveness of the powder material, resulting in tablet weight variability and insufficient tablet hardness.[18] Variability in tablet hardness can impact product performance (ie, dissolution).[42,43] Excess amount of particle fines can lead to compression problems, such as capping.[44,45] In addition, the physiochemical properties of the active ingredient could affect the propensity for temperature-dependent polymorphic transformations during the compaction process.[46]

Tablet presses are another example of equipment that currently runs continuously. However, in order for tableting to be integrated with the upstream operations in a continuous line, the dynamics of the fill level in the feed hopper may differ from those seen in traditional batch manufacturing.[18] One operating approach is to select the turret speed of the tablet press to match the desired line rate of the process. The fill level in the hopper can then be allowed to vary during operation to serve as buffer to absorb upstream flow-rate variation.

37.4.6 Coating

The film coating is typically performed for cosmetic purposes, but the film coat is also sometimes used to modify the release of API and achieve the desired tablet performance. Film coating usually involves a process where tablets are sprayed with a pigment-containing polymer solution while being rotated in a dry air stream. The drying air removes moisture, leaving behind tablets coated by a thin film of colored polymer. In continuous film coating, tablets are simultaneously loaded at one end of a long rotating perforated cylinder to pass through a multi-gun spray zone, while coated tablets continuously exit at the opposite end. The main challenges with this design are a high degree of back-mixing at low-flow rates, which result in a large variance in the amount of coating applied to each tablet. An alternative (semi-continuous) approach is to operate two short-cycle batch coaters, loading or unloading one coater while the second coater is in operation.[13] This approach can result in less intra-batch variability in film coats, but suffers from less operational flexibility with regards to adjusting to changes in the process line rate. Both approaches may be considered when designing a process train that includes a film-coating operation.[13]

37.4.7 Emerging technologies for continuous drug product production

Emerging technologies for continuous drug production manufacturing include technologies where components, primarily API and polymer excipients, are blended and homogenized. Such technologies alleviate the potential for segregation and reduce potential issues related to the flowability of materials. One challenge if the API and excipients are blended in solution is that the crystallization of the API must be taken into account in the design of the process in order to either obtain the desired API crystal form or avoid crystallization if an amorphous dispersion is desired. The properties of the resulting blend should be designed to enable the direct production of the drug product.[13] This can be more challenging for high-dose drug products where API properties have a significant impact on blend properties and thus, there is less flexibility in tuning blend properties via adjusting the formulation. Emerging continuous technologies that take advantage of these approaches include spray drying, holt melt extrusion (HME), casting, and 3D printing.[13]

Spray drying is a well-established and widely applied technology to manufacture powders and is advantageous for products where the desired solid state of the API is amorphous. The amorphous form can be utilized to improve the bioavailability of poorly

soluble APIs because drying rates are typically fast enough to prevent crystal nucleation and growth. Annealing can be used to trigger crystallization if desired, but this may not be sufficient for APIs encapsulated in a polymer matrix because the fast drying leads to a rapid viscosity increase, kinetically trapping the API in the carrier matrix.[47] Spray drying is an inherently continuous process in which a solution is sprayed through a nozzle into a vessel where a gas, such as nitrogen, is blown in order to dry the airborne droplets. The spray-drying process consists of four basic stages: atomization of the liquid, mixing of the liquid with the drying gas, evaporation of the liquid, and separation of the dried particles from the gas. Understanding the relationship between process parameters (eg, inlet temperature, drying gas properties (humidity, flow rate), feed rate, and atomization air flow rate) and formulation properties (ie, feed composition [API, carrier, solvent], solids content in the feed, solvent type, viscosity, and surface tension of the drying solution) are crucial for the reproducible production of quality material.[47,48] In order for these droplets to dry sufficiently, commercial spray-drying equipment is often required to be quite large although small-scale systems are available for process development. The main challenge for incorporating spray drying into a continuous process is that accompanying upstream and downstream steps are not inherently continuous. Specifically, upstream continuous mixing of polymer/API/solvent where the slow dissolution dynamics of polymers can impact mixing performance, and downstream secondary drying, where typically long processing times are required to meet ICH limits for residual solvents.[13] A related technique, electrospray drying, can be used to process thermolabile molecules and with sufficiently high viscosity and conductivity in which solvent evaporation from the atomized droplets takes place using an electric field at ambient temperature and pressure.[49]

HME is a continuous process that has significant potential for the manufacturing of different dosage forms and increasing the solubility of poorly soluble drugs by forming a solid dispersion in a polymer matrix.[50] The process is well-known and commonly used in the plastics industries. HME combines several unit operations in one process to produce homogeneous strands of molten material. The material is typically fed with volumetric or LIW feeders in the intake zone of the extruder. The solids melt in the plasticization zone due to high shear forces and, to a lesser extent, due to heat transfer via the extruder barrel. HME is typically limited to manufacturing drug products with stable APIs insensitive to thermal stresses because heat is applied to the formulation during processing. Next, the melt is devolatized and subsequently forced into an extrusion die.[51] The processing parameters of feeding rate, screw speed, barrel temperature profile, and screw configuration impact degree of fill, the residence time, and heat transfer. The screw configuration, for example, will impact the degree of mixing and therefore uniformity of the solid dispersion. In addition, the energy contributions from the heated barrel and from the number of mixing screw elements combined with the RTD will impact the maximum temperature of the melted phase and any thermally related attributes.[52] Tablets are relatively simple shapes that can be directly formed when an API is mixed with a flowable excipient, such as in polymer dispersions. Injection molding is one technique that can be used, since it has been used for decades to make inexpensive plastic parts.[13]

Another technology is 3D printing, in which droplets of API formulations are printed on edible substrates, such as films or excipient tablets, via an approach such as ink-jet printing.[53,54] This allows powder handling to be replaced with more readily controllable, liquid-processing operations. Liquid formulations can include solutions, polymer melts, emulsions, or suspensions. Moreover, solid depositions can be produced with API in either a crystalline or amorphous form. This approach allows for automation and precise control over material properties, fluid and deposit temperature, drug morphology, droplet size, and dissolution rate[55] and may potentially be used for personalized medication. While this approach is most advantageous for low-dose drugs, 3D printing using more conventional multilayer deposition is also feasible for high-dose drugs and has been utilized for the commercial manufacturing of an approved drug product.[56]

Strip-film manufacturing is another emerging technology that can be naturally adopted for continuous manufacturing. Solvent casting is the most widely used manufacturing method for thin films where aqueous polymer and API solutions are combined, deaerated, and transferred to the casting station where the solution is cast into films on a release liner. The cast film is dried and can then be cut into the desired shape.[57] Utilizing nanoparticle suspensions, this method can be adopted to produce finished dosage forms for poorly soluble APIs with higher drug loading.[58] Film drying via combined conduction and convection leads to commercially feasible drying times. Material properties of the polymers (eg, viscosity) used in film production have a significant impact on content uniformity and stability of the final dosage form.[59] The cutting of the film into different sizes enables flexible or metered dosing. Films can also be rolled or compressed to form multi-layer tablets, permitting the delivery of higher doses.[60] It is anticipated that other emerging technologies will be developed as the adoption of continuous pharmaceutical manufacturing spreads.

37.4.8 Process integration

In designing a continuous manufacturing process, although the analysis and optimization of individual process equipment remain important, the primary objective is to identify and evaluate design elements that pose a potential risk to product quality for the fully integrated system. In an integrated process, individual pieces of equipment (ie, unit operations) are connected in series. In such a process, a train of multiple units, one after the next, is connected via piping to sequentially perform, for example, powder-to-tablet manufacturing without isolation of intermediates. The output of a preceding unit becomes the input of the subsequent unit, with material continuously flowing from one unit to the next.

For continuous manufacturing, understanding the dynamics of this flow of material through the process is a critical aspect of process understanding and enables material traceability (the ability to preserve and access the identity and attributes of the material throughout the process). Such an understanding of process dynamics can be obtained by characterization of RTD through a tracer experiment and/or process modeling.[23,61,62] The RTD is a probability distribution that describes the amount of time a mass or fluid element remains in a process. In tracer experiments, a pulse or step change of tracer is added to the inlet of the continuous equipment, and the response of the tracer concentration profile at the outlet is measured. The overall RTD for the manufacturing process can be computed from the experiments for each unit operation measured separately, using a convolution integral.

The RTD curve can be utilized to predict the propagation of material or disturbances through the system or, in a retrospective analysis, to determine when the ingredients in a given product unit were fed to the manufacturing system. The RTD is dependent upon several factors, such as processing time, equipment parameters, and material properties and thus could be purposefully managed through active control of these process variables. One option to describe the material traveling through the system is to define a traceability resource unit (TRU).[63] A TRU can be specified as a segment of material that flows through the process together and can then serve as a unique identifier from a process history perspective to achieve traceability throughout the integrated continuous process. Understanding of process dynamics has implications on process monitoring and control, as described next.

37.4.9 Process monitoring and control

The control strategy for a continuous process should be designed to control the quality of the product in response to potential variations in the process, equipment conditions, incoming raw materials, or environmental factors over time. Due to the absence of isolated intermediates and the typically faster process dynamics, a continuous process may necessitate more frequent measurements, with real-time monitoring of process parameters and quality attributes of in-process materials, typically constituting an essential component of a control strategy for a continuous process. The adoption of an active process control system, enabled by the availability of real-time process and quality data, provides an opportunity to increase efficiency, lower operating costs, and improve control of product quality.[4] Specifically, an active process control system allows process parameters to be adjusted in response to disturbances to ensure that the quality attributes consistently conform to the established acceptance criteria. The active process control system for integrated processes should be able to appropriately respond to both fast (within a unit operation) and slow (propagating from upstream unit operations) disturbances.[64,65] The risk of producing out-of-specification product is lowered through the implementation of adaptive engineering controls.

PAT tools can be applied to measuring surrogates for the quality attributes of a final product, some of which may have already been incorporated into the control strategy for process monitoring and control. For this reason, continuous manufacturing naturally lends itself to real-time release testing (RTRT), which is the ability to evaluate and ensure the quality of in-process materials and/or final product based on process data that typically include a valid combination of measured raw material attributes and process controls.[66] A supervisory control and data acquisition system can be implemented. Such a system incorporates measurements of process parameters, incoming raw material, and in-process material attributes, as well as final product quality attributes with a model of the process to reconcile the data in order to support RTRT.[65,67] Due to a high frequency of data collection, statistical methods for large sample sizes can be applied to increase the confidence level that the batch conforms to the desired quality.[68] RTRT batch calculations should consider the observed variance in critical quality attributes over the production run to account for intra-batch variability. A risk analysis aids in consideration of PAT failure, and procedures can be developed in order to establish contingencies for process monitoring and batch release. The procedures could include end-product testing or utilizing surrogate measurements to ensure that the product maintains an acceptable level of quality.[15]

In addition to naturally lending itself to RTRT, the increase in the amount of process and quality data

collected during a continuous production facilitates the adoption of multivariate process monitoring approaches. Multivariate statistical process control (MSPC) is a process monitoring approach used to determine whether the variability in the process is stable over time.[69] It can be used to detect abnormal events in the process that may lead to adverse consequences (eg, out-of-specification product, equipment malfunction, or process safety incident) and provide diagnostic information for the event and identify points for mitigation. Taking advantage of the fact that process variables are often correlated, MSPC simplifies process monitoring by reducing the number of control charts being tracked without losing information. MSPC may also enhance the detection of abnormal process operations by identifying changes in the relationships among process parameters and quality attributes,[69] which may be difficult to detect using solely univariate process monitoring approaches.[70] Once an abnormal event is detected, then diagnosis of its cause may be facilitated by the use of the direct real-time measurement data and previously recorded abnormal event signatures to diagnose the fault and initiate appropriate mitigation actions.[71] The detection of the abnormal event can also serve as trigger for tracking the nonconforming material, which will be generated until the process returns to normal operation. Suitable strategies for segregating this nonconforming material will also be required.

37.5 CHALLENGES IN IMPLEMENTING CONTINUOUS MANUFACTURING

There are several inherent technical challenges to continuous manufacturing, including material handling, PAT, process flexibility, process models for material tracking, and optimizing process start-ups and shutdowns. The extent of these challenges will depend on the specifics of the product and manufacturing route. In continuous manufacturing, materials must continuously flow between unit operations over an extended period of time. This can be a particular challenge for powder materials, where many material attributes (eg, density, cohesion, and electrostatics) may affect flowability. The potential build-up of materials within the process over time due to adhesion presents another challenge for long manufacturing campaigns.[72]

As previously noted, real-time monitoring typically constitutes an essential component of a control strategy. The sampling interface for these PAT measurements in a continuous manufacturing system can be challenging, especially for heterogeneous powder systems. Industrial experience indicates that poor measurement performance is often attributable to sampling system issues rather than the process analyzer itself.[73] On-line and in-line measurements may reduce, but do not necessarily eliminate sampling errors.[74] Thus, sampling considerations should be assessed. For example, the location of the sensor should be evaluated to achieve representative sampling and minimize the effect of the probe on the process. Powders and dispersions limit the penetration depth of spectroscopic techniques. This may increase the importance of the sample probe location,[75] size of the sampling spot, intensity of the incident signal, etc. The sample size for the measurement should be representative of a unit dose and consider factors such as flow rate, penetration depth, and the number of scans. It is important to utilize the knowledge of the process dynamics (eg, RTD) for determining the adequate sampling frequency for PAT measurements. The measurement frequency implemented should provide sufficient resolution for the detection of a pulse of variability expected from a process disturbance.

Flexibility can be designed into a continuous manufacturing line to enable production of different drug products and/or different volumes. The first key step for incorporating flexibility is to build the process utilizing modular unit operations. Modular unit operations allow the equipment to be connected in a different order, depending on the process design (eg, the output of the blender in Fig. 37.2 can be disconnected from the input of the fluid-bed wet granulator and connected to the input of the roller compactor). Then the manufacturing line can adopt different manufacturing routes for a product through various modules, according to the formulation chosen. If a manufacturing line is design to produce multiple products, then cleanability and set-up time become extremely important.[13] Process models can facilitate the examination of different manufacturing routes. Continuous processing, compared with batch processing, offers a greater opportunity to develop and better utilize process models to gain process knowledge because their governing equations generally can be simplified. From a design standpoint, process models can be utilized as a tool to evaluate equipment configurations and manufacturing routes to determine a process configuration and ranges of unit operating parameters that will meet the desired objectives. This information can then lead to more focused experimental development efforts, which could eventually result in a higher level of process understanding. The reduction in experimentation due to process design evaluation reduces materials usage (eg, API, excipients), waste, development time, cost, and personnel exposure.[76,77]

For a given process design, process modeling can be utilized to perform sensitivity analysis to identify the

key interactions or relationships among process parameters and material or product attributes to support a quality risk assessment.[76] In addition, predictive process models can be used to understand how disturbances might propagate through a continuous process, which is another area of concern. Specifically, if a disturbance enters the first unit operation in a series, the question arises as to whether that disturbance will spread out, and if so, by how much. The RTD for each unit operation can be utilized to predict the propagation of material or disturbances through the system in order to answer this question. In addition to understanding each unit operation's transfer function, care must be taken to understand the system capacitance and delay times associated with material transport operations between steps. Care must be taken during design and testing of the individual and overall system controls to ensure that the system dynamics do not become unstable and lead to control system runaway or other chaotic phenomena because complex interconnected systems with time delays are inherently nonlinear. The careful design of mixing steps and buffer tanks in a continuous process can be used to help smooth process dynamics by dampening process variability. However, the dampening action also must be balanced against injecting sluggishness into the process dynamics, which can counteract effective control action. It is expected that process modeling can enable testing of system dynamics and control strategies offline and that model-based control of the process can be a key element in minimizing the impact of disturbances on product quality.[4,13] The development of modular equipment and the advancement of process modeling for pharmaceutical operations can enable flexible processing lines, matching the flexibility offered by batch processing.

During planned start-up and shutdown, there may be periods of time when the in-process material or product does not meet the target quality attributes. In cases where a continuous manufacturing line is producing multiple products, each manufacturing run may be a couple of days or even less than a single day, depending upon the desired production volume. Optimizing start-up and shut down then to minimize product waste is another key challenge in order to make it cost effective. Dynamic process models can be very effectively used to study and optimize start-up and shutdown strategies by taking the process through a series of well-defined intermediate states, including timely sequencing of unit operation start and stop times to decrease material losses. For example, a continuous blender could be filled completely, and mixed in a batch mode (with no discharge) for a few moments prior to allowing material to pass to the next process step. Although the process may not be at steady state, the material could still be processed so as to meet the desired quality attributes (eg, blend uniformity).[78] Utilizing available dynamic optimization methodologies can be an effective way of identifying start-up/shut-down strategies that may be challenging to discover by trial and error.[79] Reduction in wasted material can also be achieved by design by minimizing system volume to the extent possible, because the average system residence time for a given throughput will increase proportionally to the hold-up volume, and typically 3–5 residence times must pass before a process achieves steady state.

37.6 CONCLUSION

Continuous pharmaceutical manufacturing offers potential flexibility, quality, and economic advantages over batch processing, both in process development and manufacturing for the pharmaceutical sector. Over the past decade, there have been significant advancements in science and engineering to support the implementation of continuous pharmaceutical manufacturing. These investments, along with the adoption of the QbD paradigm for pharmaceutical development and the advancement of PAT for designing, analyzing, and controlling manufacturing, have progressed the scientific and regulatory readiness for continuous manufacturing. Building on this progress, research efforts should continue in several key areas to address the remaining implementation challenges.

Drug Product Approval in the United States and International Harmonization

L. Wu[1], *H. Smith*[1], *H. Zheng*[2] *and L.X. Yu*[1]

[1]U.S. Food and Drug Administration, Silver Spring, MD, United States [2]Albany College of Pharmacy and Health Sciences, Albany, NY, United States

38.1 DRUG PRODUCT APPROVAL AND THE US FOOD AND DRUG ADMINISTRATION

Any person or organization who intends to bring a drug product to market in the United States must, by law, first submit a marketing application to the US Food and Drug Administration (FDA). The FDA is responsible for reviewing each marketing application and determining whether the applicant or sponsor has provided adequate evidence of safety, efficacy, and quality to warrant marketing approval. FDA oversight of drug products extends, as described in Chapter 21 of the Code of Federal Regulations and guidance documents, over the lifecycle of marketed drug products and to all relevant drug manufacturing activities and facilities. This chapter presents a current overview of the drug approval process as it pertains to new drug applications (NDAs), abbreviated new drug applications (ANDAs), and biologics license applications (BLAs) in the context of FDA.

38.1.1 History and background of drug regulations in the United States

The US FDA is a scientific, regulatory, and public health organization, and is the oldest federal agency dedicated to consumer protection. The history of the US federal food and drug regulatory system can be traced back to the commercial and custom food laws of the 1800s. The Biologics Control Act of 1902 introduced premarket requirements for some biologic therapeutic products. The Pure Food and Drug Act of 1906 was the first comprehensive legislation for foods and drugs, identifying official standards for drugs and offering definitions for misbranding and adulteration; it was enforced by the US Department of Agriculture (USDA) Bureau of Chemistry. In 1927, the Bureau of Chemistry was reorganized within the USDA and gave rise to the Food, Drug, and Insecticide Administration, which was renamed the FDA 3 years later and moved from the USDA to become the forerunner of today's Department of Health and Human Services. The Food, Drug, and Cosmetic Act of 1938 (FDCA) was a complete overhaul of the 1906 Act and gave the FDA responsibility for approving the marketing of new drug products on the basis of safety considerations. Criteria for drug efficacy were added to the approval process with the 1962 Kefauver-Harris amendments to the FDCA.

In the 1980s, The Drug Price Competition and Patent Term Restoration Act of 1984, commonly known as the Hatch-Waxman Act, was designed to promote competitiveness in the development of innovative drug products and to bring more affordable versions of approved drugs—that is, generic versions—to the market.[1] The Hatch-Waxman Act created the ANDA process, whereby applicants of generic drug products may generally rely on the clinical studies used to support approval of an innovator product (ie, the reference listed product (RLD)) from a safety and efficacy perspective. The generic drug approval process thus avoids much of the time and cost associated with the development of "innovator" drugs. Moreover, the Public Health Service (PHS) Act of 1944 introduced oversight of biologics, whereas its amendment under section 351(k), signed into law on Mar. 23, 2010, created an abbreviated licensure pathway under the Biologics Price Competition and Innovation Act (BPCI Act) for biological products that are demonstrated to be

Developing Solid Oral Dosage Forms
DOI: http://dx.doi.org/10.1016/B978-0-12-802447-8.00038-8

"biosimilar" to or "interchangeable" with a biological product already licensed under section 351(a) of the PHS Act.[2]

More recent legislation that pertains to drug regulation by the FDA includes the FDA Safety and Innovation Act of 2012 (FDASIA).[3] Under FDASIA, the FDA has been authorized for the first time to collect user fees upon receipt of applications for the marketing of generic and biosimilar drug products; FDASIA also reauthorized, for the fifth time since 1992, the collection of prescription drug user fees. The user fee acts (UFAs) for prescription drugs (PDUFA), generic drugs (GDUFA), and biosimilars (BsUFA) commit the agency to the timely review of marketing applications and allow the agency to increase the staff and resources dedicated to this purpose.

38.1.2 Current organization of the FDA

The FDA consists of the Office of the Commissioner and four directorates—Office of Foods and Veterinary Medicine, Office of Global Regulatory Operations and Policy, Office of Medical Products and Tobacco, and Office of Operations—each including substantive centers and offices, responsible for overseeing the core functions of the agency. The Office of the Commissioner provides leadership for the FDA's science and policy initiatives and ensures consistent program direction and management across the agency. The FDA Office of the Chief Counsel provides legal services to FDA on matters involving FDA-regulated drugs, reviews and evaluates FDA enforcement actions, and helps defend the agency in litigations.

Within the four directorates, six substantive centers (Center for Drug Evaluation and Research (CDER), Center for Biologics Evaluation and Research (CBER), Center for Veterinary Medicine, Center for Food Safety and Applied Nutrition, Center for Tobacco Products, and Center for Devices and Radiological Health (CDRH)) and the Office of Regulatory Affairs (ORA) conduct the bulk of FDA's scientific and regulatory evaluations and apply statutory authority over drugs (human and veterinary), food, cosmetics, tobacco, and devices and radiological products.[4]

ORA is the lead office for all agency field activities, bearing the main responsibility for inspecting establishments that produce FDA-regulated products, including foods and veterinary medicine, medical products, and tobacco and tobacco-related products. ORA professionals work collaboratively with the six FDA centers to protect patients and consumers and provide public outreach and education.[5] ORA and CDER collaborate together to ensure quality of drugs for human use as relates to their manufacture.

38.1.3 Center for Drug Evaluation and Research (CDER) organization

CDER is responsible for the timely review of all data submitted by sponsors relevant to the safety, quality, and efficacy of drug products (which include prescription, generic, over-the-counter (OTC), and selected biologic drug products). The CDER organizational chart is shown in Fig. 38.1. A set of review

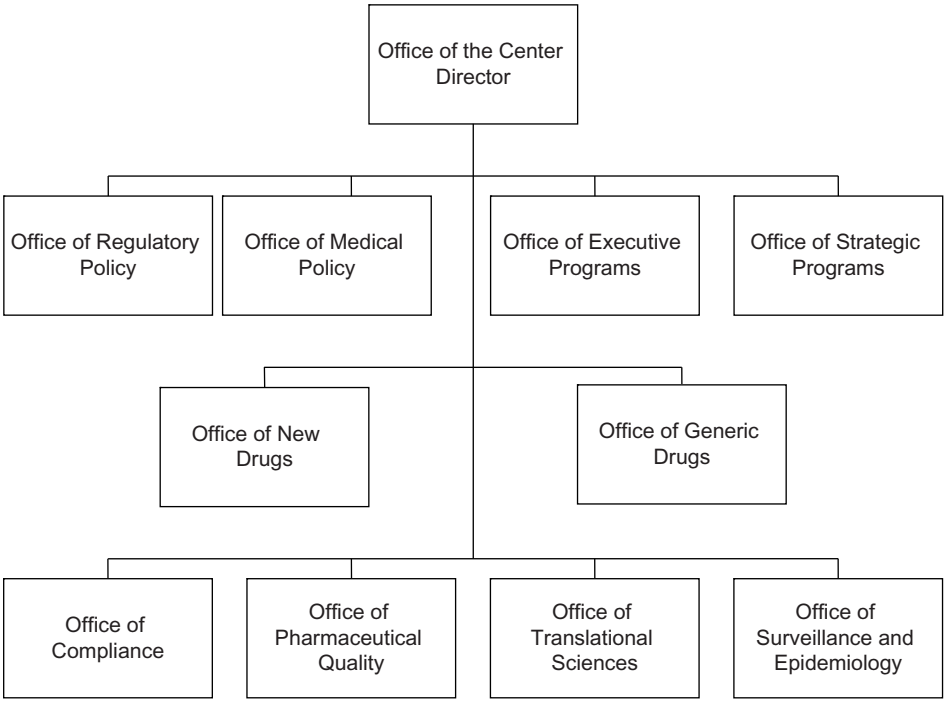

FIGURE 38.1 The organizational structure of the FDA Center for Drug Evaluation and Research.

initiatives taken at CDER, including 21st Century Review, Computational Science Center, Critical Path, Equal Voice, and Pharmaceutical Quality for the 21st Century, are essential for a current understanding of drug product evaluations within CDER.[6] In addition, the launch of Office of Pharmaceutical Quality (OPQ) in 2015 has greatly reconfigured collaborative structures within CDER as well as between CDER and ORA, strengthening the agency's focus on pharmaceutical quality, as we discuss next.

38.1.4 Pharmaceutical quality oversight[7]

The chemistry, manufacturing, and controls (CMC) section of marketing applications, wherein information is presented that is essential to the FDA assessment of the identity, strength, quality, and purity of drug substances and products, is under the purview of OPQ. OPQ is strategically organized to streamline regulatory processes, advance regulatory standards, align areas of expertise, and originate surveillance of drug quality. OPQ intends to set the global benchmark for regulation of pharmaceutical quality across all drug products (new, generic, OTC) and across all sites of manufacturing (domestic and foreign). The launch of OPQ within CDER integrates the review, inspection, surveillance, policy, and research of all drug substances (also known as active pharmaceutical ingredients (APIs)) and drug products. OPQ orchestrates many aspects of the regulatory review of NDAs, ANDAs, and BLAs, and centralizes functions for policy-making, research and science activities, project management, quality management systems, and administrative activities. The organization of OPQ is depicted in Fig. 38.2. OPQ creates a single umbrella organization that consolidates all CDER quality review by establishing its Office of New Drug Products (ONDP), Office of Lifecycle Drug Products (OLDP; for generic drug products and postapproval activities of new molecular entities (NMEs) and non-NMEs, 3 years and 1 year after approval, respectively), and Office of Biotechnology Products (OBP; for biologics and biosimilars). Process, facility, and microbiology reviewers within the OPQ Office of Process and Facilities (OPF) evaluate pharmaceutical manufacturing process design and controls and assess the feasibility of implementation at a commercial scale, participating in facility inspections as determined through risk- and science-based principles. The Office of Program and Regulatory Operations (OPRO) is accountable for leading and coordinating regulatory operations, maintaining a quality management system, and driving professional development and learning programs in collaboration with OPQ review offices. The Office of Policy for Pharmaceutical Quality (OPPQ) develops, implements, and updates science- and risk-based policies, standards, and guidance documents. The OPQ Office of Surveillance (OS) maintains information on all facilities involved in the manufacture of drugs destined for US patients and conducts risk analysis and monitoring across the entire inventory of facilities. The OPQ drug product quality laboratories (including the Office of Testing and Research (OTR) and the OBP laboratory component) conduct research to support the development of scientific standards and policies and provide

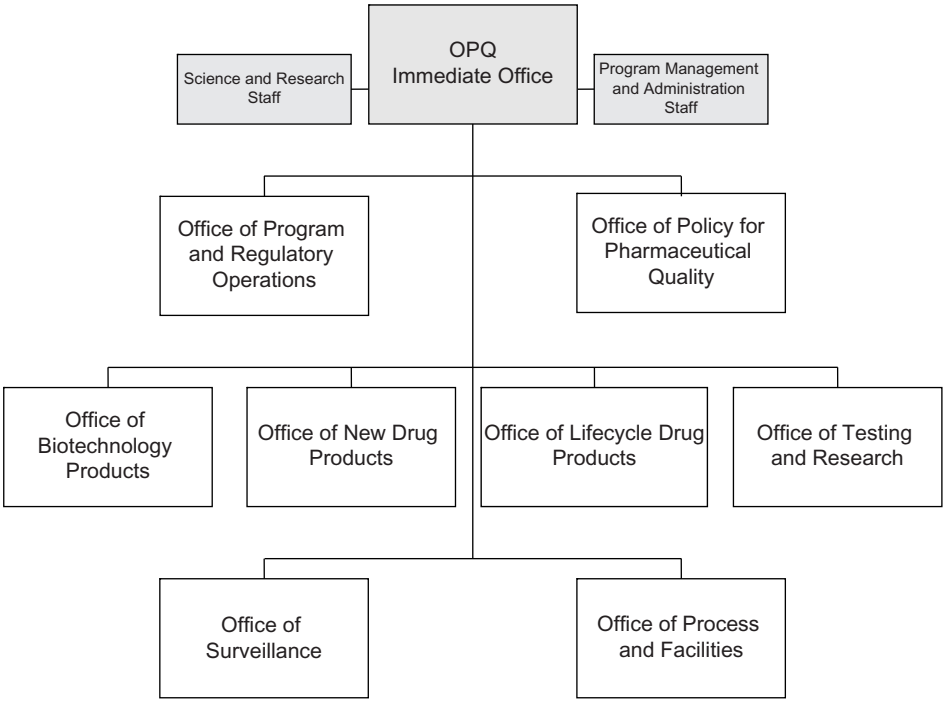

FIGURE 38.2 The organizational structure of the CDER Office of Pharmaceutical Quality.

advice, collaborative research opportunities, and scientific training for review staff. The OPQ Immediate Office consists of administrative staff and a science and research staff committed to emerging technologies and the elaboration of knowledge management within OPQ.

38.1.5 New review initiatives

As outlined in the goals for Pharmaceutical Quality for the 21st Century,[8] OPQ makes use of new review initiatives to encourage implementation of risk-based approaches that focus industry and FDA attention on the critical areas to facilitate modern quality management techniques, encourage early adoption of new technology advances, and ensure that regulatory review, compliance, and inspection policies are based on state-of-the-art pharmaceutical sciences. With the ultimate goal of putting patients first by balancing risk with availability, current initiatives in OPQ integrate review and inspection functions, under the motto of "One Quality Voice," by utilizing and developing staff expertise, facilitating continuous improvement of current review practices, and implementing question-based review (QbR) as a tool for risk-based review.

38.1.5.1 Team-based integrated quality assessment

The foundation of OPQ was conceptualized on a new review initiative known as team-based integrated quality assessment (IQA).[9] IQA maximizes reviewer expertise and effectively aligns patient-focused, science- and risk-based drug product quality recommendations, inclusive of drug substance, drug product, manufacturing, microbiology, biopharmaceutics, and facilities (Fig. 38.3). The team-building impetus within IQA integrates reviewers and field investigators and engenders effective and efficient communication, risk analysis, and quality assessments pertaining to facilities, products, and marketing applications. Reviewers and field investigators work collaboratively and are supported by project management and technical leadership; in many cases, the application reviewers participate in inspections.

Compared with the old review model that used a single reviewer for all quality information in an application, often resulting in inconsistent communication between review disciplines, the OPQ review model employs a team of experts to achieve "One Quality Voice" through collaborative assessment and consistent communication. The structure of an IQA team is shown in Table 38.1. Review disciplines may include drug substance, drug product, process, facility, microbiology, biopharmaceutics, and ORA investigators. Team advisors may come from OPQ laboratories, policy, surveillance, and other offices as needed. The application technical lead (ATL) is responsible for overseeing the scientific content of the assessment, while the regulatory business project manager (RBPM) is responsible for process and timeline.

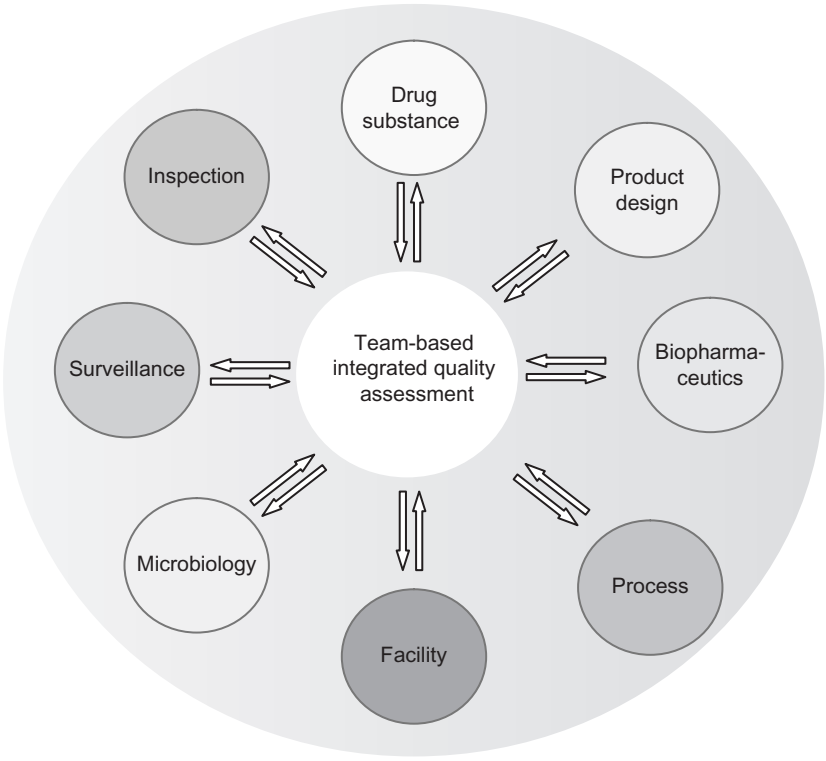

FIGURE 38.3 High-level illustration of team-based Integrated Quality Assessment.[9]

TABLE 38.1 Structure of Integrated Quality Assessment Team[10]

Role/task	Responsibility[a]
Scientific content/initial risk assessment	Application technical lead (ATL)
Process and timeline	Regulatory business project manager (RBPM)
IQA executive summary	ATL/IQA team
Assessment of drug substance	Drug substance (DS) reviewer
Assessment of drug product	Drug product (DP) reviewer
Assessment of manufacturing process	Process reviewer
Assessment of facilities	Facility reviewer
Assessment of biopharmaceutics	Biopharm reviewer
Assessment of microbiology	Microbiology reviewer
Assessment of environmental analysis	Environmental analysis (EA) reviewer
Labeling and package insert	DP reviewer
Facility inspections	ORA leads/subject matter experts (SMEs) participate
Lifecycle knowledge management	ATL/IQA team

[a]*Represents general cases.*

In a typical IQA review process, the following steps are taken: (1) the ATL performs the initial risk assessment; (2) review team is assembled; (3) timelines, preliminary findings, filing issues, etc. are discussed at the kick-off meeting; (4) there is constant communication between the review team members through formal and informal meetings and discussions; (5) consolidated quality comments are discussed, finalized, and communicated to the applicant; (6) review is finalized and the final "One Quality Voice" recommendation is communicated to CDER internal stakeholders, such as Office of New Drugs (OND) or Office of Generic Drugs (OGD). This process facilitates knowledge sharing between the team members; as members of the team, ORA investigators become apprised of any quality issue uncovered by OPQ reviewers; conversely, reviewers are updated as to any inspection findings. The collaboration between the OPQ reviewers and ORA field investigators ultimately enhances the quality assessment of the product and leads to more appropriate decisions on approvability of applications and acceptance of facilities. Moreover, by employing the IQA approach, timeframes are met effectively when aligned with user fee programs deliverables (mid-cycle, late cycle, etc.).

38.1.5.2 *Question-based review (QbR)*

QbR was fully implemented in 2007 as a tool for evaluation of CMC/quality information in ANDAs and has since been implemented as a review tool for the other applications. QbR questions were revised in 2012 and 2014 to include quality-by-design (QbD) concepts; new QbR templates for both NDA and ANDA are currently being developed that would support the integrated team-based review approach within OPQ,[11] and the trend toward using QbR will likely widen. The QbR approach transforms the CMC review into a modern, science- and risk-based pharmaceutical quality assessment; it reflects the FDA's "21st century cGMP initiatives," incorporates established components of CDER review (eg, the CDER 2004 Clinical Pharmacology and Biopharmaceutics Review Template),[12] and resonates with other regulatory authorities (eg, Health Canada). QbR is intended to guide the industry by making the FDA's CMC expectations clear and to facilitate reviewer evaluations of product quality. The wide-ranging benefits of QbR include: (1) the promotion of QbD principles by the sponsor across product development, leading to performance-based specifications; (2) facilitation of risk-based assessments by both the sponsor and the agency; (3) process improvements that minimize the need for supplement submissions; (4) consistency and transparency of CMC evaluations across the entire pharmaceutical industry; and (5) optimization of CMC review efficiency.[13]

The questions incorporated into QbR relate to drug substance and drug product quality standards, process understanding, and scale-up; help the reviewer to comprehensively assess critical formulation and manufacturing process variables; set regulatory specifications relevant to quality; and determine the level of risk associated with the manufacture and design of the product.

QbR questions and answers are incorporated in the quality overall summary (QOS) in Module 2 of the common technical document (CTD). The CMC data provided in Module 3 of the CTD are always reviewed in conjunction with the QbR questions and answers[14] (see discussions of QbR in chapters: "Modern Pharmaceutical Regulations: Quality Assessment for Drug Substances" and "Modern Pharmaceutical Regulations: Quality Assessment for Drug Products" of this edition).

38.1.5.3 *Emerging technologies*

Recognizing that drug shortages and product recalls are commonly related to compromised product or facility quality, OPQ's efforts include sustaining improvements in manufacturing quality. OPQ's Emerging Technology Team (ETT) encourages innovation through continuous dialogue with academia, industry, and other governmental agencies, and clarifies and establishes

regulatory policies for the introduction of new technologies, such as continuous manufacturing and 3D printing. The aim of ETT is to support advances in pharmaceutical manufacturing technology, which potentially will address drug shortages and product recalls and revigorate the pharmaceutical manufacturing sector in the United States. The knowledge gained from collaboration among OPQ and external stakeholders will eventually translate into new policies that reflect state-of-the-art manufacturing science and encourage manufacturers to adopt new manufacturing technologies in support of a state of continuous improvement. One example is the FDA's encouraging continuous pharmaceutical manufacturing; this technique offers potential flexibility, quality, and economic advantages over traditional batch-processing methods. Another example is 3D printing. In fact, the FDA has recently approved the first 3D-printed tablet in a review process that proved the efficiency of OPQ initiatives in team-based IQA, emerging technology, structured review format (QbR), integration of scientific research and review, as well as of facilities and inspection activities[15] (see discussions of emerging manufacturing technology and continuous manufacturing in chapter: "Emerging Technology for Modernizing Pharmaceutical Production: Continuous Manufacturing" of this edition).

38.1.6 Current drug approval overview

When a NDA/BLA is submitted to the FDA, it is the responsibility of the applicant or sponsor to provide evidence that the product(s) to be reviewed are safe, effective, and of high quality. The FDA has brought new elements of flexibility into the application review process over the past few decades, but the overall drug development and approval process generally follows a few defined steps: (1) preclinical investigation, (2) clinical investigation, (3) postapproval marketing surveillance, and (4) lifecycle management (Fig. 38.4). An overview of the stages of drug development, relevant application submissions, and corresponding regulatory paths is provided next.[16]

Before any clinical investigations may begin concerning an experimental drug, the sponsor must submit an investigational new drug (IND) application. Clinical investigation generally consists of three phases. In Phase I, safety studies are conducted in a small number of individuals (20−200 persons); in Phase II, efficacy studies begin in volunteers (up to several hundred) of the target population; and in Phase III, the most extensive and expensive part of drug development, human testing continues in a substantial number of patients (several hundred to several thousand).[17] In general, once Phase III is complete, with all clinical and nonclinical data collected, the sponsor can submit a NDA under section 505(b)(1) of the FDCA. In particular, applications for drugs that show great promise in phase II can also be submitted under FDCA 505(b)(1) and approved in an accelerated approval process with the caveat that the sponsor must still perform confirmatory phase III studies. In the case of a sponsor who intends to rely, to any extent, upon safety or effectiveness investigations that were not conducted directly by or for the sponsor, the NDA may be submitted in accordance with FDCA 505(b)(2). Whereas the 505(b)(1) application relies on full reports of investigations of safety and effectiveness conducted by or for the sponsor, or on investigations for which the sponsor has obtained a right of reference or use, for the 505(b)(2) application, at least some of the information required for approval comes from data not developed by the sponsor, such as published literature or the FDA's findings of safety and effectiveness of a previously approved drug product.[18]

Once approved, the drug product can be marketed; moderate or major modifications to approved applications should be submitted to the FDA for review as postapproval changes, referred to as supplements. After NDA approval, the next stage in the lifecycle of a drug product occurs when all forms of exclusivity (eg, patent protection) have expired for the "innovator," or RLD. At that point, under FDCA section 505(j), the RLD may be cited in the submission of an ANDA, through which the applicant seeks to market a generic version of the drug product. An ANDA contains information to show that the proposed generic product is pharmaceutically equivalent to the RLD. The proposed product and the RLD contain the same active ingredient, are of the same dosage form and route of administration, are identical in strength or concentration, and meet compendial or other established standards.[19] An important regulatory standard, termed "bioequivalence," provides the basis for establishing product substitutability (discussed next). Through reliance on bioequivalence (BE), ANDAs do not entail the

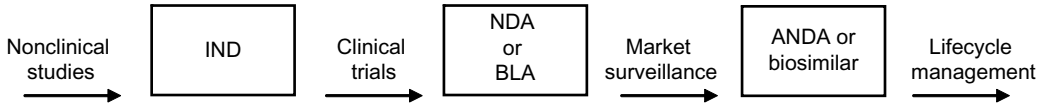

FIGURE 38.4 Typical drug development process, emphasizing the relative positions of the various drug marketing applications in the lifecycle review of drug products.

TABLE 38.2 Major Drug Approval Regulatory Pathways and Implementation Acts

Statute and CFR section	Categories	Original legislation	User fee acts
FDCA 505(b) (21CFR 314)	NDA	FDCA 1938	PDUFA
FDCA 505(b)	NDA	Waxman-Hatch 1984	PDUFA

PHS 351 (42USC 262)	Biologics	BCA/PHSA 1902/1944	PDUFA
PHS 351(k)	Biosimilars	BPCIA 2009	BsUFA

expenditures of time and money that normally characterize the submission of NDAs.

Whereas the NDA is used for marketing approval under FDCA provisions, the BLA can be used, under section 351 of the PHS Act, by applicants seeking to market biological products. Submission of a BLA obviates the need for submitting an NDA[20]; the BLA must contain information on product, manufacturing process, and manufacturing facilities, and licensure commits the applicant to the continued safety, purity, and potency of the product. The abbreviated pathway for a BLA is a biosimilar, established through section 351(k) of the PHS Act, according to which the proposed biosimilar must be highly similar—showing no clinically meaningful differences, in terms of safety and effectiveness—to an FDA-approved biological reference product. Only minor differences in clinically inactive components are allowable in biosimilar products.

A list of major approval regulatory pathways, along with their basis in statute is provided in Table 38.2. More details on the format and requirements for each type of submission can be found in corresponding individual sections of this chapter.

38.2 THE NEW DRUG APPLICATION PROCESS

Submitted NDAs should comprehensively provide all clinical and nonclinical drug development efforts undertaken by or on behalf of the sponsor. CDER reviewers will assess all data to conclude whether adequate evidence has been established with regard to safety, efficacy, risk-benefit profile, proposed labeling, and quality.[21]

38.2.1 INDs and presubmission of NDAs

Before conducting any of the clinical trials that will provide data for review in the NDA, sponsors are required to have submitted an IND application; the IND should summarize key attributes including appropriate stability of the drug substance, drug product, and their preparation, evidence of safety, and efficacy from preclinical studies, and should demonstrate the preparedness of investigators for clinical trials.[22] An IND may fall within two categories: commercial or research (noncommercial). A Commercial IND is an IND for which the sponsor is usually either a corporate entity or one of the institutes of the National Institutes of Health (NIH).[23] A Research IND is usually submitted by a physician for an unapproved drug or to investigate an approved drug for a new indication or new patient population (ie, "Investigator" IND) and anticipates the submission of an NDA. Additional types of INDs, such as Emergency-Use INDs and Treatment INDs, are essential in terms of public health. For patients who do not meet enrollment criteria for an existing study protocol, an Emergency-Use IND may make an investigational therapy available to a patient in a very short time frame. Treatment INDs may allow expanded access, in certain contexts of serious and life-threatening conditions, to experimental drugs that have not completed clinical testing.

Good communication between the sponsor and FDA can greatly facilitate the process that the FDA must follow in receiving and evaluating an IND submission. Sponsors can request a pre-IND meeting to receive the agency's feedback on adequate information about the investigational drug substance, drug product and their manufacture, data from animal pharmacology and toxicology studies, and the proposed clinical investigation protocols, including information about investigator to information pertaining to chemistry, manufacturing, and controls to be provided in the original IND submission. All the information must be provided in the original IND submission before the FDA allows the clinical study to proceed. The following list describes IND content; also see Table 38.3.

1. *Cover sheet*—contains sponsor and investigator information, identification of the clinical investigation phase(s), and any commitments
2. *Table of contents*
3. *Introductory statement and general investigational plan*—provides information about the dosage form and route of administration, a brief history of the drug, and a description of the overall plan for clinical investigations

TABLE 38.3 List of IND Content and Regulatory Source Documents[24]

Content (documentation)
1. Cover sheet (eg, 21 CFR 313.23(a)(2))
2. Introductory statement and general investigational plan (eg, 21 CFR 313.23(a)(3))
3. Investigator's brochure (eg, 21 CFR 313.23(a)(5))
4. Protocols (eg, 21 CFR 313.23(a)(6))
5. Chemistry, manufacturing, and control information (eg, 21 CFR 313.23(a)(7)(iv))
6. Pharmacology and toxicology information (eg, 21 CFR 313.23(a)(8))
7. Previous human experience with investigational drug (eg, 21 CFR 313.23(a)(9))
8. Additional information (eg, 21 CFR 313.23(a)(10))
9. Relevant information as requested by the FDA (eg, 21 CFR 313.23(a)(11))

4. *Investigator's brochure*—contains a brief description of the drug substance and formulation; information on the pharmaceutical and toxicological effects of drugs in animals and, if known, in humans; safety and effectiveness in humans from prior clinical studies; and anticipated possible risks and side effects
5. *Protocols*—contains detailed descriptions for each planned study, including objectives of the study, criteria for patient selection, design of study, methods used, and results
6. *Chemistry, manufacturing, and control information*—includes basic information on drug substance (eg, structure), drug product (eg, formulation), any placebo or comparator used in a controlled clinical trial, supportive stability data, labeling to be provided to each investigator, and environmental analysis requirements
7. *Pharmacology and toxicology information*—provides information from pharmacological and toxicological studies used to conclude that the drug is reasonably safe for clinical investigations
8. *Previous human experience with investigational drug*—contains description of prior experience with the investigation or marketing of the investigational drug either in the United States or in other countries
9. *Additional information*—contains information regarding drug dependence and abuse potential and description of studies performed for special drugs, such as radioactive dosimetry calculations or pediatric safety and effectiveness
10. *Relevant information*—contains any other relevant information, as requested by the FDA

The IND should demonstrate that the sponsor can adequately produce and supply consistent batches of the drug product, that the proposed product is reasonably safe for initial testing in humans, and that the clinical investigators are qualified to perform their assigned trial duties. The IND must be submitted to the FDA at least 30 days before the first-in-human (FIH) trial may be initiated. If the FDA does not respond to the IND within 30 days, the sponsor may proceed with clinical trials per the application. If the FDA has concerns about the IND or about the conduct or results of ongoing clinical trials, the agency may impose a "clinical hold." Successfully elaborated clinical development, per IND regulations, will typically emanate from completed clinical investigation Phase I, II, and III, as described in Section 38.1.6.[17] The FDA review of Phase I focuses on product safety, whereas in addition to ongoing safety evaluation, review of Phase II and III submissions includes assessment of efficacy, clinical investigations, and the likelihood of meeting the statutory standards for marketing approval. With regard to quality, FDA reviewers assess whether chemistry and manufacturing data, pertaining to drug substance and drug product, may indicate health risks to subjects enrolled in IND trials. Such risks may be related to impurities in the drug substance emanating from synthesis or subsequent degradation, physical/chemical instability of the drug product, or poorly characterized components, toxic chemical structures, or poorly characterized cell banks (master or working).[25] Information on the drug substance and drug product should be provided in a summary report, containing physical, chemical, and biological characteristics relevant to drug substance, composition of the drug product; a brief description of the manufacturing process; acceptable limits and analytical methods used to assess drug identity, strength, quality, purity, and stability. It is expected that the amount of the CMC information will vary with the phase of investigation, scope of the proposed clinical investigation, and production scale; upon submission of an NDA, however, CMC data and the quality of drug substance and drug product should be rigorously documented.

38.2.2 Format and content of the NDA

The purpose of the NDA is to supply documentation of "adequate and well-controlled investigations," including data gathered during preclinical (eg, animal, cell culture) and human clinical investigation for FDA review. The format and content of NDA submissions to the FDA are specified in regulations (21CFR 314.50) and reflected in "harmonized" application form FDA 356(h), used for all drug products (and therefore also in BLA requirements, as discussed next). The contents of an application specified in this form are listed next; also see Table 38.4.

TABLE 38.4 NDA Content and Regulatory Source Documents for Drugs and Biologics[26]

Content/item (documentation)
1. Index (Table of Contents)
2. Labeling (*check one*) _ Draft Labeling _ Final Printed Labeling
3. Summary (21 CFR 314.50 (c))
4. Chemistry Section
a. Chemistry, manufacturing, and controls information (eg, 21 CFR 314.50(d)(1); 21 CFR 601.2)
b. Samples (21 CFR 314.50 (e)(1); 21 CFR 601.2 (a)) (Submit only upon FDA's request)
c. Methods validation package (eg, 21 CFR 314.50(e)(2)(i); 21CFR 601.2)
5. Nonclinical pharmacology and toxicology section (eg, 21 CFR314.50(d)(2); 21 CFR 601.2)
6. Human pharmacokinetics and bioavailability section (eg, 21CFR 314.50(d)(3); 21 CFR 601.2)
7. Clinical microbiology section (eg, 21 CFR 314.50(d)(4))
8. Clinical data section (eg, 21 CFR 314.50(d)(5); 21 CFR 601.2)
9. Safety update report (eg, 21 CFR 314.50(d)(5)(vi)(b); 21 CFR 601.2)
10. Statistical section (eg, 21 CFR 314.50(d)(6); 21 CFR 601.2)
11. Case report tabulations (eg, 21 CFR 314.50(f)(1); 21 CFR 601.2)
12. Case report forms (eg, 21 CFR 314.50 (f)(2); 21 CFR 601.2)
13. Patent information on any patent which claims the drug (21U.S. C. 355(b) or (c))
14. Patent certification with respect to any patent which claims the drug (21 U.S.C. 355 (b)(2) or (j)(2)(A))
15. Establishment description (21 CFR Part 600, if applicable)
16. Debarment certification (FDCA 306 (k)(1))
17. Field copy certification (21 CFR 314.50 (l)(3))
18. User fee cover sheet (Form FDA 3397)
19. Financial information (21 CFR Part 54)
20. Other (Specify)

1. *Index*—A detailed index is necessary to guide FDA reviewers through the entire NDA. The index must clearly describe the contents and location of each section by volume and page number.
2. *Labeling*—The inclusion of drug product labeling is essential to the NDA and must be submitted electronically using structured product labeling (SPL) formatting in compliance with the Physician's Labeling Rule (PLR), as described at 21 CFR 201.56 and 201.57.[27]
3. *Summary*—The NDA summary provides an overview of safety, efficacy, and quality of the drug product for its proposed use. It states conclusions derived from the most important data within the NDA. Content of the summary should be presented as follows[28,29]:
   a. Proposed text of labeling for the drug—annotated;
   b. Pharmacological class, scientific rationale, intended use, and potential clinical benefits;
   c. Foreign marketing history;
   d. Chemistry, manufacturing, and controls summary;
   e. Nonclinical pharmacology and toxicology summary;
   f. Human pharmacokinetic and bioavailability summary;
   g. Microbiology summary (if required);
   h. Clinical data summary and result of statistical analysis;
   i. Discussion of benefit/risk relationship and proposed postmarketing studies.

   The summary is important because it provides FDA reviewers with an indication of the overall quality and accuracy of the NDA and the information it presents. The summary should be written as if prepared for publication in a recognized scientific journal and should integrate all salient information in the application to provide a general understanding of the drug product.
4. *CMC/pharmaceutical quality*—The pharmaceutical quality section (also known as the CMC, or chemistry section) provides detailed information on the composition, design, manufacture, test methods, specifications, container closure system, and stability of the drug substance and the final drug product.

   The drug substance subsection should detail all pertinent physical and chemical properties and tests performed to demonstrate the identity, purity, potency, and stability of the drug substance. The consistency and methods of its manufacture, along with a description of the manufacturer (eg, operations and operations control, facility layout, relevant product and processing portfolios, and prevention of contamination), should be described in adequate detail. Although drug substance information is often included in the NDA submission, information to be submitted in an application for drug substance is often submitted in a drug master file (addressed in Section 38.3.4.2 of this chapter).

   Similarly, the drug product subsection must present a rigorous account of product characterization, product and process design, manufacture and packaging, drug product specifications, microbiology, container closure system, and stability. Recommendations are provided next regarding the CMC information that should be included[30]:
   a. Description and composition of the drug product—states the name, function, and amount of each active and inactive ingredient in the drug product and describes the dosage form and container closure systems proposed for marketing

b. Pharmaceutical development report—contains information on the development studies conducted to establish that the dosage form, formulation, manufacturing process, container closure system, microbiological attributes, and usage instructions are appropriate for the purpose specified in the application; includes description of any QbD efforts to enhance product and process understanding and process control, including defining the quality target product profile (QTPP) as it relates to quality, safety, and efficacy, determining critical quality attributes (CQAs) of the drug product, linking raw material attributes and critical process parameters (CPPs) to CQAs and performing risk assessment, developing a design space, designing and implementing a control strategy, and managing product lifecycle and continual improvement[31,32]

c. Manufacture—states the names, addresses, and responsibilities of the manufacturers, describes the manufacturing and packaging processes, including flowcharts indicating production steps with equipment, materials and in-process controls and tests (eg, operating parameters, environmental controls, process tests, and in-process material tests) for the finished dosage form

d. Control of excipients—describes the excipients, lists all the specifications and tests performed to confirm their quality, and identifies novel excipients and excipients of human or animal origin

e. Control of drug product—describes specification and tests selected to assure product quality (related to safety and efficacy) and lot-to-lot consistency of the finished product; presents sampling procedures and method validation results; lists all expected drug product impurities; and identifies degradation products, residual solvents, and other miscellaneous drug product impurities

f. Reference standards—provides information on the reference standard(s) used to test the drug product or its impurities

g. Container closure systems—describes the proposed container closure system(s) in which the drug product will be marketed, including the identity of materials of construction and their compatibility with the drug product

h. Stability—describes the stability protocols and results supporting the proposed expiration-dating period and storage conditions; provides the postapproval stability protocol and stability commitment

i. The remaining information in the pharmaceutical quality section refers to samples of drug substance, finished product, and/or reference standard (if requested during the review), validation of analytical methods, and environmental impact. It is important that these subsections provide adequate detail so that FDA quality reviewers can thoroughly assess any scientific matter that may have a bearing on drug product performance.

5. *Nonclinical pharmacology and toxicology*—All animal and laboratory studies relevant to review of the NDA must be included. During review of this section, the FDA reviewers look for toxic effects that may be inconsistent or inadequately characterized.[33] Acute, subacute, and chronic toxicity, pharmacological activities, and potential carcinogenicity and teratogenicity must be addressed. The section should also include a statement that avers good laboratory practices (GLPs) for each study or a brief explanation for any instance of deviation from GLPs.
6. *Human pharmacokinetics and bioavailability*—Clinical pharmacokinetic and bioavailability data and analyses should be detailed, and relevant analytical and statistical methods must be described. A reasoned discussion of the pharmacokinetics, metabolism, and bioavailability of the drug product is essential.[34]
7. *Clinical microbiology*—A clinical microbiology section is provided only when effects on the physiology of a targeted microorganism are relevant to the review of the NDA (eg, review of an anti-infective drug product). This section addresses the drug action on microbial physiology, the antimicrobial spectrum affected, resistance mechanisms, and laboratory methods used. The possibility of sepsis arising from products should be addressed (eg, liquids that can support microbial growth or topical products that can spread bacteria).[35]
8. *Clinical data section*—There is an extensive set of FDA guidance documents related to clinical studies in NDA submissions, which cannot be summarized in detail here.[36] The clinical dataset is the basis of efficacy and safety of the proposed drug product and generally includes the following[37]:
   a. List of IND and NDA investigators supplied with the drug
   b. List of INDs and an overview of clinical studies

c. Other NDAs submitted for the same drug substance
d. Overview of the clinical studies
e. Description and analysis of clinical pharmacology studies; controlled clinical studies relevant to the proposed use of the drug product; uncontrolled studies; and other data pertaining to the evaluation of the drug product
f. Integrated summary of effectiveness (ISE), including support for the dosage and administration of the drug as proposed in the product labeling
g. Integrated summary of safety (ISS), with a discussion of adverse events, drug-drug interactions, pertinent animal data, and any other safety concerns (eg, abuse and overdose potential)
h. Integrated summary of risk-benefit (ISRB)
i. Compliance statement regarding good clinical practices (GCPs), the Institutional Review Board (IRB), and informed consent (IC)
j. Data regarding special populations, such as geriatrics, pediatrics, or patients with renal or hepatic impairment

9. *Safety update*—The first safety update report is usually filed as an amendment 4 months after the submission of the original NDA; other safety updates may be provided at other times specified by the FDA reviewing division. The format of the safety update report is similar to the ISS (see previous section) and contains safety information that arises from ongoing studies, animal studies, and other sources. Sponsors should work with the FDA to determine the content and format of these safety updates.
10. *Statistical*—This section of the NDA is closely linked to the clinical data section. Sponsors should work closely with the FDA prior to the NDA submission to come to an agreement on the format, content, tabulations, and statistical analyses to present. This section should be carefully addressed during the pre-NDA meetings with the FDA.
11–12. *Case reports*—Tabulations of cases of patient data and data elements with proper case report forms (CRFs) are essential. The detailed requirements can be discussed at the pre-NDA meetings or, if the FDA so requests, after submission of the NDA. The CRFs for patients who died during a clinical study and for patients who discontinued due to an adverse event should also be included. FDA reviewers may require additional CRFs as well.[37]
13–14. *Patent information and certification*—Patent certification is required for any relevant patents that claim the listed drug or any other drug on which the investigations relied, or that claim a use for the listed drug or any other drug.
15. *Establishment description*—This section provides general information about the organization, physical plant, and major equipment, as well as quality assurance functions.
16. *Debarment certification*—The FDA is authorized to debar individuals convicted of crimes related to the development, approval, or regulation of drugs. The individual should not provide any type of services to sponsors of an application.[38]
17. *Field copy certification*—Applicants based in the United States must submit a "field" copy of the pharmaceutical quality (CMC) section, application form, and summary of the NDA to the relevant FDA district office. The information will be used during the pre-approval inspection (PAI) at the manufacturing site. Within the NDA, the applicant must certify that an exact copy of the CMC section has been sent to the district office.
18. *User fee cover sheet*—FDA Form 3397 is used to determine the applicability of a user fee and indicate whether a check has been mailed to an FDA account concurrent with submission of the NDA.[39]
19. *Financial information*—Clinical investigator financial disclosures (FDA Form 3455) and certification (FDA Form 3454) must be included, describing investigator financial interests and sponsor-investigator financial arrangements that could affect the reliability of the submitted data.[40]
20. *Other information*—Any information that was submitted before the NDA should be referenced in this section. A sponsor may propose other uses of this section at the pre-NDA meeting.

38.2.3 The CTD format

The FDA highly recommends that sponsors submit all marketing applications in CTD format (see next). CTD format does not alter the data or information required for the NDA in the United States, as described previously.[41] The FDA also recommends (and beginning in 2017, will require) electronic submission of CTD-formatted applications (ie, "eCTD" submissions).[42]

The CTD is a product of the International Conference on Harmonization (ICH), an international organization composed of the pharmaceutical industry and regulatory representatives from the European Union, Japan, and the United States. The CTD provides a common format for submission of marketing applications submitted to the vast majority of agencies worldwide. The format

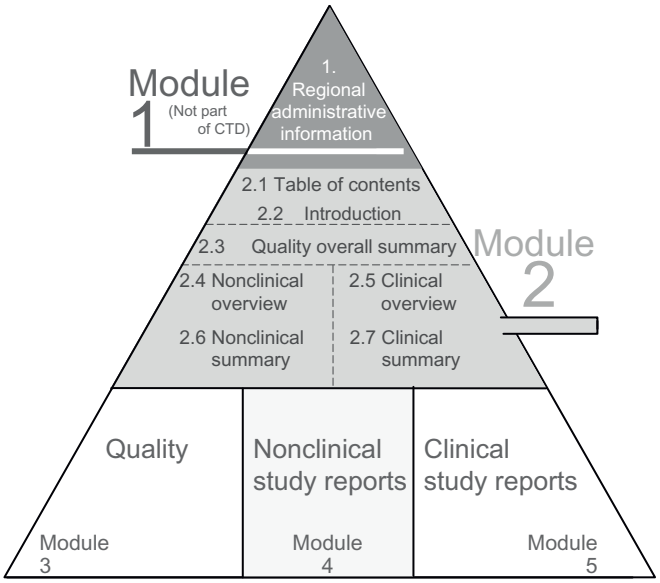

FIGURE 38.5 The common technical document (CTD) format (with Module 1 added).

and contents of CTD includes five modules, organized in the so-called "CTD triangle" diagram, as shown in Fig. 38.5.

Module 1 of CTD contains the regional administrative forms and documents as determined by each ICH region. In applications submitted to the FDA, this section contains the cover letter, form 356(h), complete table of contents of the entire CTD, and other administrative documents, such as the field copy certification, debarment certification, patent information, labeling, and the annotated labeling text. Module 2 contains the CTD summaries of information from various sections of the CTD, including a very short introduction; QOS; nonclinical overview; clinical overview; nonclinical written and tabulated summaries for pharmacology, pharmacokinetics, and toxicology; and clinical summary describing biopharmaceutics and associated analytical methods, clinical pharmacology studies, clinical efficacy, clinical safety, and a synopsis of the individual studies. Module 3 contains all of the pharmaceutical quality documents for the chemistry, manufacture, and controls of the drug substance, the drug product, and container closure system. Modules 4 and 5 contain copies of the final nonclinical and clinical study reports, respectively. The correspondence between the CTD modules and sections in an application (as described in the previous section of this chapter) is depicted in Fig. 38.6.

38.2.4 NDA review practices

38.2.4.1 Filing

Prior to submitting an NDA to the FDA, sponsors are strongly encouraged to request a meeting with the appropriate FDA review division and discuss the planned content of the application.[43] As previously discussed for the clinical phase of development (see IND Section 38.2.1), meetings between sponsors of a marketing application and FDA reviewers will help ensure that all submitted applications are complete and fileable. Marketing applications received by the FDA "central document room" are assigned a number, and the date of receipt starts the review time clock (see NDA review timelines in Fig. 38.7). When the NDA is ready for review, a regulatory project manager (RPM; note distinction from the OPQ RBPM) is charged with managing the review process and coordinating all communications with the sponsor accordingly. The RPM conducts an initial assessment (eg, whether a user fee has been paid, waived, or exempted). If all required fees have been paid and the information submitted is administratively complete, the application is then assigned to a multidisciplinary team of FDA reviewers, who by day 45 of the review (day 30 for priority reviews) must convene and discuss their respective decisions regarding the fileability of the application. All filing review issues identified by the review team are conveyed to the applicant in a single communication, which will be documented in writing and archived according to CDER standard procedures. Applications that omit necessary information not readily rectified may result in a refuse-to-file (RTF) letter that must be issued by day 60. Otherwise, a filing letter is issued and review activities are triggered within the FDA.[44]

38.2.4.2 Review

The overall NDA review and approval process (or "cycle") usually takes place in six major steps (presubmission activities, process submission, review plan, conduct review, take official action, and postaction feedback) as illustrated in Figs. 38.7 and 38.8.[45,46] Once the application is deemed fileable, a planning meeting is held with the review team to discuss timelines, high-level labeling revisions, need for advisory committees and/or inspections, and review activities. The review timelines for NDAs that are not governed under PDUFA V are 10 months from receipt for standard reviews and 6 months for priority reviews. NMEs and BLAs, as part of the PDUFA V "program," are reviewed within 12 months for standard submissions and 8 months for priority submissions from the date of submission (10 months and respectively, 6 months from the 60-day filing date). During the main review phase, each assigned reviewer, according to discipline (eg, medical officer, pharmacologist, chemist, statistician, microbiologist, clinical pharmacologist), assesses the pertinent portion of the application, proposes labeling revisions, and writes a review. Reviewers consult with each other and with their leads and communicate information requests (IR) to the applicant on a regular basis.

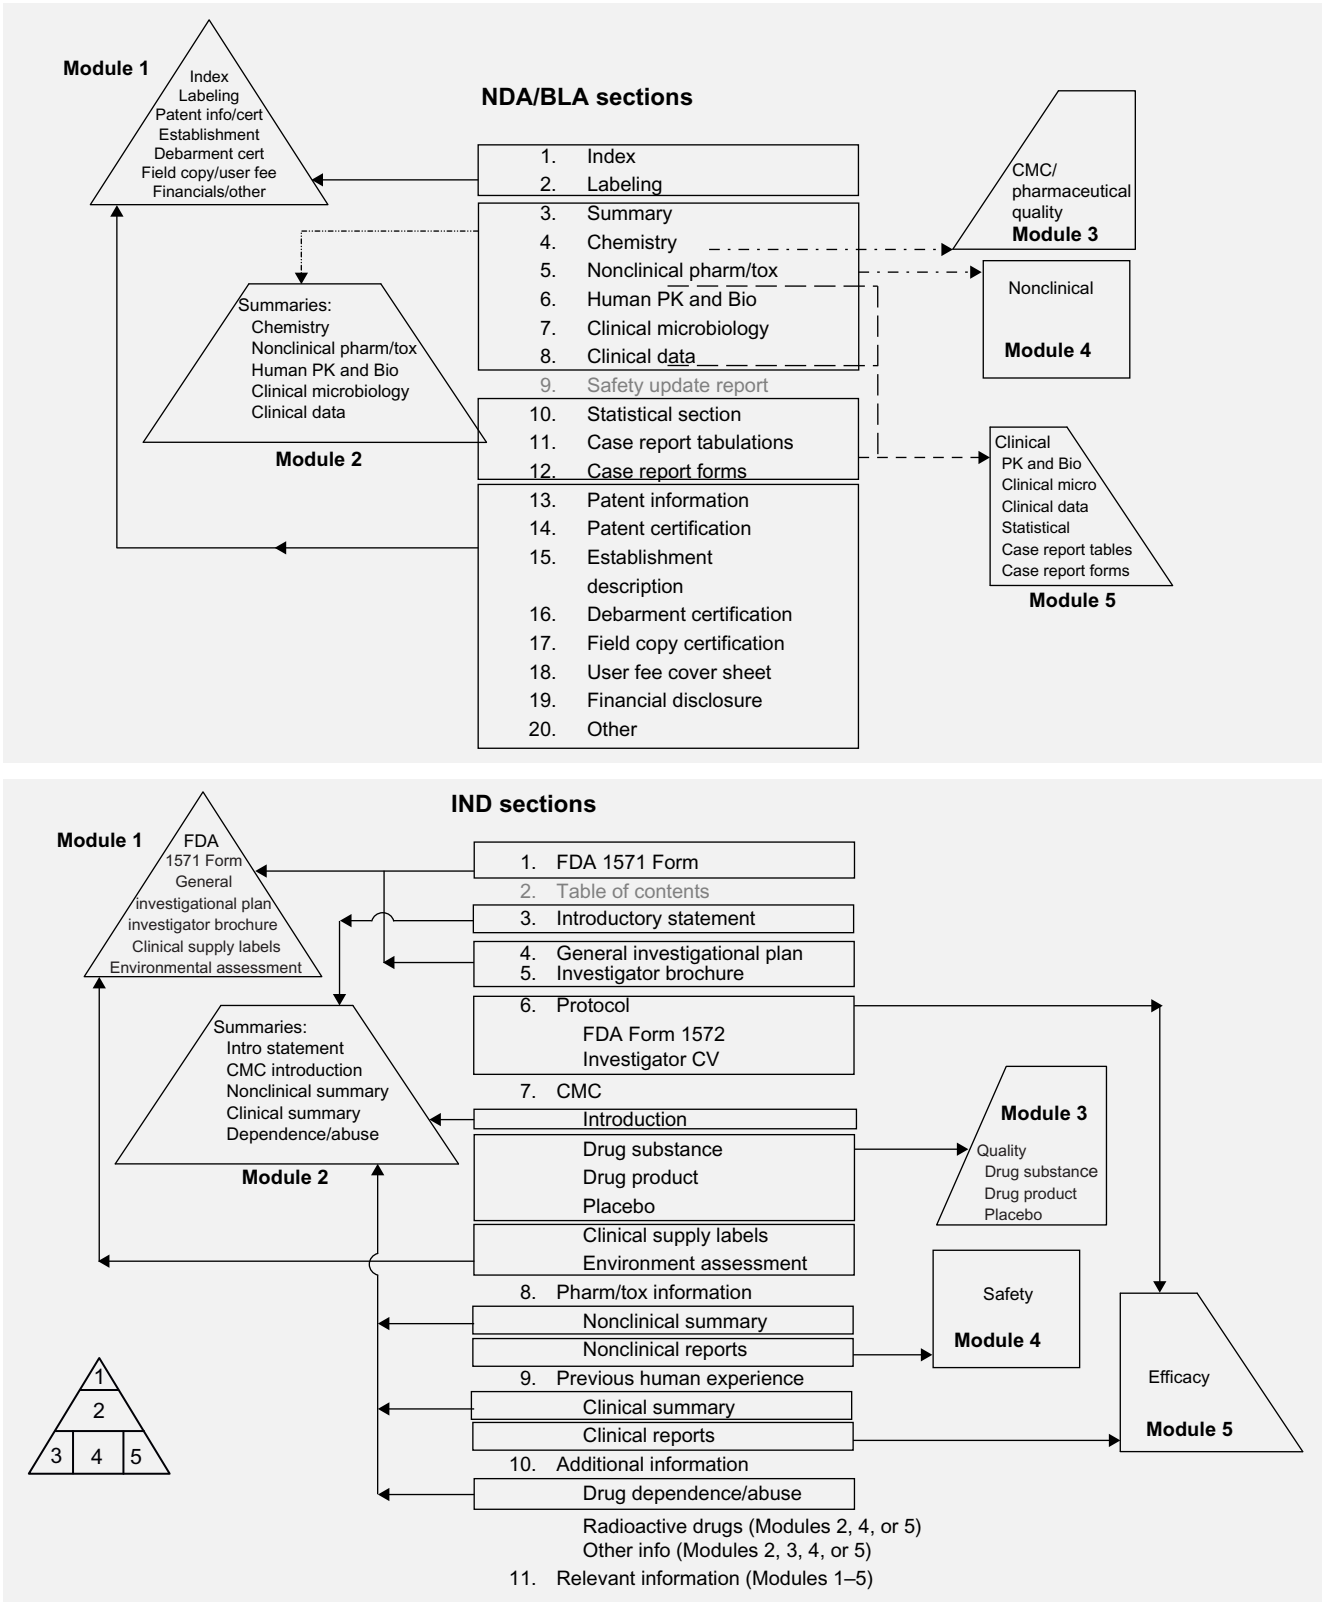

FIGURE 38.6 Mapping the NDA and IND into the five modules of the CTD triangle. *Source: Adapted from FDA internal presentation eCTD Clinic for CDER Reviewers and PMs by Valerie M. Gooding.*

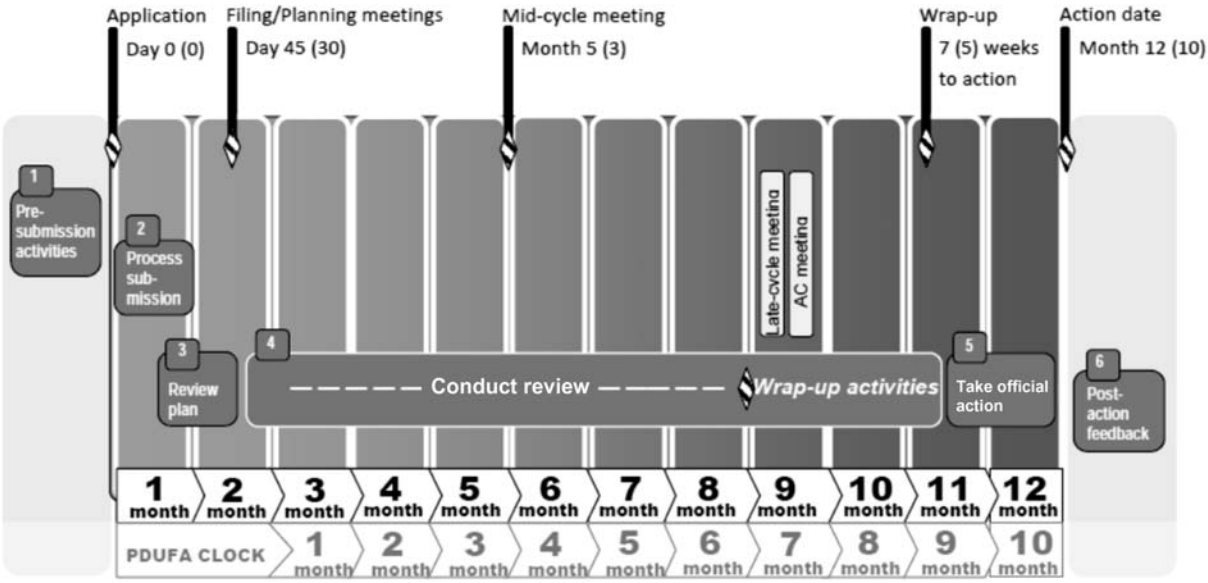

FIGURE 38.7 High-level illustration of the timeline for NDA/BLA reviews under PDUFA V. (The timeline for review of NMEs/BLAs under PDUFA V "program" extends "conduct review" phase by 2 months. Numbers in parentheses indicate priority review.)

All technical and high-level labeling issues that are critical to the approval of the application are identified by the time the mid-cycle meeting is held (ie, month 5 for standard reviews and month 3 for priority reviews). In addition to mid-cycle review, a late-cycle meeting between the review team and the applicant is generally held for standard PDUFA V "program" reviews no later than 3 months prior to the PDUFA V goal date (2 months prior to the PDUFA date for priority reviews). Deficiencies identified by respective disciplinary reviewers are usually communicated to the applicant in advance of the late-cycle meeting, although applications that involve complex issues may extend the review period by 2 months. The outcomes of all review activities, including inspection results, are integrated during the wrap-up meeting; the medical officer takes the lead to reconcile observations and written summaries, after which the action package is finalized.

In the event that the application is approved, the sponsor receives a letter that authorizes the manufacturer to distribute product in accordance with a list of agreements and any postmarketing commitments. If the agency decides on the basis of its review not to issue an approval letter, a complete response (CR) letter will be issued, citing deficiencies and offering recommendations. Mechanisms for additional feedback, after issuance of an approval letter or a CR letter, may be exercised in some cases. Postapproval meetings are offered for all NMEs (and original BLAs) and may otherwise be provided at the agency's discretion for the purpose of learning from the review experience. Applicants who receive a CR letter may request an end-of-review conference to be scheduled by the FDA to discuss deficiencies and further steps to take, including resubmission; withdrawal; or request an opportunity for hearing.[47]

38.2.4.3 Labeling

Final discussions about the package insert will usually take place near the end of the review period, possibly 2–4 weeks before the PDUFA action date (see Fig. 38.7). At this time, the FDA will communicate recommendations concerning the product label to the sponsor; and the agency and sponsor will work to reach final wording prior to the action date. The final negotiations for the labeling are often done by email or teleconference. The sponsor submits the final version as an amendment to the NDA in an electronic format.

38.2.4.4 FDA-sponsor communications during NDA review[46]

While evaluating the quality, safety, and efficacy of the drug product, based on a thorough scientific examination of the submitted application, reviewers may choose to seek clarification from the sponsor in the form of an information request email or teleconference, discipline review letter, or face-to-face meeting (appropriately documented within the agency). The RPM is involved, by phone or mail, in mediating status updates. Any information needed in support of application review must be officially submitted as an amendment to the application. Under present guidelines, communication per email is not official.

38.2.4.5 Advisory committee

If significant issues arise during the review process, the review team can seek advice from an advisory committee.

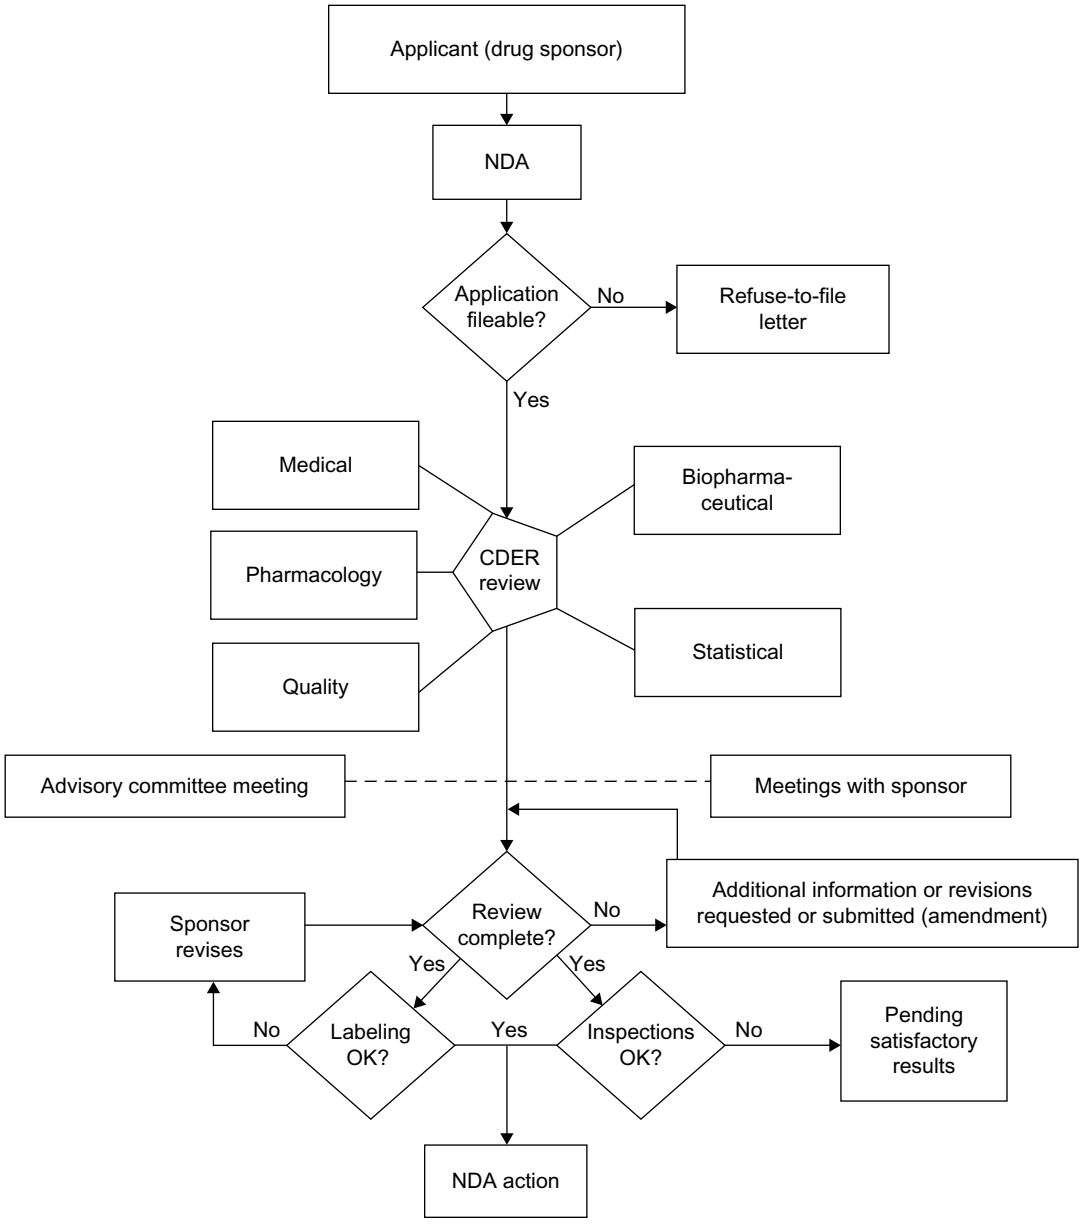

FIGURE 38.8 The NDA review process.

An advisory committee comprises a specialized group of external experts,[48] identified by the FDA, that convene to provide advice to the agency concerning any number of matters. Advisory committee meetings may be convened, for example, to discuss a NME; novel clinical trial designs or use of surrogate end points; particular safety issues or drug effectiveness in specific contexts; or public health questions arising from a proposed indication.

38.2.5 Special approval pathways for NDAs/BLAs

38.2.5.1 Expedited approval pathways

In order to increase the availability of drugs intended to treat serious and/or life-threatening conditions, four expedited drug-approval pathways have been created: priority review designation, accelerated approval, fast-track designation, and breakthrough therapy designation.[49] In 2014, among the 41 NDA/BLA applications approved by CDER, 27 (66%) fell within one of these expedited programs. Table 38.5 gives an overview of these programs. It should be noted that regulatory standards for efficacy, safety, and quality are to be rigorously upheld in all FDA review programs. Increased attention lately has been given to the breakthrough pathway, designed to expedite the development of drugs for life-threatening conditions or unmet medical needs. Scientific and logistic challenges posed by accelerated development and review can be alleviated by: (1) communication between sponsors

TABLE 38.5 Overview and Comparison of Expedited Approval Programs at FDA[49]

Program	Priority review designation	Accelerated approval approval pathway	Fast-track designation	Breakthrough therapy designation
Statuary reference	1992 PDUFA	21 CFR 314 & 601, FDCA 506(c)/ FDASIA	FDCA 506(b)/1997 FDAMA/FDASIA	FDCA 506(a)/FDASIA
Qualifying criteria	Serious condition and significant improvement in safety and effectiveness, if approved	Serious and life-threatening condition; and meaningful advantage over available therapies; effect on surrogate or intermediate endpoint reasonably likely to predict clinical benefit	Serious and life-threatening condition; and meet unmet medical needs	Serious and life-threatening condition; and substantial improvement on clinical significant endpoint over available therapies
Features	6-month review clock (compared with standard 10 month)	Approval may base on surrogate endpoint or intermediate clinical endpoint Confirmatory study obligation	Rolling review Actions to expedite development and review (eg, more frequent interactions)	Actions to expedite review Intensive FDA guidance Rolling review Organizational commitment Involvement of senior management

and the FDA regarding risk mitigation strategies to manage risk to product quality; (2) streamlining the review of stability data; and (3) using postmarketing commitments to address postapproval risk.[50]

38.2.5.2 *Orphan drug designation program*

An orphan designation signifies that a drug indication applies to a rare disease, which by definition affects fewer than 200,000 American patients per year. The Orphan Drug Act was enacted in 1983, recognizing that sponsors had little financial incentive to develop orphan drugs. The Orphan Drug Act (1983) and amendments (1992 and 2013) established several incentives to encourage the development of orphan drugs, including market exclusivity for 7 years after approval, fee waivers, tax credit on clinical research, technical assistance during the review process, as well as other federal research grants.[51]

38.2.5.3 *Pediatric exclusivity*

There have been a few FDA initiatives to improve medical product research and availability for children, including the FDA Modernization Act (FDAMA) of 1997, Best Pharmaceuticals for Children Act of 2002, FDA Amendments Act (FDAAA) of 2007, and FDASIA of 2012. Pediatric exclusivity is a 6-month extension of exclusivity added to existing periods of marketing exclusivity or patent protection.[52] The FDA is actively engaged in scientific programs that strive to improve access to drug products proven to be safe and effective for children.

38.3 THE ABBREVIATED NEW DRUG APPLICATION PROCESS

ANDAs contain information submitted to CDER for the review of generic drug products. Generic drug applications are "abbreviated" because they generally allow the sponsor to rely on preclinical (animal, cell culture) and clinical (human) data used to establish the safety and effectiveness of a RLD. In this way, generic products must be adjudicated as therapeutically equivalent to an approved drug product (ie, the RLD). Therapeutic equivalence must be established through the combined criteria of pharmaceutic equivalence and bioequivalence. Pharmaceutic equivalence signifies that the generic product and the RLD contain the identical API, API strength, dosage form, quality, performance characteristics, and that the route of administration intended use are the same for the generic and RLD.[53] Bioequivalence signifies that the generic product exposes the patient to the same amount of API in the same time course as the RLD, observed on the basis of plasma drug levels (see Section 38.3.3.2). Generic applications are filed under FDCA section 505(j) and authorized for marketing only after all forms of exclusivity for the innovator drug product have expired.

38.3.1 Format and content of the ANDA

The format and content of ANDA submissions to the FDA are specified in regulations (21CFR 314.94) and reflected in the "harmonized" application form, FDA 356(h). Table 38.6 gives the list of contents of an ANDA (described next) and shows the difference between the required contents of NDA and ANDA submissions.

1. *Index/table of contents*
2. *Basis for ANDA submission*—shows that the ANDA refers to the RLD selected by the FDA for conducting bioequivalence testing and documents a comparison between the generic drug and the RLD, including a statement according to which conditions of use recommended in the labeling proposed for the generic drug product have been previously

TABLE 38.6 Comparison of NDA and ANDA Contents

NDA	ANDA
	Basis of submission
	Comparison between generic and RLD
	Request for waiver for in vivo BA/BE studies (if applicable)
Labeling	Labeling
Summary	
Chemistry	Chemistry
Nonclinical pharmacology and toxicology	
Human pharmacokinetics and bioavailability	Human pharmacokinetics and bioavailability/bioequivalence
Clinical microbiology (if applicable)	
Clinical data	
Safety update report	
Statistical section	
Case report tabulations	
Case report forms	Case report form
Patent information	Patent information
Patent certification	Patent certification
Establishment description	
Debarment certification	Debarment certification
Field copy certification	Field copy certification
User fee cover sheet	
Financial information	Financial information
Other	References

approved for the RLD; states that the active ingredient is the same as that used in the RLD and that the route of administration, dosage form, and strength of the proposed drug product are the same as those of the RLD.

3. *Labeling*—according to 21CFR314.94, includes a side-by-side comparison of the applicant's proposed labeling (container and carton) and labeling approved for the RLD for each strength and package size; any differences (eg, those filed by petition under section 314.93 or differences owing to exclusivity under patent or under section 505(j)(4)(D) of the Act) should be explained in annotation. All labeling for a generic drug product must comply with the PLR and be provided in SPL formatting.
4. *CMC/pharmaceutical quality*—contains information as required under 21CFR 314.50(d).

The quality section of the ANDA, like that of the NDA, covers raw materials (eg, API, reagents, and excipients), manufacturing facility, manufacturing of the API and in-process controls, materials used in API packaging, controls for the finished dosage form, analytical methods, stability of the finished dosage form, sterilization assurance data, as well as samples and environmental considerations, generic enforcement act and a US agent letter of authorization (LOA). Stability requirements for generics and new drugs are identical, per ICH and FDA guidelines. A master production record (proposed or actual) and a description of the equipment to be used in the manufacture of the commercial batch of the drug product should also be provided.

There are differences between the pharmaceutical quality/CMC review for an ANDA and that for an NDA. The ANDA sponsor must typically reference a DMF previously submitted to the FDA containing proprietary information because the drug substances used in the manufacture of drug products that are the subject of ANDAs are usually obtained from third-party external manufacturers (see Section 38.3.4.2). There are also additional requirements for ANDAs that do not necessarily appear in NDAs:

- **a.** Any inactive ingredient in the proposed generic product that differs from the RLD should be identified and demonstrated as having no effect on safety and efficacy
- **b.** Specifications should be justified in reference to compendia (eg, USP, JP), ICH, and/or analysis of the RLD
- **c.** Release characteristics of the proposed generic (ie, dissolution) should be comparable to those of the RLD

Notably, in order to modernize the science- and risk-based pharmaceutical quality assessment of ANDA applications, the FDA has implemented a QbR approach (see Section 38.1.5.2), and sponsors are now generally expected to submit a QOS employing the QbR format.[54] QbR assists applicants in developing the QOS by providing specific questions to ensure that adequate information associated with the robust manufacture and reliable control is submitted for FDA review.

5. *Human pharmacokinetics and bioavailability/bioequivalence*—contains information that shows that the drug product is bioequivalent to the RLD.

According to current guidance from CDER, conclusions that two drug products are bioequivalent should reflect significant agreement in pharmacokinetic parameters (ie, area under the curve (AUC) and maximum concentration (C_{max}))

such that the entire 90% confidence interval associated with the generic-to-reference ratio of geometric means should fall within the bioequivalence limits of 80% to 125%. Exceptions exist, such as in the case of highly variable drugs and those with narrow therapeutic indices, and waivers of in vivo bioequivalence studies are also available in certain cases[55,56] (see discussions on bioequivalence in chapter: "Bioavailability and Bioequivalence" of this edition). Waivers of clinical bioequivalence studies (ie, biowaivers) can also be granted in some cases (eg, for parenteral solution or ophthalmic solution that is qualitatively (Q1) and quantitatively (Q2) the same as the RLD, or for highly soluble, or highly permeable, or rapidly dissolving drug products based on biopharmaceutics classification system (BCS)).[57]

6. *Case report forms*—(see case reports for NDAs)
7. *Patent information and certification*—contains all relevant patents for drug product, method of use, method of manufacturing, licensing agreements, disputed patent information, amended certifications, etc.

   ANDA sponsors must confirm patent certification under one of the following criteria (ie, paragraphs):
   - **a.** That no patent information on the drug product that is the subject of the ANDA has been submitted to the FDA;
   - **b.** That any such patent has expired;
   - **c.** The date on which such patent expires; or
   - **d.** That such patent is invalid or will not be infringed by the manufacture, use, or sale of the drug product from which the ANDA is submitted.
8. *Financial certification or disclosure statement* (see certification and financial information for NDAs).

   An applicant may amend an ANDA under review to revise existing information or respond to IR. In general, IR tend to involve the CMC (stability, specifications, analytical methods) or BE sections and are the major cause of delays in ANDA approvals. Applicants should take care to complete these sections prior to submission.

38.3.2 The CTD format of an ANDA

The FDA strongly recommends that all ANDAs be electronically submitted in the CTD format (eCTD); submission in eCTD format will be required as of May 15, 2017. ANDA submissions that are not in eCTD format are excluded from current GDUFA guidelines governing timelines for FDA review. The CTD format for ANDAs is similar to that for NDAs; however, the order of presentation (detailed next)[58] differs slightly.

Module 1 of the ANDA CTD submission contains several forms (ie, 356(h) (see previous NDA discussion), the GDUFA user fee cover sheet (FDA Form 3794), and Form FDA 3674), a cover letter, and administrative documents related to US agent, field copy certification, debarment certification, financial certifications, patent information and certification, as well as statements of right of reference and LOA for each DMF referenced in the ANDA. In addition, Module 1 contains information demonstrating that the generic product is the same as the RLD and if applicable, any biowaiver request. Labeling information as previously described is also submitted in Module 1. Module 2 contains the QOS, which provides an overview of the CMC section as related to drug substance and drug product; summary reports for bioequivalence studies are also submitted in Module 2. Similar to NDA submissions, Module 3 for ANDAs contains all the CMC information in the application. For drug substance, the applicant should provide general information, characterization, control of drug substance (eg, specifications, descriptions of analytical procedures, and validations), batch analysis with certificate of analysis (COA), information about reference standards or materials, container closure systems, and stability data, including retest period or expiration date. For drug product, the applicant should provide description and composition, information on the pharmaceutical development (including the pharmaceutical development report and microbial attributes), information about the manufacture (including manufacturing process and controls), information on the controls of excipients (including source and grades), information supporting the controls for the release of the drug product, information on reference standards or materials and container closure system, as well as stability data, postapproval stability protocols and stability commitments. Module 4 data do not generally apply to ANDAs. Module 5 contains the clinical study report data needed to demonstrate bioequivalence to the RLD.

38.3.3 ANDA review practices

38.3.3.1 Filing

Prior to submission, ANDA sponsors may choose to consult the FDA in the form of a controlled correspondence by requesting information on a specific element of generic drug product development, especially for first-generic products.[59] Formal meetings between the ANDA sponsors and the FDA before submission are not as common as for NDA sponsors, but they may be granted in special cases. Upon submission, the FDA determines whether each ANDA is sufficiently

complete to permit a substantive review. If the submission is incomplete, the agency can issue a refuse-to-receive (RTR) letter, which avoids extended review period, multiple review cycles and waste of resources. Common deficiencies that will elicit a RTR letter include: failure to provide the 356(h) form; nonpayment of user fees; lack of a designated US agent (for a foreign applicant); failure to provide the environmental assessment or claim of categorical exclusion; citing a suitability petition (ie, noting changes from the RLD) that is pending; lack of information for API and/or drug product (eg, inadequate stability data, batch records, or methods validation); and bioequivalence issues (eg, inadequate data, biowaiver, or dissolution). Complete ANDA submissions may be filed under Paragraph I, II, III, and IV certifications as listed in the "orange book" for the RLD (see Patent Information). An ANDA applicant who files a Paragraph IV certification must, within 20 days of filing, notify the innovator, who will have 45 days to take action upon receiving the notification. The FDA may hold the application up to 30 months, depending upon the outcome of the litigation between the innovator and the ANDA applicant, if any. A regulatory filing checklist for ANDA submissions is regularly updated on the FDA website.[60]

38.3.3.2 *Review*

As more and more RLDs have come off patent, and as more companies have entered generic drug manufacturing, the volume of ANDAs has been increasing over the past decade, resulting in a considerable backlog of submissions. An important objective of GDUFA was therefore to set timelines for review and resolve the ANDA backlog by 2017. The FDA is committed to review and act, within 15 months from submission, on 60% of those original ANDAs submitted between Oct. 1, 2014 and Sep. 30, 2015 (ie, the year 3 cohort); similarly, 75% of those submitted between Oct. 1, 2015 and Sep. 30, 2016 (ie, the year 4 cohort), must receive action. The agency must act within 10 months on 90% of submissions made between Oct. 1, 2016 and Sep. 30, 2017 (ie, the year 5 cohort). For year 1 and year 2 cohorts (ie, received between Oct. 1, 2012 and Sep. 30, 2013 or between Oct. 1, 2013 and Sep. 30, 2014, respectively), the FDA will expedite review of Paragraph IV applications.[61] GDUFA review performance goals are depicted in Table 38.7, and ANDA review timelines for cohort 5 are schematized in Fig. 38.9. To ameliorate ANDA burdens and assist ANDA applicants in improving the quality of submissions, the FDA has issued a number of guidance documents.[62]

The bioequivalence, labeling, and CMC/quality sections of the ANDA are the major components of review. Bioequivalence is evaluated by comparing the extent of absorption of test and the reference products, in crossover clinical studies on healthy subjects, as determined by the AUC of plasma concentrations plotted over time. Both the AUC and peak plasma concentration C_{max} are used in the determination of bioequivalence. Recommendations of study designs and data evaluation for bioequivalence study, as well as appropriate in vitro dissolution methods, are listed in the FDA regulatory guidance.[64] Review of labeling text focuses on differences in excipients, presentation of pharmacokinetic data, clarity of information, and the utility of labeling language with respect to pharmacy practice. Reviewers of the CMC/quality information, organized within a number of disciplines, work in parallel to assess the quality of the drug substance and drug product, manufacturing and controls, batch formulation and records, facilities, product specifications, packaging, and stability. A number of review initiatives are underway

TABLE 38.7 GDUFA Review Performance Goals[63]

	FY 2013	FY 2014	FY 2015	FY 2016	FY 2017
Original ANDA	Expedite review of paragraph IV and maintain pre-GDUFA productivity		60% in 15 months	75% in 15 months	90% in 10 months
Tier 1 first major amendment	Maintain pre-GDUFA productivity		60% in 10 months	75% in 10 months	90% in 10 months
Tier 1 minor amendments (1st—3rd)	Maintain pre-GDUFA productivity		60% in 3 months[a]	75% in 3 months[a]	90% in 3 months[a]
Tier 1 minor amendments (4th—5th)	Maintain pre-GDUFA productivity		60% in 6 months[a]	75% in 6 months[a]	90% in 6 months[a]
Tier 2 amendment	Maintain pre-GDUFA productivity		60% in 12 months	75% in 12 months	90% in 12 months
Prior-approval supplements	Maintain pre-GDUFA productivity		60% in 6 months[a]	75% in 6 months[a]	90% in 6 months[a]
ANDA amendment and PAS in backlog on Oct. 1, 2012	Act on 90% by end of FY 2017				
Controlled correspondences	Maintain pre-GDUFA productivity		70% in 4 months	75% in 2 months	90% in 10 months

[a]*10 months if inspection is required.*

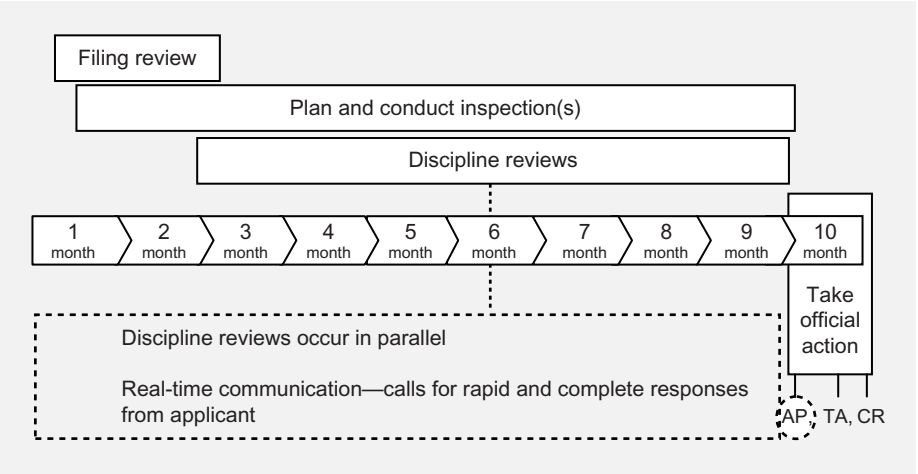

FIGURE 38.9 High-level illustration of the timeline for review of ANDA year 5 cohort.[65]

to ensure the timely review of ANDAs; some of these focus on information requests (IR), real-time communication (RTC), easily correctable deficiencies (ECD), and complete response (CR) letters. These initiatives are aimed at reducing the ANDA backlog and increasing the rate of ANDA approval.

If all review disciplines find the ANDA acceptable and if all facilities are in satisfactory standing as reviewed and inspected, the ANDA receives approval. If the ANDA review process is completed prior to the expiration of innovator drug product exclusivity, a notice of tentative approval (TA) may be issued, which does not allow the generic drug manufacturer to distribute product. An approval letter is contingent upon the resolution of litigation and issues related to product exclusivity.

38.3.4 Special considerations for ANDAs

38.3.4.1 ANDA filing and market exclusivity

New drug product exclusivity is provided by FDCA section 505(c)(3)(E) and 505(j)(5)(F). A 5-year period of exclusivity is granted to NDAs seeking to market a new chemical entity, either alone or in combination, but after 4 years, information pertaining to safety and efficacy from such an NDA approval may be used for the submission of a 505(b)(2) application or ANDA, provided that the submission supplies evidence of no infringement. If a follow-on drug product containing a previously approved active moiety is approved on the basis of new clinical investigations (other than bioavailability studies), then the follow-on product may be granted a 3-year period of exclusivity. Applicants seeking to market the first generic version of a drug product may be eligible for a 180-day period of exclusivity. Orphan drug exclusivity extends 7 years, and pediatric exclusivity gives 180 days of extension to existing patents or exclusivity.

38.3.4.2 Drug master files (DMFs)[66,67]

DMF is a document, prepared and submitted by a manufacturer that provides detailed proprietary information about facilities, process, or articles used in manufacturing processing, packaging, and storing. The submission of a DMF is not a regulatory requirement and is not a substitute for any marketing application; rather, it provides information to support an IND, NDA, ANDA, another DMF, an Export Application, or amendments and supplements to any of these. A DMF is typically filed when two or more firms work in partnership on developing or manufacturing a drug product; the DMF protects a firm's intellectual property from its partner while complying with regulatory requirements for disclosure of processing details. In the United States, DMFs can fall into one of five types[68]:

- Type I: Manufacturing site, facilities, operating procedures, and personnel (no longer applicable, such information for sterile and biotech products may be filed as a DMF Type V)
- Type II: Drug substance, drug substance intermediate, and material used in their preparation, or drug product
- Type III: Packaging material
- Type IV: Excipient, colorant, flavor, essence, or material used in their preparation
- Type V: FDA-accepted reference information

Before the FDA can review a DMF or DMF information in support of an application, the DMF holder must submit a LOA that allows the FDA to reference the DMF (the agency will review a DMF only if information in that DMF is referenced by another application). If the FDA reviewers find deficiencies in the information provided in a DMF, a letter describing the deficiencies is sent to the DMF holder. Deficiencies in a DMF cannot be disclosed to the sponsor who

references the DMF because the information is proprietary; however, the referencing sponsor is notified by the FDA if the DMF is deficient, and it is then the DMF holder's responsibility to notify the sponsor when deficiencies in the DMF have been addressed. A DMF itself is never "approved"; instead it is reviewed to determine whether it is adequate to support a particular application that references it.

DMFs are commonly used to support the drug substance information in ANDAs; such (type II) DMFs are subject to GDUFA fees, an initial "completeness assessment" (CA), and communications with DMF holders.[69] The CA review determines whether the DMF is ready to undergo a comprehensive scientific review, but does not guarantee that the DMF will be found adequate. Type II DMFs must cover characterization of the drug substance, manufacturing and controls of the drug intermediate or substance (including a list of the organic impurities, elemental impurities, and residual solvents), reference standards or materials, container closure system used for packaging the drug substance, and stability data and storage conditions. Only following the review of this information can the DMF be found adequate, allowing it to be referenced in an ANDA. A list of DMFs that have passed the completeness assessment and are available for reference by ANDAs under GDUFA is available on the FDA website.[70]

38.4 THE BIOLOGIC LICENSE APPLICATION PROCESS

Owing to the history of biological therapeutics in the United States—specifically, early vaccines and serum-derived agents—the FDA review of biologics is authorized not solely through the FDCA, but also through PHS Act section 351. Today, the spectrum of biologic drugs that are reviewed by CDER (in either the form of a BLA or an NDA) includes monoclonal antibodies and other proteins, such as cytokines, enzymes, growth factors, interferons, and nonvaccine therapeutic immunomodulators. The review of other biological products is the responsibility of the FDA CBER and includes: vaccines, blood and blood-derived components or products, plasma products, human tissues and cellular products, allergen patch tests, allergenic extracts, antitoxins, in vivo diagnostics, toxoids intended for immunization, and gene therapy.[71]

38.4.1 Format and content of the BLA

The harmonized application form FDA 356(h) used for all drug products (see previous sections of this chapter) also specifies format and content requirements for a BLA for a biologic product. The sections expected in the BLA are thus identical to those in the NDA: index, summary, CMC/pharmaceutical quality, establishment description, nonclinical pharmacology and toxicology, human pharmacokinetics and bioavailability, clinical microbiology, clinical data, statistical data, case report forms and tabulations, labeling, patent information, and establishment description. The CMC/pharmaceutical quality section in a BLA must present CMC information for both the drug substance and the finished dosage form of the product. Regardless of whether production is by fermentation, cultivation, isolation, or synthesis, the CMC information for drug substance includes description and characterization, manufacture and process control, manufacturing consistency, drug substance specifications, reprocessing, packaging, and stability. With regard to the drug product, the CMC section of the BLA must include information on composition and characterization, manufacturer and facilities, manufacturing methods, drug product specifications, container closure system, microbiology, lyophilization, and drug product stability. Typically, CMC subsection of the BLA is more detailed for the drug substance than for the drug product. Biologic drug products dosage forms are typically liquid or lyophilized, and the manufacturing process has relatively few steps. In contrast, drug substance manufacturing involves multiple steps needed to purify the intended product from a complex matrix composed of cells and other proteins. For an assessment of biosimilarity, BLA requirements additionally include data derived from analytical studies, animal studies (including assessment of toxicity), and clinical studies (including assessments of immunogenicity and pharmacokinetics/pharmacodynamics).[72] For details on the content of each section in an application, see Section 38.2.2 of this chapter.

38.4.2 BLA review practices

Biologic drugs conform to the FDCA definition of "drug" as given and are therefore subject to regulations that govern drug review and approval. Clinical studies of biologics in humans may be initiated and pursued under an IND in accordance with 21 CFR 312 (see Section 38.2.1), the results of which, along with relevant nonclinical data, can be submitted as part of a BLA. In reviewing a BLA, the FDA assesses whether the product, the manufacturing process, and the manufacturing facilities meet applicable requirements to ensure the continued safety, purity, potency, and quality of the product; the PHS Act emphasizes the importance of appropriate manufacturing controls for products, particularly where changes to the biological molecule that arise during manufacturing might not be detected by standard characterization techniques, and additional clinical studies are needed.

Similar to NDA review, the BLA review process is divided into six phases: (1) presubmission activities; (2) processing of submission; (3) plan of review; (4) conducting the review; (5) official action; and (6) post-action feedback (descriptions of these phases are provided in Section 38.2.4. of this chapter).[46] After receipt, the FDA must take action on submitted BLAs, for which a PDUFA V program is not specified, by 6 months (in the case of a priority review) or 10 months (for a standard review). (The timelines for NMEs and BLAs that fall under the PDUFA V program are discussed in Section 38.2.4.)

38.4.3 Special considerations for BLAs

38.4.3.1 Biosimilars

Section 351(k) of the PHS Act creates an abbreviated licensure pathway for biological products that are demonstrated to be "biosimilar" to or "interchangeable" with a biological product licensed under section 351(a) of the PHS Act.[73] Similar to the generic drug product approval, this pathway encourages competition and promotes affordable biologic drug products. Under the BPCI Act, a biologic is "biosimilar" if it is "highly similar to the reference product notwithstanding minor differences in clinically inactive components" and shows that "there are no clinically meaningful differences between the biological product and the reference product in terms of the safety, purity, and potency of the product."[72] The FDA applies rigorous scientific standards to assess biosimilarity and to make a determination that the biosimilar product is highly similar to the reference product and that there are no clinically meaningful differences between the biosimilar and the reference product.

Despite the analogy between biosimilar and generic products, there are fundamental differences between them.[74] Whereas the drug substances in generic drugs generally are homogeneous small molecules (of a single, readily defined structure), biologic drugs comprise large molecules, often glycosylated and subjected to posttranslational modifications. Consequently, a large number of analytical methods, including orthogonal assays, are necessary to characterize biologic drugs. In a series of recent guidelines on biosimilars,[73,75–78] the FDA has presented important scientific considerations for demonstrating biosimilarity, describing a stepwise approach that includes comparative studies of the proposed biosimilar and the reference product that evaluates structure, function, animal toxicity, human pharmacokinetic and pharmacodynamic data, clinical immunogenicity, and clinical data for safety and effectiveness. In the stepwise approach, the analytical, structural, and functional studies are the foundational elements in determining biosimilarity. These studies include comparative side-by-side analysis of primary, secondary, and higher-order structure, purity and impurity of the product, posttranslational modifications, both natural (eg, glycosylation) or chemical (eg, PEGylation), as well as an evaluation of the biological function and mechanism of action. At each step, sponsors should evaluate the results of the studies, identify any residual uncertainty, and design additional studies (nonclinical and clinical) to address the residual uncertainty.

The FDA has established biosimilar product development (BPD) meetings for sponsors to seek advice from the agency on certain aspects of the development program (analytical, nonclinical, and clinical) and obtain preliminary feedback on the similarity of the proposed product to the reference product. To ensure a successful development program, the FDA recommends that sponsors meet with the agency in early stages and at milestone steps throughout product development.[72] At the completion of the development program, sponsors submit a 351(k) BLA. The review process is the same for a 351(a) and a 351(k) BLA. The FDA will make a final determination that the proposed product is biosimilar to the reference product based on the totality of the evidence provided in the 351(k) submission.

38.4.3.2 Biosimilars and market exclusivity

Under the BPCI Act, a given marketed biologic (ie, the reference product) is granted a period of exclusivity in which the FDA cannot approve a biosimilar application (351(k) BLA) to a reference product for a period of 12 years. Furthermore, the FDA cannot file a 351(k) BLA earlier than 4 years from the expiration of the exclusivity period for the reference product. The Purple Book, published by FDA, lists licensed biological products, and their corresponding periods of exclusivity.[79]

38.4.3.3 BPCI act and protein products under NDA

The statutory definition of "biological product" evolved over the years. It was initially defined in the Biologic Control Act of 1902, and subsequently modified by the legislature in the PHS Act of 1944 to read "…any virus, therapeutic serum, toxin, antitoxin or analogous product applicable to the prevention and cure of diseases of man." The Food and Drug Act of 1906 and the Food, Drug, and Cosmetics Act of 1938 defined "drug" broadly to include, among other things, substances intended for use in the cure, mitigation, or prevention of diseases. Protein products could fall under either "biologic" or "drug" definition, and the FDA assigned jurisdiction to centers case-by-case until 1991, when an intercenter agreement clarified product jurisdiction between the Center for Drugs and

the Center for Biologics, with products assigned to CDER regulated under NDA and products assigned to CBER regulated under BLAs. As a result, some protein products were assigned to CDER and were regulated under NDA. With the BPCI Act of 2009, Congress further modified the definition of biological product, to include "protein, except any chemically synthesized polypeptide." With the new statutory definition of biological product, certain protein products, approved under section 505 of the FDCA, are now considered biological products. Congress ruled that within 10 years enactment of the BPCI, the protein products approved under NDA would be deemed BLAs. As of Mar. 23, 2020, marketing applications for a biological product (including forms of insulin, hyaluronidase, menotropins, and human growth hormones) that are currently approved as drugs under section 505 of the FDCA, will be regulated as biologics under section 351 of the PHS Act.[76]

38.5 POSTAPPROVAL ACTIVITIES AND LIFE CYCLE MANAGEMENT OF NDAs, ANDAs, AND BLAs

Whereas "amendments" are submitted to update or modify unapproved applications (IND, NDA, BLA, ANDA), "supplements" are submitted to modify approved/licensed applications. Supplements must address postapproval changes to components and composition, manufacturing sites, manufacturing processes, specifications, container closure systems, labeling, and other various aspects (eg, stability protocols or expiration dates). Supplement submissions must list all changes that may affect the drug product, with sufficient detail for the FDA to readily determine the scope of change. As described in 21 CFR 314.70, postapproval changes to an approved NDA, ANDA, or BLA are classified as major, moderate, or minor, and should be reported using one of four reporting categories[80]: prior-approval supplements (PAS), CBE-30 and CBE-0 (or CBE-immediate) supplements, or annual reports. In a recently released draft guidance, the FDA clarified which elements of the CMC information in an application constitute "established conditions" that, if changed following approval, require reporting to FDA, and where in the application these elements are generally expected to be described.[81] Established conditions include description of product, manufacturing process, facilities and equipment, and elements of the associated control strategy, as defined in the approved application, that assure process performance and product quality; any changes in established conditions must be reported as per 21 CFR 314.70 and 601.12. When finalized, this guidance will allow for a more effective postapproval submission strategy, including risk-management principles and knowledge management, by the sponsors as well as the FDA. The intent is to enhance reliance on sponsor's internal quality systems to properly asses, validate, and implement postapproval changes, which will eventually reduce and even eliminate certain reporting requirements.

38.5.1 Prior-approval Supplements

PAS describe major changes, having the substantial potential to adversely affect product safety, efficacy, and/or quality; such changes require approval by the FDA before their implementation is manifested in any distributed product. Postapproval changes to be described in a PAS include changes in formulation (eg, dosage or ingredient-release form), components and composition, moves to a new manufacturing site or establishment that could warrant an FDA inspection, or placement of aseptic sterilization or manufacturing processes, including packaging and closure systems, within new locations (eg, refurbishing or use of a location where similar processes have not been used in such manufacturing). Changes in other processes that must be described in a PAS include those that would affect dose delivery to the patient (eg, metering) and any change that can affect the impurity profile or the physical, chemical, or biological properties of drug product. Changes that could affect specifications or analytic processes used in assessing safety-, efficacy- or quality-related specifications must also be described in a PAS. Finally, the PAS should be used to describe any changes to product labeling (eg, based on postmarketing study results).

38.5.2 Changes being effected (CBE-30 and CBE-0 supplements)

CBE-30 supplements (for changes being effected in 30 days) describe changes having moderate potential to adversely affect safety and effectiveness; if, within 30 days of receiving a CBE-30 supplement, the FDA informs the applicant that a PAS is required, no drug product affected by the change may be distributed. CBE-0 supplements (without the 30-day delay prior to implementation) may also be used to describe moderate changes. Moderate changes to be reported in the CBE-30/CBE-0 supplements may pertain to manufacturing facilities or packaging sites for drug substance or drug product, manufacturing processes, equipment, starting materials, specifications, analytical procedures, container closure systems, or labeling. Examples can be found in the FDA's published guidelines.[80]

38.5.3 Annual reports

Annual reports may function as supplements to report minor changes, having little potential to adversely affect drug product. Changes reported in annual reports may be related to new manufacture sites for intermediates, new packaging sites for secondary packaging, new labeling sites, new equipment of the same design and operating principles, new specifications made to comply with an official compendium, tightening of specifications, container closure systems for nonsterile drug products, and minor labeling edits. Examples of each type of change that is appropriate for reporting in an annual report can be found in the FDA's published guidelines.[81,82]

38.5.4 Supplements to BLAs

BLA supplements are classified as major, moderate, and minor, depending on the potential effect on the identity, strength, quality, purity, or potency of the product; BLA supplements are reported according to the same categories listed previously for NDAs: PAS, CBE-30, CBE-0, and annual reports.[83,84] Changes that may require a PAS include, but are not limited to, changes to the sequence of the process, large scale-up of cell culture or purification, or changes to manufacturing sites. Other changes that would require submission of a supplement to a BLA can be inferred from the description of NDA supplements.

38.6 GLOBAL PERSPECTIVES ON PRODUCT REGISTRATION AND DRUG APPROVAL

Economic globalization has been especially challenging for the pharmaceutical sector, where harmonization must extend to standards and regulations involving a wide range of complex products. Over the past few decades, regulatory agencies and industrial stakeholders around the world have collaborated to standardize submission requirements and drug approval practices. Here, we briefly discuss initiatives from the ICH and regulatory bodies, such as the European Medicines Agency (EMA).

38.6.1 ICH harmonization in drug marketing submissions: the CTD format

Efforts that began in the 1980s to streamline the regulatory oversight of drug development around the world gave rise in 1990 to the ICH.

ICH includes participants from the world's three largest pharmaceutical and biotechnology markets: Europe, Japan, and the United States. The regulatory authorities involved in the ICH include the FDA and its counterparts in Europe, the EMA and in Japan, the Japanese Ministry of Health, Labor, and Welfare (MHLW). Industry representatives to the ICH include the Pharmaceutical Research and Manufacturers of America (PhRMA), the European Federation of Pharmaceutical Industries and Associations (EFPIA), and the Japan Pharmaceutical Manufacturers Association (JPMA). Observers to the ICH include representatives from the World Health Organization, Health Canada, and the European Free Trade Association (EFTA; EFTA member states are Iceland, Liechtenstein, Norway, and Switzerland).

The ICH objective is to ensure that good-quality, safe, and effective medicines are developed and registered in the most cost-effective and efficient way.[85] This objective is accomplished through the development and implementation of harmonized guidelines and standards in five steps:[86,87]

1. Building scientific consensus
2. Agreeing on draft text
3. Consulting with regional regulatory agencies
4. Adopting harmonized guidelines
5. Implementing guidelines in ICH regions

More than 50 guidelines on technical requirements have materialized from the ICH, relating to quality, safety, and efficacy, electronic standards for the transfer of regulatory information, CTD and eCTD, maintenance of ICH-controlled terminology, the medical dictionary for adverse event reporting and coding of clinical trial data (MeDRA), and efforts related to generic and OTC drugs. ICH harmonization activities extend from new guideline topics under development to the revision of existing topics needing clarification for implementation.[88] ICH topics related to the development and registration of drug products are grouped into four categories[89]:

- Quality—focuses on technical requirements for development, manufacturing, and control of the drug product, including stability testing, analytical validation, impurity profiles in drug substance and drug product, quality of biotechnology products, specifications for drug substance and drug product, GMP, pharmaceutical development, quality risk management, pharmaceutical quality system, and development and manufacture of drug substances (chemical entities and biotechnological/biological entities)[90]
- Safety—focuses on preclinical testing, in vitro and in vivo animal testing, including toxicity testing, carcinogenicity studies, genotoxicity studies,

reproductive toxicology, toxicokinetics and pharmacokinetics, pharmacology studies, immunotoxicity studies, and photosafety evaluation
- Efficacy—focuses on clinical testing, including collection and reporting of clinical data, dose-response studies, pharmacovigilance, ethnic considerations in conducting foreign trials, GCP, and studies in special populations, such as geriatrics and pediatrics
- Multidisciplinary—focuses on genotoxic impurities and nonclinical safety studies

The technical requirements outlined in ICH guidelines are discussed and agreed upon by all parties involved in harmonization before they are formally implemented by participating regulatory agencies (ie, FDA, EMA, and MHLW).

Although the use of the ICH guidelines initially targeted the ICH regions, globalization in drug development caused a growing interest in ICH guidelines and operations beyond these regions. Consequently, ICH Global Cooperation Group (GCG) is taking important steps toward establishing partnerships beyond ICH regions with involvement from Regional Harmonization Initiatives (RHIs) to promote better understanding of ICH guidelines.[91]

Finalization of the CTD (Fig. 38.5) in 2000, was a milestone accomplishment of the ICH. The CTD has alleviated costs and delays associated with converting registration files between the different national formats and removed redundancies in data sets.[92] Notably, the content of the CTD is not completely harmonized, as national or regional differences still exist in Module 1 and elsewhere throughout the submission, depending on differences in regulatory practice and procedures. For details on the CTD format and content, see Section 38.2.3 of this chapter.

38.6.2 EMA and comparison to FDA

The EMA is a decentralized body of the European Union, protecting and promoting public and animal health. The mission of the EMA is to foster scientific excellence in the evaluation and supervision of medicines, by the means of a centralized procedure that ensures coordination of EU scientific committees, inspection activities, safety monitoring of medicines (pharmacovigilance system), and referral or arbitration procedures for drugs approved via noncentralized authorization pathways.[93]

Both the FDA and EMA employ accelerated approval pathways to shorten the time needed for an application to be approved. However, whereas the FDA is authorized to issue marketing approvals on the basis of its scientific reviews, the EMA scope is limited to scientific evaluation only. Data are evaluated by the EMA advisory Committee for Medicinal Products for Human Use (CHMP), which includes independent experts nominated by each member state, as well as representatives of patient, consumer, and healthcare professional organizations. Once the scientific evaluation is completed in a certain timeline, the committee forms an opinion as to whether the drug product should be marketed, which is then transmitted to the European Commission (EC)—the authority that grants marketing authorizations in the European Union.[94] In Europe, the marketing authorization is done by the following procedures: centralized, national, decentralized, or mutual recognition.

A marketing authorization granted under the centralized procedure allows a drug product to be marketed in all the EU countries and European Economic Area (EEA) member states including Iceland, Liechtenstein, and Norway. The centralized procedure is a "reserved" procedure, not open to all products, but dedicated to human medicines for the treatment of human immunodeficiency virus (HIV) or acquired immune deficiency syndrome (AIDS), cancer, diabetes, neurodegenerative diseases, autoimmune and other immune dysfunctions, and viral disease; biotechnology products; veterinary medicines for use as growth or yield enhancers; and innovative products for advanced therapies, such as gene-therapy, somatic cell-therapy, or tissue-engineered medicines. Orphan drugs must also use the centralized procedure. The timeline for this procedure is 210 days.

Each European Union state member has its own national authorization system for determining drug approvability. Consequently, drug products that fall outside the scope of the centralized procedure can be granted marketing authorizations under national procedures. The national procedure allows the applicant to obtain a marketing authorization in only one member state. The timeline for this procedure is 210 days.

Under the decentralized procedure, an applicant can go directly to a national marketing authority and obtain marketing authorizations in that member state, and then seek to have other member states accept the marketing approval of the first member state. This allows the applicant to apply for authorization in more than one EU country simultaneously for products that have not been authorized in any EU country. The timeline for this procedure is 210 days.

The mutual recognition procedure allows an applicant to obtain marketing authorizations in a member state other than the member state where the drug product had previously received a marketing authorization. The timeline for the other member states to recognize the authorization of the first member state is 90 days.[95] The whole evaluation process may consume a time period of 390 days.

TABLE 38.8 Differences Between FDA and EMA Procedures Used for Drug Registration

FDA	EMA
One agency	Multiple agencies
	European medicines agency (EMA)
	Committee for Medicinal Products for Human Use (CHMP) of the EMA—scientific input
	National health agencies
One registration process	Multiple registration processes
	Centralized (all EU state members)
	National (one state member)
	Decentralized (at least two state members)
	Mutual recognition (at least two state members)
FDA reviewers within same agency	EMA just an administrative framework, national agencies provide the scientific reviewers
Specialized review of data	Overall review of benefit/risk of entire data
The changes in the approved drug can be done by filing PAS, CBE-30, CBE, annual reports	The changes in the approved drug can be done by filing Type IA, IB, and II variations

As summarized in Table 38.8, there have been differences between the United States and European Union in terms of procedures used for drug registration. Furthermore, the labeling format used to describe a drug product indication is different in the United States and European Union; whereas the FDA uses the United States Package Insert (USPI), the EMA uses the Summary of Product Characteristics. A study comparing labeling approved by the FDA and EMA showed notable differences in adverse events, black box warnings, order of information, number of approved indications, dosing regimen, and number of clinical trials described.[96]

Perhaps the most visible difference between FDA and EMA policies is regarding biosimilars; whereas interchangeability is defined by statute in the BPCI Act in the United States, in the European Union, its assessment resides with the member states. A relatively recent EMA draft guidance on biosimilar monoclonal antibodies may be used as a source of guidance for the structure and conduct of biosimilarity clinical studies for biosimilar applications in the European Union.[97]

Alignment between the FDA and EMA is increasing as a result of coordination and cooperation between these two agencies. One example of such alignment efforts between FDA and EMA is the pilot for QbD applications, which established a platform between the two agencies and allowed US and EU reviewers/assessors to exchange their views on ICH Q8. These ongoing efforts will eventually provide a streamlined procedure for drug approval and will lead to decreased costs for drug development and marketing.[50]

Acknowledgments

The authors would like to thank Dr Thomas Schultz (Johnson & Johnson), Dr Mohan Ganapathy (Merck), and Dr Emanuela Lacana (FDA) for critical review of this manuscript and their many helpful comments and suggestions.

Modern Pharmaceutical Regulations: Quality Assessment for Drug Substances*

H. Zhang, D. Johnson, D. Skanchy and L.X. Yu

U.S. Food and Drug Administration, Silver Spring, MD, United States

39.1 INTRODUCTION

Information on the chemistry, manufacturing, and controls (CMC) for the drug substance must be submitted to support the approval of original new drug applications (NDAs) and abbreviated new drug applications (ANDAs) (21 CFR 314.50[d][1] and 514.1[b]). This chapter elaborates the assessment of the CMC information for drug substances in a structure corresponding with common technical document (CTD) format,[1] preferably as an electronic CTD (eCTD).[2] Under section 745A(a) of the Federal Food, Drug, and Cosmetic Act (FD&C Act), NDA, ANDA, and master files must be submitted in eCTD format beginning May 5, 2017, and certain investigational new drug submissions must be submitted in eCTD format beginning May 15, 2018.[3]

The CTD format arose from the efforts in the International Conference on Harmonization (ICH) to harmonize the varying documentation requirements that Japan, Europe, and the United States had for the submission of technical data to support the registration of pharmaceuticals for human use. The ICH Guidance for Industry "M4: Organization of the CTD" describes a harmonized format for the CTD that will be acceptable in all three regions. The CTD is organized into five modules. Module 1 is region-specific and contains administrative information, while Modules 2-5 are intended to be common for all regions. The guidance, "the CTD for the Registration of Pharmaceuticals For Human Use: Quality-M4Q(R1)", describes the format for the quality information submitted in Module 3 of an application and the CMC information for drug substance is specified in 3.2.S. 1-7. In Module 2, the overall summary of the technical data has a corresponding subsection 2.3.S for quality overall summary (QOS) for drug substance as well. The QOS is a summary of the information provided in Module 3, and therefore would not contain information, data, or justification that was not already included in that module (ICH M4Q).

This chapter discusses the quality assessment of drug substance with focus on the question-based review (QbR) format. The QbR for quality assessment started with the FDA's generic program in early 2005 and was implemented in 2007.[4] It is a concrete and practical implementation of the underlying concepts and principles outlined by the FDA's current good manufacturing practices (cGMPs) for the 21st Century and transforms the CMC review into a modern, science- and risk-based pharmaceutical quality assessment. These principles also apply to the assessment of drug substance CMC information that is not submitted using QbR. The QbR serves two purposes for the CMC assessment. First, it provides an assessment guide in the evaluation of whether a product is of high quality and determination of the level of risk associated with the manufacture and design of the product. Second, it provides transparency to sponsors about the logic behind a CMC review.

*__Disclaimer__: The chapter reflects the views of the authors and should not be construed to represent the views or policies of the Food and Drug Administration (FDA). No official endorsement by the FDA is intended or should be inferred.

Developing Solid Oral Dosage Forms

39.2 ORIGIN OF THE QbR

The rapid growth of the generic industry has presented the agency with several challenges; namely, a significantly increased workload due to the high number of submissions, the vastly increased number of drug substances and drug product manufacturers with widely varied manufacturing experience, poor-quality CMC information being submitted, and new requirements to complete reviews in a more timely manner. In order to address these challenges, various changes have been implemented. One of these changes was the development of the QbR for quality assessment of ANDAs.[5] The QbR model is a general framework for a science- and risk-based assessment of product quality which is based on a series of focused questions divided into three broad categories: (1) drug substance quality standards, (2) drug product quality standards, and (3) process understanding and proposed drug manufacturing scale-up plans. Under the QbR review model for generic drug applications, ANDA applicants provide their responses to the questions in the QOS. The QbR model is not intended to replace the detailed supportive information in CTD Module 3.

QbR has benefited both industry and the FDA.[6] QbR provides a clear indication about what information needs to be provided to the agency. For the FDA, the sponsor-prepared QOS provides a quick overview of the entire CMC package and reduces the review time spent on documentation. It also improves the quality and consistency of the CMC information, which may lead to a reduction in the number of questions issued by the agency and a decrease in the review cycles. QbR provides an opportunity for applicants to demonstrate process understanding by addressing quality-by-design (QbD)[7]-related questions regarding the product's design, performance, manufacturing controls, and risk mitigation. QbD is a scientific, risk-based, holistic, and proactive approach to pharmaceutical development that focuses on deliberate design effort from product conception through commercialization and emphasizes a full understanding of how product attributes and the process relate to product performance. Knowledge gained through the pharmaceutical development studies and manufacturing experience provides scientific understanding of the process, which can be used to support the establishment of a design space. A design space is the multidimensional combination and interaction of input variables (eg, material attributes) and process parameters that have been demonstrated to provide assurance of quality. Upon approval, adjustments of processing parameters within an approved design space are not considered as a change and do not normally require a regulatory filing. This allows the sponsor more flexibility to execute manufacturing processes for which they have demonstrated process understanding.[8] The QbR program was fully implemented in 2007 and is currently being used by the generic industry for almost all ANDA submissions.

39.3 EVOLUTION OF THE DRUG SUBSTANCE REVIEW PROCESS

An application consists of information about both the drug substance, also known as API, and the drug product. The drug substance information may be supplied in one of two ways: (1) submitted directly in the application in 2.3.S of the QOS and 3.2.S of Module 3, or (2) submitted in a Type II Drug Master File (DMF). This type of DMF is a confidential, detailed document submitted by API manufacturers to the FDA containing the CMC information for a drug substance. Although the DMF is never actually approved, it is referenced by an application and the content is reviewed for scientific adequacy to support the action taken on the referencing application.[9]

Historically, the CMC sections and any associated DMFs were reviewed by a single discipline of chemistry. In Fall 2010, a pilot program was started in the FDA's generic program with a dedicated review team whose sole focus was the review of drug substance information found in DMFs. The 6 month pilot was very successful and led to the creation of the DMF Review Staff in early 2011.[10] The rationale for the change was to concentrate subject matter experts in the fields directly related to drug substance manufacture, such as organic synthesis, process engineering, and analytical chemistry. Another goal was to increase the consistency and efficiency of the review process by allowing the ownership of the DMF (ie, the assignment of DMF would stay in the same assessment team) until the submission is found adequate. The group has become the focal point for all drug substance quality issues and facilitates consistent and transparent communication with the DMF holders. Formation of the DMF Review Staff has allowed the agency to develop initiatives designed to improve the submission and review quality of the DMFs and has facilitated the implementation of the Generic Drug User Fee Act of 2012 (GDUFA).[11] The group has grown considerably with GDUFA hiring and eventually transformed into the Division of Lifecycle API as part of the Office of Pharmaceutical Quality (OPQ) reorganization, which is discussed next. A separation of drug substance and drug product review has also been implemented for the review of NDAs as part of the reorganization.

In parallel to the GDUFA implementation, OPQ, a new CDER super office, was strategically organized

in order to streamline the quality regulatory review processes. With a motto of "One Quality Voice," OPQ embodies the concept of putting the patient first by balancing risk and availability, as well as closer integration of review, inspection, surveillance, policy, and research activities for the purpose of strengthening pharmaceutical quality on a global scale.[12] A team-based integrated quality assessment (IQA) is reflective of the structure and function of OPQ, which brings together the field and review functions and their respective knowledge bases. This new approach makes the regulatory process more effective in the assessment of product quality and fosters the advancement of a continuous quality improvement-oriented culture.

The team-based IQA approach maximizes each team member's expertise and provides aligned patient-focused and risk-based quality recommendations for the drug substance, drug product, manufacturing process, and facilities.[13] IQA teams consist of an application technical lead (ATL), a regulatory business process manager (RBPM), discipline reviewers, and additional technical advisors as needed. Review disciplines may include drug substance, drug product, process (generally focused on drug product), facility, microbiology, biopharmaceutics, and field investigators. Technical advisors may come from OPQ laboratories, policy, surveillance, and other offices as needed. The ATL is responsible for overseeing the scientific content of the assessment, while the RBPM is responsible for driving the review process and adhering to the established timeline. The drug substance review function is consolidated into the Office of New Drug Product. The drug substance reviewers will assess the CMC information of drug substances whether it is submitted directly in the applications or in referenced DMFs.

The success of QbR and the separation of the drug substance review into the DMF Review Staff prompted another initiative, which was the development of a QbR template for API DMF review. With the reorganization to form OPQ, the QbR initiative became a joint effort among offices and divisions that deal with the drug substance quality assessment and eventually led to the recent publication of MAPP 5015.10, "Chemistry Review of QbR Submissions".[14] During development of MAPP 5015.10, the QbR was revised to improve the questions based on the lessons learned over the past several years and to encourage more incorporation of QbD elements in the CMC information submitted to the FDA.[15] While the revised QbR for drug product quality assessment will be discussed in the next chapter of this book, the following section elaborates the drug substance quality assessment.

39.4 QUALITY ASSESSMENT FOR DRUG SUBSTANCES

As mentioned previously, a QbR template for drug substance quality assessment aims to standardize the documentation practice and clarify the FDA's expectation in drug substance quality assessment. It follows the same format as the initial QbR developed for ANDAs and contains the same underlying QbD principles.

In May 2012, ICH Q11[16] was finalized; this guidance encourages manufacturers to use an enhanced approach that focuses on the use of "risk management and scientific knowledge to identify and understand process parameters and unit operations that impact critical quality attributes (CQAs) and develop appropriate control strategies applicable over the lifecycle of the drug substance which may include the establishment of design space(s) (ICH Q11)." This greater understanding of the drug substance and its manufacturing process can create the basis for more flexible regulatory approaches in a manner similar to that described in ICH Q8 for drug product. The questions developed for the drug substance QbR allow the manufacturers to demonstrate process understanding and justify control strategies other than end-product testing.

QbR is designed with the expectation that the API information is organized in CTD format and preferably submitted in eCTD format, which will become a requirement by May 2017.[3] The QOS (Module 2) follows the scope and outline of Module 3 and information provided in the QOS should be consistent with the information provided in Module 3. MAPP 5015.10 provides guiding principles for drug substance quality assessment, and can also serve as a guide for preparing the submission of drug substance information. Attachment 3 in the MAPP 5015.10 elaborates how the information will be evaluated under QbR format, but also applies to submissions that do not follow the QbR format. The companion document has many practical suggestions and considerations along with numerous example tables. In the following subsections of this chapter, additional details regarding QbR for drug substance quality assessment are discussed that extend beyond the companion document. This supplemental information may provide further insights, which can be considered in the submission and during assessment.

S.1 General Information

The general information section covers nomenclature, structure, and general properties. The nomenclature may include one or more of the following: International Nonproprietary Name, United States Approved Name, Compendial Name (eg, United States Pharmacopeia,

USP), Chemical Abstracts Service registry number, or Chemical name (using International Union of Pure and Applied Chemistry, IUPAC, nomenclature principles).

A chemical structure with molecular formula and molecular weight is commonly provided, including the stereo configuration if applicable. The presence of hydrates/solvates/salts is shown in the chemical structure, and the molecular weights for both active moiety and the salt or solvate/hydrate form are reported. When the API is a salt and the impurities are controlled at a weight/weight percent limit with respect to the API salt, attention should be paid to the calculation of the maximum daily dose. If the strength of the drug product was expressed as the active moiety in the drug product labeling, a conversion of the strength in active moiety to the strength in the salt form may be needed.

General properties may include a list of physicochemical properties, as described in the companion document, particularly those which are likely to impact the product performance and/or process design. For example, polymorphism/pseudopolymorphism and aqueous solubility characteristics may be CQAs to most solid oral dosage forms; hygroscopicity and light sensitivity may affect material handling procedure and storage configuration. The pK_a is an intrinsic property of the API molecule, but could be a factor in developing an efficient acid/base extraction procedure during API manufacture. Some of these properties may be further discussed in and referenced in section S.3: Characterization.

S.2 Manufacture

ICH M4Q does not set up subsections in Module 2, but the MAPP 5015.10 separates the questions into a subsection-format similar to the structure in Module 3.2. S; the next discussion also follows this structure for consistency.

S.2.1 Manufacturer

When addressing what facilities are involved in the manufacturing and testing activities, the following types of API-related facilities would be included in the submissions as applicable:

- API manufacturers
- API intermediate manufacturers
- API micronizers
- Facilities that sterilize the API
- Facilities that perform routine commercial testing of the API
- For animal/plant-derived APIs, the facilities that perform crude extraction prior to purification of API

It is very important to submit a complete set of facility information in the application so that all the facilities involved can be evaluated for compliance purpose and appropriate action (eg, approval or complete response) can be taken in a timely manner. A good manufacturing practices (GMP) compliance statement would be provided for each of the applicable facilities listed previously. It is less of an issue when the applicant is also the API manufacturer and well aware of what API-related facilities are involved. When manufacture of the API is contracted out or the API information is referenced to a separate submission (eg, a DMF) and the manufacturing process involves multiple sites and/or testing laboratories, it becomes critical that the applicant and the contractor or the holder communicate the facility information so that there is no missing facility in the application. A common issue that may lead to missing facility information involves starting material redesignation. For example, when an initially proposed starting material designation was not accepted, an API manufacturer may agree to redesignate a starting material in an earlier stage of the process, but these additional steps of the process may be performed at a separate site. In addition to providing the necessary CMC information for the process starting from the newly designated starting material, the DMF should also be updated with the new facility information in order for the new site to be evaluated before an action can be taken on the application.

S.2.2 Description of the Manufacturing Process and Controls

The information on the API manufacturing process typically includes route of synthesis, flow diagram, and detailed process description. A complete synthetic scheme would be the most effective way to illustrate the process, including molecular formulae and weights, chemical structures of starting materials and intermediates, the use of reagents, catalysts and solvents, and their equivalencies and relative ratio in each step. Nonisolated intermediates would normally be noted with brackets. The process is further described in the narrative process description, which should include batch size, input quantities, and yields. Some other operations, such as blending, micronization, reprocessing, or reworking should also be described as applicable, though they may not be performed routinely or may be subject to the customer requirement from time to time. When blending of small batches to increase batch size is needed, each batch for blending should have been tested against the established criteria; out-of-specification batches cannot be blended for the purpose of meeting the specification. If optional micronization or any specific operation is performed to meet a certain particle size requirement, such operation should be described and the development studies which demonstrate that such operation does not negatively impact the API quality and stability can be presented in Section 2.6 with cross reference.

When process analytical technology (PAT)[17] is proposed for routine production that allows for real-time process monitoring and control, the technology and the traditional method being replaced should be described and a discussion of how this technology will be implemented and the impact on overall control should be provided. The FDA's PAT initiative started in the early 2000s and establishes a framework to facilitate innovation with the goal of enhanced understanding and control of the manufacturing process. Process analysis has advanced significantly during the past several decades due to an increasing appreciation for the value of collecting process data. Available tools have evolved from those that predominantly take univariate process measurements, such as pH, temperature, and pressure, to those that measure chemical and physical attributes. At-line measurement refers to cases where the sample is removed, isolated from, and analyzed in close proximity to the process stream; on-line measurement is where the sample is diverted from the manufacturing process, and may be returned to the process stream; measurement where the sample is not removed from the process stream at all is in-line analysis. A description of these PAT tools and the traditional method being replaced should be provided. A discussion about how the technology will be implemented and the impact of this technology on the overall control strategy (ie, it is medium impact if it would be used for monitoring; it is high impact if it would be used for drug substance release) should be provided.

S.2.3 Control of Materials

Designation of regulatory starting material(s) is discussed in several FDA guidance documents and ICH guidelines[18] and the agency's official adoption of ICH Q11 in Nov. 2012 set a milestone in the regulatory assessment of the starting material designation.[19] Designation of starting material(s) in an NDA would typically be discussed at a pre-NDA stage. For an ANDA or its referenced DMF, the designation of starting material is assessed during the scientific review of the submission. A recently published "RTR guidance"[20] makes the appropriate designation of starting material(s) as one of the filing criteria. The guidance states that "FDA will refuse-to-receive (RTR) an ANDA if the API review (during the filing stage), whether in an ANDA or in a referenced DMF, reveals that the starting material for the API is not justified according to the principles in the ICH Q11 guidance." The inappropriate designation of regulatory starting materials represents an omission and inadequacy in the submission that impairs meaningful regulatory assessment of the API manufacturing process and quality control strategy, and would therefore render the application incomplete on its face and result in the failure of completeness assessment (CA)[21] in the case of an API DMF and possible RTR of the ANDA.

The assessment on the justification of starting material designation focuses on the overall quality control strategy, which manages and mitigates the risk associated with changes in the starting material source and/or the manufacturing process. The synthetic route and brief process description of the starting material can greatly facilitate the evaluation of the starting material control. Discussion on the relevant impurities arising from the manufacturing process of each proposed starting material and the ability of analytical procedures to detect impurities in the starting material will help justify the proposed specification of the starting material. Additional discussion on the fate and purge of those impurities and their derivatives in subsequent processing steps can address the Q11 general concept that impurities in the starting material will not have an impact on the impurity profile of the drug substance; this will further tie the starting material quality attributes to the overall control strategy.

When multiple starting material suppliers are being utilized, it is important that the starting material specification and overall control strategy are designed to address all of the various types of impurities that may arise in each synthetic route. In addition, when multiple manufacturing sites are involved during the manufacture of an API, the starting material specification(s) should ensure the same level of quality regardless of which site or starting material supplier is involved. Data demonstrating that starting material sourced from each current vendor has equivalent quality should also be provided as part of the justification of the specification for the starting material.

The first principle for designating an appropriate starting material in ICH Q11 recognizes the relationship between risk and the number of steps from the end of the manufacturing process; the second principle states that enough of the drug substance manufacturing process should be described in the application for regulatory authorities to understand how impurities are formed in the process, how changes in the process could affect the formation, fate, and purge of impurities, and why the proposed control strategy is suitable for the drug substance manufacturing process; and the third principle points out that manufacturing steps that impact the impurity profile of the drug substance should normally be included in the manufacturing process. It is also worth noting that a step, as defined in the glossary of ICH Q11, refers to a chemical transformation and typically involves C–X or C–C bond formation or breaking. Often in the justification of a regulatory starting material, the principle of "significant structural fragment"

is misinterpreted. "Significant structural fragment" in this context is intended to distinguish starting materials from reagents, solvents, or other raw materials. Justification of a late intermediate as a starting material by claiming it is a significant structural fragment is not considered a valid argument because it could apply to any intermediate in the manufacturing process. Based on these principles, selecting a regulatory starting material very late in the synthetic route may not be a viable submission strategy.[22]

If redesignating a regulatory starting material to an earlier stage of the process is deemed necessary, amending the application or its referenced DMF to address this issue may require a substantial amount of information. This process could be very involved and lengthy, especially if the originally proposed starting material is sourced externally. It is important to note that such a redesignation request cannot be simply addressed by only amending the submission with additional CMC information or referencing a separate DMF for the CMC information without actually declaring a new regulatory starting material in an earlier stage of the process because designation of regulatory starting material also has an implication in GMP compliance. Compliance with the cGMP is required from the introduction of the regulatory starting material to the manufacturing process.

Again, the general principles laid out in ICH Q11 should be considered in totality in selecting starting materials, rather than applying each general principle in isolation.

S.2.4 Control of Critical Steps and Intermediates

The intermediates addressed here are the ones that are isolated during the process so that intermediate specifications can be established and documented to ensure that quality attributes are met. The isolation of intermediates, with their corresponding specifications, provides great opportunities to purge potential impurities that may be carried from the starting materials or earlier stages. This is especially important when regulatory starting materials are in later stages of the process and/or are outsourced from multiple suppliers. The specifications should be designed to control the critical material attributes (CMAs) that may have an impact on the CQAs of a drug substance because intermediates are considered to be critical materials in API production and are thus a particularly important part of the overall control strategy.

When an API manufacturer chooses to outsource part of the GMP process, it is important to remember that GMP begins with introduction of the regulatory starting material(s) as mention in the previous subsection. A harmonized control strategy governing the entire GMP process would ensure the consistency of quality regardless of where the intermediate is produced. Batch data demonstrating that intermediates produced at all sites have comparable quality should also be provided, preferably in tabulated format. Hold-time studies need to be considered when intermediates have been outsourced and shipping between sites is required. These studies would demonstrate that the intermediate is stable in its packaging for the amount of time elapsed between manufacture and use. Hold-time studies are also appropriate for manufacturing processes, which require multiple batches of one intermediate to be combined in the next step of the process.

Potential impurities at a given intermediate stage include residual starting materials and previous chemicals, impurities carried over from the starting materials, reagents, solvents, catalysts, and reaction by-products. Investigation of impurities that are commonly observed is a key step in determining what impurities need to be controlled. It is essential for manufacturers to demonstrate process understanding by examining the origins and fates of impurities to support the proposed controls at various stages. ICH Q11 describes and recognizes that CQAs of a drug substance can be confirmed through upstream controls. Both in-process control (IPC) and impurity tests in the intermediate specification can be part of the upstream controls. When the limit for a particular impurity in the intermediate is set at a level higher than what would be acceptable in the API, inclusion of a study demonstrating how the amount of that particular impurity decreases throughout the subsequent manufacturing process from the proposed limit to an acceptable level would provide a stronger justification than submission of testing data in the final API alone and may warrant no further control in the later stages. Sometimes an impurity may not need to be specified in the final API specification if a significant margin of process purging capacity is demonstrated by spiking the impurity at a level much higher than the level it is commonly observed/generated at the intermediate stage and confirming its absence or amounts well below the acceptable level in the subsequent stage or final API. It is also important to consider whether an impurity may be transformed in later steps. Analysis of the API should also include potential by-products that may be formed due to transformation of the initial impurity into other by-products. Spike/purge studies should be conducted in a manner representative of the production process so that the outcome can predict the manufacturing capability.

S.2.5 Process Validation and/or Evaluation

Validation of the manufacturing processes is a requirement of the cGMP regulations for finished pharmaceuticals (21 CFR 211.100 and 211.110), and is considered an enforceable element of cGMP practice

for APIs under the broader statutory cGMP provisions of section 501(a)(2)(B) of the Federal Food, Drug, and Cosmetic Act. ICH Q7A[23] states that prospective validation should normally be performed for all API processes and should be completed before the commercial distribution of the final drug product manufactured from that API. ICH Q11 also indicates that the drug substance manufacturing process should be validated before commercial distribution of resulting drug product. However, none of the guidance specifically defines the submission requirement with regard to API process-validation information. The FDA Guidance to Industry, "Process Validation: General Principles and Practices",[24] does not specify what information should be included as part of a regulatory submission and refers interested persons to contact the appropriate center in determining the type of information to include in a submission. ICH M4Q mentions that process validation and/or evaluation studies for aseptic processing and sterilization should be included. ICH Q11 mentions as an observation that for nonsterile chemical entity drug substance processes, results of process validation studies are not normally included in the dossier. The "initial completeness assessments for Type II API DMFs under GDUFA"[21] is the only guidance that specifically requires "[a] summary of Process Validation and/or Evaluation information" to be submitted for a validated process (item 34 in its "Appendix 1: GDUFA Initial Completeness Assessment Checklist for Type II API DMFs").[21]

The scope of this validation summary is significantly smaller than the typical process validation report and does not involve the facility, utility, environmental control, equipment installation/operation/performance qualification (IQ/OQ/PQ), cleaning validation, etc., and analytical validation is covered in a separate section of the submission (S.4.3). Per the companion document to MAPP 50115.10, if the validation has been performed, information regarding the validation batches with lot traceability should be provided. The information should include the analytical data from the starting material(s), intermediates, in-process testing, and final drug substance, which can be provided in a tabulated format; reference to sections 2.3, 2.4 and 4.4 for the same analytical data is acceptable if the validation data is provided in those sections respectively. If the validation has not been completed, a validation commitment including the timeline and proposed scale can be provided.

S.2.6 Manufacturing Process Development

The process development summary should summarize the development effort, but should not be filled with raw study reports. It presents the results of the process development effort using summary charts and tables and some data can be cross-referenced to other sections as needed. A QbD approach or QbD elements are highly recommended to justify the choice of critical process parameters (CPPs), testing limits and ranges, and as part of risk mitigation in scale-up. There should be a discussion of how the proposed controls mitigate the identified risks in the process. The process development summary presents the opportunity to reveal the overall control strategy that the manufacturer has in place to ensure process robustness and consistent product quality.

One of the key elements of the control strategy is the impurity control, including controls of related substances, impurities with genotoxic structural alerts, reaction by-products, residual solvents, metal catalysts, and any impurities that may be carried from the starting material(s), etc. The manufacturers could demonstrate their process understanding by examining the origins and fates of impurities, discussing the probabilities and severities of their impacts to process robustness and the product quality, and conducting tests and/or purging studies to support the controls implemented at various stages.

In the case of chiral drug substances, discussion regarding how the chirality of each center is established through the synthetic process is very important. The possibility of interconversion of the chiral drug substance to the enantiomer or other diastereomers during manufacturing or storage, and the controls in place to prevent such interconversions also need to be addressed. A similar evaluation should be conducted for drug substances for which geometrical isomers are possible.

Regarding polymorphism, it should be demonstrated that the desired polymorphic form is consistently produced and retained during storage. The impact of specific process parameter(s) (eg, concentration, temperature program, choice of solvents and/or antisolvent, stirring/seeding as needed, etc.) should be discussed, and polymorphism analysis results should be provided. When there is a potential for other forms to be present, a discussion about how these forms are detected and controlled should be included. When the polymorphic form of the API is known in the literature, a reference to the patent or other literature can be provided.

The particle size of an API may impact product performance depending on the drug product dosage form, route of administration, and the product manufacturing process. If micronization or any specific particle size reduction operation is performed to meet the particle size requirement, the manufacturer should demonstrate that such operation does not negatively impact the quality and stability of the processed material. For example, complete release testing of batches could be performed after the customized

operations and a micronized sample should be put in the stability program.

S.3 Characterization

Characterization of the API should be performed irrespective of whether the drug has a compendial monograph or it is a new chemical entity as its purpose is to prove the API identity from a given process. A list of spectroscopic studies as applicable (eg, infrared [IR], ultraviolet [UV], nuclear magnetic resonance [NMR], mass spectroscopy [MS], x-ray diffraction [XRD], elemental analysis) and the interpretation of those studies summarizing the evidence of structure would be needed to adequately prove the structure. When the drug substance contains one or more chiral centers, it should be indicated whether it is a racemate or a specific stereoisomer. In the case of a specific stereoisomer, evidence of its configuration should be provided when an enantiomer or diastereomers are possible. For example, unequivocal characterization could be demonstrated by using 2D NMR spectroscopies and/or x-ray crystallography, or comparison with authentic samples or extracted reference listed drug in the case of generic or 505b(2) applications, using spectroscopic and/or chromatographic procedures that can discriminate between enantiomers or diastereomers. Alternatively, the stereochemistry can be established and controlled in the starting material or an intermediate when appropriate (eg, chirality feature inherited from the starting material or introduced in an intermediate stage). However, it should be demonstrated that subsequent process steps do not involve the chiral center(s) or won't cause its racemization. When the stereochemistry is established at an earlier stage, similar characterization should be performed at that point.

Potential genotoxic impurities (PGIs) are receiving more and more attention. Any work or studies performed to evaluate PGI's (eg, functional group identification, *in silico* analysis, Ames test, literature references, etc.) should be provided. However, it should be noted that a nonclinical consult review may be required to evaluate *in silico* and toxicological data and full copies of any study reports (ie, Ames studies, *in silico* analysis, etc.) are needed in those cases. A brief discussion about the control strategy for these impurities (ie, type of analytical procedures and sensitivity limits, in-process tests, tests in intermediate or final drug substance specifications, etc.) should be provided. A reference to process development summary may be appropriate, and the exact location of the information in S.2.6 should be provided.

The evaluation and justification of the proposed limits for an impurity with a structural alert is based on the relevant guidance, particularly the recently published ICH M7[25] and a stepwise approach can be taken to address the concern. A computational toxicology assessment can be performed using (quantitative) structure-activity relationships [(Q)SAR] methodologies that predict the outcome of a bacterial mutagenicity assay. Two (Q)SAR prediction methodologies that complement each other should be applied. The absence of structural alerts from two complementary (Q)SAR methodologies (expert rule-based and statistical) is sufficient to conclude that the impurity is of no mutagenic concern and no further genotoxicity assessments would be necessary. If warranted, the outcome of any computer system-based analysis can be reviewed using expert knowledge to provide additional supportive evidence on relevance of any positive, negative, conflicting. or inconclusive prediction and provide a rationale to support the final conclusion.

If the (Q)SAR prediction of potential mutagenicity is positive or the (Q)SAR study is not conducted, either adequate control measures at the threshold of toxicological concern (TTC)-based limits could be applied or a bacterial mutagenicity assay with the impurity alone can be conducted.[26,27] An appropriately conducted negative bacterial mutagenicity assay would overrule any structure-based concern, and no further genotoxicity assessments would be recommended. These impurities would be considered nonmutagenic; therefore, the impurity control can be based upon ICH Q3A(R2) recommendations.[28,29]

A positive bacterial mutagenicity result would warrant further hazard assessment and/or control measures (TTC-based limit). If compliance with the TTC-based limits is impossible or impractical, an in vivo gene mutation assay should be conducted to understand the relevance of the bacterial mutagenicity. Results from an appropriate in vivo assay may support setting compound specific impurity limits. In cases where control efforts cannot reduce the level of the mutagenic impurity to below the acceptable limit and levels are already as low as reasonably practicable (ALARP), a higher limit may be justified based on a risk/benefit analysis. Conversely, the application of ALARP is not necessary if the level of the mutagenic impurity is below acceptable limits.

S.4 Control of Drug Substance

This section addresses the control of the drug substance with respect to specification, analytical procedures and their validation, batch analyses, justification of specification, and overall control strategy. A specification as defined in ICH Q6A[30] is a list of tests, references to analytical procedures, and appropriate acceptance criteria for those tests, which are expressed as numerical limits, ranges, or other criteria as applicable. The drug substance must conform to this set of

criteria in order to be considered acceptable for its intended use. The specification is proposed and justified by the manufacturer and must be acceptable to regulatory authorities.

The drug substance manufacturer is encouraged to include relevant controls in the specification, but the specification is only one part of the total control strategy. As mentioned previously, ICH Q11 discusses an enhanced approach which focuses on the use of "risk management and scientific knowledge to identify and understand process parameters and unit operations that impact CQAs." Table 39.1 is from ICH Q11; it shows an example of an enhanced control strategy, which may be used by a holder to justify the use of upstream control to ensure consistent product quality.

Notice that upstream control can be a test for an impurity in the starting material or intermediate, or an in-process test. Upstream control may also be assured by process development data that demonstrates the process is able to adequately remove the impurity, in which case there is no routine testing involved. In either case, it is important that the manufacturer provide adequate information to justify their proposed control strategy. As discussed in the section S.2.4, if upstream control is established at higher than the acceptable limit or where control is achieved solely through process capability, spike/purge studies at greater than the proposed limit, and/or sufficient batch data from drug substance manufactured from starting material/intermediate containing the proposed levels of the impurity should be supplied to support the proposed limit. It is important that spike/purge studies be performed in a manner representative of the commercial process in order for the results to be predictive. A description of the analytical procedures used for these studies with information about limit on detection/limit on quantification (LOD/LOQ) should also be included.

A commonly observed issue in this section is related to the specification justification; particularly inadequate justification of proposed impurity limits.[31] For a new drug substance, the impurity justification typically goes by the threshold-based approach described in ICH Q3A. Additional justification may include the relevant development data, test data for the batches used in the toxicology and clinical studies, the data from the stability studies can be referred to as well as; reasonable variability of manufacturing process and analytical procedure should also be considered; other factors (eg, patient population, drug class effects, and clinical considerations) may be considered on a case-by-case basis.

For a drug substance subject to an ANDA, a guidance for industry has been published on how to appropriately justify impurity limits.[32] The qualification threshold in ICH Q3A should be the default

TABLE 39.1 Example of a Possible Control Strategy Summary

	Type of control			
DS CQA/ Limit	**In-process controls (including in-process testing and process parameters)**	**Controls on material attributes (raw materials/ starting materials/ intermediates)**	**Impact of manufacturing process design**	**Is CQA tested on drug substance/included in drug substance specification?**
Impurity X (NMT[a] 0.15%)	Design space of the reflux unit operation composed of a combination of %water in intermediate E and the reflux time in step 5 that delivers intermediate F with hydrolysis impurity ≤0.30% (3.2.S.2.2)			Yes/yes
Impurity Y (NMT 0.20%)	Process parameters step 4 (3.2.S.2.2) p(H2) ≥2 barg; T <50°C; In-process test step 4 (3.2.S.2.4) Impurity Y ≤0.50%			Yes/yes
S-enantiomer (NMT 0.50%)		Spec for starting material D (3.2.S.2.3), S-enantiomer ≤0.50%	Stereocenter is shown not to racemise (3.2.S.2.6)	No/no
Toluene	In-process test step 4 (3.2.S.2.4) ≤2000 ppm by GC		Process steps after step 4 are shown to purge toluene to levels significantly below (less than 10%) that indicated in ICH Q3C (3.2.S.2.6)	No/no[b]

[a]*NMT, not more than.*
[b]*This approach could be acceptable as part of a control strategy when justified by submission of relevant process data that demonstrates the adequacy of the process design and control. The manufacturing process should be periodically evaluated under the holder's quality system to verify removal of the solvent.*
Reproduced from: ICH Q11.

starting point for a specified impurity. An impurity is considered qualified when it meets one or more of the following conditions:

- The observed level and proposed acceptance criterion for the impurity do not exceed the level observed in the reference listed drug product
- The impurity is a significant metabolite of the drug substance, as confirmed by supporting data from studies or literature
- The observed level and the proposed acceptance criterion for the impurity are adequately justified by the scientific literature
- The observed level and proposed acceptance criterion for the impurity do not exceed the level that has been adequately evaluated in toxicity studies

Lack of proper justification of impurity limits may lead to RTR the application.[33]

Descriptions of the analytical procedures referenced in the specification are also reported in S.4 and the QbR companion document provides example tables that may be useful in presenting the information. There are generally two types of analytical procedures: in-house methods, which are developed by the applicant or holder, and compendial methods, which are contained in a monograph or a general chapter. In both cases, a description of the method should be provided. The method validation/verification reports for these methods may be included in this section or submitted in regional section. Full validation reports should be provided for in-house methods. If the original method validation was done at one site, such as a research and development (R&D) laboratory, and is then transferred to another site for routine release testing, a method transfer study should be conducted to verify the receiving site is capable of performing the analytical testing method for its intended use. When a compendial method is available and used, method verification should be performed. Verification under conditions of use is generally demonstrated by meeting system suitability criteria established for the method, as well as other method parameters such as: demonstration of specificity, method precision, and LOQ if applicable.[34] However, there are times when a supplemental validation of the compendial method should be performed. For example, if a compendial method is used to analyze unique in-house related substances, then validation of all parameters with regard to these impurities should be performed (eg, specificity, system/method precision, accuracy, linearity/range, robustness, etc.).

As for the batch analysis data submitted in this section of QoS, it is commonly tabulated against the specification. When the API is manufactured at more than one site, more data may be needed. As mentioned under S.2.1, adequate site information should be provided along with a GMP statement for alternative manufacturing sites. It is important to indicate when this site has previously received a satisfactory cGMP inspection and specify the type of manufacturing process covered by the inspection. The inspection status is one of the factors used to determine the post-approval filing category if the site change/addition is part of post-approval activity. Utilizing the same process in the alternative site would help to minimize the potential variation in drug substance quality, while it is acknowledged that changes to accommodate the facility and equipment difference may be necessary provided they result in no impact to the impurity profile, physiochemical properties, and control strategy. A tabulated comparison of the manufacturing process at each site with discussion/justification about any variation in equipment or process parameters is very useful in justifying changes and assists in the evaluation of their potential impact to drug substance quality. A detailed comparability study in impurity profile and physiochemical properties should be conducted and summarized to demonstrate the equivalence of the API manufactured at both sites. In addition, a summary of the plans for validation at the alternative site as elaborated under S.2.5, comparative data from the existing site should be provided and API from the alternative site should be added to the stability program.

A change in scale of the commercial batch size also requires additional information be submitted to the agency. A discussion about any variation in equipment, procedure, or control strategy caused by the scale change should be provided in the appropriate sections of the submission. A scale change, as referred to here, does not involve modification of the synthetic process. Comparative batch data between batches of API manufactured by the original process and batches manufactured by the scaled process should be provided to show that the quality is comparable.

S.5 Reference Standards

Per ICH Q6A Guideline, a reference standard, or reference material, is a substance prepared for use as the standard in an assay, identification, or purity test. Reference standards have both quantitative and qualitative uses. Reference standards for assay/purity tests for drug substances are for quantitative use, while reference standards for identification tests, system suitability tests, or chromatographic peak markers are for qualitative use. Other reference standards include performance standards and calibrators, such as dissolution calibrators, melting point standards, particle count set standards, chromatography calibration verification standards, etc. The amount of tests needed to qualify a reference standard depends on its intended use. For example, tests for the reference standards used for assay/purity tests typically include identification, assay, chromatographic purity, water, solvents, ash, and other tests as applicable. For primary standards the method of choice in

computing the assigned content value is mass balance analysis using independently determined components, such as moisture, solvent residues, inorganic residues (ash), chromatographic impurities, and ion contents.

If compendial reference standards are available and used, the compendial lot numbers would be considered sufficient. For noncompendial reference standards, source, batch/lot number, brief description of the preparation and qualification (characterization and quantification) of reference standards would be needed. The characterization data can be referenced to the data in S.3 if applicable. Quantitation is often done by means of mass balance. Certificate of analyses (COAs) of the in-house reference standards should include the storage conditions and expiry date.

The impurity reference standards, which are used in the release of a drug substance and/or validation of the analytical procedures, can be described in this section as well. Similar to the drug substance reference standards, the impurity reference standards would also need to be qualified to demonstrate their identities and purities/assays. Though often their purity values may not be on par with that of a drug substance reference standard, the impurity reference standards should be pure enough to not compromise the analysis. Normally, using a less-pure impurity reference standard may artificially inflate the reported impurity amount than its actual level. Again, if compendial impurity reference standards are available and used, the compendial lot numbers would be sufficient.

Manufacturers often utilize secondary reference standards (or working reference standards) for routine analysis in order to preserve the precious primary reference standards, which may have been highly purified and comprehensively characterized. Once identity and assay of the primary reference standard are fully established, the secondary reference standards can be qualified against the primary reference standard with a minimum of identity and assay tests. Qualification of a reference standard should not be confused with release of drug substance because the intended purpose of a reference standard is different from drug substance. The latter is used for manufacturing drug product, which would ultimately be dosed to patients; and the former is used in an analytical laboratory and consumed or disposed during or after the physical and chemical tests. Therefore, some tests required for releasing drug substance lots may not necessarily apply to the reference standard qualification; though a reference standard lot may have received a full release testing when it is sourced from a production lot.

S.6 Container Closure System

APIs are generally solids, and the container closure system for storage or shipment of a bulk solid APIs is typically a drum with double low density polyethylene (LDPE) liners that are usually heat-sealed or closed with a twist tie. A desiccant may be placed between the bags. The drum provides protection from light and mechanical strength to protect the liner during shipment and handling. The majority of the protection from air and moisture is provided by the liner. An API that is moisture-sensitive may need additional protection because LDPE is not a particularly good moisture barrier. An alternative to a LDPE bag is a heat-sealable laminate bag with a comparatively low rate of water vapor transmission.

The container closure system for the storage or shipment of a bulk liquid drug substance is typically a container with a rugged, tamper-resistant closure. Qualification of the container closure system may include characterization for solvent and gas permeation, light transmittance, closure integrity, ruggedness in shipment, protection against microbial contamination through the closure, and compatibility and safety of the packaging components as appropriate (eg, plastic, stainless steel, a glass-lined metal container, or an epoxy-lined metal). More information regarding general consideration on qualification and quality control of packaging components is discussed in the Container Closure Systems Guidance.[35]

In this section, a description of the container closure system for the bulk API as well as the composition of the specific components (container, closure, all liners, inner seal, and desiccant [if any]) can be provided. Documentation from each vendor showing compliance for each primary packaging material with 21 CFR (174-186) (food safety statement) is typically considered sufficient to establish the safety of the materials of construction.[36] Source(s) and the Certificate(s) of Analysis would demonstrate that the appropriate qualification and quality control of packaging components is in place.

A summary of how the container closure system ensures proper product quality during shipping and storage, based on known properties of the drug substance (eg, hygroscopic, light or air sensitive, etc.), should also be submitted. The summary could include a description of how the packaging system used during stability studies is representative of the commercial packaging system. In addition, the container label could capture a description of any special storage conditions (eg, protection from light, humidity, etc.). The storage condition is preferably a numerical temperature range based on the stability studies, but using USP terminology associated with a defined temperature limit or range such as "USP Controlled Room Temperature" is often acceptable. Undefined general terms, such as "room temperature," should be avoided.

The container label is often provided in this section, or may sometimes be cross-referenced to the executed

batch record (EBR) or Regional Section. Among the information on the label, it is recommended that a retest/expiry date is included. Although the COA typically has this information, it is often stored/archived separately from the actual container. Having the retest/expiry date on the container label allows the operator, auditor, and/or investigator to conveniently verify that the material is still in the valid period for use. ICH Q7A indicates that the retest date should be indicated on the label and/or COA for APIs with a retest date. The FDA Compliance Program Guidance Manual (Program 7356.002F, Chapter 56) further stresses that "Adequate expiration or retest dates should be on the label."[37] In addition, 21 CFR 201.122 also recommends a caution statement, such as "caution: for manufacturing, processing, or repacking" and prescription sign "Rx" be on the label when most of the dosage forms in which the API may be used are subject to prescription.[38]

S.7 Stability

The recent publication of the ANDA stability guidance[39] largely harmonized the stability requirements among the new and generic drug applications to ICH Q1 guidelines.[40] A question and answer guidance was published in May 2014 to further clarify the FDA's recommendations regarding stability testing data for ANDAs and referenced API DMFs.[41] A unique situation pertaining to Type II API DMF under GDUFA often causes some confusion to the applicants and/or holders. To pass the CA, DMFs should include the stability protocol, commitments, and data demonstrating that stability studies have started. The initial and one additional time point for the accelerated studies and long-term studies are sufficient. The CA is strictly triggered by the GDUFA DMF fee payment even before any ANDA submission makes reference to it. The DMF holders are encouraged to pay the DMF fee earlier to initiate the CA process in order to bring the DMFs to the status of "available for reference." If the DMF does not meet the stability data requirement specified in the ANDA Stability Guidance at the time of the CA, the DMF holder should amend the DMF with updated stability data to prepare for full scientific review.

The stability acceptance criteria is often harmonized with the release criteria and the stability protocol design and the choice of API storage condition aligns well with intended storage and use condition of the drug product. Most of the drug products in solid oral dosage forms are stored at controlled room temperature. When the long-term stability studies are conducted at $5 \pm 3^{\circ}C$ and the API is intended for storage in a refrigerator while the corresponding drug product is or will be stored at the common controlled room temperature, the choice of refrigerated storage for the API should be explained. The following questions may be used as a guide when addressing such situations:

- Have the stability studies at room temperature longer than 6 months (typical 6 months of data at $25 \pm 2^{\circ}C/60\%$, RH $\pm$ 5% RH (relative humidity), as accelerated condition when long-term condition is $5 \pm 3^{\circ}C$) been conducted?
- Have the stability studies at elevated temperatures (eg, $30 \pm 2^{\circ}C/65\%$ RH $\pm$ 5% or $40 \pm 2^{\circ}C/75\%$ RH $\pm$ 5% RH) been conducted?
- Has any stability failure or trend been observed in those studies?
- How can the stability of a drug substance, which requires refrigerated conditions, be ensured in a drug product that is stored at controlled room temperature?

When some stability failure and/or clear trend of increasing degradants is observed, efforts should be made to identify and specify these degradants so that they can be continuously monitored throughout the product's shelf life. Additional information regarding these degradants as applicable may be needed to support the control strategy for them, such as:

- The chromatograms of impurity analysis at the failed stability time points
- The impurity profile tabulated with their RT/RRT and % w/w
- The trend analysis of the degradants to project their growth rate at room temperature
- Impurity characterization effort (or semi-characterization by LC/MS)
- Inclusion of the degradants that were observed with Out of Specification (OOS) results at room temperature in both release and stability specification (eg, by RRT and Mass ID if not fully identified yet) so that the drug product manufacturer(s) will know what to follow-up
- Qualification of the degradants(s) as needed per the applicable guidance to demonstrate that its exposure will not have additional risk to the patients
- In the case of the drug substance manufacturer being different from the drug product manufacturer, commitment to provide information about any observed stability failure, including results of the investigation and impurity characterization information, to the drug product manufacture(s)

39.5 CONCLUSION

QbR facilitates a high-quality submission with the appropriate level of detail. It standardizes submission

format, clarifies the FDA's expectations, provides an opportunity for applicants and holders to address critical questions about the product's design, failure risk, and manufacturing controls from both a performance and patient usability perspective, encourages justification for choices made throughout product development and manufacture, and increases transparency in the applicant's thought processes. It may also be used within the applicant's organization as an internal communication tool in preparation for the submission. The QbR also facilitates the team-based IQA in OPQ. It is consistent with the QbD paradigm, congruent with risk management approaches and also acts as a guide for assessing the level of risk associated with the design and manufacture of the product. This helps ensure a consistent and comprehensive quality evaluation and eventually leads to more focused and efficient review.

APPENDIX QbR QUESTIONS—DRUG SUBSTANCE[14]

2.3 Introduction to the Quality Overall Summary

2.3.S.1 General Information

1. What are the nomenclature, molecular structure, molecular formula, CAS number, molecular weight, and pharmacological class of the drug?
2. What are the physical, chemical, biological and, if applicable, mechanical properties including physical description, pK_a, chirality, polymorphism, aqueous solubility as a function of pH, hygroscopicity, melting point(s), and partition coefficient?

2.3.S.2 Manufacture

3. Who manufactures the drug substance? List each participant and facility involved in drug substance manufacturing/testing activities and clearly state their function. List the date of the last FDA inspection of each facility involved and the result of the inspection. Has the manufacturer addressed all concerns raised at the FDA inspection?
4. What is the flow diagram of the manufacturing process that shows all incoming materials, reagents, reaction conditions, and in-process controls and, if appropriate, any reprocessing/reworking/alternative processes?
5. If applicable, what on-line/at-line/in-line monitoring technologies are proposed for routine commercial production that allows for real-time process monitoring and control? Provide a summary of how each technology was developed.
6. What is (are) the starting material(s) for the manufacturing process and how would changes in starting material quality and/or synthesis/source be controlled to minimize adverse effects on the drug substance quality?
7. What are the starting material specifications and how are they justified?
8. What are the specifications for reagents, solvents, catalysts, etc.? What are the critical attributes for these materials that impact the quality of the final drug substance?
9. What are the critical process parameters (CPPs) and how are they linked to drug substance quality?
10. What are the in-process controls (IPCs)/tests associated analytical procedures and acceptance criteria for each control?
11. What are the specification(s) for the intermediate(s)?
12. What process validation and/or evaluation information is provided, if any?
13. What development and scale-up information supports the commercial process and control strategy?

2.3.S.3 Characterization

14. How is the drug substance structure characterized?
15. What are the potential impurities (eg, related substances, degradants, inorganic impurities, residual solvents) in the drug substance? Which of these impurities are potentially genotoxic?

2.3.S.4 Control of Drug Substance

16. What is the drug substance specification and what is the justification? Does the specification include all of the drug substance's critical quality attributes (CQAs)?
17. For each test in the specification, provide a summary of the analytical procedure(s) and, if applicable, a summary of the validation or verification report(s).
18. How do the batch analysis results compare with the proposed specification? Provide a summary of the batch analysis results.
19. What is the proposed control strategy for the drug substance manufactured at commercial scale? What are the residual risks upon implementation of the control strategy at commercial scale?

2.3.S.5 Reference Standards

20. How are the drug substance reference standards obtained, certified, and/or qualified?

2.3.S.6 Container Closure System

21. What container closure system(s) is proposed for commercial packaging of the drug substance and how is it suitable to ensure the quality of the drug substance during shipping and storage?

2.3.S.7 Stability

22. What are the stability acceptance criteria? If applicable, what is the justification for acceptance criteria that differ from the drug substance release specification?

23. What is the proposed retest period for the drug substance? What drug substance stability data support the proposed retest period and storage conditions in the commercial container closure system? How does statistical evaluation of the stability data, if any, and any observed trends support proposed the retest period?

24. What are the post-approval stability protocols and other stability commitments for the drug substance?

Modern Pharmaceutical Regulations: Quality Assessment for Drug Products

J.A. Maguire, W. Jiang and L.X. Yu

U.S. Food and Drug Administration, Silver Spring, MD, United States

40.1 INTRODUCTION

Information on the chemistry, manufacturing, and controls (CMC) for the drug product must be submitted to the Food and Drug Administration to support the approval of original new drug applications (NDAs) and abbreviated new drug applications (ANDAs). This chapter discusses assessment of the CMC information for drug products with a focus on question-based review (QbR). The QbR is structured to facilitate the assessment of applications submitted in the International Conference on Harmonization (ICH) common technical document (CTD) format. Although QbR was initially introduced for drug products submitted in ANDAs, its principles apply equally well to drug products submitted in NDAs.

40.2 QbR HISTORY

In the early 2000s, pharmaceutical quality was redefined by the FDAs Pharmaceutical Current Good Manufacturing Practices (cGMPs) and quality-by-design (QbD) initiatives,[1] as well as ICH Q8(R2), Q9 and Q10,[2–4] and in response, applicants were encouraged to implement QbD approaches in their drug product development and manufacturing activities. Accordingly, the FDA Office of Generic Drugs (OGD) developed a new quality assessment system as a tool to enable assessment and promotion of QbD approaches in ANDAs (ie, QbR) (Fig. 40.1). However, OGD was not the first office within Center for Drug Evaluation and Research (CDER) to use a QbR assessment system. The initiative built upon the positive experiences of the Office of Clinical Pharmacology and Biopharmaceutics (OCPB), which implemented a standardized NDA review template in a question-based format to improve consistency, foster good interdisciplinary communication and teamwork, and lead the reader logically through the thought process used in resolving scientific, clinical, and regulatory issues.[5] QbR used by both OCPB and OGD are reflective of good review practices (GRPs), which are documented best practices within CDER. All GRPs share fundamental values that make them exceptional and require them to be disseminated and adopted by review staff. These fundamental values are quality, efficiency, clarity, transparency, and consistency.[6] Another impetus for the creation of QbR was feedback from other regulatory authorities (eg, Health Canada) that use the quality overall summary (QOS) as a foundation for the primary chemistry review document.[7] The development of QbR followed four underlying principles[8]:

1. quality is built into the product and process by design, development, and manufacture, and is confirmed by testing;
2. risk-based approaches should be used to maximize economy of time, effort, and resources;
3. best practices of the pre-QbR OGD review system and organization should be preserved; and
4. best available science and open communication with stakeholders should be utilized to facilitate implementation.

Under the QbR system, applications are submitted in CTD format and include a pharmaceutical development section, as outlined in ICH Q8R2 and a QOS in Module 2, that addresses the QbR questions. QbR results in a minimal change for applicants generating

Developing Solid Oral Dosage Forms

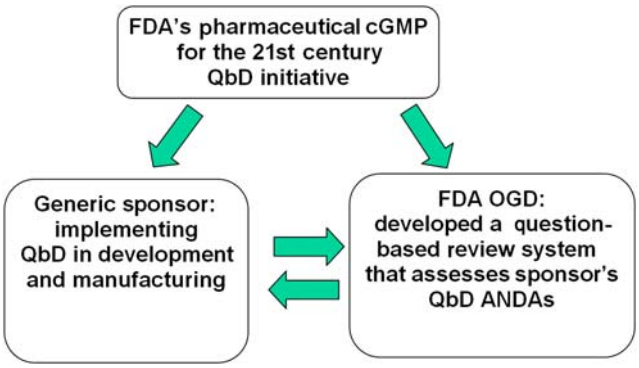

FIGURE 40.1 The Food and Drug Administration's cGMP initiative: quality by design, and question-based review.

multi-region submissions, so it does not impact the detailed submission package in Module 3. The Manual of Policies and Procedures (MaPP) 5015.10 on *Chemistry Review of Question-based Review (QbR) Submissions* clarifies how FDA reviewers should assess NDAs and ANDAs that follow a QbR format in conjunction with the FDA guidance for industry M4Q: The CTD—Quality.[9] Companion documents attached to MaPP 5015.10 detail the type of information expected within a submission in response to the QbR questions.[7]

For CMC reviews, a well-prepared QOS written by the sponsor provides the primary reviewer with a quick overview of the entire CMC package and reduces the review time spent on documentation. Pharmaceutical development information helps reviewers have a better understanding of how drug substance, formulation, and process variables affect the performance and stability of the drug product and supports appropriate performance-based specifications as well as the overall control strategy.

Due to its significant benefits, QbR was well-received by ANDA applicants and the FDA OGD chemistry reviewers, and has both parties' commitment. In Jul. 2007, more than 90% of ANDA submissions included a QOS that answered the QbR questions.[10] Today, 100% of ANDA applicants utilize QbR. Details about the impact and benefits of QbR are discussed in several commentary papers[8,11–18] and summarized in the MaPP 5015.10 and will not be repeated here.

40.3 CURRENT STATUS OF QbR

The recently published MaPP 5016.1 *Applying ICH Q8(R2), Q9, and Q10 Principles to CMC Review* establishes a policy that CMC reviewers will consider ICH Q8(R2), Q9, and Q10 recommendations when reviewing applications whether or not the applications include QbD approaches.[19] Reviewers will ensure that applications contain a quality target product profile (QTPP), critical quality attributes (CQAs) of the drug product, identification of those aspects of drug substances, excipients, container closure systems, and manufacturing processes that are critical to product quality and that support the safety and efficacy of the drug product, information that conveys an understanding of the development of the drug product and its manufacturing process, and a justified control strategy. Reviewers will take a scientific and risk-based approach during assessment of the application. The MaPP applies to both innovator and generic drugs.

CDER's quality initiative began more than a decade ago when the agency first introduced the 21st Century Initiative to modernize the FDA's regulation of the pharmaceutical quality of drugs.[1] The recent reorganization at CDER and the formation of the Office of Pharmaceutical Quality (OPQ) is a natural evolution of the review and inspection processes that allow the agency to better respond to an ever-changing world with continued globalization of the pharmaceutical industry, increasing product complexity, continued drug shortages and recalls, and legislative commitments outlined in the Prescription Drug User Fee Act (PDUFA) and the newly implemented Generic Drug User Fee Amendments of 2012 (GDUFA). OPQ further enhances CDER's quality initiative by creating a drug quality program as robust as the programs the agency already has in place for drug safety and efficacy. The formation of OPQ is a major step toward the goal of modernizing FDA regulation of drug quality and brings the CMC review of innovator and generic drug products into the same super office. The OPQ slogan is "One Quality Voice." The office integrates quality review, inspection, and surveillance over a drug product's lifecycle so that both internal and external stakeholders receive a single quality assessment capturing OPQ's overall recommendation on product approvability. OPQ emphasizes:

- A lifecycle approach to drug quality
- Proactive team-based and risk-based approaches
- Consistent and scientifically-sound quality standards for review and inspection
- Clear expectations and enforcement policies for industry
- Modernization and efficiency of drug manufacturing technologies

With widespread agreement that QbD and QbR have enhanced the quality of generic drugs, a recent initiative within OPQ focused on developing a QbR review template with overarching questions applicable to both innovator and generic drug products. The goals of the initiative were to standardize the review approach and expectations for both NDAs and ANDAs, better capture QbD expectations, incorporate

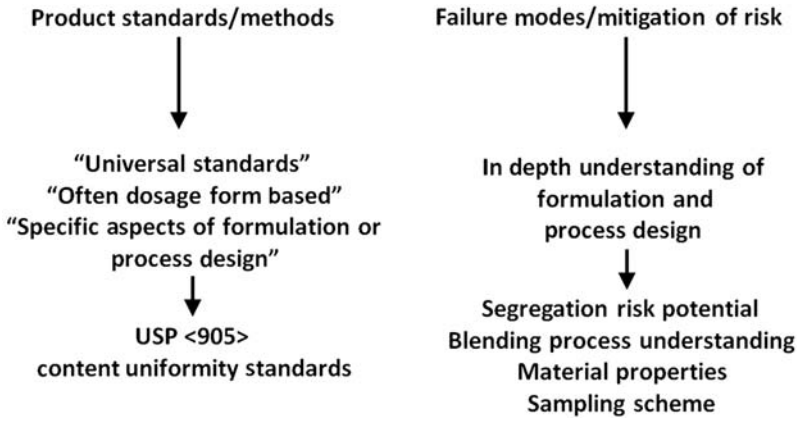

FIGURE 40.2 Conceptual dissection of a CMC review.

feedback and lessons learned from the previous QbR version implemented in 2007, support implementation of the integrated team-based review, which was introduced in chapter "Modern Pharmaceutical Regulations: Quality Assessment for Drug Substances," and facilitate communication among all quality stakeholders. The QbR questions presented in this chapter stemmed from this initiative and are covered in MaPP 5015.10 *Chemistry Review of Question-based Review (QbR) Submissions*.

The questions in the QbR recognize the two parts to a quality review that are conceptually different. Some questions reflect the need to comply with drug substance and drug product quality standards. These are universal standards that are often dosage-form based and address specific aspects of products, which are needed to deliver clinical performance. An example of a product standard is the expectation that all solid oral dosage forms include uniformity of dosage units in the drug product specification to comply with USP <905>. The USP acceptance criterion is a parametric two-sided tolerance interval test that covers 91% of the population at an 84% confidence level. This acceptance criterion ensures no more than 9% of the population will fall below 85% or exceed 115% at an 84% confidence level (ie, there is a 16% chance that a batch will be accepted with more than 9% out-of-specification). Results are generated on a sample population of up to 30 units, but batch sizes can range up to more than a million tablets or capsules. Therefore, it is debatable if passing results for such a minimal sample size is enough to demonstrate content uniformity for the entire batch. Thus, other questions go beyond compliance with general product standards and strive for a deeper, in depth understanding of the formulation and process design, probe the potential failure modes for the drug product, and focus on risk mitigation. These questions explore how risk is mitigated through reducing the probability and increasing the detectability of failures. For a low-dose drug product with a high risk of content uniformity failure, the focus is on minimizing segregation potential, optimizing mixing steps and demonstrating homogenous content with justified sampling schemes. The two parts of a quality review, product standards and risk mitigation, are illustrated in Fig. 40.2.

40.4 QbR QUESTIONS

QbR questions are designed to assess, concretely and practically, applicants' implementation of concepts and principles of QbD. At the heart of QbR are fundamental questions that reviewers ask themselves when assessing an application.

1. Will the product design ensure desired performance?
2. Will the applicant be able to scale-up to commercial scale and ensure comparable quality to the registration/exhibit batch(es)?
3. Will the applicant be able to manufacture the product with defined quality parameters over time?

The QbR questions for drug product are introduced next.

Introduction to the QOS

P.1 Description and Composition of the Drug Product

What is the description of the proposed commercial drug product? What are the components and composition of the final drug product as packaged and administered on both a per unit dose and %w/w basis? What is (are) the function(s) of each excipient?

The applicant should provide a descriptive summary of each strength of the drug product including weight, shape, dimensions, color, em/debossing, score configuration, etc. Any co-packaged components (eg, device components) should also be described. Often, a tabular

summary is an effective way of presenting this information. For generic drug products, submitting high-resolution photographs of all strengths of both the proposed generic and the reference listed drug (RLD) with a reference scale is also helpful. The composition table should be both qualitative and quantitative. All components of the drug product should be listed whether or not they appear in the drug product, including fluids used for granulation and gases used as a manufacturing aid. The subcomponents of any coating mixtures, colors, flavors, and inks should be provided. Where applicable, the composition table should clearly indicate the composition of significant drug product intermediates (eg, granules, tablet cores, beads). For each component, the quality standard and the function of that component in the formulation is needed. If a formulation contains a drug substance overage, this should be indicated in the composition table and justified in the submission.

Does any excipient exceed the FDA inactive ingredient database (IID) limit for this route of administration calculated based on maximum daily dose? If so, please justify.

This question asks for a comparison of each inactive ingredient level to the limit published in the electronic inactive ingredient database (eIID).[20] The comparison should be based on the maximum daily dose of the drug product and should be for the appropriate route of administration. Applicants should also discuss any patient safety considerations associated with the inactive ingredients when the drug product may be administered to special patient populations, such as pediatric or immunocompromised patients and/or when the drug product is meant to be administered chronically.

FDA will refuse-to-receive an ANDA if the submission proposes to use an inactive ingredient at a level that exceeds any of the eIID listings without adequate justification. In cases where the applicant wishes to use an inactive ingredient at a level per unit that is higher than what is proposed in the eIID, three options are available to facilitate receipt of the ANDA[21]:

1. Submit complete pharmacology/toxicology information
2. Cite a specific example of a CDER-approved drug product that contains the inactive ingredient at or above the proved level of use for the appropriate route of administration
3. Refer to an FDA-controlled correspondence response

If applicable, what are the differences between this formulation and the listed/RLD formulation?

This question applies specifically to 505(b)(2) applications for new drugs as well as 505(j) applications for generic drugs. Some ways in which a drug product submitted as a 505(b)(2) application may differ from the RLD include dosage form, strength, formulation, active ingredient, dosing regimen, or route of administration.[22] A generic drug product must be formulated to contain the same amount of active ingredient in the same dosage form and to meet the same compendial or other applicable standards (ie, strength, quality, purity, and identity) as the RLD.[23] A generic drug product should generally have the same score configuration as the RLD[21,24] and should be similar in size.[25] It should also have the same conditions of use; however, conditions of use for which approval cannot be granted because of exclusivity or an existing patent may be omitted. A generic drug product may differ in characteristics such as shape, color, and release mechanism.[23] With some exceptions, a generic drug product may also differ in excipients and drug substance solid state so long as safety and product performance will be equivalent to the RLD.

Any differences between the proposed generic drug product and the RLD should be justified in terms of therapeutic equivalence. Potential differences may include formulation, physical attributes, or design (eg, the generic drug product is designed as an extended-release matrix tablet, whereas the RLD is an extended-release osmotic tablet). For modified-release products, if a formulation with a different release mechanism from the RLD is used, the applicant needs to explain the differences, and provide comparative dissolution data between the RLD and the ANDA products in multiple dissolution media. In addition, it is possible for two products with very different plasma concentration profiles (such as different shapes or different T_{max}) to have equivalent AUC and C_{max}. The applicant needs to provide justification as to why the differences in plasma concentration profiles do not affect the therapeutic equivalence. Satisfactory answers to this question demonstrate scientific understanding of the underlying formulation design and biopharmaceutical principles.

P.2 Pharmaceutical Development

For 505(b)(1) applications, what is the rationale for selecting the proposed dosage form for the drug product? For 505(b)(2) and 505(j) applications, what are the characteristics of the listed/RLD product? What is the QTPP of the finished product based on the proposed indication and patient population? How is the QTPP justified?

This question solicits the scientific rationale behind the drug product design and encourages applicants to begin with the end in mind. New drug applicants should provide a brief description of the scientific and clinical rationale for the selected dosage form. Generic drug applicants should provide a complete characterization of the RLD product, including information regarding the clinical, pharmacokinetic, drug release, and physicochemical properties. Pharmacokinetic information such as AUC, T_{max}, and C_{max} is readily available

from the RLD labeling. The RLD labeling also provides critical information regarding alternative methods of administration. For example, some tablets may be crushed and suspended and some capsules may contain beads that can be sprinkled over applesauce. The applicant must bear these key design features in mind when developing a generic drug product that must be therapeutically equivalent to the RLD. Drug release properties should be investigated in several media/apparatus/dissolution conditions relevant to the specific dosage form. For solid tablets, physical characterization may include size, weight, shape, score configuration, and strength differentiation while chemical characterization may include dissolution profile, purity profile, stability, content uniformity, excipient grade and amount. The estimated composition of the RLD is usually based on the RLD labeling, patent literature, and/or reverse engineering. Another important consideration is the RLD packaging characterization, which focuses on what type of desiccant or O_2 scavengers are used.

Applicants should clearly define target product profile (TPP) and QTPP at the beginning of development. TPP is primarily expressed in clinical terms, such as clinical pharmacology, indications and usage, contraindications, warnings, precautions, adverse reactions, drug abuse and dependence, overdosage, etc. For a generic product, this information can be readily obtained from the labeling section of the RLD.[12] A generic drug product is therapeutically equivalent to the RLD in terms of dosage form, strength, route of administration, quality, performance characteristics, safety, and intended use. Therefore, a generic version and its RLD would be expected to have the same TPP.

The QTPP is a prospective summary of the quality characteristics of a drug product that ideally will be achieved to ensure the desired quality, taking into account safety and efficacy of the drug product.[4] The QTPP forms the basis of design for the development of a product that delivers the therapeutic benefit promised in the TPP.[12] Considerations for inclusion in the QTPP include the following[4,26]:

- Intended use in a clinical setting, route of administration, dosage form, and delivery system(s)
- Dosage strength(s)
- Container closure system
- Therapeutic moiety release or delivery and attributes affecting pharmacokinetic characteristics (eg, dissolution and aerodynamic performance) appropriate to the drug product dosage form being developed
- Drug product quality criteria (eg, identity, assay, content uniformity, purity, stability, drug release, sterility, and physical attributes) appropriate for the intended marketed product

Along with other available information from the scientific literature and possibly the pharmacopeia, the QTPP can be used to define product specifications, to some extent, even before the product is developed. Although it seems obvious that the target characteristics of a new product should be adequately defined before any development work commences, the value of predefining these target characteristics of the drug product has often been underestimated over the years, resulting in wasted time and valuable resources. A recent paper by Raw et al.[27] illustrates the significance of defining the correct QTPP before conducting any development. In addition, QbD examples exemplify the identification and use of QTPPs.[28–30] With a clear TPP and QTPP defined, formulation scientists can establish strategies and keep formulation efforts focused and efficient.

What are the quality attributes of the finished product? Which quality attributes are considered CQAs? For each CQA, what is the target and how is it justified?

For a solid oral dosage form, quality attributes may include identity, assay, content uniformity, degradation products, residual solvents, drug release or dissolution, moisture content, microbial limits, and physical attributes such as color, shape, size, odor, score configuration, and friability. These attributes can be critical or not critical. Identification of the drug product CQAs from the list of quality attributes in the QTPP is the next step in drug product development. A CQA is a physical, chemical, biological, or microbiological property or characteristic of an output material including finished drug product that should be within an appropriate limit, range, or distribution to ensure the desired product quality.[31] Criticality of an attribute is primarily based upon the severity of harm to the patient, should the product fall outside the acceptable range for that attribute. Probability of occurrence, detectability, or controllability does not impact criticality of the product quality attribute.

Drug product CQAs derived from the QTPP and/or prior knowledge are used to guide the product and process development. Risk assessment is used to identify the CQAs that have a high risk of failure based on characteristics of the drug product. The high-risk CQAs should be thoroughly evaluated during formulation and/or manufacturing development. A classic example of a CQA that typically has a high risk of failure is the content uniformity of a low-dose drug product. On the other hand, CQAs, such as identification, can be managed within the applicant's quality management system and are not required to be studied during pharmaceutical development because these CQAs generally have

a low risk of being affected by formulation or manufacturing variables.

The target for each CQA should be defined early in development based on the properties of the drug substance, dosing instructions, intended patient population, and characterization of the RLD product, as applicable. The target should be quantitative, where possible, and scientifically justified. During development, the target established in the QTPP may be modified or adjusted when the formulation and manufacturing process are selected and as product and process understanding is increased, as long as the rationale for the change is described.

What is the approach for meeting the CQAs related to clinical performance? If applicable, what in vitro bioperformance evaluations (ie, dissolution method, flux assay, etc.) were used during pharmaceutical development to ensure clinical performance?

A main goal of QbD is to achieve meaningful product quality specifications that are based on clinical performance. This question encourages early identification of the CQAs that are linked to efficacy and safety in the patient and development of in vitro tests to ensure clinical performance. The clinical effect may be direct or indirect depending on the pharmaceutical and toxicological determinants of the desired therapeutic performance. Such determinants of desired therapeutic performance can include therapeutic index, time to both onset and loss of clinical effect, duration of therapy (ie, acute or chronic), need for dose titration, washout or elimination period, pro-drug or metabolites, presence of toxic impurities or adventitious agents, inter and intrapatient variability, immunogenicity, and consequences of therapeutic failure. A nonexhaustive list of the CQAs that may be linked to these clinical determinants includes strength, purity, content uniformity, drug release or dissolution, and sterility. During the course of product development, the applicant should make every reasonable effort to use a dissolution test that is predictive of in vivo performance, especially for Biopharmaceutics Classification System (BCS) Class II (low solubility and high permeability) immediate-release drug products and for complex dosage forms such as extended release formulations. An acceptable response to this question would include a discussion of the relevance of the bioperformance test as a predictor of in vivo performance as well as a discussion of the method development and a description of any pilot bioavailability or bioequivalence studies performed to refine the method.

P.2.1 Components of the Product

The key objective of product design and understanding is to develop a robust product that can deliver the desired QTPP over the product shelf life. Product design is open-ended and may allow for many design pathways.[26] The QbR questions related to drug product design and understanding focus on the following key elements:

- Comprehensive characterization of the drug substance(s)
- Identification and selection of excipient type and grade, and knowledge of intrinsic excipient variability
- Interactions of drug substance and excipients
- Optimization of formulation and identification of critical material attributes (CMAs) of both drug substance and excipients

P.2.1.1 Drug Substance

What are the physical, chemical, biological and, if applicable, mechanical properties of the drug substance including physical description, pK_a, chirality, polymorphism, aqueous solubility (as a function of pH), hygroscopicity, melting point(s), and partition coefficient and, when available, BCS classification?

This question is similar to a drug substance QbR question presented in the previous chapter. With respect to the drug product, the physicochemical, biological, and mechanical properties of the drug substance that can influence the performance or stability of the drug product and its manufacturability, or the properties specifically designed into the drug substance (eg, solid state properties), should be identified and discussed. Details of these properties are presented in Table 40.1.[32,34] Solid understanding and characterization of drug substance properties are crucial to the successful development of a robust formulation and manufacturing process. Besides collecting information from literature and drug master file (DMF) sponsors, applicants are strongly encouraged to perform their own preformulation studies to obtain some key properties of drug substance, such as pH-dependant solubility and stability profile, solid state properties (eg, polymorphism), bulk and tapped density, etc. The impact of pharmaceutical solid polymorphism

TABLE 40.1 Typical Drug Substance Properties[32,33]

Physical and mechanical property	Color, odor, particle size distribution, shape, crystallinity, polymorphic form, hygroscopicity, bulk density, tapped density, true density, surface area, electrostatic charge, surface energy, elasticity, plasticity (ductility), viscoelasticity, brittleness
Chemical property	pK_a, aqueous solubility as a function of pH, chemical stability in solid-state and solution state, photolytic and oxidative stability
Biological property	Partition coefficient, membrane permeability, and/or oral bioavailability

and form transformation on product quality and performance has received much attention in recent years, and the findings have been presented in several review articles.[35–37] Decision trees that provide recommendations on monitoring and controlling polymorphs in drug substances and/or drug products can be referred to the recently published guidance.[38]

Based on the aqueous solubility, dose, and intestinal permeability of drug substance, the applicants may want to determine its BCS class.[34,39] With BCS class identified, applicants can understand and identify what may be the pertinent material attributes that can affect the drug product development and propose reasonable formulation strategies. For example, for BCS Class II drug substances, particle size reduction may be proposed as a formulation approach to improve delivery and manufacturability of a dissolution-limited drug substance. For a drug with 10 μg/mL solubility, in order for the drug product to achieve 80% dissolution in 30 minutes, the particle size has to be reduced to about 10 μm (assuming log-normal distribution, sink conditions, spheres).[40] Rohrs et al. published a paper to predict the effect of particle size distribution on content uniformity.[41] For a 1-mg dose, the particle size of drug substance, with very broad distribution (eg, geometric standard deviation is 3.5), is predicted to be about 15 μm to pass the USP <905> stage 1 content uniformity test for tablets, whereas for monodisperse particles (eg, geometric standard deviation is 1), particles around 150 μm are able to meet the content uniformity requirement. In these examples, particle size and distribution of drug substance are CMAs, which must be controlled to ensure product quality, and their specifications can be set based on understanding how they affect product performance.

In another example, oxidative degradation of the drug substance may require a stabilizer to be included in the formulation. It is key to understand the oxidation mechanisms of the drug substance, and then select appropriate stabilization strategies.[42,43] If the drug substance oxidation is heavy metal catalyzed, chelators such as ethylene diamine tetraacetic acid (EDTA) and citric acid should be used in the formulation. In cases where peroxides are believed to be the problem, stabilization strategies can be focused on careful selection of excipients with lower peroxide levels, lower concentrations of suspect excipients, and use of antioxidants.

What is the drug substance specification used to accept the incoming drug substance batches and how is it justified? For each test in the specification, provide a summary of the analytical procedure(s) and, if applicable, a summary of validation or verification report(s).

The drug substance specification should be inclusive of all quality attributes that may impact drug product manufacture and quality and may contain additional tests beyond those performed by the drug substance supplier. The specification is best presented in a tabular format with columns for the test, the acceptance criterion, the analytical method, and the full testing results for a representative lot(s) used in the registration batches. Although vendor qualification is the purview of the field, the applicant should distinguish tests that will be routinely performed by the applicant from those where the results will be taken from supplier's certificate of analysis (CoA). The applicant should also indicate what tests are performed during drug substance retesting. If complete IUPAC impurity names are not included in the table, then they may be presented as a footnote to the table. A separate table listing the impurity IUPAC name, structure and origin (process or degradant) is also helpful.

A summary of each noncompendial method should be provided. This can be in tabular or narrative form and should include the critical method parameters and the system suitability criteria. The applicant should also include a tabular summary of the method validation/verification performed per ICH Q2 and USP <1225> for all quantitative instrumental test methods (ie, assay, impurities, particle size, residual solvents, etc.) that includes the validation parameters evaluated, acceptance criteria, and results. Validation information is not necessary for USP methods or methods adopted from a DMF holder, but the suitability of the methods for their intended use should be verified (per USP <1226>) under actual operating conditions. For example, assay methods can be verified for specificity and precision and impurity methods can be verified for specificity, precision, linearity, and limit of detection (LOD)/limit of quantitation (LOQ).

When an in-house method or method from an alternative compendium (eg, European Pharmacopoeia (EP), British Pharmacopoeia (BP)) is chosen in lieu of the USP method, the results of a cross-over study to demonstrate that the method is equivalent or better than the USP method are needed. The comparison of analytical procedures is discussed in USP <1010>.

P.2.1.2 Excipients

What evidence supports excipient–drug substance compatibility and if applicable, excipient–excipient compatibility?

The inactive ingredients, or excipients, present in a formulation are themselves chemical moieties with functional groups that may be reactive. Sometimes there are unintended consequences or interactions including chemical degradation or complex formation between drug substance and excipient, loss of potency, degradation products with adverse events, or unacceptable changes in dosage form appearance or bioavailability.

QbD requires identification of mechanistic and formulation factors that affect drug product stability.

Acceptable finished drug product stability cannot be accepted as evidence of excipient–drug substance or excipient–excipient compatibility because end product testing only demonstrates that the quality was reached for the tested samples, but does not address how the product is designed to achieve the quality. Based on ICH Q8 recommendations, a drug substance/excipient compatibility study should be evaluated as a part of pharmaceutical development.[4]

Typically, a drug substance/excipient compatibility study is performed with binary mixtures or prototype formulations, which are prepared in the presence/absence of added water to mimic process steps (eg, wet granulation), stored at accelerated stability or stress testing conditions, and then analyzed by stability-indicating methodology, such as high-performance liquid chromatography (HPLC) for assay and degradation.[43,44] The addition of water allows the pH of the drug–excipient blend and the role of moisture to be investigated. Alternatively, thermal analysis methods, including differential scanning calorimetry (DSC) and isothermal calorimetry (ITC), are used to screen binary mixtures for their compatibility. However, data obtained via DSC/ITC are sometimes difficult to interpret or even misleading.[43,45]

A binary mixture approach is simple, but time and resource intensive, and may differ completely from a multicomponent system.[44] Due to these concerns, applicants can also perform drug–excipient compatibility studies via a prototype/trial formulation approach, with binary systems as a diagnostic back-up. In this complementary fashion, formulators may select one promising prototype formulation to move forward and identify any "culprit" excipient causing stability issues. The sponsor should use prior knowledge to justify inclusion or exclusion of certain excipients. For example, if the drug substance is a primary amine, and known to react with reducing sugar, the sponsor can include this as a rationale for not having lactose tested in the excipient compatibility studies. In addition, design of experiments (DOE) can be applied in the compatibility study, to determine the chemical interactions among components.

When the generic drug product is quantitatively and qualitatively the same as the RLD, in the absence of known stability problems, historical data may be acceptable in lieu of compatibility studies. However, applicants should be cautioned that excipients of different grades or excipients of the same grade, but sourced from different suppliers may contain different impurities that may interact with the drug substance. A systematic drug–excipient compatibility study will equip the product development scientist with a mechanistic understanding of formulation factors that affect drug product stability, and reduce formulation risk, leading to a decrease in development time and costs.

What is the rationale for the excipient selections?

Excipients can (1) aid in the processing of the dosage form during its manufacture; (2) protect, support, or enhance stability, bioavailability, or patient acceptability; (3) assist in product identification; or (4) enhance any other attribute of the overall safety, effectiveness, or delivery of the drug during storage or use.[46] Despite the fact that excipients can alter the stability, manufacturability, and bioavailability of drug products and are recognized as a major source of variability, the general principles of excipient selection are not well-defined, and excipients are often selected ad hoc. Note that different grades of excipients have different properties. For example, diluents may differ in particle size distribution and density and binders may differ in compressibility.

In this question, excipient choices are justified with respect to functions that are critical to product or process performance. It is important to indicate when pharmaceutical development work has demonstrated a functionality-related characteristic (ie, CMA, of an excipient plays a critical role for the manufacturability or quality attributes of the drug product). For example, when the polymer molecular weight and particle size are found to affect the release of a sustained release tablet, the relevant information should be documented in the answer. Note that compliance with USP-NF monographs is a minimum requirement. When necessary, stringent control of CMAs should be established beyond the compendial acceptance criteria to ensure consistent performance throughout the product lifecycle.[47] Formulators should anticipate lot-to-lot and supplier-to-supplier variability in CMAs and should establish specifications that will ensure consistent excipient performance.

P.2.2 Drug Product

What aspects of the formulation were identified as potentially high risk to the drug product performance?

Many attributes of the drug substance and excipients could potentially impact the CQAs of the drug product intermediates and finished drug product, making it unrealistic that a formulation scientist could investigate each identified material attribute of the drug substance and excipients during formulation development. Therefore, risk assessment leveraging common scientific knowledge, as well as the formulator's expertise, is valuable in prioritizing which material attributes warrant further study. Here, the applicant should provide a summary of the risk assessment approach used to rank or prioritize formulation variables based on their potential impact on drug product performance. It is up to the applicant to pick appropriately from a variety of recognized tools and to decide if the assessment should be formal or informal. The evaluation of the risk to quality should be based on scientific

knowledge and ultimately link to the protection of the patient; and the level of effort, formality, and documentation of the quality risk management process should be commensurate with the level of risk.[2]

Formulation variables that have been identified and justified as low risk are considered well understood. Those ranked medium risk can be considered acceptable based on current knowledge. Further investigation for medium-risk variables may be needed in order to reduce the risk to a lower level. Those ranked high risk are considered unacceptable and must be investigated to reduce the risk.

All potentially high-risk aspects of the formulation that could impact drug product performance should be addressed. For example, low drug loading of the final dosage form or key drug product intermediates may represent a high formulation risk due to the potential impact on content uniformity. Other formulation risks may include specific levels of excipients, as well excipient ratios. The level of rate controlling polymer in extended-release tablet formulations may impact drug release. The level of filler needed in a formulation could impact the tablet size. Specific excipient material attributes should also be considered in the overall formulation risk assessment and should tie into the rationale for excipient selection. For more complex dosage forms, an overall risk assessment of the formulation components (eg, IR granules, layered beads, coated beads, extra-granular excipients) can be performed followed by risk assessments of the variables involved to formulate each high-risk component (eg, for layered beads: bead selection, binder type and grade, solution viscosity, etc.). An acceptable response to this question summarizes the outcome of the risk assessment and provides the accompanying justification.

What formulation development studies were conducted? What attributes of the drug substance, excipients, and in-process materials were identified as critical and how do they impact the drug product CQAs?

By answering this question, applicants inform the FDA how they designed their product to meet the elements of the QTPP and to be safe and effective, in the case of innovator drugs, or those therapeutically equivalent to the RLD, in the case of generic drugs. A generic drug development scientist usually starts product design with studies of innovator product intellectual property, reverse engineering of the RLD, and preformulation. After studying the intellectual property of the RLD, the generic applicants may elect to go around the patent and certify that the patent is invalid, not infringed or unenforceable, or they may follow the patent and market the product after the patent exclusivity has expired.

Product understanding is exemplified by the ability to link input CMAs to output CQAs. The steps taken to gain product understanding may include the following[26]:

1. Identify all possible known input material attributes that could impact the performance of the product
2. Use risk assessment and scientific knowledge to identify potentially high-risk attributes
3. Establish levels or ranges of these potentially high-risk material attributes
4. Design and conduct experiments, using DOE when appropriate
5. Analyze the experimental data and, when possible, apply first principle models to determine if an attribute is critical
6. Develop a control strategy. For CMAs, define acceptable ranges. For material attributes shown to be noncritical, the acceptable range is the range investigated. When more than one excipient is involved, these defined acceptable ranges may be termed formulation design space

Formulation development studies are conducted to understand the impact of the potentially high-risk formulation variables identified in the preceding question on the quality of the finished drug product and to develop an appropriate control strategy to reduce the risk. For example, for problematic drugs, the formulation strategy may be to overcome limitations of the drug substance attributes such as poor solubility, poor dissolution, poor permeability, poor stability, or short plasma duration.

For each formulation development study used to identify which drug substance, excipient, or in-process material attributes (eg, particle size, blend uniformity, granulation flowability, etc.) are critical to manufacturing or product performance, a brief summary should be provided, including the objective of the study, the design and scale of the study, the factors that were investigated, the responses that were measured and how they compare with the pre-established targets, and the outcome of the study.

For complex formulations, the applicant usually investigates multiple candidate formulations during drug product development in order to obtain a bioequivalent product. This question encourages the applicant to share information on trial formulations or alternative mechanisms with the FDA. For instance, rapid dissolution of an immediate-release tablet may be achieved through particle size reduction or use of surfactant in the formulation. A controlled release product may be formulated with both immediate- and extended-release pellets or rather could employ a slow-release functional coating. Failed experiments often lead to better understanding of how formulation changes can alter performance and can help formulators identify the critical formulation or process variables. This development information may be useful to assess post-approval formulation changes, to develop

discriminating or predictive dissolution methods, and to set acceptance criteria on CMAs of the drug substance or excipients.

Applicants should also discuss how the final formulation was optimized. An optimization study is distinguished from an early screening study that explores a large range of space. An optimization study is more like fine tuning, and evaluates relatively small variations around a target formulation. Formulation optimization studies are essential to developing a robust formulation that is not on the edge of failure. Recent examples[48,49] have illustrated how formulations that are not optimized are risky because it is unknown whether any changes in the formulation itself or in the raw material properties would significantly impact the quality and performance of the drug product. However, it is not the number of optimization studies conducted, but rather the relevance and utility of the knowledge gained that is paramount to designing a quality drug product. As such, the QbD does not equal DOE, but the latter could be a valuable tool used in a QbD approach to development.[26]

How does the proposed commercial formulation differ from the formulations used during bioequivalence and/or clinical studies? What is the rationale for the formulation change? What biopharmaceutics evaluations (comparative dissolution, bioequivalence studies, biowaivers, etc.) support the formulation changes and link the development formulations to the proposed commercial formulation?

Applicants should summarize any planned formulation or finished dosage form physical attribute changes (eg, score configuration, shape, em/debossing, size) between the registration batches used for bioequivalence and/or clinical studies and the commercial batches. The rationale for such changes should be clear. The biopharmaceutical evaluation (eg, comparative dissolution, bioequivalence studies, biowaivers, etc.) conducted to support the changes should be fully described and its relevance scientifically justified. The evaluation should demonstrate that the proposed commercial formulation will not adversely impact the drug product quality, safety, and/or efficacy.

P.2.3 Manufacturing Process Development

A process is generally considered well-understood when: (1) all critical sources of variability are identified and explained, (2) variability is managed by the process, and (3) product quality attributes can be accurately and reliably predicted.[50] Similar to the steps outlined previously for product understanding, process understanding can be achieved by[26]:

1. Identifying all possible known process parameters that could impact the performance of the process
2. Using risk assessment and scientific knowledge to identify potentially high-risk parameters
3. Establishing levels or ranges of these potentially high-risk parameters
4. Design and conduct experiments, using DOE when appropriate
5. Analyze the experimental data and, when possible, determine scalability and apply first principle models to determine if a process parameter is critical. Link CMAs and critical process parameters (CPPs) to CQAs when possible
6. Develop a control strategy. For CPPs, define acceptable ranges. For process parameters shown to be noncritical, the acceptable range is the range investigated. When more than one process parameter or material attribute is involved, these defined acceptable ranges can be used to guide design space development, provided the ranges are identified via multivariate studies

The QbR questions next are designed to lead the applicant through these steps.

What is the rationale for selecting this manufacturing process for the drug product?

A pharmaceutical manufacturing process usually consists of a series of unit operations executed in batch mode or in a continuous manufacturing process. A unit operation is a discrete activity that involves physical or chemical changes, such as mixing, milling, granulation, drying, compression, and coating. The applicant should provide a schematic showing each unit operation in the drug product manufacturing process sequentially, including any reprocessing steps. The schematic should indicate all points of material entry for both raw materials and drug product intermediates and should include all in-process controls. For NDAs, the applicant can either provide a complete description of the commercial-scale manufacturing process or submit the proposed master production batch record. For ANDAs a detailed commercial-scale process description is also encouraged, but may not be submitted in lieu of the proposed or actual master production batch record.

For each unit operation, the process description should be supported by development work and should detail the following:

- batch size
- incoming raw materials (eg, excipients and processing aids and their grade, drug product intermediates from upstream unit operations) and the acceptance criteria for any material attributes known to be critical
- in-process controls and acceptance criteria
- equipment type, vendor, and model number
- process parameter settings (target and range)

Factors considered during manufacturing process selection may include the properties of the drug

TABLE 40.2 Examples of Pros and Cons of Typical Tablet Manufacturing Process[40]

Tablet manufacturing process	Pros	Cons
Direct compression	Simplified process, retains compactibility of materials	Segregation, flow
Dry granulation	Overcomes poor physical properties of API (particle size, shape)	Longer processing time, may compromise compactibility
Wet granulation	Improves uniformity, flow, and compactibility	Physical and chemical stability, residual solvents (nonaqueous granulation)

TABLE 40.3 Effect of Manufacturing Processes on Quality Attributes of the Drug Product

	Pre-blending and lubrication	Roller compaction	Milling	Final blending and lubrication	Compression
Assay	Medium	Low	Medium	Low	Medium
Content uniformity	High	High	High	Low	High
Dissolution	Medium	High	Medium	High	High
Purity	Low	Low	Low	Low	Low

substance, the desired characteristics of the drug product, and the complexity and robustness of the process. When applicable, the applicant should discuss in-house expertise with certain platform technologies or potential limitations, such as patent issues or facility and equipment availability to the extent that these scenarios guided manufacturing process selection.

Table 40.2 lists common tablet manufacturing processes and their pros and cons.[40] For example, for a drug substance with poor flowability and high drug loading, the granulation process may be considered to overcome the potential processing issues associated with direct compression. Once the process is selected, an applicant should focus on particular steps for which there are alternatives available (eg, selection of high-shear granulation vs fluid-bed granulation) with an explanation for the motivation behind each choice. Rationales can include scalability, yield, formulation aspects, expected granule characteristics, etc.[51] For granules that need to dissolve quickly, granulation techniques with lower shear forces (eg, fluid-bed granulation through top spray or bottom spray) can be selected. Fluid-bed granulation produces granules that have a more open, porous structure but are mechanically less stable.

Depending upon the product being developed, type of process, and process knowledge the development scientists have, it may be necessary to conduct preliminary feasibility studies prior to process development. Although it is not necessary to investigate alternative unit operations, if such studies were conducted to support a process choice, this information could provide very valuable support toward a better understanding of the final unit operations chosen to manufacture the drug product.

What is the potential risk of each process step to impact the drug product CQAs and how is the risk level justified?

This question is designed to connect each unit operation to its impact on the drug product CQAs and identify which process steps are high risk through risk assessment and prior knowledge. It is suggested that the applicant present the relationship between process steps and quality attributes of the drug product in the form of a matrix, as shown in Table 40.3.

Applicants should provide a concise summary of the risk assessment outcome, communicating the risk level assigned to each process step and clear justification for that assignment, whether the risk is high, medium, or low. The applicant should adequately justify low-risk process steps because these steps will not be studied extensively in the downstream development work. When justifying risk levels, the potential failure modes for each process step should be explained. For instance, if a process step is not properly controlled, the applicant should address which CQA of the drug product is likely to be affected and how it will be affected. For example, if the amount of a functional enteric coating applied to a tablet is not properly optimized, variable drug release will be observed, which may lead to noncompliance with the dissolution specification and ultimately a lack of efficacy in the patient.

For each of the potentially high-risk manufacturing unit operations:

a. *What input material attributes and process parameters were selected for study and what are the justifications for the selection?*

The previous question asks for the results of an overall risk assessment of the manufacturing process, which leads to the identification of high-risk steps that may impact the CQAs of the final drug product. For each high-risk unit operation, it is possible to identify CQAs of the drug product intermediate that are outputs of the unit operation and have a potential to impact finished drug product CQAs. Next, the process variables and material attributes, which may impact these CQAs of the drug product intermediate and, ultimately, the drug product CQAs, can be listed. Part (a) of this question focuses on the identification of

potentially high-risk material attributes and process parameters related to the identified high-risk steps that need to be investigated during development. Process parameters refer to the input operating parameters (eg, speed and flow rate) or process state variables (eg, temperature and pressure) of a process step or unit operation. Table 40.4 lists process parameters and input material attributes that could potentially impact the output quality attributes for typical pharmaceutical unit operations.[26] Equipment maintenance, operator experience and training, and standard operating procedures related to equipment use, testing, and facility supporting systems may link to product quality, directly or indirectly. Risk assessment allows the list of process parameters and material attributes to be prioritized to the vital few that pose the highest risk to impact the CQAs in order to focus development efforts. These variables are then investigated through controlled variations (eg, multivariate DOE and/or models) in order to better understand the process step and to develop a control strategy to consistently manufacture desired-quality drug product. This approach is illustrated schematically in Fig. 40.3, and can be used for each unit operation risk assessment.

The thought process depicted in the schematic is applied in the following example. Content uniformity is an element of the QTPP and is identified as a CQA for a low-dose, immediate-release tablet manufactured by blending and direct compression. The overall risk assessment of the manufacturing process identified the blending step to be high risk due to its potential impact on the content uniformity of the tablet. Next, blend uniformity is identified as a CQA of the blend (ie, drug product intermediate) because of its impact on the final tablet content uniformity. Drug substance and excipient particle size distribution and bulk density are material attributes and the number of blender revolutions and blender load level are process parameters that are most likely to impact the blend uniformity achieved during blending and are selected for further study during development.

If prior knowledge is used as the justification to fix a parameter or establish a starting point for investigation, then less justification is expected since experimental work will ensue. However, if prior knowledge is used in lieu of development studies, then more justification is expected in the application. The source and context of the prior knowledge, as well as its relevance to the current process, should be clearly communicated by the applicant.

b. *What process development studies were conducted? Provide a summary table listing batch size, process parameter ranges, equipment type, and estimated use of capacity.*

c. *What process parameters and material attributes were identified as critical and how do they impact the drug product CQAs?*

Parts (b) and (c) of this question are closely related. A concise summary of the conducted development studies that follow the logical progression of the drug product development should be provided. For each study, the objective of the study, the design and scale of the study, the factors that were investigated, the responses that were measured and how they compare with the pre-established targets, and the outcome of the study should be part of the answer. The summary should also include batch size, equipment type, equipment capacity used (or running time for continual operating equipment), process parameter set points, and ranges. A process parameter is considered critical when its intended variability is shown to have, or is likely to have, an impact on a CQA that is practically significant and, therefore, should be monitored or controlled to ensure the process produces the desired quality.

Criticality can be thought of as a continuum rather than discrete buckets (ie, critical or noncritical). When the underlying assumptions of the experiments used to determine criticality are changed, the conclusion on criticality can also change. Therefore, if future adjustments to process parameters and material attributes go beyond the investigated ranges discussed in the submission, then the conclusion on criticality should be reassessed.

At different stages of development, different approaches may be acceptable, such as screening, characterization, optimization, or verification studies. Process robustness is the ability of a process to consistently deliver acceptable drug product quality and performance while tolerating variability in the process and material inputs.[52] The effects of variations in process parameters and material attributes are investigated in process robustness studies. The relationship between input CMAs and CPPs and output CQAs is shown in Fig. 40.4. Studies to identify CMAs, CPPs, and their functional relationships to CQAs can be conducted at pilot- or laboratory-scale, and do not need to be conducted under cGMP. It is the responsibility of the applicant to demonstrate that the process is well understood, including how the interactions between the process parameters and/or material attributes impact the CQAs of the output materials, and to

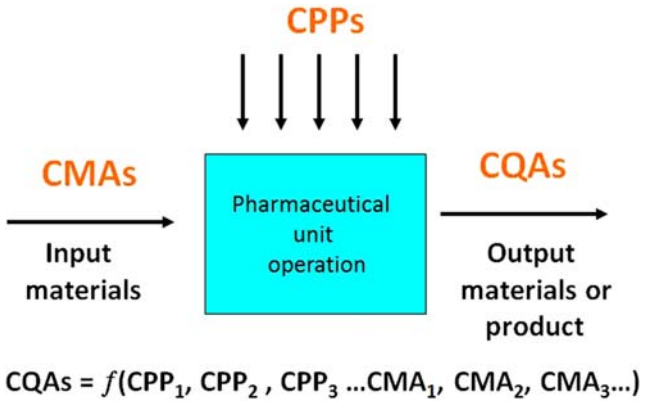

FIGURE 40.4 Linking input critical material attributes (CMAs) and critical process parameters (CPPs) to output critical quality attributes (CQAs) for a pharmaceutical unit operation.

establish limits for these CPPs (and CMAs) within which the quality of drug product is assured.

When a DOE study is performed, the *alpha* level used to judge whether a test statistic is significant should be provided and justified if it differs from the commonly used *alpha* level of 0.05. It is important to ensure that data are analyzed appropriately so that the conclusion is statistically meaningful. For example, analysis of variance (ANOVA) tables tell the overall story of the model, investigating and modeling the relationship between a response variable and one or more independent variables. When center points are included, curvature effect can be assessed and included in the ANOVA table. The saying that a picture is worth a thousand words really holds true when discussing DOE results. Pareto charts and half-normal plots are helpful when talking about what factors are significant. Main effect plots and interaction plots are also good visual aids. Contour plots are useful to see how two factors jointly affect responses and overlay plots support the selection of process parameter ranges.

When a trial and error or one-factor-at-a-time approach is taken, the applicant needs to explain how factors were determined to be significant, as well as how decisions regarding criticality were made. Information about interactions cannot be gained using this approach. Therefore, the applicant has a higher burden when justifying the chosen proven acceptable ranges.

Based on the outcome of the process development studies, the applicant can identify the process parameters, material attributes, and any interactions determined to be critical and can link these variables back to the drug product CQAs. This discussion of CPPs and CMAs conveys the process understanding gained throughout development and lays the foundation for proposing a control strategy. If no material attributes or process parameters are found to be critical, the range investigated is the range that should be reflected in the control strategy.

d. *How were the process parameters adjusted across lab, pilot/registration, and commercial scale? What are the justifications for any changes?*

Most manufacturing processes, whether as simple as making an aqueous solution of highly soluble drug substance or as complex as coating extended-release pellets to be used in a multiparticulate tablet formulation, have certain scale-dependent process parameters that will require adjustments when the manufacturing process is transferred to larger scale. Therefore, additional experimental work may be needed. Prior knowledge can play a very significant role in this regard because most pharmaceutical companies tend to use the same manufacturing technologies and raw materials on a regular basis. The functional relationship between CMAs, CPPs, and CQAs is also considered during scale-up. Monitoring CQAs of in-process material makes scaling less equipment-dependent as opposed to only monitoring CPPs.

Under part (d) of this question, the applicant should discuss the scale-up plan that builds upon experience obtained from development studies and/or the production of exhibit batch(es), scientific theory, first principles, literature references, vendor scale-up factors, laboratory scale to exhibit scale process transfer for this product, exhibit batch production, dimensional analysis, and/or mechanistic modeling. For reference to other applications, similarity of dosage form, physical properties of the drug and drug loading, excipients, equipment, and change of scale should be considered. Pharmaceutical development scientists can also make use of computer-aided process design (CAPD), and process simulation, such as roller compaction simulation, and tablet simulation, to support process development and optimization of manufacturing.[53] The increased use of CAPD and process simulation in the pharmaceutical industry should promise more robust processes are developed faster, and at a lower cost, resulting in higher quality products.

Changes made to the process parameters can be summarized in a table. An example of scale-up from lab-scale to pilot-scale and then to commercial-scale based on Johanson's model[54] for a roller compaction unit operation is summarized in Table 40.5.

The volume occupied by the batch in the processing equipment at each scale should be provided along with an assessment of capacity utilization differences on product quality and manufacturability. This assessment should also include the minimum and maximum recommended capacity utilization of the corresponding equipment at commercial scale. A similar comparison for the run time of continuous manufacturing equipment should also be provided to evaluate if/when a state of control is reached.

Equipment with different geometric design and operating principles (eg, bin blenders vs ribbon blenders) can impact blend homogeneity. In addition, various tumble blenders have significantly different designs and, therefore, operating efficiencies. For example, an asymmetrical blender such as a slant cone can be highly efficient in mixing when compared with a symmetrical blender such as a V-blender. A correlation between the two types of tumble blenders should be established through experimental studies if a change in equipment is anticipated during scale-up.

It is at the applicant's discretion to submit scale-up data, such as actual commercial-scale process performance qualification information in the application for a complex drug product that has a high risk of scale-up failure; however, in some cases it may be requested by the FDA prior to approval.

If applicable, what online/at line/in-line monitoring technologies are proposed for routine commercial production that allow for real-time process monitoring and control? Provide a summary of how each technology was developed.

Design space may be scale and equipment dependent. A limitation of design space based solely on process parameters is that the verification burden at different scales or in different equipment can limit the sought-after flexibility. An alternative to a control strategy that hinges solely on process parameter-based design space is a control strategy that actively monitors the output CQAs of intermediates (eg, blend uniformity) using process analytical technology (PAT) to adaptively adjust the input variables through feedback/feed-forward mechanisms (eg, blending time).[40]

Application of PAT involves four key components[26,55]:

- Multivariate data acquisition and analysis, which integrates product and process understanding into process control to achieve CQAs
- Process analytical chemistry tools that provide real-time and in situ data about the process status
- Process monitoring and control
- Continuous process optimization and knowledge management

TABLE 40.5 Scale-Up of the A Roller Compaction and Integrated Milling Process

Scale	Batch size (kg)	Batch size (units)	Alexanderwerk model	Roller width (mm)	Roller diameter (mm)	Roller gap (mm)	Roller pressure (bar)	Mill screen orifice size (mm)
Lab	5.0	25,000	WP120	25	120	1.2–2.4	20–77	1.0
Pilot	50.0	250,000	WP120	40	120	1.8	50	1.0
Commercial	150.0	750,000	WP200	75	200	2.0–4.0[a]	31–121[a]	1.0

[a]*The range is based on the scale-up equation and needs to be verified.*

TABLE 40.6 Process Analytical Technology (PAT) Implementation in Solid Oral Unit Operation and Its Benefits in Product Development[56]

Unit operation	PAT technologies employed	Benefits in product development
Particle size reduction	NIR spectroscopy	Design/control milling process of API and in-process agglomerates
Blending/ mixing	NIR spectroscopy FT-Raman spectroscopy	Identify safe-zone and the most appropriate mixing time
Granulation	NIR, Raman XPRD spectroscopy Thermal effusivity Combination of an image-process device and a fuzzy control system Acoustic emission Stress fluctuation spectroscopy	Justify granulation process parameter ranges with controlled granulation quality
Drying	NIR spectroscopy	Identifying drying curve and end point Justify moisture content specifications
Coating	NIR spectroscopy Raman spectroscopy	Determine coating rate and end point with minimized manufacturing variability; interpret coating uniformity
Unit dosing (compression or encapsulation)	NIR spectroscopy Raman spectroscopy	Detect drug distribution uniformity in finished product. Identify undesired process deviation

PAT can be utilized offline, at line, online, and in line, and its implementation in different solid dose unit operations is summarized in Table 40.6.[57] For instance, in the blending process, the use of online near-infrared (NIR) can evaluate the mixing status of active pharmaceutical ingredient (API) and excipients and monitor compositional variability over the entire blending time, rather than the traditional one-time sampling points at the end of blending. This allows for the evaluation of segregation or demixing potential, and identifies the safe-zone of uniform mixing or the most appropriate mixing time. Understanding of critical processes, as well as justification of process parameters and in-process specification ranges via PAT work, provides superior control quality. Ideally, PAT can help provide feedback to the control system, and manufacturers have the ability to effect continuous improvement and continuous real-time assurance of quality. Nevertheless, there are some regulatory, quality assurance, cGMP, and validation challenges associated with the adoption of PAT. Pharmaceutical industries are strongly encouraged to prepare for the challenges, and promote drug product development and process understanding via PAT efforts. The FDA has approved a number of applications that implemented PAT, including drug substance and drug product manufacturing processes for innovator products, generic products, and veterinary products, demonstrating success with this initiative.

In response to this QbR question, a description of the online/at line/in-line technology that is being used for real-time process monitoring and control should be provided as well as a discussion of how the technology will be implemented and the impact of the technology on the overall control strategy. A summary of the method development would suffice if the technology is being used for process monitoring and control. However, implementing PAT for real-time release testing (RTRT) of the drug product would require additional supportive information to be provided. The applicant should provide a description of the instrument and its location, information on the development and validation of the calibration method, and a summary of the model maintenance approach. Another consideration when PAT is utilized is having a contingency plan detailing how the process will be controlled in the event that the PAT analyzer fails in the middle of manufacturing or is not available from the very beginning of batch manufacturing.

P.2.4 Container Closure System

What specific container closure system attributes are necessary to ensure drug product integrity and performance through the intended shelf life? If applicable, what are the differences in the container closure system(s) between this product and the RLD?

The applicant may give the rationale (eg, drug product stability concerns) for selecting a particular container closure system including light resistance, moisture protection, or inert atmosphere. For example, when atmospheric oxygen is the source of drug oxidation, the formulator can select an appropriate packaging material (material with lower oxygen transmission rate), oxygen scavenger, and/or packaging method (packaging under inert gas) to overcome the oxidation problem.[42] Controlling the oxygen permeability and headspace oxygen in bottles is appropriate for drug product shelf stability, but cannot ensure drug stability after the consumer has opened the product. Therefore, blister packaging

may need to be used for some extremely oxygen-sensitive drugs.

Consideration should also be given to the intended use of the drug product and the suitability of the container closure system for shipping and handling. When applicable, the applicant should summarize studies illustrating that tablet breakage or delamination is minimized. Another consideration is the need for child protection using child-resistant closures. In some cases, data supporting that drug product quality is not adversely impacted by temperature excursions may be warranted.

When discussing differences in the container closure system between the proposed generic and the RLD for a solid oral dosage form, applicants should detail the material of construction, container size(s) and fill count/volume/weight, filler type, desiccant type and desiccant configuration (sachet, canister, etc.), and quantity.

How was the container closure system(s), including bulk containers, qualified for suitability (protection, compatibility, safety, and performance)?

There are four elements that need to be considered when qualifying a container closure system as suitable for its intended use: protection, compatibility, safety, and performance.[58] The system should adequately protect the dosage form to alleviate stability concerns. It should also be compatible with the dosage form. Possible interactions between the product and container or label components should be considered. The container closure system should also be composed of materials that are considered safe for use with the dosage form and the route of administration. Finally, if the packaging system has a performance feature in addition to containing the product, it should be shown to function properly and similarly to the RLD, as applicable. If the only rationale provided for qualifying a container closure system is that the same system was previously FDA-approved for a different drug product in a different application, this justification is generally inadequate to ensure the proposed container closure system is suitable for the current drug product under review.

P.2.5 Microbiological Attributes

When applicable, what microbiological attributes were evaluated on the finished product?

Solid oral dosage forms represent a relatively low microbiological risk to patients; therefore, the microbiological controls associated with their manufacture are not as stringent as those for sterile or aqueous nonsterile products. However, microbiological control is important in the manufacture of solid oral dosage forms in order to prevent drug product degradation, the introduction of microbial metabolites and/or toxins during the manufacturing process, and patient exposure to high numbers of harmful species of microorganisms. Minimally processed components derived from certain plant and animal sources, or manufacturing processes involving extended aqueous holding times, may carry a higher overall microbiological risk.

The rationale for performing or not performing microbial limits testing for nonsterile drug products should be evaluated (eg, Decision Tree #8 in ICH Q6A, USP <1111> and USP <1112>).[59–61] Solid dosage forms that have low water activity or are otherwise inherently antimicrobial are excellent candidates for reduced microbial testing for product release and stability.[59] A submission that proposes a waiver of microbial enumeration testing on product release should include a description of the following:

- Critical control points in the manufacturing process that may affect the bioburden of the finished drug product
- Monitoring schedule and acceptance criteria for the critical control points documented in the batch record per 21 CFR 211.188
- Microbiological testing results for stability or exhibit batches of the drug product
- Proposed stability testing schedule

Critical control points may include establishing bioburden limits on incoming materials, defining the maximum processing time for any aqueous processing steps, and justifying the maximum holding time for any aqueous coating solutions with supporting data. If extensive product history is available, and upstream controls are established, it may be feasible to propose a waiver of all microbial limits studies, including those on stability. When a significant history of product and process control is still being developed at the time of application submission, microbial enumeration testing at batch release should be proposed.

Due to the hygroscopic nature of gelatin and its greater water activity, gelatin may be capable of supporting the growth of some microorganisms over the product shelf-life, even if adequate microbiological manufacturing controls have been implemented. Stability batches of drug products containing gelatin should undergo microbial limits testing.

USP <1111> provides a risk-based standard for total aerobic microbial counts, total combined yeasts/molds count, and specified microorganisms in nonsterile drug products based upon the route of administration.

If alternate microbial limits acceptance criteria are proposed, the applicant should provide a justification for the change and supporting data. It is not required that applicants utilize USP <61> and <62> test methods for microbial enumeration. However, a detailed

description of the microbial limits and specified organism detection test methods, as well as verification of the methods suitability for the finished drug product, need to be provided.

P.2.6 Compatibility

If applicable, what supportive data demonstrates the compatibility of the drug product with the means of administration (eg, additives and/or diluents, other co-administered drugs, dosing device)?

For some solid oral drug products, further manipulation or preparation may be required prior to administration. In cases such as these, appropriate compatibility information should be submitted in the application to support the drug product labeling. For a generic drug product, assurance that the generic drug meets all of the performance characteristics of the RLD is needed. When evaluating the QTPP for the proposed drug product, thorough consideration of any alternative means of administration should be made early in the process. This is the best approach to ensure that the appropriate development studies have been conducted to support all aspects of compatibility.

Examples where supportive data to demonstrate compatibility are required include capsules containing beads that are labeled for "sprinkle over applesauce" or to be dissolved in a glass of water. Some tablets need to be crushed and suspended for administration to patients who have difficulty swallowing or for administration to a pediatric population. For instance, if the labeling indicates that "the suspension is homogenous and can be stored for either up to 30 days at room temperature (below 30°C/86°F) or up to 75 days at refrigerated conditions (28°C/35–46°F) in the glass bottle," then stability data demonstrating that the proposed drug product is stable when prepared and stored according to the conditions (eg, temperature and time) specified in the label should be provided. Furthermore, some tablets are intended for administration through a nasogastric tube or oral syringe. For these tablets, applicants should demonstrate that when the label instructions are followed, the tablet disperses into granules or particles that are small enough to ensure that the nasogastric tube or syringe used for administration is not blocked or clogged. Similarly, the same is true for capsules and bead size.

The previous examples are meant to be illustrative and not exhaustive. The data required varies on a case-by-case basis and is dependent on the means of administration and the specifics of the drug product and the associated labeling. All alternative routes of administration should be fully evaluated with respect to drug product compatibility.

P.3 Manufacture

Who manufactures the drug product? List each participant and facility involved in drug product manufacturing/testing activities and clearly state their function. List the date of the last FDA inspection of each facility involved and the result of the inspection. Has the manufacturer addressed all concerns raised at the FDA inspection?

It is imperative that the agency has a complete list of facilities associated with the application early in the submission process to ensure that the necessary facility evaluations can be performed and any necessary preapproval inspections scheduled to allow timely approval. Applicants should include the name, address, and FEI number for each site or facility involved with commercial manufacturing, packaging, or testing the drug product. Sites used to conduct stability testing of the registration batches supporting the submission should also be included if these sites differ from those planned to be used for commercial batches. When describing the responsibility of each testing site, it should be clear what component is being tested (eg, excipient, packaging component, drug substance, drug product intermediate, drug product), what test is being performed, and at what stage of manufacture (eg, in-process, release, stability). The dates of the last FDA inspection and the outcome of the inspection should be noted. If any concerns were raised by the FDA during the inspection, then a summary explaining how those concerns have been adequately addressed should be provided.

What is the commercial batch formula and how does it differ from the registration batch formula? Provide justifications for any differences.

A side-by-side comparison of the registration and commercial batch formulae should be provided. If there are any differences between the registration batch and the commercial batch formula, these should be noted and discussed in terms of the rationale for the differences as well as the potential impact on product manufacturability and CQAs. The weight or measure of each component of the batch formula should be listed (as per section 2.3.P.1.). It is helpful to also include each component on a weight percent basis. The name of the component should include a reference to its quality standard (eg, USP, in-house, etc.). For excipients where a range has been justified, the target amount and range should be included in the batch formula.

Drug substance overages are generally discouraged; however, if any an overage is used, it should be made clear and justification should be provided. Overages are added to the formulation either for a manufacturing loss that has been demonstrated to

be reproducible, or for stability concerns. The composition should reflect the actual quantities charged to the batch since the overage is a part of the formulation. For example, a product with 2% overage of the drug substance should list the drug substance as 102% in the formulation. Note that stability assessment should be based on the actual quantity used in the formulation (ie, 102%).

Processing agents (eg, water, solvents, and nitrogen or other gases) that do not remain in the finished product should be included. Any gases used during manufacture should be listed and their purpose identified (eg, blanket formulation, fill vial headspace). An asterisk after the ingredient name with a footnote below the table could be used to identify components that are removed during processing or to clarify the purpose of inert gases used during the manufacturing process.

An excess is any inactive ingredient prepared in addition to the overall formulation to compensate for certain losses during manufacturing, but that does not become part of the product formulation once manufacture is completed. For example, a certain percentage of excess coating solution is often prepared to compensate for losses of the coating solution to the walls of the equipment. Excess material can be denoted with an asterisk and explained in a table footnote. The excess material should be reasonable and well justified.

If a common formulation is used to produce multiple products' strengths, then the composition of each strength should be provided including the total weights/volumes as applicable. If the end product is a result of two or more sublots, then the composition of each sub-lot and the number of sublots should be clear. If the registration batch is manufactured as one lot, but the commercial scale batch will be manufactured using sublots, then this should also be indicated.

In some instances, separately blended or formulated materials that are later combined during manufacturing should be listed separately in the batch formula. For example, some modified-release products contain a mixture of immediate release and extended-release beads within a dosage unit. In this case, the composition table should present the batch formulas for the individual subcomponents of the dosage unit.

What is the flow diagram of the manufacturing process that shows all incoming materials, processing steps/unit operations, and in-process controls?

The flow diagram is a schematic showing each unit operation of the commercial manufacturing process consecutively from first charging of materials through packaging. It should also show each point of material entry. The material entry into a particular unit operation may be drug substance, raw materials, or drug product intermediates. The flow diagram should also include the in-process controls for each unit operation. In cases where reprocessing steps are possible, those should be included in the diagram.

What is the detailed process description, including process parameters, material attributes of raw materials and intermediates, equipment type, batch size, in-process controls, including acceptance criteria and any proposed reprocessing?

Applicants should submit a manufacturing process description for a representative commercial batch of the drug product that has the level of detail comparable to a master production batch record (NDAs) or a proposed or actual master production batch record (ANDAs). For each process step and proposed reprocessing step, the narrative should detail:

- Batch size
- Incoming raw materials/drug product intermediates and acceptance criteria for any CMAs. For raw materials, the grade should also be specified
- In-process controls and acceptance criteria
- Equipment description (type, vendor, model number, etc.)
- Process parameter settings (target and range), indicating which process parameters are critical

Process parameter ranges and in-process controls should be supported by pharmaceutical development work discussed in 3.2.P.2.3. A risk-based approach should be taken when establishing hold times for drug product intermediates. Data should be provided for studies conducted in the proposed storage container under the proposed storage conditions for the appropriate length of time to demonstrate that holding does not adversely affect quality.

What in-process sampling strategies and methods are used to monitor in-process material attributes that have a potential to affect quality?

Details about sampling for each unit operation (eg, sample size and/or quantity, sampling frequency, sampling location) should be provided for CQAs of drug product intermediates. For example, details about blend uniformity sampling in bins or drums or stratified sampling of core tablets should be provided for low-dose products that have a high segregation potential.

What are the in-process test results for each process step of the registration batch(es)? What are the differences, if any, in the in-process controls for the registration batch (es) and the intended commercial batches? What are the justifications for these differences?

It is best to present the in-process test results for each step of the process as a tabular summary listing the test, the acceptance criteria, and the observed results. Those quality attributes of the drug product intermediates that may have a significant impact on the quality of the finished drug product should be identified and monitored. In addition, if there are any

differences between the tests performed and/or the acceptance criteria between the registration batches and proposed commercial-scale batches, the differences should be explained and well justified. It should also be made clear if any of the tests are planned through validation, but not as part of the commercial manufacturing control strategy.

P.4 Control of Excipients

What are the excipient specifications and how are they justified? How do the proposed acceptance criteria for the material attributes of the excipients ensure the quality of the final drug product?

USP-NF excipients should minimally comply with the current respective monograph. In-house analytical procedures used to test compendial excipients should be appropriately validated. Any additional test(s) needed for CMAs identified during development beyond those listed in the monograph should also be included in the specification and the response to the QbR question should explain how the CMA and the proposed acceptance criterion relates to the final drug product quality. Applicants should discuss the adequacy of the specification to mitigate any associated risks to manufacturability or drug product performance for excipients where lot-to-lot variability is anticipated. Specifications including analytical procedures and method validations for the noncompendial excipients are also expected.

Applicants should provide both in-house and vendor full testing results for excipient lots used to manufacture the registration batch(es) or a representative CoA for any additional lot that has been fully tested. Note that proposals for vendor qualification and skip-lot testing are beyond the purview of the review divisions.

In cases where a novel excipient not previously used in a CDER-approved product is included in the formulation, information detailing the excipient manufacture, characterization, control, and safety qualification, or a reference to a DMF containing the previously mentioned information should be included. Applicants should provide bovine spongiform encephalopathy (BSE)/transmissible spongiform encephalopathy (TSE) certification as well as the country of origin for any excipient of animal origin.

P.5 Control of Drug Product

What is the drug product specification, what is the justification, and how is it linked to the product performance and patient safety? Does the specification include all the CQAs for the drug product?

How do the batch analysis results compare with your proposed specification? Provide a summary of the batch analysis results.

To illustrate related concepts, these questions are grouped together in this chapter, although they are presented differently in the QbR assessment system. A specification is a list of tests, references to analytical procedures, and appropriate acceptance criteria, which are numerical limits, ranges, or other criteria for the tests described.[59] The drug product should conform to the specification to be considered acceptable for its intended use. Specifications are quality standards that are proposed and justified by the applicant and approved by the FDA as conditions of approval. The specification is part of the total control strategy designed to ensure product quality and consistency. To answer this question, the applicant should present a tabular summary of the specification including columns for the test, analytical procedure, acceptance criteria, and representative results for at least one registration batch of each strength. The specification should focus on those characteristics that are useful in ensuring the safety and efficacy of the drug product including all drug product CQAs necessary to ensure the identity, strength, purity, and quality. For USP drug products, the specification should include all tests listed in the monograph as well as any additional tests that are deemed necessary for the drug product. The applicant should also provide justification for the chosen acceptance criteria for each CQA as well as a discussion linking the proposed control of the drug product to in vivo performance and patient safety. In cases where any tests of CQAs are omitted, scientific rationale should be provided.

In some cases, it may be appropriate to measure and control the drug product CQAs in-process in lieu of end-product testing. Controlling certain quality attributes upstream where the measured response provides a timely signal to make process adjustments is an effective strategy for ensuring product quality. For instance, if organic solvent is used during wet granulation, it is advantageous to control residual solvents at this step when drying time can be adjusted rather than waiting to test the compressed tablets when the only recourse for noncompliance with the residual solvent specification is batch failure. In addition, RTRT (formerly called parametric control) can be employed when the model is predictive of in vivo performance and captures the dominating factors that contribute to variability in the CQA. As a theoretical example, attributes relating to the properties of a tablet granule, such as porosity, particle size, surface area, or bulk/tapped density, if shown to have a predictive relationship with dissolution behavior, could serve as RTRT surrogates for dissolution testing.[62] Both of these approaches should be clearly presented and appropriately validated to show that test results or product

performance characteristics do not change from the in-process stage to the finished product.

The applicant should discuss how the registration batch results compare with the proposed specification. Whenever possible, results should be presented quantitatively rather than in general terms such as "complies" or "meets limit." Representative results for one registration batch of each strength can be presented with a hyperlink or reference to where additional batch results can be located in Module 3. In cases where the CQA still complies with the specification, but is on the edge of failure (eg, low assay, high Acceptance Value (AV) for content uniformity, high impurity level), the applicant may wish to discuss the root cause of the observed result and detail any further development or optimization that is planned to ensure that the CQAs will be achieved when the drug product is commercialized.

For each test in the specification, provide a summary of the analytical procedure(s) and, if applicable, a summary of the validation or verification report(s).

Applicants should identify regulatory and alternative analytical procedures when multiple analytical procedures can be used for a test. Note that the analytical procedures in the USP-NF are those legally recognized under section 501(b) of the FD&C Act (the Act) as the regulatory analytical procedures for compendial items and are the prevailing procedures used for the purposes of determining compliance with the Act. Applicants may propose to use a validated alternative analytical procedure found in other compendia, such as the BP, the EP, or the Japanese Pharmacopoeia (JP), instead of the regulatory analytical procedure.[63] The applicant should provide a rationale for its inclusion, as well as validation and comparative data to show that the alternative procedure performs equal to or better than the regulatory analytical procedure.

It is not necessary to provide a summary of the analytical procedure in the QOS when the USP procedure is followed, although the procedure details should still be submitted in Module 3. Each noncompendial procedure should be summarized in a tabular or descriptive form. It should include the critical parameters for the method and system suitability criteria, if applicable. For impurity methods where impurities are not quantified using impurity standards, the relative response factors should be provided.

Quantitative noncompendial analytical methods such as Karl Fischer, assay, impurities, and residual solvents should be fully validated per the recommendations found in ICH Q2 *Validation of Analytical Procedures: Text and Methodology*[64] and a summary table of the validation performance characteristics should be provided. The stability-indicating capability of assay and impurity methods should be demonstrated through HPLC peak purity and achievement of adequate mass balance. Stress studies should target 5−20% degradation to avoid secondary degradation. For very stable molecules that are difficult to degrade, a justification should be provided (ie, stress conditions that go beyond the usual) along with a summary of forced degradation results. Applicants should attempt to quantitate the degradants observed for each stress condition individually by name or relative retention time. The agency expects that any loss in the active peak is compensated by a corresponding increase in the amount of degradants. Any failures to obtain adequate mass balance should be fully explained.

According to USP <1226>, users of analytical methods described in USP−NF are not required to validate the accuracy and reliability of these methods, but merely verify their suitability under actual conditions of use.[65] Verification is not required for basic compendial test procedures including, but not limited to, loss on drying, residue on ignition, and pH that are routinely performed unless there is an indication that the compendial procedure is not appropriate for the article under test. A summary table of the verification performed for compendial methods should be provided. Typical performance characteristics include specificity and precision for assay methods and specificity, precision, linearity, and LOD/LOQ for impurity methods. In all cases, the applicant should demonstrate that the system suitability criteria can be achieved under actual conditions of use.

The response to this question may contain a reference or hyperlink to Module 3, the location of the full validation or verification information.

What are the drug product degradants? For each degradant, what is the structure, chemical name, origin, and mechanism of formation? How are the proposed limits justified and/or qualified for safety based on nonclinical studies? What is the control strategy for the potential drug product degradants?

Degradation products expected to occur during manufacture of the commercial product or under recommended storage conditions should be addressed in the proposed drug product specification. These degradants result from a chemical change in the drug substance brought about during manufacture and/or storage of the new drug product by the effect of, for example, light, temperature, pH, water, or by reaction with an excipient and/or the immediate container closure system.[66]

Generally, it is not necessary to test the drug product for quality attributes uniquely associated with the drug substance. Thus, process impurities present

in the drug substance need not be monitored or specified in the drug product unless they are also degradation products. If the applicant chooses to include drug substance process impurities or synthetic precursors in the drug product specification (eg, due to their presence in chromatograms or as markers in chromatograms), then those impurities should be limited at release and on stability to the same level as in the drug substance specification.

For each identified degradation product, the structure, chemical name(s), and origin should be provided. The applicant should also describe any studies performed to identify the degradant and its mechanism of formation, as well as the control strategy in place to minimize formation to the extent possible. When justifying the proposed acceptance criterion for the degradants, applicants should consider patient safety, particularly for degradants with the potential to be genotoxic or carcinogenic. In cases where applicants propose a degradant level above those recommended in the current guidance for industry for impurities in drug products and ICH Q3B,[66–68] the degradant will need to be qualified by conducting toxicity studies, submitting relevant scientific literature, demonstrating that the degradant is a significant human metabolite of the drug substance, or by showing that the RLD contains similar levels of the degradant using the same validated, stability-indicating, analytical procedure.

Degradants should be reported with the appropriate number of decimal places. Below 1.0%, the results should be reported to the number of decimal places in the applicable reporting threshold whereas at and above 1.0%, the results should be reported to one decimal place.

What is the proposed control strategy for the drug product manufactured at commercial scale? What are the residual risks upon implementation of the control strategy at commercial scale?

A control strategy is a planned set of controls derived from current product and process understanding that ensures process performance and product quality.[3,4] It can include, but is not limited to, input material attributes, facility operating conditions, and equipment operating conditions (ie, process parameters, in-process controls, specifications, sampling plans, and frequency of monitoring and control). Systematic and well-executed pharmaceutical development studies that result in enriched product and process understanding and identification of all CMAs and CPPs will culminate in the design of an appropriate control strategy to ensure the identity, strength, quality, and purity of the drug substance and the bioavailability and performance of the drug product throughout its lifecycle. Fig. 40.5 shows pictorially the different levels of control that are possible.

The most basic control is to have knowledge of the operating range, as well as the proven acceptable range of the process parameters. Proven acceptable range is defined as a characterized range of a process parameter for which operation within this range, while keeping other parameters constant, will result in producing a material meeting the relevant quality criteria.[4]

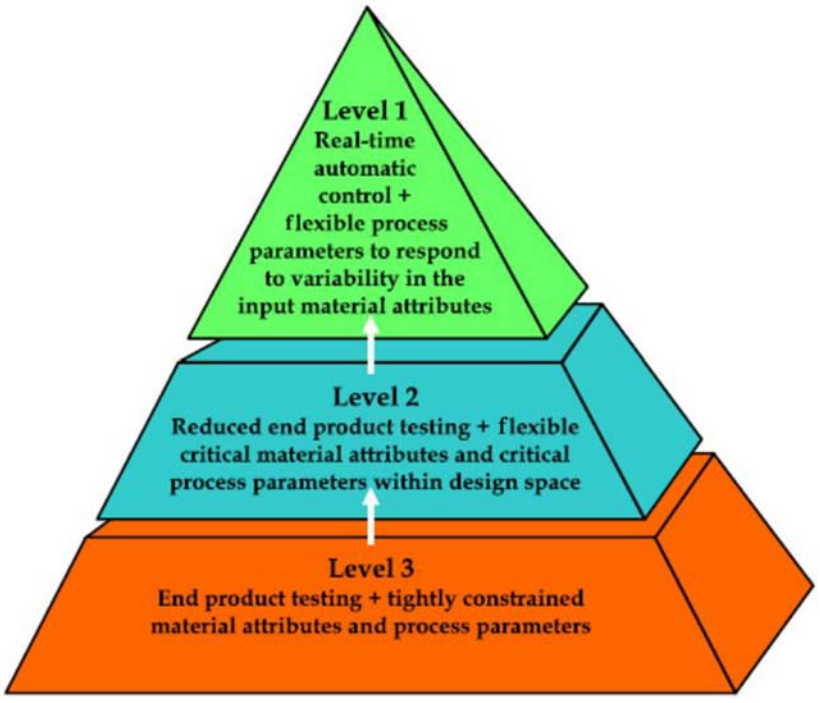

FIGURE 40.5 Control strategy implementation options.

The operating range is within the proven acceptable range, and is the routine control employed during production in order to assure reproducibility. Proven acceptable range is based on univariate experimentation and does not take into account the interaction of multiple process parameters. Proven acceptable range can provide some, but limited, information about the process.

Minimally, the control strategy should include all CMAs and CPPs; however, a more prudent approach may be to include all variables ranked as high risk in the initial risk assessment because the conclusion of the experiments is dependent on the range studied and the complex multivariate relationship between variables. In the presence of interacting CPPs and CMAs, a design space is a better approach to ensure product quality, although it is not a requirement. Design space is the multidimensional combination and interaction of input variables (eg, material attributes) and process parameters that have been demonstrated to provide assurance of quality.[4] The design space is likely established using DOE at small-scale batches and then verified at commercial scale. It is best to exploit dimensionless parameters and material attributes to define the design space because they are scale-independent. Design space is proposed by the applicant and is subject to regulatory assessment and approval. Working within the FDA-approved design space is not considered a manufacturing change. Movement out of the design space is considered to be a change, and would normally initiate a regulatory post-approval change process. Control space is within the design space, and not subject to regulatory approval. If the control space is much smaller than the design space, the process is then considered robust.

By asking about the residual risks upon implementation of the control strategy at commercial scale, the agency recognizes that in some cases, the risk of a process step to impact the drug product CQAs may only be mitigated from high risk to medium risk at the time the application is submitted. For example, an extended-release polymer-coating process can be optimized at pilot scale. However, some variability in process efficiency and polymer coating-layer thickness may be observed during scale-up from pilot to commercial scale, resulting in a slight decrease in the theoretical polymer coating level needed to achieve the target drug release profile. In this case, the impact of polymer coating process variability on drug release from tablets needs to be further monitored during validation and routine commercial manufacturing to gain additional knowledge and to facilitate continual improvement. Therefore, the risk is considered acceptable, but at a medium level in-line with current process understanding.

The additional experience and knowledge gained during routine manufacturing should be utilized for refinement of the control strategy as part of the continual improvement of the drug product during its commercial lifecycle. However, any post-approval changes in established conditions beyond the variability already provided in the application should be reported to the agency in accordance with 21 CFR 314.70 and should follow steps as outlined by guidances used for scale-up and post-approval changes.[69–74]

P.6 Reference Standards or Materials

How were the drug product reference standards obtained, certified, and/or qualified?

A reference standard is a substance prepared for use as the standard in an assay, identification, or purity test and should have a quality appropriate for its use. It is often characterized and evaluated for its intended purpose by additional procedures other than those used in routine testing.[59] In response to this question, applicants should discuss the reference standards utilized for both drug substance and degradants. If the same reference standards are used for the drug substance, it may be appropriate to reference Section 2.2.S.5. Generally, only a lot number is needed when a compendial reference standard is used as the primary reference standard. When an in-house standard is used, applicants should provide the source(s), lot number, and reference to the location of the CoA and of full characterization information in Module 3. An in-house primary reference standard should be qualified by elucidating its chemical structure using pertinent methods, such as MS, NMR, IR, UV-VIS, TGA, etc., as well as assessing its purity and should be certified by providing a certificate that gives the value of the specified property, its associated uncertainty and a statement of metrological traceability. Secondary or working standards can be qualified against primary reference standards. When USP standards are available, secondary or working standards should be qualified against the USP standards.

P.7 Container Closure System

What container closure system(s) is(are) proposed for commercial packaging of the drug product? What is the specification?

The applicant should give a description of the proposed primary container closure system for each strength of the drug product including the bottle, cap, void filler, and desiccant or the blister. A description of the label and any secondary packaging should also be provided. The applicant may give a reference to the location of the letters of authorization for Type III DMFs, as well as a reference to the location of the component specifications, technical drawings, and full testing results. The applicant should submit both in-house and

vendor CoAs with results for full testing performed to qualify the suitability of the components used to package the registration batches or a representative lot. Applicants should also submit certification per 21 CFR sections 174–186 to demonstrate that materials used in the component manufacture are safe for use in direct or indirect food contact. Note that any development studies performed to demonstrate the suitability of the selected container closure system should be submitted under the QbR question in 2.3.P.2.4.

P.8 Stability

What is the stability specification? If applicable, what is the justification for acceptance criteria that differ from the drug product release specification?

Applicants should present the stability specification in a side-by-side comparison table that highlights any differences between the release and shelf-life specification and provides justification for any differences.

What is the proposed shelf-life for the drug product? What drug product stability studies support the proposed shelf-life and storage conditions in the container closure system? How does statistical evaluation of the stability data and any observed trends support the proposed shelf-life?

Applicants may propose a shelf-life based on stability data available at the time of submission and as recommended in the relevant stability guidance documents.[75–77] The intended storage conditions to be included in the drug product labeling should be clear.

If the applicant chooses to use any bracketing or matrixing designs to support the drug product stability, then the designs should be fully explained and justified according to the considerations detailed in the applicable guidance documents.[78] Generally, 6 months of stability data at both the accelerated and long-term stability conditions are expected at the time of submission to support the proposed shelf-life. The applicant should provide a tabular summary of these data along with a reference to the location of the full stability results in Module 3. If there is a significant change observed in the accelerated data, the applicant should also submit 6 months of intermediate stability data at the time of submission. These data should be updated during the review cycle. Applicants should discuss any observed trends or out-of-specification results in the stability data and should perform appropriate statistical analysis of all quantifiable attributes in order to support any proposal for extrapolation of expiry period. Usually when significant trends or failure to comply with the acceptance criterion are observed during the accelerated study, the tentative expiration date will be determined based upon the intermediate and long-term data.

If the drug product labeling details any further manipulation or preparation prior to administration, the applicant may reference P.2.6 for studies conducted to demonstrate compatibility. In some cases, in-use stability studies should be conducted to demonstrate that the drug product quality (eg, drug product release or drug substance polymorphic form) is not impacted by patient storage in a bathroom medicine cabinet or pharmacy storage on shelf. Data to support stability in bulk packs for holding periods of more than 30 days also should be submitted. In cases where bulk drug product is transferred to another location for packaging, the applicant may consider simulated shipping studies to demonstrate that the bulk packaging is adequate to ensure the integrity of the drug product (eg, orally disintegrating tablets).

What are the post-approval stability protocols and other stability commitments for the drug product?

The applicant should submit a post-approval stability protocol for review and approval by the agency. It is a detailed plan that is used to generate and analyze stability data to support and confirm the tentative expiration date of the drug product. The post-approval stability protocol should include:

- Storage conditions
- Number of batches and packaging configurations to be entered into the stability protocol
- Testing intervals
- Tests to be performed and testing schedule

In an original submission, the applicant is also expected to make certain commitments, which constitute agreements that must be fulfilled after approval of the application. The stability commitment should include:

- The number of validation batches of the drug product, and annual production batches thereafter, to be tested for stability in accordance with the approved post-approval stability protocol. Each strength of the marketed drug product and all container closure systems should be included unless a bracketing or matrixing design was approved.
- A commitment to submit stability data in annual reports
- A description of how changes or deterioration in the distributed drug product will be handled as per 21 CFR 314.70(b)(1)(ii)

40.5 FUTURE DIRECTION

To realize the vision of OPQ, the office employs a team-based integrated quality assessment approach to maximize each team member's expertise and provide aligned patient-focused and risk-based drug quality recommendations, inclusive of drug substance, drug product, biopharmaceutics, microbiology, manufacturing, and facilities. Ideally, submissions to the agency need to be functional, meaning that they are electronic, structured, and searchable. They should also be of high quality

and demonstrate a risk- and science-based approach to drug product development. Although it seems contradictory, submissions must be both comprehensive and concise. The data should be presented in a cohesive manner that clearly tells the development story by communicating an appropriate level of detail to convey how the product and process understanding has culminated in a control strategy designed to ensure that the therapeutic benefit of the drug product promised on the label is realized by the patient. The submission should also clearly delineate what established conditions are proposed to ensure desired product quality. QbR goes a long way toward facilitating the previously mentioned needs. However, the current QbR is one-size-fits-all and was largely developed with solid oral dosage forms in mind. Therefore, future iterations may be more flexible and dosage-form specific to better focus both industry and reviewers on critical areas unique to those dosage forms.

Although this chapter focuses on the QbR questions developed for the assessment of drug product, there are also QbR questions currently used for other disciplines within OPQ, including drug substance and microbiology. The door is open for future versions of QbR to further refine the questions related to these disciplines and to add additional discipline-specific questions for biopharmaceutics and facilities. The integration of drug review, inspection, and compliance in combination with QbR tailored to each discipline will put CDER in a better position to anticipate and intervene before quality problems develop by improving the FDA's oversight of quality throughout the lifecycle of a pharmaceutical product and increasing the applicant's ability to produce high-quality products for the American public.

40.6 CONCLUSIONS

In summary, QbR questions were designed to embody QbD elements, including definition of the QTPP based on desired product performance and identification of the CQAs, systematic development studies to facilitate product and process design and gain product and process understanding, develop a comprehensive control strategy, and strive for continual improvement throughout the product lifecycle.

Quality cannot be tested into a product, but is built by design. The adoption of QbD approaches in the pharmaceutical industry is an evolving process. The goal of embracing a QbD mindset is to reduce product variability and defects, thereby enhancing product development and manufacturing efficiencies and post-approval change management. It is achieved by designing a robust formulation and manufacturing process that is understood at a mechanistic level and establishing clinically relevant specifications that are adequately controlled.

QbR establishes common submission and quality expectations and has helped to transform the CMC review into a modern, science- and risk-based pharmaceutical quality assessment. QbR is consistent with the current QbD paradigm and is congruent with risk management approaches. QbR facilitates clear communication by helping industry and the FDA speak the same "language," by clearly delineating submission expectations, and by encouraging the industry to be transparent in its thought process and to justify the choices made throughout pharmaceutical development and manufacture. Historically, industry has been reluctant to provide additional supportive information (eg, development data) within regulatory submissions to the FDA because of the presumption that providing more information will lead to more regulatory questions. From the reviewer perspective, however, the opposite is true. When the applicant does a good job responding to QbR, it conveys their product and process understanding to the agency and instills greater confidence that the drug product will meet the QTPP and deliver the promised therapeutic benefit to the patient throughout its lifecycle.

APPENDIX: QbR QUESTIONS

2.3 Introduction to the QOS

Proprietary name of drug product
Nonproprietary name of drug product
Nonproprietary name of drug substance
Proposed indication(s) including intended patient population
Duration of treatment
Maximum daily dose (MDD)
Alternative methods of administration

2.3.P Drug Product

2.3.P.1 Description and Composition

1. What is the description of the proposed commercial drug product? What are the components and composition of the final drug product as packaged and administered on both a per unit dose and %w/w basis? What is the function(s) of each excipient?
2. Does any excipient exceed the FDA IID limit for this route of administration calculated based on maximum daily dose? If so, please justify.
3. If applicable, what are the differences between this formulation and the listed/RLD formulation?

2.3.P.2 Pharmaceutical Development

4. For 505(b)(1) applications, what is the rationale for selecting the proposed dosage form for the drug product? For 505(b)(2) and 505(j) applications, what are the characteristics of the listed/RLD product? What is the QTPP of the finished product based on the proposed indication and patient populations? How is the QTPP justified?

5. What are the quality attributes of the finished product? Which quality attributes are considered CQAs? For each CQA, what is the target and how is it justified?

6. What is the approach for meeting the CQAs related to clinical performance? If applicable, what in vitro bioperformance evaluations (ie, dissolution method, flux assay, etc.) were used during pharmaceutical development to ensure clinical performance?

2.3.P.2.1 Components of the Product

2.3.P.2.1.1 Drug Substance

7. What are the physical, chemical, biological and, if applicable, mechanical properties of the drug substance, including physical description, pK_a, chirality, polymorphism, aqueous solubility (as a function of pH), hygroscopicity, melting point(s), partition coefficient and, when available, BCS classification?

8. What is the drug substance specification used to accept the incoming drug substance batches and how is it justified? For each test in the specification, provide a summary of the analytical procedure(s) and, if applicable, a summary of validation or verification report(s).

2.3.P.2.1.2 Excipients

9. What evidence supports excipient–drug substance compatibility and, if applicable, excipient–excipient compatibility?

10. What is the rationale for the excipient selections?

2.3.P.2.2 Drug Product

11. What aspects of the formulation were identified as potentially high risk to the drug product performance?

12. What formulation development studies were conducted? What attributes of the drug substance, excipients, and in-process materials were identified as critical and how do they impact the drug product CQAs?

13. How does the proposed commercial formulation differ from the formulations used during bioequivalence and/or clinical studies? What is the rationale for the formulation change? What biopharmaceutics evaluations (comparative dissolution, bioequivalence studies, biowaivers, etc.) support the formulation changes and link the development formulations to the posed commercial formulation?

2.3.P.2.3 Manufacturing Process Development

14. What is the rationale for selecting this manufacturing process for the drug product?

15. What is the potential risk of each process step to impact the drug product CQAs and how is the risk level justified?

16. For each of the potentially high-risk manufacturing unit operations:

- **a.** What input material attributes and process parameters were selected for study and what are the justifications for the selection?
- **b.** What process development studies were conducted? Provide a summary table listing batch size, process parameter ranges, equipment type, and estimated use of capacity.
- **c.** What process parameters and material attributes were identified as critical and how do they impact the drug product CQAs?
- **d.** How were the process parameters adjusted across lab, pilot/registration, and commercial scale? What are the justifications for any changes?

17. If applicable, what online/at line/in-line monitoring technologies are proposed for routine commercial production that allows for real-time process monitoring and control? Provide a summary of how each technology was developed.

2.3.P.2.4 Container Closure System

18. What specific container closure attributes are necessary to ensure drug product integrity and performance through the intended shelf life? If applicable, what are the differences in the container closure system(s) between this product and the RLD?

19. How was the container closure system(s), including bulk containers, qualified for suitability (protection, compatibility, safety, and performance)?

2.3.P.2.5 Microbiological Attributes

20. When applicable, what microbiological attributes were evaluated on the finished product?

2.3.P.2.6 Compatibility

21. If applicable, what supportive data demonstrates the compatibility of the drug product with the means of administration (eg, additives and/or diluents, other co-administered drugs, dosing device)?

2.3.P.3 Manufacture

22. Who manufactures the drug product? List each participant and facility involved in drug product manufacturing/testing activities and clearly state their function. List the date of the last FDA inspection of each facility involved and the result of the inspection. Has the manufacturer addressed all concerns raised at the FDA inspection?

23. What is the commercial batch formula and how does it differ from the registration batch formula? Provide justifications for any differences.

24. What is the flow diagram of the manufacturing process that shows all incoming materials, processing steps/unit operations, and in-process controls?

25. What is the detailed process description, including process parameters, material attributes of raw materials and intermediates, equipment type, batch size, in-process controls, including acceptance criteria and any proposed reprocessing?

26. What in-process sampling strategies and methods are used to monitor in-process material attributes that have a potential to affect quality?

27. What are the in-process test results for each process step of the registration batch(es)? What are the differences, if any, in the in-process controls for the registration batch(es) and the intended commercial batches? What are the justifications for these differences?

2.3.P.4 Control of Excipients

28. What are the excipient specifications and how are they justified? How do the proposed acceptance criteria for the material attributes of the excipients ensure the quality of the final drug product?

2.3.P.5 Control of Drug Product

29. What is the drug product specification, what is the justification, and how is it linked to the product performance and patient safety? Does the specification include all the CQAs for the drug product? Does it include all the critical drug product attributes?

30. For each test in the specification, provide a summary of the analytical procedure(s) and, if applicable, a summary of the validation or verification report(s).

31. How do the batch analysis results compare with your proposed specification? Provide a summary of the batch analysis results.

32. What are the drug product degradants? For each degradant, what is the structure, chemical name, origin, and mechanism of formation? How are the proposed limits justified and/or qualified for safety based on nonclinical studies? What is the control strategy for the potential drug product degradants?

33. What is the proposed control strategy for the drug product manufactured at commercial scale? What are the residual risks upon implementation of the control strategy at commercial scale?

2.3.P.6 Reference Standards and Materials

34. How were the drug product reference standards obtained, certified, and/or qualified?

2.3.P.7 Container Closure System

35. What container closure system(s) is(are) proposed for commercial packaging of the drug product? What is the specification?

2.3.P.8 Stability

36. What is the stability specification? If applicable, what is the justification for acceptance criteria that differ from the drug product release specification?

37. What is the proposed shelf-life for the drug product? What drug product stability studies support the proposed shelf-life and storage conditions in the container closure system? How does statistical evaluation of the stability data and any observed trends support the proposed shelf-life?

38. What are the post-approval stability protocols and other stability commitments for the drug product?

SECOND EDITION

Developing Solid Oral Dosage Forms

Pharmaceutical Theory & Practice

Edited by

Yihong Qiu, PhD
Senior Research Fellow, Oral Drug Products, Manufacturing Science and Technology, AbbVie Inc., North Chicago, IL, USA

Yisheng Chen, PhD
Vice President, Product Development, Novast Laboratories, Nantong, China

Geoff G. Z. Zhang, PhD
Senior Research Fellow, Drug Product Development, Research and Development, AbbVie Inc., North Chicago, IL, USA

Lawrence Yu, PhD
Deputy Director, Office of Pharmaceutical Science, Center for Drug Evaluation and Research, US Food and Drug Administration, Silver Spring, MD, USA

Rao V. Mantri, PhD
Executive Director, Drug Product Science and Technology, Bristol-Myers Squibb, New Brunswick, NJ, USA

The second edition of ***Developing Solid Oral Dosage Forms: Pharmaceutical Theory and Practice*** illustrates how to develop high-quality, safe and effective pharmaceutical products by providing the latest theories, techniques, tools and scientific advances in preformulation investigation, formulation and process design, characterization and scale-up, and production operations. This book continues to cover the essential principles of physical pharmacy, biopharmaceutics and industrial pharmacy and their application to the research and development process of oral dosage forms. Chapters have been added and completely revised as necessary to produce a comprehensive, well-organized and valuable reference for industry professionals and academics engaged in all aspects of the development process. New and important topics include amorphous solid dispersion using twin-screw extrusion, spray drying, modelling and simulation, bioequivalence of complex modified-released dosage forms, biowaivers and much more.

Key Features

- Written and edited by a team of international leading experts with experience and knowledge across industry, academia and regulatory settings
- Includes new chapters covering the pharmaceutical applications of surface phenomena, predictive biopharmaceutics and pharmacokinetics, the development of formulations for drug discovery support, emerging manufacturing technologies, and much more
- Incorporates new case studies throughout the book
- Contains a section completely devoted to regulatory aspects, including global product regulation and international perspectives
