Study Questions

1. Compare the chemical makeup of the extracellar "coat" or "matrix" materials secreted by the following cells: bacteria, fibroblasts, osteoblasts, plant cells, fungi.

2. The iodine number of a compound is defined as the number of grams of I_2 absorbed (through addition to C=C bonds to give a diiodo derivative) per 100 g of fat. NOTE: Iodine monochloride or iodine monobromide are the usual halogenating reagents but the iodine number is expressed in terms of grams of I_2. The saponification number is the number of milligrams of KOH needed to completely saponify (hydrolyze and neutralize the resulting fatty acids) 1 g of fat. A pure triglyceride has a saponification number of 198 and an iodine number of 59.7.

   a) What is the relative molecular mass?
   b) What is the average chain length of the fatty acids?
   c) What is the number of double bonds in the molecule?

3. Spermaceti (a wax from the head of the sperm whale) resembles high molecular mass hydrocarbons in physical properties and inertness toward Br_2 / $CHCl_3$ and $KMNO_4$; on qualitative analysis, it gives positive tests only for carbon and hydrogen. However, its IR spectrum shows the presence of an ester linkage, and quantitative analysis gives the empirical formula $C_{16}H_{32}O$. A solution of the wax in alcoholic KOH is refluxed for a long time. Titration of an aliquot shows that one equivalent of base is consumed for every 475 g of wax. Water and ether are added to the cooled reflux mixture, and the aqueous and etheral layers are separated. Acidification of the aqueous layer yields a solid A with a neutralization equivalent of 260 $\pm$ 5. Evaporation of the ether layer gives solid B, which could not be titrated. Reduction of either spermaceti or A by lithium aluminum hydride gave B as the only product.

   What is the likely structure of spermaceti?

4. Stearic acid (1.16 g) was dissolved in 100 ml of ethanol. A 10 µl portion of the resulting solution was pipetted onto a clean surface of a dilute HCl solution (in a shallow tray) where it spread to form a monolayer of stearic acid. The layer was compressed (by moving a Teflon barrier across the tray) until the surface pressure π started to rise sharply and reached ~20 dyn / cm. Note that $\pi = \gamma_o - \gamma$ where γ is the measured surface tension with the film present and γ_o is the higher surface tension of water alone. The compressed film occupied a 20 x 24 cm area. Calculate the cross-sectional area of an alkyl chain in stearic acid. [See J. B. Davenport, *in Biochemistry and Methodology of Lipids* (A. R. Johnson and J. B. Davenport, eds.), pp. 47-83. Wiley-Intersience, New York, 1971; and M. C. Phillips, *in Progress in Surface and Membrane Science* (J. F. Danielli, D. M. Rosenberg, and D. A. Cadenhead, eds.) Vol. 5, pp. 139-221. Academic Press, New York, 1972.]

5. In 1925, E. Gorter and F. Grendel (*J. Exp. Med.* **41**, 439) reported measurements in which they extracted lipid from red blood cell membranes with acetone, spread the lipids as a monolayer, and measured the area of the compressed monolayer. They then estimated the surface area of an erythrocyte and calculated that the ratio of the lipids (as a monolayer) to the surface area of the red blood cell was 1.9–2.0. More modern experiments gave the following: each erythrocyte membrane contains 4.5 x 10^{-16} mol of phospholipid and 3.1 x 10^{-16} mol of cholesterol.

   a) If the cross-sectional areas of phospholipid and cholesterol molecules in a membrane are taken as 0.70 and 0.38 nm^2, respectively, what surface area would be occupied in a monolayer?
   b) If the measured surface area of an erythrocyte is 167 μm^2, what is the ratio of the area calculated in (a) to the area of the cell surface?
   c) How might you explain the difference between this answer and that of Gorter and Grendel? See E. D. Korn (1966) *Science* **153**, 1491–1498.

Study Questions

6. The following experimental observations are related to biological membrane structure and function. Discuss the implications of each observation with respect to membrane structure.

   a) Many macrocyclic antibiotics (nonactin, valinomycin, and others) form 1: 1 complexes with alkali metal cations in a highly selective manner. The complexes are readily soluble in nonpolar organic solvents. These antibiotics increase the electrical conductance and permeability to alkali metal cations of synthetic phospholipid membranes. Valinomycin increases the electrical conductance of thylakoid membranes of chloroplasts in the presence of K^+ but not in the presence of Na^+; it also uncouples oxidative phoshorylation in mitochondria. (See Chapter 18.)
   b) Treatment of intact chloroplasts with a galactolipase releases glactose from galactosyl diglycerides. Treatment of red blood cell ghosts with phopholipase C releases about 75% of the lipid P in water-soluble form. In neither case is the structural integrity of the membrane destroyed.
   c) Using sphingomyelin as a hapten, antibodies specific for this lipid can be produced. When red blood cell ghosts are exposed to these antibodies, it can be shown that the antibodies react, but only on one side of the membrane.

7. Describe the structure of biological membranes and the characteristic functions of lipid-, protein-, and carbohydrate-containing components. Describe the differences between inner and outer membrane surfaces.

8. Compare the distribution of triglycerides, phosphatidylcholine, phosphatidylethanolamine, sphingomyelins, glycolipids, and cholesterol within cells. Consider differences between the two sides of membranes.

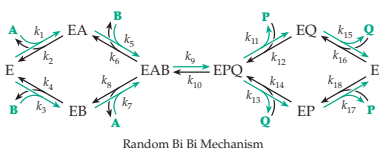
9. Consider the chemistry underlying the labeling of cell surfaces with each of the following:
   a) Lactoperoxidase,
   b) galactose oxidase,
   c) formylmethionylsulfone methyl phosphate,
   d) the diazonium salt of diiodosulfanilic acid,
   e) fluorescent antibodies,
   f) antibodies conjugated with ferritin.

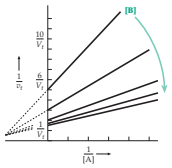
   Write the equations for the chemical reactions involved. State what surface groups will be labeled by each reagent. List special advantages of each of these reagents.

10. Which would be the more effective detergent in the pH range 2 to 3, sodium lauryl sulfonate or sodium laurate? Why?

11. Suppose that a cell contains 10 mM Na^+ and 100 mM K^+ and that it is bathed in extracellular fluid containing 100 mM Na^+ and 5 mM K^+. How much energy will be required to transport three equivalents of Na^+ out and two equivalents of K^+ in? Compare this with $\Delta G'$ for hydrolysis of ATP at pH 7. Assume that the membrane is permeable to Cl^-.

12. An *E. coli* cell is said to contain about 10^5 molecules of an envelope protein of MW = 36,500. If the latter is spherical and the spheres are closely packed in a hexogonal lattice, how much of the surface area of the bacterium would be covered? What would the diameter of the protein be? What spacing would be required if 10^5 molecules covered the surface completely? Suggest a shape for the protein molecule that is consistent with the requirement.



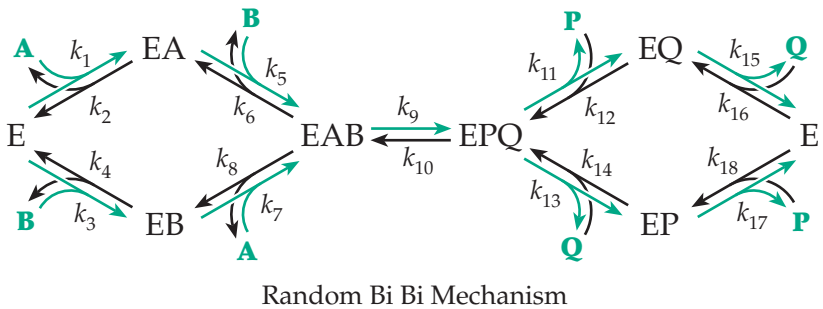


Bimolecular reactions of two molecules, A and B, to give two products, P and Q, are catalyzed by many enzymes. For some enzymes the substrates A and B bind into the active site in an ordered sequence while for others, binding may be in a random order. The scheme shown here is described as random Bi Bi in a classification introduced by Cleland. Eighteen rate constants, some second order and some first order, describe the reversible system. Determination of these kinetic parameters is often accomplished using a series of double reciprocal plots (Lineweaver-Burk plots), such as those at the right.

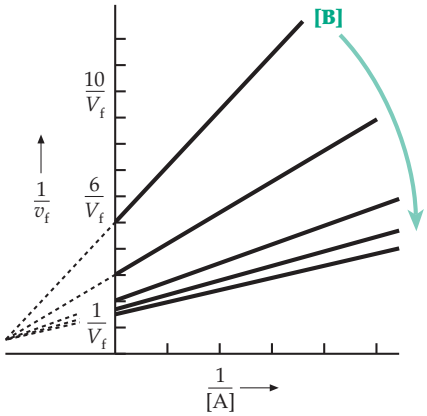
Contents

Enzymes: The Catalysts of Cells

9



Random Bi Bi Mechanism



Most of the machinery of living cells is made of enzymes. Thousands of them have been extracted from cells and have been purified and crystallized. Many others are recognized only by their catalytic action and have not yet been isolated in pure form. Most enzymes are soluble globular proteins but an increasing number of RNA molecules are also being recognized as enzymes. Many structural proteins of the cell also act as catalysts. For example, the muscle proteins actin and myosin together catalyze the hydrolysis of ATP and link the hydrolysis to movement (Chapter 19). Catalysis is one of the most fundamental characteristics of life.

How do we recognize that a protein or RNA molecule *is* an enzyme? The answer is that *enzymes are recognized primarily by their ability to catalyze a chemical reaction.* For this reason, an everyday operation for many biochemists is the measurement of the catalytic activity of enzymes. Only by measuring the rates of the catalyzed reactions carefully and quantitatively has it been possible to isolate and purify these remarkable molecules.

Since the beginning of biochemical investigation enzymes have held a special fascination for chemists and biologists. How can these easily destroyed substances catalyze reactions with such speed and without formation of significant quantities of side products? Some enzymes increase the velocity of a single chemical reaction of a specific compound by a factor of as much as 10^{10}. How can a protein do this? In this chapter we'll consider both ways of measuring enzymatic activity and basic mechanisms of catalysis.

A. Information from Kinetics

The quantitative study of catalysis by enzymes, i.e., the study of enzyme kinetics, is a highly developed branch of biochemistry. It is one of our most important means of learning about the mechanisms of catalysis at the active sites of enzymes.[1–13a] By determining **rate constants *k*** under a variety of conditions we can learn just how fast an enzyme can act, how tightly it binds its substrates to form the enzyme-substrate (ES) complexes essential to catalysis, how specific it is with respect to substrate structure, and how it is affected by compounds that inhibit or activate the catalysis.

1. Measuring the Speed of an Enzymatic Reaction

A major goal in kinetic studies is to establish a **rate equation** which describes the velocity of a reaction in terms of **kinetic constants** and other experimentally measurable parameters. To measure the velocity of any chemical reaction precisely we must start the reaction at a definite time by rapidly mixing together the two or more reactants. Then, while keeping the mixture at an accurately constant temperature and pH, we must measure the concentration of a reactant or product after a fixed time interval, or at various times. No end of ingenuity has gone into devising ways of doing this for particular enzymes. Whatever the procedure, the information we must obtain is the **rate** at which some concentration changes with time. We can then construct a **progress curve** showing the decrease in concentration [S] of the reactant (**substrate**) or the increase in the concentration of **product** [P] with time (Fig. 9-1).

BOX 9-A A HISTORICAL NOTE ON ENZYMES

While the earliest physiologists postulated a "vital force" to explain the chemical reactions of cells, the existence of biochemical substances promoting reactions outside of the body was recognized at least by the early 1600s. However, the role of yeast in fermentation was still unknown and it was thought that both alcoholic fermentation and animal digestion were caused by unknown substances called **ferments**. In 1752, Reamur demonstrated the solvent power of the gastric juice of birds and by 1783 Spallanzani had extended the studies to humans and other species.[a] In 1836 Schwann isolated the enzyme **pepsin**[b] from gastric juice.

In the same year Jacob Berzelius introduced the concept of catalysis, which he developed as a result of studies of the effects of acids and bases in promoting the hydrolysis of starch and of the effects of metals on the decomposition of hydrogen peroxide. Berzelius proposed the term **catalyst** from the Greek "katalysis," meaning "dissolution." Although he had been concerned primarily with inorganic catalysts, Berzelius recognized that a natural catalyst, an amylase that causes the hydrolysis of starch, had already been isolated from germinating barley in 1833 and that "in living plants and animals thousands of catalytic processes take place."[c] Some chemists and physiologists accepted Berzelius' concept of biochemical catalysis immediately, but many did not. The matter was complicated by Pasteur's discovery that yeast cells were the causative agent of alcoholic fermentation. Only after Edward Buchner's reports in 1897 that a juice formed by grinding yeast with sand and filtering could still ferment sugar (see Chapters 15 and 17) was the reality of enzymes in metabolism[d] generally accepted. The word **enzyme** (from the Greek "in yeast") was introduced earlier by F. W. Kuhne, professor of physiology in Heidelberg and a person who had accepted Berzelius' concept.[c]

The velocity v of an enzymatic reaction is defined as the rate at which a substrate disappears or at which a product is formed, the two being identical:

$$v = -d[\mathrm{S}]/dt = d[\mathrm{P}]/dt \qquad (9\text{-}1)$$

Under the steady-state conditions that usually apply (see p. 449), *the rate of increase of product will be the same as the rate of decrease of substrate.* The units of velocity are moles per liter per second ($\mathrm{M\ s^{-1}}$) or more traditionally in enzymology moles per liter per minute. We are interested in the **instantaneous velocity,** which at any time is given by the slope of the progress curve (Fig. 9-1). We usually want to measure the velocity immediately after the reaction is started to avoid the decrease in rate that comes from the depletion of substrate or accumulation of products. In some cases, as in the example given in Fig. 9-1, this is difficult to do with accuracy.

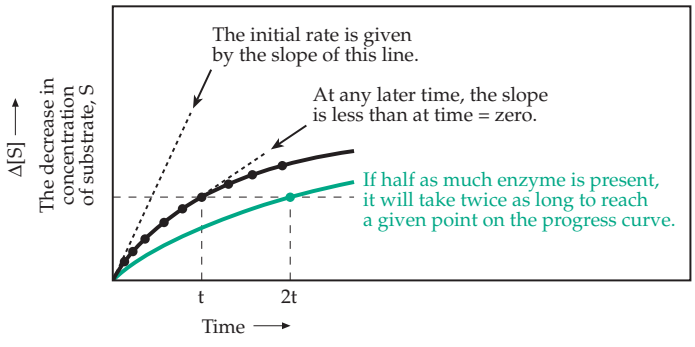

Figure 9-1 The progress curve for an enzymatic reaction in which the substrate S is converted into products.

In some chemical reactions, which involve first-order processes, a logarithmic plot of the progress curve (log[S] vs t) gives a straight line so that the initial slope need not be determined. However, most **enzyme assays** give progress curves that remain nearly linear for only short periods of time. In these cases we need very sensitive methods for detecting products. These may involve colorimetric or fluorimetric measurements or the use of radioactive substrates. One of the most sensitive approaches is to arrange the assay so that a product of the reaction serves as a catalyst for another enzymatic process, thus amplifying the amount of final product to be measured.[14,15] Another approach is to measure velocities of reactions in a very small volume, e.g., 200 nanoliters, and to continuously separate and measure products using capillary electrophoresis and fluorescence detection.[16]

If the progress curve is not a straight line at the beginning of the reaction (0 time) and if the amount of compound that reacts in a fixed

interval of time is taken as the rate, an erroneous answer will be obtained. Sometimes an **integrated rate expression** that describes the time course of product formation can be used (see Eq. 9-22). Even when the progress curve is nonlinear as shown in Fig. 9-1, it is possible to estimate relative rates by noting that in most cases if one unit of enzyme yields a certain amount of product in time t_1, the same amount of product will be formed by n units of enzyme in time t_1/n.

First-order reactions. In many chemical reactions the rate of decrease of the concentration of a given reactant [A] is found experimentally to be directly proportional to the concentration of that reactant at any given time:

$$v = -d[\mathrm{A}]/dt = k[\mathrm{A}] \qquad (9\text{-}2)$$

Such a reaction is described as **first order** and the proportionality constant ***k*** is known as the **rate constant.** Such first-order kinetics is observed for **unimolecular processes** in which a molecule of A is converted into product P in a given time interval with a probability that does not depend on interaction with another molecule. An example is radioactive decay. Enzyme–substrate complexes often react by unimolecular processes. In other cases, a reaction is **pseudo-first order**; compound A actually reacts with a second molecule such as water, which is present in such excess that its concentration does not change during the experiment. Consequently, the velocity is apparently proportional only to [A].

A first-order rate constant k has units of s^{-1}. When [A] = 1, $v = k$. Thus, k is a measure of the speed in mol l^{-1} s^{-1} of the reaction of a substance at unit activity. As a first-order reaction proceeds, [A] decreases and at time t is given by any one of the following three equivalent expressions (Eq. 9-3). These are obtained by integration of Eq. 9-2 in which t_0 is the time at which the reaction was started.

$$\begin{gathered}[\mathrm{A}] = A_0 e^{-kt} \\ \ln([\mathrm{A}_0]/[\mathrm{A}]) = kt \\ \log[\mathrm{A}_0] - \log[\mathrm{A}] = kt/2.303 \end{gathered} \qquad (9\text{-}3)$$

Equation 9-3 is the equation of exponential decay. A characteristic of exponential decay is that [A] is halved in a time that is independent of concentration. The **half-life** is $t_{1/2}$:

$$t_{1/2} = \ln 2/k = 0.693/k \qquad (9\text{-}4)$$

The **relaxation time** τ for A is defined by Eq. 9-5 and represents the time required for the concentration [A] to fall to $1/e$ (or ~0.37) of its initial value.

$$\tau = 1/\mathrm{k} = \mathrm{t}_{1/2}/\ln 2 \qquad (9\text{-}5)$$

Turnover numbers and units of activity. When an enzyme is catalyzing product formation at the maximum possible rate, V_{max}, we can usually assume that the active site of every molecule of enzyme contains a substrate in the form of an intermediate enzyme–substrate complex ES and that this complex is being converted to products according to Eq. 9-6:

$$\begin{gathered} d[\mathrm{P}]/dt = V_{max} = k[\mathrm{ES}] = k[\mathrm{E}]_t \\ \text{or} \qquad V_{max} = k_{cat}[\mathrm{E}]_t \end{gathered} \qquad (9\text{-}6)$$

Here E_t is the total enzyme, namely, the free enzyme E plus enzyme–substrate complex ES. The equation holds only at **substrate saturation,** that is, when the substrate concentration is high enough that essentially all of the enzyme has been converted into the intermediate ES. The process is first order in enzyme but is zero order in substrate. The rate constant k is a measure of the speed at which the enzyme operates. When the concentration $[E]_t$ is given in moles per liter of *active sites* (actual molar concentration multiplied by the number of active sites per mole) the constant k is known as the **turnover number**, the **molecular activity**, or $\boldsymbol{k_{cat}}$. The symbol k_{cat} is also used in place of k in Eq. 9-6 for complex rate expressions in which k_{cat} cannot represent a single rate constant but is an algebraic expression that contains a number of different constants.

Turnover numbers can be measured only when the concentration of the enzyme is known. Partly for this reason the activity of an enzyme is usually given as **specific activity,** the *units of activity per milligram of protein*. One **international unit** is the amount of enzyme that produces 1 µmol of product per minute under standard (usually optimal) conditions. The International Union of Biochemistry[17] has recommended a larger unit, the **katal** (kat), the amount of enzyme that converts one mol s^{-1} of substrate to product.

1 kat = 6×10^7 international units
1 international unit = 16.67 nkat (nanokatals)

If the enzyme is pure and is saturated with substrate under the standard assay conditions, the following relationships hold.

$$\begin{aligned} \text{Turnover No.} &= \text{katals/mol of active sites} \\ &= [\text{nkat/mg}] \times M_r \times 10^{-6}/n \\ &= [\text{international units/mg}] \times M_r \times 10^{-3}/60n \end{aligned}$$

Here M_r is the relative molecular mass of the enzyme and n is the number of active sites per molecule. Since the activity of an enzyme is dependent on both temperature and pH, these variables must be specified.

Turnover numbers of enzymes vary from <1 to ~ 10^6 s^{-1}. Trypsin, chymotrypsin, and many intracellular

enzymes have turnover numbers of ~10^2 s^{-1}. The fastest enzymes, which include **catalase** (Chapter 16), **carbonic anhydrase** (Chapter 13), and **Δ^5-3-oxosteroid isomerase** (Chapter 13), have maximum turnover numbers of 2 x 10^5 s^{-1} or more. Compare these reaction rates with those of a typical organic synthesis in the laboratory. A reaction mixture must often be heated for hours ($k < 10^{-3}$ s^{-1}). Many enzymes accelerate rates by factors of greater than 10^6 over those observed in the absence of an enzyme at a comparable temperature and pH. Enzymes often bring two or more substrates together, binding them at a specific location in their active sites. Because of this, rapid reactions can be catalyzed even when the reactants are present in low concentrations.

Second-order reactions. For a chemical reaction to occur between two molecules, A and B (Eq. 9-7), they must meet and collide.

$$A + B \xrightarrow{k_2} P \qquad (9\text{-}7)$$

The velocity of such a **second-order** process is characterized by a **bimolecular rate constant** k_2 and is proportional to the product of the concentrations of A *and* B:

$$v = k_2[A]\,[B] \qquad (9\text{-}8)$$

The units of k_2 are M^{-1} s^{-1}. If [B] is present at unit activity, the rate is k_2[A], a quantity with units of s^{-1}. We can see that the bimolecular, or second-order, rate constant for reaction of A with B may be compared with first-order constants when the second reactant B is present at unit activity. In many real situations, reactant B is present in large excess and in a virtually constant concentration. The reaction is pseudo-first order and the experimentally observed rate constant k_2[B] is an *apparent first-order rate constant*. The bimolecular rate constant k_2 can be obtained by dividing the apparent constant by [B].

Reversible chemical reactions. In any reversible process, we must consider rate constants for both the forward and the reverse reactions. At equilibrium a reaction proceeds in the forward direction at exactly the same velocity as in the reverse reaction so that no change occurs. For this reason there is always a relationship between the equilibrium constant and the rate constants. For Eq. 9-9, k_1 is the bimolecular rate constant

$$A + B \underset{k_2}{\overset{k_1}{\rightleftharpoons}} P$$

$$\text{Equilibrium constant} = K = \frac{[P]}{[A][B]} = \frac{k_1}{k_2} \qquad (9\text{-}9)$$

for the forward reaction and k_2 the unimolecular rate constant for the reverse reaction. The equilibrium constant K can easily be shown, from Eq. 9-2 and 9-8, to equal k_1/k_2 for the reaction of Eq. 9-9.

The student should be aware that in kinetic equations rate constants are usually numbered consecutively via subscripts and that the subscripts do not imply anything about the molecularity. The system which is used here employs odd-numbered constants for steps in the forward direction and even-numbered constants for steps in the reverse direction. However, *many authors number the steps in the forward direction consecutively and those in the reverse direction with corresponding negative subscripts.*

What relationships exist between experimentally observable rates and k_1 and k_2 for a reversible reaction? Consider first the simplest case (Eq. 9-10):

$$A \underset{k_2}{\overset{k_1}{\rightleftharpoons}} B \qquad (9\text{-}10)$$

If pure A is placed in a solution, its concentration will decrease until it reaches an equilibrium with the B which has been formed. It is easy to show that in this case [A] does not decay exponentially but [A] – $[A]_{equil}$ does. If log([A] – $[A]_{equil}$) is plotted against time a first-order rate constant k, characteristic of *the rate of approach to equilibrium*, will be obtained. Its relationship to $k_1$and k_2 is given by Eq. 9-11.

$$k = k_1 + k_2 \qquad (9\text{-}11)$$

The relaxation time τ for approach to equilibrium can be expressed as follows:

$$\tau^{-1} = k = \tau_1{}^{-1} + \tau_2{}^{-1} = k_1 + k_2 \qquad (9\text{-}12)$$

and for the more complex case of Eq. 9-9 as

$$k = \tau^{-1} = k_1([A]_e + [B]_e) + k_2 \qquad (9\text{-}13)$$

where $[A]_e$ and $[B]_e$ are the equilibrium concentrations of A and B.[18]

2. Formation and Reaction of Enzyme–Substrate Complexes

An abundance of evidence indicates that the first step in enzymatic catalysis is the combining of the enzyme and substrate reversibly to form a complex, ES (Eq. 9-14). Formation of the complex is normally reversible. ES can either break up to form enzyme and substrate again or it can undergo conversion to a product or products, often by a unimolecular process. Three rate constants are needed to describe this system for a reaction that is irreversible overall. A complete

description of the kinetic behavior is fairly involved.

$$E + S \underset{k_2}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_3} E + P \tag{9-14}$$

For example, the kinetics may be different within cells, where molar concentrations of enzymes often exceed those of substrate, than in the laboratory. In most laboratory experiments the enzyme is present at an extremely low concentration (e.g., 10^{-8} M) while the substrate is present in large excess. Under these circumstances the **steady-state approximation** can be used. For this approximation *the rate of formation of ES from free enzyme and substrate is assumed to be exactly balanced by the rate of conversion of ES on to P*. That is, for a relatively short time during the duration of the experimental measurement of velocity, the concentration of ES remains essentially constant. To be more precise, the steady-state criterion is met if the absolute rate of change of a concentration of a transient intermediate is very small compared to that of the reactants and products.[19]

The **Michaelis–Menten equation** (Eq. 9-15) describes the initial reaction rate of a single substrate with an enzyme under steady-state conditions.

$$v = \frac{V_{max}}{1 + K_m/[S]} = \frac{V_{max}[S]}{K_m + [S]}$$
$$\text{where } K_m = (k_2 + k_3)/k_1 \tag{9-15}$$

This can be rearranged as follows:

$$\frac{V_{max}}{v} = 1 + K_m/[S] \tag{9-16}$$

Equation 9-15 provides a relationship between the velocity observed at a particular substrate concentration and the maximum velocity that would be achieved at infinite substrate concentration. The quantities V_{max} and K_m are often referred to as the **kinetic parameters** of an enzyme and their determination is an important part of the characterization of an enzyme. Equation 9-15 can be derived by setting the rate of formation of the ES complex ($k1$[E][S]) in the steady state equal to its rate of breakdown, ([k_2 + k_3][ES]). Rearranging and substituting K_m, as defined in Eq. 9-15, we obtain Eq. 9-17.

$$[E][S] = \frac{(k_2 + k_3)}{k_1}[ES] = K_m[ES] \tag{9-17}$$

Using this equation, together with a mass balance relationship ([E] = $[E]_t$ – [ES]), we can solve for $[ES]/[E]_t$, the fraction of enzyme combined as enzyme–substrate complex (Eq. 9-18).

$$\frac{[ES]}{[E]_t} = \frac{[S]}{K_m + [S]} \tag{9-18}$$

The maximum velocity, $V_{max} = k_3[E]_t$, is attained only when all of the enzyme is converted into ES. Under other conditions $v = k_3$[ES] and Eq. 9-19 holds.

$$[ES] / [E]_t = v / V_{max} \tag{9-19}$$

Substituting from Eq. 9-19 into Eq. 9-18 gives the Michaelis–Menten equation (Eq. 9-15).

In many cases, the rate at which ES is converted back to free E and S is much greater than the rate of conversion of ES to products ($k_2 \gg k_3$). In such cases K_m equals k_2/k_1, the dissociation constant for breakdown of ES to free enzyme and substrate (sometimes called K_s). Thus, *K_m sometimes has a close inverse relationship to the strength of binding of substrate to enzyme.* In such cases, $1/K_m$ is a measure of the affinity of the substrate for its binding site on the enzyme and for a series of different substrates acted on by the same enzyme. The more tightly bound substrates have the lower values of K_m. But beware! The condition that k_3 is negligible compared to k_2 may be met with some (poorer) substrates but may not always be met by others. From Eq. 9-15 we see that K_m is always greater than or equal to K_s, but it may be less than K_s for more complex mechanisms.

Figure 9-2 shows a plot of velocity against substrate concentration as given by Eq. 9-15. The position of V_{max} on the ordinate is marked, but it should be clear that the experimental velocity (v) can never attain V_{max} unless [S] is very high relative to K_m. The value of v approaches V_{max} asymptotically. Since K_m is defined as the value of [S] at which $v = V_{max}/2$, its value can be estimated from Fig. 9-2. However, K_m cannot be determined reliably because of the difficulty of establishing the value of V_{max} from a plot of this type. Notice that the curve of Figure 9-2 is identical in form to the saturation curve for reversible binding shown in Fig. 7-1.

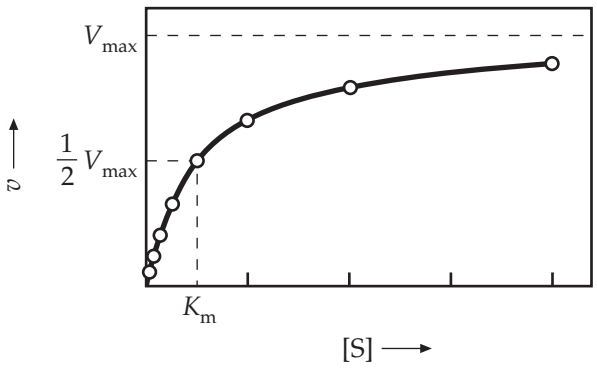

Figure 9-2 Plot of observed velocity v vs substrate concentration [S] for an enzyme-catalyzed reaction.

Linear forms for rate equations. To obtain K_m and V_{max} from experimental rate data, Eq. 9-15 can be transformed by algebraic rearrangement into one of several linear forms. The popular **double-reciprocal** or **Lineweaver–Burk** plot of $1/v$ against $1/[S]$ (Fig. 9-3) is described by Eq. 9-20. The values of K_m/V_{max} and $1/V_{max}$ can be evaluated from the slope and intercept, respectively, of this straight line plot.

$$\frac{1}{v} = \frac{1}{V_{max}} + \frac{K_m}{V_{max}}\frac{1}{[S]} \qquad (9\text{-}20)$$

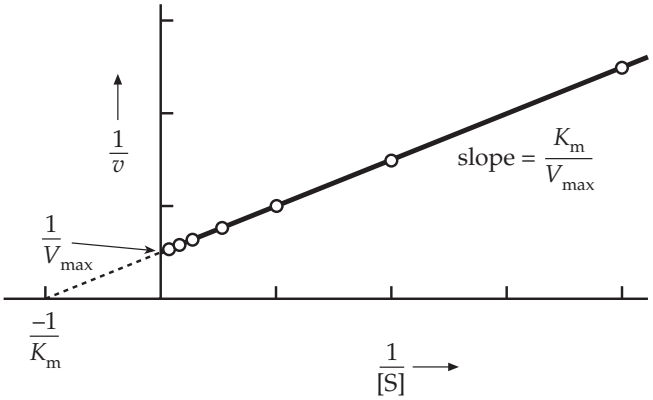

Figure 9-3 Double-reciprocal or Lineweaver–Burk plot of $1/v$ vs $1/[S]$. The intercept on the vertical axis gives $1/V_{max}$ and the slope gives K_m/V_{max}. The intercept on the horizontal axis equals $-1/K_m$.

Another linear plot, the **Eadie–Hofstee plot**, is that of $v/[S]$ vs v (Fig. 9-4). It is related to the Scatchard plot (Fig. 7-3) and is fitted by Eq. 9-21.

$$\frac{v}{[S]} = \frac{V_{max}}{K_m} - v\frac{1}{K_m} \qquad (9\text{-}21)$$

While the point for $[S] = 0$ and $v = 0$ cannot be plotted, the ratio $v/[S]$ approaches V_{max}/K_m as v approaches zero. Notice the distribution of the points in Fig. 9-4. Substrate concentrations were chosen such that the increase in velocity from point to point is more or less constant, a desirable experimental situation. The points on the Eadie–Hofstee plot are also nearly evenly distributed, but those of the Lineweaver–Burk plot are compressed at one end. (However, if the substrate concentrations for successive points are selected in the ratios 1, 1/3, 1/5, 1/7, and 1/9, the spacing will be uniform on the Lineweaver–Burk plot.) A second advantage of the Eadie–Hofstee plot is that the entire range of possible substrate concentration from near zero to infinity can be fitted onto a single plot.

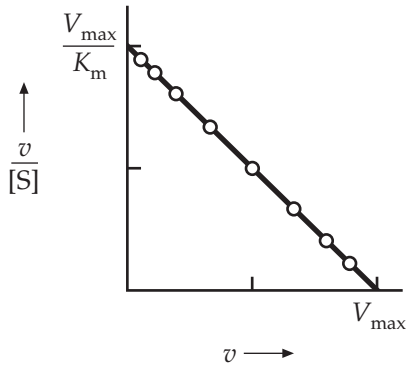

Figure 9-4 The Eadie–Hofstee plot of $v/[S]$ against v. The slope is $-1/K_m$; the intercept on the vertical axis is V_{max}/K_m and that on the horizontal axis is V_{max}.

As pointed out at the beginning of Section A, depletion of substrate with time lowers [S] from its initial value to some extent. This can have an especially adverse effect on points obtained at low [S], e.g., points on the right side of Fig. 9-3 or on the left side of Fig. 9-4. Equations 9-20 and 9-21 will be more precise if the average substrate concentration over the time period of the assay, rather than that at zero time,[20] is used.

Nonlinear equations and integrated rate equations. In discussions of the *control* of metabolism through regulation of enzymatic activity, it is often better to plot v against log [S] as in Fig. 9-5. This plot also has the virture that the entire range of attainable substrate concentrations can be plotted on one piece of paper if the point for [S] = 0 (at minus infinity) is omitted. The same scale can be used for all enzymes. The plot is S-shaped, both for simple cases that are represented by Eq. 9-15 and for enzymes that bind substrate cooperatively (Section B,5). Thus, the classification or "hyperbolic" vs "sigmoidal" is lost. However, the degree of cooperativity can be directly measured from the midpoint slope of the curve. A disadvantage is that it is awkward to measure V_{max} from a plot of this type, and it may be preferable to obtain it from a linear plot (Figs. 9-3 or 9-4). Alternatively, computer-assisted methods can be used to obtain both K_m and V_{max} and to fit a curve to the experimental points as in Fig. 9-5.

An attractive alternative to the use of initial velocities and linear plots is to measure the kinetic parameters V_{max} and K_m using points all along the progress curve (Fig. 9-1). Various procedures for doing this have been devised.[21,22] For example, the integrated form of Eq. 9-15 can be given as Eq. 9-22 or 9-23.

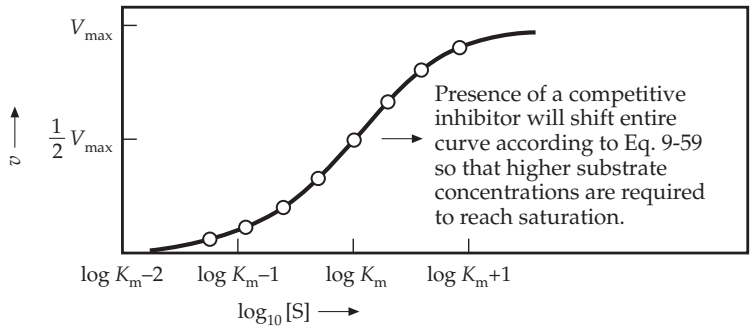

Figure 9-5 Plot of v against log [S] for an enzyme-catalyzed reaction.

$$V_{max}t = [P] + K_m \ln \frac{[S]_0}{[S]_0 - [P]} \qquad (9\text{-}22)$$

$$V_{max}\,t = [S]_0 - [S] + K_m \ln ([S]_0 / [S]) \qquad (9\text{-}23)$$

Here $[S]_0$ is the initial substrate concentration at $t = 0$ and [S] and [P] are the substrate and product concentrations at any later time. In one type of linear plot,[21] based on Eq. 9-23, $([S]_0 - [S]) / t$ is plotted against $1/t$ ln $([S]_0 / [S])$, the slope of the plot being $-K_m$ and the intercepts being V_{max} and V_{max} / K_m. Computer programs are available for analysis of enzymatic progress curves, even for complex mechanisms.[23,24]

Kinetics with high enzyme concentrations. Laboratory studies of the kinetics of purified enzymes are usually conducted with enzyme concentrations of 10^{-7} to 10^{-10} M, but within cells enzyme concentrations are probably often in the range 10^{-6} to 10^{-5} M,[25] which may be higher than the concentrations of the substrates upon which the enzymes act. Be cautious in drawing conclusions about kinetics under such circumstances! Methods have been devised for handling kinetic data when the concentration of enzyme is greater than K_m, a condition that can lead to intolerably high errors if the usual equations are applied.[26,27]

3. Diffusion and the Rate of Encounter of an Enzyme with Substrate

What determines the value of k_1 in Eq. 9-14? This rate constant represents the process by which the substrate and enzyme find each other, become mutually oriented, and bind to form ES. If orientation and binding are rapid enough, the rate will be determined by the speed with which the molecules can come together by diffusion. Large molecules in solution are free to travel for only a tiny fraction of their diameter as a result of their frequent collision with solvent molecules. The result is visible in the **Brownian movement** of microscopic particles suspended in a fluid. If an individual particle is followed, it is seen to undergo a "random walk," moving in first one direction then another. Albert Einstein showed that if the distances transversed by such particles in a given time Δt are measured, the mean square of these Δx values Δ^2 can be related by Eq. 9-24 to the diffusion constant D (which is usually given in units of $cm^2 s^{-1}$).

$$\Delta^2 = 2D\,\Delta t \qquad (9\text{-}24)$$

For molecules, the Brownian movement cannot be observed directly but the diffusion constant can be measured, for example, by observing the rate of spreading of a boundary between two different concentrations of the substance.[28] The diffusion constant for $^1H^2HO$ (HDO) in H_2O at 25°C is 2.27×10^{-5} cm^2 s^{-1}, and the values for the ions K^+ and Cl^- are about the same.[29] For many small molecules D is approximately 10^{-5} cm^2 s^{-1}, and the value decreases as the size of the molecule increases. Thus, for the 13.7-kDa ribonuclease, $D = 1.1 \times 10^{-6}$ cm^2 s^{-1}, and for the 500-kDa myosin, D is ~ 1×10^{-7} cm^2 s^{-1}. For the spherical particle the **Stokes–Einstein equation** (Eq. 9-25) can be used to relate the diffusion coefficient to the radius, the coefficient of viscosity η, the Boltzmann constant k_B, and the temperature (Kelvin) T.

$$D = \frac{k_B T}{6\pi\eta r} \qquad (9\text{-}25)$$

To estimate the rate constant for a reaction that is controlled strictly by the frequency of collisions of particles, we must ask how many times per second one of a number n of particles will be hit by another of the particles as a result of Brownian movement. The problem was analyzed in 1917 by Smoluchowski,[30,31] who considered the rate at which a particle B diffuses toward a second particle A and disappears when the two collide. Using Fick's law of diffusion, he concluded that the number of **encounters** per milliliter per second was given by Eq. 9-26.

$$\text{Number of encounters/ml s}^{-1} = 4\,\pi\,(D_A + D_B)\,(r_A + r_B)\,n_A\,n_B \qquad (9\text{-}26)$$

Here D_A and D_B are the two diffusion coefficients, r_A and r_B are the radii (in Å) of the two particles, and n_A and n_B are the numbers of particles per milliliter. The number of encounters per liter per second is $(4\pi / 1000)\,(D_A + D_B)\,(r_A + r_B)\,N^2\,[A][B]$, where N is Avogadro's number. Dividing this frequency by N gives the rate of collision v in M s^{-1}, a velocity that can be equated (Eq. 9-27) with $k_D\,[A]\,[B]$, where k_D is a second-order rate constant

which determines the **diffusion controlled limit**, that is, the maximum possible rate of a reaction.

$$v = \frac{4\pi}{1000}(D_A + D_B)(r_A + r_B)[A][B]N = k_D[A][B] \quad (9\text{-}27)$$

This equation can be rearranged to Eq. 9-28.

$$k_D = \frac{4\pi N}{1000}(D_A + D_B)(r_A + r_B)\mathrm{M}^{-1}\,\mathrm{s}^{-1} \quad (9\text{-}28)$$

While this equation is thought to overestimate the diffusion-limited rate constant slightly, it is a good approximation. If the diffusing particles are approximately spherical, diffusion constants D_A and D_B can be calculated from Eq. 9-25, and Eq. 9-28 becomes Eq. 9-29.

$$k_D = \frac{2RT}{3000\eta}\left(2 + \frac{r_A}{r_B} + \frac{r_B}{r_A}\right) \quad (9\text{-}29)$$

The value of k_D does not vary greatly as the ratio of radii r_A / r_B is changed, and in most cases it may be assumed that $r_A / r_B \approx 1$, in which case the equation simplifies (Eq. 9-30).

$$k_D \approx \frac{8RT}{3000\eta}\,\mathrm{M}^{-1}\,\mathrm{s}^{-1} \quad (9\text{-}30)$$

For water at 25°C, the coefficient of viscosity η is ~0.01 poise (1 poise = 10^{-5} newton cm^{-2}) which leads, according to Eq. 9-30, to $k_D \sim 0.7 \times 10^{10}$ M^{-1} s^{-1}. It was shown by Debye[32] that this rate constant must be multiplied by a correction factor when charged particles rather than uncharged spheres diffuse together. This factor may be of the order of 5–10 for a substrate and enzyme carrying two or three charges and may act to either increase or decrease reaction rates. Since the viscosity of cytoplasm is 0.02–0.03 poise,[33] k_D will be reduced correspondingly.

A simple alternative derivation of Eq. 9-30 was developed by Dexter French,[34] who also provided the author with most of this discussion of encounter theory. Consider a small element of volume ΔV swept out by a particle as it moves through the solution for a distance equal to its own radius. This element of volume will equal πr^3:

$$\Delta V = \pi r^2 \times r = \pi r^3 \quad (9\text{-}31)$$

It will be swept out in a time Δt which can be calculated from Eq. 9-24 as $r^2 / 2D$. Substituting the value of D given by Eq. 9-25, we obtain for Δt:

$$\Delta t = \frac{3\pi\eta r^3}{k_B T} \quad (9\text{-}32)$$

Division of Eq. 9-31 by Eq. 9-32 gives the volume swept out per second by one particle:

$$\Delta V / \Delta t = k_B T / 3\eta \ \mathrm{cm}^3\,\mathrm{s}^{-1} \quad (9\text{-}33)$$

Since the collision radius for two particles of equal size is two times the particle radius, the effective volume swept out will be four times that given by Eq. 9-33. Since both particles are diffusing, the effective diffusion constant will be twice that used in obtaining Eq. 9-28. Thus, the effective volume swept out by the particle in a second will be eight times that given by Eq. 9-33. The volume swept out by one mole of particles is equal to k_D (recall that the second-order rate constant has dimensions of liter mol^{-1} s^{-1}). Thus, when converted to a moles per liter basis and multiplied by 8, Eq. 9-33 should (and does) become identical with the Smoluchowski equation (Eq. 9-30).

The volume given by Eq. 9-33 is about 1.4×10^{-11} cm^3, which could be represented approximately by a cube 2.4 μm on a side. If we compare this volume with that of a cell (Table 1-2) or of an organelle, we see that in one second an enzyme molecule will sweep out a large fraction of the volume of a small cell, mitochondrion, chloroplast, etc.

The "cage effect" and rotation of molecules. It is of interest to compare the bimolecular rate constant for encounters calculated by the Smoluchowski theory (Eq. 9-29) with the corresponding bimolecular rate constant for molecular collisions given by the kinetic theory of gases (Eq. 9-34).

$$k(\mathrm{collision}) = \frac{N(r_A + r_B)^2}{1000}\left[8\pi k_B T\left(\frac{1}{m_A} + \frac{1}{m_B}\right)\right]^{1/2} \quad (9\text{-}34)$$

Here m_A and m_B are the masses of the two particles. This rate constant is also relatively independent of molecular size and for spheres varies from (4 to 11) x 10^{11} M^{-1} s^{-1}, over an order of magnitude greater than the rate constant for encounters. In a solution, molecules still collide at about the same rate as in a gas so that *100 to 200 collisions occur between two particles for each encounter*. However, during the time of the single encounter, the particles are together in a solvent "cage." While in this solvent cage, both substrate and enzyme molecules undergo random rotational motions. Successive collisions bring them together in different orientations, one of which is likely to lead to a sufficiently close match of complementary surfaces (of substrate and binding site) so that formation of a "productive" ES complex takes place.

Molecular rotation in a solution is described quantitatively by diffusion laws (analogous to Fick's laws)

for which a **rotary diffusion constant** θ is defined.[35,36] Consider a group of molecules all oriented the same way initially, then undergoing rotary diffusion until their orientations become random. If we measure the orientation of each molecule by an angle we see that initially the value of cos α is 1 but that when the angles become random the mean value of cos α averaged over all molecules is zero. The rotary relaxation time τ is the time required for the mean value of cos α to fall to

$1/e$ (which occurs when $\alpha = 68.5°$). For a sphere θ is given by Eq. 9-35.

$$\theta = \tfrac{1}{2}\tau = \frac{k_B T}{8\pi\eta r^3} \qquad (9\text{-}35)$$

Ellipsoidal or rod-shaped molecules have two different rotary diffusion constants while, if the dimensions of the molecules are different along all three axes, three constants must be specified.[36]

From Eq. 9-35 we can calculate (if $\eta = 0.01$ poise) the following values for a small spherical molecule (substrate) of ~1 nm length and for a spherical enzyme of 5 nm diameter:

$r = 0.5$ nm $\quad \theta \approx 1.3 \times 10^9\ s^{-1}$
$r = 2.5$ nm $\quad \theta \approx 1.0 \times 10^7\ s^{-1}$

We see that smaller molecules rotate much faster than large ones and that rotational relaxation times for small proteins are of the same order of magnitude as k_D for diffusion-limited encounter. However, for very large molecules, especially long rods, the rotary relaxation time about a short axis may be a large fraction of a second.

The rate of substrate binding. At very low substrate concentrations the Michaelis–Menten equation (Eq. 9-15) simplifies as follows:

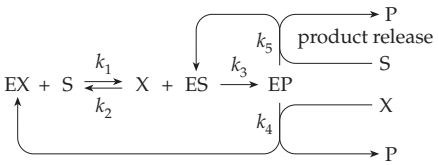
$$v = (V_{max}/K_m)[S] \qquad (9\text{-}36)$$

Since $V_{max} = k_{cat}[E]_t$ (Eq. 9-6) and at low [S] most of $[E]_t$ is free E, we obtain the following equation:[2]

$$v = (k_{cat}/K_m)[E][S] \qquad (9\text{-}37)$$

From this we see that k_{cat}/K_m is *the apparent second-order rate constant for the reaction of free enzyme with substrate*. As such it cannot exceed the diffusion controlled limit k_D of Eqs. 9-28 to 9-30 which falls in the range of $10^9 - 10^{11}\ M^{-1}\ s^{-1}$. Experimentally observed values of k_{cat}/K_m are always less than this limit, indicating that a certain time is required for a substrate molecule to become oriented and seated in the active site.[37] However, for several real enzymes values of k_{cat}/K_m of 10^7 to $3 \times 10^8\ M^{-1}\ s^{-1}$ have been observed. For triose phosphate isomerase Albery and Knowles obtained a value of $4 \times 10^8\ M^{-1}\ s^{-1}$, so close to the diffusion controlled limit that these authors regard this enzyme as a *nearly perfect catalyst*, one that could not have evolved further because it is already catalyzing the reaction with substrate at almost the maximum velocity that is possible.[37–39]

The displacement of bound ligands by substrate. Jenkins pointed out that in many instances a substrate must displace another ligand from the active site to form the ES complex.[40] For example, a binding site for an ionic substrate often already contains an ion, either of the product P or some other ion X which Jenkins calls a **substrate surrogate**. For this situation Eq. 9-14 must be replaced by the following set of equations:



(9-38)

Here k_2 and also k_4 and k_5, are second-order rate constants. The release of product, as determined by k_4 and k_5, may be rate-limiting. At zero time the reverse reactions may be ignored, and steady-state analysis shows that the Michaelis–Menten equation (Eq. 9-16b) will be replaced by Eq. 9-39. Here, D is a constant and A is also constant if X is present at a fixed concentration.

$$\frac{V_{max}}{v} = 1 + \frac{k_2[X] + k_3}{k_1[S]} + \frac{k_3(1/k_5 - 1/k_1)}{k_4[X]/k_5 + [S]}$$
$$= 1 + K_m/[S] + D/(A + [S]) \qquad (9\text{-}39)$$

When k_5, the rate constant for displacement of product by substrate, is very small, this equation simplifies to Eq. 9-40.

$$\frac{V_{max}}{v} = 1 + k_3/k_4[X] + (k_2[X] + k_3)/k_1[S]$$
$$= 1 + k_3/k_4[X] + K_m'/[S] \qquad (9\text{-}40)$$

At high concentrations of X the second term becomes negligible and the equation becomes identical to the Michaelis–Menten equation (Eq. 9-16) except that K_m', the apparent Michaelis constant, now increases as [X]

increases (Eq. 9-41). This is exactly what is observed for competitive inhibitors where

$$K_m' = \frac{k_2[\mathrm{X}] + k_3}{k_1} \tag{9-41}$$

Thus substrate surrogates at high concentrations are often competitive inhibitors. However, at low [X] the second term in Eq. 9-41 may be important and X *then serves as an activator*. Under many circumstances, Eq. 9-39 does not simplify further and a nonlinear relationship between $1/v$ and $1/[\mathrm{S}]$ is observed, with the shape of the curves being influenced by the values of constants A and D (see also Section B,4).[40]

4. Reversible Enzymatic Reactions

For some enzyme-catalyzed reactions the equilibrium lies far to one side. However, many other reactions are freely reversible. Since a catalyst promotes reactions in both directions, we must consider the action of an enzyme on the reverse reaction. Let us designate the maximum velocity in the forward direction as V_f and that in the reverse direction as V_r. There will be a Michaelis constant for reaction of enzyme with product $K_{m\mathrm{P}}$, while $K_{m\mathrm{S}}$ will refer to the reaction with substrate.

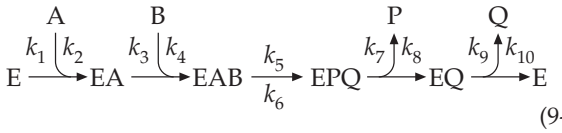
As in any other chemical reaction, there is a relationship between the rate constants for forward and reverse enzyme-catalyzed reactions and the equilibrium constant. This relationship, first derived by the British kineticist J. B. S. Haldane and proposed in his book *Enzymes*[41] in 1930, is known as the **Haldane relationship**. It is obtained by setting $v_f = v_r$ for the condition that product and substrate concentrations are those at equilibrium. For a single substrate–single product system it is given by Eq. 9-42.

$$K_{\mathrm{eq}} = V_f K_{m\mathrm{P}} / V_r K_{m\mathrm{S}} \tag{9-42}$$

Because the Haldane relationship imposes constraints on the values of the velocity constants and Michaelis constants, it is of some value in understanding regulation of metabolism. Consider the case that the maximum forward velocity V_f is high and that $K_{m\mathrm{S}}$ has a moderately low value (fairly strong binding of substrate). If the reaction is freely reversible ($K_{\mathrm{eq}} \sim 1$) and the velocity of the reverse reaction V_r is about the same as that of the forward reaction, it will necessarily be true (see Eq. 9-42) that the product P will also be fairly tightly bound. If $V_r << V_f$, the value of $K_{m\mathrm{P}}$ will have to be much *lower* than that of $K_{m\mathrm{A}}$. In such a situation P will remain tightly bound to the enzyme and since V_r is low, it will tend to clog the enzyme. Such **product inhibition** may sometimes slow down a whole pathway of metabolism. In such a case, the only way that an enzymatic sequence can keep going in the forward direction is for product P to be removed rapidly by a subsequent reaction with a second enzyme. The first enzyme may be thought of as possessing a kind of "one-way valve" that turns off the flow in a metabolic pathway when the concentration of its product rises.

Reactions of two or more substrates. Enzymes frequently catalyze the reaction of two, three, or even more different molecules to give one, two, three, or more products. Sometimes all of the substrate molecules must be bound to an active site at the same time and are presumably lined up on the enzyme molecule in such a way that they can react in proper sequence. In other cases, the enzyme may transform molecule A to a product, and then cause the product to react with molecule B. The number of variations is enormous.[1,10,12]

The order in which two molecules A and B bind to an enzyme to form a complex EAB may be completely *random* or it may be *obligatorily ordered*. Both situations occur with real enzymes. Cleland introduced a widely used method of depicting the possibilities.[42] For example, Eq. 9-43 shows the reaction of A and B in an *ordered sequence* to form the complex EAB which is then isomerized to EPQ, the complex formed by binding the two products P and Q to the enzyme. The rate constant to the left of each vertical arrow or above each horizontal arrow refers to the reaction in the



(9-43)

forward direction as indicated by the arrow while the other constants (to the right or below the arrows) refer to the reverse reactions. The velocity in the forward direction for an enzyme with ordered binding is given by Eq. 9-44a,

$$v_f = \frac{V_f[\mathrm{A}][\mathrm{B}]}{K_{\mathrm{eqA}}K_{m\mathrm{B}} + K_{m\mathrm{B}}[\mathrm{A}] + K_{m\mathrm{A}}[\mathrm{B}] + [\mathrm{A}][\mathrm{B}]} \tag{9-44a}$$

which may also be written in the reciprocal form (Eq. 9-44b):

$$\frac{1}{v_f} = \frac{1}{V_f}\left(1 + \frac{K_{m\mathrm{A}}}{[\mathrm{A}]} + \frac{K_{m\mathrm{B}}}{[\mathrm{B}]} + \frac{K_{\mathrm{eqA}}K_{m\mathrm{B}}}{[\mathrm{A}][\mathrm{B}]}\right) \tag{9-44b}$$

An alternative form of this equation (Eq. 9-45), proposed by Dalziel,[43] is sometimes used.

$$\frac{[E]_t}{v_f} = \phi_0 + \frac{\phi_1}{[A]} + \frac{\phi_2}{[B]} + \frac{\phi_{12}}{[A][B]} \qquad (9\text{-}45)$$

The kinetic parameters of Eq. 9-44 are V_f, the maximum velocity in the forward direction, the two Michaelis constants, K_{mB} and K_{mA}, and the equilibrium constant K_{eqA}, for reversible dissociation of the complex EA and which is equal to k_2/k_1. The relationship between the parameters of Eq. 9-44 (K_m's, V's, and K_{eqA}'s) and the rate constants $k_1 - k_{10}$ is not obvious. However, remember that the parameters are experimental quantities determined by measurements on the enzyme. Sometimes, but not always, it is possible to deduce some of the values of individual rate constants from the experimental parameters.

An equation similar to 9-44a can be written for the velocity v_r of the reaction of P and Q. Also an equation can be written in similar form for $v_f - v_r$, i.e., the instantaneous velocity of the reaction in any mixture of all four components A, B, P, and Q.

The kinetic parameters of Eq. 9-44b are often obtained from experimental data through the use of reciprocal plots (Fig. 9-6). However, Eq. 9-44b is linear only if the concentration of one or the other of the substrates A and B is kept constant. For this reason a series of experiments is usually performed in which [A] is varied while [B] is held constant. Then [A] is held constant and [B] is varied. Each of these experiments leads to a family of lines (Fig. 9-6A) whose slopes and intercepts are measured. The slopes and intercepts of this family of curves are then plotted against the reciprocal of the second concentration, i.e., the one that was held fixed.

From a set of these **secondary plots**, V_f and one of the Michaelis constants can be determined (Fig. 9-6B and C). Using two sets of secondary plots, all of the constants of Eq. 9-44 may be established. Alternatively, a computer can be used to examine all of the data at once and to obtain the best values of the parameters. The latter approach is desirable because estimates of the standard deviations of the parameters can be obtained. However, the user must take care to ensure that the experimental errors are correctly estimated and are not simply estimates of how well the computer has fitted the points on the assumption that they contain no error.[23]

The meaning of the kinetic parameters may be slightly difficult to grasp. V_f is the velocity that would be obtained if both [A] and [B] were high enough to saturate the enzyme. Each K_m corresponds to that for a simple system in which the concentration of the second substrate is at a high, saturating value.

For the bimolecular reaction that we have considered, there are two Haldane relationships:

$$K_{eq} = \frac{V_f K_{mP} K_{dQ}}{V_r K_{dA} K_{mB}} = \left(\frac{V_f}{V_r}\right)^2 \frac{K_{dP} K_{mQ}}{K_{mA} K_{dB}} \qquad (9\text{-}46)$$

Of these, only the first is ordinarily used.

"Ping-pong" mechanisms. A common type of mechanism that is especially prevalent for enzymes with tightly bound cofactors has been dubbed **ping-pong** because the enzyme alternates between

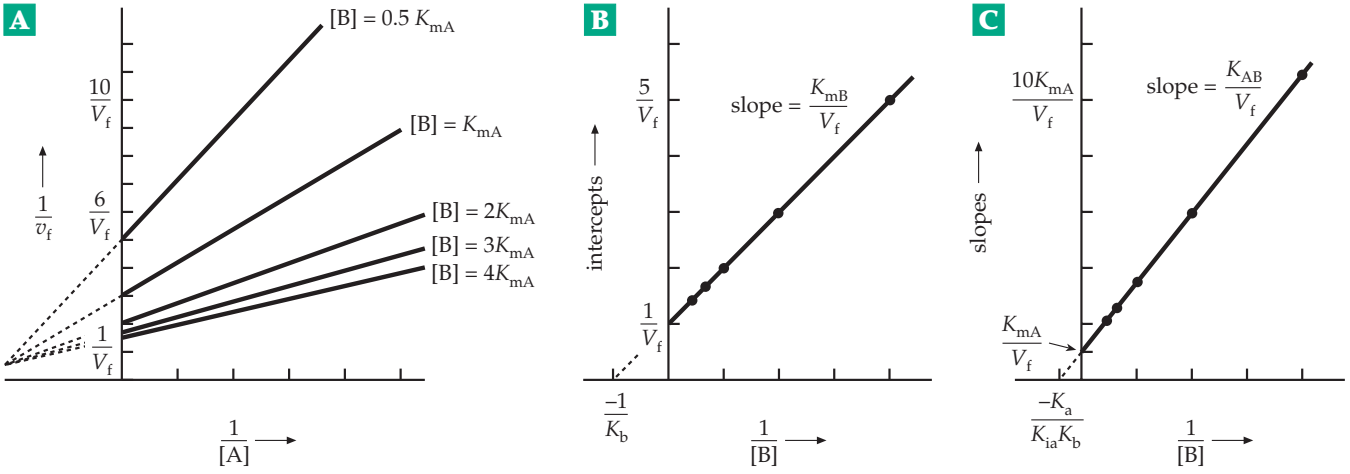


Figure 9-6 Reciprocal plots used to analyze kinetics of two-substrate enzymes. (A) Plot of $1/v_f$ against $1/[A]$ for a series of different concentrations of the second substrate B. (B) A secondary plot in which the intercepts from graph A are plotted against $1/[B]$. (C) Secondary plot in which the slopes from graph A have been plotted against $1/[B]$. The figures have been drawn for the case that $K_{mA} = 10^{-3}$ M, $K_{mB} = 2\,K_{mA}$, and $K_{AB} = K_{eqA}K_{mB}$ (Eq. 9-46) $= K_{mA}/200$ and [A] and [B] are in units of moles per liter. Eadie–Hofstee plots of $v_f/[A]$ vs v_f at constant [B] can also be used as the primary plots. The student can easily convert Eq. 9-44 to the proper form analogous to Eq. 9-21.

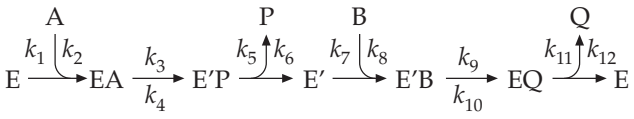
two forms E and E′ (Eq. 9-47). Substrate A reacts via complex EA to form E′, a modified enzyme that often



Ping-pong mechanism for reaction of A and B to form P and Q (9-47)

contains an altered coenzyme. At the same time A is changed to product P still bound to the enzyme. P dissociates leaving E′ which is then able to react with the second substrate B and to go through the second half of the cycle during which E′ is converted back to E. An example is provided by the aminotransferases (Eq. 14-25) in which the coenzyme pyridoxal phosphate is interconverted with pyridoxamine phosphate.

The rate equations of the ping-pong mechanism resemble that for the ordered bimolecular reaction (Eq. 9-44), but each has one less term (Eq. 9-48):

$$v_f = \frac{V_f[A][B]}{K_{mB}[A] + K_{mA}[B] + [A][B]} \qquad (9\text{-}48a)$$

or

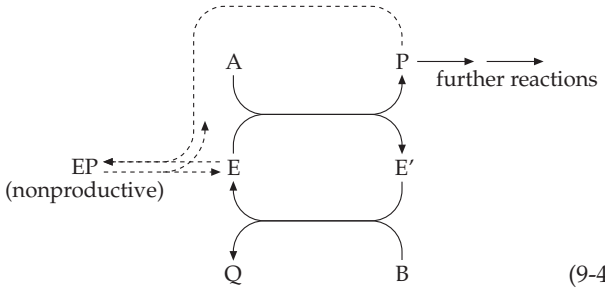
$$\frac{1}{v_f} = \frac{1}{V_f}\left(1 + \frac{K_{mA}}{[A]} + \frac{K_{mB}}{[B]}\right) \qquad (9\text{-}48b)$$

A diagnostic feature of the ping-pong mechanism is that the families of lines (in double reciprocal plots) obtained when one substrate is held constant while the other is varied no longer intersect as they do in Fig. 9-6A but are parallel. They must be truly parallel and the experimentalist must be aware that nearly parallel lines may sometimes be observed for sequential reactions. Thus, if K_{eqA} of Eq. 9-44b is small enough the last term of that equation will be small compared to the other terms and the equation will be approximated by Eq. 9-48b. The reaction will appear to be ping-pong even though it is sequential and the reaction proceeds through the ternary complex EAB.

One less kinetic parameter can be obtained from an analysis of the data for a ping-pong mechanism than can be obtained for ordered reactions. Nevertheless, in Eq. 9-47, twelve rate constants are indicated. At least this many steps must be considered to describe the behavior of the enzyme. Not all of these constants can be determined from a study of steady-state kinetics, but they may be obtained in other ways.

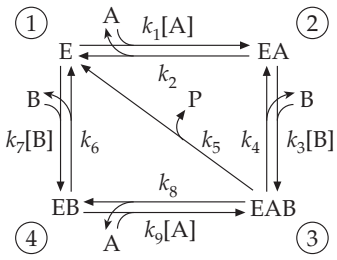
Isomechanisms. A catalyst functions over and over again without being altered. However, during a single turnover it is likely to undergo a temporary change. For example, if an enzyme assists in removing a proton from a substrate, some functional group of the enzyme will be protonated during part of the catalytic cycle. This proton must dissociate before another catalytic cycle begins, and in some instances this dissociation may be a rate-limiting step. Northrup and coworkers developed the use of product inhibition to identify such isomechanisms.[44]

Dead-end complexes. In the steady state of action of an enzyme with ping-pong kinetics, part of the enzyme is in form E and part in form E′. Ideally, E would have affinity only for A and Q, while E′ would have affinity only for B and P. However, in many real situations E also binds B and P weakly; similarly, E′ binds A and Q. This is because the products and reactants usually have structural features in common. The propensity of enzymes with ping-pong kinetics to form **dead-end complexes** (also called abortive complexes) may sometimes have a regulatory function. In Eq. 9-49 the reactions of Eq. 9-47 have been rearranged to depict a situation in which product P normally undergoes a sequence of further reactions. However, if P accumulates to a high enough concentration it can react reversibly to form a dead-end complex EP. This is an effective form of product inhibition which can be relieved only by a lowering of the concentration of P through its further metabolism.



(9-49)

Handling rate equations for complex mechanisms. While steady-state rate equations can be derived easily for the simple cases discussed in the preceding sections, enzymes are often considerably more complex and the derivation of the correct rate equations can be extremely tedious. The **topological theory of graphs**, widely used in analysis of electrical networks, has been applied to both steady-state and nonsteady-state enzyme kinetics.[45–50] The method employs diagrams of the type shown in Eq. 9-50. Here



(9-50)

the reaction of an enzyme with two substrates A and B with a **random** order of binding is depicted. (In contrast, Eq. 9-43 shows the case of ordered binding of two substrates.) When complex EAB is formed, it can decompose to free enzyme and to the single product P. Each one of the **nodes**, which are numbered 1–4 in the diagram, corresponds to a single form of the enzyme. The appropriate first-order rate constant or apparent first-order constant is placed by each arrow. The methods provide easy rules for deriving from such a scheme the steady-state rate equation.

The importance of the simplified schematic methods is apparent when one considers that the steady-state rate equation for Eq. 9-50 would have 6 terms in the numerator and 12 terms in the denominator.[51] In the more complex case in which EAB breaks down to two products P and Q with a random order of release, the rate equation contains 672 terms in the denominator. In such cases it is worthwhile to enlist the help of a computer in deriving the equation.[24,52–54]

The rapid equilibrium assumption. Rate equations for enzymes are often simplified if a single step, e.g., that of reaction of complex EAB to product in Eq. 9-50, is **rate limiting**.[54a] If it is assumed that all reaction steps preceding or following the rate-limiting step are at equilibrium, the equation for random binding with a two-substrate and two-product reaction simplifies to one whose form is similar to that obtained for ordered binding (Eq. 9-44). In the absence of products P and Q Eq. 9-44 will correctly represent the steady-state rate equation corresponding to Eq. 9-50. However, this simplification may not be valid for a very rapidly acting enzyme.

Isotope exchange at equilibrium. Consider the reaction of substrates A and B to form P and Q (Eq. 9-51). If both reactants and both products are present with the enzyme and in the ratio found at equilibrium no net reaction will take place. However, the reactants and products will be continually interconverted under the action of the enzyme. Now if a small amount of

$$A + B \rightleftarrows P + Q \qquad (9\text{-}51)$$

highly labeled reactant (A* or B*) is added, the rate at which isotope is transferred from the labeled reactant into one or the other of the products can be measured. In general, a label in one of the substrates will appear in only one of the products.

Figure 9-7A shows the rate of exchange of isotopically labeled glucose (glucose*) with glucose 6-phosphate as catalyzed by the enzyme hexokinase (Chapter 12). The exchange rate is plotted against the concentration of glucose 6-phosphate with the ratio [glucose] / [glucose 6-phosphate] constant at 1/19, such that an equilibrium ratio for reactants and products is always maintained. As can be seen from the graph, this exchange rate increases monotonically as substrate concentrations are increased. This is also true for the rate of ATP–ADP exchange. The fact that both exchange rates increase continuously indicates random binding of substrates.[55] The inequality of the two maximal exchange rates suggests that release of glucose 6-phosphate may be slower than that of ADP.

Figure 9-7B shows similar plots for lactate dehydrogenase.[53] In this case, after an initial rise (that is not regarded as significant), the pyruvate*–lactate exchange reaches a high constant value as the amount of pyruvate is increased (with a constant [pyruvate] / [lactate] ratio of 1/35). However, the NAD*–NADH exchange increases rapidly at first but then drops abruptly as the pyruvate and lactate concentrations continue to increase. This suggests an ordered mechanism (Eq. 9-43) in which NAD^+ and NADH represent A and Q, respectively, and pyruvate and lactate represent B and P. As the concentrations of B and P become very high, the

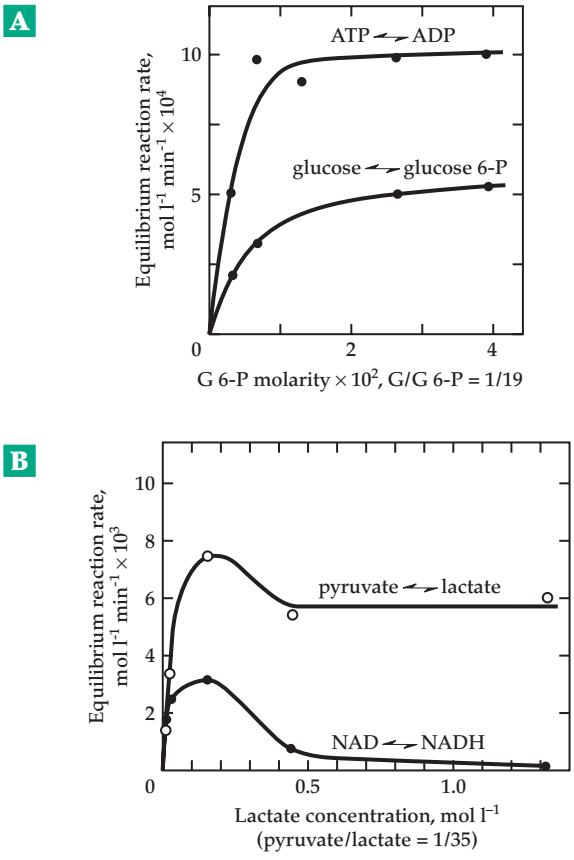


Figure 9-7 (A) Effect of glucose and glucose 6-phosphate concentrations on reaction rate of yeast hexokinase at equilibrium. Reaction mixtures contain 1–2.2 mM ATP, and 25.6 mM ADP at pH 6.5. From Fromm *et al.*[51] (B) Effect of lactate and pyruvate concentrations on equilibrium reaction rates of rabbit muscle lactate dehydrogenase. Reaction mixtures contained 1.7 mM NAD^+, and 30 – 46 µM NADH in Tris-nitrate buffer, pH 7.9, 25°C. From Silverstein and Boyer.[53]

enzyme shuttles back and forth between EA and EQ, but these two complexes rarely dissociate to give free enzyme and A or Q. Hence, the A*–Q exchange rate drops.

In other cases a label may be transferred from A into P or from B into Q. Information on such exchanges has provided a valuable criterion of mechanism which is considered in Chapter 12, Section B,4.

5. Kinetics of Rapid Reactions

The fastest steps in an enzymatic process cannot be observed by conventional steady-state kinetic methods because the latter cannot be applied to reactions with half-times of less than about 10 s. Consequently, a variety of methods have been developed[18,56–59a] to measure rates in the range of 1 to 10^{13} s^{-1}.

Flowing substrates together. One of the first rapid kinetic methods to be devised consists of rapidly mixing two flowing solutions together in a special mixing device and allowing the resulting reaction mixture to move at a rate of several meters per second down a straight tube. At a flow velocity of 10 m s^{-1} a solution will move 1 cm in 10^{-3} s. Observations of the mixture are made at a suitable distance, e.g., 1 cm, and with various flow rates. Using spectrophotometry or other observation techniques, the formation or disappearance of a product or reactant can be followed. The special advantage of this technique is that observation can be made slowly. However, it may require large amounts of precious reactant solutions, e.g., those of purified enzymes.

In the **stopped flow** technique two solutions are mixed rapidly by the flow technique during a period of only 1–2 (or a few) milliseconds. A ram drives the solutions from syringes through a mixing chamber into an observation chamber. After the flow stops light absorption, fluorescence, conductivity, or other property, is measured. A means of rapid observation of changes during the reaction is essential. For example, light absorption may be measured by a photomultiplier with data being collected by a computer. Relaxation times as short as a few milliseconds or less can be observed in this way.[59a,b]

Observing relaxation. Kinetic measurements over periods of tens of microseconds or less can be made by rapidly inducing a small displacement from the equilibrium position of a reaction (or series of reactions) and observing the rate of return (relaxation) of the system to equilibrium. Best known is the **temperature jump** method devised by Eigen and associates. Over a period of about 10^{-6} s a potential difference of ~100 kV is applied across the experimental solution. A rapid electrical discharge from a bank of condensers passes through the solution (without any sparking) raising the temperature 2–10 degrees. All the chemical equilibria for which $\Delta H \neq 0$ are perturbed. If some property, such as the absorbance at a particular wavelength or the conductivity of the solution, is measured, very small relaxation times can be determined.

While it may not be intuitively obvious, if the displacement from equilibrium is small, the rate of return to equilibrium can always be expressed as a first-order process (e.g., see Eq. 9-13). In the event that there is more than one chemical reaction required to reequilibrate the system, each reaction has its own characteristic relaxation time. If these relaxation times are close together, it is difficult to distinguish them; however, they often differ by an order of magnitude or more. Therefore, two or more relaxation times can often be evaluated for a given solution. In favorable circumstances these relaxation times can be related directly to rate constants for particular steps. For example, Eigen measured the conductivity of water following a temperature jump[18] and observed the rate of combination of H^+ and OH^- for which τ at 23°C equals 37 x 10^{-6} s. From this, the rate constant for combination of OH^- and H^+ (Eq. 9-52) was calculated as follows (Eq. 9-53):

$$H^+ + OH^- \longrightarrow H_2O \qquad (9\text{-}52)$$

$$k = 1/\{\tau([OH^-] + [H^+])\} = 1.3 \times 10^{11}\ M^{-1}\ s^{-1} \qquad (9\text{-}53)$$

Pressure jump and electric field jump methods have also been used, as have methods depending upon periodic changes in some property. For example, absorption of ultrasonic sound causes a periodic change in the pressure of the system.

Rapid photometric methods. Another useful method has been to discharge a condenser through a flash tube over a period of 10^{-12} to 10^{-4} s, causing a rapid light absorption in a sample in an adjacent parallel tube. Following the flash, changes in absorption spectrum or fluorescence of the sample can be followed. The availability of intense lasers as light sources has made it possible to follow the results of light flashes of 5–10 picosecond duration and to measure extremely short relaxation times (Chapter 23).[58,59]

Some results. Rapid kinetic methods have revealed that enzymes often combine with substrates extremely quickly,[60] with values of k_1 in Eq. 9-14 falling in the range of 10^6 to 10^8 M^{-1} s^{-1}. Helix–coil transitions of polypeptides have relaxation times of about 10^{-8} s, but renaturation of a denatured protein may be much slower. The first detectable structural change in the vitamin A-based chromophore of the light-operated proton pump bacteriorhodopsin occurs in ~5 x 10^{-8} s, while a proton is pumped through the membrane in

~10^{-4} s.[61] Interconversion between chair and boat forms of cyclohexane derivatives may have $\tau \sim 10^{-5}$ s at room temperature, while rotation about a C–N bond in an amide linkage may be very slow with $\tau \sim 0.1$ s. The nonenzymatic hydration of the aldehyde pyridoxal phosphate via Eq. 13-1 occurs with $\tau = 0.01 - 0.1$ s, depending upon the pH.[59]

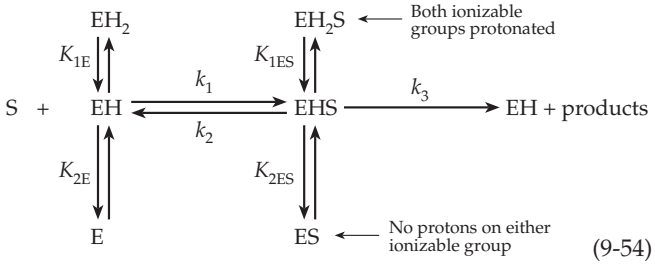
6. Cryoenzymology

An alternative to studying rapid reactions is to cool enzymes to a subzero temperature (down to –100°C) where reactions proceed more slowly.[60,62] The enzyme must be dissolved in a suitable "cryosolvent," often containing 50–80% by volume of an organic solvent or solvents such as methanol, ethanol, dimethyl sulfoxide, dimethyl formamide, or ethylene glycol. Those containing methanol are especially desirable because of their low viscosities. Kinetics can be studied by various spectroscopic methods and stopped-flow, temperature-jump, and other rapid-reaction techniques can be applied. One goal of cryoenzymology is to stabilize otherwise unstable intermediates. X-ray crystallographic measurements can also be made at these low temperatures and it should be possible to observe structures of intermediate ES complexes. A problem is that the forms of the complexes stabilized may be side-products rather than true intermediates. However, as discussed in Chapter 3, a combination of low-temperature Laue X-ray diffraction and a laser-induced temperature jump may be feasible.

7. The Effect of pH on Enzymatic Action

Because proteins contain many acidic and basic groups it is not surprising that the activity of enzymes often varies strongly with pH. However, it is usually found that the state of protonation of only a few groups has a strong effect on activity. This is understandable because most ionized groups are on the outer surface of protein molecules and most are not close to an active site. Protonation or deprotonation of those groups will hardly ever have a major influence on events in the active site. Often only one or two ionizable groups have highly significant effects.

For many enzymes a plot of V_{max} against pH is a bell-shaped curve (Fig. 9-8). The **optimum** rate is observed at some intermediate pH, which is often, but not always, in the range of pH 6–9. This type of curve can be interpreted most simply by assuming the presence in the active site of two ionizable groups and three forms of the enzyme with different degrees of protonation: E, EH, and EH_2.



(9-54)

Let us designate the acid dissociation constants (K_a) for the two groups in the enzyme as K_{1E} and K_{2E} and those of the ES complex K_{1ES} and K_{2ES}. However, as discussed in Chapter 6, Section E,2 these consecutive K_a values cannot necessarily be assigned to single groups. They may belong to a system of interacting groups. Each may be the sum of more than one microscopic K_a and there may be extensive tautomerism within the active site. The rate constants k_1, k_2, and k_3 define the rates of formation and breakdown of the ES complex.

If it is assumed that only form EHS reacts to give products, the bell-shaped curves of Fig. 9-8 are obtained. The frequent observation of such curves supports the model of Eq. 9-54. It also suggests that the two ionizable groups may be intimately involved in catalysis, one as an acid and the other as a conjugate base (see Section E,5).

For the simple case illustrated in Eq. 9-54, the pH dependence of the initial maximum velocity, the apparent Michaelis constant, and V_{max}/K_m are given by Eqs. 9-55 to 9-57.

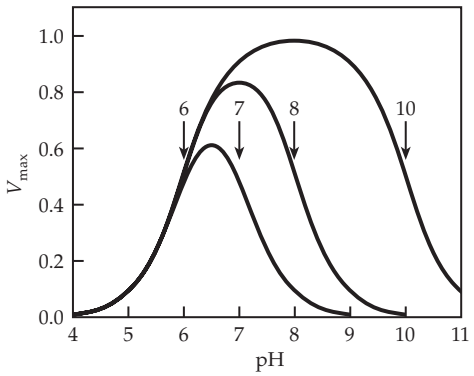


Figure 9-8 Expected dependence of V_{max} on the pH according to Eq. 9-54 with $k_3[E_t] = 1$, $pK_{1ES} = 6$, and pK_{2ES} as given on the graph. After Alberty.[63] Computer-drawn graph courtesy of Carol M. Metzler.

$$V_{max} = \frac{k_3[E]_t}{(1 + [H^+]/K_{1ES} + K_{2ES}/[H^+])} = \frac{k_3[E]_t}{F_{2ES}} \quad (9\text{-}55)$$

$$K_m = \frac{(k_2 + k_3)}{k_1} \cdot \frac{(1 + [H^+]/K_{1E} + K_{2E}/[H^+])}{(1 + [H^+]/K_{1ES} + K_{2ES}/[H^+])} = K_m F_{2E}/F_{2ES} \quad (9\text{-}56)$$

$$\frac{V_{max}}{K_m} = \frac{k_1 k_3}{(k_2 + k_3)} \cdot \frac{1}{(1 + [H^+]/K_{1E} + K_{2E}/[H^+])} = \frac{k_3[E]_t}{K_m F_{2E}} \quad (9\text{-}57)$$

The denominators (which are the Michaelis pH functions given by the first three terms of Eq. 3-6) represent the fraction of enzyme or of ES complex in the monoprotonated state. The pH dependence of enzymatic action is often more complex than that shown in Fig. 9-8 and given by the foregoing equations. However, it is easy to write Michaelis pH functions (see Chapter 3) for enzymes with any number of dissociable groups in both E and ES and to write appropriate equations of the type of

BOX 9-B GROWTH RATES OF CELLS

How do we correctly describe the rate at which a cell grows? Consider bacteria in their rapidly growing "log phase."[a] Each cell divides after a fixed length of time, the **doubling time**. For *E. coli* this may be as short as 17 min in the early stages of growth but becomes somewhat longer as time goes on. A mean value of about 26 min. for *E. coli* at 37°C is typical. In contrast, the doubling time for mammalian cells in tissue culture is often about one day.

If a given volume of culture contains N_0 cells initially, the number N_n after n cell divisions will be:

$$N_n = 2^n N_0$$

From this equation we can calculate that a single bacterium with a generation time of 20 min can produce 2^{144} cells in 48 h of exponential growth. The **exponential growth rate constant *k*** is equal to *the number of doublings per unit time*. Thus, k is the reciprocal of the doubling time. It is easy to show that the number of bacteria present at time t will be given by the following equation.

$$N_t = 2^{kt} N_0$$

This can be rewritten in a form that can be used to determine k by counting the number of bacteria at zero time and at time t.

$$kt = \log_2(N_t/N_0) = \log_{10}(N_t/N_0)/0.301$$

Another way of expressing the growth is to equate the rate of increase of the number of bacteria with a growth rate constant μ multiplied by the number of bacteria present at that time.

$$dN/dt = \mu N$$

This is a general equation for an autocatalytic reaction and N could be replaced with a concentration, for example, the total content of cellular matter per liter in the medium. From the two preceding equations the following can be derived.[a]

$$\mu = k \ln 2 = 0.69k$$

When bacteria are transferred to new medium there is usually a lag before exponential growth begins. Exponential growth eventually stops and the culture enters **stationary phase**, which is usually followed by relatively rapid death of cells in the culture. It is often desirable to study cell growth under conditions of **continuous cultivation** in which a constant generation time is maintained but the density of cells in the medium does not increase. This can be done with a simple device known as the **chemostat**.[a,b] A culture vessel containing bacteria is stirred to ensure homogeneity. Fresh culture medium continuously enters the vessel from a reservoir and part of the content of the vessel, suspended bacteria included, is continuously removed through another tube. The bacterial population in the vessel builds up to a constant level and can be maintained at the same level for relatively long periods of time.

Here are some other statistics on cell growth. Bacteria growing exponentially expand their linear dimensions by 1.5 nm and synthesize 1.6×10^7 Da of new cell material in one second. This is equivalent to ~1000 small proteins and includes 23 ribosomes and 3000 base pairs of DNA at each growing point. The much larger HeLa human tumor cell grows by 0.13 nm / s but makes 4.6×10^8 Da / s of material.[c]

Eqs. 9-55 to 9-57. Bear in mind that if the **free substrate** contains groups dissociating in the pH range of interest, a Michaelis pH function for the free substrates will also appear in the numerator of Eq. 9-56. If the pH dependence of the enyzme is regulated by a conformational change in the protein, there may be a cooperative gain or loss of more than one proton and the Michaelis pH function must reflect this fact. This can sometimes be accomplished by addition of a term related to Eq. 7-45. For more information see Dixon and Webb,[64] Cleland,[65,66] or Kyte.[67]

Plots of log V_{max} (or log-specific activity) and –log K_m or log (V_{max} / K_m) versus pH yield graphs of the type shown in Fig. 9-9. The curved segments of the graphs that extend for about 1.5 pH units on either side of each pK_a are asymptotic to straight lines of slope 1 when a single proton is involved or of a higher slope for multiple cooperative proton dissociation. The straight lines can be extrapolated and intersect at the pK_a values. (However, it is better to fit a complete curve of theoretically correct shape to the points.) Note that the curved line always passes below or above the intersection point at the value of log 2 = 0.30 except in the case of cooperative proton dissociation when it is closer.

Upward turns in the curve of log K_m vs pH correspond to pK_a values in the free enzyme or substrate and downward turns to pK_a values in ES. This approach to analysis of pH dependence has been adopted widely but often incorrectly. For example, many published curves have very sharp bends in which the curved portion covers less than 3 pH units and the curve is much closer than 0.30 to the extrapolated point. This suggests cooperative proton binding and an *apparent* pK_a that is related to $\bar{K}$ of Eq. 7-21. Cooperativity is always a possibility if a conformational change in the protein is involved.[67]

The simple treatment given above is based on the assumption that all proton dissociations are rapid compared to k_{cat}, that enzyme in only one state of protonation binds substrate, and that ES in only one state of protonation yields products. These assumptions are not always valid. It also assumes that both binding and dissociation of substrate are rapid, that is, to use Cleland's terminology the substrate is not "sticky." For a sticky substrate that dissociates more slowly than it reacts to form products ($k_3 > k_2$; Eq. 9-54), the values of pK_{1E} will be lowered and pK_{1E} of Eq. 9-53 will be raised by log (1 + k_3 / k_2).[65,66] In addition to the articles by Cleland, other detailed treatments of pH effects have been prepared by Brocklehurst and Dixon[69] and Tipton and Dixon.[70]

Fumarate hydratase (fumarase), which is discussed in Chapter 13, catalyzes the reversible hydration of fumaric acid to malic acid (Eq. 13-11). It was one of the first enzymes whose pH dependence was studied intensively. A bell-shaped pH dependence

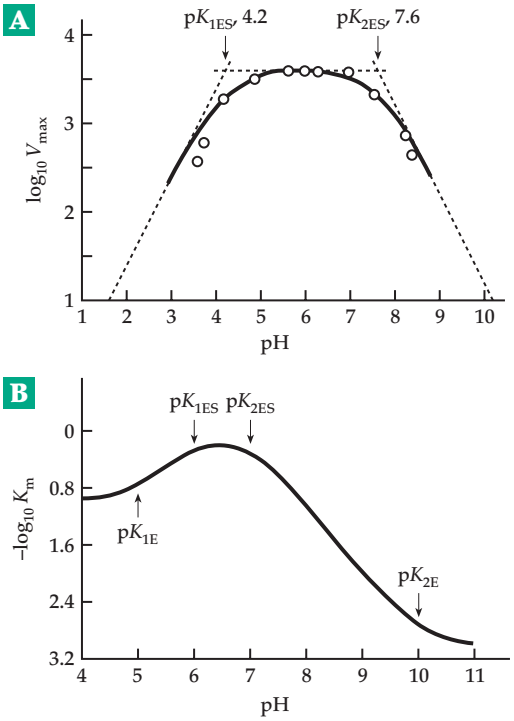

Figure 9-9 (A) Plot of log V_{max} vs pH for a crystalline bacterial α-amylase. From Ono, et al.[68] (B) Theoretical curve of log K_m vs pH for Eq. 9-56 with pK_{1E} = 5, pK_{2E} = 10, pK_{1ES} = 6, and pK_{2ES} = 7. Courtesy of C. Metzler.

for both forward and reverse reactions was observed by Alberty and coworkers[63] and, using Eqs. 9-54 and 9-55, the two apparent pK_a values were measured.

B. Inhibition and Activation of Enzymes

The action of most enzymes is inhibited by many substances. Inhibition is often specific, and studies of the relationship between inhibitor structure and activity have been important to the development of our concepts of active sites and of complementarity of surfaces of biomolecules. Inhibition of enzymes is also the basis of the action of a very large fraction of important drugs. Inhibition may be **reversible** or **irreversible**, the latter leading to permanent inactivation of the enzyme. Often, but not always, irreversible inhibition is preceded by reversible binding of the inhibitor at a complementary site on the enzyme surface.

1. Competitive Inhibitors

Inhibitors with close structural similarities to a substrate tend to bind to the substrate site. In truly competitive inhibition, substrate and inhibitor not only

compete for the same site but also their binding is reversible and mutually exclusive. The affinity of the inhibitor for the enzyme is expressed quantitatively through the **inhibition constant** K_i which is the *dissociation constant of the enzyme inhibitor complex EI* :

$$K_i = [E][I] / [EI] \tag{9-58}$$

Using the steady state assumption for the mechanism shown in Eq. 9-14, and writing a mass balance equation that includes not only free enzyme and ES but also EI we obtain an equation relating rate to substrate concentration. It is entirely analogous to Eq. 9-15 but K_m is replaced by an apparent Michaelis constant, K'_m:

$$K'_m = K_m\left(1 + \frac{[I]}{K_i}\right) \tag{9-59}$$

The relationships between v and [S] and between $1/v$ and $1/[S]$ are as follows:

$$\frac{v}{[S]} = \frac{V_{max}}{K_m'} - \frac{v}{K_m'} \tag{9-60}$$

$$\frac{1}{v} = \frac{1}{V_{max}} + \frac{K_m}{V_{max}[S]}\left(1 + \frac{[I]}{K_i}\right) \tag{9-61}$$

A commonly used test for competitive inhibition is to plot $1/v$ vs $1/[S]$ (Eq. 9-61), both in the absence of inhibitor and in the presence of one or more fixed concentrations of I. The result, in each case, is a family of lines of varying slope (Fig. 9-10) that converge on one of the axes at the value $1/V_{max}$. We see that the maximum velocity is unchanged by the presence of inhibitor. If sufficient substrate is added, the enzyme will be saturated with substrate and the inhibitor cannot bind. The value of K_i can be calculated using Eq. 9-61 from the change in slope caused by addition of inhibitor.

The effect of a fixed concentration of a competitive inhibitor on a plot of v against log [S] (Fig. 9-11) is to shift the curve to the right, i.e., toward higher values of [S], but without any change in shape (or in the value of V_{max}).

Another plot, introduced by Dixon,[71] is that of $1/v$ versus [I] at two or more fixed substrate concentrations. The student should be able to demonstrate that this plot contains a family of straight lines that intersect at a point to the left of the origin with coordinates $[I] = -K_i$ and $1/v = 1/V_{max}$. This plot may fail to distinguish certain types of inhibition discussed in the next section.[72]

Competitive inhibition is extremely common and has great significance for metabolic control and for the effects of drugs and of poisons. Simple ions are often competitive inhibitors. Since many biochemical substances carry negative charges, anions such as Cl^-, HCO_3^-, HPO_4^{2-}, and acetate$^-$ frequently act as competitive inhibitors.

Two special classes of competitive inhibitors are characterized by **slow binding** and **slow, tight binding** to active sites.[73–77] Among the very tight-binding inhibitors, which may also be slow to dissociate from active sites, are transition state inhibitors discussed in Section D,1.

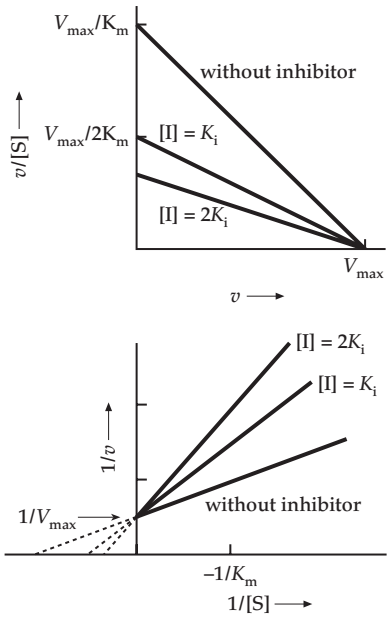

Figure 9-10 Effect of a competitive inhibitor on the Eadie–Hofstee plot (top) and on a double reciprocal plot (bottom). The apparent K_m (Eq. 9-59) is increased by increasing [I], but V_{max} is unchanged.

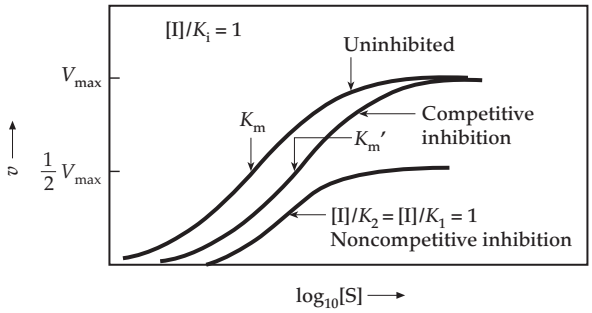

Figure 9-11 Plots of v vs. log [S] for competitive and noncompetitive inhibition.

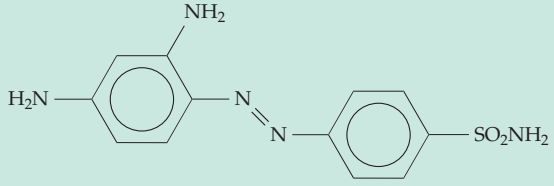
2. Noncompetitive Inhibition and Activation; Allosteric Sites

If an inhibitor binds not only to free enzyme but also to the enzyme substrate complex ES, inhibition is **noncompetitive**. In this case, S and I do not mutually exclude each other and both can be bound to the enzyme at the same time. Why does such an inhibitor slow an enzymatic reaction? In most instances, the structure of the inhibitor does not show a close similarity to that of substrate, which suggests that the binding of inhibitors is at an **allosteric site**, that is, at a site other than that of the substrate. The inhibition of the enzyme may result from a distortion of the three-dimensional structure of the enzyme which is caused by the binding of the inhibitor. This distortion may be transmitted to the active site even though the inhibitor binds far from that site. In some cases two distinctly different conformers of the protein may exist, one binding substrate well and the other binding inhibitor well (Fig. 9-12). In other instances the bound inhibitor may interfere with the catalytic action by partially overlapping the active site. In either case the ES complex reacts to give product in a normal way, but the ESI complex reacts more slowly or not at all.

Binding of a substance to an allosteric site sometimes has the effect of *increasing* the activity of an enzyme rather than inhibiting it. This may occur because the **activator** stabilizes the conformation that binds substrate best (Fig. 9-12). The quantitative treatment of such activation is similar to that of inhibition; allosteric inhibitors and activators are often considered together and are referred to as **modifiers** or

BOX 9-C THE SULFONAMIDES AS ANTIMETABOLITES

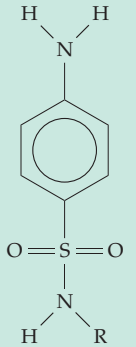
The development of the "sulfa drugs,"[a–c] derivatives of **sulfanilamide**, originated with studies of the staining of protozoal parasites by Paul Erhlich. In 1932 it was shown that the red dye 2,4-diaminoazobenzene-4'-sulfonamide (Prontosil) dramatically cured systemic infections by gram-positive bacteria. Subsequent studies revealed that bacteria converted



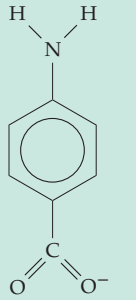
Prontosil

the azo dye to sulfanilamide, a compound with strong bacteriostatic activity; that is, it inhibited bacterial growth without killing the bacteria. Although sulfanilamide had been used in large quantities since 1908 as an intermediate in synthesis of dyes, its potential as an antibacterial agent had not been recognized.

In 1935, D. D. Woods found that the growth inhibition of sulfanilamide was reversed by yeast extract.[d] From this source, in 1940 he isolated ***p*-aminobenzoic acid** and demonstrated that the inhibitory effect of 3×10^{-4} M sulfanilamide was overcome by 6×10^{-8} M *p*-aminobenzoate. The relationship between the two compounds was shown to be strictly competitive. If the sulfanilamide concentration was doubled, twice as much *p*-aminobenzoate was required to reverse the inhibition as before. These facts led to the formulation by Woods and by P. Fildes (in 1940) of the **antimetabolite theory**.[d,e] It was proposed that *p*-aminobenzoate was needed by bacteria and that sulfanilamide competed for a site on an enzyme designed to act on *p*-aminobenzoate. We now know that the idea was correct and that the enzyme on which the competition occurs catalyzes the synthesis of dihydropteroic acid (Fig. 25-19), a precursor to folic acid.



Sulfonamides
R=H in sulfanilamide



p-Aminobenzoate

While sulfanilamide itself is somewhat toxic, a variety of related drugs of outstanding value have been developed. Over 10,000 sulfonamides and related compounds have been tested for antibacterial action.

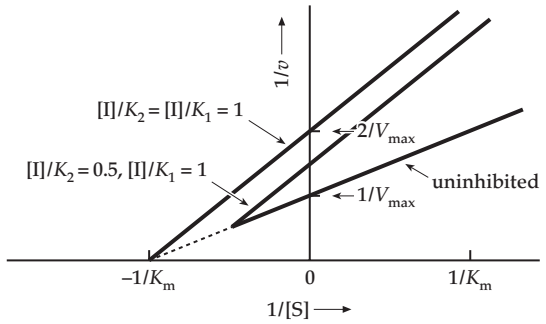

Figure 9-12 Double reciprocal plots for two cases of noncompetitive inhibition.

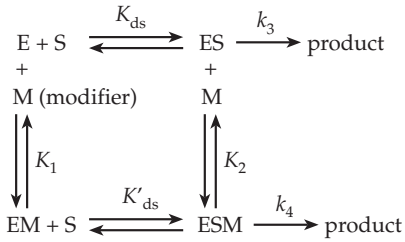
effectors. A general scheme[78,79] is given by Eq. 9-62.



(9-62)

Here K_1 and K_2 are equilibrium constants for dissociation of M from EM and ESM, respectively, while K_{ds} and K'_{ds} are the dissociation constant of ES and of ESM (to S and EM), respectively. Notice that, K'_{ds} is not independent of the others (Eq. 9-63):

$$K'_{ds} = K_{ds}K_2/K_1 \tag{9-63}$$

We have already considered competitive inhibition which is obtained when $K_2 = 0$ (and therefore $K'_{ds} = 0$). For this case, M is always an inhibitor and no activation is possible. Notice that the inhibition will appear competitive even if M binds at an allosteric site as in Fig. 9-13 or if the inhibited form does not react at all with substrate. Noncompetitive inhibition will be observed if ESM is formed but does not react, i.e., if $k_4 = 0$. Then the rate equation in reciprocal form will be given by Eq. 9-64.

$$\frac{1}{v} = \frac{1}{V_{max}}\left(1 + \frac{[I]}{K_2}\right) + \frac{K_m}{V_{max}[S]}\left(1 + \frac{[I]}{K_1}\right) \tag{9-64}$$

We see that $1/V_{max}$ is multiplied by a term containing [I] and K_2. It is a characteristic of noncompetitive inhibition that the maximum velocity is decreased from that observed in the absence of the inhibitor. Also, no matter how high the substrate concentration, inhibition cannot be reversed completely.

Figure 9-12 shows a plot of $1/v$ against $1/[S]$ at a series of fixed values of [I]. For the case that $K_1 = K_2$ **(classical noncompetitive inhibition)**, a family of reciprocal plots that intersect on the horizontal axis at a value of $-1/K_m$ is obtained. On the other hand, if K_1 and K_2 differ (the general case of noncompetitive inhibition), the family of curves intersect at some other point to the left of the vertical axis and, depending upon the relative values of K_1 and K_2, either above or below the horizontal axis. The example illustrated is for $K_2 = 0.5K_1$; that is, for the binding of M to ES being twice as strong as that to E.

Figure 9-11 shows inhibition data for both the noncompetitive and the competitive cases plotted vs log[S]. The shift of the midpoint to the right in each case reflects the tendency of the inhibitor to exclude the substrate from binding, while the lowered value of the maximum velocity in the case of noncompetitive inhibition results from the failure of the substrate to completely displace the inhibitor from the enzyme

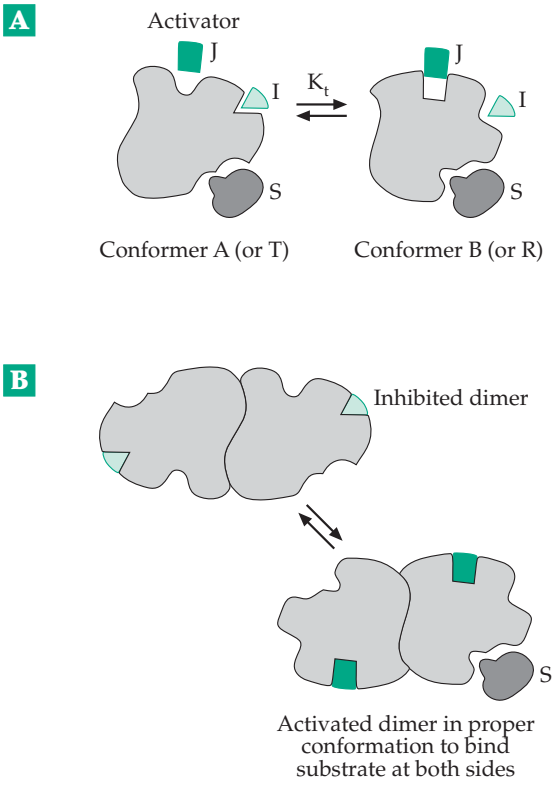


Figure 9-13 (A) An enzyme with binding sites for allosteric inhibitor I and activator J. Conformer A binds inhibitor I strongly but has little affinity for activator J or for substrate S. Conformer B binds S and catalyzes its reaction. It also binds activator J whose presence tends to lock the enzyme in the "on" conformation B. Conformers A and B are designated T and R in the MWC model of Monod, Wyman, and Changeux.[80] (B) Inhibited and activated dimeric enzymes.

even as [S] becomes very high. If an inhibitor binds only to ES and not to E, i.e., $K_1 = 0$, a family of parallel double-reciprocal plots of $1/v$ vs $1/[S]$ will be obtained. This case is referred to as **uncompetitive inhibition**. Multisubstrate enzymes with either ordered sequential or ping-pong mechanisms also often give parallel line plots with inhibitors.

Uncompetitive inhibitors of liver alcohol dehydrogenase (Chapter 15) could be used to treat cases of poisoning by methanol or ethylene glycol.[81–83] The aim is to prevent rapid oxidation to the toxic acids HCOOH and $HOCH_2COOH$, which lower blood pH, while the alcohols are excreted. Uncompetitive inhibitors have an advantage over competitive inhibitors as therapeutic agents in that the inhibition is not overcome when the substrate concentration is saturating.[84]

If rate constant k_4 of Eq. 9-62 is not zero we may observe either inhibition or activation. If $k_3 = k_4$ the effect of a modifier will be to alter the apparent K_m by either increasing it (inhibition) or decreasing it (activation). The maximum velocity will be unchanged. Monod *et al*.[80] referred to enzymes showing such behavior as **K systems**. On the other hand, if $K_1 = K_2$ and k_3 differs from k_4 we have a purely **V system**. In the general case a modifier affects both the apparent K_m and V_{max}. Although in the foregoing discussion it has been assumed that activators bind at allosteric sites, as was pointed out in Section A,11, ions and other small molecules (substrate surrogates) that act as competitive inhibitors at high concentrations may be activators at low concentrations.[40]

Activation of enzymes by specific metallic ions is often observed. In many instances the metallic ion is properly regarded as a *second substrate* which must bind along with the first substrate before reaction can occur. Alternatively, the complex of the organic substrate with the metal ion can be considered the "true substrate." Thus, many enzymes act upon the magnesium complex of ATP (Chapter 12). The enzymes can either be regarded as three-substrate enzymes requiring $Mg^{2+} + ATP^{4-}$ and another substrate or as two-substrate enzymes acting upon $ATPMg^{2-}$ and a second substrate.

3. Inhibitors in the Study of Mechanisms

A substrate analog will frequently inhibit only one of the two forms of a multisubstrate enzyme with a ping-pong mechanism.[1,72] Reciprocal plots made for various inhibitor concentrations consist of a family of parallel lines reminiscent of uncompetitive inhibition. Observation of such parallel line plots can support a ping-pong mechanism for an enzyme but cannot prove it because in some cases parallel lines are observed for inhibition of enzymes acting by an ordered sequential mechanism. The following question arises naturally for any ordered bimolecular reaction (Eq. 9-43): Of the two substrates required by the enzymes, which one binds to the enzyme first? If the concentration of one substrate is kept constant while varying concentrations of an inhibitory analog of that substrate are added and $1/v$ is plotted against the reciprocal of the concentration of the other substrate, parallel lines are obtained if, and only if, the substrate of fixed concentration is B, the substrate is adding second in the binding sequence, *and* if I is its analog. The substrate binding first (A) is the one whose concentration was varied in the experiment.

Product inhibition (Section A,12) can also provide information about mechanisms. For example, if $1/v$ is plotted against $1/[A]$ in the presence and absence of the product Q, the product will be found to compete with A and to give a typical family of lines for competitive inhibition. On the other hand, a plot of $1/v$ vs $1/[B]$ in the presence and absence of Q will indicate noncompetitive inhibition if the binding of substrates is ordered (Eq. 9-43). In other words, only the A–Q pair of substrates are competitive. Product inhibition is also observed with enzymes having ping-pong kinetics (Eq. 9-47) as a result of formation of nonproductive complexes.

4. Allosteric Effectors in the Regulation of Enzyme Activity

The binding of a substance at an allosteric site with the induction of a conformational change forms the basis for many aspects of regulation. The term **allostery** (allosterism) usually refers to the effects of allosteric modifiers, which may be either inhibitors or activators, on oligomeric enzymes. However, as we have already seen (Eq. 9-62), monomeric enzymes may also be subject to allosteric regulation by modifiers. Consider a monomer that contains binding sites for substrate, inhibitor, and activator and which exists in conformations A and B as in Fig. 9-13. Let us assume (see Eq. 7-31) that conformer B binds both substrate and activator well but that it binds inhibitor poorly or not at all. On the other hand, A binds inhibitor well but binds substrate and activator poorly. This simple combination of two conformers with different binding properties provides a means by which enzymes can be turned "on" or "off" in response to changing conditions.

If an inhibitory substance builds up to a high concentration within a cell, it binds to conformer A; if the inhibitor concentration is high enough, virtually all of the enzyme will be locked in the inactive conformation A. The enzyme will be turned off or at least reduced to a low activity. On the other hand, in the presence of a high concentration of activator the enzyme will be turned on because it is locked in the B conformation. The relative concentrations of inhibitor, activator, and substrate within a cell at any given time

will determine what fraction of the enzyme is in active conformation B. It is this interplay of inhibitory and activating effects that provides the basis for much of the regulation of cell chemistry.[80,85]

The effects of inhibitors or activators on the kinetics of the monomeric enzyme of Fig. 9-13 can be described by Eq. 9-62 to 9-64. Separate terms for both inhibition and activation can be included. The equilibrium between the two conformers can also be indicated explicitly according to Eq. 7-30. However, for monomeric enzymes it is usually not profitable to try to separate the two constants K_t and K_{BX} which describe the conformational change and binding of substrate or activator, respectively, in Eq. 7-30.

Most intracellular enzymes are oligomeric, and the binding of allosteric effectors leads to additional interesting effects. Binding constants or dissociation constants must be defined for both inhibitor and activator to both conformers A and B. Since all species must be taken into account in the mass balance, the equations are complex. However, the Monod–Wyman–Changeux (MWC) model (Chapter 7) gives a relatively simple picture. The saturation curve for an oligomeric enzyme following this model may be derived from Eq. 7-39 and is given by the following expression:

$$Y = \frac{Lc\alpha(1 + c\alpha)^{n-1} + \alpha(1 + \alpha)^{n-1}}{L(1 + c\alpha)^n + (1 + \alpha)^n} \qquad (9\text{-}65)$$

Here, L is the **allosteric constant** which is given (for a dimer) by Eq. 7-36. The constant c is the ratio of dissociation constants K_{BS} and K_{AS} for the two conformers:

$$c = K_{BS} / K_{AS} \qquad (9\text{-}66)$$

Notice that in this chapter *dissociation* constants (K_d) of ES complexes are being used, whereas the equations of Chapter 7 are all written in terms of association constant (K_f). The parameter α is defined as follows, where K_{BS} equals $1/K_{BX}$ of Chapter 7.

$$\alpha = [S] / K_{BS}) \qquad (9\text{-}67)$$

To take account of effects of inhibitor and activator the *ratios* of dissociation constants of I from BI and AI and of activator J from BJ and AJ are defined as in Eq. 9-68. Likewise, "normalized concentrations" of I and J are defined (Eq. 9-69) as β and γ, respectively.

$$d = \frac{K_{BI}}{K_{AI}} > 1 \qquad e = \frac{K_{BJ}}{K_{AJ}} < 1 \qquad (9\text{-}68)$$

$$\beta = [I]/K_{AI} \qquad \gamma = [J]K_{BJ} \qquad (9\text{-}69)$$

According to the MWC model, in the presence of inhibitor and activator at normalized concentrations β and γ an enzyme will still follow Eq. 9-65, but the allosteric constant L will be replaced by an apparent allosteric constant L' (Eq. 9-70).[86] Figure 9-14 shows plots of Y vs. log α for two different values of L' for a tetramer with a specific value assumed for c. In both

$$L' = L\left[\frac{(1 + \beta d)(1 + \gamma e)}{(1 + \beta)(1 + \gamma)}\right]^n \qquad (9\text{-}70)$$

cases, Y approaches 1 as log α increases, but since we are dealing with noncompetitive inhibition at high values of L', much of the enzyme will be in the T(A) conformation at saturation.

Noncompetitive inhibition cannot be completely reversed by very high substrate concentrations. Monod *et al*. defined for an allosteric enzyme a **function of state $\overline{R}$** (Eq. 9-71) which is the fraction of total enzyme in the $\overline{R}$ (B) conformation:

$$\overline{R} = \frac{(1 + \alpha)^n}{L(1 + c\alpha)^n + (1 + \alpha)^n} = \text{function of state} \qquad (9\text{-}71)$$

In a K system (Section B,2) it is the value of $\overline{R}$ that determines the velocity with which an enzyme reacts. Figure 9-14 also shows $\overline{R}$ as a function of log [α]. Note that when L' is low $\overline{R}$ does not approach zero even when $[S] \rightarrow 0$. In other words, the enzyme is never completely turned off, just as when L' is high the enzyme is never completely turned on.

Figure 9-14 may be compared with Fig. 9-11 which shows similar curves for noncompetitive inhibition of a monomeric enzyme. The significant difference between the two figures is that saturation of the oligomeric enzyme occurs over a narrower concentration range than does that of the monomer, i.e., saturation of the oligomeric enzyme, especially in the presence of inhibitor, is *cooperative*. Note that cooperative binding of substrate requires that the free enzyme be largely in conformation T (A), as it is in the presence of an inhibitor. Allosteric interactions between two identical molecules, whether of substrate or of effector, are described by Monod *et al*.[80] as **homotropic interactions**. Such interactions lead to cooperativity or anticooperativity in binding. Allosteric interactions between two different molecules, e.g., a substrate and an activator are designated **heterotropic**.

For many enzymes the MWC model is unrealistically simple. The more general treatment of binding equilibria given in Chapter 7 may be applicable. However, in addition to K systems there are V systems in which a conformational change alters the maximum velocity (see Eq. 9-62)[87] and sometimes both substrate

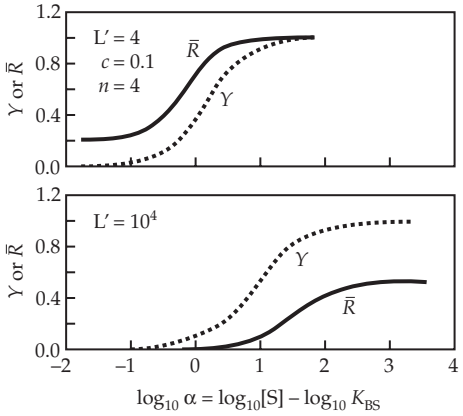

Figure 9-14 Fractional saturation Y and "function of state" $\bar{R}$ for hypothetical tetrameric enzymes following the MWC model. Curves are calculated for two different values of the apparent allosteric constant L' (Eq. 9-70) and for $c = 0.1$ (Eq. 9-66). After Rubin and Changeux.[86]

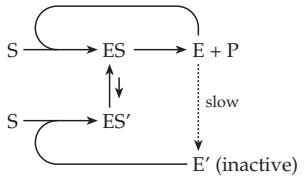
affinity and maximum velocity.

The fact that data can be fitted to an equation is not proof that a mathematical model is correct; other models may predict the results just as well. For example, Jenkins has shown that the presence of ions that act as substrate surrogates (Section A,11) can produce cooperative or anticooperative binding curves for substrates.[40,88] Rabin[89] suggested the following explanation of cooperativity for a monomomeric enzyme with a single substrate-binding site. In its active conformation E the enzyme reacts with substrate rapidly and the ES complex yields product rapidly as in the upper loop of Eq. 9-72. However, a slow conformational change interconverts E and E′, a less active form with much lower affinity for substrate.



(9-72)

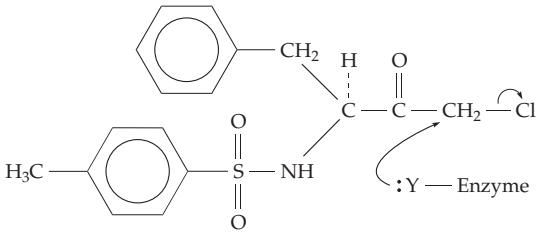
At the same time, the complex ES′, if formed, can equilibriate with ES and thereby alter the conformational state of the protein. At low substrate concentrations E′ will predominate and the enzymatic activity will be low. At high substrate concentrations most E will exist as ES and after release of product will tend to remain in the active conformation long enough to bind and act on another substrate molecule. This and other kinetic models of cooperativity are discussed by Newsholme and Start.[90]

The physiological significance of cooperative binding of substrates to enzymes is analogous to that of cooperative binding of oxygen by hemoglobin which provides for more efficient release of oxygen to tissues. However, in the presence of excess activator an enzyme is locked in the *R* (B) conformation and no cooperativity is seen in the binding of substrate. In this case, each binding site behaves independently. On the other hand, *there will be strong cooperativity in the binding of the activator*. The result is that control of the enzyme is sensitive to a higher power than the first of the activator concentration. Likewise, the turning off of the enzyme is more sensitive to inhibitor concentration as a result of cooperative binding of the latter. It seems likely that the evolution of oligomeric enzymes is at least partly a result of the greater efficiency of control mechanisms based on cooperative binding of effectors.

5. Irreversible Inhibition of Enzymes

Some of our most effective drugs, such as penicillin (Box 20-G) are irreversible inhibitors of specific enzymes. Such inhibitors are also of practical importance to biochemists who wish to inhibit specific enzymes such as proteases that might otherwise destroy proteins they are studying. Transition state analogs (Section E,1) and slow-binding inhibitors (Section B,1) may appear to inactivate an enzyme irreversibly because they bind tightly and dissociate slowly. However, true irreversible inhibitors, such as oxidizing agents or alkylating agents, cause a more permanent chemical modification, usually at or near the active site. Two groups of irreversible inhibitors are of special interest: affinity labeling agents and enzyme-activated inhibitors.

Affinity labeling agents (active-site directed inactivating reagents) have two essential properties: *a high affinity for the active site* of the specific enzyme to be inhibited and *the presence of a chemically highly reactive group* which can attack a functional group in a protein. A good example is provided by derivatives of chloromethylketones, which are reactive alkylating agents. One of these, *N*-tosylphenylalanine chloromethyl ketone (TPCK), is a potent inhibitor of chymotrypsin. In addition to the chloromethyl ketone group it contains



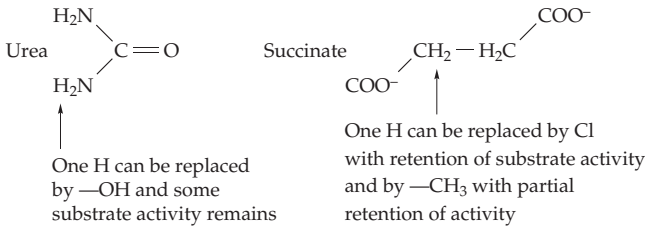
L-*N*-tosylphenylalanine chloromethylketone (TPCK)

the phenylalanine side chain, which helps direct it into the substrate binding site of chymotrypsin, and a sulfonamide linkage that mimics the normal amide linkages of the substrate. The group Y, which becomes alkylated in an S_N2-like displacement of a chloride ion (see Eq. 9-76) is thought to be His 57 of the active site (see Fig. 12-10). For additional discussion see Walsh,[91] Kyte,[67] and Plapp.[91a]

Enzyme-activated inhibitors (also called suicide substrates, k_{cat} inhibitors, or mechanism-based inhibitors) are chemically inert until they enter the active site of their target enzymes. Then, by passing through at least some of the normal stages of the catalytic action of the enzyme, they are converted to reactive intermediates that can become irreversibly bound to an enzyme.[92,93] For example, a halogen atom (F, Cl, Br) together with a proton may be eliminated from an intermediate to give an unsaturated compound to which a nucleophilic side chain of the protein adds. Several of these inhibitors are discussed in later chapters. Because of their high specificity many enzyme-activated inhibitors are potential drugs. One of them, α-difluoromethylornithine (Box 14-C), is said to bind covalently to only one protein in the body of a rat, namely, ornithine decarboxylase, the target enzyme for the drug.

C. The Specificity of Enzymatic Action

Enzymes are usually impressively specific in their action. The specificity toward substrate is sometimes almost absolute. For many years urea was believed to be the *only* substrate for the enzyme **urease** and succinate the only substrate for **succinate dehydrogenase**. Even after much searching for other substrates, only



one or two closely related compounds could be found that were acted on at all. In other cases enzymes can use a class of compounds as substrates. For example, the **D-amino acid oxidase** of kidney oxidizes a variety of D-amino acids but does not touch L-amino acids.

Almost as impressive as the substrate specificity of enzymes is the specificity for a given type of reaction. Many substrates are capable of undergoing a variety of different chemical reactions, either unimolecular or with water or some other compound present in the cell. The enzyme catalyzes only one of these reactions. Although side reactions may occur to a small extent, the most impressive thing in comparing an enzyme-catalyzed reaction with an uncatalyzed organic reaction is that the latter often produces large amounts of side reaction products, but the enzymatic reaction does not.

1. Complementarity of Substrate and Enzyme Surfaces

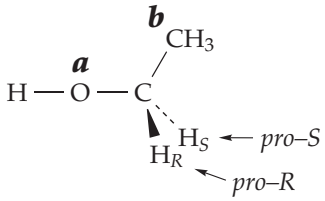
Impressed by the specificity of enzymatic action, biochemists early adopted a "lock-and-key" theory which stated that for a reaction to occur the substrate must fit into an active site precisely. Modern experiments have amply verified the idea. A vast amount of kinetic data on families of substrates and related competitive inhibitors support the idea and numerous X-ray structures of enzymes with bound inhibitors or with very slow substrates have given visual evidence of the reality of the lock-and-key concept. Directed mutation of genes of many enzymes of known three-dimensional structure has provided additional proof.

As anticipated, hydrophobic groups of substrates or inhibitors usually contact hydrophobic regions of the protein and the fit is tight. For example, the active site of chymotrypsin contains a "hydrophobic pocket" designed to hold a large hydrophobic side chain, thus providing the specificity observed with this enzyme (Table 3-2). Likewise, polar groups of substrates contact polar groups of the enzyme. The interactions are complementary, positive charges fitting against negative and with correctly formed hydrogen bonds. Trypsin, whose structure is similar to that of chymotrypsin, exerts its specificity for a positively charged side chain next to the bond cleaved (Table 3-2) by virtue of the presence of a negatively charged carboxylate at the bottom of the hydrophobic pocket. Several C=O and N–H groups of the peptide linkages in the substrate form hydrogen bonds to the edge of a β sheet in the protein, in effect making the substrate an added β strand in the sheet (Fig. 12-10). Aspartate aminotransferase acts on the dicarboxylic amino acids glutamate and aspartate. A pair of arginine side chains bind the two carboxylates of the substrate while the $-NH_3^+$ of the substrate is attracted to a negatively charged group in the coenzyme pyridoxal phosphate, which is also present in the active site (Eq. 14-39, Fig. 14-10).

2. Stereospecificity and Prochiral Centers

Most enzymes possess an infallible ability to recognize the difference between the right side and the left side of an organic substrate even when the latter has perfect bilateral symmetry. In fact, this ability is limited to **prochiral centers** of molecules and is a natural consequence of their reaction with the chiral

enzyme.[94–98] Consider carbon atom number 1 of ethanol. The two attached hydrogen atoms are chemically identical and would react identically with a nonchiral reagent. Nevertheless, these atoms are no more equivalent stereochemically than are your right and your left arms. We say that the molecule has a prochiral center at C-1. A prochiral center on a tetrahedrally bonded carbon atom always contains two identical atoms or groups but a total of three different kinds of atoms or groups. If the priority of this H is elevated, e.g., by substitution of ^2H for ^1H the configuration would be *R* (the priority of this ^2H would become **c**).



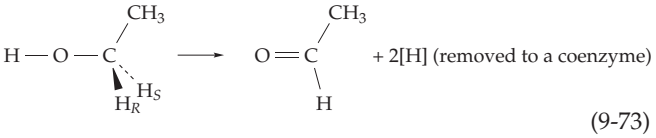
BOX 9-D RECEPTORS, AGONISTS, AND ANTAGONISTS

Inhibition of enzymes provides the basis for many of the effects of antibiotics and other chemotherapeutic substances (e.g., see Box 9-B). However, some drugs act on cell surface **receptors** which have ordinarily not been regarded as enzymes. According to receptor theory, developed around 1937, structurally similar drugs often elicit similar responses because they bind to the same receptor. A receptor may normally bind a hormone, neurotransmitter, or other metabolite whose geometry is partially shared by a drug. Binding of drugs of one class, termed **agonists** in the pharmacological literature, to an appropriate receptor triggers a response in a cell, similar to that of a hormone. On the other hand, compounds of related structure often act as **antagonists**, binding to receptor but failing to elicit a response. Agonist and antagonist often act in a strictly competitive fashion as in competitive inhibition of enzyme action.

We know now that many receptors *are* enzymes, some of which may act quite slowly. The active site may sometimes be far from the receptor binding site and sometimes in a separate subunit. The receptor can be viewed as an allosteric effector which binds at a distant site or as a ligand for a regulatory subunit of the enzyme complex. Alternatively, the active site may be viewed as the site for relaying a signal received from the hormone or other agonist.

The two hydrogen atoms on C-1 of ethanol are called **enantiotopic** because replacement of one or the other by a fourth different kind of atom or group would produce a pair of enantiomers (page 41). This fact suggests a way of naming the positions occupied by two enantiotopic atoms or groups. We first assign priorities to all of the atoms or groups attached to the central carbon atom according to the *RS* system. Now, we ask whether the configuration will be *R* or *S* when the priority of one of the two identical groups is raised, e.g., by substitution of one of the hydrogen atoms by deuterium. If the configuration becomes *R*, that group occupies a *pro-R* position; if the configuration becomes *S*, it occupies a *pro-S* position. Referring to the preceding diagram, it is easy to see (by viewing down the bond to the group of lowest priority and applying the usual rule for determining configuration) that if the *pro-R* hydrogen (H_R) is replaced by deuterium (^2H), the configuration will be *R*. Conversely, replacement of H_S by deuterium will lead to the *S* configuration.

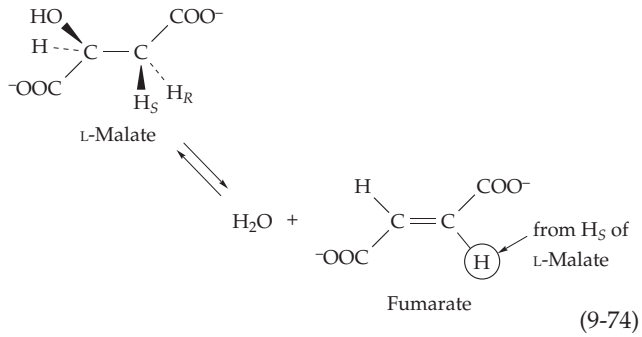
When ethanol is oxidized by the action of **alcohol dehydrogenase** (Eq. 9-73), only the *pro-R* hydrogen atom is removed. If the reaction is reversed in such a way that deuterium is introduced into ethanol from the reduced coenzyme the optically active *R*-2-deuterioethanol is formed. The ability of an enzyme to



(9-73)

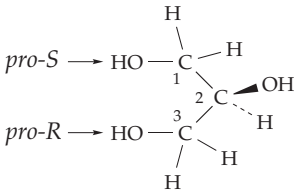
recognize a single hydrogen of a pair of hydrogens on a CH_2 group was at first a surprise to many biochemists.[99] However, it is a natural result of the complementarity of enzyme and substrate surfaces, just as the fit of a shoe is determined by the complementarity of surfaces of foot and shoe. Only a chiral catalyst can have this ability.

Another example is provided by malic acid, a chiral molecule which also contains a prochiral center (see Eq. 9-74). In this case replacement of the *pro-R* or *pro-S* hydrogen atom by another atom or group would yield a pair of diastereoisomers rather than enantiomers. Therefore, these hydrogen atoms are **diastereotopic**. When L-malic acid is dehydrated by fumarate hydratase (Chapter 13) the hydrogen in the *pro-R* position is removed but that in the *pro-S* position is not touched. This can be demonstrated by allowing the dehydration product, fumarate, to be hydrated to malate in ^2H_2O (Eq. 9-74). The malate formed contains deuterium in the *pro-R* position. If this malate is now isolated and placed with another portion of enzyme in H_2O, the deuterium is removed cleanly. The fumarate produced contains no deuterium.



(9-74)

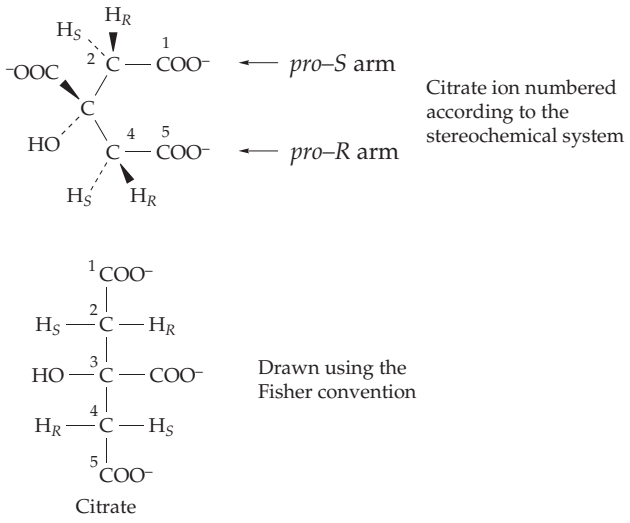
Stereochemical numbering. In some prochiral molecules, such as glycerol, the two ends of the main carbon chain form identical groups. Since the two ends are distinguishable to an enzyme, it is important to decide which should be labeled C-1 and which C-3. Hirschmann proposed a stereochemical numbering system[100] in which the carbons are numbered beginning with the end of the chain that occupies the *pro-S* position.



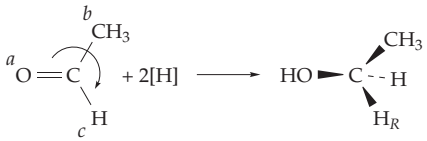
Stereochemical numbering for a symmetric prochiral molecule. Carbons are numbered beginning with the end of the chain that occupies the *pro-S* position.

In this numbering system derivatives of the parent prochiral compound are given the prefix *sn*-. Thus, glycerol phosphate, used by cells to construct phospholipids, usually bears a phosphate group on the $-CH_2OH$ in the *pro-R* position of glycerol and is therefore *sn*-3-glycerol phosphate.

The **citrate ion**, a very important prochiral metabolic intermediate, has three prochiral centers at C-2, C-3, and C-4, respectively. That at C-3 distinguishes the *pro-R* and *pro-S* arms and determines the stereochemical numbering. Citrate containing ^{14}C in the *sn*-1 position is called *sn*-citrate[1-^{14}C] and is the form of labeled citrate that is synthesized in living cells from oxaloacetate and [1-^{14}C]acetyl coenzyme A (see Fig. 10-6). The first step in the further metabolism of citrate is the elimination of the –OH group from C-3 together with the H_R proton from C-4 through the action of the enzyme **aconitate hydratase** (aconitase). In this case the proton at C-4 (in the *pro-R* arm) is selected rather than that at C-2.



Trigonal prochiral centers. Planar trigonal atoms, such as those of aldehydes, ketones, and alkenes, are also prochiral if they are attached to three different kinds of atoms or groups. The two faces are enantiotopic or diastereotopic, if another chiral center is present. Hanson[94,94a] proposed that the faces be named as indicated in Eq. 9-75. The trigonal atom is viewed from one side and the three groups surrounding the carbon atom are given priorities, *a*, *b*, and *c*, as in the *RS* system (Chapter 2). If the sequence *a*, *b*, and *c* of priorites is clockwise, the face toward the reader is *re* (*rectus*); if counterclockwise, it is *si* (*sinister*). Priorities can often be assigned on the basis of the atomic numbers of the first atoms in the three groups (as in the example shown)

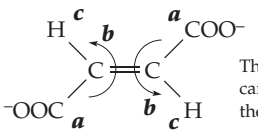


(9-75)

but, if necessary, replica atoms must be added as described in Chapter 2. Replica atoms attached to an originally trigonal carbon are ignored completely, but those attached to O or N of C=O or C=N may be required to establish the priorities of the groups around the carbon atom. For C=O and C=N the faces of the O and N atoms are taken to be the same as that of the attached trigonal carbon atom. In C=C the two carbons may have their *re* faces either on the same side or on opposite sides of the group.

Notice that addition of an atom of ^2H to the *re* face of acetaldehyde would give *R*-deuteroethanol (Eq. 9-75; reverse of Eq. 9-73). This is the reaction catalyzed by alcohol dehydrogenase. Addition of ^1H to the *re* face places the entering hydrogen in the *pro-R* position. Addition to the *si* face would place it in the *pro-S*

position. Fumarate has two trigonal carbon atoms. The *si* faces of both are toward the viewer in the following structure (also shown in Eq. 9-74). Referring to Eq. 9-74, we see that an HO^- ion from water adds to the *si* face of one carbon atom of fumarate to give *s*-malate (L-malate). At the same time, a proton combines with the *re* face of the adjacent unsaturated carbon atom to enter the *pro-R* position.



The *si* faces of both trigonal carbon atoms are toward the viewer.

Fumarate

3. Induced Fit and Conformational Changes

Results of many X-ray studies indicate that the lock-and-key picture of enzyme action must be modified. If an enzyme is a "lock" and the substrate the "key," *the entrance of the key into the lock often induces a conformational change in the protein*. Binding of substrates may be imperfect in the initially formed ES complex but may be more nearly perfect a few nanoseconds or microseconds later as the protein readjusts its structure to accommodate the substrate. The substrate has induced a fit. For example, when an amino acid substrate binds to aspartate aminotransferase one whole domain of the enzyme moves inward, packing hydrophobic side chains of the protein against the substrate (Chapter 14). This strengthens the electrostatic interactions between the ion pairs that orient the substrate and align it for reaction. Similar conformational changes have been observed for citrate synthase, glycogen phosphorylase, various kinases (Chapter 12), alcohol dehydrogenase (Chapter 15), and a growing list of other enzymes. Accompanying changes in circular dichroism, ultraviolet spectra, and sedimentation constants are often observed.

For many other enzymes the observed conformational changes are subtle. A single loop of polypeptide chain or even of a side chain moves to cover the bound substrate. With trypsin and other serine proteases a flexible segment of the peptide chain becomes immobilized and forms more hydrogen bonds after substrate binds than before. It is probably quite unusual for a major unfolding and refolding of parts of a protein to take place. The term induced fit usually refers to substrate binding, but as substrates are interconverted within active sites successive changes in geometry and in charge distribution occur. Small conformational changes may be required at several stages of an enzymatic reaction to ensure that complementarity of substrate and enzyme is preserved.[101] In line with this idea are the facts that proteins are less tightly packed at active sites than in other parts of the molecules, and that active sites often lie between domains and usually are formed by several loops of the peptide chain (Chapter 2).[102]

Although conformational changes allow proteins to maintain good complementarity with substrates, it does not follow that substrates are therefore bound very tightly. This is easiest to understand for reversible reactions in which a substrate is the product of the reverse reaction. Not only binding but also the rate of release of product must be rapid. Very tight binding would retard release and cause product inhibition. Furthermore, as we can see from Eq. 9-37, the velocity of catalysis is the product of [S][E] x k_{cat} / K_m, where [E] is, *free enzyme*. Catalysis can be made more efficient in two ways: by increasing k_{cat} or by decreasing K_m, that is, by tighter binding. However, tighter binding will be advantageous only if K_m is not so low that the enzyme is approaching saturation with substrate. Otherwise, [E] will fall as K_m is lowered and little increase in rate will be observed.[2]

In fact, it appears that enzymes have evolved to have high values of k_{cat} and *high* values of K_m, that is, *weak binding* of substrates.[2] Frequently, in one conformational state of a protein the active site is open, with solvent molecules or substrate surrogates present, while in a second state of nearly equal energy it is closed around the substrate. The functional groups of the enzyme's active site can be bound either to external ions or to ionic groups of substrates and either to water or to hydrogen-bonding groups of substrates. In some cases two ionic groups in the protein may pair with each other in the open conformation and with ionic groups of the substrate in the closed conformation. Thus, the energy changes accompanying the conformational changes can be small but very good complementarity can exist in the ES complex, an important factor in establishing specificity.

4. Specificity and k_{cat}

Enzyme specificity is often observed not only in binding but also in the rate at which ES is converted to products. Thus, it is the values of k_{cat} / K_m that determine specificity. Good examples are provided by chymotrypsin and related serine proteases (Chapter 12),[2] for which substrates with the shortest chains are often bound as well as those with longer chains but react more slowly. For example, *N*-acetylphenylalanine amide binds to chymotrypsin about as well as does the longer *N*-acetylphenylalanylalanine amide but reacts only 1/47 as fast.[2] One might anticipate that increasing the length of the substrate would make it bind more tightly because of the greater number of contacts between substrate and enzyme. It has often been suggested that the reason that this does *not* happen is that the

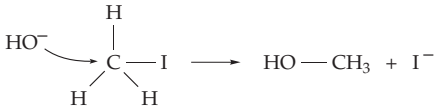
binding of the longer, more specific substrates distorts the enzyme and that *the binding energy is now stored in the enzyme. It is as if the enzyme contained an internal spring which would be compressed when the substrate binds.* This would keep the binding weak but the energy in the spring might then be used to increase the velocity.

5. Proofreading

Although enzymes may be very specific they do make mistakes. This is of particular concern for processes such as protein synthesis in which the correct amino acid is placed at each position in the sequence with an error rate that has been estimated for *E. coli* as only 1 in 10^4. It would be impossible for an enzyme designed to attach valine to its specific transfer RNA to avoid attaching the smaller alanine if discrimination between the two were based solely on the Gibbs energy differences of binding.[103] However, it would be easier for an enzyme to exclude *larger* amino acids. This problem may be resolved by use of multistep screening.[104,105] For example, isoleucyl-tRNA synthetase (Chapter 29) does occasionally attach the smaller valine to the specific $tRNA^{Ile}$ but when it does the enzyme in a "proofreading and editing" step hydrolyzes off the incorrect amino acid. The active site for this hydrolyzing activity, whether at a different place on the enzyme surface or created by a conformational change, may be able to exclude sterically the larger isoleucyl residue while acting on the valyl-tRNA. This editing mechanism for isoleucyl-tRNA synthetase was demonstrated directly in 1998 by X-ray crystallography on complexes of the enzyme with L-isoleucine and L-valine. Both substrates fit into the ATP-requiring synthetic site but neither isoleucine nor isoleucyl-tRNA will fit into the editing site which is located in an adjacent β-barrel domain.[104,105] Proofreading steps based on differing chemical properties as well as size can also be visualized.[103,106]

D. Mechanisms of Catalysis

Kinetic studies tell how fast enzymes act but by themselves say nothing about *how* enzymes catalyze reactions. They do not give the **chemical mechanism** of catalysis, the step-by-step process by which a reaction takes place. Most of the individual steps involve the simultaneous breaking of a chemical bond and formation of a new bond. Consider a simple **displacement reaction**, that of a hydroxyl ion reacting with methyl iodide to give the products methanol and iodide ions.

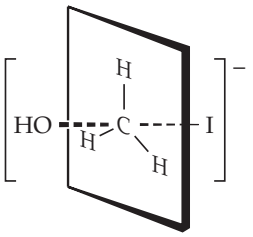


(9-76)

The reaction can be thought of as an "attack" by the OH^- ion on the "back side" of the carbon atom of the methyl groups with a simultaneous displacement of the I^-.

1. The "Transition State"

A reaction such as that of Eq. 9-76 is not instantaneous, and at some time between that at which the reactants exist and that at which products have been formed the C–I bond will be stretched and partially broken and the new C–O bond will be partially formed. The structure at this point is not that of an ordinary compound and is energetically unstable with respect to both the reactant and the products. The intermediate structure of the least stability is known as the **transition state**. Although no one has actually seen a transition state structure, we might represent that for Eq. 9-76 as follows:



Transition state structure

The negative charge is distributed between the attacking HO^- group and the departing iodide. The bonds to the central carbon atom are no longer tetrahedrally arranged but the C–H bonds lie in a single plane and the partial bonds to the OH and iodine atom lie at right angles to that plane.

It is useful in discussing a reaction mechanism to construct a **transition state diagram** in which Gibbs energy *G* is plotted against **reaction coordinate** (Fig. 9-15A). Energy *E* or enthalpy *H* may be plotted in the same way and authors frequently do not state whether *G*, *E*, or *H* is meant. The reaction coordinate is usually not assigned an exact physical meaning but represents the progress from reactants toward products. It is directly related to the extent to which an existing bond has been stretched and broken or a new one formed. The high energy point is the transition state. A somewhat more detailed idea of a transition state is obtained from a contour diagram such as that of Fig. 9-15B. Here, energy is plotted as a function of two distances, e.g., the lengthening C–I bond distance and the shortening C–O distance for Eq. 9-76. The path of minimum energy across the "saddle point" representing the transition state is indicated by the dashed line.

In a reaction coordinate diagram the difference in value of *G* between reactants and products is the

overall Gibbs energy change ΔG for the reaction, while the difference in G between the transition state and reactants is $\Delta G^{\ddagger}$, the **Gibbs energy of activation**. The magnitude of $\Delta G^{\ddagger}$ represents the "energy barrier" to a reaction and largely determines the rate constant.

The diagrams in Fig. 9-15 are too simple because enzymatic reactions usually occur in several intermediate steps. There will be transition states for each step with valleys in between. The valleys correspond to intermediate species, which are sometimes very unstable. The passing from reactants to products in an enzymatic reaction can be likened to wandering through a series of mountain ranges of various heights and finally reaching the other side.

Quantitative transition state theory.[107–113] In the 1880s Arrhenius observed that the rate of chemical reactions varies with temperature according to Eq. 9-77 in a manner similar to the variation of an equilibrium constant with temperature (integrate Eq. 6-37 and compare). Here, k is a first-order rate constant, the quantity E_a is known as the **Arrhenius activation energy**, and the constant A is referred to as the "pre-exponential factor" or the "frequency factor".

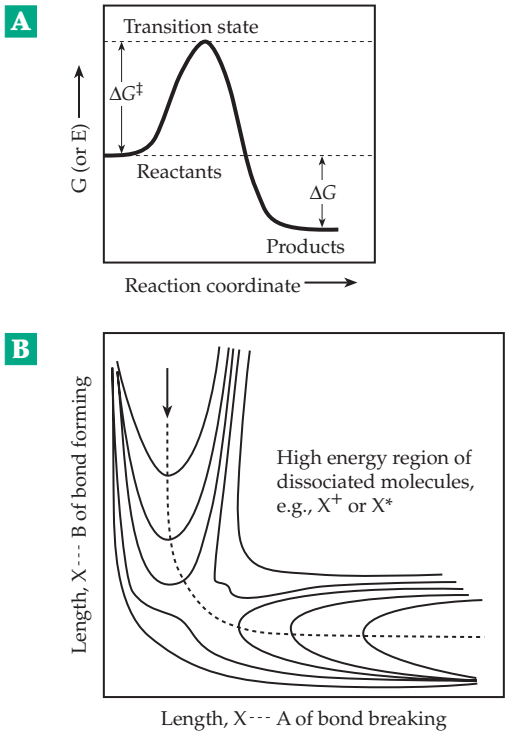


Figure 9-15 (A) Transition state diagram illustrating Gibbs energy vs reaction coordinate for conversion of reactants to products in a chemical reaction. (B) Contour map of Gibbs energy vs interatomic bond distances for reaction B + X – A → B – X + A.

$$k = A e^{-E_a / RT} \tag{9-77}$$

The Arrhenius equation, together with studies of the effects of salts on reaction rates and observation of quantitative correlations between rates and equilibrium constants, suggested that a rate constant for a reaction might be a product of a constant term which is nearly independent of temperature and a constant $K^{\ddagger}$ which has the properties of an equilibrium constant for formation of the transition state. Eyring made this quantitative in 1935 with his "absolute rate theory"[112] according to which all transition states break down with a rate constant $\kappa k_B T/h$. Eyring reached this conclusion by assuming that *the rate of a chemical reaction is determined by the frequency of stretching of the bond that is being broken in the transition state*. To be more precise, it is the "normal-mode" oscillation of the transition state complex along the reaction coordinate.[109] This frequency ν was deduced by describing the vibrational energy as $h\nu$ (from quantum mechanics) and as k_B/T (from classical mechanics) and setting them equal.

$$h\nu = k_B T \quad \text{and} \quad \nu = k_B T/h$$

k_B is the Boltzmann constant
h is Planck's constant. (9-78)

The right side of Eq. 9-78 is usually multiplied by a **transmission coefficient** κ, which may vary from 1 to 0.1 or even much less. However, for lack of any better value, κ is usually assumed to be 1. From Eq. 9-78, at 25°C $\nu = 6.2 \times 10^{12}$ s^{-1}. This is the maximum rate for a chemical reaction of molecules in the transition state. This is the rate for a single molecule and must be multiplied by the concentration of the reacting substance X in the transition state. This concentration $[X]^{\ddagger}$ is determined by the equilibrium constant $K^{\ddagger} = [X]^{\ddagger}/[X]$. The velocity of the reaction becomes

$$\frac{-\mathrm{d}[X]}{\mathrm{dt}} = \nu = \frac{k_B T}{h} \cdot K^{\ddagger}[X] \tag{9-79}$$

The first-order rate constant is

$$k_1 = \frac{-\mathrm{d}[X]/\mathrm{dt}}{[X]} = K \frac{k_B T}{h} \cdot K^{\ddagger} \quad \mathrm{s}^{-1} \tag{9-80}$$

Since $\Delta G^{\ddagger} = -RT \ln K^{\ddagger}$, Eq. 9-80 can be rewritten as Eq. 9-81, in which $\Delta G^{\ddagger}$ is the Gibbs energy of activation.

$$k_1 \approx \frac{k_B T}{h} \cdot e^{-\Delta G^{\ddagger}/RT} \quad \mathrm{s}^{-1} \tag{9-81}$$

At 25°C, $\Delta G^{\ddagger}$ in kJ/mol, the following "practical" form of Eq. 9-81 can be written.

$$k_1 = 6.2 \times 10^{12}\, e^{-\Delta G^{\ddagger}/2.48}\ s^{-1}$$
$$\log k_1 = 12.79 - \Delta G^{\ddagger}/5.71$$
$$\text{and } \Delta G^{\ddagger} = 73.0 - 5.71 \log k_1$$

Equation 9-81 is approximate and a more correct statistical mechanical treatment is available.[113,114] See also comment on p. 288 about log k (and log k_1) being unitless. Employing Eq. 6-14, we may expand Eq. 9-81 as follows:

$$k \approx \left(\frac{k_B T}{h} e^{\Delta S^{\ddagger}/R}\right) e^{-\Delta H^{\ddagger}/RT}\ s^{-1} \qquad (9\text{-}82)$$

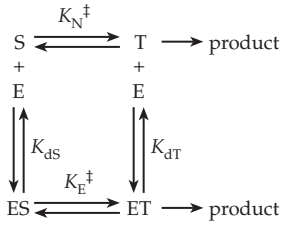
From this it appears that $\Delta H^{\ddagger} \quad E_a$, the Arrhenius activation energy. A more correct treatment gives $\Delta H^{\ddagger} = E_a - RT$ for reactions in solution. However, since RT at 25°C is only 2.5 kJ mol^{-1}, the approximation that $\Delta H^{\ddagger} = E_a$ is often used. The preexponential term, in parentheses in Eq. 9-82, depends principally on $\Delta S^{\ddagger}$, the entropy change accompanying formation of the transition state. The quantities $\Delta G^{\ddagger}$, $\Delta H^{\ddagger}$, and $\Delta S^{\ddagger}$ are sometimes measured for enzymatic reactions but useful interpretations are difficult.

Equations 9-81 and 9-82 also show that a small decrease in transition state energy will give a large increase in rate; stabilization of the transition state by 5.7 kJ / mol (1.4 kcal / mol) will increase the rate 10-fold. If $\Delta G^{\ddagger}$ = 400 kJ/mol, as for a strong covalent single bond, $k_1 = 5 \times 10^{-58}$ s^{-1} and the half-life $t_{1/2} = .693 / k_1 = 1.3 \times 10^{57}$ s (4×10^{49} years, greater than the ~10^{10} years estimated age of the universe). If $\Delta G^{\ddagger}$ = 100 kJ / mol, $\log k_1 \approx -4.7$ s^{-1}, $k_1 = 1.9 \times 10^{-5}$, and $t_{1/2} \approx 10$ h. This is about the rate of a typical nonenzymatic "model" reaction at 25°C. If $\Delta G^{\ddagger}$ = 50 kJ / mol, $\log k_1 \approx 4$, as for a *fast* enzyme.

We can conclude that *enzymes make use of relatively small energy differences in catalyzing reactions*. The energies of numerous van der Waals interactions of hydrogen bonds and electrostatic attraction or repulsion of charges are sufficient. Nevertheless, we can see that anything that stabilizes the transition state (decreases $\Delta G^{\ddagger}$) will increase the rate of reaction. The role of a catalyst is to permit the formation of a transition state of lower energy (higher stability) than that for the uncatalyzed reaction. Stabilization of the transition state of a reaction by an enzyme suggests that the enzyme has a higher affinity for the transition state than it does for substrate or products, an idea that appears to have been expressed first by Haldane[41] and popularized by Pauling.[115]

> *I think that enzymes are molecules that are complementary in structure to the activated complexes of the reactions that they catalyze. The attraction of the enzyme molecule for the activated complex would thus lead to a decrease in its energy, and hence to a decrease in energy of activation of the reaction and to an increase in the rate of the reaction.*

Transition state inhibitors. Suppose that a chemical reaction of a compound S takes place with rate constant k_N through transition state T. Let the equilibrium constant for formation of T be $K_N^{\ddagger}$. Assume that an enzyme E can combine either with S with dissociation constant K_{dS} or with the compound in its transition state structure T with dissociation constant K_{dT} (Eq. 9-83).



(9-83)

If equilibrium is assumed for all four sets of double arrows it is easy to show that Eq. 9-84 holds.

$$K_E^{\ddagger} / K_N^{\ddagger} = K_{dS} / K_{dT} \qquad (9\text{-}84)$$

According to transition state theory, if the transmission coefficient $\kappa = 1$, T and ET will be transformed to products at the same rate. Thus, if the mechanisms of the nonenzymatic and enzymatic reactions are assumed the same, the ratio of maximum velocities for first-order transformation of ES and S will be given by Eq. 9-85. For some enzymes the ratio

$$k_E / k_N = K_E^{\ddagger} / K_N^{\ddagger} = K_{dS} / K_{dT} \qquad (9\text{-}85)$$

k_E / k_N may be 10^8 or more. Thus, if $K_{dS} \approx 10^{-3}$ the constant K_{dT} would be $\approx 10^{-11}$. The enzyme would be expected to bind the transition state structure (T) 10^8 times more tightly than it binds S.

The foregoing reasoning suggests that if structural analogs of T could be found for a particular reaction, they too might be very tightly bound—more so than ordinary substrate analogs.[116] Wolfenden[117] listed a series of compounds which may be **transition state inhibitors** of this type and many others have been described.[117a] Nevertheless, very tight, reversible binding is no *proof* that an inhibitor is actually binding to the transition state structure of the enzyme. For example, an inhibitor may bind to a conformational form of the enzyme that lies off to a side rather than directly on the reaction pathway for catalysis.

Describing the transition state. How can we describe the structure of the transition state when we have no direct knowledge of its structure? We can try

BOX 9-E CHORISMATE MUTASE

Bacteria, fungi, and plants convert products of glucose metabolism into the aromatic amino acids phenylalanine, tyrosine, and tryptophan by a complex sequence of reactions that is described in Chapter 25. One of these reactions, the conversion of **chorismate** into **prephenate,** is unique among enzyme-catalyzed reactions. It is a Claisen rearrangement that occurs readily *without catalysis* in an aqueous solution. However, the rate is increased over one million-fold by the enzyme **chorismate mutase**. The enzyme from *Bacillus subtilis* is a trimer of identical, small 127-residue subunits. Many studies, both of the nonenzymatic and enzymatic reactions, have suggested a "pericyclic" mechanism involving a polar chairlike transition state whose presumed structure is shown in the accompanying equation.[a–f] The transition state analog, whose structure is also depicted, is a powerful inhibitor. X-ray structural studies show that this inhibitor binds in the conformation shown with a number of interactions with polar side chain groups.[d,g] Some of these interactions are shown for the *E. coli* enzyme in the figure;[g] they are different in enzymes from *B. subtilis*[d] and yeast.[h] However, in no case are there groups in obvious positions to serve as acid–base catalysts and the maximum velocity V_{max} is independent of pH.[b] NMR studies show that the bound product prephenate displays large shifts in some ^{13}C resonances, indicating strong interaction with the polar side chains of the protein.[c] Theoretical calculations also suggested that these interactions, especially those with Arg 90 and Glu 78 of the *B. subtilis* enzymes,[f–l] help to stabilize the partial charge separation in the polar transition state. Studies of mutant enzymes have confirmed that the charged Arg 90 (Lys 39 for *E. coli*) side chain is essential.[k]

to predict the atomic coordinates of all of the atoms of the reacting substrates and of the protein. The transition state structure of the substrate must be between that of the last ES complex and the first EP complex formed. It should be similar to that of a transition state inhibitor. We can hope to obtain suitable X-ray or NMR structures and deduce an appropriate enzyme structure by molecular modeling. Theoretical calculations using quantum chemical methods are of value in this effort.[118,119]

Lengths of the breaking and forming bonds in a transition state are often estimated using **kinetic isotope effects** (KIEs) on the velocity of the reaction.[118–122] This is somewhat indirect. Nevertheless, by measuring these effects for a large number of substrates and several isotopes a picture of the transition state structure that is good enough to use as a model for design of an enzyme inhibitor may be obtained.[117a,121–124] Other physical measurements such as Raman difference spectroscopy of isotopically labeled inhibitors can also be of value.[125]

Getting to the transition state. Since some bonds must lengthen and some shorten and bond angles must also change, it may not be simple for an enzyme to catalyze necessary steps prior to the rate-limiting breakdown of the transition state. Hydrogen bonds within the protein may need to be broken and reformed with new bonding partners. Nonpolar side chains may need to shift to give a packing arrangement that will allow the movement of nuclei that must occur in forming the transition state structure. The enzyme must not only stabilize the transition state but also hold the substrate and escort it into the transition state configuration.

The attacking hydroxyl ion in Eq. 9-76 carries a negative charge which becomes distributed more or less equally between the hydroxyl and the iodine atom in the transition state. In this state the CH_3 group carries a partial positive charge as well. To provide good complementarity between an enzyme and this transition state, a change in the initial charge distribution within the enzyme will also be required. If a positively charged group initially binds the OH^- ion it may have to lose part of its charge and a group next to the iodide atom may have to gain positive charge. In the nonenzymatic reaction of Eq. 9-76 the ionic atmosphere provided by positive counterions in solution can continuously readjust to keep the negative charge effectively balanced at every step along the reaction coordinate and through the transition state. Within enzymes this adjustment may occur via redistribution of electrical charges within the polarizable network of internal hydrogen bonds. The enzyme structure must allow this. Because of the complexity of an enzymatic transition state it may be hard to compare it with the transition state of the corresponding nonenzymatic reaction. Effects of pressure[125a] and of temperature[125b] also raise doubts about the simple picture of Eq. 9-83. It also follows that tight binding of substrates in the ground state does not necessarily interfere with transition state stabilization.[126–129a]

2. Microscopic Reversibility

The important statistical mechanical principle of microscopic reversibility asserts that *the mechanism of any chemical reaction considered in the reverse direction must be exactly the inverse of the mechanism of the forward reaction*. A consequence of this principle is that if the mechanism of a reaction is known, that of the reverse reaction is also known. Furthermore, it follows that the *forward and reverse reactions catalyzed by an enzyme must occur at the same active site* on the enzyme and the transition state must be the same in both directions. The principle of microscopic reversibility is often useful when the likelihood of a given mechanism is being considered. If a mechanism is proposed for a reversible reaction in one direction the principle of microscopic reversibility will give an unambiguous mechanism for the reverse reaction. Sometimes this reverse mechanism will be chemically untenable and, recognizing this, the enzymologist can search for a better one.

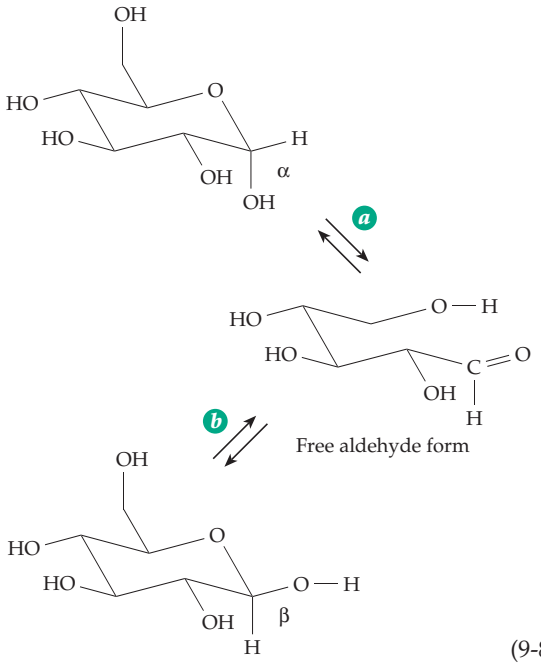
3. Acid and Base Catalysis

Many reactions that are promoted by enzymes can also be catalyzed by acids or bases or by both. An example is **mutarotation**, the reversible interconversion of the α- and β-anomeric forms of sugars (Eqs. 4-1 and 9-86). This reaction is catalyzed by a specific **mutarotase** and also by inorganic acids and bases. The frequently observed bell-shaped curve for the dependence of rate of catalysis on pH (e.g., Eqs. 9-55 to 9-57 and Fig. 9-8) also suggests participation of both protonated and unprotonated acid–base groups present in enzymes.

Acidic and basic groups in enzymes. In this discussion the symbols HB or H^+B will be used for acids and B^- or B for their conjugate bases. Remember that *strong acids* have *low pK_a values* and that the *conjugate bases formed from them are weak bases*. Likewise, *very weak acids have high pK_a values and their conjugate bases are strong*. The following are among the pK_a values that may be important in considering an enzyme mechanism. However, depending upon the environment of the side chain in a protein, these pK_a values may fall substantially outside of the indicated ranges.

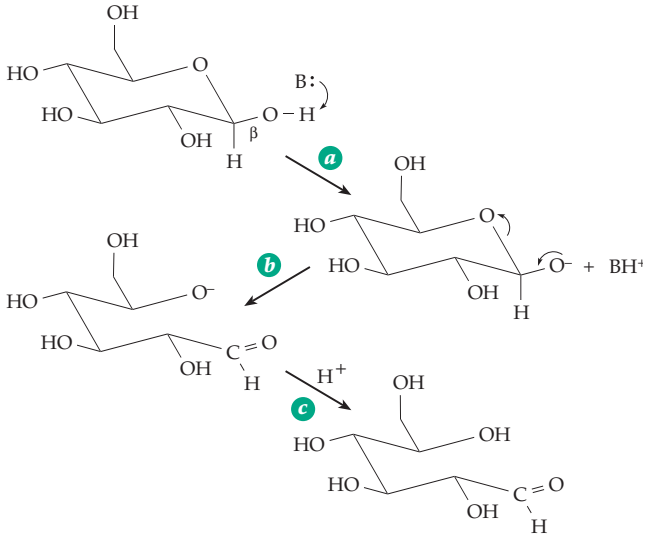
−1.74	H_3O^+ in 55.5 M water
~3.6	−COOH, terminal in peptide
4.3–4.7	−COOH in a glutamic or aspartic acid side chain
6.4–7.0	Imidazole (histidine) and phosphate ($-OPO_3H^-$)
7.5–8.0	$-NH_3^+$, terminal in peptide
8.5–10	−SH of cysteine side chains
9.5–11	Phenolic −OH of tyrosine
~10.5	$-NH_3^+$ of lysine side chain
~13.6	$-CH_2OH$ of serine side chain
15.7	free HO^- in 55.5 M H_2O, 25°C

Acid–base catalysis of mutarotation. The mutarotation of glucose proceeds through the free aldehyde form as an intermediate (Eq. 9-86). A hydrogen atom is removed as H^+ from the oxygen at carbon 1 in step *a* and a proton (probably a different one) is transferred to the oxygen of the ring with cleavage of the O – C bond to the anomeric carbon atom. A similar process in reverse is required for step *b*. Transfers of hydrogen ions between atoms of oxygen, nitrogen, and sulfur atoms are a common feature of biochemical reactions. The bonds between hydrogen and O, N, and S atoms tend to be polarized strongly, leaving a partial positive charge on the hydrogen atoms. Consequently, the groups are weakly acidic and protons can be transferred from them relatively easily. It is reasonable to suppose that acid and base catalysis is related to these proton transfers.



(9-86)

General base and general acid catalysis. Base-catalyzed mutarotation might be formulated as follows: A hydroxyl ion or some other base attacks the proton on the anomeric −OH group of the sugar, removing it to form an anion and the conjugate acid BH^+ (Eq. 9-87,



(9-87)

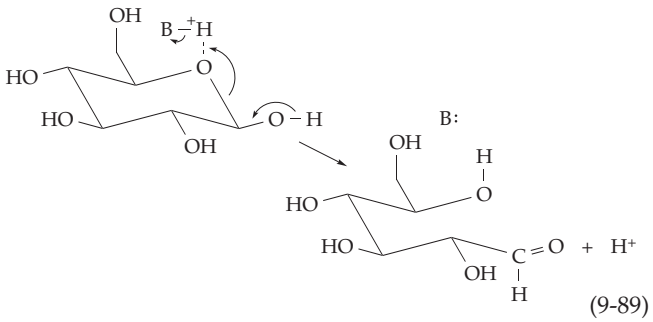
step *a*). The anion is isomerized to a second anion with the ring opened (step *b*). Addition of a proton (transfer of a proton from H_3O^+) produces the free aldehyde form of the sugar (step *c*).

The catalytic base B: might be HO^- or a weaker base such as ammonia or even water. For reactions the rate is proportional only to the concentration of OH^- and the presence of other weaker bases has no effect.[129b] Such catalysis is referred to as **specific hydroxyl ion catalysis**.[19] More commonly, the rate is found to depend both on $[OH^-]$ and on the concentration of other weaker bases. In such cases the apparent first-order rate constant (k_{obs}) for the process is represented by a sum of terms (Eq. 9-88). The term k_{H_2O} is the rate in

$$k_{obs} = k_{H_2O} + K_{OH^-}[OH^-] + k_B[B] \qquad (9\text{-}88)$$

pure water and represents catalysis occurring by the action of water alone as either an acid or a base. The last two terms represent the contributions to the catalysis by OH^- and by the other base, respectively. The term $k_B[B]$ represents **general base catalysis**.

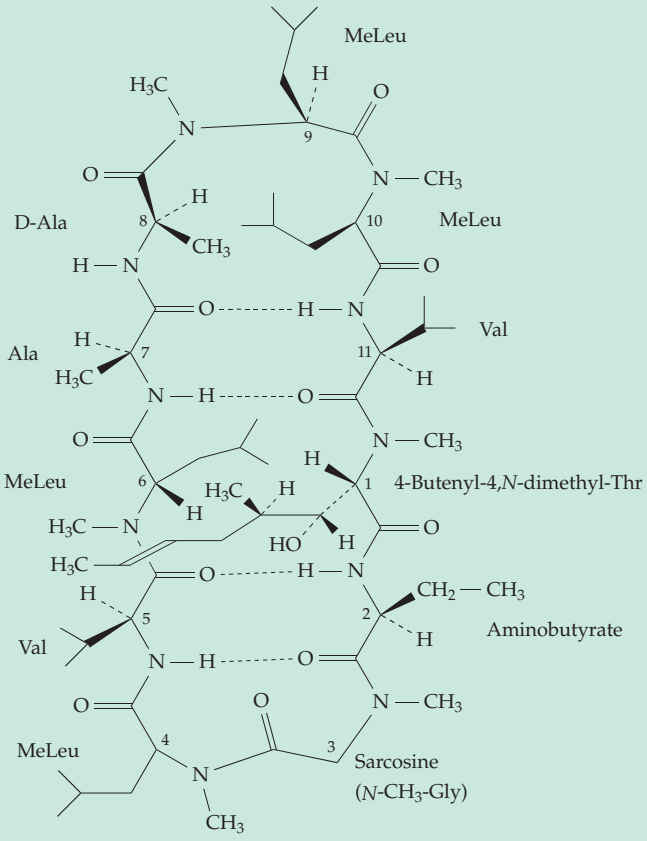
Catalysis of mutarotation by acids occurs if an acid donates a proton to the oxygen in the sugar ring as



(9-89)

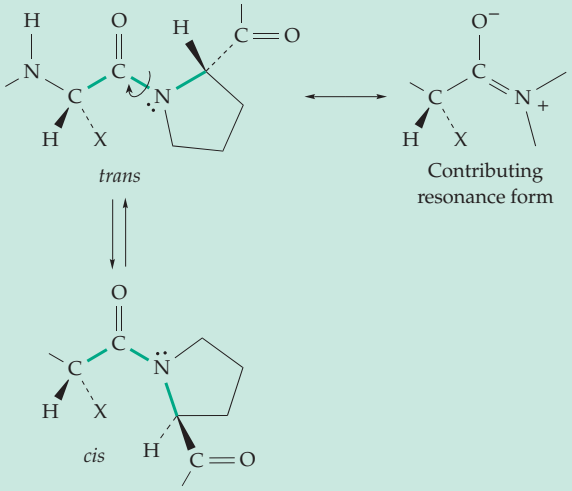
BOX 9-F IMMUNOPHILINS AS ROTAMASES

Since its introduction into clinical use in about 1979 the immunosuppresant **cyclosporin** has been responsible for a revolution in human organ transplantation.[a–c] The exact mechanism of action in suppressing T-lymphocyte-mediated autoimmune responses is still not completely clear, but cyclosporin, a cyclic lipophilic peptide from a fungus, was found to bind to specific proteins that were named **cyclophilins**.[d] Human cyclophilin A is a 165-residue protein which associates, in the crystal form, as a decamer with five-fold rotational and dihedral symmetry.[e] This protein is also found in almost all other organisms and has a highly conserved sequence.[f] Another immunosuppresant, a synthetic molecule known only as **FK506**, has an action similar to that of cyclosporin but binds to distinctly different proteins, the FK506-binding proteins (FKBPs), of which the 107-residue FKBP-12 is the best known.[g–j] These proteins also bind another immunosuppresant, **rapamycin**, which, however, has different biological properties than does FK506. Both FK506 and rapamycin are macrocyclic compounds but with structures very different from that of cyclosporin.

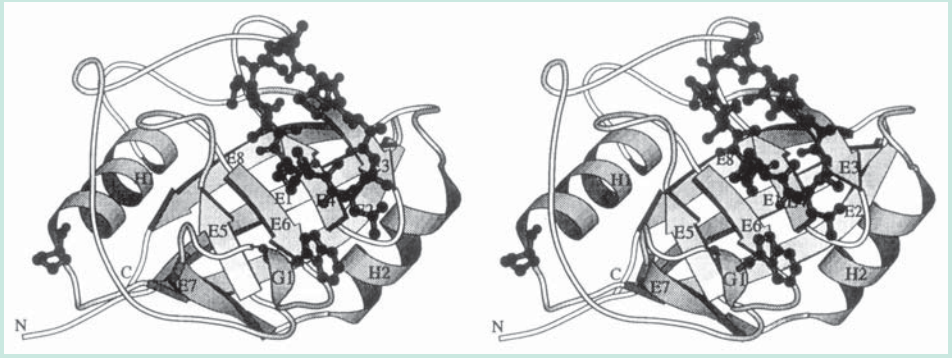


Cyclosporin A

It was a surprise to discover that all of the cyclophilins and FK506-binding proteins are **peptidyl prolyl *cis–trans* isomerases** or **rotamases**. They all catalyze the following simple and reversible reaction of a prolyl peptide linkage:



The transition state energy for the reaction is lowered by 33 kJ mol^{-1} by cyclophilin A[k] and by 27 kJ mol^{-1} by FKBP-12[g] with corresponding rate increases of ~ – 6 x 10^5- and 5 x 10^4-fold, respectively.



Cyclosporin (black) bound to human cyclophilin. From Pflügl *et al.*[e] Courtesy of J. N. Jansonius.

BOX 9-F (continued)

For both enzymes the maximum velocity is independent of pH over a wide region. For cyclophilin the rate is nearly independent of the nature of residue X in the foregoing structure but FKBP prefers a hydrophobic residue.

How do these enzymes work? One possibility would be for the protein to transfer a proton to the nitrogen atom of the proline ring. This would destroy the partial double-bond character of the amide linkage and allow free rotation about a single bond. The same thing could be accomplished if a nucleophilic group from the enzyme formed a covalent adduct with the C=O of the substrate. However, this seems unlikely because there is no suitably placed nucleophile. A third possibility is that the enzyme distorts the substrate and stabilizes the transition state using only noncovalent interactions.[g,h,l] This would account for the lack of pH dependence and observable solvent isotope effects. However, in human cyclophilin the guanidinium group of arginine 55 hydrogen bonds to the peptide C=O of the substrate's proline residue and could easily shift to place a guanidinium proton against the proline ring nitrogen effectively protonating it and permitting rotation about the peptide linkage.[m]

Do cyclosporin and FK506 act as transition state inhibitors? If so, we might learn something about the mechanism from the three-dimensional structures of the inhibited rotamases.[i,l,n,o] From these structures as well as those with simpler substrate analogs, it is seen that the substrate is desolvated and that many nonbonded (van der Waals) interactions stabilize the binding. Hydrogen bonding is also important.[p,q] The presence of distinct hydrogen bonds to the peptide NH and C=O groups on the N-terminal side of the substrate X-Pro linkage and less well-defined bonding on the terminal side suggests that the C-terminal part may be rotated while the enzyme holds the N-terminal part.[p] It can also be concluded that mechanisms are probably not identical for all rotamases.

Cyclophilins and FKBPs are large families of proteins. In *E. coli* there are two cyclophilin genes,[r,s] three encoding FK506-binding proteins, and one of a third family of bacterial rotamases (parvulins) that lack sequence similarity to the other two families.[t,u] Yeast contains at least five cyclophilins[v] and even more eukaryotic FKBPs are known.[j] There is abundant evidence that these proteins play an important role in protein folding *in vivo* (Chapter 29).

shown in Eq. 9-89. Again, either **specific acid catalysis** (by H_3O^+) or **general acid catalysis** is possible.

Enzymes are not able to concentrate protons or hydroxyl ions to the point that *specific* base or acid catalysis would be effective. However, either general acid or general base catalysis can be accomplished by groups present in an enzyme in their normal states of protonation at the pH of the cell. Thus, if one of the enzymes must be dissociated to its conjugate base and a second must be protonated for reaction to take place (as in Eq. 9-54), it is reasonable to suppose that these two groups participate in acid–base catalysis. Of the acidic and basic groups present in proteins, the imidazole group of histidine would appear to be the

most ideal both for general base catalysis and, because both forms may exist in nearly equal amounts at pH 7, for general acid catalysis. However, carboxyl, thiol, lysyl, tyrosyl, and N-terminal amino groups are all thought to function in various enzymes.

The mutarotase of *E. coli* has a turnover number of 10^4 s^{-1}. The plot of $-\log K_m$ vs pH indicates two pK_a values in the free enzyme at 5.5 and 7.6, while the plot of log V_{max} yields a single pK_a of 4.75 for the ES complex.[130] The latter might represent a carboxyl group on an imidazole group in its conjugate base form. Why doesn't the group having pK_a 7.6 in the free enzyme also show a pK_a in the ES complex? Either the group has no catalytic function so that EH_2S of Eq. 9-54 reacts to form products just as fast as does HES or the pK_a is so strongly shifted by substrate binding that it is not detected in the log V_{max} plot.

The Brönsted relationships. The effectiveness of a specific base as a general base catalyst can usually be related to its basicity (pK_a) via the **Brönsted equation** (Eq. 9-90). Here, k_B is defined by Eq. 9-88 and G_B is a

$$\log k_B = \log G_B + \beta\,(\mathrm{p}K_a) \tag{9-90}$$

constant for a particular reaction. A similar equation (9-91) relates the constant k_A for general acid catalysis

$$\log k_{HB} = \log G_A - \alpha(\mathrm{p}K_a) \tag{9-91}$$

to pK_a. These equations are linear Gibbs energy relationships similar to the ones discussed in Box 6-C. For the Brönsted equations to hold, the Gibbs energy of activation for the reaction must be directly related to the basicity or acidity of the catalyst.

The exponents β and α of Eqs. 9-90 and 9-91 measure the *sensitivity* of a reaction toward the basicity or acidity of the catalyst. It is easy to show that as β and α approach 1.0 general base or general acid catalysis is lost and that the rate becomes exactly that of specific hydroxyl ion or specific hydrogen ion catalysis.[131] As β or α approach zero basic or acidic catalysis is indetectable. Thus, general base or general acid catalysis is most significant when β or α is in the neighborhood of 0.5. Under these circumstances it is easy to see how a moderately weak basic group, such as the imidazole group of histidine, can be an unusually effective catalyst at pH 7.

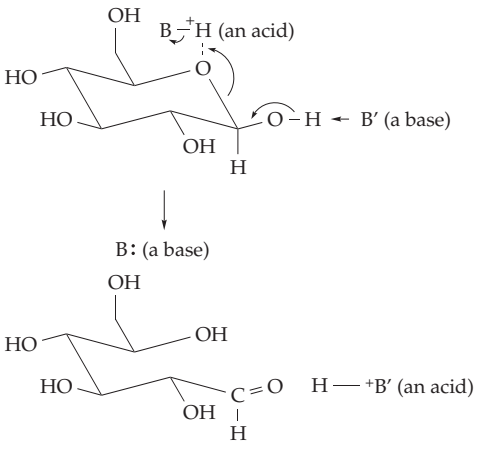
To determine α or β experimentally a plot of log k_B or log k_{HB} vs pK_a (a **Brönsted plot**) is made and the slope is measured. Statistical corrections (Chapter 7) should be applied for dicarboxylic acids and for ammonium ions from which one of three protons may be lost from the nitrogen atom. General base or general acid catalysis implies an important feature of any mechanism for which it is observed, namely, that removal of a proton or addition of a proton is involved in the rate-determining step of a reaction.

Concerted acid–base or tautomeric catalysis. A third possible type of catalysis requires that a base and an acid act *synchronously* to effect the breaking and formation of bonds in a single step. Thus, tetramethylglucose mutarotates very slowly in benzene containing either pyridine (a base) or phenol (an acid). However, when both pyridine and phenol are present, mutarotation is rapid. This suggested to Swain and Brown[132] a **concerted mechanism** (Eq. 9-92) in which both an acid and a base participate.

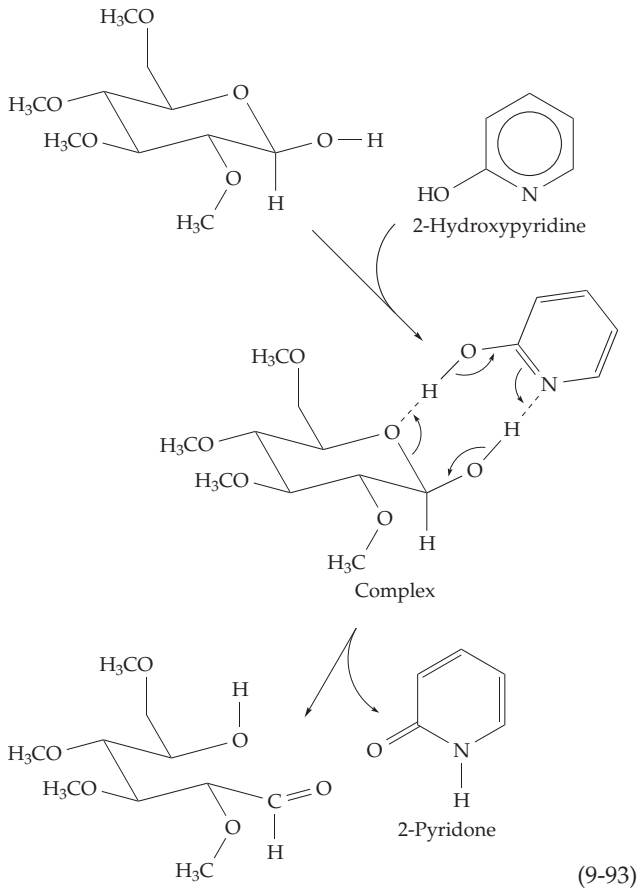
During the reaction shown, the acid BH^+ is converted to its conjugate base B and the base B′ to its conjugate acid H^+B'. It might seem that these agents, having been altered by the reaction, are not serving as true catalysts. However, a simple proton exchange will restore the original forms and complete the catalytic cycle. In aqueous solutions, water itself might act as the acid or the base or even both in concerted catalysis.

The original experimental evidence for concerted acid–base catalysis of the mutarotation in benzene is now considered unsound[133,134] and concerted acid–base catalysis has been difficult to prove for nonenzymatic reactions in aqueous solution. However, measurements of kinetic isotope effects seem to support Swain and Brown's interpretation.[135] Concerted acid–base catalysis by acetic acid and acetate ions may have been observed for the enolization of acetone[136] and it may be employed by enzymes.[136a]

Swain and Brown showed that a more effective catalyst for the mutarotation of sugars than a mixture of an acid and a base can be designed by incorporating the acidic and basic groups into *the same molecule*.[132,135] Thus, with 0.1 M tetramethylglucose in benzene solution, 0.001 M α-hydroxypyridine is 7000 times as effective a catalyst as a mixture of 0.001 M pyridine + 0.001 M phenol. Swain and Brown suggested the following completely concerted reaction mechanism for the **polyfunctional catalyst α-hydroxypyridine** in which the hydrogen-bonded complex formed (Eq. 9-93) is analogous to an enzyme–substrate complex. The product of the catalyst is 2-pyridone, a tautomer of



(9-92)



(9-93)

2-hydroxypyridine, with which it is in a rapid reversible equilibrium.

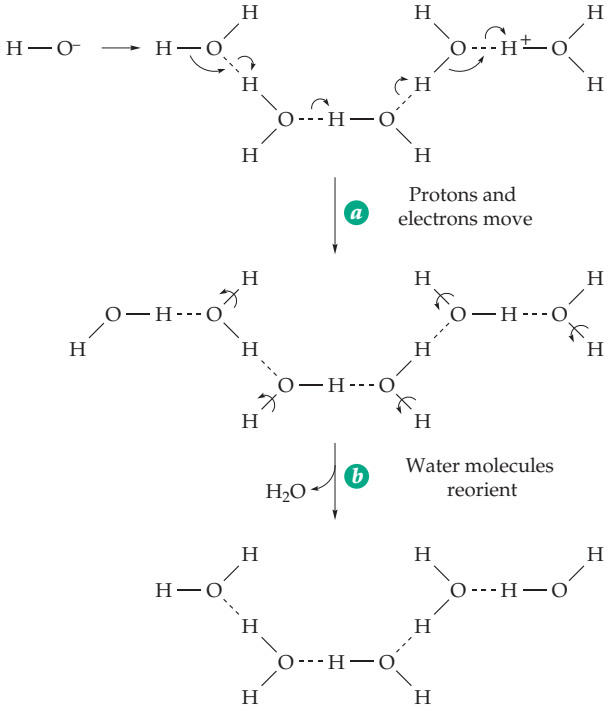
Rony called catalysis of the type illustrated in Eq. 9-93 tautomeric catalysis and suggested that its efficiency lies not simply in the close proximity of acidic and basic groups in the same molecule but also in the ability of the catalyst to repeatedly cycle between the two tautomeric states.[133] For an enzyme the tautomerization of the free catalyst could sometimes be rate determining (see Section A,4 on isomechanisms).

4. Hydrogen Bonding and the Transfer of Protons within Active Sites

An extensive network of hydrogen bonds runs throughout most proteins and may be especially complex within active sites. The network often runs through bound substrate molecules and immobilized water molecules in the active site cavity. This network arises in part because of the frequent occurrence of acidic and basic catalytic groups in active sites and by the fact that many substrates contain polar groups. The structure of an enzyme often seems to be more rigid in a complex with substrates or inhibitors than in the free state. Does this network of linked hydrogen bonds play a role in catalysis? If so, what? Wang suggested that rapid transfer of protons along rigidly and accurately held hydrogen bonds in the ES complex may be an essential feature of enzymatic catalysis.[137] This conclusion is supported by many more recent observations. A remaining question is whether this proton transfer can take place in such a way that the transition state barrier is lowered.

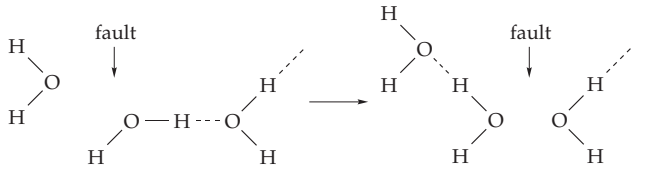
Ultrafast proton transfer. The diffusion-controlled limit for second-order rate constants (Section A3) is ~ 10^{10} M^{-1} s^{-1}. In 1956, Eigen, who had developed new methods for studying very fast reactions, discovered that protons and hydroxide ions react much more rapidly when present in a lattice of ice than when in solution.[138] He observed second-order rate constants of 10^{13} to 10^{14} M^{-1} s^{-1}. These represent rates almost as great as those of molecular vibration. For example, the frequency of vibration of the OH bond in water is about 10^{14} s^{-1}. The latter can be deduced directly from the frequency of infrared light absorbed in exciting this vibration: Frequency ν equals wave number (3710 cm^{-1} for –OH stretching) times *c*, the velocity of light (3×10^{10} cm s^{-1}).

This ultrafast transfer of protons can be explained as follows: The OH^- ion and the proton, which is combined with a water molecule to form H_3O^+, are both hydrogen-bonded to adjacent water molecules. In ice a chain of hydrogen-bonded water molecules links the hydroxide and the hydrogen ions (Eq. 9-94). By synchronous movement of electron pairs from the OH^- ion and from each of the water molecules in the



(9-94)

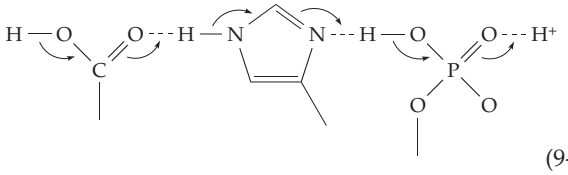
chain (as indicated by the little arrows) the neutralization can take place during the time of one molecular vibration (step *a*, Eq. 9-94). The positions of the oxygen atoms remain unchanged at the end of the reaction but the protons that were engaged in hydrogen bond formation have moved toward the left and are now attached to different oxygen atoms. The central chain of water molecules can be restored to its original state if each molecule rotates around one of its single bonds, swinging a hydrogen from right back to left (Eq. 9-94, step *b*). This must be a slower process which may occur one molecule at a time. The rotation of the leftmost water molecule would leave an empty space between two O-atoms, a "fault" in the H-bonded chain of the ice structure. This fault can be corrected by



(9-95)

rotation of the second molecule (Eq. 9-95); however, this would create a fault at the right of the second water molecule. This would induce rotation of the third molecule, etc., causing the fault to migrate from left to right across the entire chain of water molecules (Eq. 9-94, step *b*) and leaving the chain ready to function again in transferring another proton.

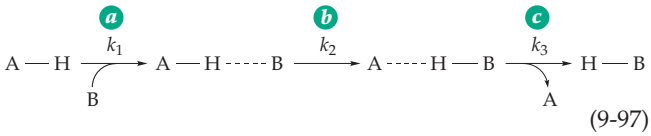
Because of the disorder present in ice, an array of water molecules such as that in Eq. 9-94 wouldn't revert to its exact original form in step *b*. However, active sites of enzymes are highly structured and proton transfers may occur with precision. For example, a synchronous shift of protons in an array of carboxylic acid, imidazolium, and phosphate groups can be envisioned readily (Eq. 9-96). The net effect of the process is to transfer a proton from one end of the chain to the other (as in Eq. 9-94) with facile tauto-



(9-96)

merization reactions providing the pathway. Such a pathway might be constructed by protein side chains to join the two sides of an active center promoting a concerted acid–base catalyzed reaction such as that of Eq. 9-92. Other tautomerization processes are possible within proteins if the existence of less stable minor tautomers of selected amide groups in the peptide backbone is allowed.[139] Nagle and Morowitz suggested a process similar to that of Eq. 9-94 but involving side chains of serine residues.[140]

Proton transfer rates. Consider the reversible reaction of a proton acceptor B with acid H-A (Eq. 9-97). Eigen pointed out that the reaction will be fastest if the two reactants form a hydrogen-bonded complex (Eq. 9-97, step *a*).[138] The hydrogen bonding shortens the distance from the proton to B and allows for very rapid transfer of the proton from A to B within the



(9-97)

hydrogen-bonded complex (step *b*). The activation energy is close to zero. The complex dissociates in step *c* to form the products. The reactions are reversible, even though they have been indicated by unidirectional arrows.

The hydrogen-bonded complexes A–H—-B and A—-H–B can be formed readily if A and B are oxygen or nitrogen bases such as $-COO^-$, –OH, $-NH_2$, or imidazole. In such cases, as in ice, the interconversion of the two complexes (step *b* in Eq. 9-97) is very fast. The overall rate of the proton transfer will then be limited by diffusion of B and H–A together or by diffusion of A and H–B apart. It might seem that these two processes should also both be very fast. However, the rates will be determined by the concentration ratio [A–H—- B]/[A—- H–B]. If [A–H—- B] equals [A—- H – B] the rate of dissociation of A–H–B will be half what it is if nearly all of the complex is A—-H–B. If A–H—-B predominates by 1000 to 1, the rate will be slowed much more.

The equilibrium constant for the reaction of Eq. 9-97 will be:

$$K_{eq}^{AB} = K_a^{HA} / K_a^{HB} = k_f / k_r$$

or

$$\log K_{eq} = pK_a^{HA} - pK_a^{HB} = \log k_f - \log k_r \qquad (9\text{-}98)$$

Here k_f and k_r refer to the rates in the forward and reverse directions. If the pK_a's of HA and HB are equal k_f and k_r will be the same, but if they are very far from equal the reaction will be slowed in one direction. If proton transfer is a step in an enzymatic reaction it may be slowed enough to become rate limiting.

The difference in pK_a values between the proton donor and the proton acceptor in Eq. 9-97 can be expressed as the Gibbs energy change which at 25°C is equal to ±5.71 x ΔpK_a. This is often referred to as the **thermodynamic barrier** ΔG° to a reaction and $\Delta G^\ddagger$ can be expressed as the sum of the thermodynamic barrier ΔG° plus an **intrinsic barrier** $\Delta G^\ddagger_{int}$. For the proton transfer of Eq. 9-97 the intrinsic barrier (for step *b*) is thought to be near zero so that $\Delta G^\ddagger \approx 5.71\ \Delta pK_a$.

From this we can conclude that two pK_a values can be as much as eight units apart and $\Delta G^{\ddagger}$ will still be less than 50 kJ / mol, low enough to permit rapid enzymatic reactions. However, for transfer of a proton from a C–H bond to a catalytic group, for example, to form an enolate ion for an aldol condensation (Chapter 13), the intrinsic barrier is known to be about 50 kJ / mol.[141] In this case, to allow rapid enzymatic reaction either the thermodynamic barrier must be very low, as a result of closely matching pK_a values, or the enzyme must lower the intrinsic barrier. It may do both.

Marcus theory. Discussion of intrinsic barriers is often approached using a quantitative theory proposed by Marcus.[142–145] It was first applied to electron transfer (Chapter 16) but has been used for a great variety of nonenzymatic and enzymatic reactions. As used by Gerlt and Gassman,[141] the Marcus formalism describes the reaction coordinate (Fig. 9-15A) as an inverted parabola whose shape is determined by the overall Gibbs energy change $\Delta G°$ and the intrinsic barrier $\Delta G^{\ddagger}_{int}$. The value of the Gibbs energy at any point on the curve is designated G and the reaction coordinate x is taken as 0 for the reactants and 1 for the products.

$$G = -4\,\Delta G^{\ddagger}_{int}\,(x - 0.5)^2 + \Delta G°\,(x - 0.5)$$
$$\text{Limits: } \Delta G°/4 \le \Delta G^{\ddagger}_{int} \le 4\,\Delta G° \qquad (9\text{-}99)$$

Differentiation of Eq. 9-99 yields the position of the transition state coordinate $x^{\ddagger}$ as follows:

$$x^{\ddagger} = 0.5 + \Delta G°/8\,\Delta G^{\ddagger}_{int} \qquad (9\text{-}100)$$

and it follows that

$$\Delta G^{\ddagger} = \Delta G^{\ddagger}_{int}\,(1 + \Delta G°/4\,\Delta G^{\ddagger}_{int})^2 \qquad (9\text{-}101)$$

Diffusion-controlled dissociation of protons. The direct proton transfer between C-1 and C-2 during the action of sugar isomerases may seem puzzling. How can a highly mobile proton remain attached to a group in the enzyme for a millisecond or more instead of being transferred out to a solvent molecule? This can mean that the enzyme promotes the transfer of a hydride ion or of a hydrogen atom rather than a proton (see Chapter 13). If so, the observed proton exchange with solvent would be an unimportant side reaction. On the other hand, could the group in the enzyme that removes the proton be out of contact with the aqueous medium and thus able to hold onto the proton more tightly? In recent years, it has been recognized that neither of these explanations may be necessary. An imidazole group is a likely proton-carrying group at many active sites and it is thought that a proton cannot be expected to transfer out from an imidazolium group with a rate constant greater than ~10^3 s^{-1}.

The argument is as follows.[146] The rate of donation of a proton from H_3O^+ to imidazole (reverse of Eq. 9-102) is known to be diffusion controlled with a rate constant of 1.5 x 10^{10} M^{-1} s^{-1}.

$$ImH^+ + H_2O \rightleftharpoons [ImH^+\cdots OH_2] \rightleftharpoons Im + OH_3^+$$
$$\uparrow$$
$$\text{Very fast diffusion controlled}$$
$$k \sim 1.5 \times 10^{10}\ M^{-1}\ s^{-1} \qquad (9\text{-}102)$$

The equilibrium constant for Eq. 9-102, calculated from the pK_a of 7.0 for imidazole, is 10^{-7} M. Since K_{eq} is also the *ratio of the overall rate constants for the forward and reverse reactions*, we see that for the forward reaction $k_f = 10^{-7}$ x 1.5 x 10^{10} = 1.5 x 10^3 s^{-1}. This slow rate results from the fact that in the intermediate complex (in brackets in Eq. 9-102) the proton is on the imidazole group most of the time. For a small fraction of the time it is on the coordinated molecule H_2O but reverts to being on the imidazole many times before the imidazole and OH_3^+ separate (see also Eqs. 9-97 and 9-98). Because of this unfavorable equilibrium within the complex, the diffusion-controlled rate of proton transfer from a protonated imidazole to water is far less than for proton transfer in the reverse direction.

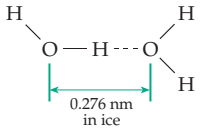
Coupled proton transfers. Enzymatic reactions often require the transfer of two or more protons. They may move individually, one proton at a time, or as in Eq. 9-93 they may move synchronously in a **coupled** or concerted process. Such coupled movement is generally not possible for heavier nuclei.[147] However, studies of solvent isotope effects using a **proton inventory** technique[111,148,149] have provided evidence favoring coupled proton transfers for a variety of enzymes. Movement of protons along hydrogen-bonded paths, as well as electron transfer, may take place with some participation of **quantum mechanical tunneling**.[150–152] Coupling to vibrational modes of the hydrogen-bonded protons may provide **vibration-assisted tunneling**.[153–154d] These reactions are associated with unusually large kinetic isotope effects.

Unusually strong hydrogen bonds. The strength of a hydrogen bond is thought to be directly related to the length, which is ordinarily taken to be the distance between the two surrounding heavier atoms (see Chapter 2, Section B,3). Hydrogen bonds are sometimes classified on the basis of N–H---O distances[155,156] as:

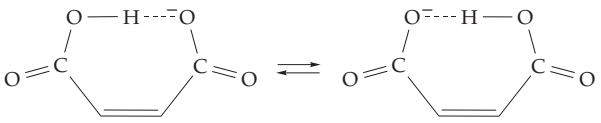
<0.25 nm	very strong
0.25–0.265 nm	strong
>0.28 nm	weak
>0.37 nm	no van der Waals contact but electrostatic interaction still occurs

N–H---O distances may be a little longer than these.

The 0.276-nm hydrogen bonds in ice are regarded as moderately strong. However, if one of the oxygen atoms in an O–H---O hydrogen bond carries a negative charge, as in the maleate monoanion, it will be



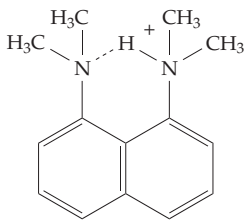
shorter.[156–158] Although the proton will be closer to one oxygen atom than to the other, it will be able to move between them by passing a very low transition state barrier. For this to occur the microscopic pK_a values for the two groups (when they are protonated) must be similar; for the maleate anion they are identical.



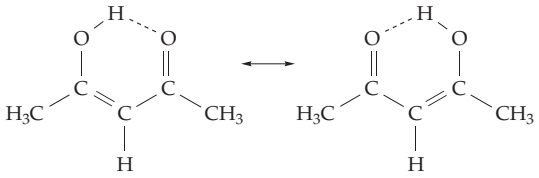
Monohydrogen maleate

The *strength* of a hydrogen bond can be measured for hydrogen-bonded complexes in the gas phase and range from 10–100 kJ/mol and even higher[155] for such complexes as $(FHF)^-$. It is more difficult to establish the strength in the liquid state or within the active site of an enzyme, but shorter hydrogen bonds are usually stronger than longer ones. Hydrogen bond distances in crystals of small molecules can be measured precisely by X-ray or neutron diffraction but greater uncertainty is present in distances within proteins. Lengths and probably strengths of hydrogen bonds in proteins can be measured by NMR methods.[158a,b] For example, solid-state NMR measurements on crystals of amino acids and other carboxylic acids have provided a plot of ^1H chemical shift vs hydrogen bond length.[159] For very short (0.24- to 0.25-nm) hydrogen bonds the ^1H chemical shift may be as great as 21 ppm. See also Fig. 3-30 and associated discussion. When dissolved in an ^1H_2O–^2H_2O mixture strongly hydrogen-bonded protons within a protein become enriched in ^1H. The ^1H / ^2H ratio of the hydrogen-bonded protons provides another measure of the hydrogen bond strength.[158c]

A short hydrogen bond is also present in such cations as the following:



The pK_a for dissociation of its proton is 12.3 and the hydrogen-bonded proton is probably located in the *center* of the bond with both amino groups sharing the charge.[160] Enols can also form unusually strong "resonance-assisted" hydrogen bonds:



The structure can be thought of as a resonance-stabilized enolate anion with a proton bound between the two oxygen atoms and equidistant from them.[156,157]

Do these short "**low-barrier hydrogen bonds**" have a special significance in enzymology? Proposals that they contribute to stabilization of transition states[161–166] have received some support[154,167] and aroused controversy.[158b,168–173] In later chapters we will examine specific enzymes in which low-barrier hydrogen bonds have been observed.

5. Covalent Catalysis

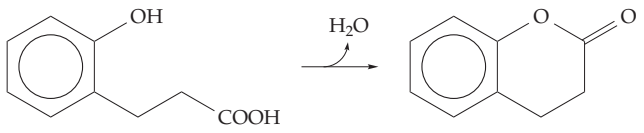
In addition to participating in acid–base catalysis, some amino acid side chains may enter into covalent bond formation with substrate molecules, a phenomenon that is often referred to as covalent catalysis.[174] When basic groups participate this may be called **nucleophilic catalysis**. Covalent catalysis occurs frequently with enzymes catalyzing nucleophilic displacement reactions and examples will be considered in Chapter 12. They include the formation of an acyl-enzyme intermediate by chymotrypsin (Fig. 12-11). Several of the coenzymes discussed in Chapters 14 and 15 also participate in covalent catalysis. These coenzymes combine with substrates to form reactive intermediate compounds whose structures allow them to be converted rapidly to the final products.

6. Proximity and Orientation

One of the earliest ideas about enzymes was that they simply brought reactants together and bound them side by side for a long enough time that the reactive groups might bump together and finally react. How important is this **proximity factor**? Page and Jencks estimated that rate enhancements by factors of 10^3 or more may be expected solely from the loss in the entropy of two reactants when they are bound in close proximity on an enzyme surface.[107,175,176] In view of the large entropy decrease involved, *the enthalpy of*

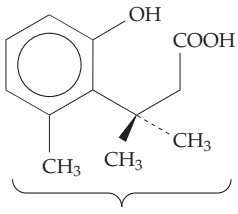
binding must be high, and if this explanation is correct the *binding of the substrates* to the enzyme provides much of the driving force for catalysis. Westheimer described this by stating that enzymes use the substrate-binding force as an **entropy trap**.[108] The losses of translational and rotational entropy, which Page and Jencks estimated as up to –160 to –210 J/deg/mol, overcome the unfavorable entropy of activation that is usual in bimolecular reactions.

How precise must the orientation of substrates be for rapid reaction?[107,177,177a] Compounds such as the acid shown in Eq. 9-103 form an internal ester (lactone) spontaneously with elimination of water.



(9-103)

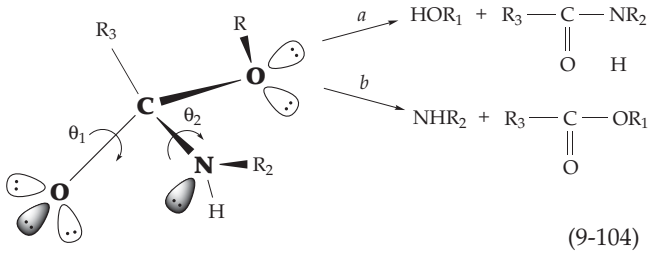
However, the following compound reacts at a rate over 10^{11} times that of the acid shown in Eq. 9-102. This is presumably because its conformation is highly restricted and the –COOH is constrained to frequently collide with the – OH group.[178,179] The three methyl



groups interdigitate and form a **trialkyl lock**. Orientation must also play a large role in enzymatic catalysis. As previously emphasized, enzymes often orient substrates precisely by formation of multiple hydrogen bonds. Small distortions by mutation or substitution of an essential metal by a different one can have very great effects. For example, because of an altered coordination pattern isocitrate dehydrogenases with Ca^{2+} in the active site has a maximum velocity of catalysis only 2.5×10^{-3} that with the normal Mg^{2+}-containing enzyme.[180] Bruice and associates concluded that enzymes must bring reacting groups into close proximity with orbitals of the reactants properly aligned in the ground state prior to moving to the transition state. They suggested that enzymes preorganize the enzyme-substrate complex into a **near attack conformation** in which the positions of reacting groups, the arrangements of hydrogen bonds, and the local dielectric constant in the active site, resemble those in the transition state. In this conformation the energy barrier to the transition state may be very low.[128-128b] Preorganization of the complex also acts to eliminate the slow components of solvent reorganization required for reaction in aqueous solutions.[128c,128d]

The necessity for reacting groups of substrates to collide with an orientation that allows productive interaction of electronic orbitals is often called a **stereoelectronic effect**. An example is the addition reaction of Eq. 9-74. The orbital of an unshared pair of electrons on the HO^- ion must be perpendicular to the plane of the double bond. Furthermore, if the proton becomes attached to the adjacent carbon in a synchronous or concerted manner it must enter from the opposite side, as it does in Eq. 9-74.

In many biochemical reactions an alcohol or amine is eliminated from a tetrahedrally bonded intermediate as in Eq. 9-104. Deslongchamps proposed a stereoelectronic theory[181,182] according to which elimination of either NH—R_2 or –O—R_1 from this intermediate will depend upon the values of the torsion angles θ_1 and θ_2 (Eq. 9-104). The theory asserts that for rapid elimination of OR_1 (Eq. 9-104*a*), unshared electron pairs on *both* the $-O^-$ and N atoms must be antiperiplanar to the bond being broken (see Figure 2-2). If rotation around the C–O bond (θ_1) occurs an orientation can be found in which an electron pair on each of the two oxygens will be antiperiplanar to the bond to NHR_2. From this orientation the latter will be eliminated (Eq. 9-104*b*). The theory has been supported by much experimental evidence involving reaction rates and product distribution among competing reactions of small conformationally restricted organic molecules.[181–184] Although more recent experiments[185] suggest that stereoelectronic factors may be of less significance than had been assumed, even a small decrease in transition state energy can be significant in an enzyme-catalyzed reaction. Enzymes may not only orient substrates in accord with stereoelectronic principles but also be able to promote conformational alterations in intermediates that allow them to take advantage of stereoelectronic factors. Examples are considered in Chapter 12.



(9-104)

7. The Microenvironment

A substrate bound at an active site may be in an environment quite different than that in an ordinary

aqueous solution. In fact, the protein often surrounds the substrate to the extent that *the protein is the solvent*. What kind of **microenvironment** does the protein provide and can it assist in the catalytic process? Charged and dipolar groups of the protein provide an electrostatic field that provides part of the binding energy and which may also assist in catalysis, a concept expressed by Quastel as early as 1926.[183a] The ends of protein helices often seem to point at active centers.[186,187] In many cases more than one N terminus with its positive electrical potential (see Chapter 2) or more than one C terminus (negative potential) of a helix point to an active site. These helix dipoles may be important in stabilizing transition state structures[188] or in altering pK_a values of functional groups.[186] Fluctuations in charge distribution within a protein and in the hydrogen-bonding pattern of the protein with solvent and substrate may also be important.[189]

For some enzymatic reactions a transition state will be favored by a medium of very low dielectric constant and a correctly constructed active site can provide just such a surrounding.[189a] Hydrophobic groups may be packed around a site where an ion pair or other ionic interaction between enzyme and substrate occurs increasing the strength of that interaction. Conformational changes may enhance such effects. The dehydration of polar groups that must often occur upon binding of substrate may make these groups more reactive.[187,190,191] It has been suggested that the substantial volume changes ($\Delta V^{\ddagger}$) that sometimes occur during formation of transition states for enzyme-catalyzed reactions may result largely from changes in hydration of groups on the enzyme surface and that these changes may play an important role in catalysis.

In the past most enzymologists tacitly assumed that the external medium in which enzymes act must be aqueous. However, many enzymes function well in media containing largely hydrocarbons. Enzymes in a dry, powdered form have been suspended directly in organic solvents.[192,193] Under these conditions, enzymes may contain only tightly bound "structural" water, together with less than one equivalent of a monolayer of water outside the protein. The enzymes often remain active and are able to catalyze reactions with an altered substrate specificity as well as different reactions overall.

8. Strain and Distortion

The fact that enzymes appear to bind their substrates in such a way as to surround and immobilize them means that something other than the kinetic energy of the substrate is needed to provide energy for the ES complex to pass over the transition state barrier. What is the source of this activation energy? As with nonenzymatic reactions, it must come ultimately from the translational energy of solvent or solute molecules bombarding the complex. Can enzymes act as "energy funnels" that effectively channel kinetic energy from spots on the enzyme surface to the active site?[194] This could either be through strictly mechanical movement or through induction by fluctuations of the electrical field.[195]

It is often suggested that enzymes assist in catalysis by distorting bond lengths or angles away from their normal values. If the distorted structure were closer to the transition state geometry than the undistorted structure, catalysis would be assisted (see *lysozyme*, Chapter 12). However, Levitt[196] concluded (see also Fersht[2]) that forces provided this way by a protein are small and that the protein would become distorted rather than a substrate. On the other hand, if binding of a substrate distorts the protein, could the resultant "stored energy" be used in some way to assist in catalysis? If binding of a substrate bends a "spring" (Section C,4), can the tension in the spring then be used to distort the enzyme to be more exactly complementary to the transition state? This concept has become popular.[2,113,197]

The amino acid side chains of proteins are usually well packed. However, neither the side chains nor the main chain are rigid and immobile. Some regions of the protein will contain empty spaces – packing defects. Lumry called these **mobile defects** because, as a result of fluctuations in side chain packing, they can move within a protein from one site to another for a considerable distance.[198] Much evidence, including X-ray studies at low temperatures,[199] supports the existence of many **conformational substates** in proteins. Some substates may bind substrates better than others and some may allow conversion to the transition state more readily than do others. Rotation of histidine rings, peptide linkages, – OH groups, or amide side chains[199a] may be required and has, in fact, been observed for some enzymes. Perhaps in one of the substates of an enzyme–substrate complex an especially favorable vibrational mode[200] leads the complex to the transition state. In the transition state the packing of side chains may be especially tight. A mobile defect present in the active site may have moved elsewhere. The binding of substrates to the protein in the transition state will also be tighter because of the conformational alterations that have occurred. The binding energy of the substrates is now being utilized to lower the transition state barrier. The substrate is literally squeezed into the transition state configuration.

Is it possible that the protein domains forming an active site act like **ferroelectric crystals**, which change their dipole moment in response to a change in electric field? The highly polarizable hydrogen-bonded network, the amide linkages, imidazole rings, guanidinium group, etc. of active sites may permit a flip-flop of the dipole moment as in domains of ferroelectric crystals.

In such crystals, e.g., those of the hydrogen-bonded KH_2PO_4, a 180° change of dipole-moment direction results from very small movements of heavy atoms together with larger movements of the hydrogen-bonded protons.[200a,b,c] Could a similar flip-flop in a protein domain be coupled to the passage of a substrate over the transition state barrier? I have not seen any discussion of this possibility, but the structure of protein domains would seem to allow it. One could also imagine that with a small change in the hydrogen-binding arrangement of protein groups an active site could become preorganized to favor a flip-flop along a hydrogen-bonded chain in a different direction for a subsequent step in a reaction sequence.

9. Why Oligomeric Enzymes?

As we have seen (Chapter 7), a large fraction of all proteins exist as dimers, trimers, and higher oligomers. Oligomeric proteins raise the osmotic pressure much less than would the same number of monomeric subunits and this may be crucial to a cell. Another advantage of oligomers may be reflected in the fact that active sites of enzymes are often at interfaces between two or more subunits. This may enhance the ability of enzymes to undergo conformational rearrangements that are required during their action, just as hemoglobin changes its oxygen affinity in concert with a change in intersubunit contacts (Fig. 7-25).

A curious observation is that crystals of the dimeric pig heart malate dehydrogenase bind only one molecule of the substrate NAD^+ per dimer tightly; the second NAD^+ is bound weakly.[201,202] Similar *anticooperativity* has been reported for other crystalline dehydrogenases[203] and various other enzymes. An intriguing idea is that anticooperativity in binding might reflect a cooperative action between subunits during catalysis. Suppose that only conformation A of a dehydrogenase bound reduced substrate and NAD^+, while conformation B bound NADH and oxidized substrate. If reduced substrate and NAD^+ were present in excess and if oxidized substrate were efficiently removed from the scene by further oxidation, the following cooperative events could occur in the mixed AB dimer. The subunit of conformation A would bind substrates, react, and be converted to conformation B. At the same time, because of the strong AB interaction, the subunit that was originally in conformation B would be converted back to A and would be ready to initiate a new round of catalysis. Since conformation A has a low affinity for NADH, dissociation of the reduced coenzyme, which is often the slow step in dehydrogenase action, would be facilitated.[204–207] Such a **reciprocating** or **flip-flop** mechanism, suggested first by Harada and Wolfe,[204] is attractive because it provides a natural basis for the existence of the many known dimeric enzymes that do not exhibit evident allosteric properties. Attempts to verify this idea have largely failed. However, recent crystallographic studies of both glyceraldehyde phosphate dehydrogenase[206,207] and thymidylate synthase[208] are consistent with the proposal. There is still a possibility that coordinated reciprocal changes in distribution of electrical charges in the two subunits may also be important.

10. Summary

It appears that enzymes exert their catalytic powers by **first** bringing together substrates and binding them in proper orientations at the active site. **Second**, they often provide acidic and basic groups in the proper orientations to promote proton transfers within the substrate. **Third**, groups within the enzyme (especially nucleophilic groups) may enter into covalent interaction with the substrates to form structures that are more reactive than those originally present in the substrate. **Fourth**, the protein often closes around the substrate to immobilize it and to hold it in an environment, often lacking water, which could impede catalysis. The enzyme is also probably able to make small readjustments of its structure to provide good complementarity to the substrate at every stage and especially to the transition state structure. **Fifth**, the enzyme may be able to induce strain or distortion in the substrate perhaps accompanying a conformational change within the protein. The following question is often asked: "Why are enzymes such large molecules?"[209] At least part of the answer is that an enzyme usually interacts, sometimes via special domains, with other proteins.[206] Another part of the answer is evident when we consider that the formation of a surface complementary to that of the substrate and possessing reasonable rigidity requires a complex geometry in the peptide backbone. In addition, the enzyme must provide functional groups at the proper places to enter into catalysis. It may require a certain bulk to provide a low dielectric medium. Finally, if essential conformational changes occur during the course of the catalysis, we can only be surprised that nature has succeeded in packing so much machinery into such a small volume.

E. Classification of Enzymes

An official commission of the International Union of Biochemistry (IUB) has classified enzymes in the following six categories:[210]

1. *Oxidoreductases.* Enzymes catalyzing dehydrogenation or other oxidation and reduction reactions.

2. *Transferases*. These catalyze group transfer reactions.
3. *Hydrolases*. Enzymes catalyzing transfer of groups to the HO^- ion of H_2O.
4. *Lyases*. Enzymes promoting addition to double bonds or the reverse.
5. *Isomerases*. Enzymes catalyzing rearrangement reactions.
6. *Ligases* (synthetases). Enzymes that catalyze condensation with simultaneous cleavage of ATP and related reactions.

As an example, chymotrypsin is classified EC 3.4.4.5 according to the IUB system.[210] In this book a more mechanistically based classification is used. Because some official names are quite long, traditional trivial names for enzymes often have been retained. Remember that to be precise it is always necessary to mention the species from which an enzyme was isolated and, if possible, the strain. Also remember that almost every significant genetic difference is reflected in some change in some protein. It is possible that the enzyme you are working with is slightly different from the same enzyme prepared in a different laboratory.

Study Questions

1. Give two reasons why enzymes are important to living organisms.

2. If an enzyme catalyzes the reaction A→ B + C, will it also catalyze the reaction B + C → A?

3. Can an enzyme use a site to catalyze a reverse reaction different from what it uses to catalyze the reaction in the forward direction? Explain your answer.

4. Define the "steady state" of living cells and contrast with a state of chemical equilibrium.

5. How is the instantaneous initial velocity of an enzymatic reaction measured? What precautions must be taken to ensure that a true instantaneous velocity is being obtained?

6. How is the rate of an enzyme action influenced by changes in:
   a) temperature
   b) enzyme concentration
   c) substrate concentration
   d) pH

7. In what ways are enzymatic reactions typical of ordinary catalytic reactions in organic or inorganic chemistry, and in what ways are they distinct?

8. In general, for a reaction that can take place with or without catalysis by an enzyme, what is the effect, if any, of the enzyme on
   a) standard Gibbs energy change of the reaction
   b) energy of activation of the reaction
   c) initial velocity of the reaction
   d) temperature coefficient of the rate constant

9. What are the dimensions of the rate constant for zero-, first-, and second-order reactions? If a first-order reaction is half completed in 2 min, what is its rate constant?

10. A sample of hemin containing radioactive iron, ^{59}Fe, was assayed with a Geiger-Müller counter at intervals of time with the following results:

Time (days)	Radioactive counts per min
0	3981
2	3864
6	3648
10	3437
14	3238
20	2965

Determine the half-life of ^{59}Fe and the value for the decay constant.

11. The kinetics of the aerobic oxidation of enzymatically reduced nicotinamide adenine dinucleotide (NADH) have been investigated at pH 7.38 at 30°C. The reaction rate was followed spectrophotometrically by measuring the decrease in absorbance at 340 nm over a period of 30 min. The reaction may be represented as

$$NADH + H^+ + \text{riboflavin} \rightarrow NAD^+ + \text{dihydroriboflavin}$$

Time (days)	A (at 340 nm)
1	0.347
2	0.339
5	0.327
9	0.302
16.5	0.275
23	0.254
27	0.239
30	0.229

Determine the rate constant and the order of the reaction.

12. You have isolated and purified a new enzyme (E) which converts a single substrate (S) into a single product (P). You have determined M_r by gel filtration as ~ 46,400. However, in SDS gel electrophoresis, a molecular mass of ~ 23 kDa was indicated for the single protein band observed. A solution of the enzyme was analyzed in the following way. The absorbance at 280 nm was found to be 0.512. A 1.00 ml portion of the same solution was subjected to amino acid analysis and was found to contain 71.3 nmol of tryptophan. N-terminal analysis on the same volume of enzyme revealed 23.8 nmol of N-terminal alanine.

   a) What is the approximate molecular mass of the enzyme? Discuss this answer. Be sure to use an appropriate number of significant figures in this and other calculations.
   b) What is the concentration of your enzyme in moles per liter of active sites?
   c) What is the molar extinction coefficient ε at 280 nm where A = εcl; A = absorbance, c = mol / liter, and l = cell width in cm. Assume that all spectrophotometric measurements are made in 1.00 cm cuvettes.

A second preparation of the enzyme had an absorbance at 280 nm of 0.485. This enzyme was diluted very carefully: 1.00 ml into 250 ml and this diluted enzyme was used for the following experiments (I to III).

Study Questions

Experiment I. A 1.00 ml portion of the diluted enzyme was added to 250 ml of buffered substrate at pH 7.0 and was mixed rapidly. The resulting initial substrate concentration $[S]_o$ was 1.000 mM. This reaction mixture was held at 25.0°C and portions were removed periodically at time t for analysis of the product P formed. The results follow. Plot [P] vs. time.

Time t (s)	[P] (mM)	Time t (s)	Remaining [S] (mM)
200	0.104	2800	0.070
400	0.208	3200	0.040
800	0.392	3600	0.022
1200	0.554	4400	0.0060
1600	0.695	6000	0.00048
2000	0.800		
2400	0.881		

The integrated rate equation corresponding to the Michaelis–Menten equation

$v = V_{max}\,[S] / (K_m + [S])$ is as follows:

$$V_{max} \cdot t = [S]_o - [S] + K_m \ln ([S]_o / [S])$$

d) Plot $([S]_o - [S])/t$ vs. $1/t \times \ln([S]_o/[S])$. From this plot evaluate K_m and V_{max}. Make this and other plots to appropriate scale on good quality graph paper.

e) What is k_{cat}?

Experiment II. In a second experiment, a series of test tubes were set up, each containing a different amount of buffered substrate at pH 7 but each in a volume of exactly 4.00 ml. The same enzyme solution used in part d (absorbance at 280 nm = 0.485) was diluted 2.00 ml in 250 ml as in I, then again 2.00 ml in 200 ml. Portions of 1.00 ml of this twice diluted enzyme were added at $t = 0$ to each of the test tubes of buffered substrate. The reaction was stopped in just 10.0 minutes by adding perchloric acid; a suitable reagent was added to provide for a colorimetric determination of the product. The results were as follows:

[S] (mM)	Amount of product (µmol/tube)	[S] (mM)	Amount of product (µmol/tube)
10.0	2.29	0.600	1.31
5.00	2.18	0.400	1.07
2.50	2.00	0.200	0.686
1.200	1.69	0.100	0.400
0.800	1.48		

f) Plot $1/v$ vs. $1/[S]$ where v is in units of µmol per tube and [S] in millimoles / liter. Evaluate K_m, V_{max}, and k_{cat} from this plot. Fit your data by eye. It is generally agreed that a linear least squares fit is inappropriate unless suitable weighting factors are used.

g) Plot the same data as $v/[S]$ vs. v. Again evaluate K_m and V_{max}.

Experiment III. The preceding experiment was repeated but an inhibitor was present in each tube in a concentration equal to 5.00 mM, 10.0 mM, or 25.0 mM. Two different inhibitors were used, A and B. The following results were obtained.

µmol of product formed in 10 min/tube

[S] (mM)	[I] = 5.00 mM Inhibitor: A	5.00 mM B	25.0 mM Inhibitor: A	10.0 mM B
5.00	2.00	1.09	1.50	0.727
2.50	0.71	1.00	1.09	0.667
1.20	1.31	0.848	0.686	0.565
0.800	1.07	0.739	0.505	0.492
0.600	0.900	0.654	0.400	0.436
0.400	0.686	0.533	0.282	0.356
0.200	0.400	0.343	0.150	0.229
0.100	0.218	0.200	0.077	0.133

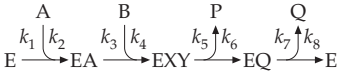
h) Plot $1/v$ vs. $1/[S]$ for each of these sets of data. For each case evaluate V_{max}, apparent K_m, and inhibitor constants $K_I = [I][E]/[EI]$. There may be two K_I values.

i) For uninhibited enzymes, when [S] = 0.4 mM what fraction of the enzyme is ES? Free E?

j) For enzyme in the presence of 10.00 mM inhibitor and 0.8 mM substrate, what fraction of the total enzyme is ES? EI? free E?

k) Recall that $v = [ES]\,k_{cat} = [E][S] \cdot k_{cat}/K_m$ in many cases. What will be the relative rates of product formation from your substrate S and another competing substrate S′ present at the same concentration which also reacts with your enzyme with $K_m = 0.01$ mM and $k_{cat} = 200$ / s if [S] = [S′]?

13. Using the method of graphs, write the initial rate equation for the following system with A, B, P, and Q present.



Odd-numbered rate constants are for forward reactions; even-numbered constants are for reverse.

a) Satisfy yourself that

$$\frac{-d[A]}{dt} = k_1[A][E] - k_2[EA]$$

$$= \frac{-d[B]}{dt} = k_3[B][EA] - k_4[EXY]$$

$$= \frac{d[P]}{dt} = k_5[EXY] - k_6[P][EQ]$$

$$= \frac{d[Q]}{dt} = k_7[EQ] - k_8[E][Q]$$

The determinants (given by the method of graphs) which provide the steady-state concentrations of [E] and of the various exzyme–substrate and enzyme–product complexes are

$$[E] = k_2k_7[k_4 + k_5] + k_3k_5k_7[B] + k_2k_4k_6[P]$$

$$[EA] = k_1k_7[k_4 + k_5][A] + k_1k_4k_6[A][P] + k_4k_6k_8[P][Q]$$

$$[EXY] = k_1k_3k_7[A][B] + k_2k_6k_8[P][Q] + k_1k_3k_6[A][B][P] + k_3k_6k_8[B][P][Q]$$

$$[EQ] = k_2k_8[k_4 + k_5][Q] + k_1k_3k_5[A][B] + k_3k_5k_8[B][Q]$$

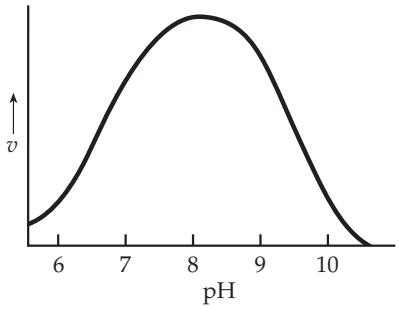
b) To obtain an expression for v_f the expression for $-d[A]/dt$ may be multiplied by $[E]_t$ and divided by $[E] + [EA] + [EXY] + [EQ] = [E]_t$. Then the above determinants may be substituted.

c) What is $V_{max,forward}$ and $V_{max,reverse}$? HINT: $V_{max,forward}$ is obtained when $[P] = [Q] = 0$ and $[A] = [B] = \infty$. What are K_{mA} and K_{mB}? K_{mA} is obtained when $[P] = [Q] = 0$, $[B] = \infty$, and $v = 1/2\ V_{max,forward}$.

d) With a knowledge of the kinetic parameters, indicate how the eight rate constants may be obtained if the total concentration of enzyme, $[E]_t$, is known.

14. Anticooperativity was observed in the plot of velocity vs. substrate concentration for an enzyme. Can this observation be explained by the Monod–Wyman–Changeux model for oligomeric enzymes? By the model of Koshland? Explain.

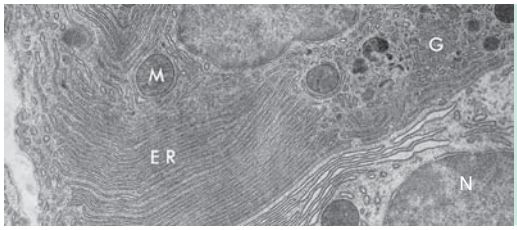
15. Interpret, for each of the following cases, the curve showing measured initial velocity at constant substrate concentration (*not* maximum velocity) against pH for an enzyme-catalyzed reaction.



a) The substrate is neutral and contains no acidic or basic groups. The Michaelis constant is found to be independent of pH over the range studied.

b) The substrate is neutral and contains no acidic or basic groups, and the maximum velocity is found to be independent of pH.

c) The substrate is an α-amino acid, and the maximum velocity is found to be independent of pH.



This electron micrograph of a thin section of pancreatic epithelial cells shows parts of two secretory cells that are synthesizing proenzymes (zymogens). Nuclei (N) are seen at the top center and lower right. Numerous ribosomes (barely seen here) line the many membranes of the endoplasmic reticulum (ER) and are most abundant near lateral and basal (left) surfaces of the cells. A few mitochondria (M) are present. The synthesized proteins move toward the apical surfaces (a small piece is seen at upper right), passing through the Golgi region (G) and accumulating in zymogen granules (Z) before secretion. An Introduction to Metabolism

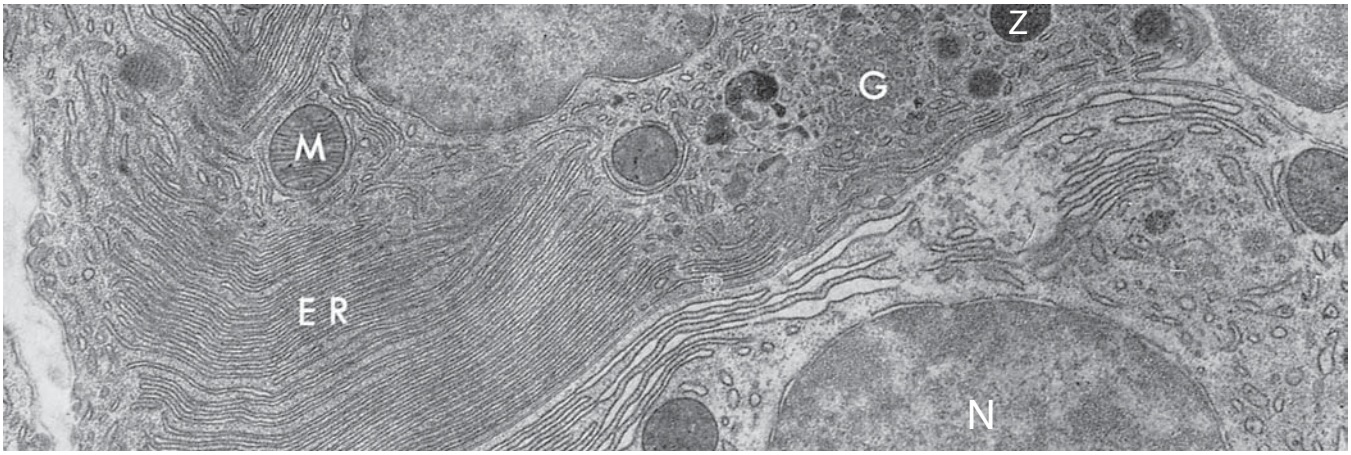
10



The first section of this book has dealt with the basic structures and with many of the complexities of the materials formed by living cells. In the next major section we will look at the chemical reactions that build and maintain a cell and that permit it to grow and to be responsive to external stimuli. These reactions are organized into **metabolic sequences** or **pathways** that form a complex, branched, and interconnected network. It would be pointless to try to memorize all of them. However, at this point it will be worthwhile to consider the significance of a few of the major sequences, which describe central pathways of metabolism.

Beginning in the nineteenth century, the investigation of these pathways and of the associated enzymes has provided much of our knowledge about the chemistry of living things. The protein products that are encoded in the structural genes that direct these pathways make up a large fraction of the material in a cell. It will be well worth the reader's effort to examine the chemistry of these metabolic sequences in detail. Regulatory mechanisms that are applicable to them, and to other pathways, are described in Chapter 11 and chemical details of enzyme action are considered in Chapters 12–16. Then, in Chapter 17, the chemical logic of the reaction sequences is considered in more detail.

A. The Starting Materials

All cells of all organisms take in chemical starting materials and give off chemical products. They all have a source of energy and generate heat during their metabolism. They all synthesize complex organic substances and maintain a high degree of organization, that is, a state of relatively low entropy. The materials taken up by cells are often organic compounds which not only supply material for the synthesis of cellular constituents but also may be degraded to provide energy. A characteristic of all cells is the ability simultaneously to synthesize thousands of complex proteins and other materials and, at the same time, to break down (catabolize) the same types of compounds. Since cells both synthesize and catabolize most cellular components there is a continuous turnover of the very structural components of which they are composed. Metabolism encompasses all of these processes.

The most rapid catabolic reactions are usually those that provide the cell's energy. Organisms vary greatly in the materials used for food. Human beings, as well as many other organisms, break down carbohydrates, lipids, and proteins to obtain energy and starting materials for biosynthesis. In contrast, some organisms use only one or a few simple organic compounds while autotrophs satisfy their needs entirely with inorganic materials. Looking at all of the species of living things we find an extraordinary range of specialization in metabolism as well as in structure. Nevertheless, there are many common features of metabolism. For example, most cells utilize glucose or a close relative as a source of biosynthetic intermediates. Pathways for synthesis of nucleic acids and proteins are similar in all species. Even the control of growth and development depends upon proteins whose structures are often conserved throughout the living world.

1. Digestion

We humans must digest most foods before we can utilize them. The same is true for most bacteria, which need amino acids generated by the breakdown of

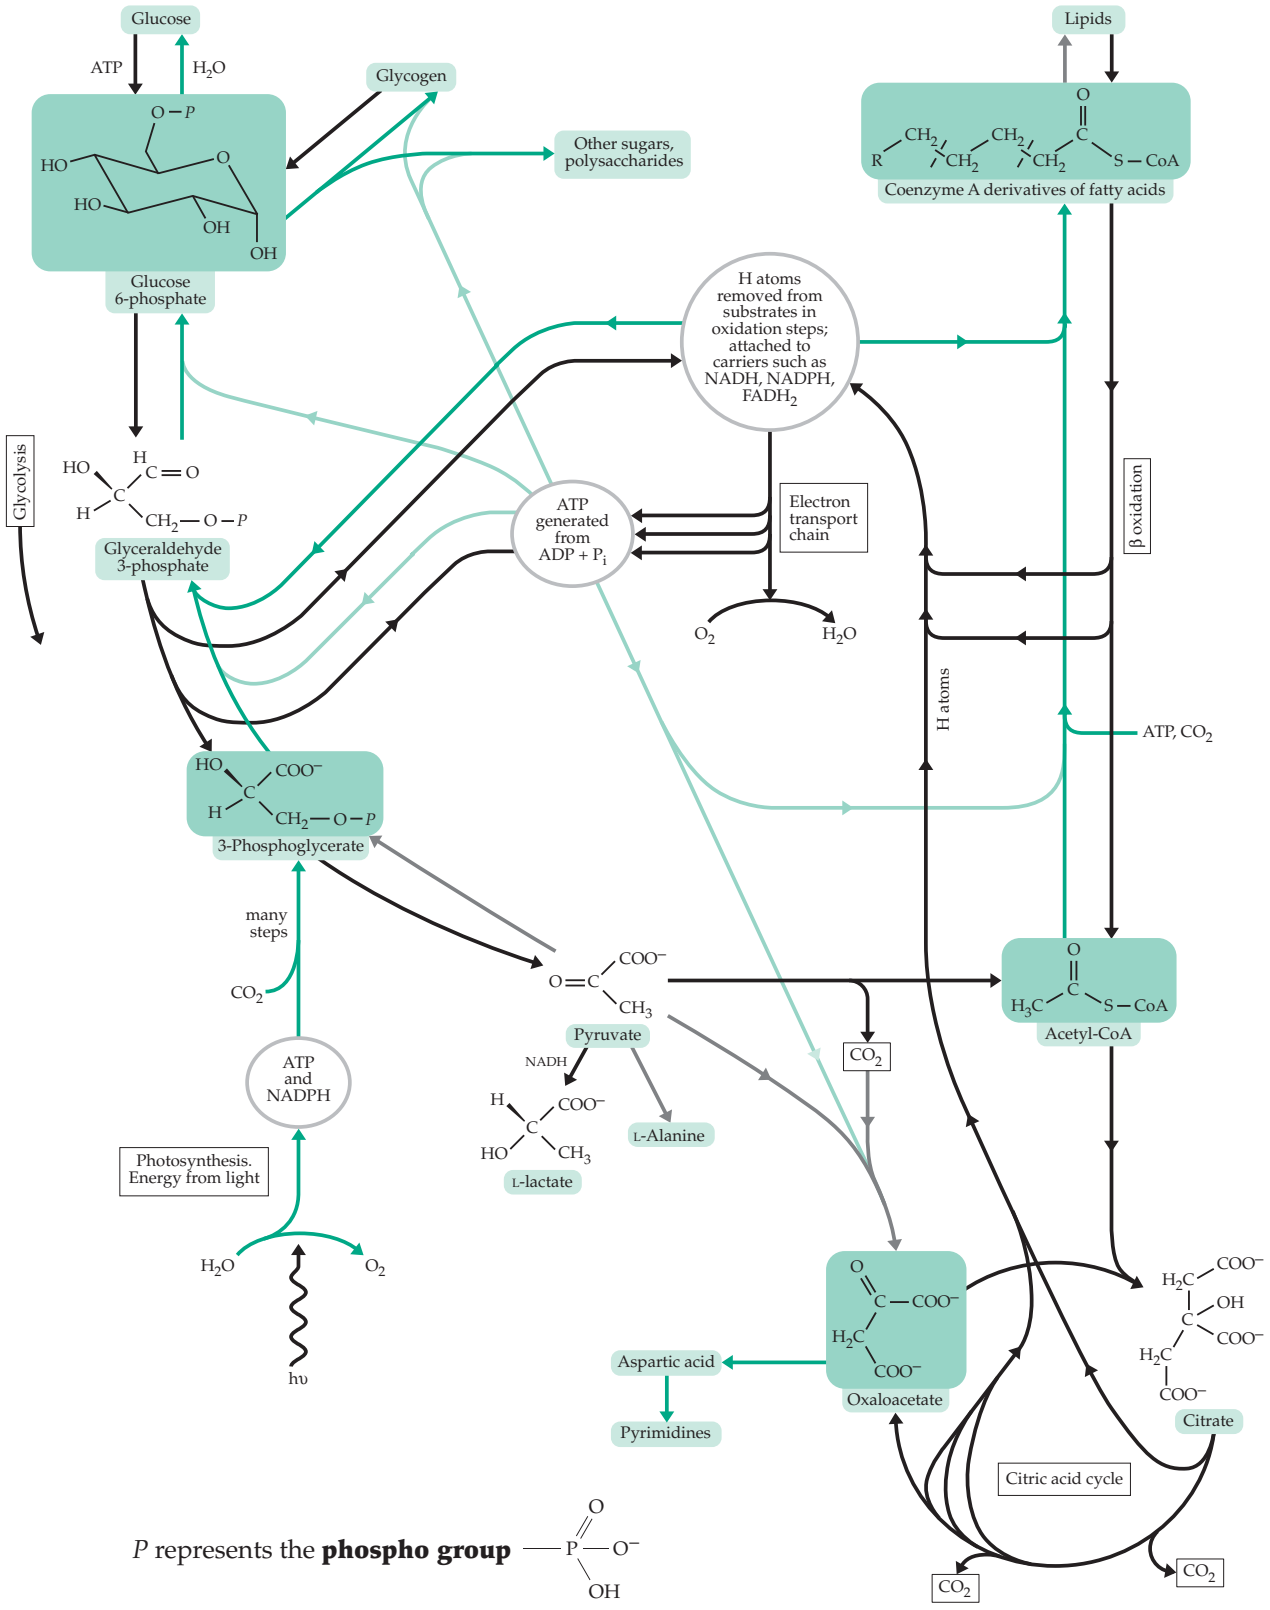


Figure 10-1 An overall view of some metabolic sequences. Several major pathways of catabolism are indicated by heavy lines. The glycolysis pathway, leading to pyruvate and lactate, starts at the top left, while the β oxidation pathway of fatty acids is on the right. Biosynthetic routes are shown in green lines. A few of the points of synthesis and utilization of ATP are indicated by the lighter green lines. Some of the oxidation–reduction reactions that produce or utilize the reduced hydrogen carriers NADH, NADPH, and $FADH_2$ are also indicated. The citric acid cycle, a major supplier of these molecules, is shown at the bottom right, while photosynthesis, the source of reduced hydrogen carriers in green plants, and the source of nearly all energy for life, is shown at the bottom left.

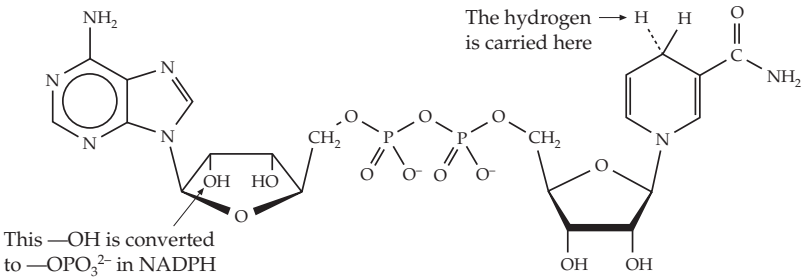
proteins. Our digestive enzymes, which act on carbohydrates, proteins, lipids, and nucleic acids, are synthesized by cells in the salivary glands, stomach, pancreas, and intestinal lining. The properties of these enzymes are described in Chapter 12. Bacteria secrete digestive enzymes into their surroundings. Although most green plants have no need to digest foods, they too have enzymes closely related to our digestive enzymes. These enzymes break bonds in proteins or carbohydrate polymers to allow expansion of leaves and stems, ripening of fruits, and other physical changes. All cells carry out **processing** or **maturation** of their newly synthesized polymers. This often involves the cutting off of one or more pieces of a protein, polysaccharide, or nucleic acid. The processing enzymes are also relatives of digestive enzymes.

2. Sources of Energy

All cells require a source of chemical energy. This is provided to a large extent by ATP (Chapter 6), whose hydrolysis can be coupled to reactions of synthesis, to transport across membranes, and to other endergonic processes. For this reason, all cells have active pathways for the synthesis of ATP. *Biosynthesis often also involves chemical reduction* of intermediates; therefore, cells must have a means of generating suitable reductants. The reagent of choice is often the hydrogen-carrying coenzyme **NADPH**. It is a phosphorylated form of NADH, a derivative of the vitamin **nicotinamide** (Box 15-A), whose structure follows. Reduction of metabolic intermediates by NADPH provides a second mechanism by which chemical energy is harnessed for biosynthesis. A third source of energy, which is considered in Chapter 18, is the gradient of hydrogen ions that is set up across cell membranes by oxidative or photochemical processes.



The reduced coenzyme NADH

B. Catabolism and the Synthesis of ATP

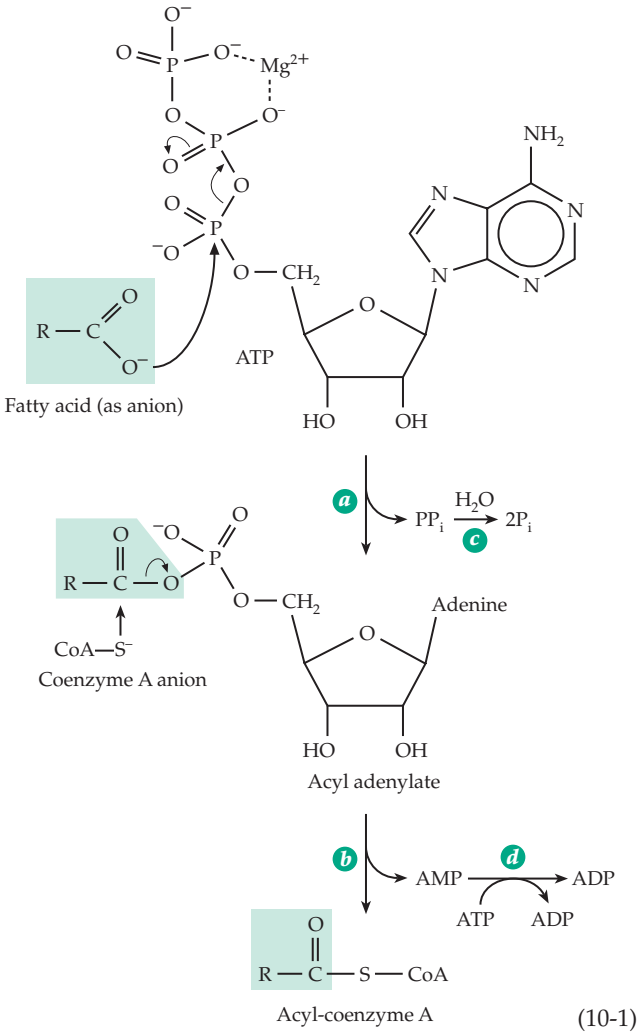
The catabolic sequences by which cells obtain energy often appear dominant. For animals, fungi, and nonphotosynthetic bacteria these pathways are used to metabolize large amounts of food and to produce large amounts of ATP. Because they are also related to biosynthetic pathways they have a central importance in virtually all organisms.

1. Priming or Activation of Metabolites

After a polymeric nutrient is digested and the monomeric products are absorbed into a cell, an energy-requiring **priming reaction** is usually required. For example, the hydrolysis of fats (whether in the gut or within cells) produces free fatty acids. Before undergoing further metabolism, these fatty acids are combined with the thiol compound **coenzyme A** to form **fatty acyl-CoA** derivatives. This requires a thermodynamically unfavorable reaction that necessitates the "expenditure" of ATP, that is, its hydrolysis to AMP and inorganic pyrophosphate (PP_i). Likewise, glucose, when taken into cells, is converted into the phosphate ester glucose 6-phosphate (glucose-6-*P*), again with an associated cleavage of ATP. *The major metabolic pathways often start with one of these two substances: a fatty acyl-CoA derivative or glucose 6-phosphate.* The structures of both are given at the top of Fig. 10-1, which is designed to provide an overall view of metabolism.

The phospho group of glucose-6-*P* is not very reactive but it provides a "handle" which helps enzymes to recognize and to hold onto this glucose derivative. Likewise, the coenzyme A molecule, whose complete structure is given in Chapter 14, provides a large and complex handle for enzymes. However, from a chemical viewpoint, the formation of the thioester linkage of a fatty acid with the –SH group of coenzyme A in the acyl-CoA is more important. This alters the electronic structure of the fatty acid molecule, "activating" it toward the reactions that it must undergo subsequently. Thus, priming reactions often provide chemical changes essential to the mechanisms of subsequent reactions.

Activation of a carboxylic acid by formation of an acyl-CoA derivative (Eq. 10-1) is of special importance because of its widespread use by all organisms. The basic reaction occurs by two steps. The first (Eq. 10-1, step *a*) is a displacement reaction on the phosphorus atom of ATP to form an **acyl adenylate**, a mixed anhydride of the carboxylic acid and a substituted phosphoric acid. Such mixed anhydride intermediates, or **acyl phosphates**, are central to much of cellular energy metabolism because *they preserve the high group-transfer potential of a phospho group of ATP (Chapter 6) while imparting a high group-transfer potential to the acyl group*. This allows the acyl group to be transferred in step *b*



(10-1)

of Eq. 10-1 onto the sulfur atom of coenzyme A to form an acyl-coenzyme A in which the high group transfer potential of the acyl group is conserved (see Table 6-6). Two additional steps are linked to this sequence. In step *c* the inorganic pyrophosphate that is displaced in step *a* is hydrolyzed to two molecules of HPO_4^{2-} (P_i), and in step *d* the AMP formed is phosphorylated by ATP to form ADP. The overall sequence of Eq. 10-1 leads to hydrolysis of two molecules of ATP to ADP + P_i. In other words, two molecules of ATP are spent in activating a carboxylic acid by conversion to an acyl-coenzyme A.

2. Interconversions of Sugar Phosphates

The strategy employed by most cells in the catabolism of several 6-carbon sugars is to convert them to glucose 6-phosphate and, in the several steps outlined in Fig. 10-2, to cleave this hexose phosphate to two equivalent molecules of **glyceraldehyde 3-phosphate**. This triose phosphate can then be metabolized further. Notice the chemical nature of the reactions involved in the formation of glyceraldehyde 3-phosphate. The first step (Fig. 10-2, step *a*) is the transfer of the phospho group from ATP to the 6 position of glucose. Step *b* is the reversible opening of the sugar ring and step *c* the isomerization of an aldose to a ketose. Step *d* is a second transfer of a phospho group from ATP, another priming reaction that provides the second of the phosphate handles for the two molecules of triose phosphate that are formed. Step *e* is an aldol cleavage which breaks the C–C bond in the center of the ketose chain, while step *f* is another sugar isomerization that is chemically similar to the one in step *c*.

We see that in the six steps shown in Fig. 10-2 for conversion of glucose to two molecules of glyceraldehyde 3-phosphate, there are only four kinds of reaction: (1) phospho transfer from ATP; (2) opening of a sugar ring; (3) aldose-ketose isomerization; and (4) aldol cleavage. These types of reactions, which are described in more detail in Chapters 12 and 13, occur in many places in metabolism. As is indicated in Fig. 10-2, glucose 6-phosphate can also be generated from glycogen or starch. The first step (Fig. 10-2, step *g*) is phosphorolysis, cleavage by an inorganic phosphate ion. This leads directly to glucose 1-phosphate. The latter is isomerized by a phospho transfer process (step *h*).

3. Glycolysis and Fermentation

A major route of breakdown of carbohydrates is the **Embden–Meyerhof–Parnas** pathway, often referred to simply as **glycolysis**. It is indicated on the left side of Fig. 10-1 and in more detail in Figs. 10-2 and 10-3. The pathway begins with the reactions of Fig. 10-2, with either free glucose or glycogen as starting materials. Its end products may be reduced materials such as **lactic acid** or **ethanol**, which are formed under *anaerobic conditions* (Fig. 10-3). However, under *aerobic conditions* the product is **acetyl-coenzyme A**, whose acetyl group can then be oxidized to carbon dioxide and water in the **citric acid cycle**.

After the sugar chain is cleaved in the glycolysis sequence, the two resultant molecules of glyceraldehyde 3-phosphate are oxidized to 3-phosphoglycerate (Fig. 10-3, steps *a*,*b*). The oxidant is the hydrogen carrier NAD^+, the oxidized form of NADH. Cells frequently use NAD^+ to dehydrogenate alcohols to aldehydes or ketones, with one atom of hydrogen and an electron from the alcohol becoming attached to the NAD^+ to give NADH and the other hydrogen being released as H^+ (Eq. 10-2).

The oxidation of glyceraldehyde 3-phosphate is considerably more complex. The oxidation of an aldehyde to a carboxylic acid is a strongly exergonic process and the oxidation of glyceraldehyde 3-phosphate by cells is almost always coupled to the synthesis

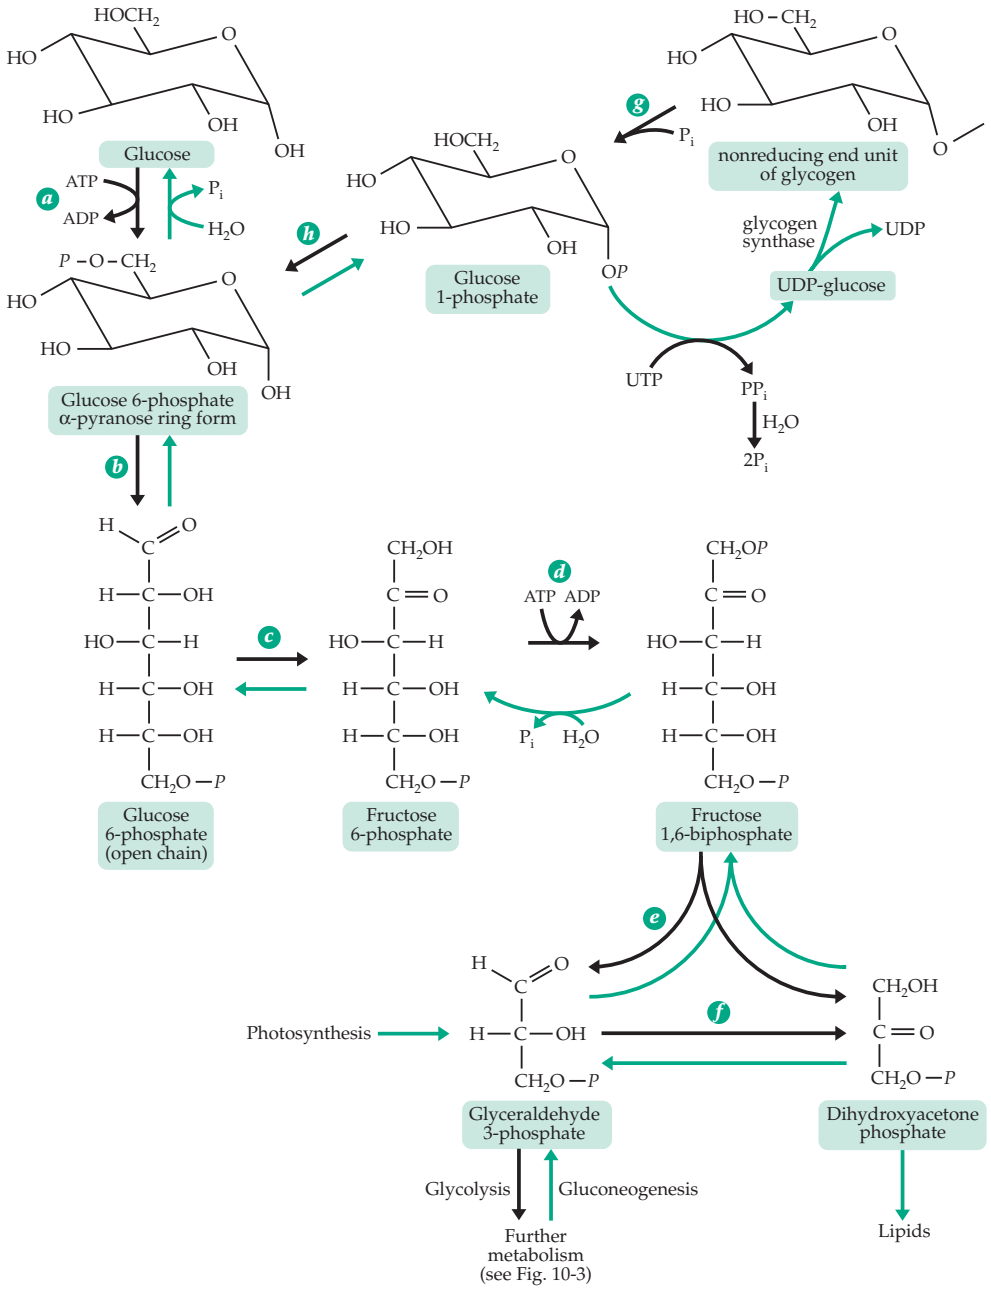


Figure 10-2 The interconversion of glucose, glycogen, and glyceraldehyde-3-phosphate in the pathways of glycolysis, gluconeogenesis, and glycogen synthesis. Pathways of catabolism are indicated with black lines and those of biosynthesis with green lines.

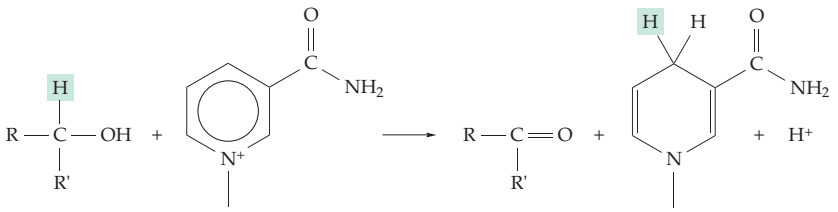
of ATP. The importance of this coupling can be understood by the fact that *for many organisms living by anaerobic fermentation reactions, this one oxidation step provides the sole source of ATP*. It is the mechanism for coupling this oxidation to synthesis of ATP that accounts for the complexity of the glyceraldehyde 3-phosphate dehydrogenase reaction, whose chemistry is presented in detail in Chapter 15. As is indicated in the simplified version of Fig. 10-3 (step *a*) inorganic phosphate (P_i) is a reactant and the product released by the enzyme is 1,3-bisphosphoglycerate. This compound, which has been formed by the oxidative process, is an anhydride of phosphoric acid with 3-phosphoglyceric acid. The phospho group of such **acyl phosphates**, like that of ATP, has a high group transfer potential and can be transferred to ADP to generate ATP (Fig. 10-3, step *b*). Since each glucose molecule is cleaved to two molecules of triose phosphate, two molecules of ATP are

generated in this process by the fermentation of one molecule of glucose. This is enough for a bacterium to live on if it ferments enough sugar.

Further metabolism of 3-phosphoglycerate involves an isomerization by means of a phosphotransferase (mutase reaction, step *c*) to form 2-phosphoglycerate which then loses water in an elimination reaction (step *d*). Elimination of a hydroxyl group in a β position relative to a carboxyl group together with an α-proton is another very frequently used type of metabolic reaction. In this case the product, **phosphoenolpyruvate** (PEP), is a unique and important metabolite. It is a key intermediate in the biosynthesis of aromatic amino acids and in numerous other biosynthetic sequences.



(10-2)

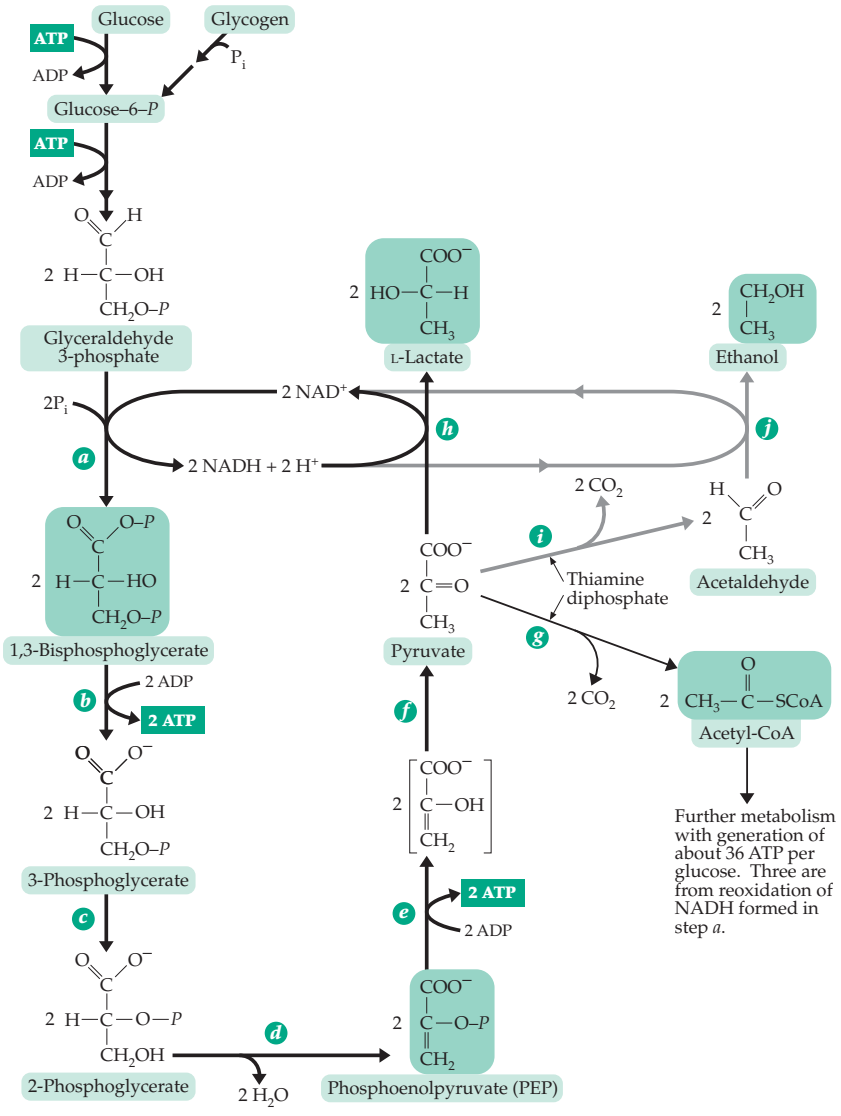


Figure 10-3 Coupling of the reactions of glycolysis with formation of lactic acid and ethanol in fermentations. Steps *a* to *g* describe the Embden–Meyerhof–Parnas pathway. Generation of 2 ATP in step *b* can provide all of the cell's energy.

In the Embden–Meyerhof–Parnas pathway PEP transfers its phospho group to ADP (step *e*) to generate ATP and pyruvate. The latter is shown enclosed in brackets in Fig. 10-3 as the enolic form, which, tautomerizes to the oxo form (step *f*). The fact that the oxo form of pyruvate is much more stable than the enol gives the phospho group of phosphoenolpyruvate its high group transfer potential. The metabolic significance of this step is that the phosphate handles of the glycolytic intermediates, which were initially transferred on from ATP, are now returned to ADP with the regeneration of an equivalent amount of ATP.

The product of this metabolic sequence, **pyruvate**, is a metabolite of central importance. Its fate depends upon the conditions within a cell and upon the type of cell. When oxygen is plentiful pyruvate is usually converted to acetyl-coenzyme A, but under anaerobic conditions it may be reduced by NADH + H^+ to the alcohol **lactic acid** (Fig. 10-3, step *h*). This reduction exactly balances the previous oxidation step, that is, the oxidation of glyceraldehyde 3-phosphate to 3-phosphoglycerate (steps *a* and *b*). With a balanced sequence of an oxidation reaction, followed by a reduction reaction, glucose can be converted to lactate in the absence of oxygen, a **fermentation** process. The lactic acid fermentation occurs not only in certain bacteria but also in our own muscles under conditions of extremely vigorous exercise. It also occurs continuously in some tissues, e.g., the transparent lens and cornea of the eye.

In the well-known fermentation of sugar to ethanol by yeast, the pyruvate generated by glycolysis is first decarboxylated to acetaldehyde (Fig. 10-3, step *i*). This decarboxylation of a 2-oxo acid is chemically difficult and the enzyme catalyzing it makes use of a special reagent known as a **coenzyme**. For this type of reaction, the coenzyme is the diphosphate (pyrophosphate) ester of **thiamin** (**vitamin B_1**). Its mode of action is discussed in Chapter 14. It is usually needed when a 2-oxo acid is decarboxylated. The alcoholic fermentation by yeast is completed by reduction of acetaldehyde to ethanol (Fig. 10-3, step *j*), again using the NADH produced in the oxidation of glyceraldehyde 3-phosphate. The conversion of glucose to lactic acid or to ethanol and CO_2 are just two of many fermentation reactions, most of which are carried out by bacteria and which are dealt with further in Chapter 17. An important requirement is that the Gibbs energy change for the overall fermentation reaction be sufficiently negative that ATP synthesis can be coupled to it. Thus, using data from Table 6-4:

$$C_6H_{12}O_6 \text{ (glucose)} \rightarrow 2\ C_3H_5O_3 \text{ (lactate)} + 2H^+$$
$$\Delta G' \text{ (pH 7)} = -196 \text{ kJ/mol } (-46.8 \text{ kcal/mol}) \qquad (10\text{-}3)$$

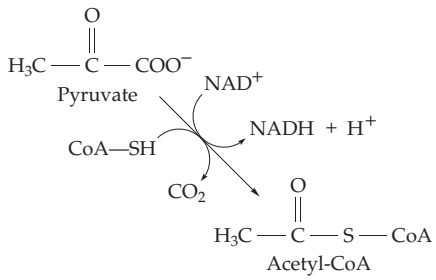
$$2ADP^{3-} + 2P_i^{2-} + H^+ \rightarrow H_2O + ATP^{4-}$$
$$\Delta G' \text{ (pH 7)} = +69 \text{ kJ/mol} \qquad (10\text{-}4)$$

$$\text{Sum: } C_6H_{12}O_6 + 2ADP^{3-} + 2P_i^{2-} \rightarrow H_2O + 2\ C_3H_5O_3 + 2H^+ + 2\ ATP^{4-}$$
$$\Delta G' \text{ (pH 7)} = -127 \text{ kJ/mol} \qquad (10\text{-}5)$$

A requirement for all fermentations is the existence of a mechanism for coupling ATP synthesis to the fermentation reactions. In the lactic acid and ethanol fermentations this coupling mechanism consists of the formation of the intermediate 1,3-bisphosphoglycerate by the glyceraldehyde 3-phosphate dehydrogenase (Fig. 10-3, step *a*). This intermediate contains parts of both the products ATP and lactate or ethanol.

4. Pyruvate Dehydrogenase

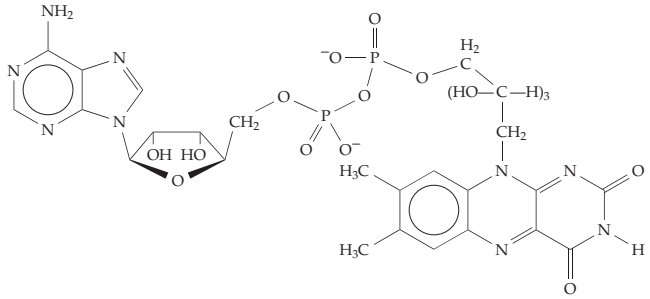
In most organisms undergoing aerobic metabolism, pyruvate is oxidized to acetyl-CoA in a complex process involving its decarboxylation (Eq. 10-6). This **oxidative decarboxylation**, like the decarboxylation of pyruvate to acetaldehyde, requires thiamin diphosphate. In addition, an array of other catalysts participate in the process (see Fig. 15-15). Among these are the electron carrier **flavin adenine diphosphate** (**FAD**), which is derived from the vitamin **riboflavin**. Like NAD^+, this



(10-6)

compound can accept two electrons (plus two protons) to form $FADH_2$. However, it sometimes serves as a one-electron carrier.

Acetyl-CoA is another major metabolic intermediate.



The coenzyme flavin adenine diphosphate (FAD)

It is an acyl-CoA of the type mentioned in Section 1 and can also be formed from acetate, ATP, and coenzyme A. Although the human diet contains some acetic acid, the two major sources of acetyl-CoA in our bodies are the oxidative decarboxylation of pyruvate (Eq. 10-6) and the breakdown of fatty acid chains. Let us consider the latter process before examining the further metabolism of acetyl-CoA.

5. Beta Oxidation

Whether fatty acids are oxidized to obtain energy or are utilized for biosynthesis, they are first converted to their acyl-CoA forms and are then cleaved to the two-carbon units represented by the acetyl groups of acetyl-CoA. The **beta oxidation** sequence, by which this occurs, is represented by the solid vertical arrow on the right side of Fig. 10-1 and is shown in greater detail in Fig. 10-4. We see from the latter figure that there are two dehydrogenation steps. The first (step *b*) removes hydrogen atoms from the α- and β-carbon atoms to produce a *trans* α, β unsaturated fatty acyl-CoA (Enoyl-CoA). The hydrogen acceptor is FAD. It is needed because this reaction requires a more powerful oxidant than does the dehydrogenation of an alcohol, for which NAD^+ is adequate. Addition of water to the double bond of the unsaturated acyl-CoA (step *c*)

generates an alcohol which is then dehydrogenated (step *d*) by NAD^+ to form a β-oxoacyl-CoA. This is cleaved (step *e*) by a reaction (thiolysis) with another molecule of coenzyme A to form acetyl-CoA and a new acyl-CoA with a shortened chain. The latter is "recycled" by passage through the β oxidation sequence repeatedly until the chain is shortened to a 2- or 3-carbon fragment, acetyl-CoA, or propionyl-CoA. Since most dietary fatty acids contain an even number of carbon atoms, acetyl-CoA is the predominant product.

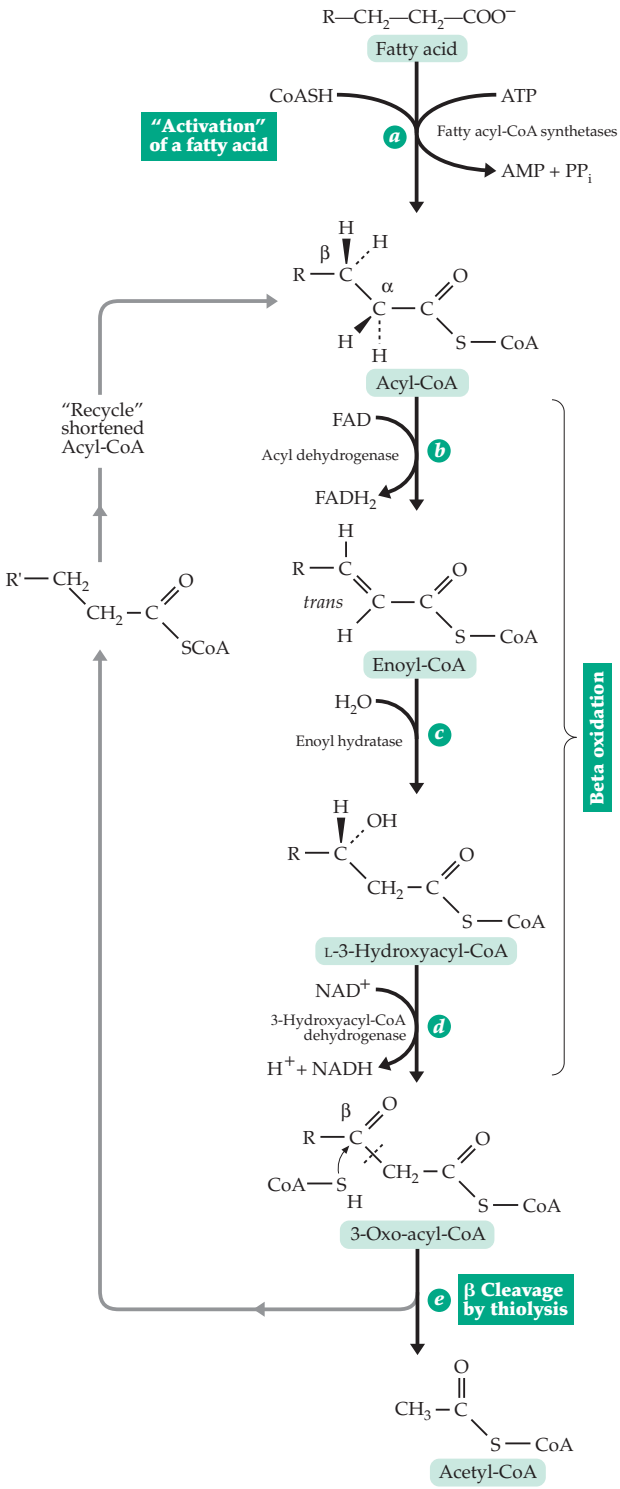


Figure 10-4 Reactions of fatty acid activation and of breakdown by β oxidation.

The beta oxidation of fatty acids, like the dehydrogenation of pyruvate to acetyl-CoA, takes place within the inner **matrix** of the mitochondria in eukaryotic organisms. The reduced hydrogen carriers $FADH_2$ and NADH transfer their electrons to other carriers located within the **inner membrane** of the mitochondria. In bacteria the corresponding reactions occur with electron carriers present in the plasma membrane. Both FAD and NAD^+ are regenerated in this way and are able to again accept hydrogen from the beta oxidation reactions. This transfer of hydrogen atoms from substrates to hydrogen carriers is typical of biological oxidation processes.

6. The Electron Transport Chain, Oxidative Phosphorylation

Reoxidation of the reduced carriers NADH and $FADH_2$ actually involves a sequence of electron carriers, the **electron transport chain**, whose function is indicated below the circle near the center of Fig. 10-1. The oxidation of reduced NADH by O_2 (Eq. 10-7) is a highly exergonic process and is accompanied by the

$$\text{NADH} + \text{H}^+ + 1/2\ \text{O}_2 \rightarrow \text{NAD}^+ + \text{H}_2\text{O}$$
$$\Delta G' \text{ (pH 7)} = -219 \text{ kJ/mol} \qquad (10\text{-}7)$$

generation of about three molecules of ATP (from ADP and inorganic phosphate). This process, termed **oxidative phosphorylation**, is the principal source of usable energy (in the form of ATP) provided by breakdown of both carbohydrates and fats in the human body.

The mechanism of oxidation of NADH in the electron transport chain appears to occur by transfer of a hydrogen atom together with two electrons (a hydride ion H^-). Oxidation of $FADH_2$ to FAD might occur by transfer of two hydrogen atoms or by transfer of $H^- + H^+$. However, it is useful to talk about all of these compounds as **electron carriers** with the understanding that movement of one or both of the electrons may be accompanied by transfer of H^+. The electron transport complex is pictured in a very simplified form in Fig. 10-5.

The electrons donated from NADH or other reductants, upon entering this complex, travel from one carrier to the next, with each carrier being a somewhat more powerful oxidant than the previous one. The

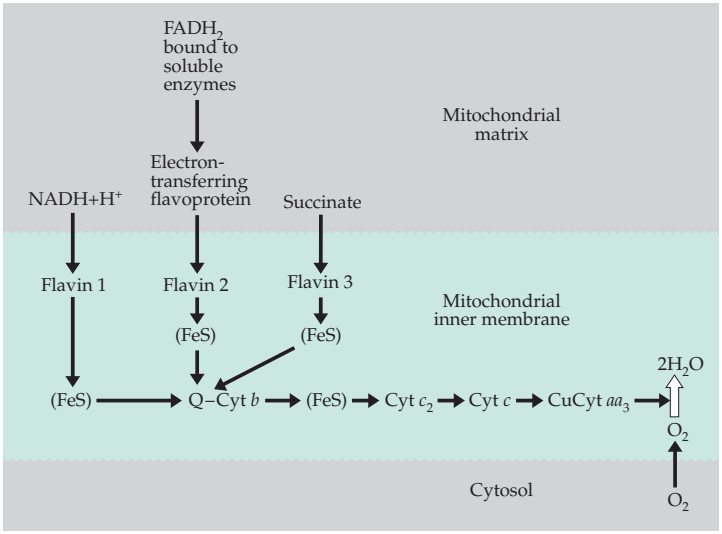

Figure 10-5 An abbreviated version of the electron transport chain of mitochondria. Four electrons reduce O_2 to 2 H_2O. For details see Figs. 18-5 and 18-6.

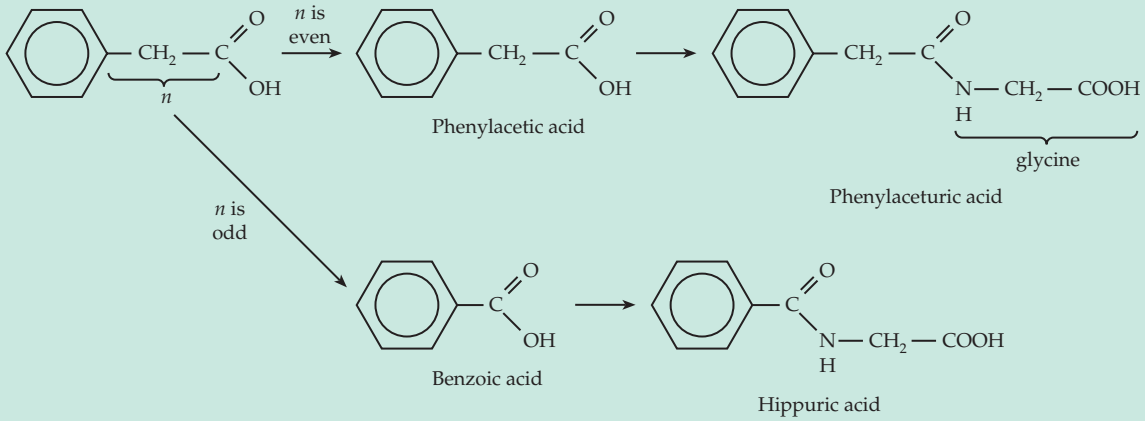
final carrier, known as cytochrome aa_3 or **cytochrome oxidase**, reacts with molecular oxygen. Each molecule of O_2, together with 4 H^+, is converted to two molecules of water. This stoichiometry requires that two molecules of NADH pass four electrons down the chain for each O_2 reduced.

The chemical structures of the components of the mitochondrial electron transport chain are varied but fall into several distinct classes. Most are proteins but these proteins always contain special coenzymes or **prosthetic groups** able to engage in oxidation–reduction reactions. At the substrate end of the chain NADH passes a hydrogen atom together with its bonding electron pair to a riboflavin-containing coenzyme **riboflavin 5'-phosphate** (FMN), which is tightly bound into a protein (designated Flavin 1 in Fig. 10-5). Similar **flavoproteins**, Flavin 2, and Flavin 3, act as oxidants for $FADH_2$ arising during beta

BOX 10-A AN EARLY LABELING EXPERIMENT

In 1904, long before the advent of radioactive tracers, Knoop synthesized fatty acids labeled by chemical attachment of a benzene ring at the end opposite the carboxyl group. He prepared these compounds with both odd and even numbers of carbon atoms in straight chains and fed them to dogs. From the dogs' urine he isolated **hippuric acid** and **phenylaceturic acid**, which are the amides of glycine with benzoic acid and phenylacetic acid, respectively. Knoop showed that the phenylacetic acid was produced from those fatty acids with an even number of carbon atoms, while the benzoic acid was formed from those with an odd number. From these experimental results, Knoop deduced that *fatty acid degradation occurs two carbon atoms at a time* and proposed his famous **β oxidation theory**.

Later experiments using isotopic labeling with ^{13}C verified Knoop's proposals,[a] but study of isolated enzymes was not possible until after the discovery of coenzyme A in 1950. Then, studies of fatty acid oxidation by extracts from isolated mitochondria established the details of the pathway.[b]



[a] Weinhouse, S. (1995) *FASEB J.* **9**, 820–821
[b] Quastel, J. H. (1984) *Trends Biochem. Sci.* **9**, 117–118

oxidation and oxidation of succinate, whose significance to metabolism is discussed in the next section.

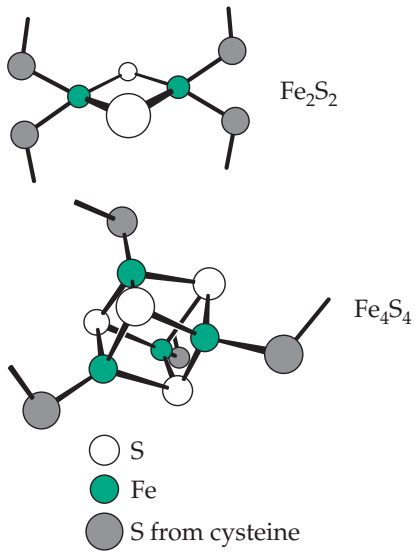
A significant difference between NADH and $FADH_2$ is that the former diffuses freely between the **dehydrogenases** that transfer hydrogen to it and the flavoprotein NADH dehydrogenase (Flavin 1) that reoxidizes it. However, FAD, whether in its oxidized state or as $FADH_2$, stays tightly bound to proteins at all times. Only hydrogen atoms or electrons are transferred into or out of these proteins. During beta oxidation the $FADH_2$ generated remains tied to the fatty acyl-CoA dehydrogenase protein. However, the two hydrogen atoms of this $FADH_2$ are transferred to another molecule of FAD, which is bound to an **electron-transferring flavoprotein.** This protein carries electrons one at a time, as FADH, by diffusion to the inner surface of the inner mitochondrial membrane. There it transfers the hydrogen atoms that it carries to the flavoprotein designated Flavin 2 in Fig. 10-5. The electron-transferring flavoprotein can also be viewed as a carrier of single electrons, each accompanied by H^+.

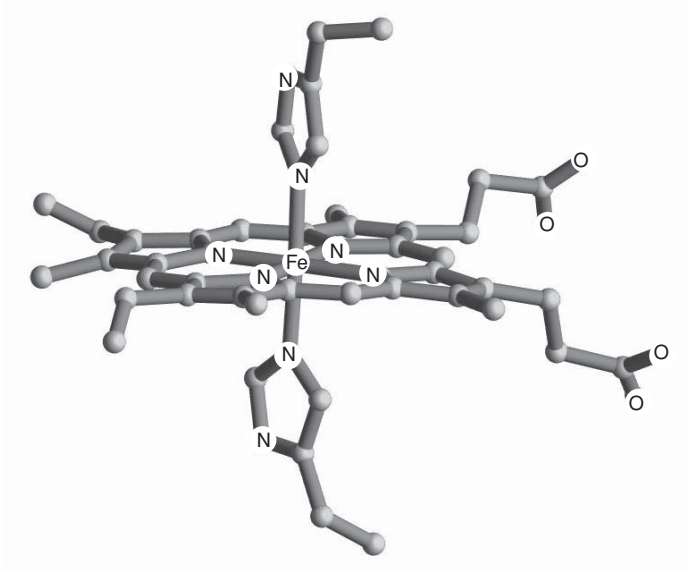
A second group of electron carriers in mitochondrial membranes are the **iron–sulfur [Fe–S] clusters** which are also bound to proteins. Iron–sulfur proteins release Fe^{3+} or Fe^{2+} plus H_2S when acidified. The "inorganic clusters" bound into the proteins have characteristic compositions such as Fe_2S_2 and Fe_4S_4. The sulfur atoms of the clusters can be regarded as sulfide ions bound to the iron ions. The iron atoms are also attached to other sulfur atoms from cysteine side chains from the proteins. The Fe–S proteins are often tightly associated with other components of the electron transport chain. For example, the flavoproteins Flavin 1, Flavin 2, and Flavin 3 shown in Fig. 10-5 all contain Fe–S clusters as does the Q-cytochrome *b* complex. All of these Fe–S clusters seem to be one-electron carriers.

A third hydrogen carrier of mitochondrial membranes, and the only one that is not unequivocally associated with a specific protein, is the isoprenoid quinone **ubiquinone** or **coenzyme Q** (Q in Fig. 10-5). Ubiquinone apparently serves as a common carrier, collecting electrons from three or more separate input ends of the chain and directing them along a single pathway to O_2.

The final group of mitochondrial redox components are one-electron carriers, small proteins (**cytochromes**) that contain iron in the form of the porphyrin complex known as **heme**. These carriers, which are discussed in Chapter 16, exist as several chemically distinct types: *a*, *b*, and *c*. Two or more components of each type are present in mitochondria. The complex cytochrome aa_3 deserves special comment. Although cytochromes are single-electron carriers, the cytochrome aa_3 complex must deliver four electrons to a single O_2 molecule. This may explain why the monomeric complex contains two hemes and two **copper** atoms which are also able to undergo redox reactions.[1,2]

Although the components of the electron transport chain have been studied intensively, there is still some mystery associated with the process by which ATP synthesis is coupled to electron transport (oxidative phosphorylation). A theory originally proposed by Mitchell[3] and now generally accepted[4,5] is that passage of electrons through the chain "pumps" protons from the inside to the outside of the tight inner mitochondrial membrane. As a result, protons accumulate along the outside of this membrane, as do negative counterions along the inside. The membrane becomes charged like a miniature electrical condenser. The synthesis of ATP takes place in the small knoblike **ATP synthase** which is partially embedded in the same membranes. The Gibbs energy for the formation of ATP from ADP and inorganic phosphate is apparently supplied by the flow of protons back to the inside of the membrane through the ATP synthase. Possible





Iron in a heme in a *b* type cytochrome

ways in which this may occur as well as many other aspects of electron transport are dealt with in Chapter 18.

7. The Citric Acid Cycle

The 2-carbon acetyl units removed from fatty acid chains or generated from sugars by glycolysis and the action of pyruvate dehydrogenase must be completely oxidized to carbon dioxide to provide cells with the maximum amount of energy. The oxidation of an acetyl group is a difficult chemical process, and probably for this reason nature has devised an elegant catalytic cycle, the **citric acid cycle**, which is indicated at the lower right in Fig. 10-1 and is shown in detail in Fig. 10-6. The cycle begins when the 4-carbon **oxaloacetate** (also spelled oxalacetate) is condensed with an acetyl group of acetyl-CoA to form the 6-carbon **citrate**. Then, in the remaining reactions of the cycle, two carbon atoms are removed as CO_2 and oxaloacetate is regenerated. Several oxidation steps are involved, each of which feeds additional **reducing equivalents** (i.e., hydrogen atoms removed from substrates) into the pool of hydrogen carriers and allows for more synthesis of ATP via the electron transport chain. The importance of this pathway to an organism can be understood from the fact that when glucose is oxidized completely to CO_2 and water via the citric acid cycle, about 38 molecules of ATP are formed, 19 times as much as by fermentation.

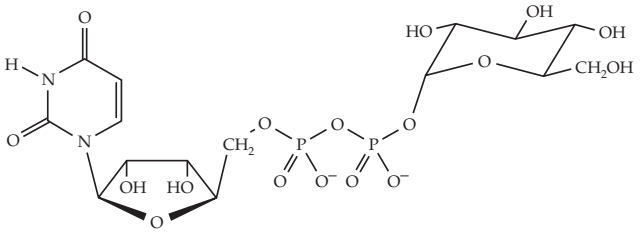
Although oxaloacetate is regenerated and therefore not consumed during the operation of the citric acid cycle, it also enters other metabolic pathways. To replace losses, oxaloacetate can be synthesized from pyruvate and CO_2 in a reaction that uses ATP as an energy source. This is indicated by the heavy gray line leading downward to the right from pyruvate in Fig. 10-1 and at the top center of Fig. 10-6. This reaction depends upon yet another coenzyme, a bound form of the vitamin **biotin**. Pyruvate is formed from breakdown of carbohydrates such as glucose, and the need for oxaloacetate in the citric acid cycle makes the oxidation of fats in the human body dependent on the concurrent metabolism of carbohydrates.

C. Biosynthesis

At the same time that cells break down foodstuffs to obtain energy, they are continuously creating new materials. The green lines in Fig. 10-1 indicate some pathways by which such biosynthesis takes place. Examining the left side of the figure, we see that either pyruvate or 3-phosphoglycerate can be converted back to glucose 6-phosphate and that the latter can be used to synthesize glycogen or other sugars or polysaccharides.

1. Reversing Catabolic Pathways

Breakdown of carbohydrates is thermodynamically spontaneous. Therefore, *cells cannot simply use catabolic pathways operating in reverse without finding ways of coupling the cleavage of ATP to synthesis.* In the formation of glucose from pyruvate in the liver, a process known as **gluconeogenesis**, there are three distinct points at which the enzymes used differ from those used in catabolism: (1) Pyruvate is converted to phosphoenolpyruvate by a mechanism utilizing more than one molecule of ATP, a pathway that is discussed in detail in Chapter 17; (2) as is shown in Fig. 10-2, fructose 1,6-bisphosphate is hydrolyzed to fructose 6-phosphate and inorganic phosphate by a **phosphatase** rather than through reversal of step *d*, which would form ATP; and (3) glucose-6-phosphate is hydrolyzed by a phosphatase rather than following the reverse of step *a* in Fig. 10-2. Furthermore, glycogen is synthesized from glucose 6-phosphate, not by reversal of the phosphorylase reaction (Fig. 10-2, step *g*), but via a new intermediate, **uridine diphosphate glucose** (UDPG), whose formation involves cleavage of UTP. The latter is generated by phospho transfer from ATP. Inorganic **pyrophosphate** (PP_i) is a product of UDPG formation and is removed by hydrolytic cleavage to two molecules of inorganic phosphate by the enzyme **pyrophosphatase**. This reaction helps to make the biosynthesis thermodynamically spontaneous by removing one of the reaction products.



Uridine diphosphate glucose (UDPG)

A similar situation exists in the case of fatty acid synthesis, which proceeds from acetyl-CoA and reverses fatty acid breakdown. However, both carbon dioxide and ATP, a source of energy, are needed in the synthetic pathway. Furthermore, while oxidation of fatty acids requires NAD^+ as one of the oxidants, and generates NADH, the biosynthetic process often requires the related NADPH. These patterns seen in biosynthesis of sugars and fatty acids are typical. *Synthetic reactions resemble the catabolic sequences in reverse, but distinct differences are evident.* These can usually be related to the requirement for energy and often also to control mechanisms.

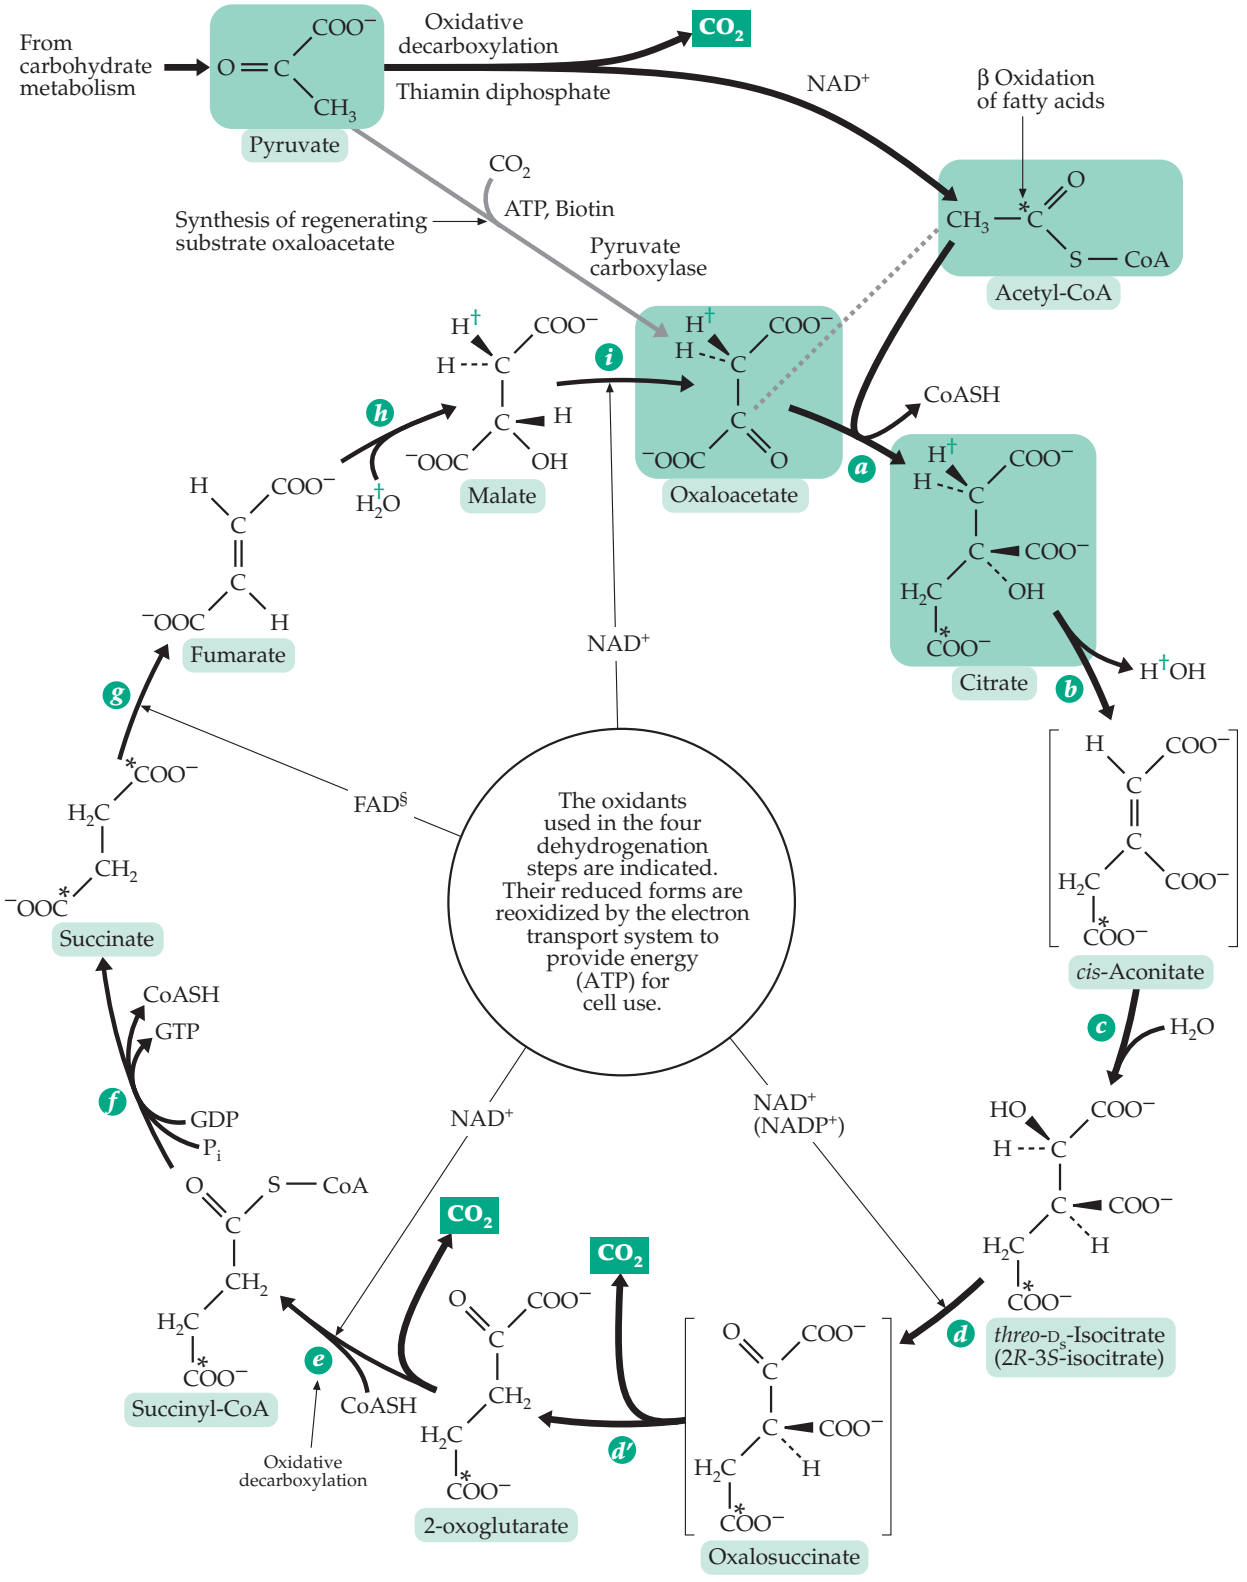


Figure 10-6 Reactions of the citric acid cycle (Krebs' tricarboxylic acid cycle). Asterisks designate positions of isotopic label from entrance of carboxyl-labeled acetate into the cycle. Note that it is *not* the two carbon atoms from acetyl-CoA that are immediately removed as CO_2 but two atoms from oxaloacetate. Only after several turns of the cycle are the carbon atoms of the acetyl-CoA completely converted to CO_2. Nevertheless, the cycle can properly be regarded as a mechanism of oxidation of acetyl groups to CO_2. Green daggers (†) designate the position of ^2H introduced into malate as $^2H^+$ from the medium. FAD§ designates covalently bound 8-histidyl-FAD (see Chapter 15).

BOX 10-B DISCOVERY OF THE CITRIC ACID CYCLE (KREBS' TRICARBOXYLIC ACID CYCLE)

One of the first persons to study the oxidation of organic compounds by animal tissues was T. Thunberg, who between 1911 and 1920 discovered about 40 organic compounds that could be oxidized by animal tissues. Salts of succinate, fumarate, malate, and citrate were oxidized the fastest. Well aware of Knoop's β oxidation theory, Thunberg proposed a cyclic mechanism for oxidation of acetate. Two molecules of this two-carbon compound were supposed to condense (with reduction) to succinate, which was then oxidized as in the citric acid cycle to oxaloacetate. The latter was decarboxylated to pyruvate, which was oxidatively decarboxylated to acetate to complete the cycle. *One of the reactions essential for this cycle could not be verified experimentally.* It is left to the reader to recognize which one.

In 1935, A. Szent-Györgyi discovered that all of the carboxylic acids that we now recognize as members of the citric acid cycle stimulated respiration of animal tissues that were oxidizing other substrates such as glucose. Drawing on this knowledge, Krebs and Johnson in 1937 proposed the citric acid cycle.[a,b,c] Krebs provided further confirmation in 1940 by the observation that malonate, a close structural analog and competitive inhibitor of succinate, in concentrations as low as 0.01 M blocked the respiration of tissues by stopping the oxidation of succinate to fumarate.[c]

$^{-}OOC—CH_2—COO^{-}$
Malonate

$^{-}OOC—CH_2—CH_2—COO^{-}$
Succinate

In muscle, 90% of all respiration was inhibited and succinate was shown to accumulate, powerful proof of the importance of the citric acid cycle in the respiration of animal tissues.

2. Photosynthesis

The principal means of formation of glucose in nature is through photosynthesis in green plants (Fig. 10-1, lower left). Light energy is captured by chlorophyll and is used to transfer electrons from chlorophyll to other electron carriers, the most important of which is $NADP^+$. It is reduced to NADPH which is used to reduce carbon dioxide to sugar phosphates in a complex series of reactions known as the **reductive pentose phosphate pathway**, which is described in Chapter 17. ATP is also required for photosynthetic reduction of CO_2. It is generated by allowing some of the electrons to flow back through an electron transport chain in the membranes of the chloroplasts. This chain closely resembles that from Q to cytochrome *c* in mitochondria (Fig. 10-5), and the generation of ATP in this **photosynthetic phosphorylation** occurs in a manner analogous to that in the electron transport chain of mitochondria. In green plants the electrons removed from chlorophyll in one light-requiring reaction are replaced by electrons formed during the cleavage of water in a second light-dependent reaction, a reaction that also releases oxygen, O_2, and generates hydrogen ions (H^+). The first stable product from reduction of CO_2 in photosynthesis is 3-phosphoglycerate. It can be converted to sugars by pathways analogous to those employed by animals in gluconeogenesis. One interesting difference is the use in chloroplasts of NADPH + H^+ in reduction of 3-phosphoglycerate (reverse of step *a* in Fig. 10-3).

A small number of other biosynthetic pathways, which are used by both photosynthetic and nonphotosynthetic organisms, are indicated in Fig. 10-1. For example, pyruvate is converted readily to the amino acid **L-alanine** and oxaloacetate to **L-aspartic acid**; the latter, in turn, may be utilized in the biosynthesis of pyrimidines. Other amino acids, purines, and additional compounds needed for construction of cells are formed in pathways, most of which branch from some compound shown in Fig. 10-1 or from a point on one of the pathways shown in the figure. In virtually every instance biosynthesis is dependent upon a supply of energy furnished by the cleavage to ATP. In many cases it also requires one of the hydrogen carriers in a reduced form. While Fig. 10-1 outlines in briefest form a minute fraction of the metabolic pathways known, the ones shown are of central importance.

D. Synthesis and Turnover of Macromolecules

Proteins make up the bulk of the catalytic machinery of cells and together with other macromolecules most of the structure. Therefore, the synthesis and degradation of proteins and the control of those processes are of great importance to cells. Although the emphasis

in this section is on proteins, similar considerations apply to nucleic acids, polysaccharides, and other macromolecules.

With the exception of some antibiotics and other short-chain molecules, all polypeptides are formed on ribosomes, which assemble proteins according to the sequences of nucleotides in the messenger RNA (mRNA) molecules. The basic chemistry is simple. The carboxyl groups of the amino acids are converted to reactive acyl adenylates by reaction with ATP, just as in Eq. 10-1. Each "activated" amino acid is carried on a molecule of transfer RNA (tRNA) and is placed in the reactive site of a ribosome when the appropriate codon of the mRNA has moved into the site. The growing peptide chain is then transferred by a displacement reaction onto the amino group of the activated amino acid that is being added to the peptide chain. In this manner, new amino acids are added one at a time to the carboxyl end of the chain, which always remains attached to a tRNA molecule. The process continues until a stop signal in the mRNA ends the process and the completed protein chain is released from the ribosome. Details are given in Chapter 29.

1. Folding and Maturation of Proteins

A newly synthesized peptide chain probably folds quickly. However, the cytosol provides an environment rich in other proteins and other macromolecules that can interact with the new peptide and may catalyze or inhibit folding. Among the most abundant proteins of bacteria or eukaryotes are proteins known as **chaperonins**. They apparently help polypeptide chains to fold correctly, partly by "chaperoning" them through the cytoplasm and across cell membranes, protecting them from becoming entangled with other proteins and macromolecules while they fold.[6–9] There are several classes of chaperonins. Most are oligomers made up of 10- to 90-kDa subunits. They have a variety of names, which may be somewhat confusing. The first chaperonins were identified only as **heat shock proteins** (Hsp). They are produced in large amounts by bacteria or other cells when the temperature is raised quickly, and are designated Hsp70, Hsp90, etc., where the number is the subunit mass in kDa. Other chaperonins were recognized as products of genes needed for replication of the DNA of bacteriophage λ in *E. coli.* Consequently, one major chaperonin of the Hsp70 class is designated **DnaK**. The Hsp70 protein of mitochondria was named "binding protein" or BiP.[10] Other workers have abbreviated chaperonins as Cpn70, Cpn60, etc.

The abbreviations Hsp70, Cpn70, DnaK, and BiP all refer to a group of similar 70-kDa proteins that are apparently found in all organisms. Their role seems to be to stabilize unfolded proteins prior to final folding in the cytosol or after translocation into the endoplasmic reticulum (ER) or into mitochondria or other organelles. Each of these proteins consists of two functional domains. A 52-kDa domain at the C terminus binds 7- or 8-residue segments of unfolded peptide chains in an elongated conformation.[9] At some point in its reaction cycle the N-terminal 40-kDa domain, which binds ATP tightly, causes the ATP to be hydrolyzed to ADP and inorganic phosphate: $ATP + H_2O \rightarrow ADP + P_i$. Binding and release of a polypeptide by the *E. coli* DnaK protein is coupled tightly to this exergonic **ATPase** reaction.[10a,10b] The reaction is dependent upon potassium ions[11] and is regulated by two **co-chaperones, DnaJ** (Hsp40)[11a-11c] and **GrpE**.[10a] Both ATP and extended polypeptides bind weakly to DnaK, and the ATP in the DnaK•polypeptide•ATP complex is hydrolyzed slowly to ADP and inorganic phosphate.[10a,10b,12] Co-chaperone DnaJ, which shares a largely α-helical structural motif with J-domains in various other proteins, binds to the complex.[11a, 11b, 11c] It probably induces a conformational change that leads to rapid hydrolysis of ATP. In the resulting complex both ADP and the polypeptide are bound tightly to the DnaK protein and dissociate from it very slowly. The *E. coli* co-chaperone GrpE acts as a **nucleotide exchange factor** that catalyzes rapid loss of ADP from the complex. If ATP binds to this DnaK•polypeptide complex the polypeptide is released.[10a] This cycle, which can be repeated, accomplishes the function of DnaK in protecting extended polypeptides and releasing them under appropriate conditions. There is also evidence that DnaK participates in refolding of misfolded proteins.[11d] It cooperates with a ribosome-associated prolylisomerase in bacteria.[11e] The three-dimensional structure of the ATPase domain of Hsp70 is strikingly similar to that of the enzyme **hexokinase** (Chapter 12) and to that of the muscle protein **actin**, Fig. 7-10.[13,14] Archaeal chaperonins lack the Cpn10 ring but have lid-like extensions at the cylinder ends.[15a]

The Cpn60 class of chaperonins are amazing cage-like structures. Each oligomer is composed of two rings, each made up of seven 60-kDa subunits stacked back-to-back. Cpn60 structures from archaeobacteria are similar but may have 8- or 9-subunit rings.[15,15a] The best known member of this group is the *E. coli* protein known as **GroEL** whose three-dimensional structure is depicted in Box 7-A.[16,17] This 14-subunit oligomer of GroEL is a cylinder which is capped by a smaller ring composed of seven 10-kDa subunits of **GroES**, a Cpn10 protein.[17,18] Like Hsp70, GroEL has ATPase activity and an ATP binding site in its large equatorial domain.[16] Archaeal chaperonins lack the Cpn10 ring but have lid-like extensions at the cylinder ends.[15a]

Within the GroEL–GroES cage polypeptide chains can fold without becoming entangled with other proteins or being cleaved by protein-hydrolyzing enzymes

of the cytoplasm. An unfolded or partially folded protein may diffuse into the open end of the complex and bind temporarily via noncovalent interactions. The hydrophobic inner surface of the complex may favor the formation of helices within the folding protein. Binding of the polypeptide substrate and capping with GroES causes a major cooperative conformational change with doubling of the internal volume (Box 7-A). The character of the inner wall also changes as a result of exposure of hydrophilic groups.[18a,18b] Perhaps the expansion also stretches segments of the unfolded polypeptide. Subsequent hydrolysis of ATP may be coupled to release of the bound polypeptide, which may then leave the complex or bind again for another chain to fold correctly.[17,19] The two ends of the GroEL•GroES complex may function alternately, with each end in turn receiving the GroES cap.[17]

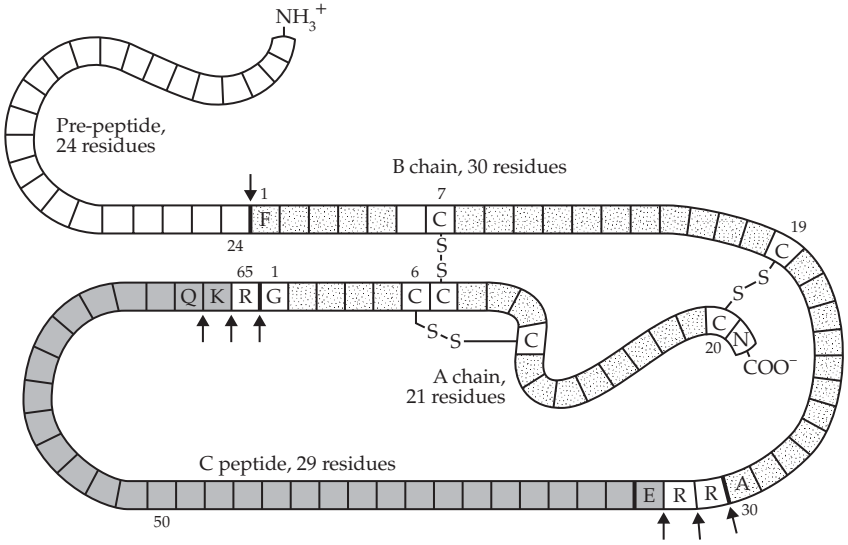

Figure 10-7 Schematic diagram of the structure of human preproinsulin. The 24-residue prepeptide, the 29-residue C-peptide and basic residues 31, 32, 64, and 65 are cut from the peptide upon conversion to insulin as indicated by the small arrows. Some amino acid residues are identified using the one-letter codes. See Fig. 7-17 for details of insulin structure.

Hsp90 is one of the most abundant cytosolic proteins in eukaryotic cells, but it seems to chaperone only a few proteins, among which are steroid-hormone receptors.[20,20a] Another group of over 30 different chaperone proteins participate in assembly of external bacterial cell-surface structures such as pili (Fig. 7-9). The chaperone PapD consists of two domains, both having an immunoglobulin-like fold.[20b] PapD binds to the pilin subunits, escorting them to the site of pilus assembly. Folding of integral membrane proteins may be facilitated by a chaperone function of membrane lipids.[20c]

For most proteins the initial synthesis is followed by a sequence of **processing** or **maturation** reactions. These reactions sometimes involve alteration of amino acid side chains and very often include hydrolytic cleavages by which pieces of the peptide chain are cut off. The initially synthesized polypeptides are often not functional and gain biological activity only after one or more pieces have been removed. For example, digestive enzymes are usually secreted as **zymogens** or **proenzymes** which are activated by hydrolytic cleavages only after secretion into the digestive tract. Many proenzymes are components of the extremely complex cascades of activating reactions involved in **blood clotting** (Chapter 12) and in the defensive **complement system** (Chapter 31).

Most peptide hormones are cut out from larger proteins. For example, human insulin is synthesized as a 110-residue **preproinsulin** which is converted in stages to the active two-chain, 51-residue hormone (Eq. 10-8 and Fig. 10-7).[20d,20e]

$$\underset{(110\ \text{residues})}{\text{preproinsulin}} \rightarrow \underset{\substack{(86\ \text{residues,}\\ \text{one chain})}}{\text{proinsulin}} \rightarrow \underset{\substack{(51\ \text{residues, two}\\ \text{disulfide-linked}\\ \text{chains})}}{\text{insulin}} \qquad (10\text{-}8)$$

The 24-residue prepeptide is cleaved from preproinsulin within a few minutes of synthesis. Then, over a period of about an hour additional cleavages occur to give the final product.[21] This crystallizes as the zinc hexamer (Fig. 7-18) within the "dense cores" of storage vesicles from which it is released into the bloodstream as needed.[22] Other examples are described in Section 3.

2. Transport of Proteins to Their Destinations within a Cell

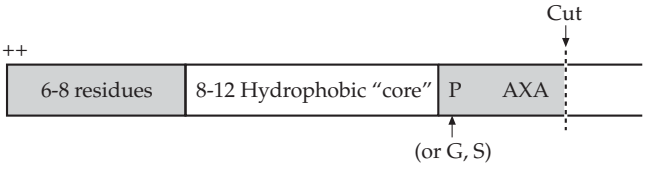
The synthesis of peproinsulin on ribosomes in the cytosol and the release of mature insulin from secretion vesicles involve not only the chain cleavages but also transport of the polypeptide across membranes of the ER, Golgi compartments, and secretion vesicles.

Signal sequences and translocation. In 1971, Blobel and Sabatini postulated that for some proteins an N-terminal segment of newly synthesized polypeptide chains contains a signal sequence or leader peptide of 15–30 amino acids which carries information concerning the location of the mature protein in the cell.[23–28b] The rather nonpolar signal sequences of proteins destined for secretion from cells would interact

with and pass through the membrane of the ER. On the other side of the membrane, a **signal peptidase** would cut off the signal peptide. In many cases, glycosyltransferases would add sugar residues near the N terminus to create a hydrophilic end which would help to pull the rest of the peptide chain through the membrane. A similar situation would hold for secretion of proteins by bacteria.

The signal hypothesis has been proven correct but with considerable added complexity. It now appears that when the N terminus of a new polypeptide chain carrying the proper signal sequence emerges from a ribosome it is intercepted by a **signal recognition particle (SRP)**, a 250-kDa ribonucleoprotein consisting of six polypeptide chains and a small 300-residue 7S RNA chain.[29–33] Binding to the ribosome, the SRP temporarily blocks further elongation of the peptide chain until it bumps against and binds to a 72-kDa membrane protein called the **SRP receptor** or **docking protein**. Then translation begins again and the protein moves into the ER, where it is cleaved by the signal peptidase and is modified further. Although the bacterial SRP is a single protein called **Ffh** (for 54 homolog),[33a] the basic machinery for signal recognition and secretion is remarkably conserved from *E. coli* to humans.[33b] Bacterial proteins that are destined for secretion or for a function in the periplasmic space or in external membranes also contain signal sequences which are cut off by a signal peptidase embedded in the plasma membrane.[33c]

Signal sequences vary in structure but usually have a net positive charge within the first 5–8 residues at the N terminus. This region is followed by a "hydrophobic core" made up of 8–10 residues with a strong tendency toward α helix formation. This sequence is often followed by one or a few proline, glycine, or serine residues and then a sequence AXA that immediately precedes the cleavage site. Here, A is usually alanine in prokaryotes but may also be glycine, serine, or threonine in eukaryotes. Residue X is any amino acid.[25,27,28a,28b]



It had often been assumed that a hydrophobic signal sequence, perhaps folded into a hairpin loop, spontaneously inserts itself into an ER membrane to initiate translocation. However, study of the genetics of protein transport suggests otherwise. Over 50 different genetic loci affect the translocation of proteins in yeast.[31,32,33d] Products of these **secretory genes**, which are named *SEC* 61, *SEC* 62, *SEC* 63, etc., are proteins with corresponding names, e.g., Sec 61 protein (or Sec 61p). Study of these proteins suggested that the Sec 61, Sec 62, and Sec 63 proteins are all directly involved in transport into the ER.[31,34,35] Additional proteins are needed for movement of vesicles out from the Golgi and for delivery of secretory vesicles to the plasma membrane.[33d] The protein Sec 61p has been identified as homologous to the α subunit of a similar trimeric αβγ Sec 61p complex of mammalian tissues.[32] It also appears to correspond to Sec Y, a protein required for secretion of proteins through the plasma membrane of *E. coli* into the periplasmic space. Proteins corresponding to the β and γ subunits of mammalian related proteins have been identified in yeast and *E. coli*[36] and in *Arabidopsis*, where it is necessary to bring proteins into the thylakoid membrane of the chloroplasts.[37]

In *E. coli* the products of genes *SecY, SecE,* and *SecG* are integral membrane proteins that, together with additional proteins, form a proteinaceous pore through which proteins pass.[38–40a] Additional proteins required for translocation of some bacterial proteins are the chaperonin **SecB**, a tetramer of 17.3-kDa subunits,[41] and **SecA**, a soluble ATPase that may participate in docking and serve as an engine for transport throught the pore.[38,40a,42] In eukaryotic cells a membrane-bound Ca^{2+}-dependent chaperonin called **calnexin** assists in bringing the protein into the ER in a properly folded state.[43,44]

Unlike transport across the membranes of the ER, transport across plasma membranes of bacteria often requires both hydrolysis of ATP and energy provided by the membrane electrical potential.[33,38,44–48] Secretion into the periplasmic space has been well characterized but less is known about transport of proteins into the external membranes of *E. coli*.[48] A 16 kDa periplasmic chaperone may be required.[48a]

Many bacteria have a second complete secretion system.[48b] This multi-gene type II system is present but usually inactive in *E. coli*. A third (type III) system is present in many pathogenic bacteria, and has evolved for delivery of specialized structural and regulatory proteins into host cells.[48c,48d]

Ticketing destinations. We have seen that proteins that contain suitable signal sequences are exported from the cytoplasm while other proteins remain. Some proteins are secreted while others take up residence as integral or peripheral membrane proteins or as soluble proteins within an organelle. All of the available evidence indicates that it is the sequence of a protein that determines its destination. Proteins targeted to pass through the inner mitochondrial or chloroplast membrane have 20- to 70-residue presequences that are rich in arginine and lysine and which are removed when the protein reaches its

destination.[49–53] Proteins meant to go to the intermembrane space or the outer membrane of mitochondria have a sequence containing basic amino acids followed by a long stretch of uncharged residues.[54] Peroxisomal preproteins may have signal sequences such as SKL at the C terminus[54–56] and proteins destined to become attached to phosphatidylinositol glycan anchors (Fig. 8-13)[57] as well as some bacterial surface proteins[57a] have signal peptides at both N and C termini. Some lysosomal membrane glycoproteins have an LE pair in the N-terminal cytoplasmic tail[58] and proteins with suitable dileucine and related pairs are often taken up in lysosomes.[59] Soluble proteins that are resident in the cisternae of the ER often have the C-terminal sequence KDEL or HDEL.[29,60–64] It may serve both as a **retention signal** and as a **retrieval signal** for return of the protein if it passes on into the Golgi vesicles.[65,66]

Transport of proteins into mitochondria is dependent upon both cytosolic chaperonins and mitochondrial chaperonins of the Hsp70 and Hsp60 classes.[67–70] Entrance into mitochondria[71–73] resembles passage through membranes of the ER. However, entry to the nucleus through the nuclear pore complex requires other localization signals[73a] as well as specialized proteins.[74,74a] The sorting of proteins into six different compartments within a chloroplast requires a whole series of recognition signals as well as chaperonins and channel proteins.[75–79] The various signal sequences that determine a protein's interactions with chaperonins, docking proteins, and proteinaceous pore complexes may be complex and overlapping but evolution has selected sequences that allow cells to live and function. Computer programs for detecting sorting signals are being developed.[79a] Not only proteins but also other macromolecules are automatically sorted to their correct destination.

Vesicular transport and the Golgi system. Movement of secreted proteins through the cytosol from the ER to the external surface occurs through the formation and opening up of small vesicles about 70 nm in diameter. It occurs in steps that involve passage from the ER to the various Golgi membranes. Figure 10-8 provides a sketch of the system of ER, Golgi, secretion vesicles, and lysosomes.[63] Newly formed secretory proteins flow from the ER into an intermediate compartment where vesicles are formed and are carried to the *cis* Golgi network (CGN). They move step-by-step through the Golgi stack (GS) and into the *trans* Golgi network (TGN). New vesicles are formed to carry proteins between each pair of membranous compartments. In each compartment new glycosylation reactions or other modifications may occur. Finally, vesicles carry the mature proteins to the plasma membrane, lysosomes, or vacuoles.[79b] A related process is *uptake* of proteins by endocytosis to form, consecutively, early and late endosomes which fuse with lysosomes (Chapter 8, Section C,6, Fig. 10-8).

At every step in these processes vesicles are formed and are carried to the next destination where the vesicles fuse with the new membrane and discharge their contents.[80–85a] This remarkable process is complex and highly specific. Rothman proposed that the vesicles to be transported are "docked" on appropriate receptor molecules (called SNARES) on the destination membrane. This is accomplished with the aid of specific soluble marker proteins (called SNAPS) with surfaces complementary to those of the receptors.[80] Proteins are sorted in this way according to their destination signals. The Golgi system is considered further in Chapter 20.

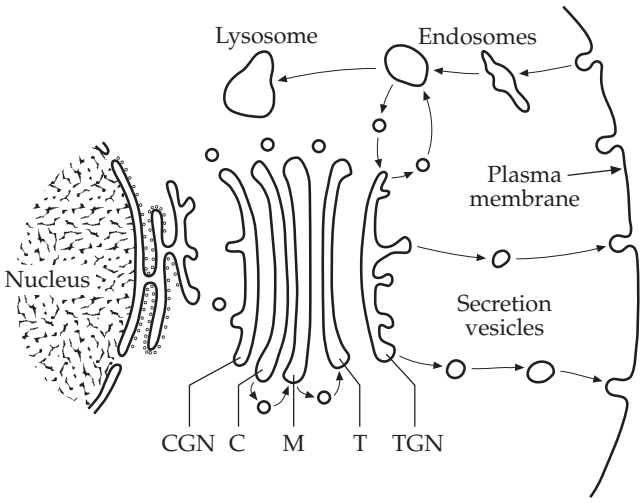


Figure 10-8 Current version of protein synthesis and processing via ER, Golgi, and secretory vesicles. CGN, *cis*-Golgi network: C, T, M are the *cis*, medial, and *trans* compartments of the Golgi stack; TGN, *trans* Golgi network. Arrows indicate some of the movements of transport vesicles.

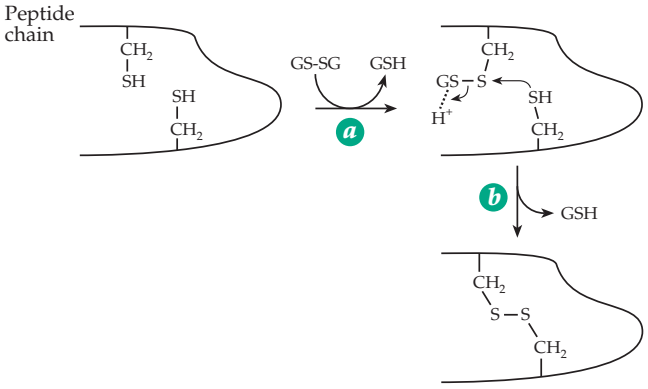
3. Posttranslational Alterations

Chemical alterations to a protein begins as soon as the peptide chain is formed. Proteins translocated into the periplasmic space of bacteria or into the cisternae of the ER of eukaryotic cells meet several important enzymes. Peptidylprolyl isomerase (discussed in Box 9-F) assists the folding of the peptide chain and protein disulfide isomerases help to form disulfide linkages. The cytosol provides a reducing environment in which many proteins that have cysteine side chains carry free –SH groups. In contrast, the periplasmic space and the ER have more oxidizing environments in which disulfide bridges may form. As shown in Eq. 10-9, the oxidizing agent is often assumed to be the disulfide form of the tripeptide **glutathione** (see Box 11-B),



(10-9)

which is commonly abbreviated GS–SG. It can react with proteins by disulfide exchange reactions to form mixed disulfide groups with release of reduced glutathione, GSH (Eq. 10-9, step *a*). The mixed disulfides can be converted to disulfide bridges by a second exchange reaction (Eq. 10-9, step *b*). However, in the bacterial periplasm the dithiol protein DsbA appears to be the major oxidant (see Box 15-C). It functions together with other proteins, some of which carry electrons from the electron transport chains of the bacteria.[85a,85b] The rates of these reactions are greatly increased by the protein disulfide isomerases.[85a–85e,86–91] These enzymes tend to promote formation of disulfide linkages between the correct pairs of SH groups. If there are three or more –SH groups in a chain some incorrect pairing may, and often does, occur. The protein disulfide isomerases break these bonds and allow new ones to form.[92] The active sites of these isomerases contain pairs of –SH groups which can be oxidized to internal –S–S– bridges by NAD^+-dependent enzymes. These enzymes and their relatives **thioredoxin** and **glutaredoxin** are discussed further in Box 15-C. Glutathione and oxidation–reduction buffering are considered in Box 11-B.

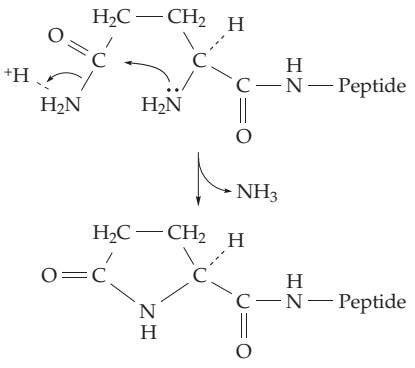
Proteolytic processing. For proteins exported from the cytosol, a signal peptidase (or leader peptidase) is usually waiting in the bacterial plasma membrane or in membranes of the ER. The *E. coli* leader peptidase is an integral membrane protein with its catalytic domain in the periplasm.[45,93] For insulin the 24-residue prepiece serves as the signal sequence which is hydrolyzed off in the ER. However, the other cleavages shown in Fig. 10-7 appear to take place in immature secretory granules.[21,22] For many proteins proteolytic processing begins earlier than this and may occur in more than one location. Eukaryotic processing proteases often resemble the bacterial protease subtilisin[20e] but cut peptide chains preferentially after dibasic amino acid pairs, e.g., Arg-Arg, Arg-Lys.[94–96] There are also other processing enzymes with differing specificities.[97]

Although most polypeptides leave ribosomes as single proteins, some are **polyproteins**, which give rise to two or more functional peptides. Polyproteins occur in all cells but are especially prevalent among virally encoded peptides. For example, the polio virus polyprotein is cut into at least ten pieces by proteases, some present in the host cell normally and some encoded by the virus.[98] Many neurohormones arise from polyproteins that undergo processing as they travel down an axon from the cell body before being secreted into a synapse (Chapter 30). Within our own brains the peptide **prepro-opiomelanocortin** undergoes numerous cleavages to give rise to at least seven different neurohormones (see Fig. 30-2).[96,99–101]

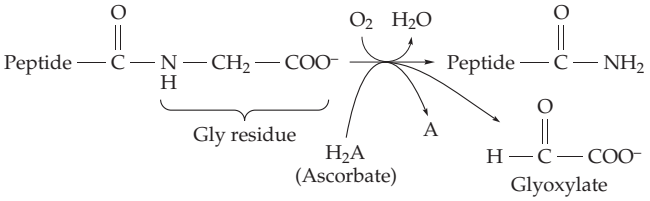
Altered ends. Proteins often contain "blocked" end groups in place of free $-NH_3^+$ or $-COO^-$. For many of the cytosolic proteins, which do not carry leader sequences, the N-terminal methionine that is always used to initiate the ribosomal synthesis of proteins in eukaryotes is removed. If the next residue after the N-terminal methionine is small and uncharged, the methionine is usually hydrolyzed off enzymatically after 30–40 residues have been added to the growing peptide chain.[102–105] An acetyl group is transferred onto the NH_2 termini of about 85% of all cytosolic proteins, whether or not the initiator methionine has been removed.[106] In other cases fatty acyl groups may be transferred to the terminal $-NH_2$ group or to side chain SH groups. For example, a **myristoyl** (tetradecanoyl) group is frequently combined in amide linkage at the N terminus of cellular and virally encoded proteins. A palmitoyl group is joined in thioester linkage to a cysteine side chain near the N terminus of the *E. coli* periplasmic lipoprotein (Fig. 8-28).[107] Together with the N-terminal myristoyl group it forms a membrane anchor for this protein. Polyprenyl groups are transferred onto cysteine –SH groups at or near the C termini of many eukaryotic proteins to form a different membrane anchor.[108–110] Some of the enzymes act on the sequence CAAX, where X = M, S, Q, C but not L or I. After transfer of a farnesyl or geranylgeranyl group onto the cysteine the AAX is removed proteolytically and the new terminal cysteinyl carboxyl group is methylated. Surface proteins of gram-positive bacteria are joined by amide linkage from their C termini to a pentaglycine chain of the peptidoglycan layer (Fig. 8-28)[57a]

A pyroglutamyl N terminus is found in the thyrotropin-releasing hormone (Fig. 2-4) and in many other peptide hormones and proteins. It presumably arises by attack of the α-NH_2 group of an N-terminal glutamine on the side chain amide group with release of NH_3 (Eq. 10-10).[111,112]

Another frequent modification at the C terminus of peptide hormones and of other proteins is **amidation**. In this reaction a C-terminal glycine is oxidatively removed as glyoxylate in an O_2^-, copper- and ascorbate



(10-10)



(10-11)

(vitamin C)-dependent process (Eq. 10-11).[113–117] See also Chapter 18, Section F,2.

An example of both of these modifications is formation of thyrotropin-releasing hormone shown in Fig. 2-4 from its immediate precursor:

$$\text{Gln–His–Pro–Gly} \rightarrow \text{pyroglutamyl–His–Pro–NH}_2 \qquad (10\text{-}12)$$

Proteins with long C-terminal hydrophobic signal sequences may become attached to phosphatidylinositol-glycan anchors embedded in the plasma membrane (Fig. 8-13). An example is a human alkaline phosphatase in which the α carboxyl of the terminal aspartate residue forms an amide linkage with the ethanolamine part of the anchor. Attachment may occur by a direct attack of the $–NH_2$ group of the ethanolanine on a peptide linkage in a transacylation reaction that releases a 29-residue peptide from the C terminus.[118,119] (See Chapter 29).

Many other covalent modifications of proteins are dealt with in other sections of the book.[120–122] A few are described in Chapter 2, Eqs. 2-14 to 2-22. Reversible alterations used to regulate enzymes are considered in Chapter 11. Of these, the phosphorylation of –OH groups of serine, threonine, and tyrosine is the most important. A large fraction of all cellular proteins appear to be modified in this way. Protein glycosylation, the transfer of glycosyl groups onto –OH side chain groups of serine and threonine (Chapter 4, and Chapter 20) and nonenzymatic glycation (Eq. 4-8) also affect many proteins, often at turns in the peptide chain. Hydroxylation, glycosylation, and other modifications of collagen are described in Chapter 8. Another common reversible alteration is formation of sulfate esters of tyrosine –OH groups.[99,123] Reactions by which cofactors become attached to proteins[124] are described in Chapters 15–17.

Methylation,[125] hydroxylation, and other irreversible modifications often affect specific residues in a protein. Oxidative alterations occur during aging of proteins (Chapter 18).[126] A few proteins even undergo "splicing" that alters the amino acid sequence (Box 29-E).[127] All of these reactions not only affect the properties of the proteins but also participate in driving the turnover of these macromolecules.

4. Intracellular Degradation of Proteins

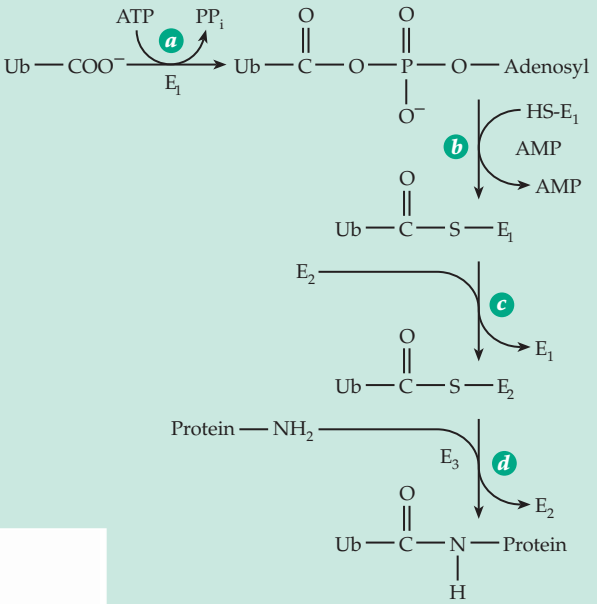
Once a protein has reached its correct location and has acquired its proper function, it usually has a limited lifetime, which may average only a few hours or a few days. The protein is then hydrolytically degraded back to its constituent amino acids.[128] Defective and damaged proteins are usually degraded much more rapidly than are intact proteins.[129,130] Under conditions of starvation, proteins are broken down more rapidly than usual to supply the cell with energy. Rapid degradation of proteins is often induced at certain stages of differentiation. For example, spore-forming bacteria contain a protease that becomes activated upon germination of the spore.[131] Within minutes this enzyme digests stored proteins to provide amino acids for the synthesis of new proteins during growth.

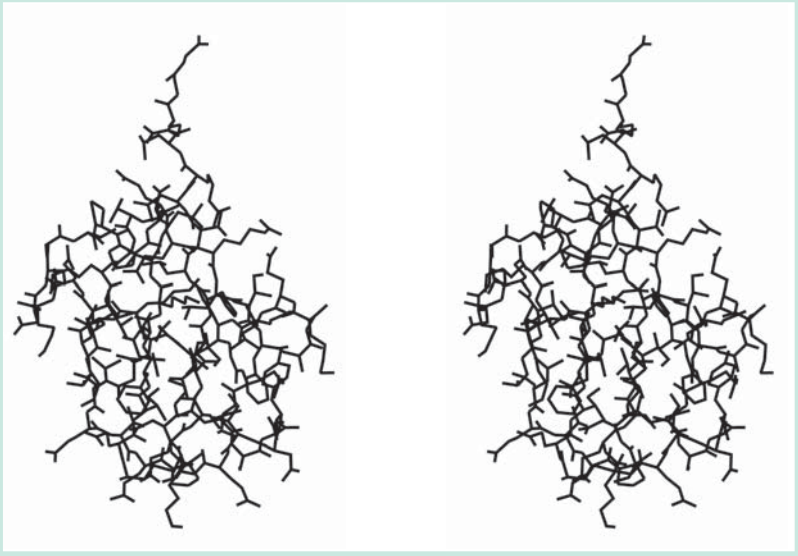
Eukaryotic cells degrade proteins within both the cytosol and lysosomes. Lysosomes apparently take up many proteins but have a preference for N-terminal KFERQ[132] and also for particular types of glycosylation (Chapter 20). Lysosomes act on many long-lived proteins.[133,133a] Once within the lysosomes, the proteins are broken down into amino acids with a half-life of ~8 minutes. During nutritional deprivation, the rate of uptake of proteins by lysosomes increases markedly. The same is true during certain developmental changes, for example, when a tadpole loses its tail.

Many short-lived proteins are degraded within the cytosol in ATP-dependent processes. A major process involves the small protein **ubiquitin** (Box 10-C).[134] Once "labeled" by formation of an isopeptide linkage to ubiquitin, a peptide is attacked by proteases in the **proteasome** complexes (Box 7-A, Chapter 12). There it is quickly degraded. Other proteases, most of which do not require ATP, are also present in the cytoplasm (Chapter 12). How do these enzymes as well as those within the lysosomes work together to produce a harmonious turnover of the very substance of our tissues? How is it possible that one protein has a long half life of many days while another lasts only an hour or two in the same cell? The answer seems to be that

BOX 10-C UBIQUITIN

The small 76-residue protein called ubiquitin[a-c] is probably present in all eukaryotic cells. Found in the nucleus, cytoplasm, cell surface membranes, and extracellular fluids, ubiquitin is often joined by isopeptide linkages from its C-terminal glycine to the ε-amino groups of lysine side chains of other proteins. Ubiquitin has one of the most conserved of all known amino acid sequences. No amino acid substitutions have been found among animal species and only three differences distinguish plant ubiquitins from that of humans. In its three-dimensional structure ubiquitin is compact, tightly hydrogen bonded, and roughly spherical. It contains an α helix, a mixed β sheet, and a distinct hydrophobic core.





Stereoscopic drawing of human ubiquitin. The C terminus is at the top. From Vijay-Kumar *et al.*[c] Courtesy of William J. Cook

Linkage of ubiquitin to other proteins occurs through the action of a ligase system which catalyzes four sequential reactions as shown in the accompanying equation. In step *a* a **ubiquitin activating enzyme** (E_1) forms a C-terminal acyl adenylate by reaction of ubiquitin (Ub) and ATP.[d,e] In step *b* a sulfhydryl group of the same enzyme then displaces the AMP part to form a thioester linkage to ubiquitin. The chemistry of the reaction is the same as that in Eq. 10-1. The activated ubiquitin is next transferred (step *c*) by transacylation to several **ubiquitin-conjugating enzymes** (E_2), also called ubiquitin-carrier proteins.[f-i] These in turn (step *d*) transfer the ubiquitin to amino groups of lysine side chains of target proteins (Prot-NH_2). A third protein, **ubiquitin-protein ligase** (E_3), is sometimes required for this last step. Most E_2 enzymes, acting without E_3, couple ubiquitin with amines or with small basic proteins whose cellular functions are still unclear. For example, an E_2 which is the product of the yeast gene CDC34 appears to function in the **cell cycle** (Fig. 11-15). Its absence from yeast is lethal[f,i,j] and it is clear that ubiquitin-mediated hydrolysis of the specialized proteins called **cyclins** is essential to operation of the cycle.[k,l]

The best understood function of ubiquitin is in nonlysosomal degradation of proteins.[j,m,n] Protein E_3 appears to select the proteins for degradation, binding them and catalyzing the formation of the isopeptide linkage to substrate. After one ubiquitin molecule has been attached, and while still held by E_3, a second activated ubiquitin is coupled to Lys 48 of the first ubiquitin. This process may continue until several molecules of ubiquitin are joined by Gly-Lys isopeptide linkages to form a **polyubiquitin** chain. Sometimes more than one lysine of the substrate becomes polyubiquitinated to form branched chains. A free α-NH_3^+ group on the protein being degraded is essential for rapid conjugation with ubiquitin and certain N-terminal residues such as arginine favor the conjugation and subsequent hydrolytic breakdown. Some proteins become attached to ubiquitin only after arginine is transferred

BOX 10-C (continued)

onto their N-termini from an aminoacyl-tRNA.[o]

Polyubiquitin chains serve as recognition markers that induce rapid hydrolysis of the marked proteins in the 2000 kDa 26S proteasome or **multicatalytic** protease.[p–s] This complex is discussed in Box 7-A and again in Chapter 12. During hydrolytic destruction of the protein the ubiquitin is released for reuse by **ubiquitin carboxyl-terminal hydrolases** or **isopeptidases** which cleave the thioester or isopeptide linkages that tie ubiquitin to proteins.[t,u]

While proteins may be modified to favor rapid ubiquitination, others may be altered to protect them from ubiquitination. For example, calmodulin produced from a cloned gene in bacteria is a good substrate for ubiquitination but within cells it appears to be protected by the posttranslational conversion of Lys 115 to trimethyllysine.[v]

About 10% of the histone H2A present in higher eukaryotes is ubiquitinated at Lys 119.[w] In the slime mold *Physarum* the content of ubiquitinated histones H2A and H2B changes rapidly during the various stages of mitosis. Apparently, ubiquitin must be cleaved from the histones to permit packaging of DNA into metaphase chromosomes and must become attached to the histones in some regions of the chromosomes to allow unfolding of the highly packed nucleosomes. A yeast enzyme that attaches ubiquitin to histones is encoded by the gene *RAD6*, which is required for DNA repair, sporulation, and other cellular processes. Terminal differentiation of reticulocytes to form erythrocytes involves loss of specific enzymes as well as of entire mitochondria. These processes also depend upon ubiquitin. Ubiquitin is one of the components of the paired helical filaments present in brains of persons with Alzheimer's disease.[x]

In most organisms there are two arrangements for ubiquitin genes. There is a cluster of up to 100 tandomly repeated genes whose transcription gives rise to polyubiquitin, a chain of ubiquitin molecules joined by Gly-Met linkages. These must be cleaved, perhaps by the same ubiquitin C-terminal hydrolase that releases ubiquitin from its conjugates.[y] Other ubiquitin genes are fused to genes encoding ribosomal proteins. The resulting polyproteins have the ribosomal peptides fused to the C termini of the ubiquitin sequences and must be proteolytically cleaved to give mature proteins.[z]

Recently a variety of modifiers of ubiquitin ligases have been discovered[aa,bb] as have ubiquitin-like domains in other proteins.[cc] These findings elucidate the complexity of the sorting of proteins and removal of improperly folded and otherwise defective proteins from the secretory pathway and return to the proteasomes in the cytosol.[dd,ee] They also suggest important roles for ubiquitination in a broad range of metabolic controls.

TABLE 10-1
Types of Biochemical Reactions with Ionic Mechanisms

1. Nucleophilic displacement, often via an addition–elimination sequence

A. 
(Examples: methyl-, glycosyl-transferases)

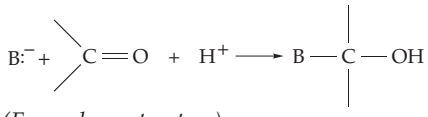
B. 
(Examples: esterases, peptidases)

C. 
(Examples: phosphatases, kinases, phosphomutases, ribozymes)

D. 
(Examples: sulfatases, sulfotransferases)

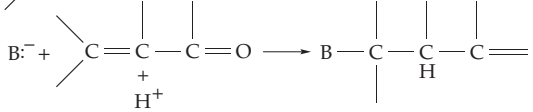
2. Addition

A. To polarized double bonds such as  and 
(This reaction most often occurs as a step in an enzymatic process e.g., formation of hemiacetals, hemiketals, hemimercaptals, carbinolamines)



(Example: mutarotase)

B. To double bond conjugated with  or 



(Examples: acyl-CoA, fumarate hydratases, aspartase)

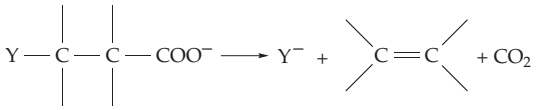
C. To isolated double bonds *(Example: oleate hydratase)* *(see p. 689)*

3. Elimination

A. and B. Precisely the opposite of *addition*

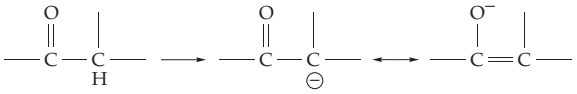
(Eliminations that are the reverse of type 2A are frequent steps in more complex enzyme mechanisms)

C. Decarboxylative elimination

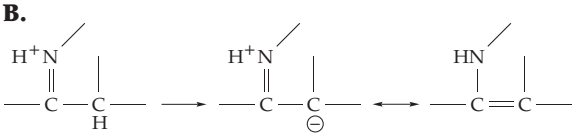


4. Formation of stabilized enolate anions and enamines

A.

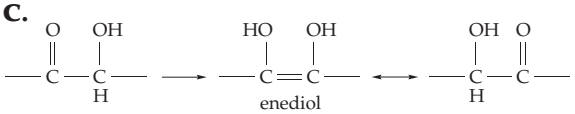


B.



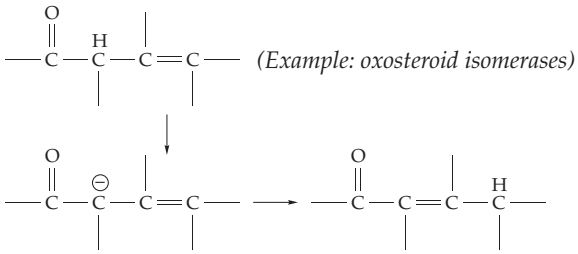
Isomerization reactions

C.



(Example: sugar isomerases)

D.

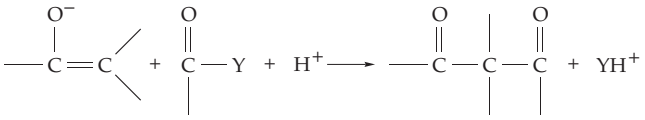


(Example: oxosteroid isomerases)

TABLE 10-1
(continued)

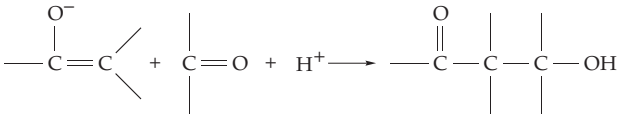
5. Stabilized enolate anions as nucleophiles: formation of carbon–carbon bonds (β condensation)

A. Displacement on a carbonyl group



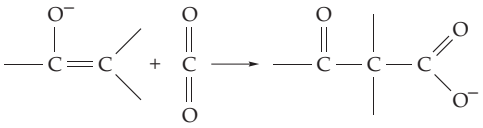
(Example: 3-Oxoacyl–CoA transferase (Y = —S—CoA)

B. Addition to a carbonyl group: aldol condensation



(Examples: aldolases, citrate synthases)

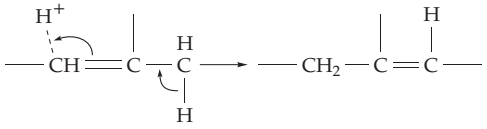
C. Addition to a carbon dioxide (β carboxylation); decarboxylation



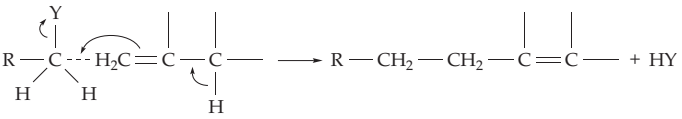
(Examples: phosphoenolpyruvate carboxylase, oxaloacetate decarboxylases)

6. Some isomerization and rearrangement reactions

A. Allylic rearrangement (1,3-proton shift)

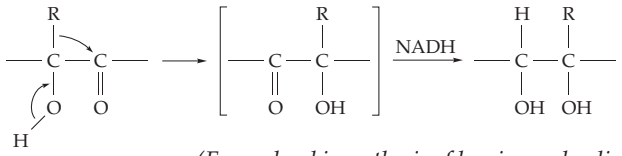


B. Allylic rearrangement with condensation



(Example: condensation of dimethylallyl pyrophosphate with isopentenyl pyrophosphate)

C. Rearrangements with alkyl or hydride ion shift



Glyoxalase

(Examples: biosynthesis of leucine and valine, xylose isomerase, glyoxalase)

the turnover rate of a protein is determined in large part by its sequence. Some proteins are tightly folded and have few bends on the outside that have sequences meeting the specificity requirements of intracellular proteolytic enzymes. These have long half lives. Other proteins may have external loops with sequences susceptible to attack or sequences that favor rapid reaction with the ubiquitin system or uptake into lysosomes. Prematurely terminated proteins and peptide fragments from partial degradation of proteins may tend to be unfolded at the N terminus and to be attacked rapidly.[128,135] Proteins that have undergone covalent modifications or oxidative damage also seem to be hydrolyzed rapidly.[136]

Regions rich in proline, glutamate, serine, and threonine (PEST regions) may be good substrates for Ca^{2+}-activated cytosolic proteases.[137] The ubiquitin system appears to act most slowly on a protein when the normal initiation amino acid methionine is present at the N terminus. For example, the half-life of β-galactosidase in yeast is over 20 hours. Replacement of the methionine with S, A, T, V, or G has little effect. However, replacement with other amino acids shortens the half-life as follows: I and E, 30 min.; Y and Q, 10 min.; F, L, D, and K, 3 min.; and R, 2 min.[138–140a]

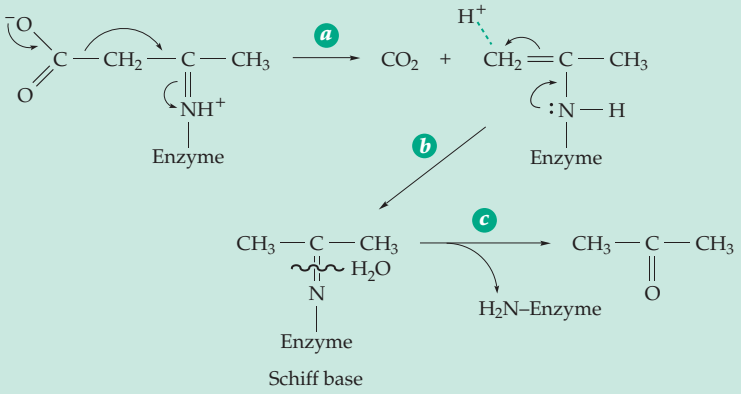
5. Turnover of Nucleic Acids

Because of its special role in carrying genetic information, DNA is relatively stable. An elaborate system of repair enzymes (Chapter 27) act to correct errors and to help DNA to preserve its genetic information. However, in some specialized cells such as those forming immunoglobulin, the DNA too undergoes major rearrangements (Chapter 31). RNA molecules are subject to extensive processing. This includes the conversion of RNA bases to modified forms, chain cleavages during maturation of ribosomal and transfer RNAs, cutting and splicing of gene transcripts to form mRNAs and finally degradation of the mRNA (Chapter 28). Proteins that serve as **RNA chaperones** assist in folding these molecules.[141]

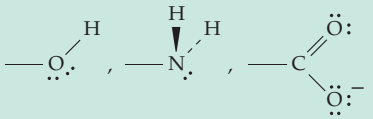
BOX 10-D DRAWING THOSE LITTLE ARROWS

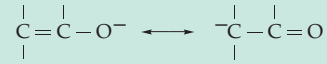
Organic mechanisms are often indicated by arrows that show the flow of electrons in individual steps of a reaction. Many errors are made by students on exams and even in published research papers. The arrows are often drawn backward, are too numerous, or do not clearly indicate electron flow. Here are some tips.

1 Always write a mechanism step-by-step. Never combine two steps (e.g., *a* and *b* at right) *in which electron flow occurs in opposite directions*. Notice that step *c*, the hydrolysis of a Schiff base, is also a two-step process. The reaction is a familiar one that is commonly indicated as shown here. However, this scheme does not show a detailed mechanism for step *c*.



2 Identify the **nucleophilic** and **electrophilic** centers before starting to write a mechanism. Oxygen, sulfur, and nitrogen atoms are usually nucleophilic, e.g., those in —OH, —NH_2, —COO^-, —SH, —OPO_3^{2-}, and enolate anions. The weak nucleophiles —OH and —SH may be converted into strong nucleophiles —O^- —S^- by removal of a proton by a basic group of an enzyme. The nonnucleophilic —NH_3^+ becomes the good nucleophile —NH_2 by loss of a proton. Nucleophilic centers contain unshared electron pairs. Nucleophiles are basic but the basicity, as indicated by proton binding (by the pK_a), is not necessarily proportional to nucleophilic strength (nucleophilicity). Enolate anions and enamines provide nucleophilic centers on carbon atoms, important in formation and cleavage of C—C bonds.





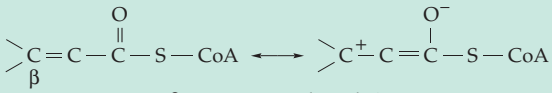
Enolate anion

Enamine

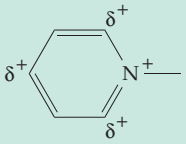
Groups with nucleophilic centers indicated by unshared electron pairs and/or negative charge.

Carbonyl

Protonated imine



α,β-Unsaturated acyl-CoA

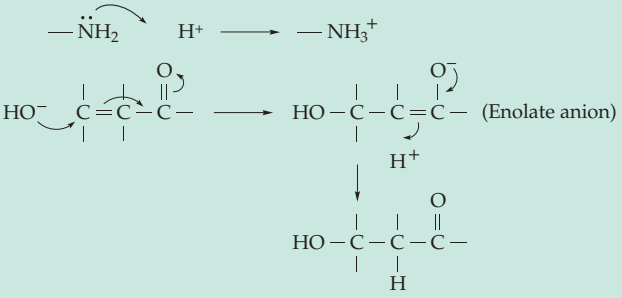


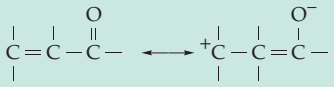
Some electrophilic centers are indicated by + or δ^+

Electrophilic centers include acidic hydrogen atoms, metal ions, the carbon atoms of carbonyl groups, and the β-carbon atoms of α, β unsaturated acids, ketones, or acyl-CoA derivatives. Highly polarized groups such as carbonyl and enamine generate electrophilic centers as indicated by the positive charges. They also affect more distant positions in conjugated systems, e.g., in α, β-unsaturated acyl-CoA derivatives, and in intermediates formed from thiamin diphosphate and pyridoxal phosphate.

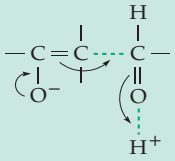
BOX 10-D (continued)

3 When an ionic organic reaction (the kind catalyzed by most enzymes) occurs a nucleophilic center joins with an electrophilic center. We use arrows to show the movement of pairs of electrons. The movement is always *away* from the nucleophile which can be thought of as "attacking" an electrophilic center. Notice the first step in the second example at right. The unsaturated ketone is polarized initially. However, this is not shown as a separate step. Rather, the flow of electrons from the double bond, between the α- and β-carbons into the electron-accepting C=O groups, is coordinated with the attack by the nucleophile. Dotted lines are often used to indicate bonds that will be formed in a reaction step, e.g., in an aldol condensation (right). Dashed or dotted lines are often used to indicate partially formed and partially broken bonds in a transition state, e.g., for the aldol condensation (with prior protonation of the aldehyde). However, *do not put arrows on transition state structures.*

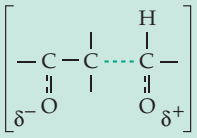




Polarized unsaturated ketone

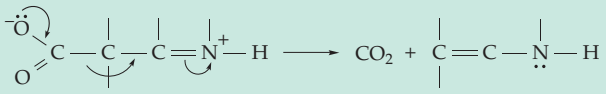


Aldol condensation



Transition state

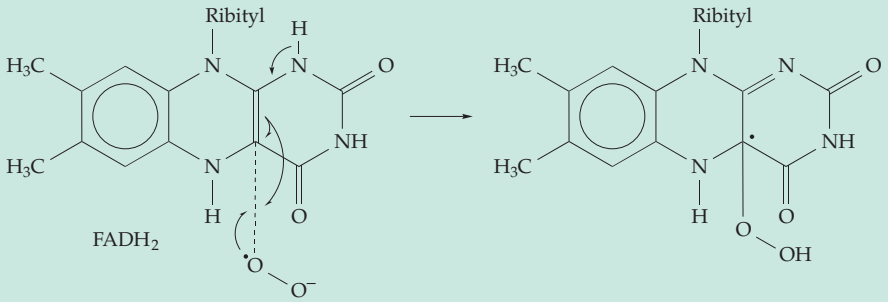
4 In a given reaction step all of the arrows must point the same way. *The arrows point into bonds that are forming* or toward atoms that will carry an unshared electron pair in the product. *Arrows originate from unshared electron pairs or from bonds that are breaking.*



All arrows point the same way

5 Never start an arrow from the same bond that another arrow is forming; i.e., electrons flow out of *alternate* bonds.

6 For reactions of radicals (homolytic reactions) arrows are used to indicate motion of single electrons rather than of electron pairs. It is desirable to use arrows with *half-heads*. For example, reaction of a superoxide radical ($\bullet O_2^-$) with $FADH_2$ could occur as follows:



Half-heads on arrows indicate one-electron movement

E. Classifying Enzymatic Reactions

The majority of enzymes appear to contain, in their active centers, only the side chains of amino acids. Most of the reactions catalyzed by these enzymes can be classified into a small number of types as is indicated in Table 10-1: (Type 1) **displacement** or **substitution** reactions in which one base or nucleophile replaces another, (Type 2) **addition** reactions in which a reagent adds to a double bond, and (Type 3) **elimination** reactions by which groups are removed from a substrate to create double bonds. Note that the latter are the reverse of addition reactions. Two other groups of reactions depend upon formation of transient **enolic forms**. These include (Type 4) **isomerases** and (Type 5) **lyases**, a large and important group of reactions that form or cleave carbon–carbon bonds. Finally, there is a group (Type 6) of **isomerization** and **rearrangement** reactions that do not appear to fit any of the foregoing categories. Another quite different group of enzyme-catalyzed reactions, which are considered in Chapter 16, function with the participation of free radical intermediates.

Biochemical displacement reactions include all of the hydrolytic reactions by which biopolymers are broken down to monomers as well as most of the reactions by which the monomers are linked together to form polymers. Addition reactions are used to introduce oxygen, nitrogen, and sulfur atoms into biochemical compounds and elimination reactions often provide the driving force for biosynthetic sequences. Complex enzymatic processes are often combinations of several steps involving displacement, addition, or elimination. The reactions involving formation or cleavage of C–C bonds are essential to biosynthesis and degradation of the various carbon skeletons found in biomolecules, while the isomerization reactions provide connecting links between the other kinds of reactions in the establishment of metabolic pathways.

In Chapters 12 and 13 the individual reactions of metabolism are classified into these types and the enzymes that catalyze them are described in some detail. The chemistry of coenzymes and metalloenzymes are presented systematically in Chapters 14 to 16, and in Chapter 17 the logic of the combining of individual reactions into metabolic sequences is considered. It is not necessary to read Chapters 12–16 in their entirety since much of their content is reference material. In the later chapters on metabolism, cross-references point out the discussions of individual enzymes in Chapters 12–16.

The following are topics that may be especially valuable to the student and which might be read initially: in Chapter 12, lysozyme (Section B,5), chymotrypsin (Section C,1), kinases (Section D,9), multiple displacement, reactions (Section G); in Chapter 13, imines (Section A,2), addition to C=C bonds (Section A, 4,5), beta cleavage and condensation (Section C); in Chapter 14, thiamin diphosphate (Section D), pyridoxal phosphate (Section E); in Chapter 15, NAD (Section A).

Study Questions

1. Outline in detail, using structural formulas, the enzyme-catalyzed reactions by which cells in the human body convert glyceraldehyde 3-phosphate into pyruvate.

2. Describe, using chemical structural formulas, the reactions involved in the breakdown of glycogen to glucose 1-phosphate and the synthesis of glycogen from glucose 1-phosphate.

3. Describe the reaction steps in gluconeogenesis by which pyruvate is converted into glyceraldehyde 3-phosphate.

4. Compare the reactions of pyruvate that give rise to the following three compounds. List coenzymes or electron-carriers involved in each case and indicate any intermediate compounds.
   a) Ethanol
   b) Lactic acid
   c) Acetyl-Coenzyme A

5. Mammalian sperm cells metabolize D-fructose preferentially as a source of energy. Fructose is formed in cells of the seminal vesicle from D-glucose via reduction to the sugar alcohol sorbitol using NADPH, followed by oxidation of sorbitol to fructose using NAD^+. The fructose concentration in human semen is about 12 mM, whereas the glucose concentration within cells is usually less than 1 mM. If the ratio $[NADPH]/[NADP^+]$ is 10^4 times higher than the ratio $[NADH]/[NAD^+]$, what is the minimum glucose concentration in cells that could allow formation of 12 mM fructose? The standard Gibbs energies of formation from the elements G^o_f in kJ/mol at 25°C are: D-glucose –917, D-fructose –915.

6. Outline the reactions by which glyceraldehyde 3-phosphate is converted to 3-phosphoglycerate with coupled synthesis of ATP in the glycolysis pathway. Show important mechanistic details.

7. Why can't acetyl CoA be converted to glucose in animals?

8. Describe the parallel reaction sequences between the citric acid cycle and the β oxidation pathway.

9. Contrary to legend, camels do not store water in their humps, which actually consist of a large fat deposit. How can these fat deposits serve as a source of water? Calculate the amount of water (liters) that can be produced by the camel from 500 g of fat. Assume for simplicity that the fat consists entirely of tripalmitin.

Study Questions

10. A little-known microorganism carries out the following net reaction in a series of enzymatic steps:

$$\text{heptanoyl CoA} + \text{CoASH} + \text{NAD}^+ + \text{FAD} + \text{H}_2\text{O} \rightarrow \text{pentanoyl CoA} + \text{acetyl CoA} + \text{NADH} + \text{FADH}_2 + \text{H}^+$$

The net result is exactly the same as that of the β oxidation pathway, but for this microorganism, the pathway is demonstrably different in that pentanal, $CH_3(CH_2)_3CHO$, is an intermediate in the sequence. Which enzyme(s) of the β oxidation pathway does this microorganism lack? Propose an enzymatic reaction to account for the formation of this intermediate and a series for its conversion to the acyl CoA. ATP is not required.

11. Most natural fatty acids are even-numbered. What is the product of the *final* thiolase reaction to form an odd-chain fatty acid? Give a brief explanation.

12. It has been calculated that an average man takes in 1.5 kg of solid food and 1.4 kg of water per day. He gives off 3.5 kg of waste and 0.75 kg of sweat. It would thus appear that he should be losing over 1 kg per day through normal activites. How do you account for the fact that his weight remains relatively constant?

13. Suppose that fatty acids, instead of being broken down in two carbon fragments, were metabolized in three carbon units. What product(s) would Dr. Knoop have observed in the urine of his experimental dogs?

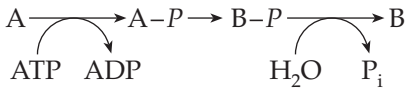
14. A renowned pharmacologist has announced the discovery of a new drug that specifically inhibits the fatty acid oxidation pathway within minutes of ingestion. The effects last for several hours only. The drug has no other effects on the subjects. The pharmacologist argues that this will increase athletic performance by shifting oxidative metabolism entirely to the more rapidly mobilized carbohydrate degradation pathway. Assume that the drug does work exactly as he suggests. Explain in a sentence or two how the drug would affect the performance of
    a) a sprinter in the 100 meter dash
    b) a long-distance runner in a marathon

15. Some bacteria use a "dicarboxylic acid cycle" to oxidize glyoxylate $OHC{-}COO^-$ to CO_2. The regenerating substrate for this cycle is acetyl-CoA. It is synthesized from glyoxylate by a complex pathway that begins with conversion of two molecules of glyoxylate to tartronic semialdehyde: $^-OOC{-}CHOH{-}CHO$. The latter is then dehydrogenated to D-glycerate. Write out a detailed scheme for the dicarboxylate cycle. Also indicate how glucose and other cell constituents can be formed from intermediates created in this biosynthetic pathway.

16. Write a balanced fermentation sequence by which glycogen can be converted rapidly to *sn*-glycerol 3-phosphate and pyruvate in insect flight muscle. How many molecules of ATP per glucose unit of glycogen will be formed?

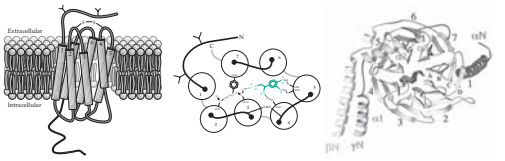
17. Show which parts (if any) of the citric acid cycle are utilized in each of the following reactions and what if any additional enzymes are needed in each case.
    a) Oxidation of acetyl-CoA to CO_2
    b) Catabolism of glutamate to CO_2
    c) Biosynthesis of glutamate from pyruvate
    d) Formation of propionate from pyruvate

18. a) If the Gibbs energy change $\Delta G'$ (pH 7) for the reaction A → B is +25 kJ/mol at 25°C, what would the ratio of [B]/[A] be at equilibrium?
    b) Suppose that the reaction were coupled to the cleavage of ATP as follows:



Suppose further that the group transfer potential ($-\Delta G'$) for the phospho group of A–*P* at 25°C, pH 7 is 12 kJ/mol and that the equilibrium constant for conversion of A–*P* to B–*P* is the same as that for conversion of A to B. Calculate the concentrations of A, B, A–*P* and B–*P* at equilibrium if the phosphorylation state ratio R_p is $10^4\ M^{-1}$.

19. This problem refers to the 13 meter climb described in Chapter 6, Study Question 14.
    a) Assuming that muscle accounts for 30% of total body mass, estimate the amounts (mmol/kg, total mmol, and total grams) of each of the following in their coenzyme forms: nicotinamide, pantothenic acid, thiamin. You may be able to obtain rough estimates from the vitamin content of pork.
    b) Calculate how many times, on the average, each molecule of nicotinamide would undergo reduction and re-oxidation (i.e., turn over) during the climb. Do the same for pantothenic acid (cycling between acyl-CoA and free CoA forms) and for thiamin through its catalytic cycles.

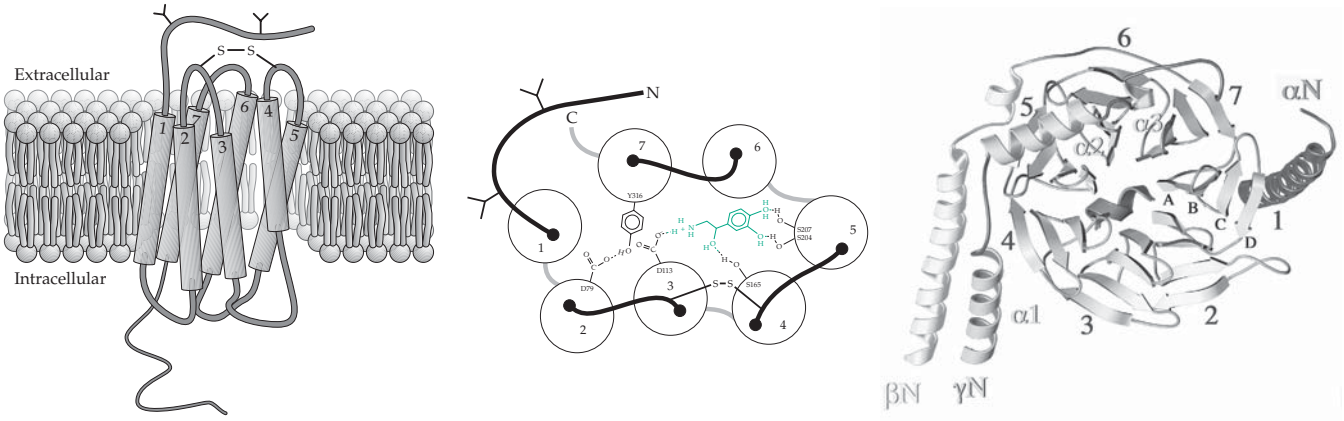


Much of the control of cellular metabolism is accomplished by hormones and other molecules that bind to receptor proteins embedded in the plasma membrane. Left: Many receptors are seven-helix transmembrane proteins, the best known being the light receptors of the rhodopsin family (Chapter 23). Center: A related adrenergic receptor, viewed here from the extracellular side, has a molecule of the hormone adrenaline (green) bound in the center (Fig. 11-6). Right: These receptors interact with GTP-hydrolyzing "G proteins," which pass signals, often for short periods of time, to enzymes and other proteins. One structural domain of a G protein (Fig. 11-7C) shown here contains a β propeller domain which binds to the Ras-like domain of the α subunit. A few residues of the latter are visible in the center of this image.

Contents

The Regulation of Enzymatic Activity and Metabolism

11



Living cells must operate with controls that provide a stable environment and a relatively constant supply of materials needed for biosynthesis and for meeting the energy needs of cells. They must also be responsive to changes in their environment and must be able to undergo mitosis and reproduce when appropriate. The necessary control of metabolism and of growth is accomplished largely through mechanisms that regulate the locations, the amounts, and the catalytic activities of enzymes. The purpose of this chapter is to summarize these control mechanisms and to introduce terminology and shorthand notations that will be used throughout this book. Many of the **control elements** considered are summarized in Fig. 11-1.

A. Pacemakers and the Control of Metabolic Flux

Metabolic control can be understood to some extent by focusing attention on those enzymes that catalyze rate-limiting steps in a reaction sequence. Such **pacemaker enzymes**[1–4] are often involved in reactions that determine the overall respiration rate of a cell, reactions that initiate major metabolic sequences, or reactions that initiate branch pathways in metabolism. Often the first step in a unique biosynthetic pathway for a compound acts as the pacemaker reaction. Such a reaction may be described as the **committed step** of the pathway. It usually proceeds with a large decrease in Gibbs energy and tends to be tightly controlled. Both the rate of synthesis of the enzyme protein and the activity of the enzyme, once it is formed, may be inhibited by **feedback inhibition** which occurs when an end product of a biosynthetic pathway accumulates and inhibits the enzyme. Enzyme activity may also be turned on or off by the effect of a hormone, by some other external stimulus, or by internal mechanisms that sense the metabolic state of the cell. Enzymes, other than the pacemaker, that catalyze reactions in a pathway may not be regulated and may operate at a steady state close to equilibrium.

If conditions within a cell change, a pacemaker reaction may cease to be rate limiting. A reactant plentiful in one circumstance may, in another, be depleted to the point that the rate of its formation from a preceding reaction determines the overall rate. Thus, as we have seen in Chapter 10, metabolism of glucose in our bodies occurs through the rapidly interconvertible phosphate esters glucose 6-phosphate and fructose 6-phosphate. The pacemaker enzyme in utilization of glucose or of glycogen is often **phosphofructokinase** (Fig. 11-2, step *b*) which catalyzes further metabolism of fructose 6-phosphate. However, if metabolism by this route is sufficiently rapid, the rate of formation of glucose 6-phosphate from glucose catalyzed by **hexokinase (**Fig. 11-2, step *a*) may become rate limiting.

Some catabolic reactions depend upon ADP, but under most conditions its concentration is very low because it is nearly all phosphorylated to ATP. Reactions utilizing ADP may then become the rate-limiting pacemakers in reaction sequences. Depletion of a reactant sometimes has the effect of changing the whole pattern of metabolism. Thus, if oxygen is unavailable to a yeast, the reduced coenzyme NADH accumulates and reduces pyruvate to ethanol plus CO_2 (Fig. 10-3). The result is a shift from oxidative metabolism to fermentation.

Pacemaker enzymes are often identified by the fact that the measured **mass action ratio**, e.g., for the reaction A + B → P + Q ,the ratio [P][Q]/[A][B], is far

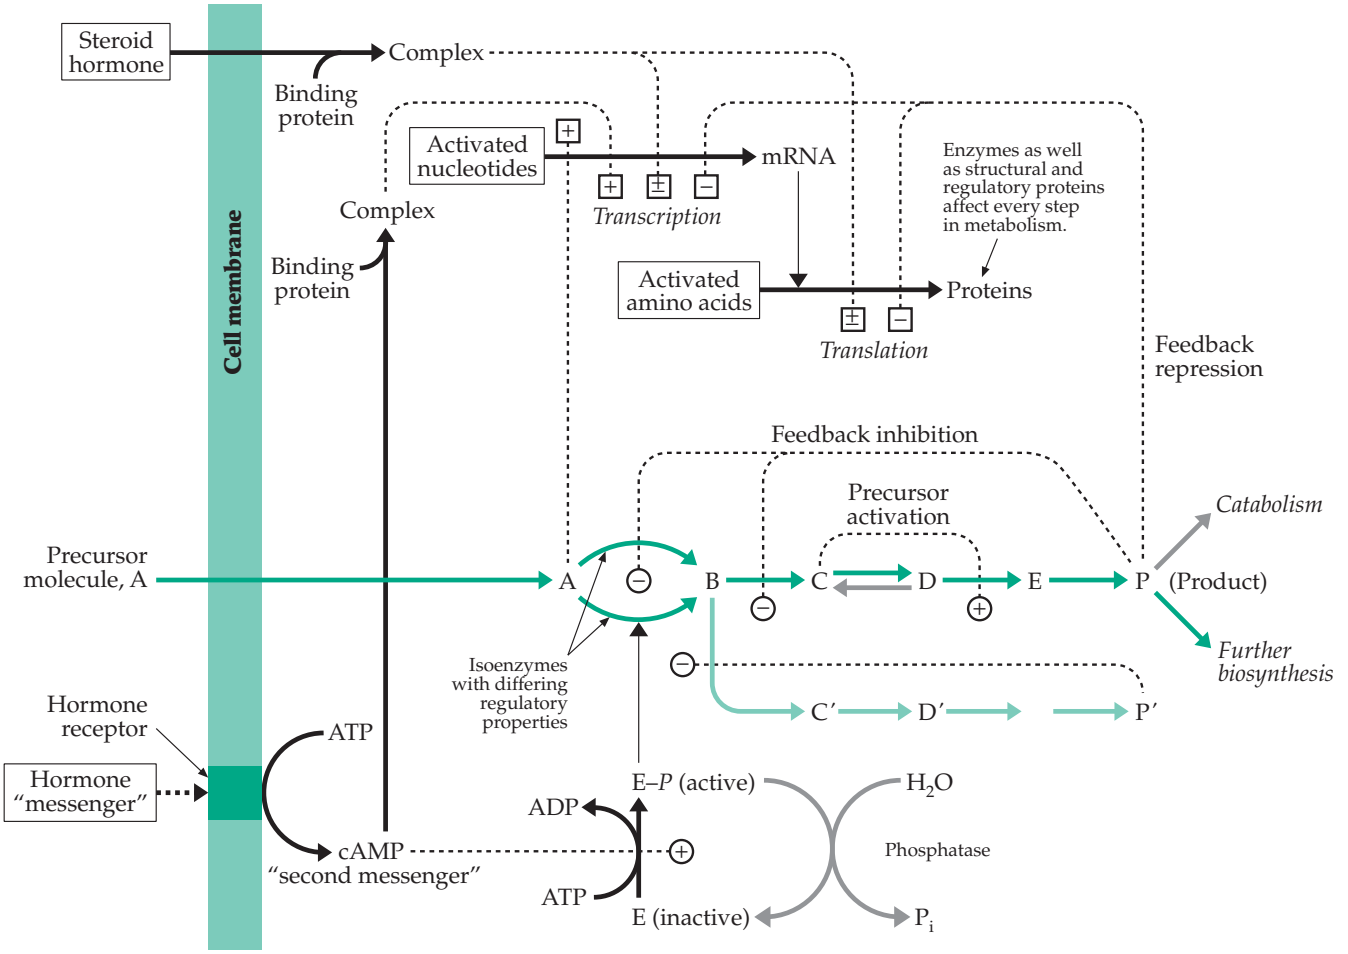


Figure 11-1 Some control elements for metabolic reactions. *Throughout the book modulation of the activity of an enzyme by allosteric effectors or of transcription and translation of genes is indicated by dotted lines from the appropriate metabolite.* The lines terminate in a minus sign for inhibition or repression and in a plus sign for activation or derepression. Circles indicate direct effects on enzymes, while boxes indicate repression or induction of enzyme synthesis.

from that predicted by the known equilibrium constant for the reaction. Another approach to identifying a pacemaker enzyme is to inhibit it and observe resulting changes in steady-state metabolite concentrations.[5] If the pacemaker enzyme is inhibited, its substrate and other compounds preceding the step catalyzed by this enzyme will accumulate. At the same time the concentrations of products of the pacemaker reaction will drop as a result of their relatively more rapid removal by enzymes catalyzing subsequent steps. However, conclusions drawn by this approach may sometimes be erroneous.[6]

In spite of its usefulness, the pacemaker concept is oversimplified. It is often impossible to identify a specific pacemaker enzyme. When both catabolism and biosynthesis occur (e.g., as in the scheme in Fig. 11-2) it may be more useful to model the entire system with a computer than to try to identify pacemakers.[7,8] It is also important to realize that reaction rates may be determined by the rate of diffusion of a compound through a membrane. Thus, membrane transport processes can serve as pacemakers.

A general approach to analysis of complex metabolic pathways or to cell growth was introduced by Savageau,[9–11] and similar approaches have been followed by others.[3,12–19] They emphasize the **flux** of material through a pathway under steady-state conditions and recognize that every enzyme in a sequence can have some effect on the overall rate. Consider a chain of enzymes E_1 to E_n acting on substrate S_0, which is converted via substrates S_1, S_2 ... S_{n-1} into product S_n:

$$S_0 \xrightarrow{E_1} S_1 \xrightarrow{E_2} S_2 \xrightarrow{E_3} S_3 \cdots \longrightarrow S_{n-1} \xrightarrow{E_n} S_n \qquad (11\text{-}1)$$

The flux $F = d[S_n]/dt$ is a constant. If the concentration of E_i were to change by an infinitesimal amount a corresponding change in F might be observed. The

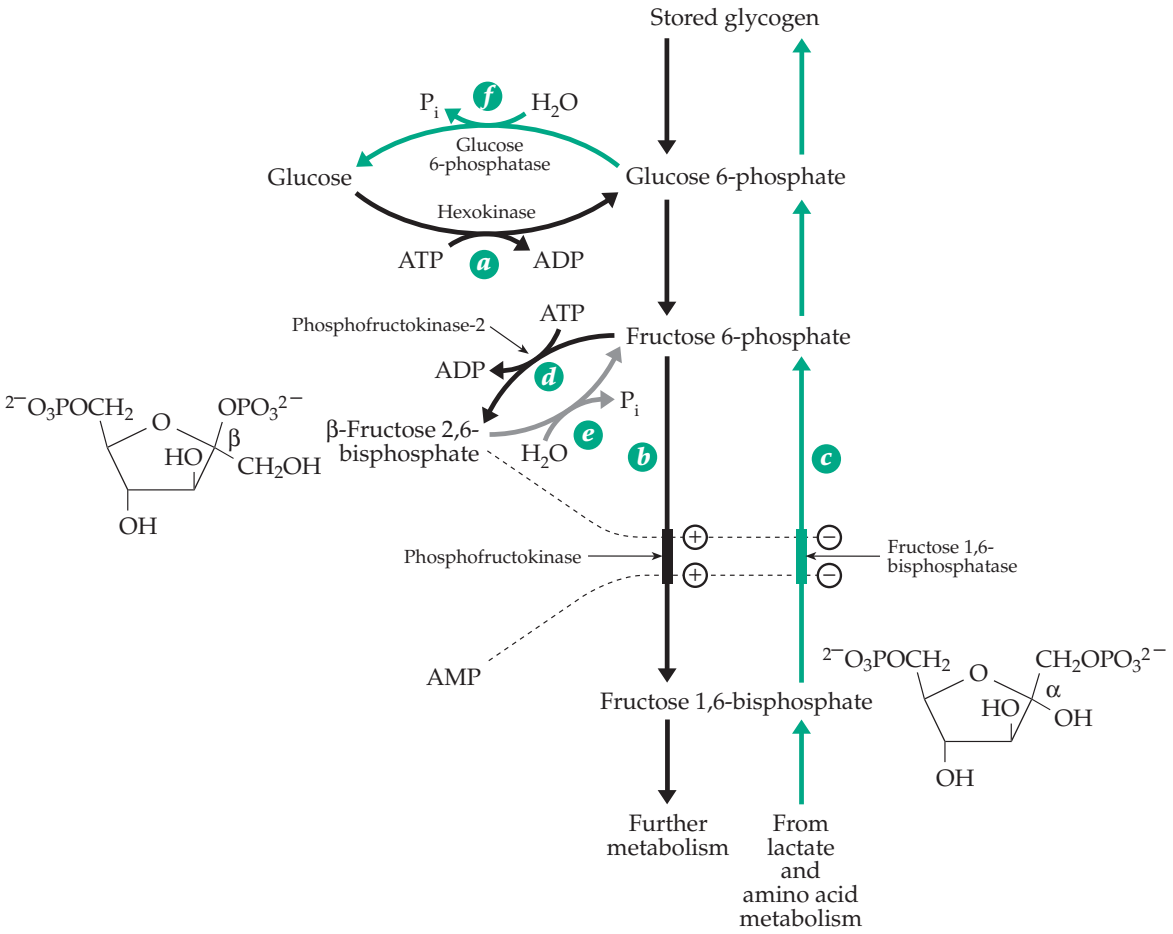

Figure 11-2 Roles of phosphofructose kinase and fructose 1,6-bisphosphatase in the control of the breakdown (⟶) and storage (⟶) of glycogen in muscle. The uptake of glucose from blood and its release from tissues is also illustrated. The allosteric effector fructose 2,6-bisphosphate (Fru-2,6-P_2) regulates both phosphofructokinase and fructose 2,6-bisphosphatase. These enzymes are also regulated by AMP if it accumulates. The activity of phosphofructokinase-2 (which synthesizes Fru-2,6-P_2) is controlled by a cyclic AMP-dependent kinase and by dephosphorylation by a phosphatase.

ratio of the change in flux to the change in $[E_i]$ is the sensitivity coefficient Z_i:

$$Z_i = \frac{dF/F}{d[E_i]/[E_i]} = \frac{d \ln F}{d \ln[E_i]} \tag{11-2}$$

The sensitivity coefficient can range from 1 for a pacemaker enzyme to almost zero for a very active enzyme that does not significantly limit the flux. The sum of Z_1 to Z_n is equal to 1:

$$\sum_{n}^{i=1} Z_i = 1 \tag{11-3}$$

Not only can the concentration $[E_i]$ change but also allosteric effectors can alter the activity. Kacser and Burns defined this in terms of a **controllability coefficient κ**, the ratio of the logarithmic change in velocity to the change in the concentration of an effector:

$$\kappa = d \ln v / d \ln [P] \tag{11-4}$$

It follows that the logarithmic change in flux $d \ln F$ can be related to the change in effector concentration [P] in the following way:

$$d \ln F = Z_i \kappa d \ln [P] \tag{11-5}$$

From this equation we see that for the flux to be sensitively dependent upon [P], both Z_i and κ must be reasonably large. This is exactly the case for many of the enzymes that have been identified as pacemakers. This approach can be applied to many aspects of metabolic control including cell growth.[20]

B. Genetic Control of Enzyme Synthesis

All cellular regulatory mechanisms depend upon the synthesis of proteins, that is, upon the expression of genetic information. Within a given cell many genes are transcribed continuously but others may remain unexpressed. The rates of both transcription and degradation of mRNA are regulated, as are the rates of synthesis of enzymes on the ribosomes in the cytoplasm and the rates of protein turnover. Although a single copy of a gene in each member of a pair of chromosomes is often adequate, there are situations in which extra copies of part of the DNA of a cell are formed. Such **gene amplification**, which is dealt with further in Chapter 27, provides the possibility for very rapid synthesis of an enzyme or other protein. It often happens in highly specialized cells such as those of the silkworm's silk glands which must make enormous amounts of a small number of proteins.[21]

1. One Gene or Many?

Many enzymes exist within a cell as two or more **isoenzymes**, enzymes that catalyze the same chemical reaction and have similar substrate specificities. They are not isomers but are distinctly different proteins which are usually encoded by different genes.[22,23] An example is provided by aspartate aminotransferase (Fig. 2-6) which occurs in eukaryotes as a pair of cytosolic and mitochondrial isoenzymes with different amino acid sequences and different isoelectric points. Although these isoenzymes share less than 50% sequence identity, their internal structures are nearly identical.[24–27] The two isoenzymes, which also share structural homology with that of *E. coli*,[28] may have evolved separately in the cytosol and mitochondria, respectively, from an ancient common precursor. The differences between them are concentrated on the external surface and may be important to as yet unknown interactions with other protein molecules.

Isoenzymes are designated in various ways. They are often *numbered in the order of decreasing electrophoretic mobility* at pH 7 to 9: Most enzymes are negatively charged in this pH range and the one that migrates most rapidly toward the anode is numbered one. This is the same convention used in the electrophoresis of blood proteins (e.g. see Box 2-A).

Lactate dehydrogenase exists in the cytoplasm of humans and most animals as *five forms* which are easily separable by electrophoresis and are evenly spaced on electropherograms.[8] This enzyme is a tetramer made of two kinds of subunits. Isoenzyme 1, which has the highest electrophoretic mobility, consists of four identical type B subunits. The slowest moving tetramer (isoenzyme 5) consists of four type A subunits, while the other three forms, AB_3, A_2B_2, and A_3B, contain both subunits in different proportions. The two subunits are encoded by separate genes which are expressed to different extents in different tissues. Thus, heart muscle and liver produce mainly subunit B, while skeletal muscle produces principally subunit A. A third subunit type (C) is found only in the testes.[29]

Why do cells produce isoenzymes? One reason may be that enzymes with differing kinetic parameters are needed.[30] Substrate concentrations may vary greatly between different tissues; between different subcellular compartments; and at different developmental stages of an organism. While the need for various isoenzymes of lactate dehydrogenase is not well understood,[31] it is easier to understand the roles of the multiple forms of hexokinase, the enzyme that catalyzes the reaction of step *a* in Fig. 11-2. The brain enzyme has a high affinity for glucose (K_m = 0.05 mM). Thus, it is able to phosphorylate glucose and to make that substrate available to the brain for metabolism, even if the glucose concentration in the tissues falls to low values.[31a] On the other hand, **glucokinase**, the hexokinase isozyme found in liver, has a much higher K_m of ~10 mM. It functions to remove excess glucose from blood, whose normal glucose content is ~5.5 mM. Glucokinase reaches its maximal activity only when the glucose concentration becomes much higher.[32] This happens after a meal when the absorbed glucose passes through the portal circulation directly to the liver.

Another important source of variation in enzymes as well as in other proteins is **alternative splicing** of mRNA.[33] For example, transcription of the mouse α-amylase gene in the salivary gland starts at a different site (promoter) than does transcription in the liver. The two common isoforms of the insulin receptor (Fig. 11-11) arise because a 36-nucleotide (12-amino acid) exon is spliced out of the mRNA for the shorter protein. Isoenzymes of aldolase[34] and of many other proteins are formed in a similar manner. **Frame-shifting** during protein synthesis (Chapter 29) and also post-translational alterations may give rise to additional modified forms. They are often synthesized in relatively small amounts but may be essential to the life of the cell. In addition, genetic variants of almost any protein will be found in any population. These often differ in sequence by a single amino acid.

2. Repression, Induction, and Turnover

The synthesis of some enzymes is referred to as **constitutive**, implying that the enzyme is formed no matter what the environmental conditions of the cell. For example, many bacteria synthesize the enzymes required to catabolize glucose under all conditions of growth. Other enzymes, known as **inducible**, are often produced only in small amounts. However, if

cells are grown in specific inducing conditions for these enzymes, they are synthesized in larger quantities. For example, when *E. coli* is cultivated in the presence of lactose, several of the enzymes required for the catabolism of that disaccharide are formed. Synthesis of these enzymes is normally **repressed**. The genes which code for them are kept turned off through the action of protein **repressors** which bind to specific sites on the DNA and block transcription of the genes that they control (Fig. 11-1). Repressors have allosteric properties; in one conformation they bind tightly to DNA but in another they do not bind. For example, the free tryptophan repressor binds to DNA only weakly, but if a high concentration of tryptophan develops within the cell the tryptophan binds to an allosteric site on the repressor protein (Fig. 5-35). This changes the conformation to one that binds tightly to the appropriate control sequence in the DNA. In the case of lactose catabolism the free repressor binds to control sequences in the DNA until the **inducer**, allolactose (Chapters 4 and 28), binds at an allosteric site. This decreases the affinity of the repressor for DNA and the controlled genes are **derepressed**. There are also many protein **transcription factors** that have a positive effect, binding to DNA and promoting transcription of specific genes.

Synthesis of many enzymes is repressed most of the time. The appearance of an enzyme at a particular stage in the life of an organism as well as the differing distributions of isoenzymes within differentiated tissue result from derepression. The control of enzyme synthesis may also be exerted during the splicing of transcripts and at the translational level as well. These control mechanisms are often relatively slow, with response times of hours or even days. However, effects on the synthesis of some hormones, such as insulin (Section G), may be observed within a few minutes.

Genetic factors influence the rate of not only synthesis of proteins but also their breakdown, i.e., the rate of turnover. As we have seen in Chapter 10, some enzymes are synthesized as inactive proenzymes which are later modified to active forms, and active enzymes are destroyed, both by accident and via deliberate hydrolytic pathways. Protein **antienzymes** may not only inhibit enzymes but may promote their breakdown.[35] An example is the antienzyme that controls ornithine decarboxylase, a key enzyme in the synthesis of the polyamines that are essential to growth.[36,37] As with all cell constituents, the synthesis of enzymes and other proteins is balanced by degradation.

3. Differences among Species

Catalytic mechanisms of enzymes have usually been conserved throughout evolution, and certain residues in an enzyme may be invariant among many species. However, there are usually many differences in the distribution of amino acid residues on the surface of the proteins. Since changes in the surface shape of a protein molecule may alter the sensitivity to a potential allosteric effector, very different regulatory properties are sometimes found between species.

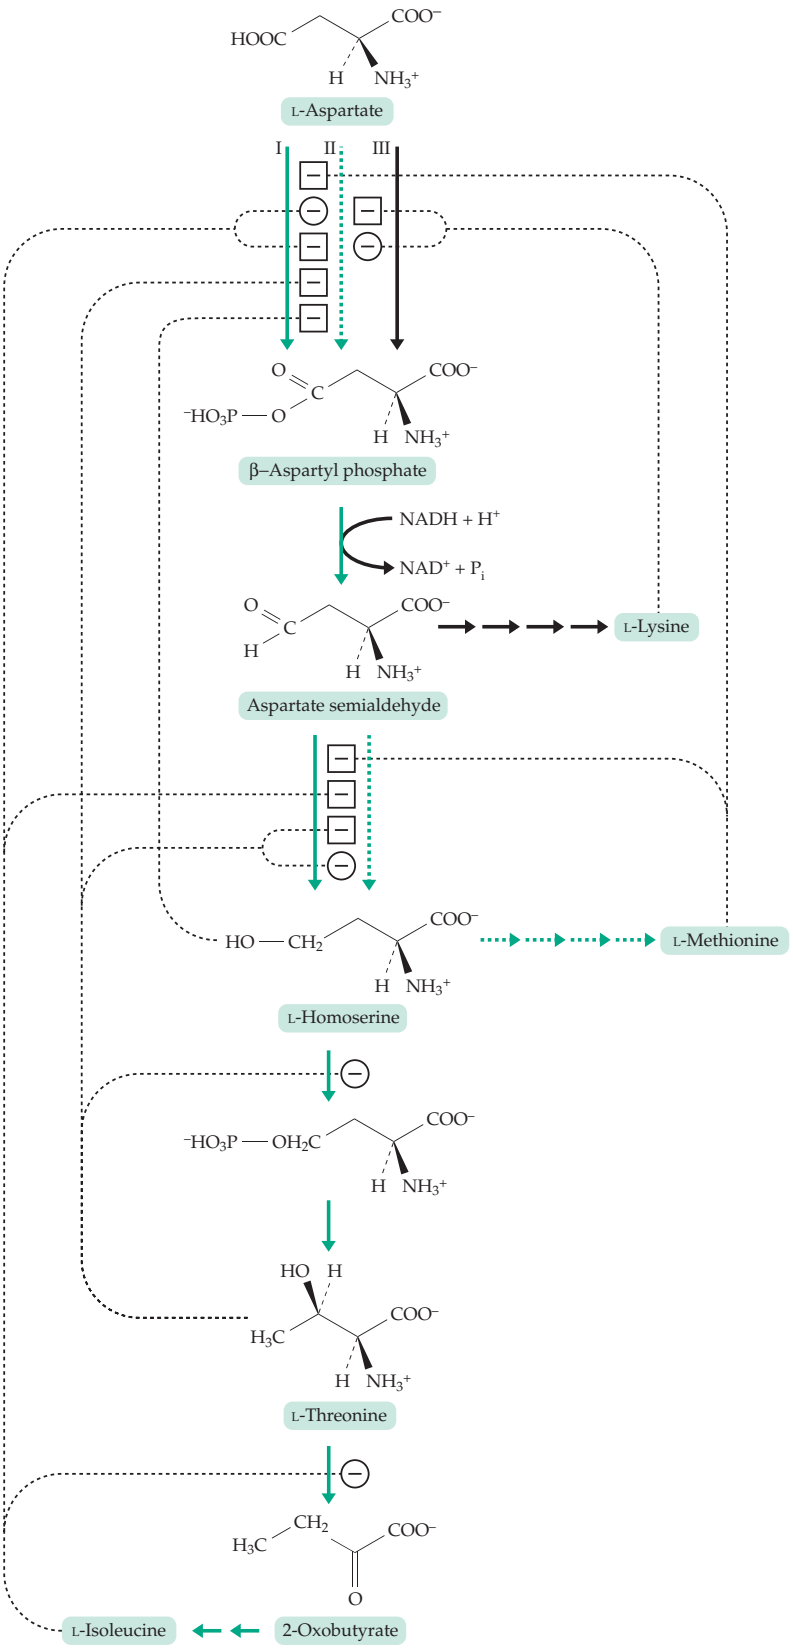
C. Regulation of the Activity of Enzymes

Some regulation of metabolism is provided by the kinetic properties of the enzymes. Thus, the value (mol/l) of the Michaelis constant K_m for an enzyme is usually low if the substrate normally occurs in very low concentration. It is likely to be higher if the enzyme acts on an abundant substrate. A tightly bound product of an enzymatic reaction will be released slowly from an enzyme if the product concentration within the cell is too high. However, while some regulation of metabolism is provided in such simple ways, the rapid changes that result from stimulation by hormones or by nerve impulses depend upon additional specific regulatory mechanisms that are discussed in the following sections.

1. Allosteric Control

Probably the most common and widespread control mechanisms in cells are **allosteric inhibition** and **allosteric activation**. These mechanisms are incorporated into metabolic pathways in many ways, the most frequent being **feedback inhibition**. This occurs when an end product of a metabolic sequence accumulates and turns off one or more enzymes needed for its own formation. It is often *the first enzyme unique to the specific biosynthetic pathway for the product that is inhibited.* When a cell makes two or more isoenzymes, only one of them may be inhibited by a particular product. For example, in Fig. 11-1 product P inhibits just one of the two isoenzymes that catalyzes conversion of A to B; the other is controlled by an enzyme modification reaction. In bacteria such as *E. coli*, three isoenzymes, which are labeled I, II, and III in Fig. 11-3, convert aspartate to β-aspartyl phosphate, the precursor to the end products threonine, isoleucine, methionine, and lysine. Each product inhibits only one of the isoenzymes as shown in the figure.

Feedback can also be positive. Since AMP is a product of the hydrolysis of ATP, its accumulation is a signal to *activate* key enzymes in metabolic pathways that generate ATP. For example, AMP causes allosteric activation of glycogen phosphorylase, which catalyzes the first step in the catabolism of glycogen. As is shown in Fig. 11-5, the allosteric site for AMP or IMP binding is more than 3 nm away from the active site. Only a



subtle conformational change accompanies binding of IMP.[38] However, ^{31}P NMR studies indicate that binding of the activator may induce a change in the state of protonation of the phosphate group of the coenzyme pyridoxal phosphate at the active site as explained in Chapter 12.

A second pattern of allosteric control may be referred to as **precursor activation** or feed**-**forward control. A metabolite acting as an allosteric effector turns on an enzyme that either acts directly on that metabolite or acts on a product that lies further ahead in the sequence. For example, in Fig. 11-1, metabolite C activates the enzyme that catalyzes an essentially irreversible reaction of compound D. An actual example is provided by glycogen synthase, whose inactive "dependent" or D form is activated allosterically by the glycogen precursor glucose 6-phosphate.[39] See also phosphorylase kinase (Section 2).

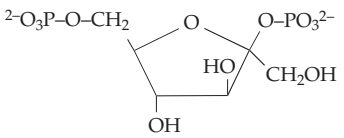
Regulatory subunits. Some enzymes consist not only of catalytic subunits, which contain the active sites, but also of **regulatory subunits**. The latter bind to the catalytic subunits and serve as allosteric modifiers. The binding of inhibitors or activators to specific sites on the regulatory subunits induces conformational changes in these subunits, altering their interaction with the catalytic subunits. A well-known example is aspartate carbamoyltransferase (ACTase) from *E. coli* (Fig. 7-20).[40–42] Its regulatory subunits carry binding sites for cytidine triphosphate (CTP), which acts as a specific allosteric inhibitor of the enzyme. The significance of this fact is that ACTase catalyzes the first reaction specific to the pathway of synthesis of pyrimidine nucleotides (Chapter 25). CTP is an end product of that pathway and exerts feedback inhibition on the enzyme that initiates its synthesis. ATP also binds to the regulatory subunits and causes inhibition of the enzyme.

Figure 11-3 Feedback inhibition of enzymes involved in the biosynthesis of threonine, isoleucine, methionine, and lysine in *E. coli*. These amino acids all arise from L-aspartate, which is formed from oxaloacetate generated by the biosynthetic reactions of the citric acid cycle (Fig. 10-6). ⊖ Allosteric inhibition. ⊟ Repression of transcription of the enzyme or of its synthesis on ribosomes.

In the presence of CTP the binding of the substrates is cooperative, as would be anticipated if there is a two-state conformational equilibrium involving the catalytic subunits. This would be similar to the case depicted in Fig. 9-13 except that trimers rather than dimers are involved and the inhibitor is a part of the regulatory subunit and is controlled by binding of CTP.

Binding of ATP to ACTase decreases the cooperativity in substrate binding, again as predicted for a two-state model. However, as suggested by its structure, this enzyme system is more complex, as also indicated by the observed anticooperative binding of the activator CTP. X-ray studies show that binding of ligands causes a movement along subunit interfaces as well as localized conformational changes within the subunits. These are reminiscent of the changes seen upon binding of oxygen to hemoglobin (Fig. 7-25).

Glycolysis and gluconeogenesis. The highly regulated enzymes phosphofructokinase and fructose 1,6-bisphosphatase catalyze steps *b* and *c* of the reactions in Fig. 11-2, reactions that control glucose metabolism in cells. These enzymes have been studied for many years but the important allosteric effector **β-fructose 2,6-bisphosphate** was not discovered until 1980.[43–46]



β-Fructose
2,6-bisphosphate

This compound, which is formed from fructose 6-phosphate by a new enzyme, **phosphofructokinase-2** (also called fructose 6-phosphate 2-kinase) in step *d*, Fig. 11-2 activates phosphofructokinase allosterically. At the same time it inhibits fructose 1,6-bisphosphatase, an enzyme required for reversal of glycogen breakdown, that is, for the conversion of various metabolites arising from amino acids into glycogen (Fig. 11-2, step *c*).[46a] These same two key regulated enzymes are also affected by many other metabolites. For example, ATP in excess inhibits phosphofructokinase, decreasing the overall rate of glucose metabolism and consequently of ATP production. Citrate, which is exported from mitochondria when carbohydrate metabolism is excessive, inhibits the same enzyme. On the other hand, AMP acts together with fructose 2,6-bisphosphate to activate the pathway for glycogen breakdown and to inhibit that for its synthesis (Fig. 11-2). The concentration of the regulator fructose 2,6-bisphosphate is controlled by mechanisms that are discussed in the following section.

2. Covalent Modification by Phosphorylation and Dephosphorylation

Rapid alteration of the activities of enzymes is often accomplished by **reversible covalent modification**.[39,47] Many different modification reactions are known (Table 11-1) and there are doubtless many more to be discovered. Probably the most widespread and certainly the most studied is **phosphorylation**, the transfer of a phospho group from ATP or other suitable donor to a side chain group on the enzyme. An example is the phosphorylation by ATP of hydroxyl groups of specific serine residues in the two enzymes glycogen phosphorylase and glycogen synthase. These modifications are accomplished through a series or **cascade** of reactions initiated by the binding of hormones to cell surface receptors or by nerve impulses as is shown in Fig. 11-4. In the absence of such a stimulus, glycogen phosphorylase is present in its unphosphorylated or *b* form. Although this form can be activated allosterically by AMP, it is normally nearly inactive. When an appropriate hormone binds to the cell surface a cascade of reactions, as described in Section D, leads to activation of an enzyme called **phosphorylase kinase**.[47a] This enzyme transfers a phospho group from ATP to the –OH group of the side chain of Ser 14 in each subunit (Fig. 11-4, left center), converting the enzyme into the active glycogen-degrading **phosphorylase *a***. This switches the cellular metabolism from that designed to deposit the storage polysaccharide glycogen to one that degrades glycogen to provide the cell with energy. Serine 14 of glycogen phosphorylase is located adjacent to the allosteric AMP binding site (Fig. 11-5) and is surrounded by positively charged arginine and lysine side chains. Phosphorylation induces a rearrangement of hydrogen bonds involving these residues and in some way sends an appropriate signal to the active site. It also increases the affinity for AMP in the allosteric sites.[48,48a] Phosphorylase kinase is allosterically activated by AMP, a product of its action – a feed-forward activator.

The control of glycogen phosphorylase by the phosphorylation–dephosphorylation cycle was discovered in 1955 by Edmond Fischer and Edwin Krebs[50] and was at first regarded as peculiar to glycogen breakdown. However, it is now abundantly clear that similar reactions control most aspects of metabolism.[51] Phosphorylation of proteins is involved in control of carbohydrate, lipid, and amino acid metabolism; in control of muscular contraction, regulation of photosynthesis in plants,[52] transcription of genes,[51] protein syntheses,[53] and cell division; and in mediating most effects of hormones.

Protein kinases and cyclic AMP. Phosphorylase kinase is one of hundreds of different protein kinases which differ in specificity toward their substrates, in

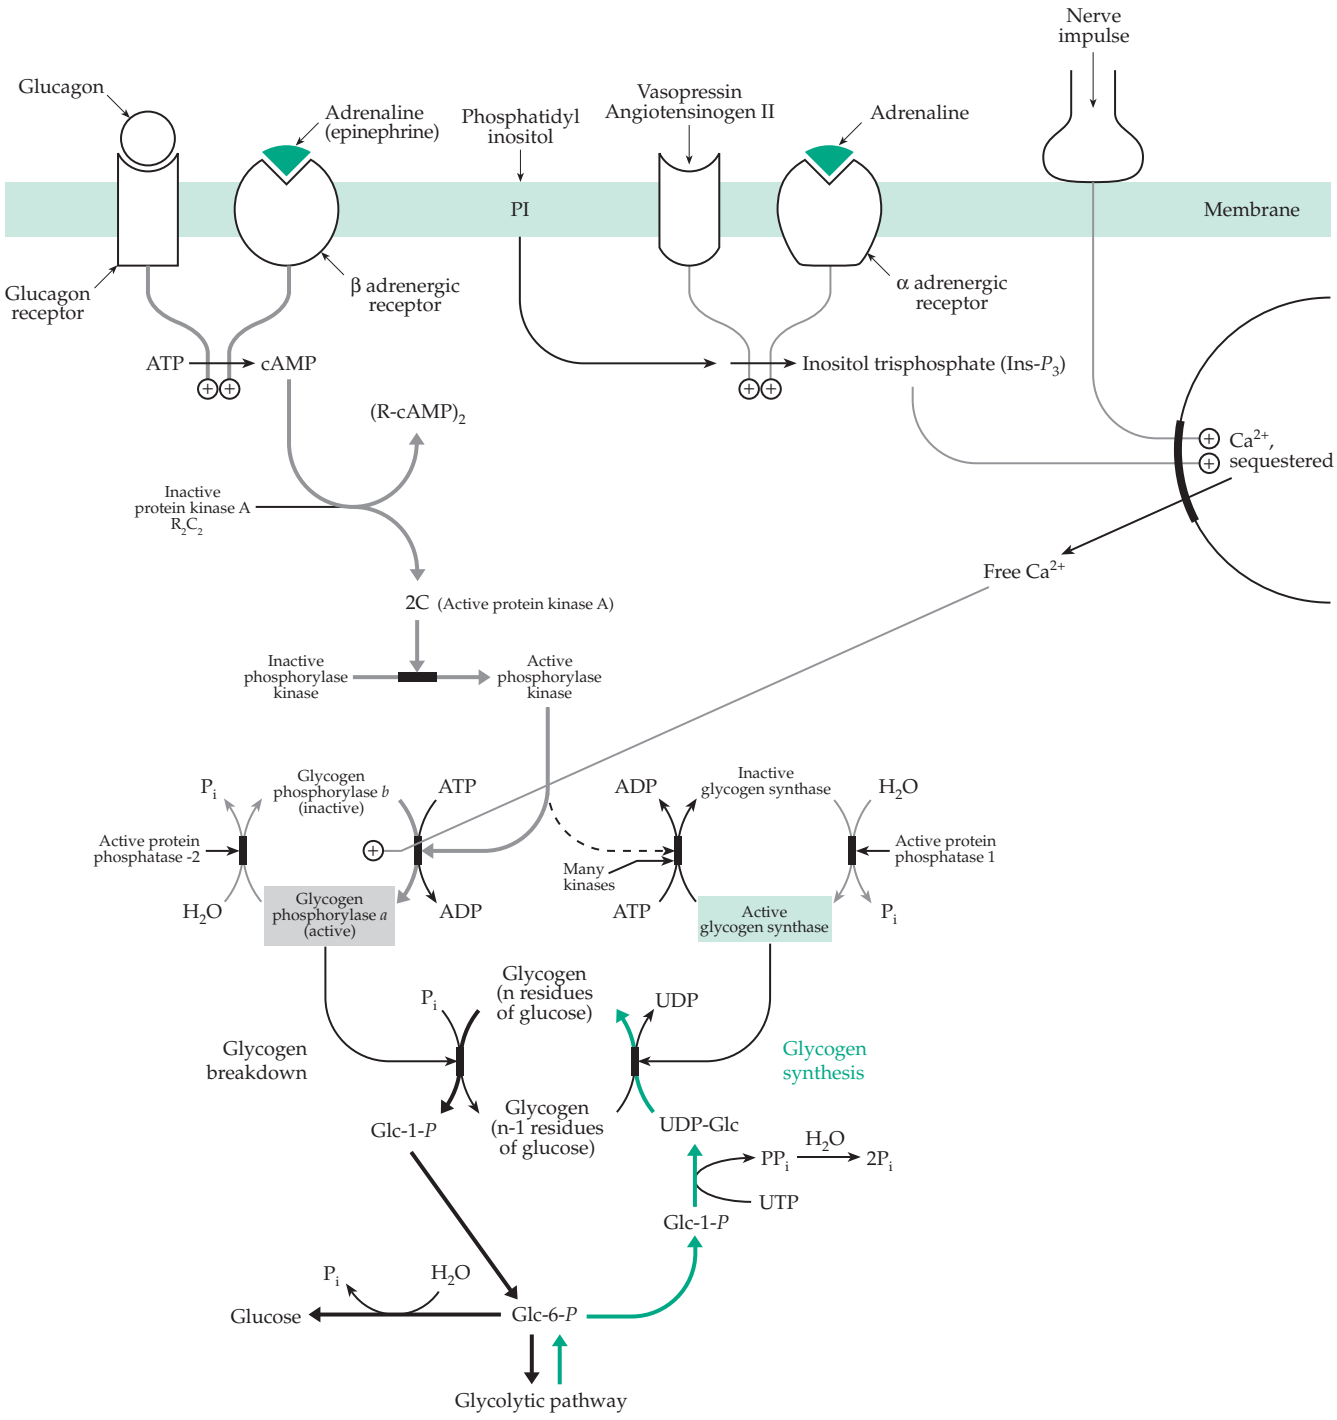


Figure 11-4 Cascades of phosphorylation and dephosphorylation reactions involved in the control of the metabolism of glycogen. Heavy arrows (➞) show pathways by which glucosyl units of glycogen are converted into free glucose or enter the glycolytic pathway. Green arrows (➞) trace the corresponding biosynthetic pathways. Gray arrows (➞) trace the pathway of activation of glycogen phosphorylase by a hormone such as adrenaline (epinephrine) or glucagon and by the action of protein kinases. A few of the related pathways in the network of reactions that affect glycogen metabolism are also shown. This includes protein phosphatases, which remove phospho groups from proteins and allow cells to relax to the state that preceded activation. One of these (protein phosphatase 1) is activated by phosphorylation by an insulin-stimulated protein kinase.[49] However, the significance is uncertain; control of glycogen synthase is complex.[49a]

TABLE 11-1
A Few Covalent Modification Reactions Utilized to Control Metabolism

Reaction	Example	Location of discussion
A. Phosphorylation–dephosphorylation		
Phosphorylation of Ser, Thr	Glycogen phosphorylase	This section
Phosphorylation of Tyr	Insulin receptor	Section G
Adenylylation, Uridylylation	Glutamine synthetase	Chapter 25

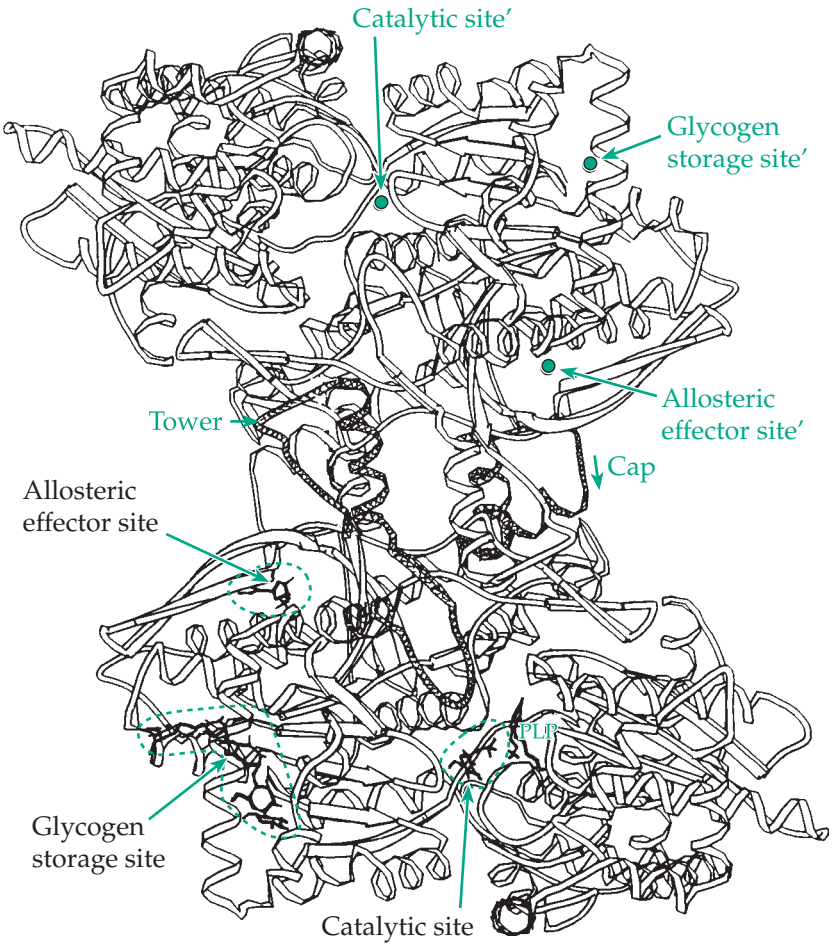

Figure 11-5 Schematic diagram of the glycogen phosphorylase dimer. The view is down the twofold axis of the dimer with the allosteric and Ser-*P* sites toward the viewer. Access to the catalytic site is from the far side of the molecule. The diagram shows the major change in conformation of the amino-terminal residues on phosphorylation. Residues 10–23 of glycogen phosphorylase *b* are shown as a thick solid line. These residues are not well ordered and make intrasubunit contacts. Upon phosphorylation, residues 10–23 change their conformation and are shown dark crosshatched with the position of Ser14-*P* indicated at the intersubunit interface. The fold of residues 24–80 through the α1 helix, the cap, and the α2 helix is shown lightly cross-hatched. The AMP allosteric effector site is located between the α2 helix and the cap region of the other subunit. The glycogen storage site is located on the surface of the subunit and is associated with a long α helix. The catalytic site is at the center of the subunit where the two domains come together. Courtesy of Louise N. Johnson.[48]

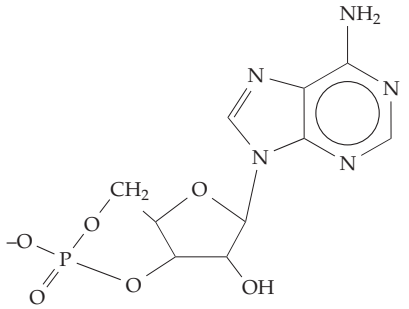
the functional groups phosphorylated, and in their allosteric activators.[39,51,54–56] There may be more than 1000 different protein kinase genes in vertebrate animals, accounting for ~2% of the genome.[57] Many cytosolic protein kinases transfer a phospho group from ATP to either a serine or threonine side chain at a β bend or other surface feature of the substrate protein. Some sites of phosphorylation in the substrate proteins contain lysine or arginine residues, separated from the serine or threonine by only one residue but many other sequences may also surround phosphorylation sites.[51,58] In the case of the 750-residue glycogen synthase, seven serine residues in different parts of the chain are phosphorylated by the action of at least five different kinases.[49,49a,59,60] The various kinases phosphorylate groups at different sites and their effects are roughly additive.

Some of the best known protein kinases (designated PKA or cAPK) are those that depend upon **3', 5'-cyclic AMP (cAMP)** as an allosteric effector. They are oligomeric proteins of composition R_2C_2, where R is a regulatory subunit and C is a catalytic subunit. Unless



3',5'-cyclic AMP

cAMP is present, the regulatory subunits interact with the catalytic subunits, keeping them in an inactive inhibited form. However, when cAMP is present it binds to the regulatory subunit dimer, releasing the two active catalytic units (Eq. 11-6). This reaction is

$$R_2C_2 + 4\ \text{cAMP} \rightarrow R_2\ (\text{cAMP})_4 + 2C \qquad (11\text{-}6)$$

reversible and as the concentration of cAMP is reduced by hydrolysis (see Eq. 11-8) the regulatory units recombine with the catalytic subunits and again inhibit them.

There are two prominent types of mammalian cAMP-dependent protein kinases.[51,61] The catalytic subunit is identical for both; the 41-kDa peptide as isolated from beef heart has 350 residues and an N terminus blocked by a myristoyl (tetradecanoyl) group.[62] One phosphoserine and one phosphothreonine are also present.[51] The ~50-kDa regulatory subunits vary in size and may also be subject to additional regulation by phosphorylation.[63] Three-dimensional structures are known for both the catalytic[62,64,65] and the regulatory[66] subunits. A **cyclic GMP** (cGMP)-activated protein kinase is present in some mammalian tissues[67,68] and is widespread in invertebrates.[51,67] The cyclic nucleotide-binding domains of these kinases have structures similar to that of the *E. coli* catabolite activator protein (Fig. 28-6)[51,68] and the catalytic domains are structurally similar to those of many other kinases.

Among the kinases that phosphorylate glycogen synthase is a **casein kinase**, named for the fact that the milk protein casein is also a good substrate. A family of casein kinases are found in the cytoplasm and nuclei of all eukaryotic cells. They phosphorylate serine and threonine side chains but have structures distinct from those of the cAMP-dependent kinases.[69–72] Casein kinase-2 (CK2) phosphorylates many proteins, including several that function in gene replication, transcription, and cell growth and division.[72a] **Theileriosis**, a parasitic disease of cattle in Africa, is caused by the tick-borne protist *Theileria parva*. The condition is often fatal as a result of a leukemia-like condition resulting from overexpression of the casein kinase-2 gene.[72]

Phosphorylase kinase is one of a large group of *specialized* protein kinases, each of which acts on a small number of proteins. It is regulated both by covalent modification and allosterically by **calcium ions**.[73–78] It contains four different kinds of subunits ranging in size from 17 kDa to about 145 kDa and has the composition $(\alpha\beta\gamma\delta)_4$. Phosphorylation of one serine on each of the 145-kDa α and 120-kDa β regulatory subunits is catalyzed by a cAMP-dependent protein kinase. The δ subunit is the Ca^{2+}-binding protein **calmodulin** (Fig. 6-8) and serves as a regulatory subunit sensitive to Ca^{2+}. The 45-kDa γ subunit contains the catalytic domain as well as a calmodulin-binding domain.[79] Other Ca^{2+}-dependent protein kinases include the **protein kinase C** family, which is discussed further in Section E, Ca^{2+}/calmodulin-dependent protein kinases,[80,81] and a plant kinase with a regulatory domain similiar to calmodulin.[82]

Protein tyrosine kinases (PTKs) place phospho groups on the phenolic oxygen atoms of tyrosyl residues of some proteins.[83–85] The resulting phosphotyrosine accounts for only about 1/3000 of the phospho groups in proteins but has aroused interest for two reasons. First, binding of growth hormones, such as **epidermal growth factor** (EGF), **platelet-derived growth factor** (PDGF), and **insulin**, to their receptors stimulates tyrosine-specific protein kinase activity of the receptor proteins (see Figs. 11-11 to 11-13).[69,83,86] Second, a number of cancer-causing **oncogenes** encode similar kinases (Section H). Tyrosine protein kinases are essential components of the cell division cycle (see Fig. 11-15).

Protein phosphatases. Most regulatory alterations in enzymatic activity are spontaneously reversible. The concentration of the allosteric effector soon drops and the covalent modifications are reversed so that the system relaxes to a state approximating the

original one. Among the enzymes required for this reversal are the protein phosphatases that remove the phospho groups placed on amino acid side chains by kinases.[54,86–91] For example, four different phosphatases act on the (inactive) phosphorylated glycogen synthase and on the phosphorylated forms of glycogen phosphorylase and phosphorylase kinase. At least one of these (a protein phosphatase 1; see Fig. 11-4) is regulated by phosphorylation that is stimulated by insulin.[49,49a] The matter is made yet more complex by the presence in tissues of small protein inhibitors which can prevent the action of these phosphatases.[88,92–94] Another naturally occurring inhibitor is the polyether fatty acid **okadaic acid**, a "shellfish poison," actually produced by dinoflagellates but which accumulates in sponges and in mussels and other bivalves.[94] See also Chapter 12, D,4.

Most protein phosphatases are specific toward phosphoserine and phosphothreonine[89,95] or toward phosphotyrosine residues.[90,96–98] Some have a dual specificity.[99] There are Ca^{2+}-activated phosphatases[100] and phosphatases with transmembrane segments connected to receptors on the external cell surface. Some phosphorylation–dephosphorylation regulatory systems utilize bifunctional enzymes consisting of a protein kinase fused to a protein phosphatase. For example, the same *E. coli* enzyme that phosphorylates isocitrate dehydrogenase also hydrolyzes off the phospho group that it has put on.[101] Another bifunctional kinase–phosphatase catalyzes both the formation (reaction *d* of Fig. 11-2) and breakdown (reaction *e*) of fructose 2,6–bisphosphate in eukaryotic tissues. This kinase–phosphatase enzyme is, in turn, controlled by phosphorylation by a cAMP-dependent protein kinase. In the liver, this latter phosphorylation strongly inhibits the kinase activity preventing buildup of fructose 2,6-bisphosphate, the allosteric activator of phosphofructokinase-1, which catalyzes reaction *b* of Fig. 11-2. Consequently, when a pulse of cAMP is generated within a hepatocyte, glycolysis is blocked but **glycogenolysis**, the breakdown of glycogen by phosphorylase, is stimulated. The glucose 6-phosphate that is formed is hydrolyzed by glucose-6-phosphatase releasing glucose into the bloodstream. On the other hand, in heart and probably in most other tissues, a different isoenzyme form of the bifunctional enzyme is present. Phosphorylation by cAMP activates the kinase and inhibits the phosphatase. Consequently, in these tissues cAMP induces the activation of glycogenolysis and glycolysis coordinately.[102–105] In brain a different allosteric activator, **ribose 1, 5-bisphosphate**, may regulate phosphofructokinase-1.[106]

Phosphorylation in bacteria. A bacterial enzyme whose activity is controlled by phosphorylation is **isocitrate dehydrogenase**. Transfer of a phospho group to the –OH of Ser 113 completely inactivates the *E. coli* enzyme,[107,108] causing isocitrate to build up in the citric acid cycle (Fig. 10-6) and to be diverted into the glyoxylate pathway, which is depicted in Fig. 17-16. In this instance, it appears likely that the negative charge of the added phospho group causes electrostatic repulsion of the substrate isocitrate. In agreement with this concept, mutation of Ser 113 of this enzyme to Asp (mutant S113 D) also inactivates the enzyme.[109]

In addition to kinase–phosphatase cycles, bacteria use at least two other ATP-dependent regulatory mechanisms.[110] In the **sensor kinase/response regulator** (or "two-component") systems[110-111] a sensor protein, upon being allosterically activated, phosphorylates itself (autophosphorylation) on a specific histidyl residue to form an *N*-phosphohistidine derivative. The phosphohistidine then transfers its phospho group onto a specific aspartyl group in the response regulator causing the regulator to bind to its target protein and to exert its regulatory effect. The best known example involves the control of the motion of bacterial flagella which is discussed briefly in Section D,5 and further in Chapter 19.

The third bacterial regulatory device is the phosphoenolpyruvate:sugar phosphotransferase system (Eq. 8-4). It is involved not only in transport but also in controlling a variety of physiological processes.[110,112,113]

3. Other Modification Reactions Involving Group Transfer

Nucleotidylation, the transfer of an entire nucleotidyl unit, rather than just a phospho group, to a protein is sometimes utilized for regulation. For example, glutamine synthetase of *E. coli* is modified by **adenylylation**, transfer of an adenylyl group from ATP to a tyrosine side chain.[114–116] Relaxation to the unmodified enzyme is catalyzed by a deadenylylating enzyme. A regulatory protein that undergoes reversible uridylylation[117] also functions in this system (see Fig. 24-7). Several mitochondrial and cytoplasmic proteins are modified by attachment of ADP-ribosyl groups to specific guanidino groups of arginine and other side chain groups.[114,118–123] This **ADP–ribosylation** requires the coenzyme NAD^+ as the ADP-ribosyl donor and is also catalyzed by bacterial toxins such as cholera toxin (Box 11-A) and by diphtheria toxin (Box 29-A). A second kind of ADP–ribosylation occurs within nuclei where the enzyme **poly(ADP–ribose) synthase** catalyzes both an initial ADP–ribosylation of an amino acid side chain group and also addition of more ADP-ribosyl units to form a polymer[124] (see Chapter 27).

Like inorganic phosphate, inorganic sulfate can be converted into an activated form in which the sulfate resembles the terminal phospho group of ATP (Eq. 17-38). The resulting **activated sulfo group** can be transferred to other compounds including enzymes. Formation of

BOX 11-A CHOLERA TOXIN AND OTHER DANGEROUS PROTEINS

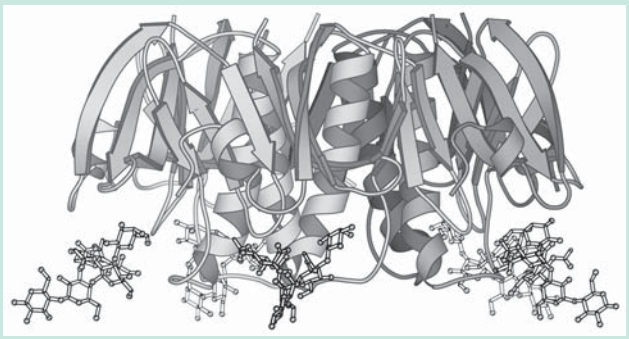
As recently as 1980 it was estimated that there were ~ 100 million cases of acute diarrhea in Asia, Africa, and Latin America;[a] in 1991 there were four million deaths among children under five years of age.[b] The causative agents are bacteria and one of the most dangerous is *Vibrio cholerae*, which multiplies in the small intestine and secretes an **exotoxin**. Cholera toxin causes such a rapid loss of fluid and salts from the body that death occurs very quickly, even in adults. There is little cellular damage and almost all deaths can be prevented by intravenous administration of water, salts, and the antibiotic tetracycline. Fluids can also be given orally if glucose, which promotes intestinal absorption, is included with the Na^+, K^+, Cl^-, and HCO_3^- salts.[b]

Cholera toxin consists of one 240-residue A subunit and a ring of five 103-residue B subunits.[c–e] The latter is a "targeting complex," a bacterial lectin each subunit of which binds to the galactose and sialic acid termini of a single molecule of ganglioside G_{M1}.

Galβ1→3Galβ1→4Galβ1→4Glcβ1–Ceramide
3
↑
NeuNAcβ2

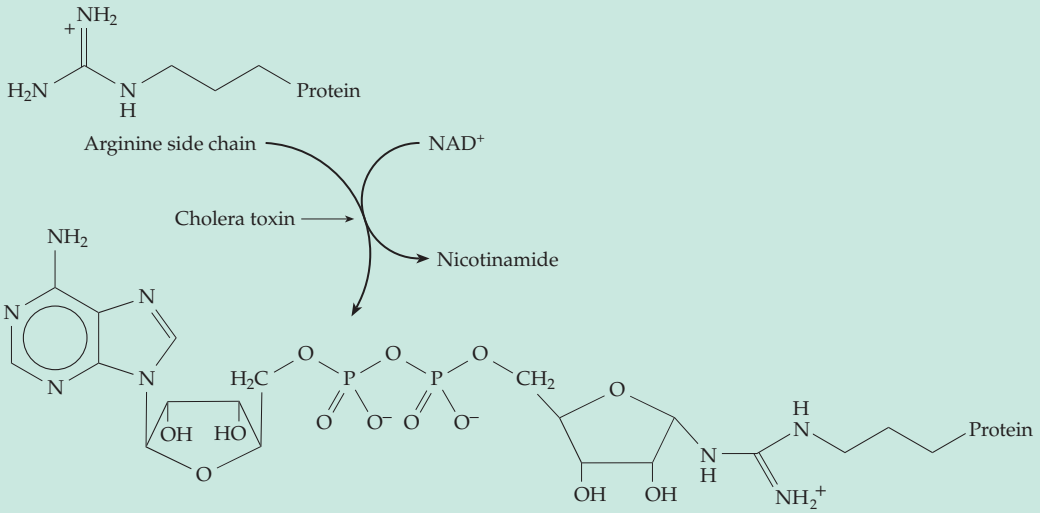
Ganglioside G_{M1} (See also Fig. 20-11)

The nonpolar ceramide chains of the ganglioside are buried in the membrane bilayer. The initial tight binding (K_f ~ 2 x 10^7 M^{-1}) of the toxin is followed by a poorly understood process in which the A subunit enters the cell. The peptide chain of this subunit is cut by bacterial proteases to give A_1 and A_2 fragments joined by an S–S bridge. Within the victim's cells the disulfide is reduced to generate the active toxin, the 192- to 194- residue A_1 fragment.[f,g]

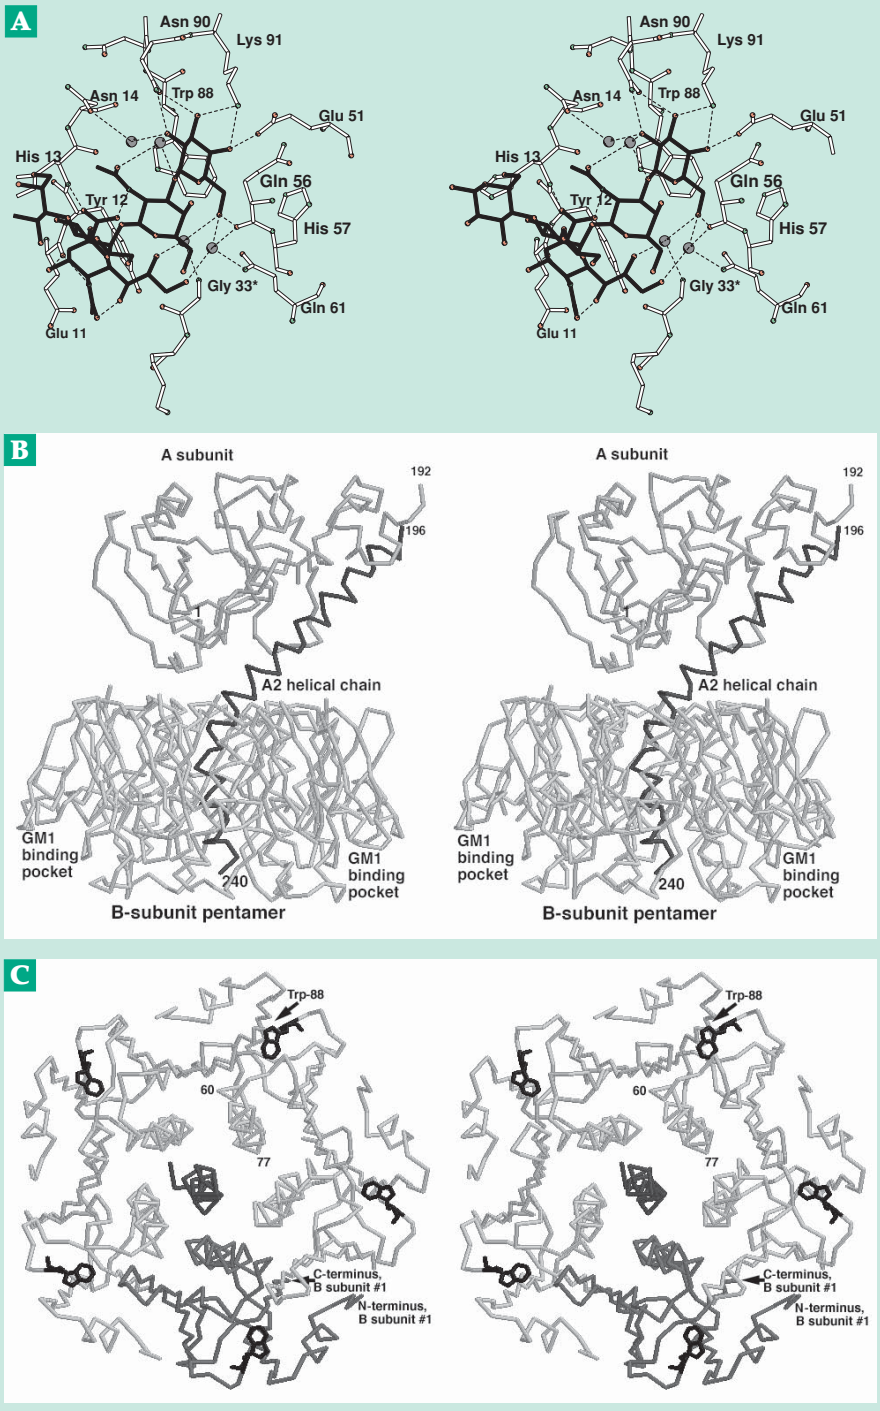


The three-dimensional structure of cholera toxin.[e] Side view of the β subunit pentamer as a ribbon drawing. Bound noncovalently to it are five molecules of the ganglioside G_{M1} (compare with the structure in Fig. 7-5). The diacyl glycerol parts of the gangliosides are buried in the membrane that lies below the toxin molecule. Courtesy of W. G. J. Hol.

This toxin subunit is an enzyme, an ADP-ribosyltransferase which catalyzes transfer of ADP-ribosyl units from the coenzyme NAD^+ to specific arginine side chains to form *N*-ADP-ribosyl derivatives of various proteins. Of the proteins modified by cholera toxin, the most significant is the guanyl nucleotide regulatory protein G_s of the adenylate cyclase system.[c,f,h] ADP ribosylation of arginine 201 of the α subunit of protein G_s inhibits the GTP hydrolysis that normally allows the protein to relax to an unactivated form.[e] The ADP-ribosylated G_s keeps adenylate cyclase activated continuously and



BOX 11-A (continued)



(A) Stereoscopic view of the G_{M1} pentasaccharide binding site, showing both direct and solvent-mediated hydrogen bonding interactions between sugar and protein residues. The viewpoint is from "underneath" the membrane binding surface of the B pentamer. Starred residues are from an adjacent monomer. The terminal galactose residue of the pentasaccharide (upper right) is most deeply inserted into the binding site and is involved in the greatest number of identifiable binding interactions. The sialic acid residue, near the bottom of the figure, is also involved in several hydrogen-bonding interactions. Hydrophobic interactions include the approach of the sialic acid acetyl group to the edge of the Tyr 12 phenyl ring and the positioning of the terminal galactose sugar ring parallel to the indole ring of Trp 88. Figures generated using program MolScript (Kraulis, 1991). From Merritt *et al.*[e] (B) Side view of the intact AB_5 toxin as an α-carbon trace. The nicked A chain is at the top. The nick can be seen in the upper right corner, as can a disulfide bridge connecting the A_1 and A_2 segments. A single α helix extends into the "pore" in the center of the B pentamer. The side chains of Trp 88 of the B subunits have been added to mark the ganglioside binding sites. These side chains are also seen in (A). (C) View of the AB_5 molecule from the bottom showing the helix from the A_2 fragment surrounded by a tight cage of five long helices from the B subunits. Residues 237–240 of the A_2 fragment have the KDEL sequence and may extend from the pore to contact the membrane. (B) and (C) courtesy of Edwin M. Westbrook. See Zhang *et al.*[c]

generating abnormally high concentrations of cAMP. It is the effect of the cAMP on proteins of the intestinal mucosal cell membranes that causes the disastrous excessive secretion of water and salts that are characteristic of cholera.

Most strains of *V. cholerae* are relatively harmless but they may suddenly be transformed into a virulent toxin-producing form by infection with a bacterial virus similar to M13 (Chapter 5), which carries the toxin gene. Entrance into the *Vibrio* cell occurs with the help of pili which are present in many strains.[i,j]

Many other bacterial toxins have AB_n structures similar to that of cholera toxin. For example, toxin-producing strains of *E. coli* are also important causes of diarrhea in humans and in domestic animals.[k–m]

BOX 11-A CHOLERA TOXIN AND OTHER DANGEROUS PROTEINS (continued)

The heat-labile *E. coli* enterotoxin, whose gene is carried on a plasmid, is a close relative of cholera toxin[n,o] and also catalyzes ADP ribosylation of arginine 201 of the $G_{s\alpha}$ subunit.[m] *Bordetella pertussis*, which causes whooping cough, forms a similar toxin that attacks the inhibitory regulatory protein G_i[p,q] as well as transducin and inactivates them by ADP ribosylation. Diphtheria toxin (Box 29-A), the exotoxin from *Pseudomonas aeruginosa*, and the toxin from *Clostridium botulinum* also catalyze ADP-ribosylation reactions.[k,r]

Some bacteria produce effects similar to those of cholera toxin in different ways. For example, among a variety of toxic proteins produced by *Bacillus anthracis*, the causative agent of anthrax, is an adenylate cyclase that is able to enter the host's cells.[s] Similarly, *B. pertussis*, in addition to its ADP-ribosylating toxin, produces a calmodulin-stimulated adenylate cyclase which, when taken up by phagocytic cells, disrupts their function in the body's defense system.[t–w] In addition to the heat-labile enterotoxin, some strains of *E. coli* produce *heat-stable* toxins, small 18-residue peptides related in structure to the intestinal peptide **guanylin**.[l,x] These peptides bind to a membrane-bound guanylate cyclase activating fluid secretion into the intestine.

Why do our cells obligingly provide both initial receptors and means of uptake for these dangerous toxic proteins? Some ADP-ribosylation reactions are a natural part of cell function[y] and some hormones, for example thyrotropin, seem to stimulate their activity. It may be that the toxins use mechanisms designed to respond to normal hormonal stimulation.

tyrosine-*O*-sulfate residues may be a widespread regulatory mechanism.[125–127] One of the proteins known to contain a tyrosine sulfate residue is the blood protein fibrinogen. Many polysaccharides and oligosaccharides on glycoproteins exist in part as sulfate esters (Fig. 4-11).[128,129]

Carboxyl groups of certain glutamate side chains in proteins that control bacterial **chemotaxis** are methylated reversibly to form methyl esters.[130] This **carboxylmethylation** occurs as part of a reaction sequence by which the bacteria sense compounds that can serve as food or that indicate the presence of food (Section D,5, Fig. 11-8, and Chapter 19). Demethylation occurs by hydrolysis, which is catalyzed by esterases. Carboxylmethylation also occurs in eukaryotic cells but is often substoichiometric and part of a mechanism for repair of isomerized or racemized aspartyl residues in aged proteins (Box 12-A). However, the major eukaryotic protein phosphatase 2A is carboxylmethylated at its C terminus,[131] as are the Ras proteins discussed in Section D,3.

It was pointed out in Chapter 4 that many proteins, especially those secreted from cells or taking up residence within membranes, are **glycosylated**. Specific

glycosyl groups may be removed or added to a protein. Such alterations may all be regarded as parts of control mechanisms that direct the proteins to their proper locations or determine the length of time that they remain active. The nuclear histones undergo extensive and reversible **acetylation**[132,133] which is thought to be important to replication of DNA and to transcription (Chapters 27 and 28).

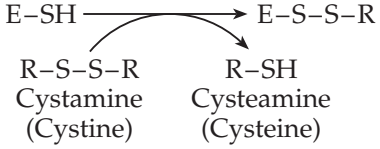
4. Thiol-Disulfide Equilibria

The activity of enzymes is sometimes controlled by the formation or the reductive cleavage of disulfide linkages between cysteine residues within the protein. An example is provided by the effects of light on enzymes of chloroplasts. Light absorbed by the photosynthetic reaction centers generates NADPH, which in turn reduces **thioredoxin**. This is a small protein containing a readily accessible S–S bridge that can be reduced to a pair of SH groups (Box 15-C). Within illuminated chloroplasts, these newly formed SH groups reduce disulfide bridges to activate a series of enzymes including fructose 1,6-bisphosphatase that participate in the photosynthetic incorporation of CO_2 into sugars[134,135] (see Chapter 23). Thioredoxins also function within bacteria, fungi, and animals, serving as electron carriers for processes, some of which are involved in metabolic control. A number of known enzymes and other proteins, including insulin, contain reducible S–S bridges within peptide loops as in the thioredoxins. Another possible control mechanism for SH-containing enzymes depends upon formation of **mixed disulfides** with small SH-containing metabolites. For example, **cysteamine disulfide**, a minor constituent of cells, cysteine, or some small disulfide, could be released

$$H_3^+N{-}CH_2{-}CH_2{-}S{-}S{-}CH_2{-}CH_2{-}NH_3^+$$

Cysteamine disulfide (cystamine)

following hormonal or other stimulation and could react by disulfide exchange (Eq. 11-7) to either inactivate or activate an enzyme.



(11-7)

Almost all cells contain a high concentration (3–9 mM) of the thiol-containing tripeptide **glutathione** (G–SH, Box 11-B). In its disulfide form it participates in forming disulfide bridges in secreted extracellular proteins (Eq. 10-9) via intermediate mixed disulfides. Mixed disulfides with glutathione as well as with other thiols can also be formed within cells by oxidative reactions. Reduction of these disulfides by reduced glutathione will return the enzymes to their reduced states. The small protein **glutaredoxin**, whose eukaryotic forms are also called **thioltransferase**, resembles thioredoxins. It undergoes reduction by glutathione and, in turn, reduces S–S linkages in a different set of proteins than those reduced by thioredoxin.

Low-molecular-mass thiols such as coenzyme A and protein-bound thiol cofactors such as phosphopantetheine are present in all cells. Their SH groups can also be oxidized to disulfides and it is of interest that in resting bacterial spores these compounds exist largely as disulfides or mixed disulfides. Upon germination of the spores special enzymes reduce the disulfides.[136] Some proteins involved in control of protein synthesis contain SH groups that add covalently to C-6 atoms of a uracil ring in specific mRNA molecules. Control of their state of reduction may also be important.[137]

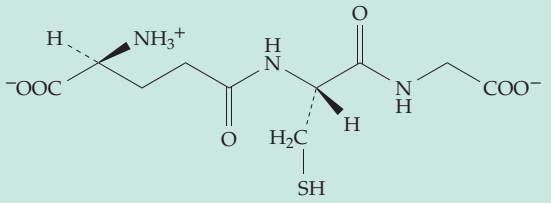
5. Regulatory Effects of H^+, Ca^{2+}, and Other Specific Ions

The pH of the cytoplasm is controlled tightly. Yet transient changes can occur and may affect many aspects of metabolism. For example, rapid glycolysis leads to lactic acid formation with an associated drop in internal pH. Both increases and decreases in pH have been associated with successive stages in embryonic or larval development.[138] Cytoplasmic pH changes may serve as regulatory signals. A well-understood example is the Bohr effect on oxygenation of hemoglobin (Chapter 7). Another is the protein kinase C-stimulated H^+/Na^+ exchange through membranes. Because the Na^+ concentration is high outside cells and low inside, the exchange leads to an increase in cytosolic pH with many resultant effects on metabolism.[139,140] Exchange of external Cl^- for internal HCO_3^- also affects pH.[141]

Uptake of Ca^{2+} into cells, or release of this ion from intracellular stores, is a major regulatory mechanism in many if not all cells (see Section E). Mn^{2+} activates **phosphoenolpyruvate carboxykinase** (Eq. 13-46) and may be a regulator of gluconeogenesis.[142] Iron controls the synthesis of ferritin and of transferrin receptors[137] (Chapter 16). The specific metal ions present in many biological macromolecules are likely to participate in additional regulatory processes.

Phosphate and bicarbonate ions are important substrates for many enzymatic processes and as such have regulatory functions. Bicarbonate controls the key enzyme of photosynthesis, **ribulose bisphosphate carboxylase**, by carbamate formation (Fig. 13-12). Chloride ions activate amylases and may affect the action of "G proteins" that mediate hormone actions. Other observed effects of ions are too numerous to mention.

BOX 11-B GLUTATHIONE, INTRACELLULAR OXIDATION–REDUCTION BUFFER



Glutathione (γ-L-Glutamyl-L-cysteinylglycine)

In 1888, de Rey-Pailhade discovered the sulfur-containing tripeptide that we now know as glutathione (G–SH).[a] By 1929 it had been characterized by F. G. Hopkins and others as an unusual tripeptide present in most, if not all, eukaryotic cells. Within animal cells the concentration is typically 1–5 mM. Lower levels are found in many bacteria.[b–g]

The most interesting chemical characteristics of glutathione are the γ-glutamyl linkage and the presence of a free SH group. The latter can be oxidized to form a disulfide bridge linking two glutathione molecules.

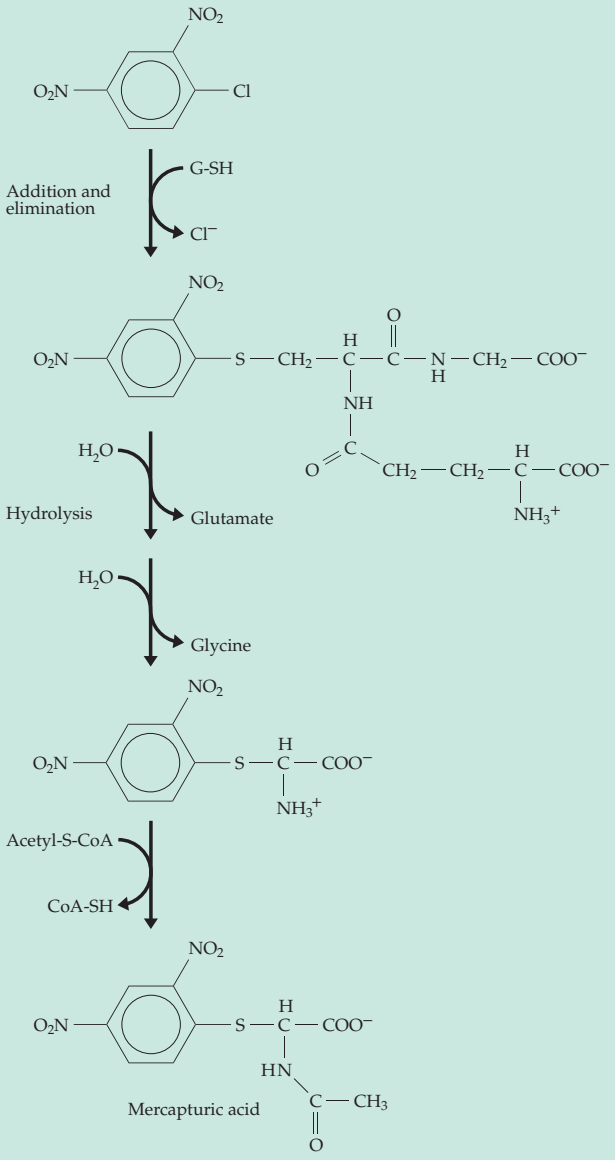
$$2G\text{—}SH - 2[H] \rightarrow G\text{—}S\text{—}S\text{—}G$$
$$E^{\circ\prime}\ (pH\ 7) = -0.25\ V$$

It is this redox reaction that has focused attention on glutathione as an intracellular reducing agent whose primary function may be to keep the SH groups of proteins reduced (see Section C). Glutathione is usually maintained in its reduced form by the flavoprotein glutathione reductase (Fig. 15-12).

Although it is primarily an intracellular compound, glutathione is secreted by epithelial and other cells. It may regulate the redox state of proteins in plasma and other extracellular fluids as well as within cells. In addition, glutathione released from the liver may be an important source of cysteine for other tissues. In the endoplasmic reticulum and the periplasm of bacteria glutathione functions in crosslinking thiol groups in newly formed proteins (Eq. 10-9).

Glutathione also has a series of **protective functions**. It reduces peroxides via the selenium-containing **glutathione peroxidase** (Box 15-H) and is part of a system for trapping and detoxifying harmful free radicals. The importance of this function is suggested by the fact that *Entamoeba histolytica*, an organism that lacks both mitochondria and aerobic respiration, produces no glutathione.[h] It may be that the primary function of glutathione in eukaryotes is to protect cells against oxygen toxicity associated with their mitochondria.[i] The renewal of free radicals and regeneration of protein –SH groups may involve the cooperation of glutathione, glutaredoxin (Box 15 - C), and ascorbic acid.[j]

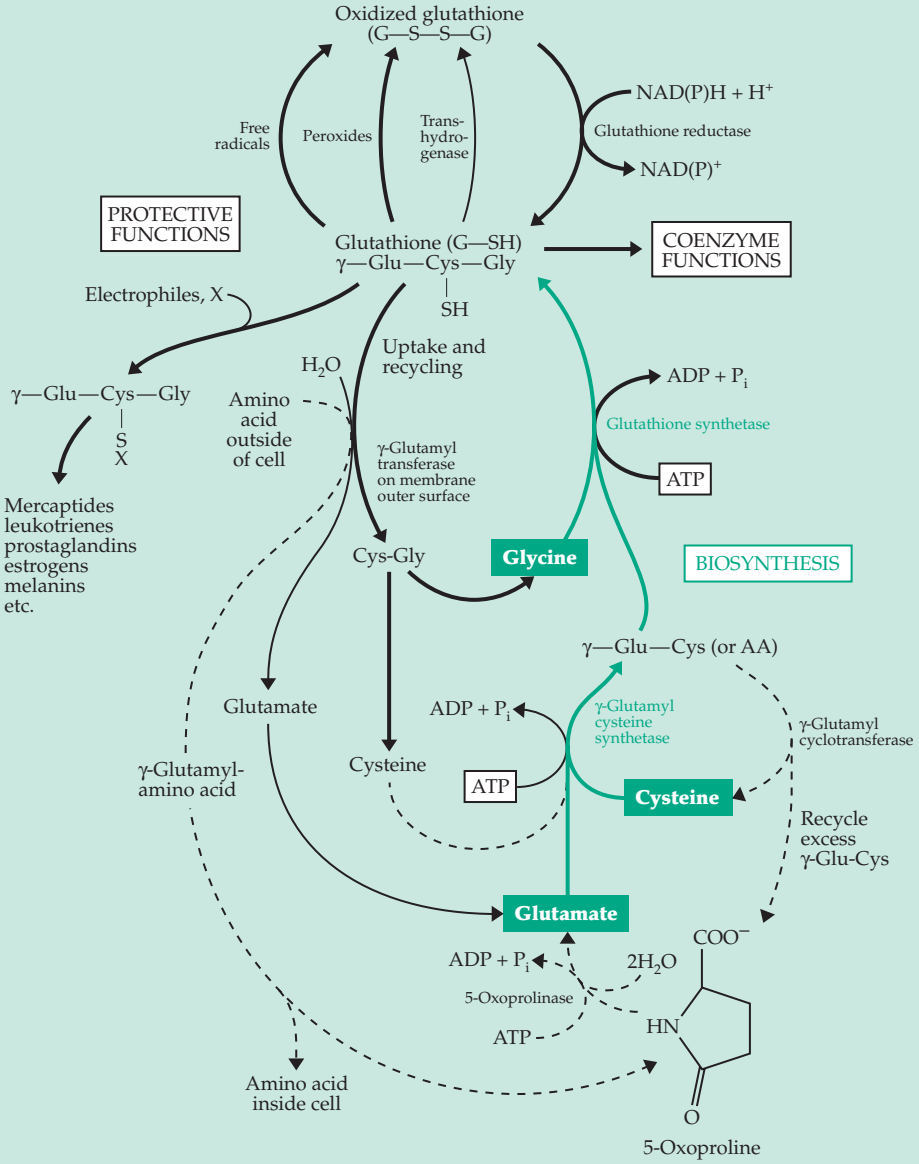
Another protective function is fulfilled by the formation of soluble **mercaptides** and other "conjugates" of glutathione with many foreign substances (**xenobiotics**). These conjugates are made by the action of a large family of **glutathione transferases**[e,k,l] (see also Chapter 13) which catalyze addition reactions of the thiolate group of glutathione with epoxides, alkylating compounds, and chlorinated aromatic hydrocarbons. The addition step is often followed by elimination, e.g., of chloride ion, as in the following example. Two steps of hydrolysis and an acetylation by acetyl-CoA form a mercapturic acid:



BOX 11-B (continued)

The mercapturic acids and related compounds can then be exported from cells by an ATP-dependent export pump.[m] Glutathione is a coenzyme for **glyoxalase** (Eq. 13-33), **maleylacetoacetate isomerase** (Eq. 13-20), and **DDT dehydrochlorinase**. The latter enzyme catalyzes elimination of HCl from molecules of the insecticide and is especially active in DDT-resistant flies.[a] Glutathione is said to be the specific factor eliciting the feeding reaction of *Hydra*; that is, the release of glutathione from injured cells causes the little animal to engulf food.

Synthesis of glutathione occurs within cells via the ATP-dependent reactions in the following scheme.[n,o] Much more γ-glutamylcysteine is synthesized than is converted to glutathione and the excess is degraded by γ-glutamyl cyclotransferase to form the cyclic amide 5-oxoproline. Cleavage of ATP is required to reopen the ring to form glutamate. Although biosynthesis is exclusively intracellular, most glutathione appears to be secreted and degraded by extracellular enzymes. The membrane-bound γ-glutamyl transferase catalyzes hydrolysis of



Scheme illustrating interrelationships of the biosynthesis and protective, coenzymatic, and transport functions of glutathione. See also Meister.[c]

BOX 11-B GLUTATHIONE, INTRACELLULAR OXIDATION–REDUCTION BUFFER (continued)

glutathione to cysteinylglycine which is further cleaved by a peptidase. The activity of γ-glutamyltransferase varies among tissues and is especially high in cells of the kidney tubules. The cysteine and glycine released by the peptidase may reenter the cells by a Na^+-dependent process. Meister proposed that the γ-glutamyltransferase, acting on amino acids, forms γ-glutamyl amino acids (see scheme) which are released *within* cells and are cleaved by γ-glutamyl cyclotransferase.[c] The cleavage of glutathione would provide the driving force for amino acid uptake. However, this is probably a minor pathway.[p]

Trypanosomes contain little glutathione but a large amount of **trypanothione** [N^1,N^8-bis (glutathionyl) spermidine].[q] This diamide of spermidine (Chapter 24) is in equilibrium with its disulfide, a 24-membered macrocyclic structure, and appears to have functions similar to those of glutathione. Trypanothione reductase, which is unique to trypanosomes, is a potential target for antitrypanosomal drugs,[q–s] as is trypanothione synthetase.[t] Bacteria that do not synthesize glutathione usually accumulate some other thiol, e.g., α-glutamylcysteine or coenzyme A, in high concentrations.[u,v]

6. Compartments and Organized Assemblies

The geometry of cell construction provides another important aspect of metabolic control. In a bacterium, the periplasmic space (Fig. 8-28) provides a compartment that is separate from the cytosol. Some enzymes are localized in this space and do not mix with those within the cell. Other enzymes are fixed within or attached to the membrane. Eukaryotic cells have more compartments: nuclei, mitochondria (containing both matrix and intermembrane spaces), lysosomes, microbodies, plastids, and vacuoles. Within the cytosol the tubules and vesicles of the endoplasmic reticulum (ER) separate off other membrane-bounded compartments. The rate of transport of metabolites through the membranes between compartments is limited and often is controlled tightly.

While many enzymes appear to be dissolved in the cytosol and have no long-term association with other proteins, enzymes that catalyze a series of consecutive reactions may form complexes within which substrates are **channeled**.[143–147] Many enzymes are attached to membranes where they may be held close together as organized assemblies.[146] This appears to be the case for oxidative enzymes of mitochondria (Chapter 18) and for the cytoplasmic fatty acid synthetases (Chapter 21). In bacterial fatty acid synthesis, the product of the first enzyme is covalently attached to a "carrier" and, while so attached, is subjected to the action of a series of other enzymes. In eukaryotes several enzymes form domains of a single fatty acid synthase. Efficient substrate channeling results. Tryptophan synthase (Fig. 25-3) passes indole through a tunnel between subunits.[146a] Both NH_3 and carbamate ions pass through tunnels between subunits of *E. coli* carbamoyl phosphate synthetase (Eq. 24-22). The product carbamoyl phosphate may then be passed directly to aspartate carbamoyltransferase for synthesis of carbamoylaspartate in the pyrimidine biosynthetic pathway.[146b] Channeling is sometimes difficult to

prove. Geck and Kirsch have provided a generally useful technique for testing. A large amount of a genetically modified, inactive form of an enzyme is added. Unless channeling occurs, this will decrease the rate of a reaction whose rate is limited by diffusion or by instability of an intermediate.[146c]

Proteasomes (Box 7-A) have enzymatic sites within a protected box which limits the escape of long peptide fragments. Membrane anchors (Chapter 8), often consisting of acyl or polyprenyl groups, hold many proteins to cell surfaces and strong protein–protein bonds hold many others.[146d] Enzymes involved in cell signaling, and discussed in the following section, are often anchored close together on membrane surfaces.[148,149]

D. Hormones and Their Receptors

A major element in the control of the metabolism of a cell is provided by chemical messages sent from *other cells* and sensed by receptors on the cell membrane or in the cytoplasm. Hormones such as insulin, adrenaline, and the sex hormones are released from an organ and travel through the blood, affecting tissues throughout the body. There are many such hormones. A large number of other hormones have more local effects, influencing mostly adjacent cells. When released at nerve endings these substances are called **neurotransmitters**. Chemical messages are probably sent from virtually all cells to their immediate neighbors, affecting both their growth and their behavior. In recent years the very reactive and toxic compounds **nitric oxide (NO)** and **carbon monoxide (CO)** have been identified as important hormones. These compounds can diffuse rapidly and react with many compounds within cells. Their actions are more rapid, more rapidly ended, and probably less specific than those of most hormones.

Hormones bind to **receptors** on their "target" cells. The receptors are often integral membrane proteins on cell surfaces. Binding of the hormone often causes a conformational alteration that "activates" the receptor. In some cases the receptor is an enzyme and the hormone an allosteric activator. In others, the activated receptor interacts with an enzyme in the cytoplasm or on the membrane facing the cytoplasm. This enzyme may generate a **second messenger**, a substance that can diffuse throughout the cell and alter metabolism by exerting allosteric effects on various other enzymes. The best known second messenger is cyclic AMP but there are many others, a few of which are listed in Table 11-2.

Some hormone–receptor complexes enter the cell via endocytosis in coated vesicles. Within the cell both the receptor and the bound hormone, if a peptide, may be degraded by proteases. The initial binding of the hormone may induce the release of a second messenger, while the degradation of the receptor complex at a later time releases peptides that may be additional second messengers. This is one way in which hormones may elicit a rapid response followed by delayed responses.

While many hormones bind to surface receptors the steroid hormones, which are lipid in nature, pass through the cell membrane and bind to receptor proteins in the nucleus. The resulting hormone–protein complexes induce changes in gene expression through regulation of transcription (Fig. 11-1, top). These receptors are considered in Chapter 22 and hormones are considered further in Chapter 30.

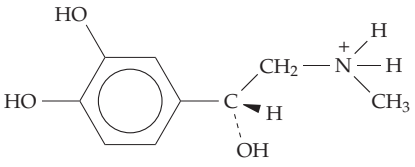
1. Beta Adrenergic Receptors and Related Seven-Helix Proteins

Sites that bind **adrenaline** (epinephrine), **noradrenaline** (norepinephrine), and related **catecholamines** (see Chapter 30) to almost all cell surfaces are classified as either **α adrenergic** or **β adrenergic receptors**. The β receptors, which have been studied the most,[150] occur as two major types. The β_1 receptors have approximately equal affinity for adrenaline and noradrenaline, whereas the β_2 receptors, the most common type, are more nearly specific for adrenaline. Binding of the hormone or other agonist such as **isoproterenol** to any of the β receptors stimulates cAMP formation within the cell.[153] The receptors belong to a family of integral membrane proteins related in sequence to the **opsins** of the retina and the light-operated proton pump bacteriorhodopsin (Fig. 23-45) and probably have a very similar three-dimensional structure. Based upon the known three-dimensional structures of rhodopsin and bacteriorhodopsin (Chapter 23), sequence comparisons, and much other evidence, all of these receptors are probably folded into groups of seven hydrophobic membrane-spanning helices arranged as closely packed bundles with folded loops protruding into the cytoplasm and into the extracellular space. The N termini of the proteins are thought to be in the extracellular space and the C termini in the cytoplasm as shown in Fig. 11-6.[153a,b,c] Defects in structure or functioning of human β receptors have been associated with both asthma[154] and heart failure.[155,155a,b]

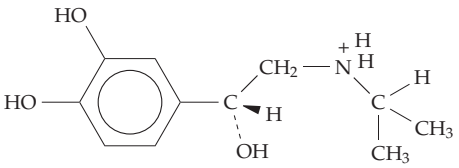
Among the proteins phosphorylated in response to formation of cAMP are the β adrenergic receptors themselves. Phosphorylation occurs within a cluster of serine and threonine residues near the C terminus as is indicated in Fig. 11-6A by the action of various kinases including a **receptor kinase**[156,156a] which may be anchored nearby.[157] The effect of this C-terminal phosphorylation is to decrease the sensitivity of the receptor so that after a few minutes it conveys a diminished response. Thus, cAMP exerts feedback inhibition of its own synthesis. *Desensitization upon continuous occupancy*

TABLE 11-2
Some Molecules (Second Messengers) That Carry Intracellular Signals

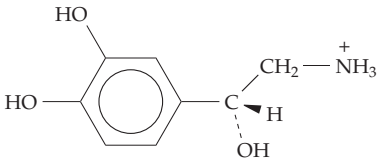
Compound	Metabolic state	Response	Location of discussion
Cyclic AMP	Stimulation of β adrenergic receptors	Increased glycogenolysis, glycolysis	Sections C,2 and D,2;
Cyclic GMP	Visual stimulation	Neuronal signal	Chapter 23, Section D
Ca^{2+}	Ca^{2+} channels open	Muscular contraction, others	Box 6-D, Section E Chapter 19, Section B,4
Inositol-1,4,5-trisphosphate and related compounds	Stimulation of α adrenergic receptors, various other stimuli	Opens Ca^{2+} channels in ER	Section E
Diadenosine 5'-tetraphosphate (Ap_4A)	Oxidative or heat stress		Chapters 28, 29
Guanosine 5'-diphosphate, 3-diphosphate (ppGpp)	Nutritional stress		Chapter 29
Mn^{2+}	Low glucose	Increased PECK activity	Chapter 17, Section L
		Increased arginase activity	Chapter 16, Section E
Cyclic ADP-ribose (cADPR) and 2'-P-cADPR			Chapter 15, Section E



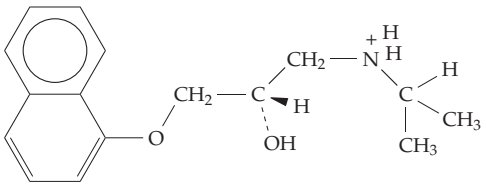
Adrenaline (epinephrine)



Isoproterenol



Noradrenaline



Propranolol

by an agonist is a property of many other receptors as well. When a receptor is no longer occupied, phosphatases remove the phospho groups added by the receptor kinase permitting the sensitivity to rise again. This phosphorylation–dephosphorylation cycle appears to be only one of several mechanisms by which cells regulate receptor sensitivity.[155b,158,158a,158b]

Many other receptors also have a seven-helix structure similar to that of the adrenergic receptors. These include receptors for the following: **glucagon**, one of the pancreatic hormones regulating glucose metabolism;[159,160] **vasopressin** (Fig. 2-4);[161,162] **lutropin**, another pituitary hormone;[163] other gonadotropins;[164] the **thyrotropin-releasing factor** (TRF; Fig. 2-4);[165] a receptor for **KDEL** peptide sequences. The KDEL receptor functions in the return of soluble proteins containing the KDEL motif from the Golgi to the endoplasmic reticulum.[152]

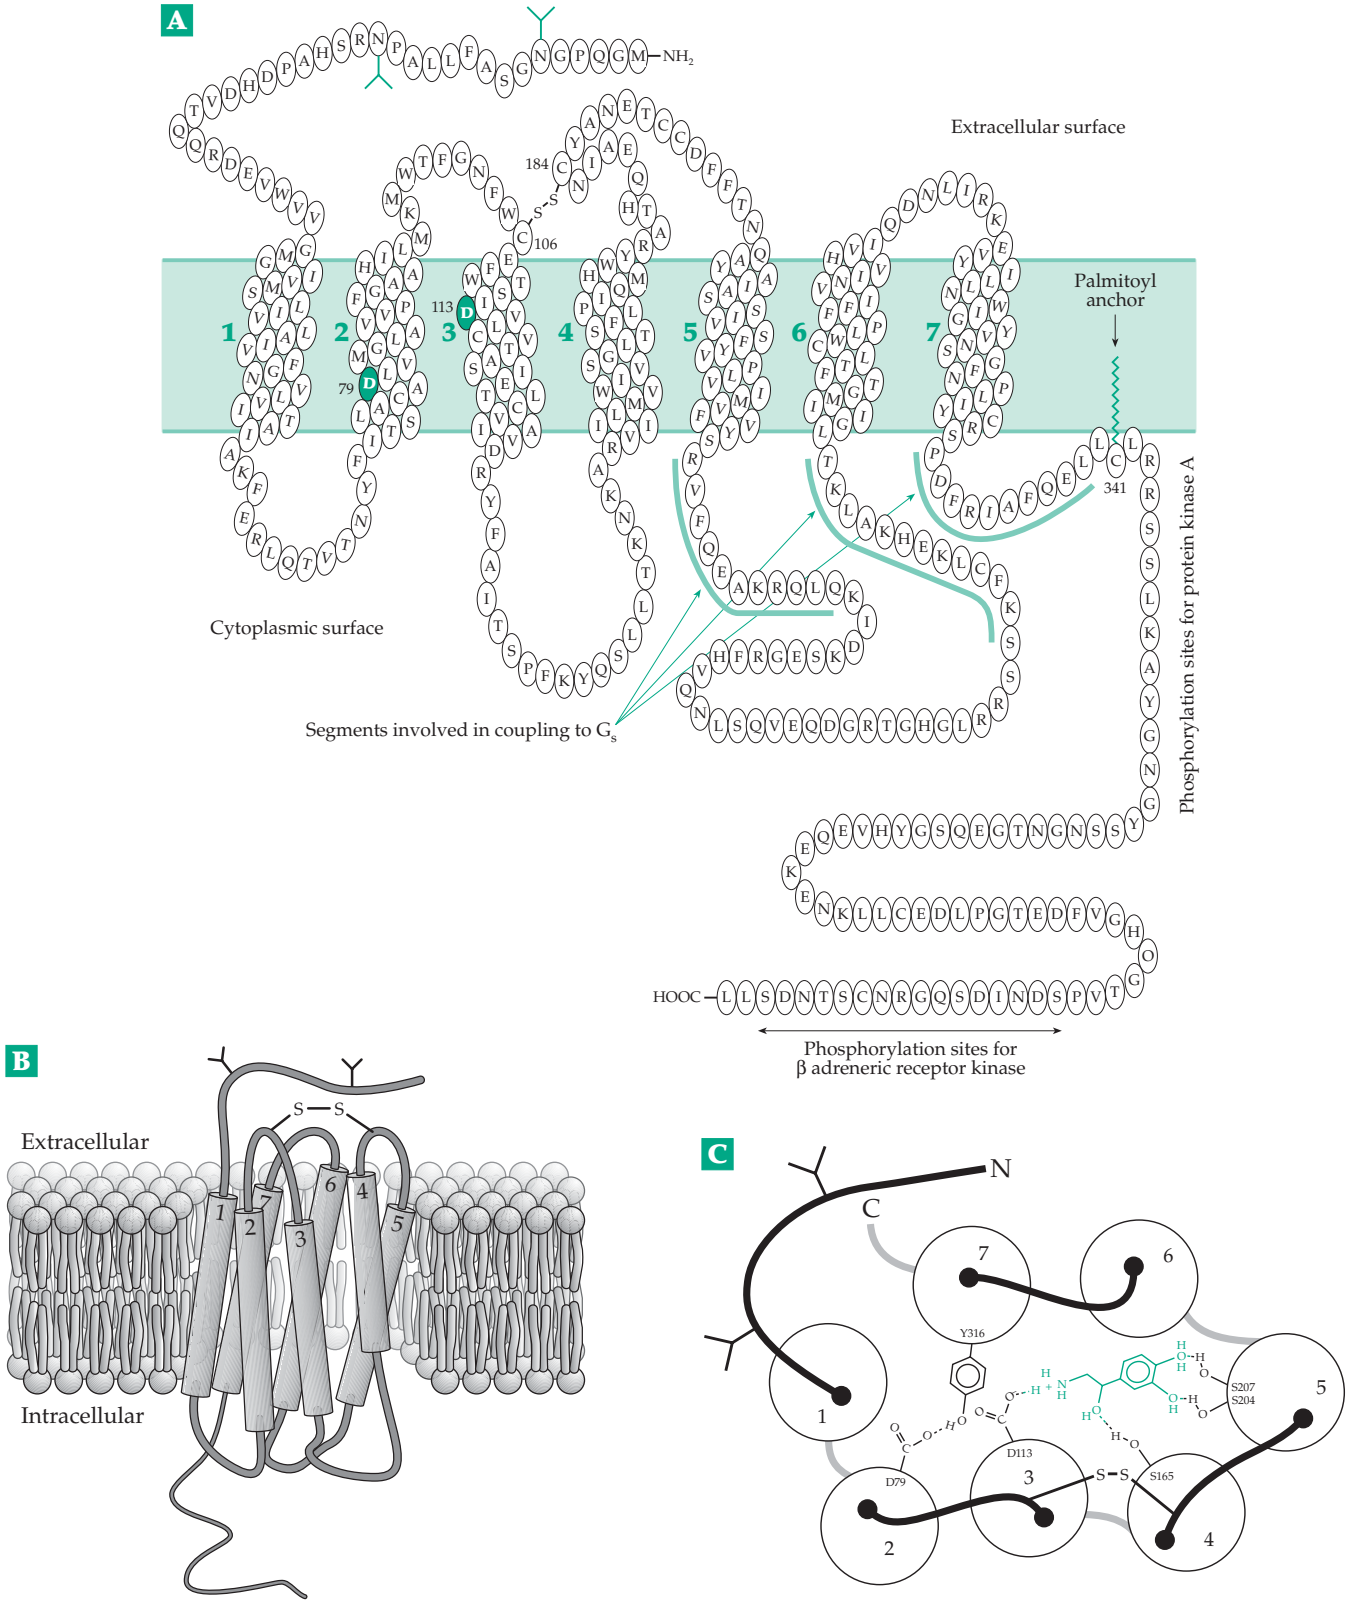


Figure 11-6 (A) Proposed organization of the human β_2 adrenergic receptor. The 413-residue polypeptide chain is arranged according to the model for rhodopsin as seven transmembrane helices. The two N-glycosylation sites, which may carry very large oligosaccharides, are indicated by Y. The palmitoylated cysteine 341 is shown with its alkyl side chain embedded in the membrane. Aspartates 79 and 113, also shown in (C), are shaded. After Strosberg[151] and Scheel and Pelham.[152] (B) Arrangement of the seven helices suggested by the rhodopsin structure. (C) Hypothetical view of the receptor from the external membrane surface showing a molecule of noradrenaline bound to hydrophilic residues deep in the cleft between the helices. From Strosberg.[151]

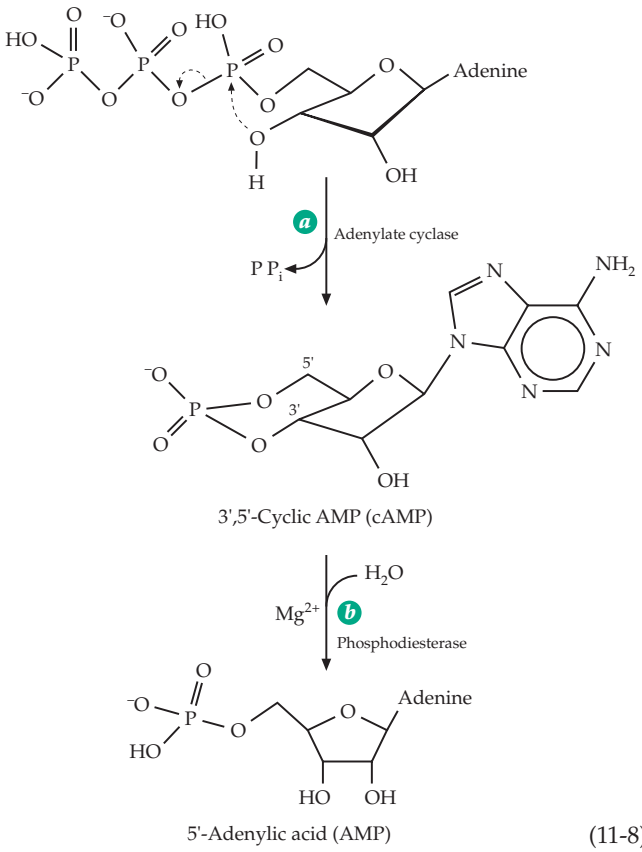
2. Adenylate Cyclases (Adenylyl Cyclases)

All of the effects of the catecholamines bound to β adrenergic receptors and of **glucagon**, **ACTH**, and many other hormones appear to be mediated by **adenylate cyclase**. This integral membrane protein catalyzes the formation of cAMP from ATP (Eq. 11-8, step *a*). The reaction, whose mechanism is considered in Chapter 12, also produces inorganic pyrophosphate. The released cAMP acts as the second messenger and diffuses rapidly throughout the cell to activate the cAMP-dependent protein kinases and thereby to stimulate phosphorylation of a selected group of proteins (Fig. 11-4). Subsequent relaxation to a low level of cytosolic cAMP is accomplished by hydrolysis of the cAMP by a phosphodiesterase (Eq. 11-8, step *b*).[166,167] In the absence of phosphodiesterase cAMP is extremely stable kinetically. However, it is thermodynamically unstable with respect to hydrolysis.

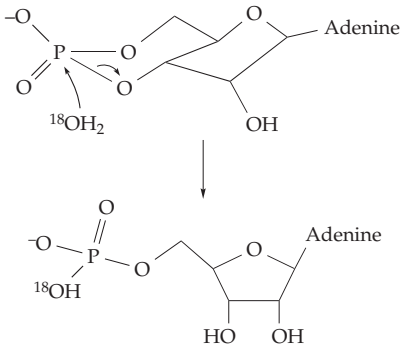
The existence of cAMP as a compound mediating the action of adrenaline and glucagon on glycogen phosphorylase was first recognized in 1956 by Sutherland.[168,169] However, for many years most biochemists regarded cAMP as a curiosity and the regulatory chemistry of phosphorylase as an unusual specialization. That view was altered drastically when cAMP was found to function as a second messenger in the action of over 20 different hormones. Phosphorylation by cAMP-dependent protein kinases regulates several enzymes concerned with energy metabolism or with the control of cell division. Phosphorylation reactions can lead to different responses in different specialized cells. Proteins of membranes, microtubules, and ribosomes are phosphorylated, as are nuclear histones. Cyclic AMP mediates the action of some neurotransmitters released at synapses and functions as a signal between cells of some slime molds (Box 11-C). Transcription of genes can be either stimulated or inhibited by cAMP.[170] Even in *E. coli* cAMP is generated and acts as a positive effector for transcription of some genes (Chapter 28). Cyclic AMP may function in signaling *stress* in plants.[171]

The isolation and characterization of adenylate cyclases have been difficult because of their location within membranes and because there is so little (usually only 0.001– 0.01%) of the membrane protein.[172] The 1060- to 1250-residue, 120 kDa proteins are also easily denatured. However, the sequences of cloned adenylate cyclase genes and the observed patterns of synthesis of the corresponding mRNAs have been revealing. There are at least eight mammalian adenylate cyclase genes with complex regulatory properties.[173 – 177] The sequences suggest that most of the isoenzymes are integral membrane proteins, *each with 12 transmembrane helices* organized as two sets of six with a large ~40-kDa cytoplasmic domain between the sets. This is similar to the organization of the cystic fibrosis transmembrane conductance regulator (Box 26-A) and some other membrane transporters. However, there is no firm evidence that adenylate cyclases contain ion channels. These enzymes are also discussed in Chapter 12, Section D,9.

A quantitative indication of the importance of the cAMP system within cells can be derived from measurement of the kinetics of the incorporation of ^{18}O from water into the α-phospho groups of AMP, ADP, and ATP. This incorporation will result from hydrolysis of cAMP by the phosphodiesterases that allow relaxation to a low cAMP level (Eq. 11-8). It is thought that in human blood platelets this represents the major pathway of this labeling (Eq. 11-9), which occurs at a rate of about 1.1 μmol of ^{18}O $kg^{-1}s^{-1}$.



(11-8)



(11-9)

Stimulation of the platelets by prostacyclin (prostaglandin I_2; see Chapter 22) leads to a 10- to 40- fold increase in cAMP concentration and a 4- to 5-fold increase in the rate of ^{18}O incorporation.[178] A quite different *soluble* adenylate cyclase is present in spermatozoa. It is stimulated directly by bicarbonate ions. It may be a **bicarbonate sensor** in sperm cells and in some other bicarbonate-responsive tissues as well as in cyanobacteria.[178a,178b]

3. Guanine Nucleotide-Binding Proteins (G Proteins)

The β adrenergic receptors are not coupled directly to adenylate cyclase but interact through an intermediary stimulatory protein $\mathbf{G_s}$, which contains three subunits, α, β, and γ.[179–182] We know that the G_s protein associated with β adrenergic stimulation is only one of a very large number of related **G proteins**, so named because of their property of binding and hydrolyzing GTP. In its unactivated state the α subunit of a $G_{\alpha\beta\gamma}$ heterotrimer carries a molecule of bound GDP. Apparently, the G_s proteins and the hormone receptors, which are activated by the binding of hormones, diffuse within the membrane until they make contact and form molecules of the G_s•GDP complex (Eq. 11-10, step *b*). The complex then undergoes a rapid exchange of the bound GDP for GTP, after which the hormone and receptor dissociate. The G_α•GTP complex may also dissociate from the complex, perhaps entering the cytosol as a soluble protein (Eq. 11-10, step *c*). The G_α•GTP complex combines with adenylate cyclase (step *d*) and activates it to generate cAMP. However, the activation is transient. G_α also contains GTP-hydrolyzing (GTPase) activity and within a few minutes G_α•GTP is completely converted to G_α•GDP and the adenylate cyclase dissociates (Eq. 11-10, step *e*). The G_α•GDP recombines with the βγ complex which may serve as a membrane anchor, to complete the regulatory cycle. The overall effect is for hormone binding to cause a rapid release of cAMP in a short burst that may last only about 15 s.

It is not the binding of GTP but a slow subsequent conformational alteration that activates the G_α•GTP adenylate cyclase complex. This was deduced by study of analogs of GTP, such as guanosine 5'-(β, γ-imido) triphosphate (GMP-*P*-(NH)-*P* or GppNp), which are

BOX 11-C THE ATTRACTION OF *DICTYOSTELIUM* TO CYCLIC AMP

In higher animals cyclic AMP (cAMP) is an intracellular second messenger, but in the cellular slime mold *Dictyostelium discoideum* it serves to convey signals *between* cells.[a–c] As was mentioned on p. 20, the organism exists as individual amebas until the food supply is exhausted. Then the cells begin to signal their lack of food by secreting pulses of cAMP. Because they also secrete a phosphodiesterase, the cAMP is short-lived.[d] However, it is present long enough for any other nearby ameba to sense the gradient of cAMP concentration from one end of the cell to the other. As little as a 2% difference in concentration can induce chemotaxis.[e] The amebas move toward the source of cAMP and emit pulses of the compound. This results in the formation of aggregation centers in which the concentration of cAMP oscillates spontaneously as the cAMP moves outward in waves. The cells move up the concentration gradient until the peak of a wave reaches them. Then they move in a random direction until the next wave reaches them and again orients their motion.

After ~50 movement steps an aggregation center contains ~10^5 cells which now follow a "development program." The amebas adhere to each other to form 1- to 2 mm-long multicellular "slugs" in which all of the cells move forward together. About 30 h after aggregation begins the slugs stop and form stalks with spore-containing fruiting bodies on top. The lead cells in a slug become the stalk.[a,c]

Two types of G protein-coupled cAMP receptors in the cell membranes of the amebas have been identified. One leads to activation of adenylate cyclase and the release of new pulses of cAMP and the other to activation of guanylate cyclase.[e] This enzyme causes a rapid 7- to 10-fold increase in intracellular cGMP which plays an important role in controlling chemotaxis.

Some species of cellular slime molds use other chemical attractants (**acrasins**). For example, *D. minutum* secretes an analog of folic acid[f] and cells of *Polysphondylium violaceum* are attracted by the ethyl ester of *N*-propionyl-γ-L-glutamyl-L-ornithine-δ-lactam.[g]

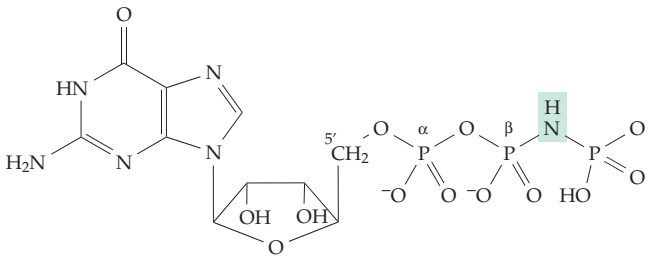
not hydrolyzed to GDP. These compounds may require many minutes to activate the complex, but because the GppNp is not hydrolyzed, the complex remains activated and able to catalyze cAMP formation continuously.



Guanosine 5'-(β,γ-imido) triphosphate (GppNp); in place of the NH, O is present in GTP, S is present is GTPγS

Occupied receptors for adrenaline, glucagon, ACTH, and histamine activate adenylate cyclase via G_s proteins. Other G_s proteins, which contain subunits designated α_{olf} and which exist as a number of subtypes, mediate **olfactory responses**. Subunit α_o is another specialized polypeptide which is located primarily in neural tissues. A variety of additional G proteins have been discovered in organisms ranging from bacteria to mammals.[179,183–186] All have similar structures with 39- to 45-kDa α subunits, 35- to 36-kDa β subunits and 5- to 8-kDa γ subunits. Whereas the α subunits are unique to each G protein, β and γ subunits may be shared among several G proteins. These proteins appear to function with many kinds of hormone receptors and in nerve transmission, secretion, and endocytosis.[187] Mammals can form at least 23 different α_s subunits, which are coded for by 16 genes. Some of the forms arise by alternative splicing of mRNA transcribed from a single gene.[180] There are at least 6 β and 12 γ subunits.[179,180,182,188,189] Other G proteins, found in heart muscle, induce the opening of K^+ or Ca^{2+} channels in cell membranes.[185,190] It has often been assumed that all of the effects of G proteins are mediated by activated α subunits. However, the βγ complex, which sticks together very tightly, can also have signaling functions.[191] For example, an auxiliary protein called **phosducin** binds to the βγ complex of G_s, slowing the reconversion to the αβγ trimer.[192] Phosducin was discovered in rod cells of the retina but has been found to be distributed broadly in other tissues as well.[192,193] In yeast the βγ subunit of a G protein linked to the receptor for the yeast mating factor initiates the pheromone response of a cell.[193a]

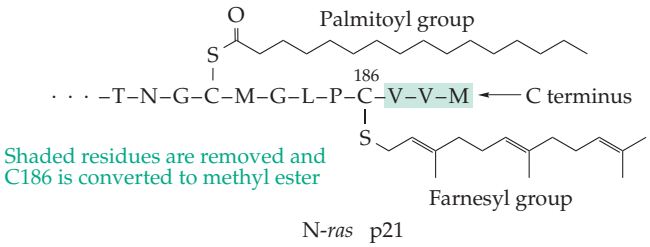
There is another large class of receptors whose occupancy by an agonist leads to *inhibition* of adenylate cyclase. These include the α_2 adrenergic receptors, receptors for acetylcholine, adenosine, prostaglandin E_2 (Chapter 21), somatostatin, and some receptors for dopamine. Their responses are mediated by inhibitory proteins G_i, which closely resemble G_s in their sizes, amino acid sequences, and heterotrimeric structures, but which inhibit adenylate cyclase when activated.[180] A clear distinction between the G_s and G_i proteins is evident in the fact that G_s is irreversibly activated by the action of cholera toxin, while G_i loses its ability to respond to occupied receptors when modified by the action of *Pertussis* toxin (Box 11-A). A specialized heterotrimeric G_i protein known as **transducin** mediates the light-induced activation of a **cyclic GMP phosphodiesterase** in the retina[194,195] (see Chapter 23). Its α subunit is designated α_t. The related **gustducin** is found in taste buds.[196]

Monomeric G proteins. An entirely different class of G proteins was discovered when it was found that the small 189-residue, 21-kDa protein products of the human oncogenes and proto-oncogenes known as **ras** are monomeric G proteins.[186,197–200] There are over 80 related proteins of this group of nine families.[200a] They include the much larger **elongation factor** EF-Tu, which functions in protein synthesis (Chapter 29). Even though there is a large difference in size, the three-dimensional structures of the GTP-binding domains of EF-Tu[201–204] and of the 21-kDa Ras p21 proteins[205–209] are very similar (Fig. 11-7). They also resemble that of adenylate kinase (Fig. 12-30).[205] The human genome contains four "true" *ras* genes: H-*ras*, N-*ras*, K-*ras*, and K-*rasB*. The occurrence of mutations in these genes in human cancer is discussed in Section H, as are the complex signaling functions of r*as* genes, (see also Fig. 11-13).[210]

Other proteins in the Ras superfamily include some members of the **Rho** family, which function in the cytoskeleton.[200a,211,212,212a,b,c,213] These include at least 14 mammalian proteins, among them RhoA, RhoB, etc., Rac1, Rac2, etc., and Cdc42. The latter is associated with the formation of fingerlike extensions of the cell membrane containing actin bundles.[200a,212d,212e] Genes *rac1* and *rac2* encode proteins involved in the initiation of superoxide radical formation by activated phagocytes (Chapter 18).[214] The **Rab** family of proteins are involved in exocytosis and endocytosis and vesicular transport. There are 24 or more human *rab* genes.[212,215,216] Yeast cells also contain Ras proteins. One *RAS* gene must be present for yeast to form spores.[217] **ADP-ribosylation factors** (ARFs), which stimulate the action of cholera toxin A subunit (Box 11-A) are also members of the Ras superfamily.[120,217a]

Like the trimeric G proteins, the monomeric proteins also serve as "timed switches" that are turned on by GDP–GTP exchange and are turned off by the hydrolysis of the bound GTP. In the absence of other regulatory proteins both the exchange of bound GDP for GTP and the hydrolysis of bound GTP are slow. While the receptor-associated trimeric G proteins are activated by the hormone receptors, the monomeric G proteins are activated toward GDP–GTP exchange by binding to proteins called **guanine nucleotide dissociation stimulators** (**GDSs**).[217b] They speed the release of GDP from the G protein allowing the active GTP complex to be formed. The velocity of hydrolysis of the bound GTP in the activated G protein is greatly increased by **GTPase activating proteins** (**GAPs**). These auxiliary proteins can be thought of as signaling molecules that pass their messages to the G protein, controlling the extent of its activation and therefore the strength of a signal that it sends on to the processes that it is controlling.[200,210,218] One group of GAP proteins are known as **regulators of G-protein signaling** (RGS).[218-218b] These proteins, which contain a characteristic 12-residue core, were first recognized as negative regulators of signaling in yeast cells called **GDP-dissociation inhibitors** (GDIs).[219] They can also be regarded as a family of GAPs.

Acylation and prenylation. The amino terminus (usually glycine) of the α subunit of any G protein is nearly always converted to an ***N*-myristoyl group**.[220–223] This modification occurs in a **cotranslational process** after removal of the initiating methionine (Chapter 29) and can be described as an acyl transfer from coenzyme A.[224] The C termini of the γ subunits of heterotrimeric G proteins, and also of the monomeric proteins of the Ras family, also undergo processing. For example, the C-terminal end of an intact Ras protein contains 18 residues which probably assume a largely α-helical conformation. A cysteine side chain near the terminus and having the sequence CAAX is converted within cells to a **thioether** with all-*trans*-farnesol or longer polyprenyl alcohols.[225] Another nearby cysteine may form a **thioester** with palmitic acid,[221,226,227] for example:



The farnesyl (or longer) polyprenyl and palmitoyl groups, together with nearby nonpolar side chains, serve as a membrane anchor. After the prenylation the C-terminal three amino acids (VVM in N-*ras* p21) are removed proteolytically and the new terminal carboxyl group of the farnesylated Cys 186 is converted to a methyl ester.[212c,225,228] N-terminal myristoylation is usually regarded as irreversible. However, the thioester linkages by which palmitoyl groups are attached to proteins are labile and may be cleaved rapidly by hydrolases. It follows that palmitoylation can be a rapid, regulated modification of proteins,[229–230a,b] strongly affecting the location and extent of adherance to membrane surfaces.

Three-dimensional structures. The structure of the GTP-binding domain of elongation factor EF-Tu was determined by Jurnak in 1985[201] and that of the complete three-domain structure later.[202,203] When the structure of the *catalytic domain* of the first Ras protein was determined (Fig. 11-7A) it was clear that it was similar to that of EF-Tu.[205,207] The same was true for the transducin α_t,[194,231,232] for the inhibitory $G_{i\alpha 1}$,[218b,233,234] and for other G proteins.[235] In every case the differences in structure of the enzyme with GDP or with analogs of GTP were small and limited to a region close to the γ-phospho group of the bound GTP. This group can be seen clearly in Fig. 11-7A adjacent to residue 60 of the protein. See also Fig. 12-36.

The β strands and helices in the GTP-binding domain of the G proteins are connected by a series of loops. The first, second, and fourth loops (residues 10–17, 32–40, and 57–65, respectively) in the Ras structure of Fig. 11-7A form the catalytic site in which the hydrolysis to GDP takes place. The first loop, also called the P loop, is conserved in all GTP-binding proteins. In the Ras proteins it has the following sequence:

10	17	
G–A–G–G–V–G–K–S		Ras
G–X–X–X–X–G–K–S(T)		Consensus

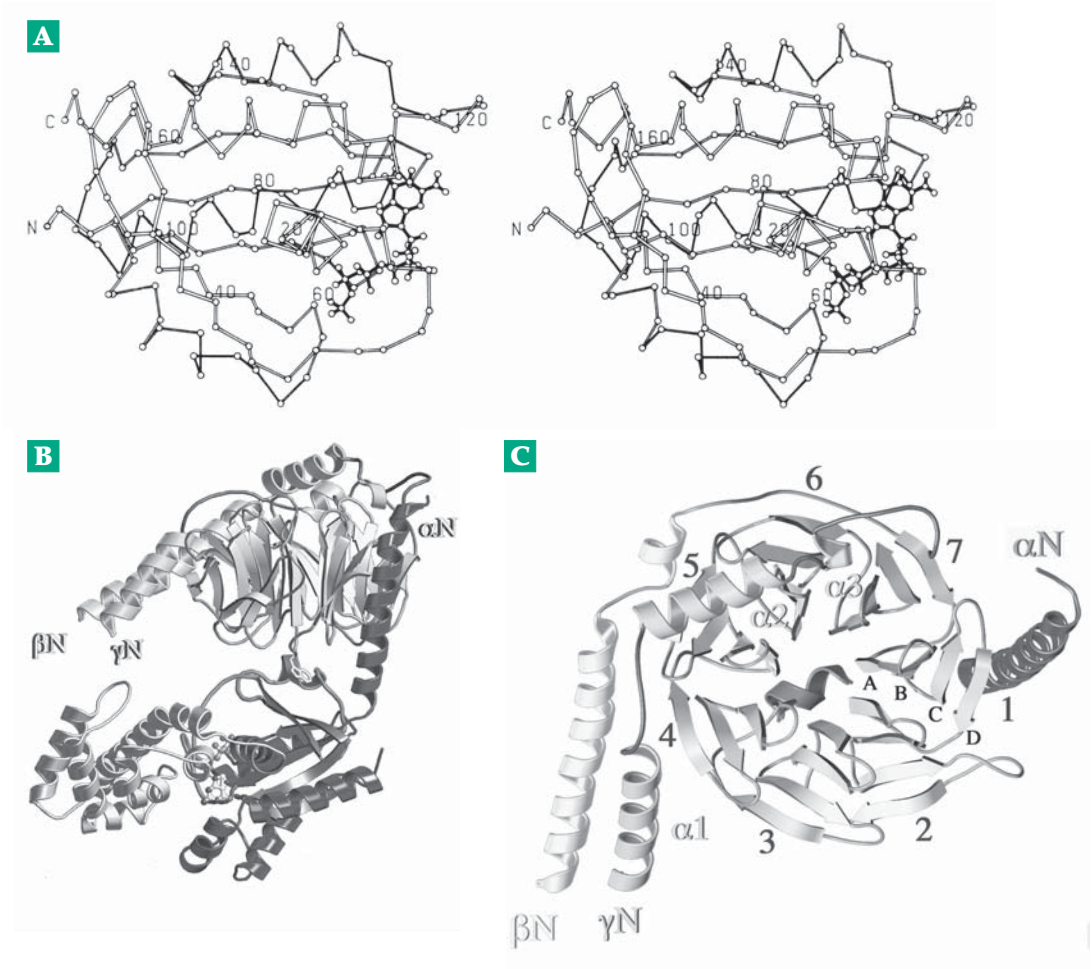


Figure 11-7 (A) Stereoscopic drawing showing α-carbon positions in the 166-residue "catalytic domain" of the human c-H-*ras* gene product and the bound GTP analog GppNp (solid bond lines). The intact protein contains an additional 23-residue C-terminal extension. From Pai *et al.*[241] (B), (C) Ribbon drawings showing two nearly orthogonal views of a hetero-trimeric inhibitory G_i brain protein produced using a cloned bovine gene. (B) The amino termini (N) of the three subunits are seen in the left-to-right order: γ, β, α. A side view of the β propeller domain of the β subunit is seen at top center. The Ras-like domain and the additional large helical domain of the α subunit are marked. (C) View from the flared end of the β propeller looking toward the α subunit. The strands of each propeller blade are labeled A, B, C, and D and the seven blades are numbered around the periphery of the propeller. From Wall *et al.*[242] (B) and (C) courtesy of Stephen Sprang.

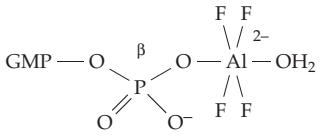
Also shown here is the "consensus" sequence for all GTP-binding proteins. Cancer cells frequently have mutations in Ras at Gly12, which may be substituted by Asp, Lys, Val, or Arg, and at Gly 13 and Gln 61. The latter is in loop 4, a part of the sequence that appears especially mobile but is highly conserved. These mutations all activate the protein, i.e., they decrease the GTPase activity, allowing the G protein to remain in its active conformation longer than normal.

Ras proteins fulfill their functions by interacting closely with two or more proteins in signaling pathways as described in Section H. Other G proteins have additional domains. The 405-residue EF-Tu from *Thermus thermophilus* has three domains: the C-terminal nucleotide-binding domain and two β-barrel domains following it. A major difference in conformation is observed between forms of the protein with bound GTP or bound GDP, the GDP form being opened up by a hinging motion of ~ 90° between domains I and II.[202,203] The conformational change is triggered by the GDP–GTP exchange. An enhanced rate of GTP hydrolysis, which results from binding of a transfer RNA and binding to a ribosome, is apparently accomplished by interaction with loop 2 of the catalytic domain (corresponding to residues 32 – 40 in Fig. 11-7A). The function of this protein is considered further in Chapter 29.

Transducin has a 113-residue domain inserted into loop 2 of the catalytic domain. In this case, too, a large hinging movement is associated with the GDP–GTP exchange. The light-activated receptor rhodopsin induces the conformational change.[194,231] Again, structural changes resulting from the presence or absence of interactions of the protein with the γ-phospho group

of GTP are involved. The GTPase activity of heterotrimeric G proteins can also be activated by aluminum fluoride AlF_4.[232,236] From the X-ray structure of the transducin α•GDP•AlF_4^- complex it is seen that hydrated AlF_4^- is covalently bonded in the position of the γ-phospho group and makes hydrogen bonds to active site groups, mimicking a possible transition state for the GTPase reaction[232] (see Chapter 12, Section D).



The β subunit of the βγ complex of transducin is a **seven-bladed β propeller** (Fig.11-7C). It is composed of seven GH–WD repeat units: $-[GH-X_n-WD]_{4-8}-$ where GH = Gly – His, WD = Trp–Asp, and X_n is a core repeating sequence, usually 32–42 residues in length. This motif is also found in at least 40 other eukaryotic proteins.[188,237–240] In the βγ complex (Fig. 11-7B) the γ subunit assumes an elongated, largely α-helical structure. It is often anchored at its C terminus by a farnesyl or geranylgeranyl chain, while G_α may be myristoylated or palmitoylated.[195,230,243]

The three-dimensional structure of the GDP complex of the intact transducin heterotrimer[195] also shows a tight interaction between α and β subunits. The major interaction is probably disrupted by replacement of the bound GDP by GTP and the conformational change that occurs around the γ - phospho group. This explains the dissociation of the α subunit from βγ upon activation. An entirely similar picture has been obtained for the action of the inhibitory G protein, G_{i2}, for which structures of the α subunit and of the αβγ heterotrimer (Fig. 11-7,B,C) have been determined.[188,233,234,242] The structures resemble those of transducin, but differ in details.

4. Guanylate Cyclase (Guanylyl Cyclase), Nitric Oxide, and the Sensing of Light

Formation of the less abundant cyclic guanosine monophosphate (cGMP) is catalyzed by guanylate cyclases found in both soluble and particulate fractions of tissue homogenates.[244–247] However, its significance in metabolism is only now becoming well understood. There are cGMP-dependent protein kinases,[247] but, until recently cGMP could not be regarded as a second messenger for any mammalian hormone. Now we know that cGMP has several essential functions. It mediates the effects of the **atrial natriuretic factor**, a peptide hormone causing dilation of blood vessels (Box 23-D),[245,248–250] and also of a peptide called **guanylin**, which is formed in the intestinal epithelium.[245,251] The receptors for both of these peptides are *transmembrane proteins with cytoplasmic domains that have guanylate cyclase activity*. The released cGMP appears to induce relaxation of smooth muscles of the blood vessel walls. Another mediator of smooth muscle relaxation is the **endothelial cell-derived relaxing factor**, which is evidently **nitric oxide**, **NO**[252] (see Chapter 18). A soluble guanylate cyclase appears to be an NO receptor and is activated by binding of the NO to a heme group in one of the two subunits of the cyclase.[253–255] The cyclase can also be activated by carbon monoxide, CO, in a similar fashion.[256,257] Carbon monoxide is produced in the body by degradation of heme (Fig. 24-24) and is thought to be a neurohormone.[258]

Cyclic GMP also plays an important role in vision. Specific phosphodiesterases hydrolyze cGMP to GMP. The cGMP phosphodiesterases of the rod and cone cells of the retina are activated by the G protein transducin, which has been activated by light absorbed by the visual pigments.[194] The resulting decrease in the cGMP concentration is thought to cause the closing of cation channels and thereby to initiate a nerve impulse (see Chapter 23). Cyclic nucleotide forms of the pyrimidine nucleotides are present only in very small amounts in cells.

5. Bacterial Chemoreceptors

Bacteria are attracted to foods with the aid of chemoreceptors that bind certain amino acids such as aspartate. The receptors send signals to the mechanisms that ensure that the bacterium is swimming toward the food[113,259,259a] (more details are given in Chapter 19). The aspartate and serine chemoreceptors found in membranes of *E. coli* and *Salmonella typhimurium* are among the most carefully studied of all receptors. Like the seven-helix receptors, they have an extracellular sensory domain to which the signaling molecule, aspartate or serine, binds, and a transmembrane helical bundle. In these receptors the transmembrane part consists of four helical segments coming from the two subunits of the dimeric protein. For the aspartate receptor there is a high-resolution X-ray structure for the cytoplasmic domain[260,261] including the bound aspartate[262] as is shown in Fig. 11-8A,B.[260,263] The structures of the receptors for aspartate, serine, and many other signaling molecules are evidently very similar. The structure of the cytosolic domain of the serine receptor has been determined and a model for the complete receptor has been proposed.[259a] The molecular mass of the 188-residue extracellular domain is ~18 kDa, while that of the larger cytoplasmic domains is ~36 kDa. The latter includes a linker region as well as a long four-helical bundle domain which can be divided into a methylation domain and a signaling domain as shown in (Fig. 11-8C).

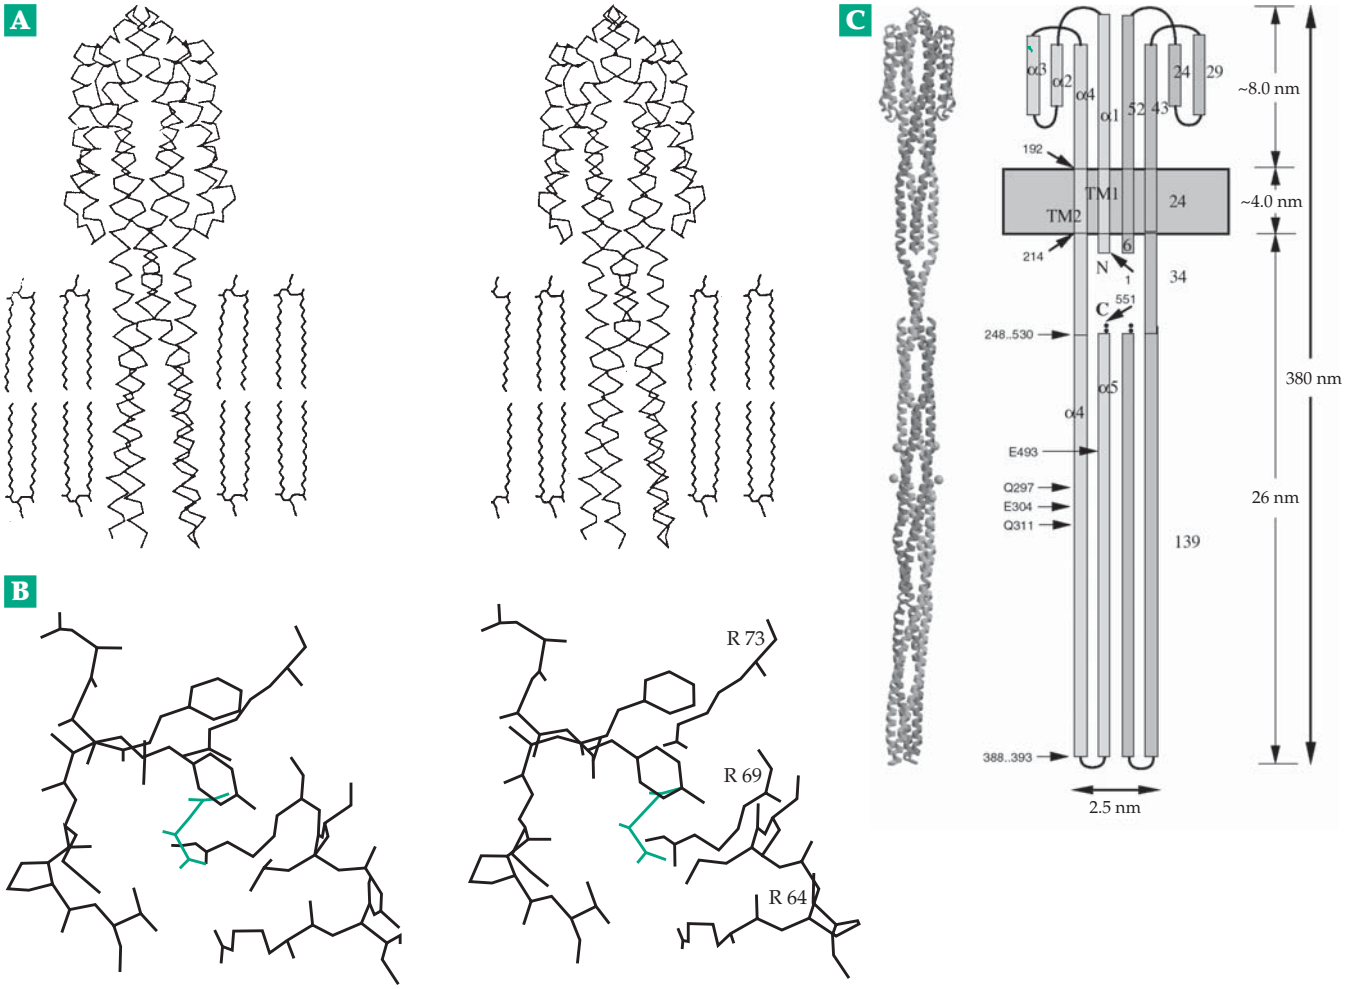


Figure 11-8 (A) Stereoscopic view of the sensory domain of the dimer with modeled transmembrane region. Each monomer contains a four α-helix bundle with two helices continuing through the membrane. From Scott *et al.*[260] (B) Stereoscopic image of aspartate in the major binding site of the receptor. The atomic model of aspartate (green) has been fitted into the observed difference electron density map. From Yeh *et al.*[262] (C) Model of an intact *E. coli* serine chemoreceptor. Left. Ribbon drawing viewed perpendicular to the molecular twofold axis. Methylation sites are represented by the dark balls by the cytoplasmic domain. The bound serine is drawn as a partially hidden green ball at the upper left in the extracellular domain. Right. Diagram of the receptor. The presumed membrane bilayer is represented by the gray band. Positions of some residues are marked on the left side. On the right, the numbers of residues in various peptide segments are indicated. From Kim *et al.*[259a] Courtesy of Sung-Hou Kim.

What happens chemically when aspartate binds into a deep pocket in the center of the sensory domain? What kind of signal can be passed from the aspartate to the "signaling domain"? Several possibilities were discussed by Kim,[264] who suggested that the binding of aspartate causes the rotation of the sensory domain of one subunit relative to that of the other and that this rotation is transmitted through the membrane to the signaling domain. The signaling domain of the receptor forms a complex with a multimeric **protein histidine kinase** called **CheA** (chemotaxis protein A) together with an auxiliary protein **CheW**. A more likely possibility is that some kind of "piston" action occurs between the transmembrane helices of the two subunits.[264a] Binding of aspartate to the receptor, and the associated alterations in the receptor•CheA•CheW complex, causes a strong *decrease* in the catalytic activity of CheA.

In its active form CheA undergoes **autophosphorylation**, that is, the phosphorylation of a histidine imidazole group in one of its subunits by the protein kinase active site of an adjacent subunit. The phospho group is then transferred from phospho-CheA to another protein, **CheY**. Phospho-CheY interacts with the flagellar motor proteins (Chapter 19) periodically causing a reversal of direction of the bacterial flagella. As a result the bacteria tumble and then usually move

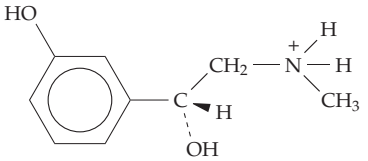
in a new direction. If the attractant molecule aspartate is present on the receptor the signal is weakened and the bacteria continue to swim in the same direction–toward food. Phospho-CheY is spontaneously hydrolyzed to remove the phospho group, but the dephosphorylation is promoted by an additional protein **CheZ**. At least two other auxiliary proteins also function in this control system. **CheR** is a **methyltransferase** that methylates the glutamate side chain carboxylates in the methylation domain of the coiled coil region and **CheB** is a **methylesterase** that removes the methyl groups. These two proteins control the methylation level in the coiled coil region of the receptor (Fig. 11-8A). Increased methylation increases the strength of the signal sent from the receptor, perhaps because methylation removes negative carboxylate charges that repell each other and weaken the structure, interfering with signaling.[259] See also Fig. 19-3.

E. Calcium, Inositol Polyphosphates, and Diacylglycerols

Calcium ions entering cells from the outside or released from internal stores trigger many biological responses (see Box 6-D). Within cells Ca^{2+} often accumulates in mitochondria, in the ER, or in vesicles called **calciosomes**.[265] Release of the stored Ca^{2+} is induced by hormones or by nerve impulses. For example, impulses flow from the nerve endings into the muscle fibers and along the invaginations of the plasma membrane called transverse tubules (Chapter 19). There they induce release of Ca^{2+} from the ER. The released ions activate enzymes[266] and induce contraction of the muscle fibers. In many cells, Ca^{2+} causes release of secreted materials, for example, neurotransmitters in the brain.[267,268]

1. Alpha Adrenergic Receptors

The release of stored Ca^{2+} is often triggered by α adrenergic receptors.[269] Like β adrenergic receptors, the α receptors are activated by adrenaline. Specific inhibitors distinguish them. For example, the β receptors are inhibited by propranolol, while the α receptors are blocked by phenoxybenzamine. The synthetic agonist **phenylephrine** activates only α receptors and no increases in cAMP or in protein kinase activity are observed.



Phenylephrine

There are two major α adrenergic receptor subtypes.[151,269] Activation of the α_2 receptors, which are present in various tissues including blood platelets, causes *inhibition* of adenylate cyclase. This inhibition is evidently mediated by the G_i protein considered in Section D,3. The nucleotide sequences of cloned α_2 receptor genes and other properties suggest close structural similarity to the β receptors.[270–273] Subtle differences in hydrogen bonding to the serine side chains shown in Fig. 11-6C may distinguish α_2 from β_2 receptors.[273] A characteristic of α_2 receptors is that pertussis toxin (Box 11-A) abolishes the inhibition of adenylate cyclase, which they mediate. In contrast, the action of α_1 adrenergic receptors is not affected by pertussis toxin.

The α_1 receptors are activated not only by catecholamines but also by the hormones **vasopressin** and **angiotensin II**. Binding of these hormones to α_1 receptors induces a complex response that involves rapid hydrolysis of **phosphatidylinositol** derivatives and release of Ca^{2+} into the cytoplasm, and of diacylglycerols into the lipid bilayer of the membrane. The response is mediated by another G protein called G_q.[274,275] When this G protein is activated it induces the hydrolysis of **phosphatidylinositol 4,5-bisphosphate** (PtdInsP_2), a normal minor component of the lipid bilayer, by **phospholipase C** (phosphoinositidase C).[265,276–281]

$$\text{Receptor} \rightarrow G_q \rightarrow \text{phospholipase C} \rightarrow \begin{cases} \text{inositol phosphates} \\ + \text{ diacylglycerol (DAG)} \end{cases} \rightarrow \text{increased } [Ca^{2+}] \quad (11\text{-}11)$$

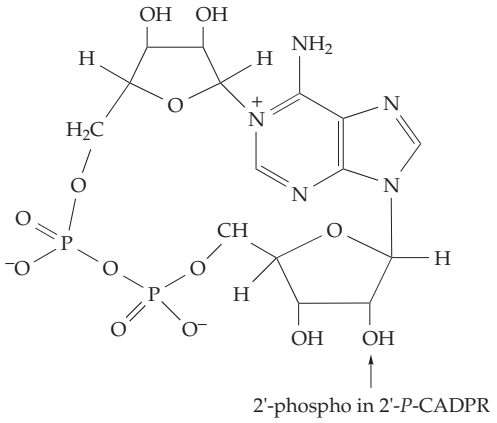
The products, **inositol 1,4,5-trisphosphate** [abbreviated InsP_3 or Ins(1,4,5)P_3], and **diacylglycerol** (DAG) are both regarded as second messengers for the catecholamines acting on α_1 receptors and for about 20 other hormones, neurotransmitters, and growth factors upon binding to their specific receptors.[269,282] In addition to vasopressin, the gonadotropin-releasing hormones, histamine, thrombin (upon binding to platelet surfaces), and acetylcholine (upon binding to its "muscarinic" receptors; Chapter 30) all stimulate inositol phosphate release.

2. Phosphatidylinositol and the Release of Calcium Ions

The phosphoinositides constitute ~2–8% of the lipid of eukaryotic cell membranes but are metabolized more rapidly than are other lipids.[265,278,279,283–285] A simplified picture of this metabolism is presented in Fig. 11-9. Phosphatidylinositol is converted by the consecutive action of two kinases into phosphatidylinositol 4,5-bisphosphate.[286,287] The InsP_3 released from this precursor molecule by receptor-stimulated phospholipase C is thought to mobilize calcium ions by

opening "gates" of calcium channels in membranes of the ER or of calciosomes.[282,288–289a] It diffuses across the peripheral cytoplasm to **Ins*P*$_3$ receptors** which are embedded in the membranes of the ER.[282,290] One of the several isotypes of InsP_3 receptors is a 2749-residue protein thought to contain a calcium ion channel.[290] Similar receptors are also found in inner membranes of the nucleus.[291,292]

Several uncertainties have complicated our understanding of the role of Ca^{2+} in signaling. What is the source of Ca^{2+}? How much of it enters cells from the outside and how much is released from internal stores? Where are the internal stores? What other kinds of ion channels are present and what second messengers regulate them? The sarcoplasmic reticulum of skeletal muscle and also membranes in many other cells contain **ryanodine receptors** as well as InsP_3 receptors.[282,293] Both of these receptors have similar structures and contain Ca^{2+} channels. However, the ryanodine receptors are activated by **cyclic ADP ribose** (cADPR),[294,295] which was first discovered as a compound inducing the release of Ca^{2+} in sea urchin eggs.[296] The 2-phospho derivative of cADPR may also have a similar function.[297]



Cyclic ADP-ribose (cADPR)

Phospholipase C, which initiates the release of phosphatidylinositol derivatives, also requires Ca^{2+} for activity. It is difficult to determine whether release of Ca^{2+} is a primary or secondary response. There are three isoenzyme types of phospholipase C–β, γ, and δ– and several subforms of each with a variety of regulatory mechanisms.[298–300a] For example, the γ isoenzymes are activated by binding to the tyrosine kinase domain of receptors such as that for epidermal growth factor (see Fig. 11-13). In contrast, the β forms are often activated by inhibitory G_i proteins and also by G_q, which is specific for inositol phosphate release.

Calcium ions are usually released in distinct pulses or "quanta." The kinetic characteristics of the system of receptors, diffusing InsP_3, calcium buffers, and calcium pumps in the cell membrane, and the membrane potential may account for this behavior.[174,301–306] Since the phosphoinositols are chelators of Ca^{2+}, the equilibria involved in this control system are complex.[307]

In addition to InsP_3, several other inositol derivatives are released by adrenergic stimulation. **Inositol 1,3,4,5-tetrakisphosphate** (InsP_4) is formed from InsP_3 by action of a soluble kinase.[308,309,309a,b] A controversial suggestion is that InsP_4 may induce opening of Ca^{2+} channels through the outer membrane of the cell[310–312] and may also function to promote storage of Ca^{2+}. It also acts as a transcriptional regulator. Other possible second messengers are inositol 1,2-cyclic-3,4-trisphosphate and related metabolites that arise by the action of phospholipase C on PtdIns 4-*P* followed by additional actions of kinases and phosphatases.[278,309,313–315] A different inositol tetrakisphosphate, Ins(3,4,5,6)P_4, may control chloride ion channels.[316,317] Both inositol 1,3,4,5,6-pentakisphosphate (**Ins*P*$_5$**) and inositol hexakisphosphate (**Ins*P*$_6$**) are also found in plants[318] and animals.[319] InsP_5 serves as an allosteric effector regulating hemoglobin in avian erythrocytes (Chapter 7). InsP_6, also known as **phytate**, is present in large amounts in cereals and recently has been found to play a role in regulating the export of mRNA from the nucleus.[319a] Additional phospho groups can be added to InsP_6 to form pyrophosphates[320,320a] and other complex polyphosphates.[321] Both InsP_5 and InsP_6 can also serve as precursors to Ins(1,3,4,5)P_4 and Ins(1,4,5)P_3 by hydrolytic dephosphorylation.[322]

Following stimulation of a cell the induced metabolism of phosphoinositides decays rapidly. The diacylglycerols are converted into phosphatidic acid and resynthesized into phospholipids (Chapter 21). The InsP_4, InsP_3, and other inositol metabolites are hydrolyzed by phosphatases.[278,309,323–327] Two of these phosphatases are inhibited by Li^+ as indicated in Fig. 11-9. They may represent one site of action of **lithium ions** in the brain.[324,327,328] Lithium salts are one of the most important drugs for treatment of **bipolar (manic-depressive) illness**. By blocking the release of free inositol, which can be resynthesized into PtdInsP_2, Li^+ may prevent neuronal receptors from becoming too active. However, the basis for the therapeutic effect of lithium ions remains uncertain.

The diacylglycerols released by phospholipase C diffuse laterally through the bilayer and, together with the incoming Ca^{2+}, activate **protein kinases C**. These kinases also require **phosphatidylserine** for their activity and phosphorylate serine and threonine side chains in a variety of proteins.[329–330b] They are stimulated by the released unsaturated diacylglycerols. In addition protein kinases C can be activated by **phorbol esters**, which are the best known tumor promoters (Box 11-D). The diacylglycerol requirement favors a function for these protein kinases in membranes. They also appear to cooperate with calmodulin to activate the Ca^{2+}-dependent contraction of smooth muscle.[330]

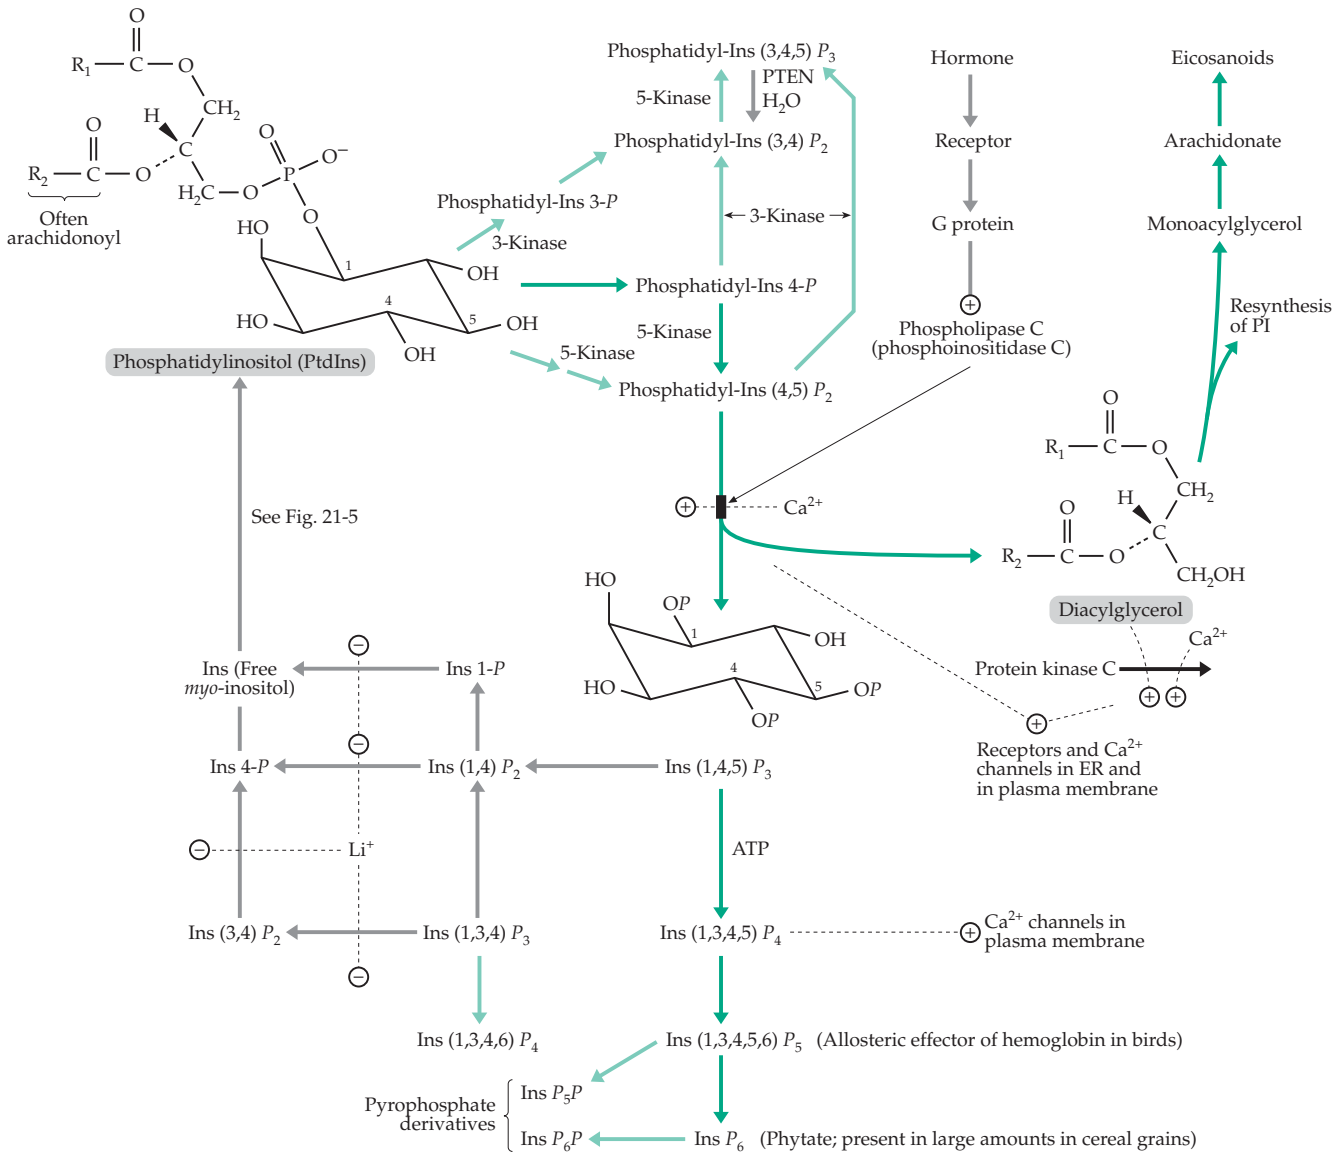


Figure 11-9 Scheme showing synthesis and release of diacylglycerol and inositol phosphates and their regulation of calcium concentration in response to hormonal stimulation.

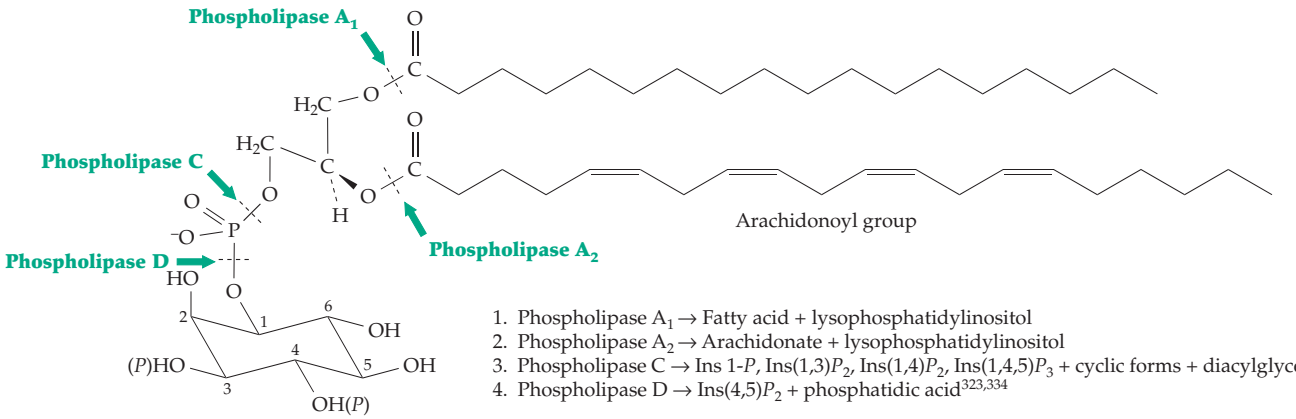
Diacylglycerols released by phospholipase C usually contain **arachidonic acid** in the 2 position. Hydrolytic cleavage of this linkage[284,331] is a major source of arachidonate for synthesis of **eicosanoids** such as the **prostaglandins** whose functions are discussed in Chapter 21. Arachidonate can also be formed directly by the action of phospholipase A_2 on membrane phospholipids[332,332a] (see the structure on p. 566). It has been suggested that protein G_q, which activates the hydrolysis of phosphoinositides, may also regulate phospholipase A_2 directly. Released diacylglycerols may not only activate protein kinases C but also have a direct role in promoting the membrane fusion required in exocytosis and endocytosis.[332] Other breakdown pathways of phosphatidylinositols are also indicated in the following structure.[298,333]

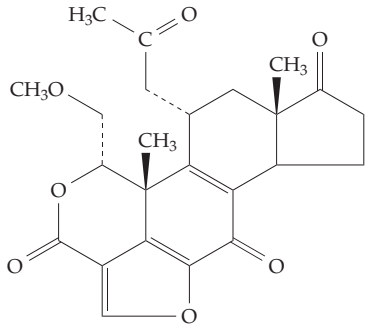
Initially most attention was paid to the water-soluble inositol phosphates that are released from phosphoinositides. However, phosphoinositol derivatives that retain the diacylglycerol part of the molecule have regulatory functions while remaining in membranes. A phosphatidylinositol 3-kinase phosphorylates the 3-OH of inositol in PtdIns, PtdIns 4-*P* and PtdIns (4,5)P_2 to give PtdIns 3-*P*, PtdIns(3,4)P_2, and PtdIns(3,4,5)P_2, respectively.[335–337d] However, they are ideally suited to function as spatially restricted membrane signals.[337a] They affect protein kinase C as well as the Ser / Thr protein kinase Akt (discussed in Section F,3),[326b] and have several functions in vesicular membrane transport and in regulation of the cytoskeleton.[337e,f]



1. Phospholipase $A_1 \rightarrow$ Fatty acid + lysophosphatidylinositol
2. Phospholipase $A_2 \rightarrow$ Arachidonate + lysophosphatidylinositol
3. Phospholipase C $\rightarrow$ Ins 1-*P*, Ins(1,3)P_2, Ins(1,4)P_2, Ins(1,4,5)P_3 + cyclic forms + diacylglycerol
4. Phospholipase D $\rightarrow$ Ins(4,5)P_2 + phosphatidic acid[323,334]

Phosphatidylinositol

Characteristic of many of the phosphoinositide-regulated proteins is a proline-rich PH domain (Table 7-3) which can transmit regulatory signals to additional proteins in a cascade. Their importance is emphasized by the finding that a 405-residue phosphatase **PTEN** (named after its gene symbol) which catalyses hydrolytic removal of one phospho group from PtdIns(3,4,5) P_3 to form PtdIns(3,4) P_2, (Fig. 11-9) is a major human tumor suppressor (see Box 11-D).[338,338a,b] These lipids are also important in insulin action (Section G,3). The steroid-like fungal metabolite wortmannin is a specific inhibitor of the 3-kinase.[339,339a]



Wortmannin

F. Regulatory Cascades

The effect of a regulated change in the activity of an enzyme is often amplified through a cascade mechanism. The first enzyme acts on a second enzyme, the second on a third, etc. The effect is to rapidly create a large amount of the active form of the last enzyme in the series.

We have already considered regulatory cascades initiated respectively by the β and α_2 adrenergic receptors. The effect of these cascades on glycogen phosphorylase is outlined on the left side of Fig. 11-4. One branch of the cascade sequence begins with release of adrenaline under control of the autonomic nervous system. In muscle, binding of this hormone to the β receptors on the cell membrane releases cAMP which activates a protein kinase. The kinase then phosphorylates phosphorylase kinase. At this point the muscles are prepared for the rapid breakdown of glycogen. However, an additional initiating signal is the release of Ca^{2+} into the cytoplasm in response to impulses to specific muscles via the motor neurons. Calcium ions can also be released in the liver by α adrenergic stimulation. Phosphorylase kinase is activated by the calcium ions, and in their presence it converts inactive phosphorylase *b* to the active phosphorylase *a*. Both protein kinases and phosphorylase kinase also act on glycogen synthase, phosphorylating it and converting it to an inactive form. This turns off the biosynthetic pathway at the same time that glycogenolysis (glycogen breakdown) is turned on. Spontaneous reversion of the enzymes to their resting states occurs through the action of phosphatases that cut off the phospho groups placed on the protein by the kinases. Also essential are phosphodiesterases, which destroy the cAMP, and the calcium ion pump, which reduces the concentration of the activating calcium ion to a low level.

Elaborate cascades initiate the clotting of blood (Chapter 12) and the action of the protective complement system (Chapter 31). Cascades considered later in the book are involved in controlling transcription (Fig. 11-13) and in the regulation of mammalian pyruvate dehydrogenase (Eq. 17-9), 3-hydroxy-3-methylglutaryl-CoA reductase and eicosanoids (Chapter 21), and glutamine synthetase (Chapter 24).

1. Advantages of Regulatory Cascades

Computer simulations as well as studies of experimental models have led to the following conclusions.[340,341] Even simple cascade mechanisms, such as the one shown in Fig. 11-10, can provide a more flexible response

to allosteric effectors (such as e_1 in the figure) than if the effector acted directly on the enzyme rather than on the protein kinase. The cascade also provides **amplification**. This is especially true if additional cycles are added. A response can result from the binding of only a small number of hormone molecules to a receptor in a cell membrane or from activation of only a few molecules of a protease in the initiation of blood clotting. A striking amplification occurs in visual responses. Under appropriate conditions a single quantum of light falling on a receptor cell in the retina of an eye can initiate a nerve impulse (Chapter 23). The latter requires the flow of a large number of Na^+ ions across the plasma membrane. It would be hard to imagine how absorption of one quantum could initiate a photochemical reaction leading to that much sodium transport without intermediate amplification stages. Another advantage of cascades is that they may provide **ultrasensitive responses**. Not only can a response be sensitive to a higher power than the first of the concentration of a signaling molecule but also the amplification provided by the cascade confers a high sensitivity to the response.[342]

Cascade systems also provide for response to more than one allosteric stimulus in a single pathway. Thus, as shown in Fig. 11-4, glycogen catabolism can be initiated in more than one way. Two pathways are known for initiation of both blood clotting and activation of the complement system. Many pathways activate the MAP kinase pathway shown in Fig. 11-13.

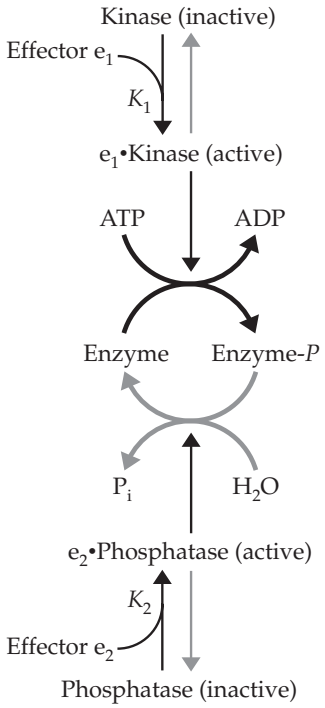


Figure 11-10 A "monocyclic" regulatory cascade involving phosphorylation and dephosphorylation of an enzyme. After Stadtman and Chock.[341]

2. Substrate Cycles

Although cascade systems offer advantage to cells, there is a distinct energy expenditure associated with the controls.[343] As can be seen in Fig. 11-10, in addition to providing for turning on and turning off the regulated enzyme, the kinase and the phosphatase together catalyze hydrolysis of ATP to ADP and inorganic phosphate. Thus, the regulated enzyme is continually cycling between active and inactive forms. The relative amounts of each are determined by the amounts of the effectors e_1 and e_2, the concentrations of modifying enzymes, and the kinetic constants. Such cycles have sometimes been called "futile cycles" because they seemingly waste ATP. This is particularly true of cycles that involve major metabolites, sometimes called **substrate cycles**. An example is the conversion of fructose 6-*P* to fructose 1,6-bisphosphate by phosphofructokinase and hydrolysis of the bisphosphate back to fructose 6-*P* by a phosphatase (Fig. 11-2). However, *the cycles are not futile* because the hydrolysis of the ATP provides the energy required to maintain the concentrations of modified (phosphorylated) enzyme or enzymes at steady-state levels that are required for efficient catalysis.[341,344] The energy utilized in this way in regulation of enzymes is often small.[345] Substrate cycles are not only an unavoidable consequence of the need to regulate enzymes but also provide for improved sensitivity in metabolic control. Consider Fig. 11-2 again. If the enzymes are set for conversion of fructose 1,6-P_2 to glycogen (backwards direction), the flux of materials flowing in the forward direction (glycolysis) will be efficiently curtailed because any fructose 1,6-P_2 formed will be hydrolyzed rapidly by the active phosphatase. Under these circumstances the flux in the forward direction will be ultrasensitive to the activation of phosphofructokinase and to the inhibition of fructose 1,6-bisphosphatase.[346,347]

G. Insulin and Related Growth-Regulating Hormones

Since its isolation in 1921, insulin has been the object of an enormous amount of experimentation aimed at clarifying its mode of action. It is produced by the β cells of the pancreatic islets of Langerhans and released into the bloodstream in response to elevated glucose levels. The absence of insulin or of a normal response to insulin results in the condition of **diabetes mellitus**, which is the most prevalent human metabolic disorder (see Box 17-G).[348]

Insulin or insulin-like material is also produced in ciliated protozoa, vertebrate and invertebrate animals, fungi, green plants,[349,350] and even in *E. coli*.[351]

1. Metabolic Effects of Insulin

Insulin has many effects on metabolism.[348,352,353] (Some of these are listed in Table 17-3). They can be summarized by saying that: (1) In most tissues insulin stimulates synthesis of proteins, glycogen, and lipids. (2) It affects the permeability of membranes, promoting the uptake and utilization of glucose and amino acids and of various ions from the blood. (3) It promotes both synthesis of glycogen and the breakdown of glucose by glycolysis. At the same time, it inhibits synthesis of glucose from amino acids by the gluconeogenesis pathway. The effects are not uniformly the same in all tissues. Some can be observed within a few minutes after administration, presumably as a result of regulation of enzymes. Effects on mRNA metabolism, protein synthesis, and cell growth are seen at later times.

The uptake of glucose by brain, liver, kidneys, erythrocytes, and the islets of Langerhans is unaffected by insulin. However, in muscle and adipose tissues insulin stimulates glucose uptake. Part of this effect results from insulin-induced translocation of molecules of the 509-residue glucose transport protein GLUT4 (Chapter 8) from the cytosol into the plasma membrane where it can function.[354–356a] Insulin apparently also increases the rate of synthesis of the transporters.

Insulin stimulates the phosphorylation of serine side chains of many proteins, including ATP citratelyase, acetyl-CoA carboxylase, and ribosomal subunit S6. At the same time it stimulates the dephosphorylation of other proteins, including acetyl-CoA carboxylase, glycogen synthase in skeletal muscle (Fig. 11-4),[49] pyruvate dehydrogenase, and hormone-sensitive lipase in adipose tissue. Yet another effect of insulin is to alter the amounts of specific messenger RNA molecules. For example, the transcription of the gene for phosphoenolpyruvate carboxykinase (PEPCK; Eq. 13-46) a key enzyme in gluconeogenesis, is inhibited by insulin within seconds after binding. The hexokinase isoenzyme called **glucokinase** phosphorylates glucose to glucose-6-*P* in liver and in pancreatic β cells. Its synthesis in liver is induced by insulin. (However, in the β cells the synthesis of glucokinase is induced by glucose.)

2. Insulin Receptors

All of the effects of insulin appear to result from its binding to insulin receptors, of which ~10^2 to 10^5 are present in the plasma membranes of most animal cells. First isolated in 1972,[357] insulin receptors and their cloned genes have been studied intensively. The receptors are $\alpha_2\beta_2$ disulfide crosslinked oligomers composed of pairs of identical 120- to 135-kDa α subunits and 95-kDa β subunits. An α and a β subunit are cut from a single precursor chain. The human insulin receptor precursor exists as two isoforms, A and B, which arise as a result of a difference in splicing of the mRNA.[358] Twenty-one introns are removed by splicing to form the mRNA for the 1355-residue B precursor.[348,358a] The mRNA for the A form lacks a 36-nucleotide segment (exon 11) that is discarded during splicing. The α chains come from the N-terminal part of the precursor and the β chains from the C-terminal part. The receptor sequence is numbered as in the longer B form precursor. (However, many authors number the chains of the A form receptor as in its precursor, 12 less than the numbers given here for residues 719 or higher[359]). The B form receptor has 731-residue α chains while the A form has 719-residue α chains as a result of the missing sequence from exon 11 (see Fig. 11-11A). Four residues (732–735 in the B form) are cut out and discarded, leaving 620-residue β chains for both isoforms. The chains become linked by three or more disulfide crossbridges.[360]

The two α subunits, which contain the insulin binding sites, are apparently present entirely on the outer surface of the plasma membrane. The β subunits pass through the membrane with their C termini in the cytoplasm.[361–363] Both α and β subunits are glycoproteins. Study of the amino acid sequences suggests that only one 23-residue segment (residues 930–952 of the B isoform) of hydrophobic amino acid residues in each β subunit is likely to exist as an α helix that spans the membrane. This raises several questions. How can a signal be sent from the cell surface into the cytoplasm through a single pair of α helices? Are there additional parts of the receptor that span the bilayer of the membrane? To make it easier to visualize these questions refer to Fig. 11-11B, which is a more realistic, although fanciful, drawing than that in Fig.11-11A. Electron microscopy and crystallography are now providing the first direct images of the receptor.[363a, b, c]

One possible way in which a signal could be sent through the membrane is for binding of insulin to promote aggregation of two or more receptors.[364] If insulin induces the receptors to stick together on the outside of the cell, the parts protruding into the cytoplasm would also tend to aggregate. This could induce a response. A second possibility is that a conformational change in the α subunits pulls or pushes on the β subunit allowing the latter to be exposed less or more on the cytoplasmic side. This difference might be sufficient to cause a conformational change in the cytoplasmic domain of the subunit. A third possibility involves activation by a twisting mechanism as proposed for the aspartate receptor (Fig. 11-8).

A large part of the cytoplasmic domain of the insulin

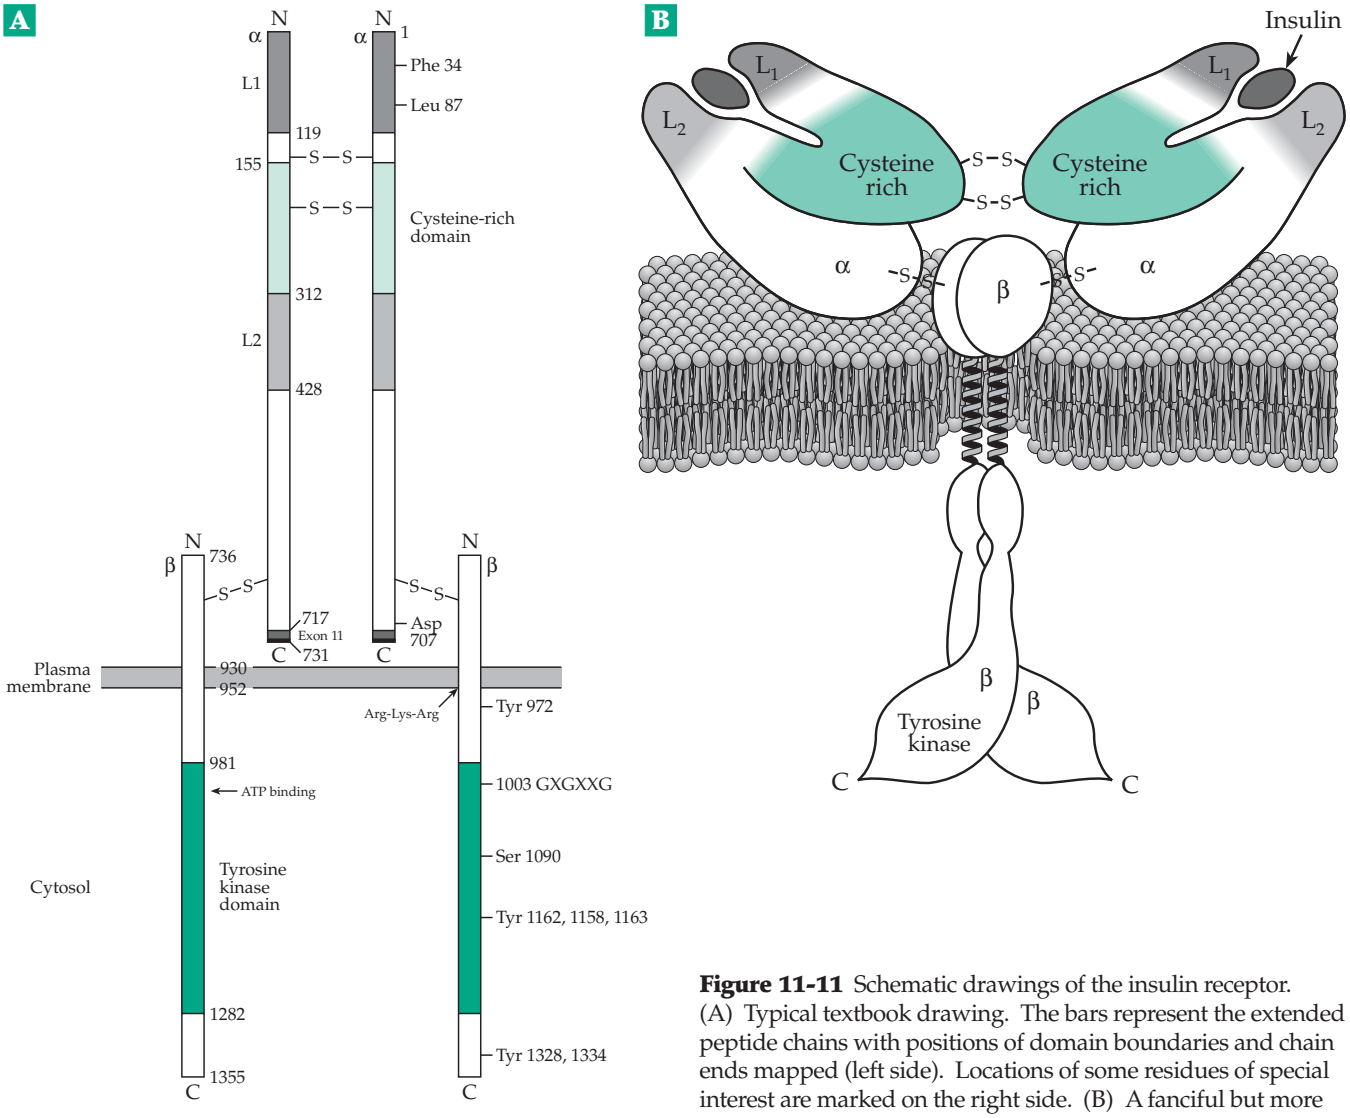

Figure 11-11 Schematic drawings of the insulin receptor. (A) Typical textbook drawing. The bars represent the extended peptide chains with positions of domain boundaries and chain ends mapped (left side). Locations of some residues of special interest are marked on the right side. (B) A fanciful but more realistic picture of the receptor. See Fabry *et al.*[367]

receptor consists of a tyrosine-specific protein kinase whose three-dimensional structure is depicted in Fig. 11-12.[365,365a] Not only can it phosphorylate –OH groups on tyrosine side chains of other proteins[362] but also it catalyzes ATP-dependent **autophosphorylation** of several residues in the C-terminal region. The most readily phosphorylated residue is Tyr 1158.[366] Some diabetic individuals have receptors with impaired tyrosine kinase activity.[362]

Using directed mutation of the cloned receptor gene, Lys 1018 in the ATP-binding part of the tyrosine kinase domain was replaced by alanine. This caused a loss both of kinase activity and of biologic response to insulin.[362] Thus, both the tyrosine kinase activity and autophosphorylation appear essential. If so, aggregation of two or more receptors may increase the extent of autophosphorylation and initiate a response.

Studies of many mutant proteins indicate that insulin binds to the α chains of the receptor between the two domains labeled L1 and L2 in Fig. 11-11.[368] Among essential residues is Phe 39 (marked).[369] Insulin contains three disulfide linkages (Fig. 7-16) and might undergo a thiol–disulfide exchange reaction (Eq. 11-7) with SH groups present in a cytoplasmic cysteine-rich domain of the α subunit of the receptor or with an external thiol compound.[369a,b] Such an exchange may also be essential for activation of the receptor.[370]

3. A Second Messenger for Insulin?

The known regulatory effects of insulin (Table 17-3) often involve phosphorylation of serine or threonine side chains on specific proteins. The tyrosine kinase of the activated insulin receptors does not catalyze such phosphorylation. Therefore, it seems likely that one or more second messengers or mediator substances are needed. Much effort has gone into searching for

Figure 11-12 (A) Stereoscopic view of an α-carbon trace of the insulin receptor kinase domain. Every tenth residue is marked with a filled circle and every twentieth residue is labeled. (B) Locations of missense mutations in noninsulin-dependent diabetes mellitus patients mapped onto the receptor kinase structure. The mutations are R993Q, G1008V, A1048D, R1164Q, R1174Q, P1178L, W1193L, and W1200S. Here, R993Q is the mutant in which arginine 993 is replaced with glutamine, etc. From Hubbard *et al*.[365]

substrates for the tyrosine kinase,[353,362,371,372] whose activity on external protein substrates reaches a maximum after receptor tyrosines 1158, 1162, and 1163 have been autophosphorylated. Phosphorylation of such **insulin receptor substrates (IRSs)** as well as of some smaller "adapter" proteins is thought to initiate a series of complex cascades that serve to pass the insulin signal on to a variety of sites of action within a cell.[373–376] The large 185-kDA **insulin receptor substrate-1 (IRS-1)**, which is present in most cells, is phosphorylated on several tyrosines, usually within the sequences YXXM or YMXM. Phosphotyrosine within such sequences is known to be a ligand for the recognition domain SH2, which is present in many proteins. Binding of SH2 domains of other proteins to IRS-1 allows the insulin signal to be passed to several different proteins in the branched signaling pathways. Other insulin receptor substrates include **IRS-2**,[376a,b] protein Gab-1[376c], and the smaller protein called **Shc**, which occurs as 46-, 52-, and 66-kDa isoforms and is discussed further on p. 568.[376,377] Shc is an adapter protein which forms a complex that triggers the activation of the G protein Ras and the MAP kinase cascade shown in Fig. 11-13.[377,378] This pathway (see Section H,2) is thought to mediate the mitogenic (growth promoting) effects of insulin and also to promote phosphorylation of serine and threonine side chains of many proteins in the cytoplasm, the cytoskeleton, ribosomes, membranes, and the nucleus.[379,380] One serine kinase specifically phosphorylates the insulin receptor on serine 1078.[381]

In addition to IRS-1, IRS-2, and Shc, there are additional adapter proteins that interact with the phosphorylated tyrosine kinase domain of the insulin receptor.[382] Furthermore, the receptor tyrosine kinase may catalyze *direct* phosphorylation of some proteins, e.g. a cytoplasmic loop of the β_2 adrenergic receptor (Fig. 11-6), without intervention of an adapter.[383]

Phosphorylated IRS-1 activates a second signaling pathway by interacting with an 85-kDa SH2-containing protein that is a subunit of phophatidylinositol 3-kinase.[384–386] This activates the 110-kDa catalytic subunit of the 3-kinase, which catalyzes formation of phosphatidylinositol 3-phosphate as well as PtdIns (3,4)P_2 and PtdIns (3,4,5)P_3.[387,387a] These compounds, which remain within membranes, activate other branches of the signaling cascade, some of which may converge with those of the MAP kinase cascade. However, there appears to be specific activation of a ribosomal Ser/Thr kinase that, among other activities, phosphorylates ribosomal protein S6, a component of the small ribosomal subunit.[388] It also phosphorylates some isoforms of protein kinase C and other enzymes. PtdIns 3-kinase may also activate 6-phosphofructo-2-kinase (Fig. 11-2, step *d*).[384,388]

One of the most important effects of insulin is to increase glucose uptake by cells.[373,389] The mechanism is thought to depend upon the transporter protein GLUT4, which is stored within the membranes of small cytoplasmic vesicles. Binding of insulin to its receptors induces movement of these vesicles to the plasma membrane where fusion with the plasma membrane makes the GLUT4 molecules available for glucose transport.[390] Phosphatidylinositol 3-kinase also plays an important role. The PtdIns(3,4)P_2 and PtdIns(3,4,5)P_3 generated by this enzyme (Fig. 11-9)

remain in the membrane and provide sites to which various proteins, e.g., those containing PH domains (Chapter 7) may bind. Among the proteins "recruited" to the inner membrane surface in this way is a Ser/Thr protein kinase known as PKB/Akt. The Akt abbreviation refers to its relationship to a particular viral oncogene.[390a–390e] and the phosphatidyl-inositol derivatives generated by the 3-kinase may have a direct effect upon the exocytosis of the GLUT-4 containing vesicles as may Gq-coupled receptors.[391]

Although insulin unquestionably stimulates phosphorylation of many proteins, the major metabolic effect appears to result from *dephosphorylation* by phosphatases of phosphorylated forms of several enzymes.[379,392] These include **glycogen synthase** and **pyruvate dehydrogenase**, which are both activated by dephosphorylation, and **glycogen phosphorylase**[393] and **hormone-sensitive lipase**, which are deactivated by dephosphorylation. These changes result in increased synthesis and storage of both glycogen and triacyglycerols. Insulin also stimulates a membrane-bound cAMP phosphodiesterase causing a reduction in cAMP concentrations.[394]

Insulin injected into the human body has a half-life of only 5–10 minutes. Much of the hormone is destroyed by hydrolytic cleavage of the peptide chain by a non-lysosomal protease.[395–397] The receptors together with the hormone are taken into cells by endocytosis from clathrin-coated pits and both may be degraded in the lysosomes.[396,398] Some signaling may arise from insulin receptors in endosomes.[399] Some of the hormone enters the nucleus, perhaps still bound to the receptors,[400] and may have a direct effect upon gene transcription. Some receptors are recycled to the cell surface.[398] This latter process, together with that of new receptor synthesis, controls the number of receptors on the surface and, in turn, the sensitivity of the cell to insulin. This is only one mechanism used for desensitization or **downregulation** of receptor sensitivity and numbers, something that happens normally for any hormone when its concentration is high.[401,402]

H. Growth Factors, Oncogenes, and the Cell Cycle

Insulin is just one of a large number of proteins that are secreted by cells and which influence the growth of nearby cells.[403–405] For example, blood platelets, which aggregate at the site of an injury to a blood vessel, contain granules (α granules) which, when the platelet is "activated" (see Box 8-A) release **platelet-derived growth factor** (PDGF), a 28- to 31-kDa glycosylated peptide which stimulates growth and tissue repair in the injured region.[406,407] There are many other protein growth factors, a few of which are considered here. Others are discussed in Chapters 30–32.

1. Oncogenes and Proto-oncogenes

Studies of cancer-causing cellular oncogenes and **proto-oncogenes** (**c-*onc***) identified in the human genome[408–411] have contributed greatly to our understanding of the action of growth factors. Proto-oncogenes are segments of DNA that code for proteins that have a normal function but which may become "activated" by a mutation or by chromosomal rearrangement to become cancer-causing oncogenes (Box 11-D). Oncogenes were discovered first in oncogenic (cancer-causing) retroviruses,[412] where they are designated v-*onc*. The v-*onc* genes are usually very similar but not identical to the corresponding c-*onc* genes and are thought to have arisen from them. The v-*onc* genes are often incomplete or have become fused to other genes by genetic recombination. Considerable excitement has attended the discovery that *many solid human tumors contain activated oncogenes*,[413] several of which are listed in Table 11-3.

In 1983 it was found that the oncogene *sis*, which is carried by the simian sarcoma virus, has a 104-residue sequence nearly identical to that of human PDGF.[404,414] The PDGF receptor has a large extracellular domain consisting of five immunoglobulin-like domains. Like the insulin receptor, it has tyrosine kinase activity which resides in a C-terminal cytoplasmic domain.[406,407,415] This suggests that the malignant transformation of cells by the viral v-*sis* gene leads to an excessive production of normal PDGF and, consequently, to excessive growth. The sequences related to v-*sis* are often found in human tumors and are located on chromosome 22.[416] Rearrangements by which part of this chromosome is moved to another location are well known and sometimes lead to conversion of the proto-oncogene to an active cancer-inducing oncogene.

The avian v-*erbB* oncogene and oncogene *neu*[417-419] both have sequences homologous to that of the gene for the receptor for the 53-residue **epidermal growth factor** EGF.[420–423a] The corresponding cellular c-*erbB* is the gene for the EGF receptor, a large 170-kDa 1186-residue protein. It also resembles the insulin receptor in having an N-terminal domain outside the cell, a single hydrophobic helix that spans the membrane, and a cytoplasmic domain with tyrosine-specific protein kinase activity.[403,419,424,425] It differs from the insulin receptor in being a single peptide chain. However, when EGF binds, the receptor dimerizes and the protein kinase is activated.[426] It phosphorylates its own Tyr 1173 near the C terminus, as well as tyrosines in the **lipocortins**, 36- to 38-kDa calcium-binding proteins located on the cytosolic face of plasma membranes.[427] The activated receptor also stimulates phospholipase C with a resultant increase in concentrations of inositol trisphosphate and Ca^{2+} (see Fig. 11-13).[428] The active oncogene v-*erbB* encodes a major fragment of the EGF receptor. However, most of the N-terminal domain

TABLE 11-3
A Few Oncogenes That Have Interested Biochemists

Oncogene Symbol	Source	Properties
v-*sis*	Simian sarcoma virus	Gene product is closely related to the B-chain of platelet-derived growth factor
v-*erbB*	Avian erythroblastosis virus	Gene product is shortened version of the EGF receptor, a tyrosine kinase
neu	(Her-2) Rat neuroblastomas A similar gene is found in human breast cancers and adenocarcinomas	Homologous to EGF receptor; has tyrosine kinase activity; may control phosphotidylinositol 3-kinase
v-*src*	Rous avian sarcoma virus	Gene product is another tyrosine-specific protein kinase
abl	Chronic myelogenous leukemia	Similar to *src*; characteristic chromosomal translocations yield cancer
ras, *has*, v-H-*ras* v-K-*ras* N-*ras*	Human bladder, colon, lung carcinomas	Homology with G_s and G_i regulatory proteins; several human proto-oncogenes exist; a single mutation in H-*ras* may lead to cancer
bas, *kis*	Murine sarcoma viruses	
v-*myc*	Burkitt's lymphoma, mouse plasmacytomas, avian retrovirus MC29	Nuclear location for gene product; which forms complex with protein Jun
mos	Burkitt's lymphoma, mouse plasmacytomas	
v-*fos*	Osteosarcoma virus (mouse)	Nuclear location for gene product, which forms complex with protein Jun
v-*jun*		Protein product is subunit of transcription factor AP-1
*bcl*1		Cyclin D1

including the EGF binding site is missing and the C-terminal end has been shortened. The tyrosine kinase domain is intact but Tyr 1173 is missing.

The rat *neu* oncogene (also called *erbB*-2 and *HER*-2), which apparently is derived from the gene for another growth factor receptor, differs from normal *neu* by a single nucleotide. This change causes valine to be substituted for glutamic acid at position 664 in the membrane-spanning domain of the 185-kDa protein.[418] This evidently gives an overactive and perhaps uncontrolled tyrosine-specific protein kinase. The c-*erbA* proto-oncogene appears to be the nuclear receptor for the thyroid hromone **triiodothyronine** (Chapter 25).

The Rous sarcoma virus oncogene v-*src* and a family of related oncogenes are derived from protein tyrosine kinases that are attached with the aid of a myristoyl anchor to the inner, cytoplasmic surfaces of membranes.[429–431] They may be activated by interaction with an occupied surface receptor. It has been difficult to understand the functioning of the normal Src protein. However, inactivation of c-*src* in mice caused the serious bone disease **osteopetrosis** in which the osteoclasts fail to function properly in resorbing the bone matrix, thereby allowing excessive accumulation of calcium phosphate.[432,433] A c-*src* deficiency also decreases formation of the bone adhesion protein **osteopontin**, an RGD protein.[434] There is actually a *family* of src proteins, some of which have important functions in lymphocytes.[435–438] The gene for one of these is mutated in the β cell disorder **agammaglobulinemia**.[437]

Another oncogene derived from a tyrosine kinase

BOX 11-D CANCER

Although cancer occurs in about 200 clinically distinct types, most cancers can be classified into four categories. In **leukemias**, which account for 3% of the ~700,000 cases of cancer diagnosed per year in the United States, an abnormal number of leukocytes are produced by the bone marrow. **Lymphomas**, such as Hodgkin's disease and Burkitt's lymphoma, arise from lymphocytes. They account for ~5% of human cancers. In these diseases malignant cells are produced in the spleen and lymph nodes and sometimes aggregate in lymphoid tissues. **Sarcomas**, solid tumors of bone or other connective tissue, contribute ~2% to the total of human cancers, while **carcinomas**, cancers of epithelial tissue, account for 85%. Carcinomas may develop from either the external or the internal epithelia, including the glands, lungs, and nerves.[a–d] More than one-third of all cancers in the United States are nonmelanoma carcinomas of the skin;[e] for these the mortality rate is low. Lung, colorectal, breast, and prostate tumors account for 55% of cancer deaths.[c] Carcinomas predominate in humans, but lymphomas, leukemias, and sarcomas are much more prevalent in laboratory animals and fowl.

An important characteristic of cancer cells is their uncontrolled proliferation. They don't respond to the normal signals from adjacent cells that indicate that cell division should stop. Cancer cells also differ dramatically from those present in warts and other benign tumors and in psoriasis. These conditions also result in excessive proliferation of cells and partial derangement of normal regulatory processes.

A second characteristic of cancer cells is that they usually appear less differentiated than the tissues from which they arise and are more like embryonic cells. Many cancers produce **ectopic proteins**, proteins inappropriate to the tissue involved and often identical to proteins synthesized by embryonic or fetal cells. A well-known example is **α-fetoprotein**, a 72-kDa glycoprotein normally present in serum in almost undetectable amounts but present in large amounts when some types of cancer are present.[f] A third property of cancers is the tendency toward **metastasis**, the detachment of cells from the cancer and their development in distant parts of the body.[g–i]

Cancer cells don't grow any faster than normal cells but they continue to divide when normal cells would not. For this reason, a cancer can grow rapidly and its demands for nutrients can literally starve the host. Cancer tends to weaken the immune system, making the host more susceptible to infections. In addition, cancers often interfere directly with the functioning of various organs and may cause death in this way.

What initiates a cancer? We know that cancers can arise from only one or a very small number of cells and that cancer can be induced by carcinogenic chemical compounds, by certain viruses, and by radiation. Use of tobacco appears to be responsible for about 30% of all human tumors.[c,j] Diet also affects the likelihood of developing cancer. For example, diets containing less animal fat and more fruits and vegetables are associated with lower levels of colon cancer.[c,k] Many carcinogenic compounds are naturally present in foods. Genetic factors help to determine susceptibility to cancer[b,l] and characteristic chromosomal aberrations are usually associated with cancer.[m–o] The incidence of cancer increases markedly with age.

A common feature of all the agents that induce cancer is the production of mutations and cancer probably always involves some alteration in the cell's DNA. The long lag between exposure to carcinogenic materials and development of cancers, often 20 years or more, suggested that more than one mutation or chromosomal rearrangement is required for production of a cancer. Recent evidence confirms that several mutations are required.[b,p] Relevant to this conclusion is the fact that carcinogenic compounds can be applied to the skin in amounts sufficient to cause a number of mutations in the epithelial cells but insufficient to actually induce cancer. Then, even many years later, irritant compounds known as **cancer promoters** can be applied and cancer will develop promptly. The promoters apparently induce cell proliferation which leads to more errors in DNA replication, converting an initially mutated cell to a cancerous cell. The most studied promoters are the phorbol esters, which are known to activate the protein kinase C isoenzymes (Section E,2). Any factors that increase rates of cell division such as some hormones, excess calories, or chronic inflammation cause increased cancer.[c] Cell divisions are accompanied by errors in replication of DNA and sometimes by translocation or deletion of parts of chromosomes. Chronic infection by bacteria, viruses, or other organisms may cause cancer as a result of continuing inflammation. Other cancers arise from integration of viral DNA into the host's DNA.

Virally induced cancers are often epidemic among poultry and rodents. When infected with cancer-causing viruses from these animals, cells in culture often become **transformed**. Whereas normal cells tend to respond to **contact inhibition** and grow as a monolayer, transformed cells continue to divide after the monolayer is complete. In laboratory studies, transformation of cells is often taken as the equivalent to an early step in cancer production in an animal. Studies of transformation led to the identification and characterization of several **viral oncogenes** which cause the transformation. These are designated by abbreviations such as v-*src* (the oncogene of Rous sarcoma virus, which induces cancer in chickens) and v-*sis* (the oncogene of simian sarcoma virus, which causes cancers in monkeys). Some other oncogenes are described in the main text. Naturally occurring gene

BOX 11-D CANCER (continued)

sequences closely homologous to those of the viral oncogenes have been found in many solid human tumors. Study of oncogenes has shown that they are related to and derived from **proto-oncogenes**, normal cellular genes that are involved in control of growth and differentiation.

Oncogenes are often "amplified" in tumor cells so that their copy number is greater than that of the corresponding genes in normal cells. For example an oncogene related to the viral oncogene *neu* is amplified in many human breast and ovarian cancers[q] and oncogene *src* in many colon cancers.[r] Mutated *ras* genes have been found in over one-third of human colorectal cancers.[s] Amplified oncogenes *ras*, *myc*, and *myb* have been observed in other cancers.[t] Oncogenes are often overexpressed or are responsible for over-expression of other genes. One idea that developed from these observations is that cancer cells may secrete new or mutated growth factors that stimulate their own receptors (**autocrine** stimulation) in a way that promotes uncontrolled growth.[u]

Cancer develops in stages and in many cases defective proto-oncogenes appear before truly malignant cells appear. The latter must result from additional mutations that often involve *loss* of parts of chromosomes. A major breakthrough in our understanding of cancer and how it is induced by loss of genes has come from studies of some rare cancers that are inherited in a Medelian fashion. One of these is **retinoblastoma**, an intraocular tumor which affects 1 child in 20,000. Homozygotes always develop the disease between the ages of 1 and 5. The hereditary defect has been traced to the absence of a functional retinoblastoma gene *RB1*, which is found in band q14 of chromosome 13.[v] Additional mutational events are required to induce cancer. The *RB1* gene was the first **tumor-suppressor** gene (anti-oncogene) identified. These suppressor genes encode proteins that inhibit growth.[w–z] The retinoblastoma gene encodes a 105-kDa DNA-binding phosphoprotein (Rb-*P*).[aa–bb] The Rb protein is phosphorylated and dephosphorylated in a cyclic fashion that is synchronized with the cell replication cycle (Fig. 11-15). It forms a complex with a transcription factor E2F that functions in transcription of the adenovirus genes and is also involved in control of the cell replication cycle.[cc] Deletion of the Rb gene from mice leads to death of embryos homozygous for the mutation.[dd]

Study of other rare hereditary cancers has led to the location of 20 or more additional probable tumor-suppressor genes. One of these, ***p53***, is inactive in over 50% of all human cancers and over 90% of sqamous cell carcinomas of the skin.[ee] In small-cell lung cancers and osteosarcoma *both RB* and *p53* are inactive.[z] Protein p53 is a stronger tumor suppressor than protein Rb. Results of a variety of experiments have suggested that p53, a DNA-binding protein of known structure,[ff] plays a key role in checking DNA for damage at the G_1 to S-phase checkpoint in the cell cycle. If the DNA has too many defects the cycle is stopped in the G_1 stage and the cell may be killed by the process known as **apoptosis**.[gg–jj] Protein p53 has been called the "guardian of the genome." The mechanisms by which it functions are complex and poorly understood. It may act with the assistance of Rb and many other proteins. Mutations in DNA and their repair are discussed in Chapter 27 and the cell cycle is discussed in this chapter and further in Chapters 26 and 32.

Many other cancer susceptibility genes also encode suppressors. Mutation in genes *BRACA1*[kk] and *BRACA2*[ll] are responsible for early onset ovarian and breast cancer. Gene *DPC4* may be a suppressor of pancreatic cancer.[mm] The gene *ptc* (patched), first studied as a developmental gene in *Drosophila*, may encode a suppressor of basal cell carcinoma, the commonest form of human skin cancer.[nn] Gene *p16* (also called *CDKN2*) may be a major suppressor that is mutated in many cancers including the dangerous skin melanoma.[oo] Mutations in the *NF* gene, which may be a cytoskeletal protein, are associated with **neurofibromatosis**,[pp] a relatively common hereditary disease causing tumors of the nervous system. The tumors are usually not malignant but are numerous and disfiguring. Several cancer susceptibility genes are associated with faulty mismatch repair of DNA. Among these is the *APC* gene, whose malfunction is associated with human **familial adenomatous polyposis** which causes thousands of benign tumors in the lining of the large intestine and often colorectal cancer.[qq,rr,ss] In the much more common nonpolyposis colon cancer a complex pattern of instability in several genes is associated with DNA repair,[tt] a topic dealt with further in Chapter 27. The *ATM* gene defective in **ataxia telangiectasia** (Chapter 27) may encode a phosphatidylinositol kinase that is in some way involved in repair of DNA.[ss,uu,vv] A transcription factor gene *nm23* may be a suppressor gene for metastasis[ww] and the cell–cell adhesion molecule **E-cadherin** may suppress tumor invasion in some kinds of breast cancer.[xx] The **VHL** (van Hippel-Lindau cancer syndrome) suppressor protein is defective in the majority of kidney cancers. It normally binds to the **elongin complex**, a DNA-binding complex that functions in control of transcription.[zz]

In addition to treatment by surgery there are numerous chemical approaches to combating cancer.[xy] They usually exploit the tendency of cancers to grow continuously. For example, a toxic analog of a metabolite needed for growth, such as methotrexate (Chapter 16) and 5-fluorouridine (Box 28-C) may be taken up more rapidly by tumor cells than by normal cells. A variety of DNA-binding compounds are useful in chemotherapy (Box 5-B). Alkylating agents such as the nitrogen mustards (Eq. 5-20) and certain antibiotic compounds are also used widely, as are intercalating compounds

BOX 11-D (continued)

such as adriamycin (14-hydroxydaunomycin; Fig. 5-22) and cisplatin (Box 5-B). A disadvantage to most present-day chemotherapy is that normal proliferation of cells, especially of glandular tissues, intestinal epithelium, hair, etc., is severely damaged. A possibility for circumventing this problem is to put normal growth "on hold" temporarily while cancer growth is being inhibited. Some inhibitors of **topoisomerase I** (see Chapter 27) have low toxicity and could be useful. Another therapeutic approach is based on the fact that one function of the immune system is to destroy cancerous or precancerous cells. The immune system tends to weaken with age, which may be one reason that the incidence of cancers rises rapidly in older age Are there ways of stimulating the immune system into increased activity against cancer cells? Another approach is to find ways of increasing the activity of tumor-suppressor genes.

Can drugs be developed to *prevent* cancer? Such "chemoprevention"[yz] may be appropriate for persons carrying genes that make them highly susceptible to cancer. The antiestrogenic drug tamoxifen (Chapter 22) is currently being tested on women with a high risk for breast cancer. Use of oral contraceptives appears to have cut the risk of endometrial cancer substantially.[yy] Newer approaches to contraception may help prevent breast cancer and chemoprevention may also be possible for prostate cancer.[yy]

gene is the Abelson murine leukemia virus v-*abl*.[438a] In the mouse the c-*abl* gene is split into at least ten exons. However, v-*abl* contains all of these as a correctly spliced sequence suggesting that v-*abl* was derived from a c-*abl* messenger RNA. Part of one exon of the cellular gene is missing in v-*abl* and there is at least one base substitution mutation as well. Human c-*abl* is located on the long arm q of chromosome 9. This arm has long been known to be translocated to chromosome 22 (the "Philadelphia translocation") in patients with chronic myelogenous leukemia. There the c-*abl* gene is fused with another gene.[439] The human c-*sis* gene is also located in the region of chromosome 22 that is translocated to chromosome 9 in the same patients.

A group of human pituitary tumors have been shown to contain an oncogene that is apparently a mutated gene for the stimulatory protein G_s.[440] This is the protein that activates adenylate cyclase in response to hormonal activation. The oncogenic mutations inhibit the GTPase activity that normally turns off this activation. These tumors secrete growth hormone which binds to receptors on the tumor cells activating the defective G_s proteins and causing excessive synthesis of cAMP. This in turn promotes growth of the tumor.

The ras oncogenes. Activated *ras*-oncogenes have been found in at least 25% of all human tumors. The proto-oncogenes, which are designated c-H-*ras*, c-K-*ras*, and c-N-*ras*, are found on the short arms of chromosomes 11, 12, and 1, respectively. A single base substitution (G → T) at position 35 of any of the genes, resulting in a Ras protein containing valine instead of glycine at position 12 of the 21 kDa protein product (usually designated p21) produces an active oncogene. Substitutions at position 13 or at positions 59 and 61, which are adjacent to Gly 12 in the three-dimensional structure, can also activate the oncogenes.[441] From the drawing in Fig. 11-7A the locations of glycines 12 and 13 and of residues 59/61 are seen to be close to the β phospho group of bound GTP. Proteins encoded by activated *ras* oncogenes are less active in catalyzing GTP hydrolysis than are the corresponding normal proteins. In addition, the GTPase-activating protein (GAP) that binds to normal *ras* proteins and stimulates their GTPase activity does not affect the mutant oncogenic proteins.

A single-base alteration is capable of activating a *ras* gene with respect to cell transformation. However, initiation of a malignant tumor requires the additional presence of at least a second activated oncogene such as *myc*[442,443] or *fos*[444] or previous transformation of a fibroblast into a nonmalignant but "immortalized" form by treatment with carcinogens. The c-*myc* gene, which is found in active form in plasmacytomas (tumors of B lymphocytes) of mice as well as in the human Burkitt's lymphoma, is normally located on human chromosome 8. In most Burkitt's lymphomas a translocation has brought the c-*myc* gene into the locus of the immunoglobulin heavy chains on chromosome 14. There its transcription may be subject to different controls than in its original location.[445,446] During the translocation process the c-*myc* gene is often broken within the first intron. Thus, the activated gene lacks the first exon and is placed after a new controlling sequence that may drastically alter its transcription rate. Viral *myc* genes are found in at least one human virus, **cytomegalovirus**, which has been associated with carcinomas.

Transcription factors. The proto-oncogenes c-*myc*[447–451a], c-*myb*,[452–454] c-*fos*, c-*jun* and c-*ets*[455] all encode nuclear proteins involved in regulation of transcription. The 39 kDa protein Jun, which is encoded by c-*jun*, is a major component of the **transcriptional activator** called **AP-1**.[456–459] It binds to palindromic **enhancer** sites (Chapter 28) in DNA promoters to increase the transcription rate for a group of genes. Jun is actually a multigene family whose encoded proteins bind to DNA as complexes formed with the 62 kDa phosphoprotein Fos, the product of the c-*fos* gene.[460] The heterodimeric Fos/Jun complex is held together, at least in part, by interactions between leucine side chains lying along a pair of parallel α-helices in a "leucine zipper" (Fig. 5-36; Fig. 2-21).[461,462]

Regulation of the synthesis of Jun is complex, but growth factors such as Neu, EGF,[463] and PDGF stimulate transcription of c-*jun* in cultured cells. Messenger RNA for synthesis of Fos appears within a few minutes of stimulation of PDGF receptors.[464,465] This is one of the earliest known nuclear reactions to a mitogenic stimulus and suggested that a Ras p21 protein is involved in stimulating transcription of c-*fos* in the signaling pathway from PDGF.[466] Synthesis of Fos is also induced by a variety of other stimuli.[456] Upon translocation into the nucleus Fos combines with preexisting Jun to form AP-1, which binds to sites on DNA and induces the transcription of a large number of proteins (Chapter 28). Deletion of the c-*fos* gene in mice leads to defects in developing bone, teeth, and blood cells,[467] while excessive synthesis of Fos has been associated with the human bone disease **fibrous dysplasia**.[468]

2. The MAP Kinase Cascade

Insulin, platelet-derived growth factor (PDGF), epidermal growth factor (EGF), and many other proteins have **mitogenic activity**, that is, they induce cells to transcribe genes, to grow, and to divide. How is this accomplished? Study of such oncogenes as *src* and *ras* suggested that the proteins that they encode also participate in the process, as do transcription factors, including those encoded by the proto-oncogenes

Table 11-4
A Few Abbreviations Used in Discussions of Cell Signaling

AP-1	A major transcriptional activator protein
βARK	Beta adrenergic receptor kinase
EGF	Epidermal growth factor
EGFR	Epidermal growth factor receptor
ERK-1, ERK-2	Extracellular signal-regulated protein kinases (proline-directed protein kinases)
Fos	Protein encoded by proto-oncogene *fos* (Table 11-3)
Grb2	Adapter protein containing one SH2 and two SH3 domains
IGF-1	Insulin-like growth factor 1
InsRTK	Insulin receptor tyrosine kinase
InsP_3 or IP_3	Inositol (1,3,5)-trisphosphate
Jun	Protein encoded by proto-oncogene *jun*, an AP-1 gene
MAPK	Mitogen-activated protein kinase (also designated ERK)
MAPKK	A kinase acting on MAPK
MEK-1,MEK-2	Mitogen-activated ERK-activating kinases; dual function Ser/Thr and Tyr protein kinases; also called MAP kinase kinases
c-*myc*	A cellular proto-oncogene
PDGF	Platelet-derived growth factor
PtdIns (or PI) 3-kinase	Phosphatidylinositol 3-kinase
PKA (cAPK)	cyclic AMP-dependent protein kinase
PKC, PKCα, β, γ	Protein kinase C,α, β, γ subforms
PKR	dsRNA-activated protein kinase
PLA	Phospholipase A
PLC	Phospholipase C
PP2A	Protein phosphatase, type 2A
PTK	Protein tyrosine kinase
PTP (PTPase, PTP 1B, etc.)	Protein tyrosine phosphatases
pY	Phosphotyrosine residue
Raf-1	A cytoplasmic serine/threonine protein kinase; also called MAP kinase kinase kinase (MAP3K)
Ras	A monomeric G protein encoded by the proto-oncogene *ras*
RSK	Ribosomal protein S6 kinase
RTK	Receptor tyrosine kinase
RTK-*P*	Phosphorylated receptor tyrosine kinase
SH2, SH3	Src homology domains 2 and 3
Sos	"son of sevenless," a GDP – GTP exchange factor named for a similarity to the protein encoded by the *Drosophila* sevenless gene
Src	Protein tyrosine kinase encoded by oncogene *src* (Table 11-3); contains recognition domains SH2 and SH3
V2R	Type 2 vasopressin receptor
Shc	A proline-rich adapter protein containing SH2 and PH domains

myc, *fos*, and *jun*. The Src and Ras proteins are anchored on the inner surfaces of cytoplasmic membranes. Although the exact functional relationships of all of the components, one to another, has not been completely established, a general picture, usually described as the **mitogen-activated protein kinase** (MAP kinase) **cascade**, has emerged.[69,380,469-470b] This is sketched in simplified form in Fig. 11-13. The many amplification steps provide for ultrasensitive responses.[342]

The binding of a hormone or growth factor (a ligand) to a dimeric receptor activates the protein kinase domain of the receptor which phosphorylates a number of tyrosine hydroxyl groups of the receptor itself. This autophosphorylation is followed by a variety of events, which include phosphorylation of tyrosine side chains of various other proteins.[426] Another major event is the *binding of a variety of different protein molecules containing recognition domains to the phosphotyrosyl groups of the activated receptors.*[471] The major recognition motif is the SH2 domain. See Figs. 7-30 and 11-14.[472–475] Proteins containing SH2 domains can bind to the phosphotyrosyl groups of the activated receptors and while bound become phosphorylated by the receptor tyrosine kinase action and/or be activated allosterically.

Other proteins interact with the receptors indirectly through adapter molecules which have no catalytic activity. Two well-known adapter proteins are **Grb**2[476] and **Shc**.[477,478] The 25-kDa protein Grb2 consists entirely of recognition domains, one SH2 and two SH3 domains (Fig. 11-14). The larger Shc, which is found in all mammalian tissues, contains a 200-residue phosphotyrosyl-binding PH domain (Chapter 7) at the N terminus, a

collagen-like domain that binds to Grb2 and an SH2 domain at the C terminus.[376,377,477]

Adapter Grb2 binds to a phosphotyrosine side chain of an activated receptor, such as that for EGF, and simultaneously binds to the GDP-GTP exchange protein called **Sos** (Table 11-4). This signals Sos to activate the membrane-bound Ras protein by converting it into the GTP form. The second adapter Shc may also participate in formation of the receptor kinase - Grb2–Sos complex,[479] perhaps permitting formation of a more robust complex that may receive signals from more than one kind of receptor. Functions of other members of the Grb adapter family are being discovered.[479a]

Activated Ras binds to and activates the cytoplasmic serine/threonine protein kinase called **Raf-1**.[380,480,481] This kinase becomes transiently activated within 2–3 min of the binding of a mitogen to a receptor. Raf-1 initiates a cascade of other protein kinases by acting on the dual-function Ser/Thr and tyrosine protein kinases called **MEK-1** and **MEK-2**. The phosphorylated, active MEK proteins phosphorylate the mitogen-activated protein kinases **MAPK** which act on a variety of other proteins. Two of the best known MAPK proteins are designated **ERK-1** and **ERK-2**. These are *proline-directed* kinases which phosphorylate serines and threonines that are neighbors to prolines, e.g. in the sequence PLS/TP.[380] The activated ERKs are able to phosphorylate a large number of different proteins including nuclear proteins that control the transcription of such protein transcription factors as AP-1 and Myc. A protein known as the **serum response factor** binds to nucleotide sequences $CC(A/T)_6GC$ in the DNA to locate initiation sites for transcription. Other proteins that have been phosphorylated by the MAP kinase cascade then induce transcription.[482] The induction of c-*fos* mRNA is one of the earliest identified responses to growth factors.[375,456,483] Protein Jun, whose synthesis is induced independently by almost all growth factors, is usually present in excess.

The Fos/Jun complex is transcription factor AP-1, which induces transcription of many genes needed for cell growth. However, transcription of specific genes often depends upon additional nucleotide sequences. For example, the sequence CGGAAA is present in an **insulin response element** found in the promoter sequences of genes encoding such proteins as phosphoenolpyruvate carboxykinase, glyceraldehyde phosphate dehydrogenase, and prolactin–proteins whose synthesis is induced by insulin.[484]

The MAPK cascade also has direct effects upon protein synthesis, i.e., on the translation of mRNA messages. For example, insulin stimulates phosphorylation of proteins that regulate a translation initiation factor, a protein called eIF-4E (see Chapter 29). Phosphorylation of inhibitory proteins allows them to dissociate from the initiation factor so that protein synthesis can proceed.[485,486]

The scheme in Fig. 11-13 is complex, but in reality it is *much* more complex than is shown. Each protein kinase (receptor kinase, Raf-1, MEK, and MAPK) will phosphorylate not only the proteins indicated in this scheme but also any others that meet the specificity requirements of the kinases. Thus, there will be branches diverging from the pathways shown.[486a,b,c] There are isoenzymes that provide further divergence and interaction.[487] Not only do pathways diverge but also others *converge*. Thus, binding of many different ligands to their receptors activates the same MAPK cascade. For example, seven-helix G protein-coupled receptors release their βγ subunits which may also activate Ras as indicated on the right edge of Fig. 11-13A. At the same time the α subunits of the heterotrimer G proteins can affect not only adenylate cyclase but also phospholipases C which can, in some cases, also activate the MAP kinase pathway.[488,489] Sphingosine 1-phosphate may be released from membrane spingolipids and activate the same cascade.[490] However, hormones do not all affect cells in the same way. In view of all the converging pathways, how is this possible? Part of the answer lies in the proximity or spatial separation of components of the pathway. The kinases exist in complexes with other signaling proteins and may phosphorylate them, sending a signal back, as well as forward via other protein substrates. There are also unknown kinetic considerations. Hormones, neurotransmitters, and calcium ions are often released in pulses. The signaling system must integrate effects of all the stimuli that arise from different parts of the cell, at different times, and from differing receptors. At the same time all of the phosphorylated proteins are acted upon by phosphatases that may either activate or deactivate the proteins and by proteases that process newly formed peptides and modify or destroy mature proteins. The various modifying enzymes act on cytosolic proteins, proteins of membranes, of the cytoskeleton, and of the nucleus. The regulatory processes that we discuss in such minute detail involve the very substance of living cytoplasm which is ever-changing and responding to its surroundings. The flow of energy, provided by synthesis of ATP and by the use of ATP by kinases, phosphatases, and the protein synthetic machinery, goes along with the flow of information and drives the signaling network. Evolution has shaped this system to allow it to respond appropriately for every species.

3. The Cell Cycle and Control of Growth

When a cell divides it is of utmost importance that the DNA be replicated reliably. This requires that the dividing cell be large enough and contain enough biosynthetic precursor materials to complete the elaborate process of DNA synthesis and of mitosis. The **cell**

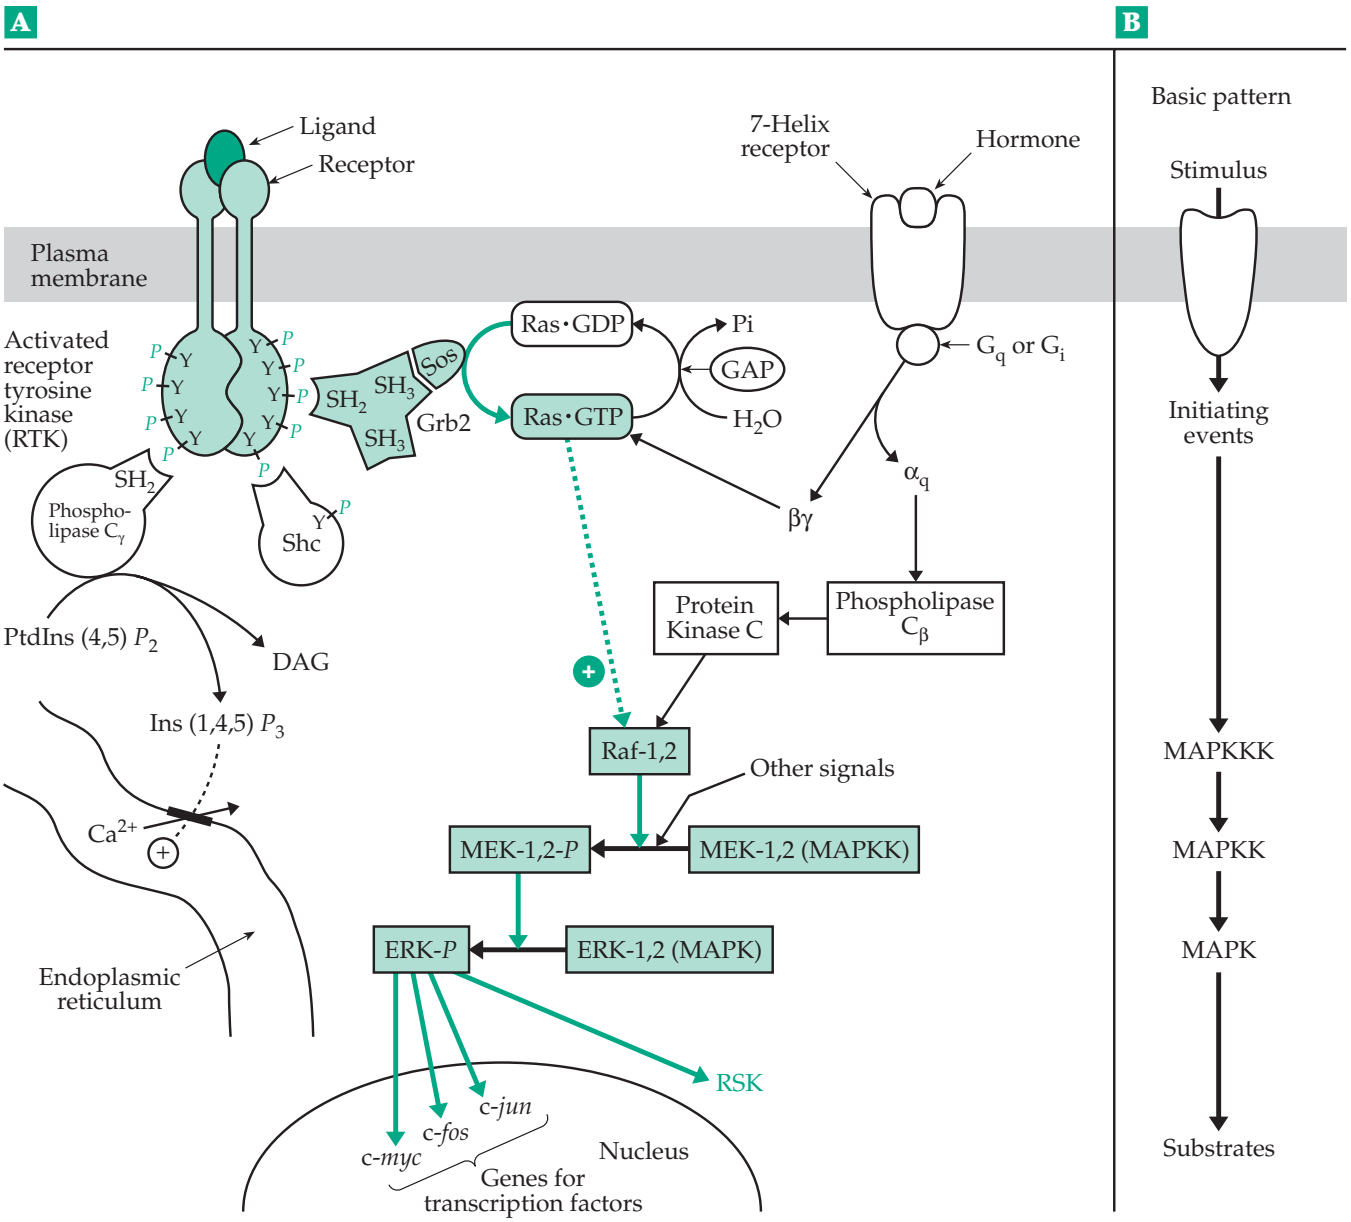

Figure 11-13 (A) A simplified version of the mitogen-activated kinase (MAPK) signaling cascade. At left is shown a hormone receptor, e.g., that for the epidermal growth factor (EGF). The receptor tyrosine kinase undergoes autophosphorylation on numerous tyrosines. The resulting phosphotyrosyl (Y-P) groups bind to SH2 domains of adapters such as Grb2 and Shc. Two pathways from the activated receptor are shown. At the left is activation of phospholipase Cγ and formation, at a membrane-bound site, of inositol trisphosphate and diacylglycerol (DAG). The main pathway, in the center, activates Ras with the aid of the G protein Sos. Activated Ras, in turn, activates Raf and successive components of the MAPK cascade. At the right a seven-helix receptor activates both phospholipase Cβ and Ras via interaction with a βγ subunit. (B) A generalized scheme for the MAP kinase pathway. See Seger and Krebs.[380]

replication cycle (or simply cell cycle) is commonly shown as a circle in which the time from one cell division to the next, in a rapidly growing organism or tissue, is represented by the circumference. The time required for DNA synthesis is the **S-phase** and the time required for mitosis the mitotic or **M-phase** (Fig. 11-15). After metaphase there is a **gap** in time denoted $\mathbf{G_1}$. A second gap $\mathbf{G_2}$ separates the synthetic S-phase and the M-phase. The total time required for one cycle varies with conditions. It may be as short as 8–60 min in an early embryo but is usually two hours or more. A slowly growing cell may pause before the G_1 phase in a nongrowing **G_0 phase**.[491,492]

What controls the cell replication cycle? Signals

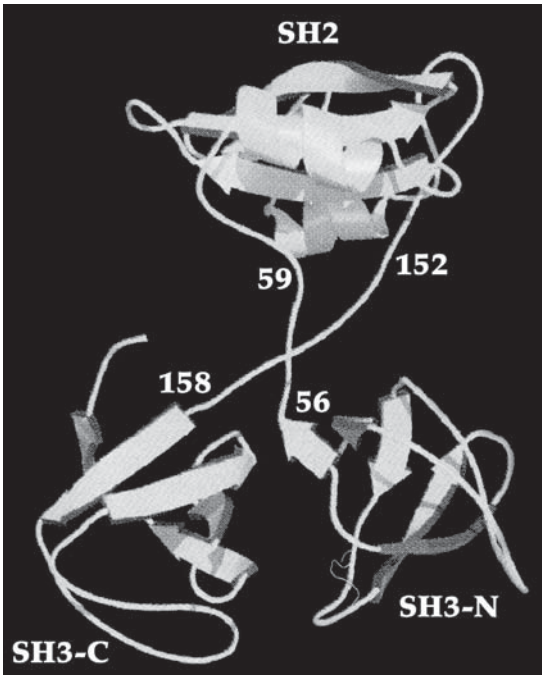

Figure 11-14 Ribbon drawing of the three-dimensional structure of adapter protein Grb2. The two SH3 domains at the N and C termini are labeled, as is the central SH2 domain. Produced with programs MolScript and Raster3D. From Maignan *et al.*[476] Courtesy of Arnaud Ducruix.

from growth factors can stimulate a cell to leave G_0 and enter G_1. However, to go further the cell depends upon a large number of proteins of which two types are prominent. The **cyclins** are labile 45- to 60-kDa proteins which are degraded by the ubiquitin system as part of the cycle. The cyclins associate with a series of protein Ser/Thr kinases known as **cyclin-dependent kinases** (**CDK**s). It is the cyclin–CDK complexes that signal the start of the next step in the cycle.[493–495]

The number of different cyclins and CDK enzymes needed varies with the organism, often being greater for more complex species. As a rule, there are at least two types of cyclins. The **G_1** or **start cyclins** initiate the passage through the start (G_1 checkpoint) into the S-phase, while **mitotic cyclins** initiate the passage from the S-phase into the M-phase. Both vertebrates and *Drosophila* utilize at least four different types of cyclin (A, B, D, and E) and also four or more CDKs (CDK1, CDK2, CDK4, and CDK6).[492] A somewhat different set of these proteins are found in yeast.

Control of cell growth is directly related to the cell cycle. Mitogenic signals from growth factors act to initiate progression through G_1, apparently by stimulating transcription of D-type cyclins.[496] They may affect other steps as well. Oncogenic signals can arise from such oncogenes as *ras* and *abl*.[497,498] As pointed out in Box 11-D, the tumor-suppressor protein Rb becomes phosphorylated in synchrony with the cell

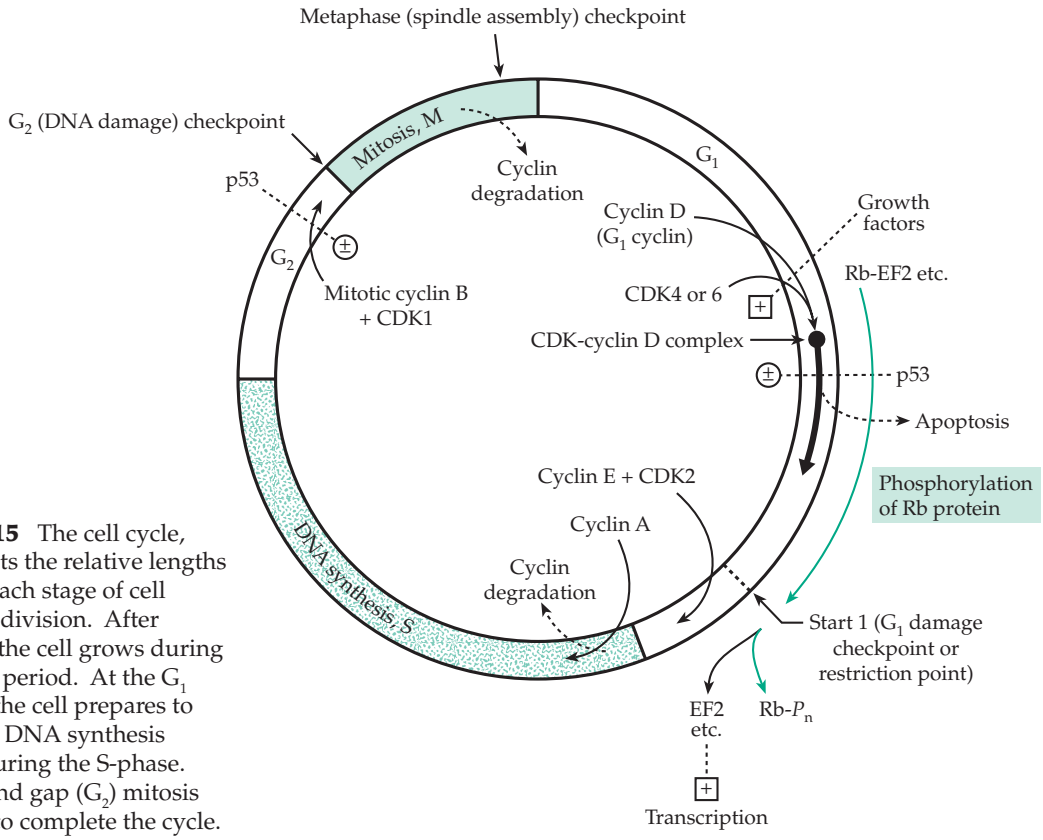

Figure 11-15 The cell cycle, which depicts the relative lengths of time for each stage of cell growth and division. After mitosis (M) the cell grows during the G_1 (gap) period. At the G_1 checkpoint the cell prepares to divide, with DNA synthesis occurring during the S-phase. After a second gap (G_2) mitosis takes place to complete the cycle.

cycle. This seems to be an essential process for passage through the G_1 "checkpoint." The checkpoints in the cycle should be viewed not as points but as essential interlocking processes that must be accomplished before transcription of genes essential for the next step in the cycle can take place.[499] A possibility is that the cyclin-dependent kinase in the cyclin D•CDK4 (or CDK6) complex phosphorylates the Rb protein which in its unphosphorylated state forms a complex with transcriptional regulators of the E2F family. Phosphorylation of Rb allows this complex to dissociate and permits E2F to induce transcription of genes encoding essential proteins for the next step in the cycle.[499a,b,c] Each CDK may also phosphorylate its associated cyclin, a modification that may be essential to the proteolysis of the cyclin and progression to the next stage of the cycle.

The powerful cancer suppressor, p53, which is also described in Box 11-D, in some way senses DNA damage. It prevents passage through the G_1 checkpoint and also through the G_2 checkpoint if the DNA has not been adequately repaired.[496,497] Protein p53, whose three-dimensional structure is known,[500,501] binds to DNA and also induces transcription of genes that cause arrest of the cell cycle. It may also induce cell death (apoptosis), a process that may also require the protein product of protooncogene c-*myc*.[502-505] A variety of protein kinases and phosphatases act on p53 and influence its activity.[506]

Study Questions

1. Illustrated is a generalized metabolic pathway in which capital letters indicate major metabolites in the pathway, small letters indicate cofactors and numbers indicate enzymes catalyzing the reactions.

   List and describe four different ways in which the pathway might be regulated, referring to the specific enzymes, reactants, and cofactors indicated in the diagram. NOTE: Do not just refer to four different reactions as possible sites of regulation, but give four different general methods for regulation.

2. Describe the role of β-fructose-2,6-bisphosphate in the control of the further breakdown and resynthesis of glucose 1-phosphate.

3. It has been proposed that the substrate cycle involving phosphofructokinase and fructose bisphosphatase is used by bumblebees to warm their flight muscles to 30°C before flight begins. Clark *et al.* (1973) *Biochem. J.* **134**, 589–597 found maximal rates of catalytic activity for both enzymes to be about 44 μ mol / min / g of fresh tissue. In flying bees glycolysis occurred at a rate of about 20 μ mol / min / g of tissue with no substrate cycling. In resting bees at 27°C no cycling was detected, but at 5°C substrate cycling occurred at the rate of 10.4 μ mol / min / g while glycolysis had slowed to 5.8 μ mol / min / g. If the cycling provides heat to warm the insect, estimate how long it would take to reach 30°C if a cold (5°C) bee could carry out cycling at the maximum rate of 40 μ mol / min / g and if no heat were lost to the surroundings.

4. a) Compare the reaction cycle of a small GTPase (G protein) that is regulated by the actions of a GTPase-activating protein (GAP) and a guanine-nucleotide exchange factor (GEF) with that of a G protein linked to a receptor.
   b) Some G proteins have been described as "timed switches" and others as "triggered switches." In what ways might these two groups differ? See Kjeldgaard *et al.* (1996) *FASEB J.* **10**, 1347–1368.

View of a modified bovine fibrinogen molecule. The 45-nm-long disulfide-linked dimer is composed of three nonidentical polypeptide chains. The N termini of the six chains from the two halves come together in the center in a small globular "disulfide knot." The C termini form globular domains at the ends. The 340-kDa molecule has been treated with a lysine-specific protease which has removed portions of two chains to give the ~285-kDa molecule whose crystal structure is shown. Arrows point to attached oligosaccharides. From Brown *et al.* (2000) *Proc. Natl. Acad. Sci. U. S. A.* **97**, 85–90. Courtesy of Carolyn Cohen.

Transferring Groups by Displacement Reactions

12

The majority of enzymes that are apt to be mentioned in any discussion of metabolism catalyze nucleophilic displacement reactions (Type 1, Table 10-1). These include most of the reactions by which the energy of ATP cleavage is harnessed and by which polymers are assembled from monomers. They include reactions by which pieces, large or small, are transferred onto or off of polymers as well as the reactions by which polymers are cleaved into pieces.[1–3d]

In these reactions a **nucleophilic group** (a base), designated B^- in Table 10-1, approaches an **electrophilic center,** often an electron-deficient carbon or phosphorus atom. It forms a bond with this atom, at the same time displacing some other atom, usually O, N, S, or C. The displaced atom leaves with its bonding electron pair and with whatever other chemical group is attached, the entire unit being called the **leaving group**. This is designated YH in Table 10-1. Simultaneous or subsequent donation of a proton from an acidic group of the enzyme, or from water, to the O, N, or S atom of the leaving group is usually required to complete the reaction. The entering base B, which may or may not carry a negative charge, must often be generated by enzyme-catalyzed removal of a proton from the conjugate acid BH. If BH is water, the enzyme is a **hydrolase**; otherwise, it is called a **transferase**.

For purposes of classifying the reactions of metabolism, in this book the nucleophilic displacements are grouped into four subtypes (Table 10-1). These are displacements on (A) a saturated carbon atom, often from a methyl group or a glycosyl group; (B) a carbonyl group of an ester, thioester, or amide; (C) a phospho group; or (D) a sulfur atom. In addition, many enzymes employ in sequence a displacement on a carbon atom followed by a second displacement on a phosphorus atom (or vice versa).

A. Factors Affecting Rates of a Displacement Reaction

In Chapter 9, the displacement of an iodide ion from methyl iodide by a hydroxide ion (Eq. 9-76) was considered. Can we similarly displace a methyl group from ethane, $CH_3–CH_3$, to break the C–C bond and form CH_3OH? The answer is no. Ethane is perfectly stable in sodium hydroxide and is not cleaved by a simple displacement process within our bodies. Likewise, long hydrocarbon chains such as those in the fatty acids cannot be broken by a corresponding process during metabolism of fatty acids. Not every structure will allow a nucleophilic displacement reaction to occur and not every anion or neutral base can act to displace another group.

At least four factors affect the likelihood of a displacement reaction:[1–3d]

(1) *The position of the equilibrium in the overall reaction*. An example is provided by the hydrolases that catalyze cleavage of amide, ester, and phosphodiester linkages using water as the entering nucleophile. Because enzymes usually act in an environment of high water content, the equilibrium almost always favors hydrolysis rather than the reverse reactions of synthesis. However, in a nonaqueous solvent the same enzyme will catalyze synthetic reactions.

(2) *The reactivity of the entering nucleophile*. Nucleophilic reactivity or **nucleophilicity** is partly determined by basicity. Compounds that are strong bases tend to react more rapidly in nonenzymatic displacement reactions than do weaker bases; the hydroxyl ion, HO^-, is a better nucleophile than $–COO^-$. However, enzymes usually act optimally near a neutral pH. Under these conditions the $–COO^-$ group may be

more reactive than strongly basic groups such as $-NH_2$ or HO^- because at pH 7 the latter groups will be almost completely protonated and the active nucleophile will be present in low concentrations.

A second factor affecting nucleophilic reactivity is **polarizability**, which is the ease with which the electronic distribution around an atom or within a chemical group can be distorted. A large atomic radius and the presence of double bonds in a group both tend to increase polarizability. In most cases, the more highly polarizable a group, the more rapidly it will react in a nucleophilic displacement, apparently because a polarizable group is able to form a partial bond at a greater distance than can a nonpolarizable group. Thus, I^- is more reactive than Br^-, which is more reactive than Cl^-. Polarizable bases such as imidazole are often much more reactive than nonpolarizable ones such as $-NH_2$. Sulfur compounds also tend to have a high nucleophilic reactivity. In displacement reactions on carbonyl groups (reaction type 1B), the less polarizable "hard" nucleophiles are more reactive than polarizable ones such as I^-. Attempts have been made to relate quantitatively nucleophilic reactivity to basicity plus polarizability.[1]

Certain chemical groups, e.g., those in which an atom with unpaired electrons is directly bonded to the nucleophilic center undergoing reaction, are more reactive than others of similar basicity. This **α effect** has been invoked to explain the high reactivity of the poisons hydroxylamine (NH_2OH) and cyanide ion[4] and other puzzling results.[1]

(3) *The chemical nature of the leaving group that is displaced*. The chemistry of the leaving group affects both the rate and the equilibrium position in nucleophilic displacements. The leaving group must accommodate a pair of electrons and often must bear a negative charge. A methyl group displaced from ethane or methane as CH_3^- would be an extremely poor leaving group; the pK_a of methane as an acid[5] has been estimated as 47. Iodide ion is a good leaving group, but F^- is over 10^4 times poorer.[5] In an aqueous medium, phosphate is a much better leaving group than OH^-, and pyrophosphate and tripolyphosphate are even better.

(4) *Special structural features present in the substrate*. Enzymes are usually constructed so that they recognize unique features in substrates. As a consequence, they have many ways of lowering the energy of the transition state and increasing the apparent nucleophilic reactivity.

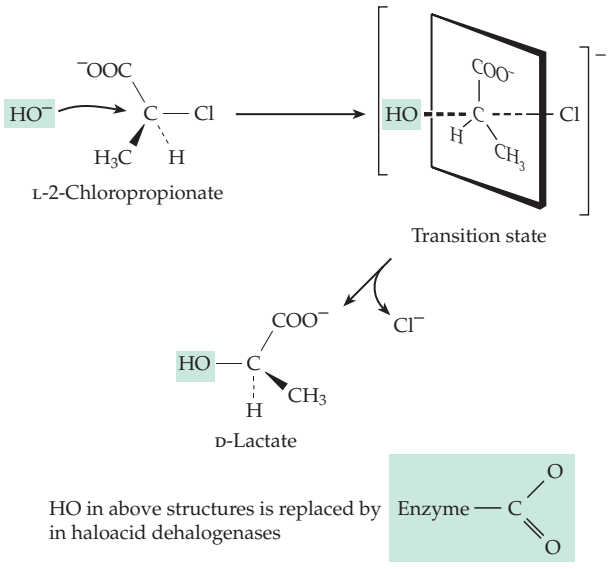
B. Nucleophilic Displacements on Singly Bonded Carbon Atoms

The enzymatic counterpart of Eq. 9-76, the displacement of I^- from a saturated carbon atom by HO^-, is catalyzed by the **haloacid dehalogenases** of soil pseudomonads (Eq. 12-1).[6–8] Even the poor leaving group F^- can be displaced by OH^- in the active site of these enzymes.

$$HO^- + F{-}CH_2COO^- \rightarrow HO{-}CH_2{-}COO^- + F^- \qquad (12\text{-}1)$$

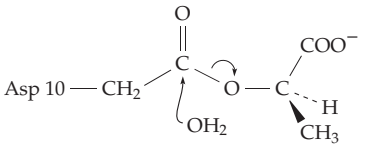
1. Inversion as a Criterion of Mechanism

An interesting result was obtained when a haloacid dehalogenase was tested with a substrate containing a chiral center.[6] Reaction of L-2-chloropropionate with hydroxyl ion gave only D-lactate, a compound with a chirality opposite to that of the reactant. A plausible explanation is that the hydroxyl ion attacks the central carbon from behind the chlorine atom (Eq. 12-2). The resulting five-bonded transition state (center) loses a chloride ion to form the product D-lactate in which inversion of configuration has occurred. *Inversion always accompanies single displacement reactions in which bond breaking and bond formation occur synchronously, as in Eq. 12-2*. This is true for both enzymatic and nonenzymatic reactions. However, the occurrence of inversion does not rule out more complex mechanisms. Indeed, in this case the displacing group is evidently not HO^- but a carboxylate group from the enzyme.



(12-2)

In one of the haloacid dehalogenases, a 232-residue protein for which the three-dimensional structure is known,[8,9] Asp 10 is in a position to carry out the initial attack which would give an enzyme-bound intermediate with an ester linkage:



Hydrolytic cleavage, as indicated in the diagram, yields the product D-lactate.[7] Thus, we have a direct displacement with inversion followed by an additional hydrolytic step. This is an example of **covalent catalysis**, the enzyme providing a well-oriented reactive group instead of generating a hydroxyl group from a bound water molecule.

Related **haloalkane dehalogenases** as well as **epoxide hydrolases** and a large superfamily of other enzymes utilize similar mechanisms.[10,11,11a] In the active site of a haloalkane dehalogenase from *Xanthobacter* (Fig. 12-1) the carboxylate of Asp 124 acts as the attacking nucleophile that displaces Cl^- from the substrate dichloroethane, which is held in a small cavity with the aid of two tryptophan indole rings.[12–14] However, the histidine–aspartate pair and the bound water molecule shown in Fig. 12-1 are essential for the subsequent hydrolysis of the intermediate ester. (see also Fig. 12-11).[15] The substrate shown in Fig. 12-1 is 1,2-dichloroethane, a widespread environmental pollutant that is not known to occur naturally. An interesting question considered by Pries *et al.*[16] is how this dehalogenase has evolved in the years since 1922 when industrial production of dichloroethane began.

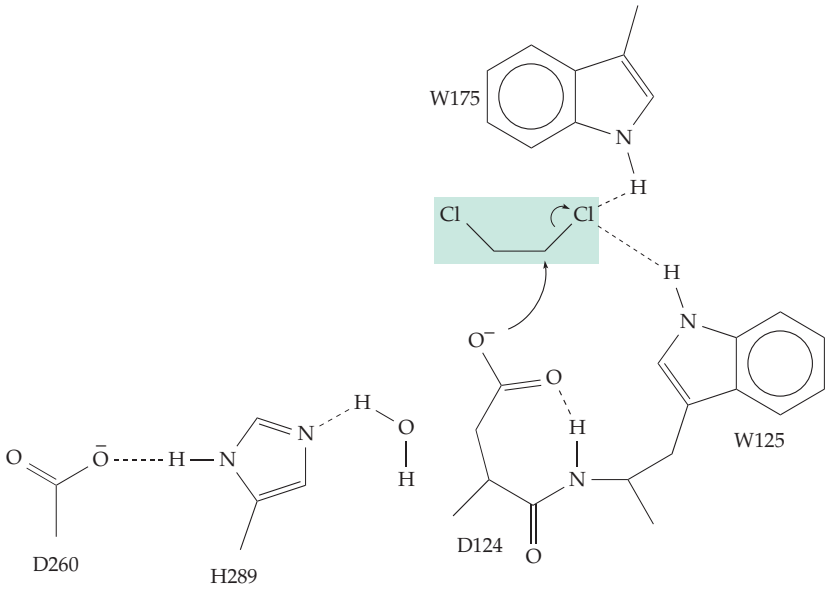


Figure 12-1 The active site structure of haloalkane dehalogenase from *Xanthobacter autotrophicus* with a molecule of bound dichloroethane. See Pries *et al.*[13] The arrows illustrate the initial nucleophilic displacement. The D260 – H289 pair is essential for the subsequent hydrolysis of the intermediate ester formed in the initial step.

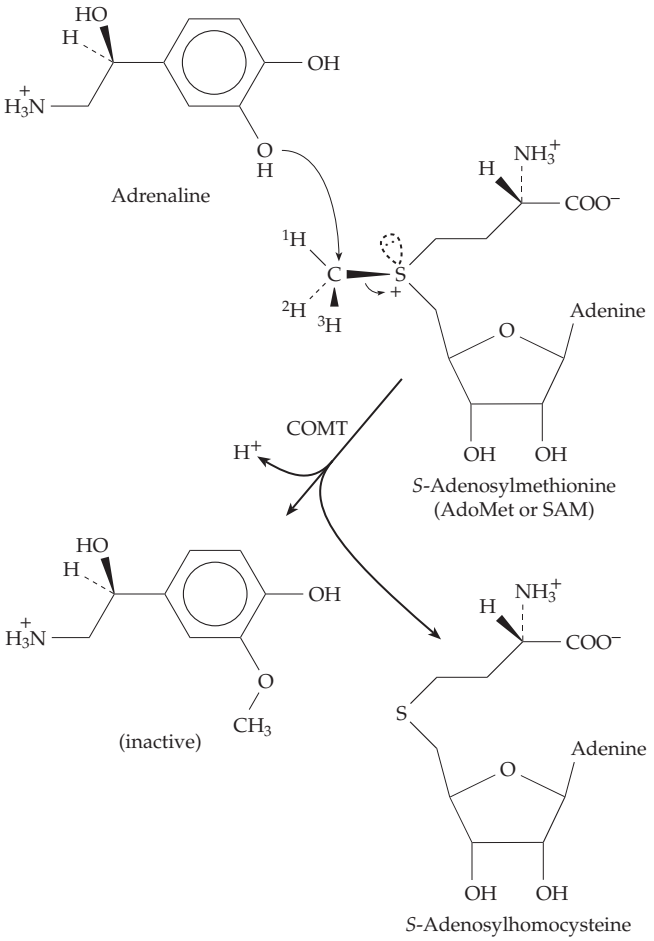
2. Transmethylation

Nucleophilic attack on a methyl group or other alkyl group occurs most readily if the carbon is attached to an atom bearing a positive charge, for example, the sulfur atom of a sulfonium ion such as that present in ***S*-adenosylmethionine** (abbreviated **AdoMet** or SAM). The ensuing **transmethylation** reaction results in the transfer of the methyl group from the sulfur to the attacking nucleophile (Eq. 12-3). Transmethylation is an important metabolic process by which various oxygen, nitrogen, and other atoms at precise positions in proteins, nucleic acids, phospholipids, and other small molecules are methylated.[17] The methyl group donor is usually *S*-adenosylmethionine. This compound has two chiral centers, one at the α-carbon of the amino acid and one at the sulfur atom, with an unshared electron pair serving as the fourth group around the S atom. In the naturally occurring AdoMet both centers have the *S* configuration.[18] The reaction of Eq. 12-3, which is catalyzed by **catechol *O*-methyltransferase** (COMT), inactivates the neurotransmitters adrenaline, dopamine, and related compounds by methylation. When the substrate contains a chiral methyl group (– $C^1H^2H^3H$; see also Chapter 13), the inversion of the methyl group expected for a simple S_N2-like reaction is observed.[19]

Structural features similar to those of COMT[20] are found in glycine *N*-methyltransferase[21] and guanidinoacetate methyltransferase[22] from liver, and transferases that place methyl groups on N-6 of adenine[23–25a] and N-4 of cytosine or on C-5 of cytosine[26] in nucleic acids.[27] A stereoscopic view of the active site of glycine *N*-methyltransferase is shown in Fig. 12-2. An acetate ion present in the active site in the crystal has been converted into glycine by computer-assisted modeling. The amino group of the bound glycine is adjacent to the methyl group of AdoMet. A nearby glutamic acid side chain (E15) may have removed a proton from the glycine dipolar ion to create the free $–NH_2$ group required for the reaction. In COMT a magnesium Mg^{2+} ion binds to the two aromatic hydroxyl groups of the substrate and helps to hold it correctly in the active site.[28–29a]

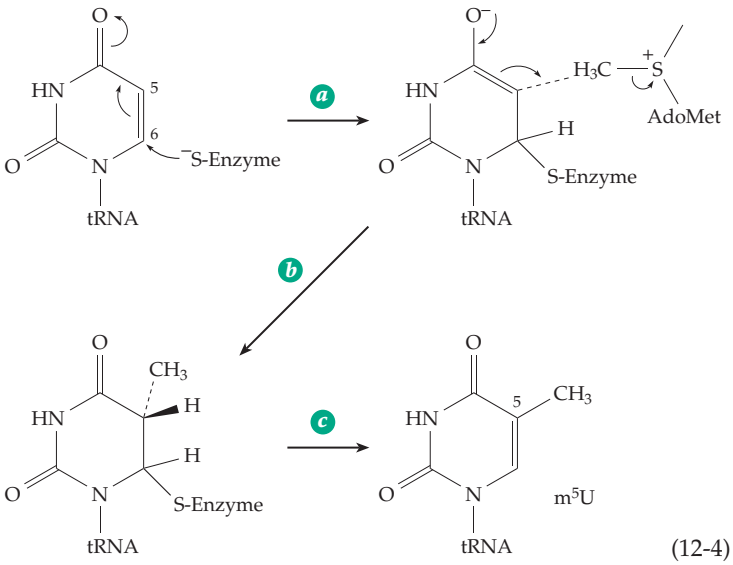
In the case of the more difficult C-methylation of uracil 54 in transfer RNA, an –SH group from Cys 324 of the methyltransferase adds to the C-6 position of U54 of the substrate, which may be any of the *E. coli* tRNAs (Eq. 12-4, step *a*) .[30] In the



(12-3)

adduct carbon atom C-5 acquires substantial nucleophilic character which permits the transfer of the methyl group in step *b*. The adduct breaks up (step *c*) and the product is released.

Methylation of nucleic acids is considered further in Chapers 27 and 28. Methylation of carboxyl groups of certain proteins regulates motion of bacterial flagella (Chapter 19) and other aspects of metabolism[31] while methylation of isomerized aspartyl residues is part of a protein repair process (Box 12-A). Methyl groups are usually transferred from *S*-adenosylmethionine, but sometimes from a folic acid derivative (Chapter 15) or from a cobalt atom of a corrin ring (Chapter 16).



(12-4)

3. Kinetic Isotope Effects

An S–^{12}C bond breaks a little faster than an S–^{13}C bond in a nucleophilic displacement reaction. This **primary kinetic isotope effect** (KIE)[3a,3b,31a–d] is usually discussed first for breakage of a C–H bond. In a linear transition state, in which the C–H bond is being stretched, then cleaved, the difference between the transition state barrier for a C–^{1}H bond and a C–^{2}H bond is thought to arise principally from a difference in the energies of the C–H stretching vibration.[3a] This vibrational energy, in the ground state of a molecule (the zero-point energy) is equal to $1/2\,h\nu_0$ where ν_0 may be observed in the infrared absorption spectrum (see Fig. 23-2). For a C–^{2}H bond, with a stretching vibration at a wave number of ~2900 cm^{-1}, the zero point energy is about + 17.4 kJ mol^{-1}. For a C–^{2}H bond, with a stretching wave number of ~2200 cm^{-1}, it is about +17.4 kJ mol^{-1}. This difference is a result of the difference in mass of ^{1}H (1.67 x 10^{-24} g) and ^{2}H (2.34 x 10^{-24} g). The isotope effect arises because the vibration occurs along the axis of the bond being broken, and the vibrational energy is converted into translational motion along the reaction coordinate, in effect lowering the transition state barrier by $\Delta G^{0\ddagger}$. The difference in this effect between ^{1}H and ^{2}H ($\Delta\Delta G^{0\ddagger}$) gives the ratio of expected rate constants as follows:

$$\frac{k^{C-H}}{k^{C-D}} = e^{-\Delta\Delta G^{0\ddagger}/RT} = 7$$

For heavier nuclei, such as C, N, O the kinetic isotope effect is much smaller.

When ^{13}C was introduced into the methyl group of *S*-adenosylmethionine and its rate of reaction with catechol *O*-methyltransferase was compared with that of the normal ^{12}C-containing substrate, the expected effect on V_{max}, expressed as a first-order rate constant, was seen: $k_{12}/k_{13} = 1.09 \pm 0.05$. This effect is small but it can be measured reliably and establishes that the methyl transfer step rather than substrate binding, product release, or a conformational change in the protein is rate limiting.[32]

Substitution of ^{1}H by ^{2}H in the CH_3 group has a larger effect. This **secondary kinetic isotope effect** (or α-deuterium

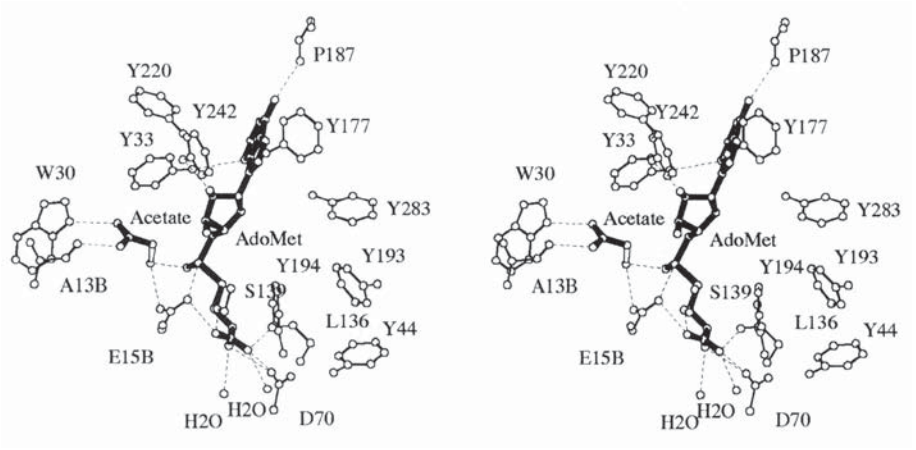


Fig. 12-2 *S*-Adenosylmethionine (AdoMet, solid bonds) bound in the active site of glycine *N*-methyltransferase together with an acetate ion bound in the glycine site. Glycine was built by attaching an amino group (open bond) to the acetate (solid bonds). Possible polar interactions (O–O and O–N < 0.31 nm and O–S < 0.4 nm) are indicated by dotted lines. Tyrosine residues located at the inner surface of the active site are also shown. From Fu *et al.*[21]

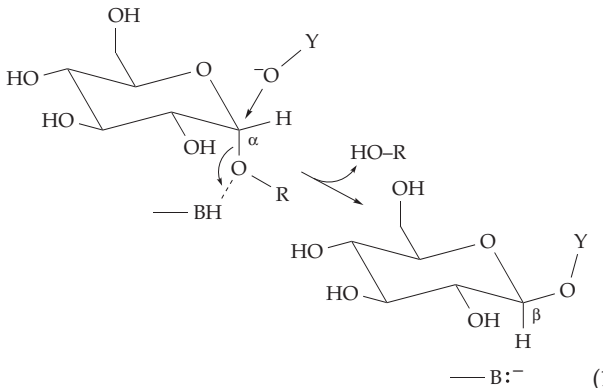
effect) arises because of small differences in the vibrational energies of the methyl group resulting from the differences in mass of ^{1}H and ^{2}H. It often leads to a more rapid reaction for the ^{1}H-containing substrates. In a model nonenzymatic displacement reaction of a similar type[32] the ratio of rate constants was $k_{1_H} / k_{2_H} = 1.17 \pm 0.02$. However, for COMT an inverse α-deuterium effect was seen: $k_{(c1_{H_3})} / k_{(c2_{H_3})} = 0.83 \pm 0.05$. Theoretical calculations suggested that such an effect might be observed if the enzyme compresses an S_N2-like transition state, shortening the bonds from the central carbon atom to both the oxygen atom of the entering nucleophile and the sulfur atom of the leaving group.[33,34] However, more recent calculations suggest that it is difficult to draw such conclusions from secondary isotope effects.[35,36] Calculations by Zheng, Kahn, and Bruice predict that in the gas phase the two substrates, upon collision, will react with a very low energy barrier.[29,29a] For this enzyme, as for the haloalkane dehalogenase (Fig. 12-1), it has been concluded that the enzyme excludes water from the active site and binds the two substrates very close together and in a correct orientation for reaction. The computations predicted secondary isotope effects for the enzymatic reaction similar to those measured by Hegazi *et al.*[32] suggesting that the transition states for the enzymatic reactions closely resemble those for the gas phase.

4. Glycosyltransferases

The polarization of a single C–O bond in an ether is quantitatively much less than that of the C–S^+ bond of *S*-adenosylmethionine, and simple ethers are not readily cleaved by displacement reactions. However, glycosides, which contain a carbon atom attached to *two* oxygen atoms, do undergo displacement reactions which lead to **hydrolysis**, **phosphorolysis**, or **glycosyl exchange**. The corresponding enzymes are glycosylhydrolases, phosphorylases, and glycosyltransferases. Two characteristics are commonly used to classify glycosylhydrolases that act on polysaccharides: **Endoglycanases** cut at random locations within the chains of sugar units, while **exoglycanases** cut only at one end or another, usually at the nonreducing end. **Inverting enzymes** invert the configuration at the anomeric carbon atom which they attack, while **retaining enzymes** do not. Although simple glycosides undergo acid-catalyzed hydrolysis readily, uncatalyzed hydrolysis is extremely slow, the estimated first order rate constant[37] at 25°C being about 2×10^{-15} s^{-1}. Polysaccharides may be the most stable of all bioploymers.

Glycosyltransferases are numerous. For example, the amino acid sequences for about 500 glucosidases, which hydrolyze linkages between glucose residues, have been determined and this one group of enzymes has been classified into over 60 families[38,39] and eight larger groups.[40] Many three-dimensional structures have been reported and numerous studies of the reaction mechanism for both enzymatic and nonenzymatic hydrolysis of glycosides have been conducted. Most of the experimental results have been carefully verified. Nevertheless, they serve to illustrate how difficult it is to understand how enzymes catalyze this simple type of reaction.[41]

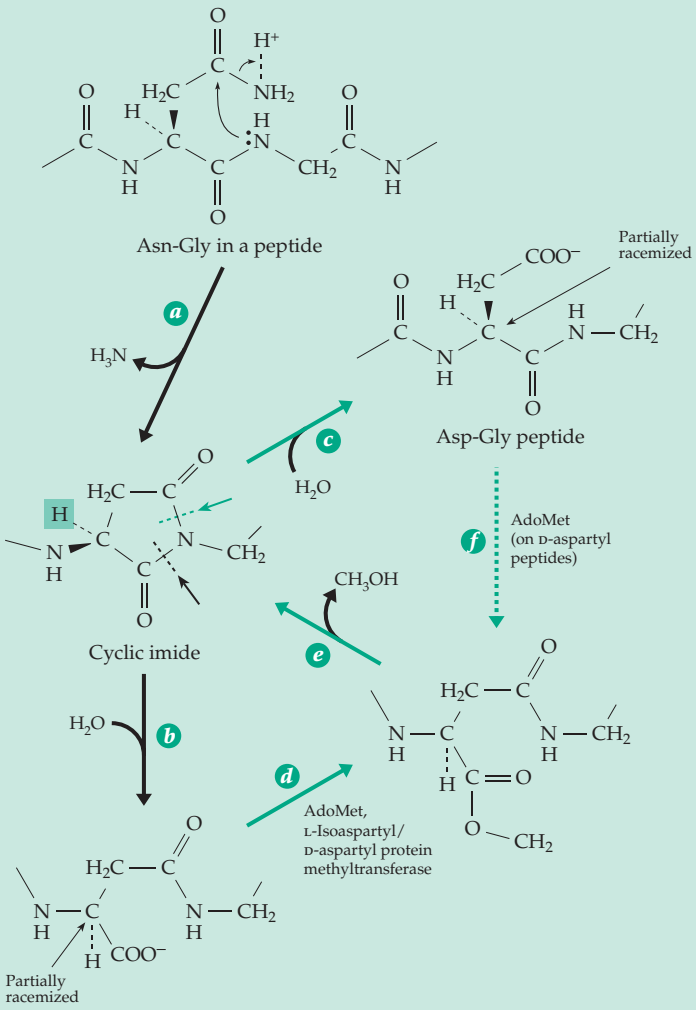
Inversion or retention? Equation 12-5 pictures the reaction of a glycoside (such as a glucose unit at



(12-5)

BOX 12-A CARBOXYMETHYLATION OF PROTEINS

Methylation and demethylation of the carboxyl groups of the side chains of specific glutamyl residues play a role in bacterial chemotaxis (Chapter 19, Section A). However, similar functions in eukaryotes have not been found. There is a specific methyltransferase that methylates C-terminal carboxyl groups on prenylated and sometimes palmitoylated peptides.[a] Another type of carboxylmethyltransferase acts on only a small percentage of many proteins and forms labile methyl esters. These methyltransferases have a dual specificity, acting on L-**isospartyl** residues and usually also on D-**aspartyl** residues. Both of these amino acids can arise from deamidation of asparagine, especially in Asn-Gly sequences (Eq. 2-24 and steps *a* and *b* of following scheme).[b–g] A similar isomerization of aspartyl residues occurs more slowly. Asn-Gly sequences are present in many proteins and provide weak linkages whose isomerization is an inevitable aspect of aging.[e,h] Furthermore, the α proton of the cyclic imide (green box) is more readily dissociated than in a standard peptide, leading to racemization (step *c*). The isoaspartyl and D-aspartyl residues provide kinks in the peptide chain which may interfere with normal function and turnover.



The L-isoaspartyl / D-aspartyl methyltransferase (step *d*), which is especially abundant in the brain,[i,j] provides for partial repair of these defects.[k–o] The methyl esters of isoaspartyl residues readily undergo demethylation with a return to a cyclic imide (step *e*). The cyclic imide is opened hydrolytically (step *c*) in part to an isoaspartyl residue, but in part to a normal aspartyl form. The combined action of the carboxylmethyltransferase and the demethylation reaction tends to repair the isomerized linkages. Methylation of D- aspartyl residues returns them to the cyclic imide (steps *f*, *e*), allowing them to also return to the normal L configuration. Nevertheless, the protein will have a different net charge than it did originally and must be considered a new modified form.

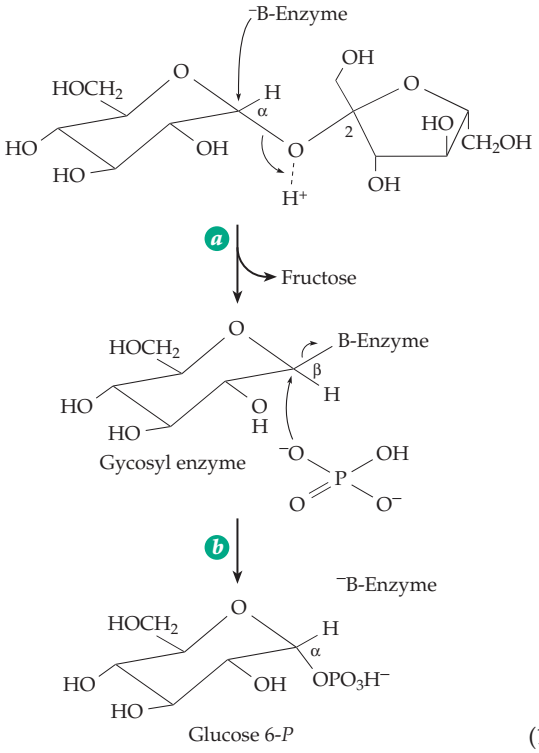
the end of a starch chain) with a nucleophile $Y-O^-$ as the displacing group. An enzyme-bound acidic group $-BH$ is shown assisting the process. Inversion of configuration with formation of a product of the β configuration at the anomeric carbon atom would be predicted and is observed for many of these enzymes. However, many others do *not* cause inversion.[41,42] An example is the reaction catalyzed by **sucrose phosphorylase** from *Pseudomonas saccharophila*:

Sucrose (an α-glucoside of fructose) + inorganic phosphate (P_i) → α-D-glucose 1-phosphate + fructose (12-6)

Two possible explanations for the lack of inversion during this reaction are that the enzyme acts by a **double-displacement** reaction or through a stabilized **carbocationic intermediate**. Let us consider these possibilities in turn.

Double-displacement mechanisms. In a double-displacement mechanism sucrose phosphorylase would catalyze two consecutive single displacements, each with inversion. A nucleophilic group of the enzyme would react in Eq. 12-7, step *a*. In step *b*, a phosphate would react to regenerate the enzyme with its free nucleophilic group $-B^-$.



(12-7)

Four kinds of experiments were used to identify this double-displacement mechanism.

(1) *Kinetics*. In a double-displacement mechanism the enzyme shuttles between free enzyme and the intermediate carrying the substrate fragment (here, the glycosyl enzyme). With sucrose phosphorylase the maximum velocity varies with the concentrations of sucrose and HPO_4^{2-} in the characteristic fashion expected for this "ping-pong" mechanism (Eq. 9-47).[43]

(2) *Exchange reactions*. In a double-displacement mechanism sucrose containing ^{14}C in the fructose portion of the molecule should react with free enzyme E to form glycosyl enzyme and free radioactive fructose (Eq. 12-8). The ^{14}C-containing groups are designated here by the asterisks.

D-Glucosyl-fructose* + E ⇌ glucosyl-E + fructose* (Sucrose) (12-8)

If a very low molar concentration of enzyme is present, and a large excess of nonradioactive fructose is added, the enzyme will catalyze no net reaction but will change back and forth repeatedly between the free enzyme and glucosyl enzyme. Each time, in the reverse reaction, it will make use primarily of unlabeled fructose. The net effect will be catalysis of a sucrose–fructose exchange:

Sucrose* + fructose ⇌ sucrose + fructose* (12-9)

This exchange reaction, as well as other predicted exchanges, has been observed.[44] Although the exchange criterion of the mechanism is often applied to enzymatic processes, the observation of exchange reactions does not *prove* the existence of a covalently bound intermediate. Furthermore, enzymes using double-displacement mechanisms may not always catalyze the expected exchanges.

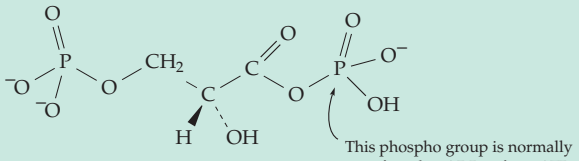
(3) *Arsenolysis*. Sucrose phosphorylase also catalyzes the cleavage of sucrose by arsenate and promotes a rapid cleavage (**arsenolysis**) of glucose 1-phosphate to free glucose. This reaction is evidently a result of a displacement by arsenate on a glycosyl enzyme intermediate. The resulting unstable glucose 1-arsenate (see Box 12-B) is hydrolyzed rapidly. Arsenolysis is a general way of trapping reactive enzyme-bound intermediates that normally react with phosphate groups. Arsenate is one of many substrate analogs that can be used to siphon off reactive enzyme-bound intermediates into nonproductive side paths.

(4) *Identification of glycosyl-enzyme intermediates*. Studies with pure enzymes often make it possible to confirm directly the existence of enzyme-bound intermediates. The intermediates detected are frequently **glycosyl esters** of glutamate or aspartate side chain

BOX 12-B ARSENIC

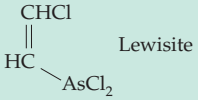
Arsenate, AsO_4^{3-}, is chemically similar to phosphate in size and geometry and in its ability to enter into biochemical reactions. However, arsenate esters are far less stable than phosphate esters. If formed in the active site of an enzyme, they are quickly hydrolyzed upon dissociation from the enzyme. This fact accounts for some of the toxicity of arsenic compounds.[a]

Arsenate will replace phosphate in all phosphorolytic reactions, e.g., in the cleavage of glycogen by glycogen phosphorylase, of sucrose by sucrose phosphorylase, and in the action of purine nucleoside phosphorylase.[b] Glucose 1-arsenate or ribose-1-arsenate is presumably a transient intermediate which is hydrolyzed to glucose. The overall process is called **arsenolysis**. Another reaction in which arsenate can replace phosphate is the oxidation of glyceraldehyde 3-phosphate in the presence of P_i to form 1,3-bisphosphoglycerate:



1,3-Biphosphoglycerate

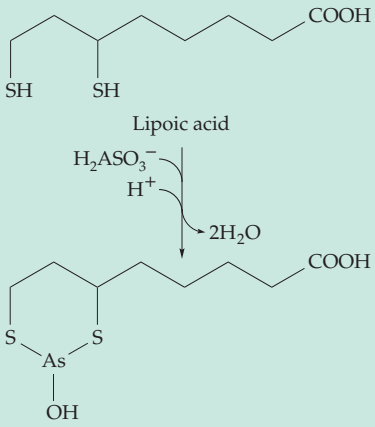
The subsequent transfer of the 1-phospho group to ADP is an important energy-yielding step in metabolism (Chapter 12). When arsenate substitutes for phosphate the acyl arsenate (1-arseno-3-phosphoglycerate) is hydrolyzed to 3-phosphoglycerate. As a consequence, in the presence of arsenate oxidation of 3-phosphoglyceraldehyde continues but ATP synthesis ceases. Arsenate is said to **uncouple** phosphorylation from oxidation. Arsenate can also partially replace phosphate in stimulating the respiration of mitochondria and is an uncoupler of oxidative phosphorylation (Chapter 18). Enzymes that normally act on a phosphorylated substrate will usually catalyze a slow reaction of the corresponding unphosphorylated substrate in the presence of arsenate. Apparently, the arsenate ester of the substrate forms transiently on the enzyme surface, permitting the reaction to occur.



Lewisite

Arsenite is noted for its tendency to react rapidly with thiol groups,[c] especially with pairs of adjacent (vicinal) or closely spaced –SH groups[d] as in lipoic acid. By blocking oxidative enzymes requiring lipoic acid (Chapter 15), arsenite causes the accumulation of pyruvate and of other 2-oxo acids. Similar chemistry underlies the action of the mustard gas Lewisite, which also attacks lipoic acid.[de]

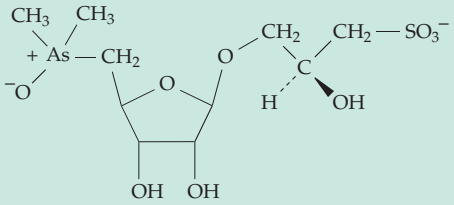
Many, perhaps all, organisms have enzyme systems for protection against arsenic compounds.



Lipoic acid

In *E. coli* arsenate is reduced to arsenite by a glutaredoxin- and NADH-dependent system.[e–g] The arsenite as well as antimonite and tellurite are pumped out by an ATP-dependent transporter. The genes for reductase, periplasmic-binding protein, and transporter components are encoded in a conjugative plasmid.[h,i] A quite similar system functions in yeast.[j]

Marine algae as well as some higher aquatic plants detoxify and excrete arsenate by conversion to various water-soluble organic forms such as trimethyarsonium lactic acid (Chapter 8) and the following ribofuranoside.[a]



2-Hydroxy-3-sulfopropyl-5-deoxy-5-(dimethylarseno)-ribofuranoside

Arsenic-containing phospholipids are also formed (Chapter 8).[k]

Arsenic is present at high levels in some soils and contamination of drinking water with arsenic is a major problem is some areas of the world. In West Bengal, India, millions of people drink contaminated well water. As a result hundreds of thousands have developed debilitating nodular keratoses on their feet.[l,m] The problem is made worse by the increasing

BOX 12-B (continued)

use of fresh water for irrigation and the difficulty of removing arsenic contamination.

Although it is most known for its toxicity, arsenic may be an essential nutrient. Data from feeding of chicks, goats, rats, and miniature pigs suggest a probable human need for arsenic of ~12 μg / day.[n]

Compounds of arsenic have been used in medicine for over 2000 years, but only in the past century have specific arsenicals been created as drugs. In 1905, it was discovered that sodium arsanilate is toxic to trypanosomes. The development by P. Ehrlich of **arsenicals** for the treatment of syphilis (in 1909) first focused attention on the possibility of effective chemotherapy against bacterial infections.

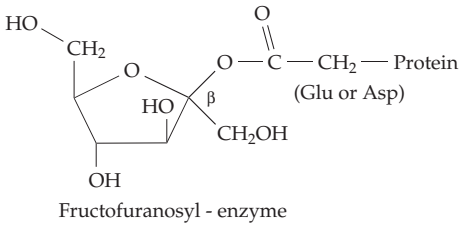
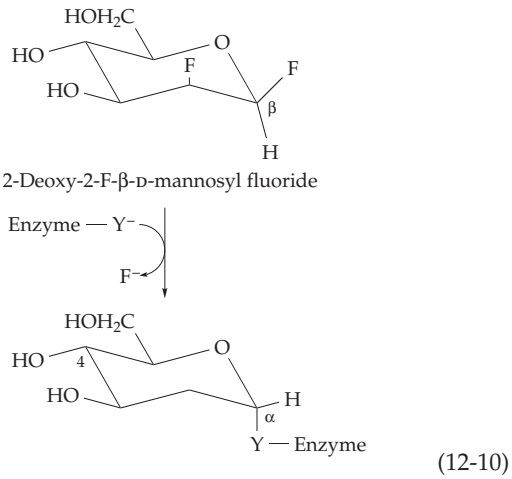
carboxyl groups. Such an intermediate, fructofuranosyl-enzyme, was identified tentatively for sucrose phosphorylase and also for a related levan sucrase.[45] Recently, identification of glycosyl-enzyme intermediates has been accomplished for many other glycosyltransferases. Among these are human pancreatic and salivary α-amylases,[42,46] α-glucosidases, and some cellulases and xylanases.



For these hydrolytic enzymes the glycosyl-enzyme would be attacked by a hydroxyl ion derived from H_2O, whose deprotonation would presumably be assisted by the conjugate base (—B: in Eq. 12-5) of the catalytic acidic group.

A convenient way to form and identify covalently linked glucosyl-enzyme intermediates, developed by Withers and coworkers, employs enzyme-activated inhibitors such as 2-deoxy-2-fluoroglycosyl fluorides (Eq. 12-10).[42,47,48] The 2-F substituent greatly decreases both the rate of formation of a glycosyl-enzyme and its rate of breakdown by hydrolysis or transglycosylation. This may be in part because these compounds lack the 2–OH group which helps to stabilize, by hydrogen bonding, the complexes of normal substrates. A second factor is the high electronegativity of –F versus –OH, which leads to significant loss of stability for a transition state in which the anomeric carbon atom carries a significant amount of positive charge (see next section). Having a good leaving group, such as fluorine or 2,4-dinitrophenyl, the compounds react rapidly to give stable glucosyl-enzymes which can be characterized. In the example shown in Eq. 12-10, the mannosyl-enzyme was identified by the chemical shifts and linewidths of the ^{19}F resonances of the intermediates and the anomeric configuration was established. More recently, mass spectrometry has been used.[49] For example, a maltotriosyl-enzyme intermediate in the

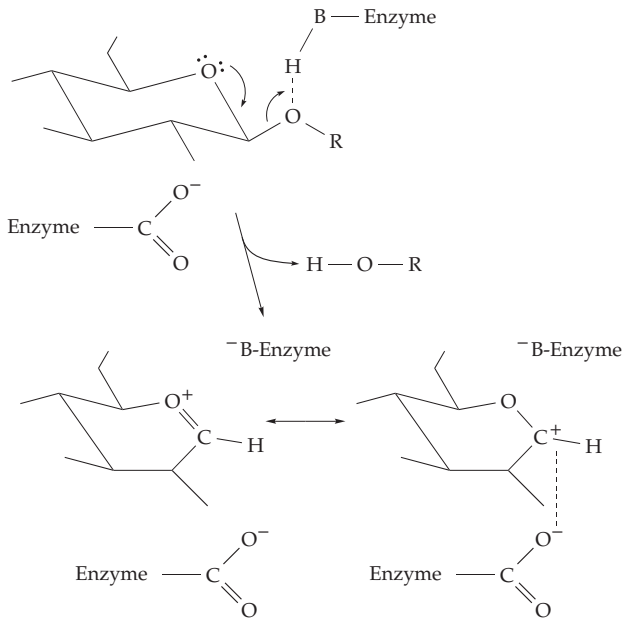
action of glycogen-debranching enzyme was identified by separation of an active site peptide by HPLC followed by mass spectrometry (Chapter 3).[50]



2-Deoxy-2-F-β-D-mannosyl fluoride

(12-10)

Carbocationic intermediates. In a second mechanism of nucleophilic displacement the leaving group departs (often in a protonated form) before the entering nucleophile reacts.

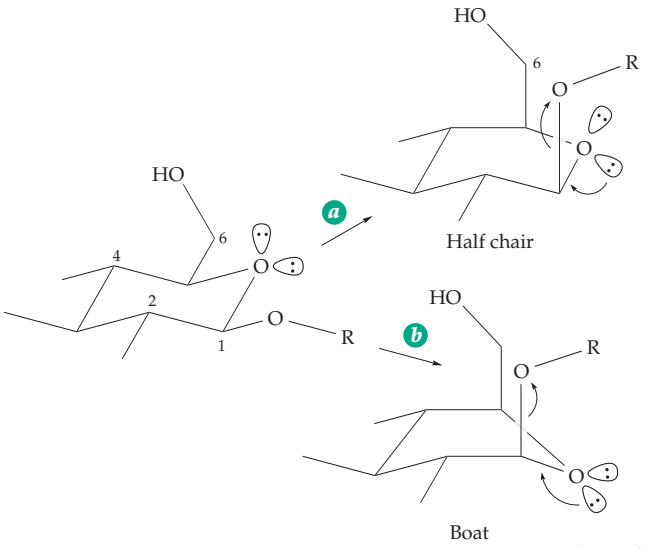


Oxocarbenium ion, a stabilized carbocation

(12-11)

A carbocation is formed as shown in Eq. 12-11, which represents just one-half of the overall displacement reaction. In the common terminology of physical organic chemistry this is an S_N1 reaction rather than an S_N2 reaction of the kind shown in Eqs. 12-3 and 12-5. This terminology is not quite appropriate for enzymes because the breakdown of ES complexes to product is usually a zero-order process and the numbers 1 and 2 in the symbols S_N1 and S_N2 refer to the order or molecularity of the reaction. It is better to speak of S_N1-like or S_N2-like reactions.

The carbocation in Eq. 12-11 is depicted as a resonance hybrid of two forms. One of these is an **oxocarbenium** (or oxonium) ion which contains a double bond between carbon and oxygen.[50a] This double-bonded structure can be visualized as arising from the original structure by an internal displacement or elimination by the unshared electrons on oxygen, as indicated by the small arrows. In the oxocarbenium ion, the ring atoms C-2, C-1, and C-5 and the oxygen atom are almost coplanar and the ring conformation is described as **half-chair** or **sofa**. As pointed out in Chapter 9, the theory of stereoelectronic control predicts that elimination of the group –OR of Eq. 12-11 should occur most easily if a lone pair of electrons on the ring oxygen atom are antiperiplanar to the O–R bond. This is impossible for a β-glycoside with a ring in the chair conformation shown in Eq. 12-11. This fact suggested that enzymes cleaving β-glycosides may preferentially bind substrate with the appropriate sugar ring in a less stable half-chair or flexible boat conformation prior to bond cleavage (Eq. 12-12).[51,52] This would allow an unshared pair of electrons on oxygen antiperiplanar to the C-1 to O – R bond to participate in the elimination reaction as is indicated in the following diagrams.



(12-12)

On the other hand, Bennet and Sinnott provided evidence that an antiperiplanar lone electron pair is *not* needed in acid-catalyzed cleavage of glycosides via a carbocationic intermediate.[53,54] Theories of stereoelectronic control must be applied to enzymes with caution!

5. Lysozymes and Chitinases

Polysaccharide chains in the peptidoglycan layer (Fig. 8-29) of the cell walls of bacteria are attacked and cleaved by lysozymes,[55] enzymes that occur in tears and other body secretions and in large amounts in egg white. Some bacteria and fungi, and even viruses, contain lysozymes.[56] Their function is usually to protect against bacteria, but lysozyme of phage T4 is a component of the baseplate of the virus tail (Box 7-C). Its role is to cut a hole in the bacterial cell wall to permit injection of the virus' own DNA. Egg white lysozyme, the first enzyme for which a complete three-dimensional structure was determined by X-ray diffraction,[55] is a 129-residue protein. The active site is in a cleft between a large domain with a nonpolar core and a smaller β-sheet domain that contains many hydrogen-bonded polar side chains (Figs. 12-3, 12-4). Human lysozyme has a similar structure and properties.[57–59] The T4 lysozyme has an additional C-terminal domain whose function may be to bind the crosslinking peptide of the *E. coli* peptidoglycan. Goose lysozyme is similar in part to both hen lysozyme and T4 lysozyme. All three enzymes, as well as that of our own tears, may have evolved from a common ancestral protein.[60] On the other hand, *Streptomyces erythaeus* has developed its own lysozyme with a completely different structure.[61] An extensive series of T4 lysozyme mutants have been studied in efforts to understand protein folding and stability.[61–63]

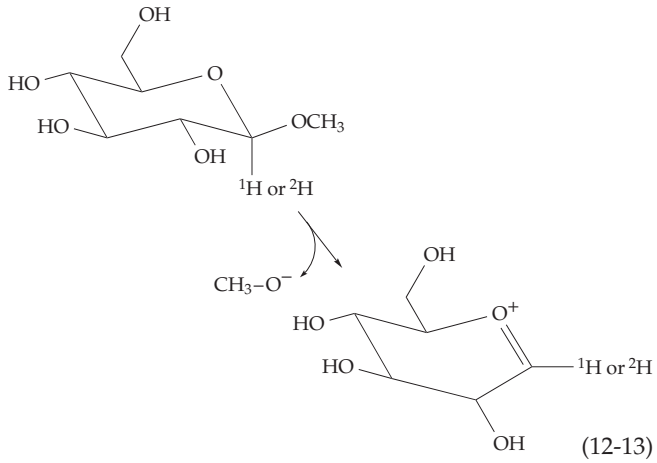
Figure 12-3 Stereoscopic MolScript view of hen egg white lysozyme complexed with a trisaccharide of *N*-acetylglucosamine $(GlcNAc)_3$ in binding subsites A, B, and C. The side chain of Trp 62 and the trisaccharide above it are shown in ball-and-stick form. From Maenaka *et al.*[65] Courtesy of Izumi Kumagai.

Catalytic side chain groups. Six *N*-acetylglucosamine (GlcNAc) or *N*-acetylmuramic acid (MurNAc) rings of the polysaccharide substrate are able to fit precisely into six subsites (designated A to F) in a groove between the two structural domains of egg white lysozyme (Fig. 12-4). The bond between the fourth and fifth rings (subsites D and E) is then cleaved. At the active site, the side chain carboxyl group of Glu 35 is positioned correctly to serve as the proton donor BH of Eq. 12-11, while the carboxyl of Asp 52 lies on the opposite side of the groove. Both Glu 35 and Asp 52 have relatively high pK_a values for carboxyl (microscopic pK_a's are ~5.3 and 4.6, respectively, in the fully protonated active site when the ionic strength is ~ 0.2)[64] as a result of the hydrophobic environment and hydrogen bonding to other groups. If the pH is raised from an initially low value, a proton from Asp 52 usually dissociates first and the electrostatic field of the resulting anion keeps Glu 35 largely protonated until the pH approaches 6. Positively charged basic groups nearby affect the pK_a values; hence, the behavior of the enzyme is sensitive to the ionic strength of the medium.[63] The Asp 52 anion lies only ~ 0.3 nm from the center of positive charge expected for an oxocarbenium ion intermediate and presumably stabilizes it. Replacement of Glu 35 by Gln destroys all catalytic activity and replacement of Asp 52 by Ala or Asn decreases activity to ~4–5% of the original.[66–68] Less than 1% activity remained for the D52S mutant.[69]

Nevertheless, Asp 52 is not absolutely essential for lysozyme activity. Goose lysozyme lacks this catalytic aspartate.[70] Matsumura and Kirsch suggested that carboxyl groups of glycine residues covalently attached to *N*-acetylmuramic acid rings in the natural substrates may participate in catalysis.[66] Many mutant forms of lysozyme have been studied. Of special interest is the D52E mutant. In this enzyme the carboxylate of the longer glutamate side chain reacts with the oxocarbenium ion intermediate to form a covalent adduct and apparently alter the basic mechanism.[71] Replacement of asparagine 46, which can hydrogen bond to Asp 52, also decreases k_{cat} greatly, suggesting a role in catalysis.[72]

The lysozyme-catalyzed reaction is completed by stereospecific addition of a hydroxyl ion to the oxocarbenium ion with the original β configuration being retained in the product. Such stereospecificity for reactions of enzyme-bound carbocations is not surprising because the enzyme probably assists in generation, on the appropriate side of the sugar ring, of the attacking hydroxyl ion.

Kinetic isotope effect for lysozyme. A secondary kinetic isotope effect is expected because a molecule with ^1H in the number 1 position can be converted to the corresponding oxocarbenium ion somewhat more easily than the molecule with ^2H in the same position (Eq. 12-13). For example, in the nonenzymatic acid-catalyzed hydrolysis of a methyl- glucoside, a reaction also believed to proceed through a carbocation intermediate,[41,75] the ratio k_{1_H} / k_{2_H} is 1.14 for the α anomer and 1.09 for the β anomer.[53] In the base-catalyzed hydrolysis of the same compound, which is believed to occur by a double-displacement reaction involving participation of the neighboring OH group on C-2, the ratio k_{1_H} / k_{2_H} is 1.03. The corresponding ratio measured



(12-13)

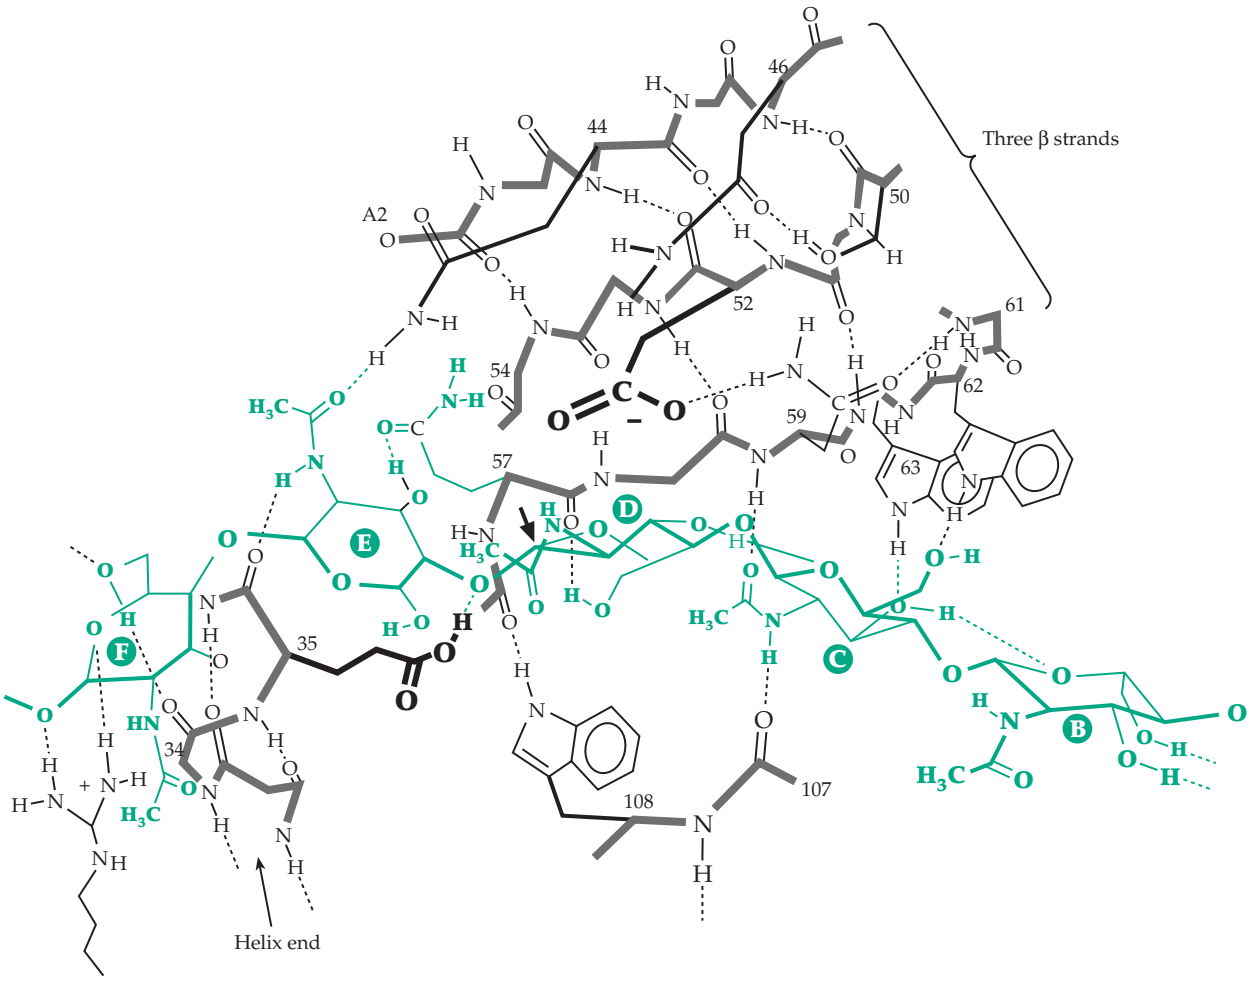


Figure 12-4 Schematic drawing of the active site of egg white lysozyme with substrate in place and about to be cleaved. Three strands of the small β-sheet domain, which contains an extensive hydrogen bond network, are seen at the top. Notice that this view into the active site is different from that in Fig. 12-3. A 180° rotation of either figure will make the views more similar. The three-strand β sheet can be seen (in stereo) at the lower right in Fig. 12-3 and the helix end carrying Glu 35 in the right center foreground. A segment of a chitin oligosaccharide (green), whose reducing end is to the left, is bound into subsites B –F. Cleavage occurs between rings D and E as indicated by the heavy arrow which points to the anomeric carbon atom of ring D. The side chain of Glu 35 is shown protonating the bridge oxygen. Ring D has been distorted into a twist conformation to facilitate cleavage. A larger domain, which contains one long α helix, is at the bottom of the drawing. The active site lies in a cleft between the domains. Notice the chain of hydrogen bonds between the carbonyl of residue 107 in the large domain and the peptide NH of residue 59 in the small domain. Also notice the aromatic side chains which are usually present in carbohydrase active sites. Drawing is based in part on those of Irving Geis[73] and Levitt[74] and on a sketch by author from a three-dimensional model.

for the action of lysozyme is 1.11, much closer to that of the oxocarbenium ion mechanism than to that of the double-displacement mechanism. Similar observations have been made with amylases.[76] Kinetic isotope effects have also been measured for ^{12}C vs ^{13}C in the anomeric position, ^{16}O vs ^{18}O in the leaving group ($-OCH_3$) of the methyl glucosides, and for other locations[53] as well as for hydrolysis of glucosyl fluorides.[77–79] The results are generally supportive of the oxocarbenium ion mechanism for lysozyme. However, as mentioned in Section B,3, the interpretation of secondary isotope effects is difficult. Such effects cannot reliably identify a carbohydrase mechanism.[80,81]

For acid-catalyzed hydrolysis of methyl glucosides[53] the kinetic isotope effect observed for the oxygen of the leaving group was $k_{16_O}/k_{18_O} = 1.024-1.026$. Observation of similar effects for enzymes supports the participation of an acidic group of the protein (Glu 35 of lysozyme) in catalysis but does not eliminate the possibility of concerted involvement of a nucleophilic group, e.g., Asp 52 in lysozyme.[81,82]

Does lysozyme distort its substrate? An early study of models indicated that for six sugar rings of a substrate to bind tightly into the active site of lysozyme, the ring in subsite D, which contains the carbon atom on which the displacement occurs, had to be distorted from its normal chair conformation into the half-chair conformation.[83] This is illustrated in Fig. 12-4. It was suggested that by binding the substrate chain at six different sites the enzyme provides leverage to distort the ring in subsite D into a conformation similar to that of the transition state. This idea was criticized on the basis that an enzyme would be too flexible to act in this manner.[74] Furthermore, the non-hydrolyzed trisaccharide MurNAc–GlcNac–MurNAc was shown to fit into subsites B, C, and D of the active site groove without distortion.[84] However, it is bound weakly.

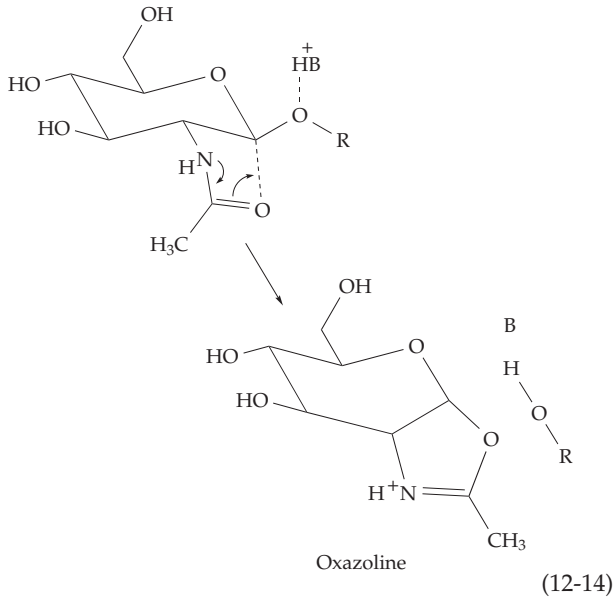
Can electrical forces acting within the active site help to distort the substrate and assist in formation of the carbocation intermediate? Levitt and Warshel suggested this possibility and proposed that the necessary electrostatic force arises from the arrangement of dipoles within the peptide backbone of the protein and in the amino acid side chains.[74] As can be seen from Fig. 12-4, the enzyme forms many hydrogen bonds with the substrates. Of special interest is a chain of hydrogen bonds that passes from the backbone carbonyl of Ala 107 through the 2-acetamido group of the substrate in subsite C and into the edge of the β sheet at the backbone NH of Asn 59. This interaction provides specificity toward GlcNac-containing substrates. Perhaps oscillation of charge within such polarizable chains of hydrogen bonds can also help a substrate to move toward its transition state structure.[85,86]

From simulations of lysozyme action by the methods of molecular dynamics, Post and Karplus observed that Glu 35 tended not to hydrogen bond to the exocyclic bridge oxygen, even though that would be a logical step in the protonation (by –BH) shown in Eq. 12-11. They suggested that Glu 35 may protonate the ring oxygen.[87] The ring could then open to form an exocyclic oxonium ion, which could hydrolyze and cyclize to the final product. The initial elimination could receive stereoelectronic assistance from the antiperiplanar lone pair of electrons on the bridge oxygen. This proposal has been criticized.[81,88] For example, it is hard to explain the rapid cleavage of glycosyl fluorides by this exocyclic oxonium mechanism.

As attractive as the arguments for a oxocarbenium mechanism in lysozyme are, is it still possible to explain the experimental observations by a double displacement in which Asp 52 serves as the nucleophile to form a glycosyl enzyme?[38,82,82a] Sucrose phosphorylase and other glucosyl transferases, like lysozyme, apparently have a carboxylate ion at the active site. In some enzymes, the carboxylate ion forms a covalent glucosyl enzyme, whereas in lysozyme it apparently only stabilizes a carbocation. Is there really a difference in mechanism? Do glucosyl enzymes form only with certain substrates or upon denaturation of the enzymes? Nature hides her secrets well. The difficulty in pinning down the fine mechanistic details of enzymatic action makes it essential to be skeptical, to examine data critically, and to try to imagine all possible alternatives –even when things seem to be proven beautifully.

Help from a neighboring group. In the 1960s it was suggested that the acetamido group of *N*-acetylglucosamine residues might participate as a nucleophile, either stabilizing an oxocarbenium ion or forming an oxazoline intermediate.[89–91] The proposal received little support, as applied to lysozyme, until sequences and structures of many larger carbohydrases were determined. Among these are **chitinases**, enzymes that act on the same substrates as the small lysozymes. One group of plant chitinases have a structure similar to that of egg white lysozyme. The 243-residue enzyme from barley seeds apparently has Glu 67 as a proton donor and Glu 89 as a possible stabilizing nucleophile.[92] Another group of chitinases from both plants and bacteria have active sites at ends of $(\alpha\beta)_6$ barrels.[93–95] They all have a proton-donating glutamate in a conserved position but *no aspartate* that could serve as a nucleophile. Study of complexes with substrates and inhibitors with these enzymes has provided direct evidence of ring distortion and of the probable role of the acetamido group as indicated in Eq. 12-14.[94,95] The distortion is beyond that in a sofa conformation and allows for maximum stereoelectronic assistance as well as participation of the acetamido group.

In these relatively large enzymes the substrate is deeply buried and cannot reach a conformation



Oxazoline (12-14)

approaching that of the transition state without having a strained ring conformation. These enzymes may use binding forces exerted on many parts of the substrate to stabilize the transition state structure.

6. Cellulases and Other β-Glycosidases

Cellulose, the most abundant of all biopolymers, is extremely stable but is attacked by a host of bacterial and fungal β-glycanases.[96] Animals do not ordinarily produce cellulases but some termites do.[97] Cellulase structures are varied, being represented by 10 of 57 different glycosylhydrolase families.[98] Most, like lysozyme, retain the β configuration in their products but some invert.[98–100]

Among the cellulases are **endoglycanases**, which cleave chains at random positions, and **exoglycanases** (also called **cellobiohydrolases**) that cleave cellobiose units from ends of chains. Some act on the nonreducing ends and some on reducing ends; a mixture of enzymes is most effective.[99,101,102] In some bacteria a whole series of different cellulases, together with a large (197-kDa) organizing protein, form a **cellusome**, a complex with high catalytic activity for crystalline cellulose.[103–105] Cellulases usually have tightly packed catalytic domains which may vary in size from ~200 residues[98] to over 400.[106] In most cases the catalytic domain is connected by a flexible linker to one or more small, globular **cellulose-binding domains**. These vary in size from 36 to 200 residues and often have a β-barrel fold.[104,107–108a] Their function is to hold the enzymes to the cellulose surfaces. They may also facilitate disruption of the tightly hydrogen bonded cellulose structure (Fig. 4-5). As with other carbohydrases, carboxyl groups of amino acid side chains provide the major catalytic groups (Table 12-1). An extensive hydrogen-bond network which often includes imidazole groups may influence activity.[109,110]

A striking feature of a 411-residue endoglucanase from *Fusarium* was revealed by the binding of a nonhydrolyzable thiooligosaccharide substrate analog. The pyranose ring at the cleavage site was distorted in an identical manner to that mentioned in the preceding section for a chitinase thought to use the substrate's acetamido group as a nucleophile (Eq. 12-14).[106] The distortion observed is beyond that required for a sofa conformation and allows for the maximum stereoelectronic assistance (Eq. 12-12*b*). An oxygen atom of the E197 carboxylate, the catalytic nucleophile, occupies a position in the complex that is coincident with that of the C2 acetamido oxygen in the catalytic site of the chitinase discussed in the previous section.

The *inverting* β-glucanases also have two catalytic acid base groups but they are ~0 .9 – 1.0 nm apart rather than ~ 0.6 nm for retaining enzymes. This allows space for a water molecule whose $^{-}$OH is the nucleophilic reactant ($^{-}$OY in Eq. 12-5) and in which a carboxylate group assists in dissociating the water molecule.[98] (This mechanism is illustrated for glucoamylase in Fig. 12-7).

Structural features met in some cellulases include an α,α barrel[111] similar to that of glucoamylase (Fig. 2-29) and, in a cellobiohydrolase,[101] a 5-nm-long tunnel into which the cellulose chains must enter. Ten well-defined subsites for glycosyl units are present in the tunnel.[101] A feature associated with this tunnel is **processive** action, movement of the enzyme along the chain without dissociation,[105] a phenomenon observed long ago for amylases (see Section 9) and often observed for enzymes acting on nucleic acids.

Another group of **β-glucanases**, found in plants and their seeds, hydrolyze β-1,3-linked glucans[112] and, in some cases, also mixed 1,3- and 1,4-linked polysaccharides. A characteristic enzyme is found in barley (Table 12-1).[113,114] Similar enzymes are produced by some bacteria[113] and also by molluscs.[115]

Xylanases act on the β-1,4-linked xylan, the most abundant of the **hemicelluloses** that constitutes over 30% of the dry weight of terrestrial plants.[116] They resemble cellulases and cooperate with cellulases and **xylosidases**[117] in digestion of plant cell walls.[110,116,118–121] **Galactanase** digests the β-1,4-linked component of pectins.[122]

The final step in degradation of cellulose is hydrolysis of cellobiose to glucose. This is accomplished by **β-glucosidases**, enzymes that also hydrolyze lactose, phosphorylated disaccharides, and cyanogenic glycosides.[123 – 126] Lactose is also cleaved by **β-galactosidases**.[127] The large 1023-residue β-galactosidase from *E. coli*[128] is famous in the history of molecular biology as a component of the *lac* operon.[129 – 132] Its properties are also employed to assist in the cloning of genes (Chapter 26).

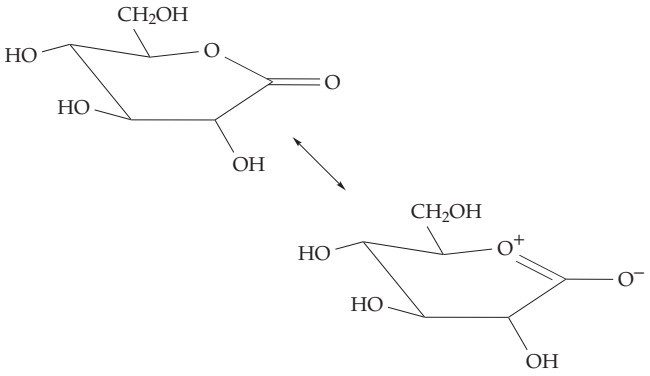
7. Glycogen Phosphorylase

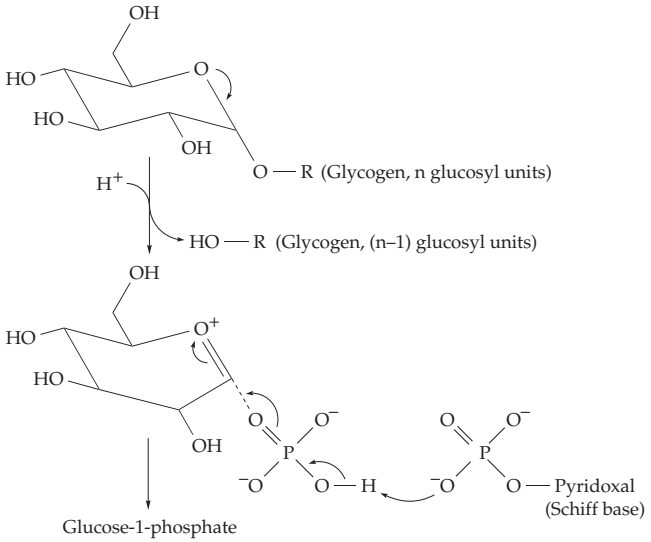
A large number of different glycosyltransferases act on the α1,4 linkages of glycogen, starch, and related polysaccharides. Among these, one of the most studied is glycogen phosphorylase. It is not a hydrolase, but it catalyzes cleavage of α1,4 linkages at the nonreducing ends of glycogen molecules by displacement with inorganic phosphate to give α-D-glucose-1-phosphate. It is a very large enzyme (841 residues in rabbit muscle) whose structure is shown in Fig. 11-5. Its complex regulatory mechanisms were discussed briefly in Chapter 11.

Neither partial exchange reactions nor inversion of configuration occur when glycogen phosphorylase acts on its substrates. The enzyme apparently does nothing until both substrates are present. These are glycogen + inorganic phosphate or, for the reverse reaction, glycogen (shifted over by one sugar binding subsite) + glucose-1-phosphate. The active site is in a deep groove in the enzyme. Evidently, the protein must close and fold around the substrates before it becomes active.[133] An oxocarbenium ion mechanism has also been proposed for this enzyme, partly on the basis of strong inhibition of phosphorylase by **5-gluconolactone**,[134,135] a compound having a half-chair conformation and perhaps acting as a transition state inhibitor (Chapter 9). This gluconolactone also inhibits many other carbohydrases.[123,136]



5-Gluconolactone

An unexpected discovery was that glycogen phosphorylase contains a molecule of the coenzyme pyridoxal 5'-phosphate (PLP) bound into the center of the protein behind the active site[134,135,137–139] with its phosphate group adjacent to the binding site of the phosphate of glucose-1-phosphate. It probably serves as a general base catalyst, e.g., assisting the attack of a phosphate ion on the oxocarbenium formed by cleavage of the glycogen chain (Eq. 12-15).[137,140–142] A key observation by Graves and associates was that pyridoxal alone does not activate apo-phosphorylase but that pyridoxal



(12-15)

plus phosphite, phosphate, or fluorophosphate does provide up to 20% of full activity.[143] X-ray crystallography confirmed that these activating anions are bound into the active site at the approximate position of the phosphate group of PLP.[139,143a] Glycogen phosphorylase is being studied by X-ray diffraction techniques that allow observation of structural changes in as short a time as a few milliseconds (see Chapter 3, Section H).[144]

The regulation of glycogen phosphorylase, like that of many other allosteric proteins, depends upon the existence of two distinct conformational states, whose structures have been established by crystallography.[137] It is not immediately evident how they can affect the active site. In the R-state the enzyme has a low affinity for both substrates and activators such as AMP. In the T-state the affinities are much higher. For example, that of inorganic phosphate is raised by a factor of fifteen.[137] As we have already seen (Figs. 11-4, 11-5) the relatively inactive phosphorylase *b* is converted to the active phosphorylase *a* by phosphorylation of the side chain of serine 14, a structural change which favors the R-state. In the inactive T-state of phosphorylase *b*, an 18-residue N-terminal segment of the polypeptide is not seen by X-ray diffraction, presumably because it does not assume a fixed conformation but projects into a solvent channel in the crystal and moves freely within it. However, in the active R-state of phosphorylase *a*, in which Ser 14 has been phosphorylated, the N-terminal segment is rigid. The phospho group on Ser 14 binds to Arg 69 and other arginine, lysine, and histidine side chains from both subunits.[137,145] The phosphorylation of Ser 14 occurs 1.5 nm from the active sites. The conformational changes induced by phosphorylation of Ser 14 cause a rotation of about 10° between subunits, somewhat reminiscent of the changes accompanying oxygenation of hemoglobin (Fig. 7-25).

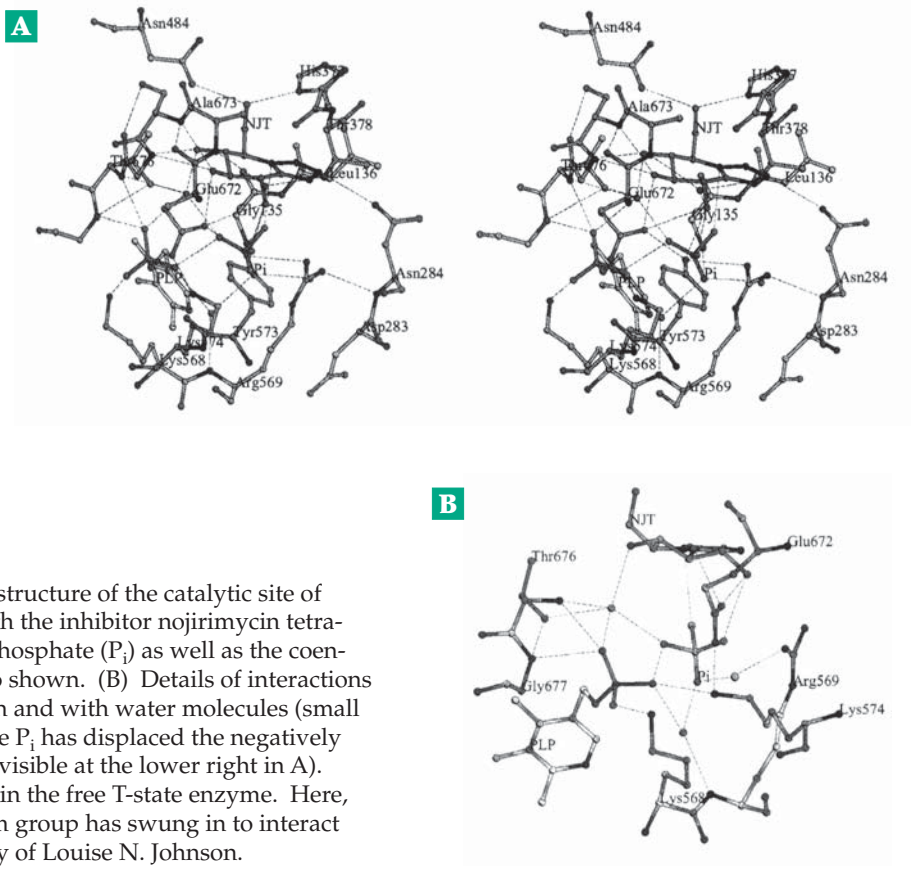


Figure 12-5 (A) Stereoscopic view of the structure of the catalytic site of phosphorylase *b* in the inhibited T-state with the inhibitor nojirimycin tetrazole bound into the active site. Inorganic phosphate (P_i) as well as the coenzyme pyridoxal 5'-phosphate (PLP) are also shown. (B) Details of interactions of the inhibitor, P_i, and PLP with the protein and with water molecules (small circles). This is a weak-binding state but the P_i has displaced the negatively charged side chain carboxylate of Asp 283 (visible at the lower right in A). This carboxylate blocks access to the P_i site in the free T-state enzyme. Here, the positively charged Arg 569 guanidinium group has swung in to interact with the P_i. From Mitchell *et al.*[133] Courtesy of Louise N. Johnson.

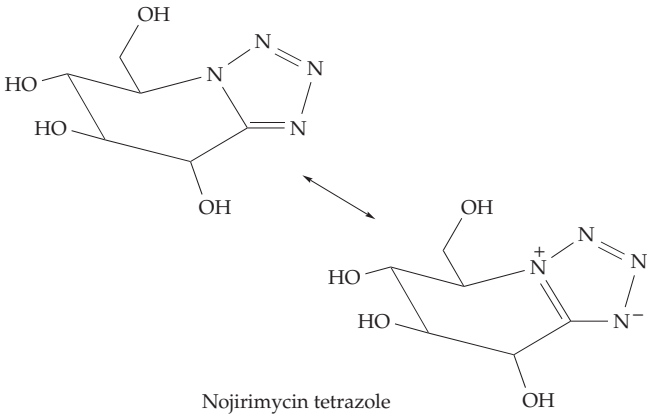
A related structural change accompanies binding of caffeine, adenosine, or AMP at high concentrations. These substances inhibit the enzyme by binding at a site next to the catalytic site (Fig. 11-5), stabilizing the T-state and causing a loop of protein to move into the catalytic site and to block it.[137] The catalytic site lies deeply buried in the protein between the two large structural domains (Fig. 11-5). The substrate is held by a network of hydrogen bonds, some of which are shown in Fig. 12-5, in which the active site contains an inhibitory substrate analog **nojirimycin tetrazole**, which is viewed toward the edges of the two rings.



Nojirimycin tetrazole

The enzyme is in the weak-binding T-state but inorganic phosphate (P_i) is bound below it and next to the phosphate group of PLP, as required by the mechanism of Eq. 12-15.

The difference in binding affinities for the T- and R-states lies in a flexible loop of residues 280–288, which in the T-state blocks access to the substrate-binding cleft. The universally conserved Asp 238 behaves as a substrate mimic, occupying the P_i site.[137,146,147] In the R-state this residue moves, allowing P_i to enter and bind (Fig. 12-5).

Most of the structure of mammalian phosphorylases is conserved in species as diverse as *E. coli* and the potato.[148] However, *E. coli* maltodextrin phosphorylase[143a,149–151] and potato phosphorylases have less sophisticated regulatory mechanisms than do the animal enzymes. Another feature of glycogen phosphorylase is a "glycogen storage site" about 2.5 nm from the active site (Fig. 11-5).[152] This provides a means for the enzyme to hold onto the giant glycogen molecule while "nibbling off" the outside ends of nearby branches.

8. Starch-Hydrolyzing Enzymes

Among the hydrolases are the widely distributed **α-amylases**, *endo*-glycosidases which hydrolyze

starch chains by random attack at points far from chain ends to form short polysaccharide chains known as **dextrins** as well as simpler sugars.[153] The catalyzed reactions proceed with retention of the original α configuration. Alpha-amylases are found in fungi, plants, and animals. One powerful enzyme of this class is present in the saliva of most humans and other isoenzymes are formed by the pancreas.[154] They are encoded by a family of genes, a fact that accounts for the existence of some healthy individuals completely lacking salivary amylase.[155]

Structures are known for human[154] and porcine[156–159] α-amylases as well as for corresponding enzymes from barley,[160] mealworms,[161] fungi, and bacteria.[162–164] The α-amylase from *Aspergillus oryzae* (Taka-amylase), widely used in laboratory work, was the first for which a structure was determined.[165,166] The α-amylases fold into three domains (Fig. 12-6), with the active site in the center of an $(\alpha/\beta)_8$ barrel. All of the α-amylases contain one or more bound Ca^{2+} ions. Some, including the human α-amylases, also require a **chloride ion**. The Cl^- is held by a pair of arginine guanidinium groups[154] and interacts with adjacent carboxyl groups, inducing pK_a shifts and allosteric activation.[163]

The sequences of α-amylases vary widely but a conserved cluster of one glutamate and two aspartates is usually present (Table 12-1).

Studies of the **action patterns**, i.e., the distribution of products formed by α-amylases when acting on a variety of α 1,4-linked oligosaccharides, suggested that the substrate binding region of the porcine pancreatic enzyme has five subsites, each binding one glucose residue.[153] The α-glucan chain is cleaved between the residues bound at the second and third subsites (numbered from the reducing end of the substrate) by a lysozyme-like mechanism. Endolytic enzymes, which cleave biopolymer chains internally, are usually thought to carry out random attack. However, after the initial catalytic reaction one of the polysaccharide products of porcine pancreatic amylase action often does not leave the enzyme. The polysaccharide simply "slides over" until it fully occupies all of the subsites of the substrate binding site and a second "attack" occurs. An average of seven catalytic events occur each time it forms a complex with amylase.[167] Is there a mechanism by which the enzyme deliberately promotes the "sliding" of the substrate in this **multiple attack** or **processive** mechanism[168,169] or does the dissociated product simply diffuse a short distance while enclosed in a solvent cage? The latter explanation may be adequate for some enzymes. In contrast to pancreatic α-amylase a bacterial "maltogenic" α-amylase produces principally maltose as a product.[169a,b]

Digestion of starch and glycogen by α-amylases produces a mixture of glucose, oligosaccharides, and dextrins, which in the human body are further degraded by **α-glucosidases** of the brush border membrane of the small intestine.[154] A lysosomal form of the enzyme is missing in Pompe's disease (Box 20-D).[170,171] The α-glucosidases are also members of the α-amylase family.[46,172] For digestion of the branched amylopectin and glycogen a **debranching enzyme** and **α-1,6-glucosidase** activity are required. In mammals these activities are found in a single polypeptide chain with separate but adjacent active sites.[50,173,174] The debranching enzyme catalyzes transfer of oligosaccharide chains from α1,6-linked branch positions to new locations at ends of chains with α1,4 linkages. A bacterial oligo-1,6-glucosidase has a catalytic site formed from

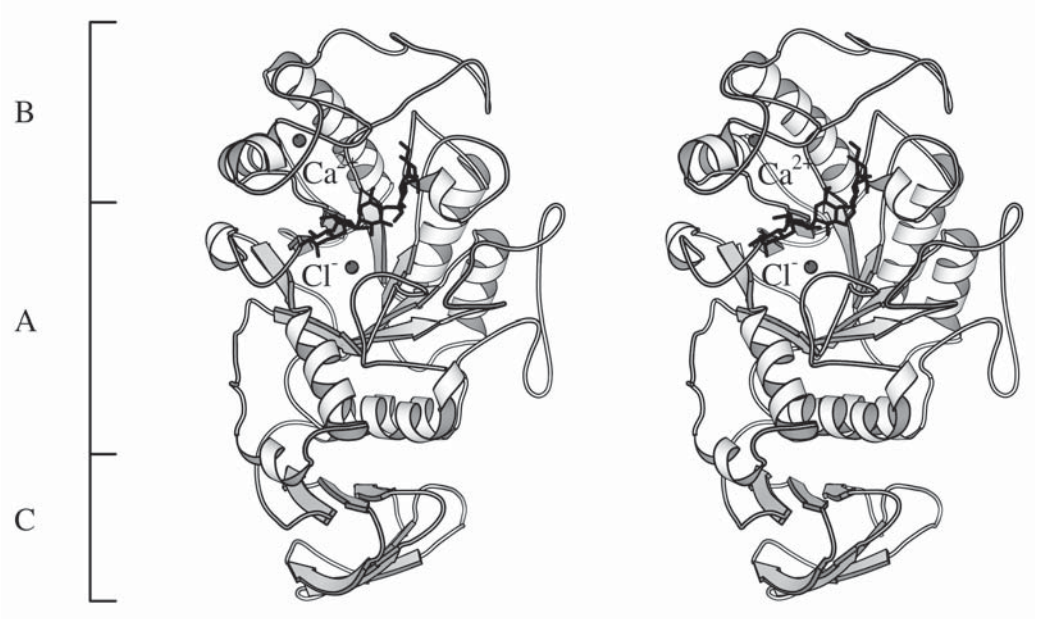


Figure 12-6 Drawing showing the overall polypeptide chain fold and relative positioning of the three structural domains of human pancreatic α-amylase. Also drawn are the locations of the calcium and chloride binding sites. Overlaid is the placement of a modified form of the inhibitor acarbose (p. 607) that binds in the active site cleft. MolScript drawing courtesy of G. Sidhu and G. Brayer.

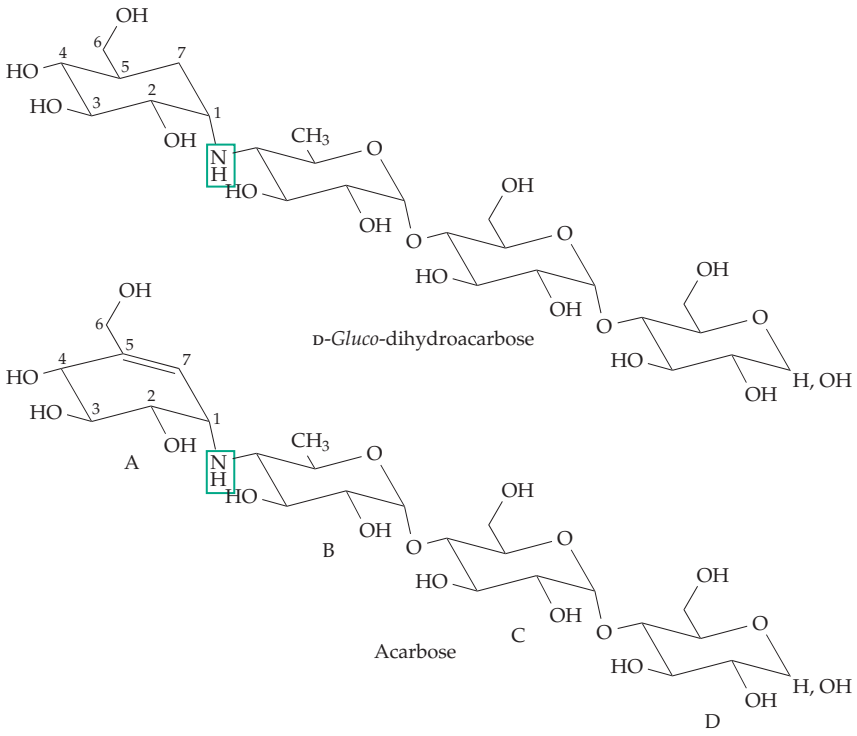
D199, E255, and D329 similar to that of α-amylases.[175]

Another member of the α-amylase family has principally a glycosyltransferase activity. **Cyclodextrin glucanotransferase** forms cyclodextrins (Box 4-A) by a transferase reaction in which a 6- to 8- member oligo-saccharyl group is transferred from a straight amylase chain onto a protein side chain (Glu 257) and then joins the ends of the oligosaccharide to form the cyclo-dextrin rings (an overall double-displacement process).[176–177b] However, large circular dextrins are produced initially and are then converted into the smaller cyclodextrins.[178]

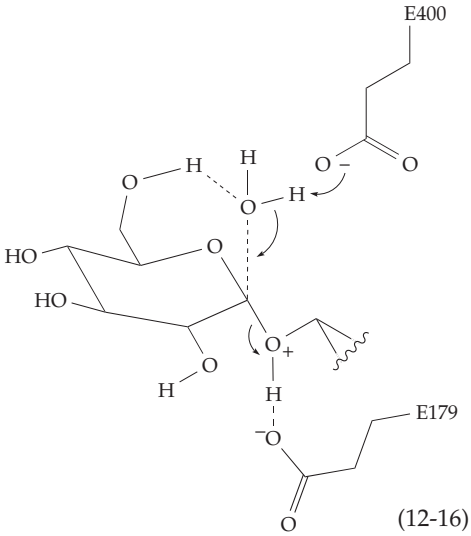
A starch-digesting enzyme of great industrial importance is **glucoamylase**, whose $(\alpha,\alpha)_6$-barrel structure is shown in Fig. 2-29. That figure also shows the tetrasaccharide inhibitor **acarbose** in the active site. The ring at the nonreducing end is deeply embedded in the protein and, as shown in Fig. 12-7 for the related D-*gluco*-dihydroacarbose, is held by many hydrogen bonds. This slow enzyme (k_{cat} ~50 s^{-1} at 45°C)[179] cuts off a single glucose unit, then releases



itself from the starch before releasing the glucose and rebinding to the starch. The catalytic acid has been identified as the carboxyl group of Glu 179. In Fig. 12-7 it is seen, presumably as a carboxylate group, tightly hydrogen bonded to what is doubtless the bridge $-NH_2^+-$ between rings A and B of the inhibitor D-*gluco*-dihydroacarbose. Thus, the complex mimics that of a true substrate protonated on the bridge oxygen, a possible first step in normal catalysis. In accord with this mechanism (Eq. 12-16), glucoamylase is an inverting enzyme.

Notice in Fig. 12-7 the abundance of polar groups, many of which are charged. Four carboxyl groups, from D55, E179, E180, and E400, are present in the active site region and participate in the hydrogen bonded network. Active sites of other carbohydrases differ from that of glucoamylase. However, the presence of many hydrogen-bonded polar groups, including two or more carboxyl groups, is characteristic. As illustrated in Figs. 9-8 and 9-9, the pH dependence of the maximum velocity v_{max} is often determined by these carboxyl groups. At least one of them must be protonated for maximum catalytic activity and if two are protonated activity may fall again. Under these circumstances a single proton bound to a molecule of enzyme may spend a fraction of its time on each of several different carboxylate, imidazole, or other groups.[181] In the case of glucoamylase it was concluded from the X-ray structure that the catalytic acid group, E179, is probably *unprotonated* most of the time.[181] However, it can still bind to starch. Then, after a fraction of a second a proton may be transferred onto the Glu 179 carboxylate and from there to the bridge oxygen of the substrate, inducing reaction according to Eq. 12-16. It may even be necessary to have enzyme protonated initially on a group other than E179 to allow small conformational changes to occur prior to formation of the final activated complex. Such essential conformational changes have often been invoked for glucoamylase.[182]

Just as most cellulases have special cellulose-binding domains, glucoamylase has a compact C-terminal starch-binding domain (residues 509–616) similar to the



(12-16)

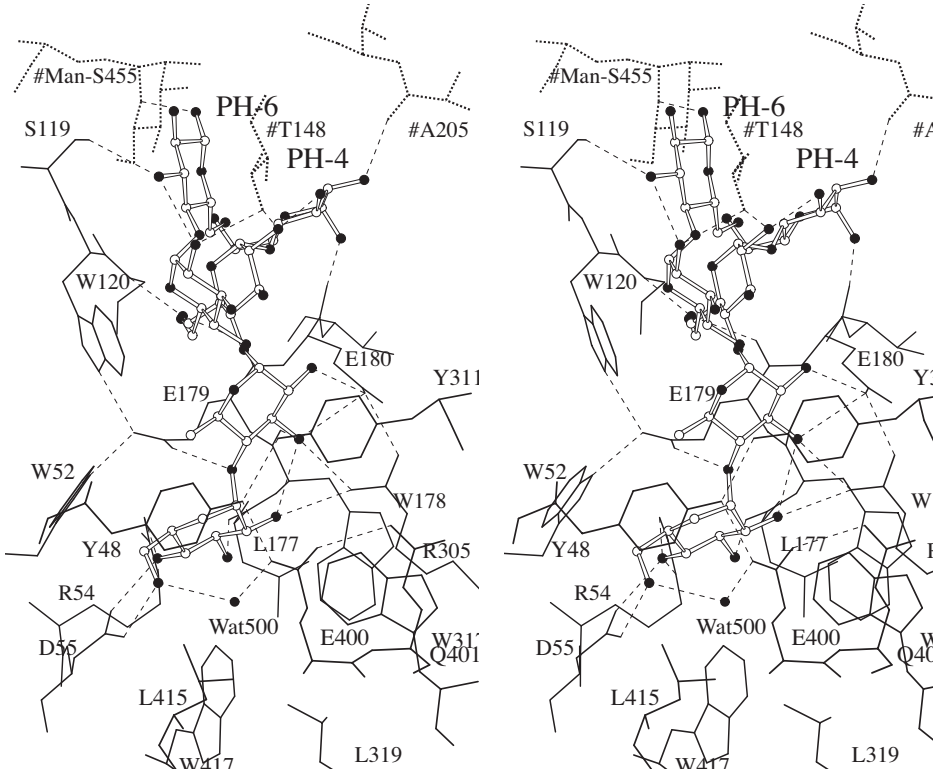


Figure 12-7 Stereoscopic view of the inhibitor D-*gluco*-dihydroacarbose in its complex with glucoamylase of *Aspergillus*. Residues from symmetry-related molecules of the enzyme are shown as dotted lines. Ring A at the nonreducing end of an amylase chain is thought to bind in a similar way (with ring A at the bottom in this figure). Cleavage is between the A and B rings E178 acting as a proton donor to the bridge oxygen (or NH for the inhibitor). The attacking nucleophile is thought to be a water molecule, which is labeled Wat 500 and is held by the assisting carboxylate of E400.[180] Courtesy of Alexander Aleshin.

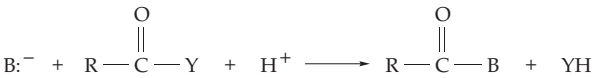
corresponding domain of cellulases.[183] It is connected by a glycosylated linker to the 470-residue catalytic subunit. Cyclodextrin glucanotransferase also has a starch-binding domain.[184]

Beta-amylases, characteristic plant and bacterial enzymes[184a], have an *exo* action, cutting off chain ends two sugar units at a time as *maltose*. The original α linkage is inverted, the product being β-maltose. The $(\alpha/\beta)_8$-barrel structure is unlike that of glucoamylase, but the spacing of active site carboxyl groups suggests that a water molecule is held and activated as in glucoamylase.[185,186] The multiple subsite structure of the active site may permit the substrate amylase to slip forward after a maltose product molecule leaves the site. This may account for the observed processive action.[186]

Many specialized glycosyl transferases synthesize glycogen, starch, cellulose, and other polysaccharides and add glycosyl groups to glycoproteins and glycolipids.[187,188] Often the glycosyl group is transferred from a carrier such as uridine diphosphate (UDP). An example is glycogen synthase (Fig. 11-4), which transfers glucosyl groups of UDP-glucose to the 4'–OH groups at the nonreducing ends of the bushlike glycogen molecules. Other similar synthetic reactions are considered in Chapter 20.

C. Displacement Reactions on Carbonyl Groups

A second major class of nucleophilic displacement reactions (Type 1B in Table 10-1) involve replacement of a group Y attached to a carbonyl carbon:

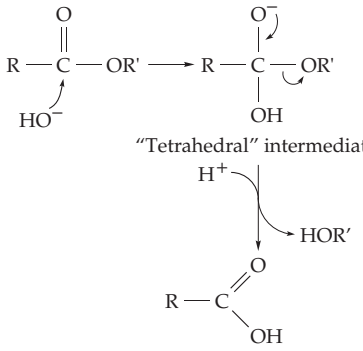


(12-17)

Group Y may be –OR (esters), –SR (thioesters) or –NHR (amides or peptides). If B^- is a hydroxyl ion formed from H_2O, the reaction is **hydrolysis**. If B^- is the anion of an alcohol, thiol, or amine, the reaction is **transacylation**. Transacylation is an essential process in biosynthesis of proteins and lipids, but it is the digestive enzymes, which catalyze hydrolysis, that have been studied most intensively.

Uncatalyzed hydrolysis of a peptide linkage is very slow with $t_{1/2}$ at neutral pH and 25°C of ~300–600 years.[189] Both acids and bases catalyze hydrolysis, but enzymes are needed for rapid digestion. The carbonyl group C=O is highly polarized, with the resonance form $C^+–O^-$ contributing substantially to its structure. An attack by a base will take place readily on the electrophilic carbon atom. While the reactivity of the carbonyl group in esters and amides is relatively low

because of the resonance stabilization of these groups, the carbon atom still maintains an electrophilic character and may combine with basic groups. Thus, in the base-catalyzed hydrolysis of esters a hydroxyl ion adds to the carbonyl group to form a transient single-bonded "tetrahedral" intermediate (Eq. 12-18). Similar intermediates are believed to form during the action of many enzymes. However, for purposes of classification, we can regard them as simple displacement reactions on a carbon atom with the understanding that there are probably transient single-bonded intermediates.



(12-18)

A large number of hydrolytic enzymes, the **proteases**, and **peptidases** act on peptide linkages of proteins.[190] At present the traditional name protease, which implies proteolysis, is most often used. However, the IUB encourages use of the name **proteinase**. Although this seems less specific in meaning, its use will probably increase. Some proteases trim newly formed peptide chains, others convert proteins from precursor forms into biologically active molecules, and others digest proteins. In addition to endopeptidases, such as trypsin and chymotrypsin, which cleave at positions *within* a long peptide chain, there are many enzymes that cleave amino acids from the *ends* of chains. These are usually called peptidases and are designated **aminopeptidases** if they cleave from the N terminus and **carboxypeptidases** if they cleave from the C terminus. Most of these enzymes can be classified into **serine** proteases, **cysteine** proteases, **aspartic** proteases, **metallo** proteases, or **N-terminal nucleophile** hydrolases, depending upon the chemical nature of the active site. These groups are further divided into families or "clans."[190]

1. The Serine Proteases

The digestive enzymes **trypsin**, **chymotrypsin**, **elastase**, and **proteinase E** are related serine proteases. All three are synthesized in the pancreas which secretes 5–10 g per day of proteins, mostly the inactive proenzymes (zymogens) of digestive enzymes.[191,192] These proenzymes are synthesized and "packaged" as **zymogen granules** which travel to the surfaces of the secretory cells. The contents of the granules are secreted into the extracellular medium and are discharged via the pancreatic duct into the small intestine. At their sites of action, the zymogens are converted into active enzymes by the cutting out of one or more pieces from the precursor. This occurs in a cascade-type process triggered by **enteropeptidase** (historically enterokinase), another serine protease which is secreted by the intestinal lining.[192a] Human enteropeptidase consists of a 235-residue catalytic subunit bonded through a disulfide bridge to a larger 784-residue membrane-anchoring subunit.[193–195] It attacks specifically **trypsinogen**, converting it to active trypsin.[196,197] Trypsin in turn activates the other zymogens, as is indicated in Fig. 12-8. Trypsin can also activate its own zymogen, trypsinogen, in an autocatalytic process.

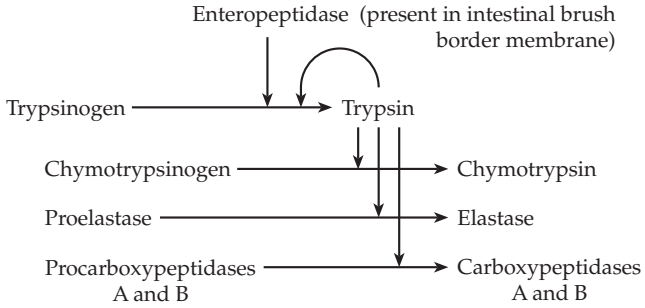


Figure 12-8 Cascade of reactions that activate pancreatic proteases. Enteropeptidase, or trypsin, cleaves the proenzyme (zymogen) at specific sites.

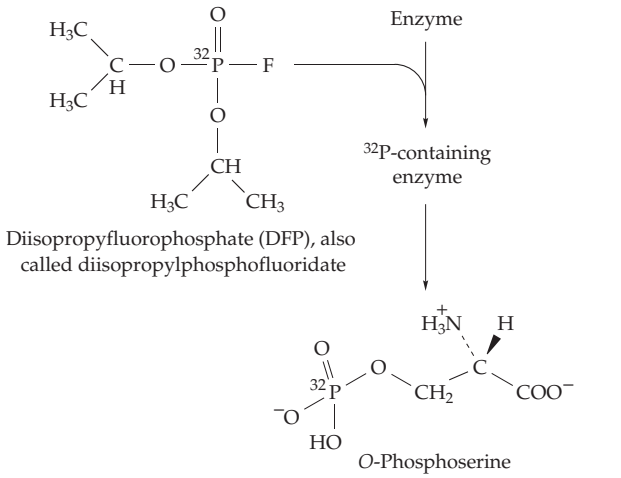
Chymotrypsinogen consists of a single 245-residue chain. The amino acid residues in chymotrypsin, trypsin, and elastase are usually all numbered according to their position in this zymogen. Inactive proenzymes are formed as precursors to enzymes of many different classes and are activated in a variety of ways. A part of the polypeptide chain of the proenzymes is often folded over the active site, interacting in a nonsubstrate-like fashion and blocking the site.[197a]

Serine as a nucleophile. An early clue to the mechanism of action of chymotrypsin came from investigation of the related **acetylcholinesterase**. This key enzyme of the nervous system is inactivated irreversibly by powerful phosphorus-containing poisons that had been developed as insecticides and as war gases (nerve gases, Box 12-C). Around 1949, the nerve gas diisopropylfluorophosphate (DFP) was shown also to inactivate chymotrypsin. When radioactive ^{32}P-containing DFP was allowed to react the ^{32}P became

covalently attached to the enzyme. When the labeled enzyme was denatured and subjected to acid hydrolysis the phosphorus stuck tightly; the radioactive fragment was identified as *O*-phosphoserine. It was evident that this product could be formed by an attack of the hydroxyl group of the serine side chain on the phosphorus with displacment of the fluoride ion. This is a nucleophilic displacement on phosphorus, occurring on an enzyme that normally catalyzes displacement on C=O. The DFP molecule acts as a pseudosubstrate which reacts with the enzyme in a manner analogous to that of a true substrate but which does not complete the reaction sequence normally.



(12-19)

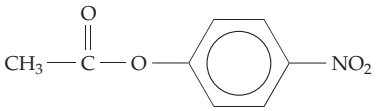
From study of peptides formed by partial hydrolysis of the ^{32}P-labeled chymotrypsin, the sequence of amino acids surrounding the reactive serine was established and serine 195 was identified as the residue whose side chain hydroxyl group became phosphorylated. The same sequence Gly-Asp-Ser-Gly was soon discovered around reactive serine residues in trypsin, thrombin, elastase, and in the trypsin-like **cocoonase** used by silkmoths to escape from their cocoons.[198] We know now that these are only a few of the enzymes in a very large family of serine proteases, most of which have related active site sequences.[199,200] Among these are **thrombin** and other enzymes of the blood-clotting cascade (Fig. 12-17), proteases of lysosomes, and secreted proteases.

Numerous serine proteases, including trypsin-like enzymes called **tryptases**[201–204a] and chymotrypsin-like chymases,[205–207] are found within tissues in which they are stored in granules of mast cells,[208] neutrophils, lymphocytes, and cytotoxic T cells.[205] Secretory granules of mast cells present in skin and other tissues contain high concentrations of tryptase and chymase precursors[202,206] which may be released as part of an inflammatory response. Tryptase may be involved in asthma and other allergic resposes.[201] **Cathepsin G**[209] (proteinase II), **neutrophil elastase**, and **proteinase III**[210] are found in granules of neutrophils and monocytes as well as in mast cells.[209] Cytoplasmic granules of cytotoxic T cells contain at least seven proteases called **granzymes** that can be released to attack target cells.[211–213a]

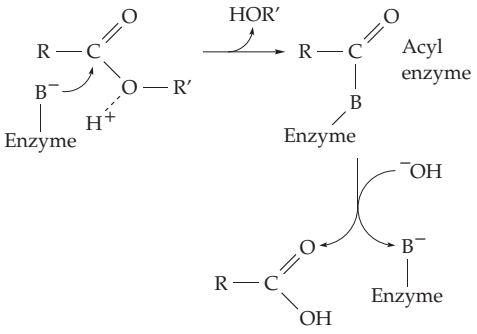
Many secreted proteins, as well as smaller peptide hormones, are acted upon in the endoplasmic reticulum by tryptases and other serine proteases. They often cut between pairs of basic residues such as KK, KR, or RR.[214–216] A substilisin-like protease cleaves adjacent to methionine.[217] Other classes of proteases (e.g., zinc-dependent carboxypeptidases) also participate in this processing. **Serine carboxypeptidases** are involved in processing human prohormones.[218] Among the serine carboxypeptidases of known structure is one from wheat[219] and **carboxypeptidase Y**, a vacuolar enzyme from yeast.[220] Like the pancreatic metallocarboxypeptidases discussed in Section 4, these enzymes remove one amino acid at a time, a property that has made carboxypeptidases valuable reagents for determination of amino acid sequences. Carboxypeptidases may also be used for modification of proteins by removal of one or a few amino acids from the ends.

The variety of bacterial serine proteases known include the 198-residue **α-lytic protease** of *Myxobacter*,[221] a family of at least 80 **subtilisins** which are produced by various species of *Bacillus*[222–225a] as well as by many other organisms,[226] and a trypsinlike enzyme from *Streptomyces griseus*.[227,228] **Tripeptidyl peptidases**, subtilisin-like enzymes, cut tripeptides from the N-termini of proteins.[228a,b,c] One participates in lysosomal protein degradation and the other, an oligomer of 138 kDa subunits, cuts precursor proteins to form neuropeptides and other hormones (Chapter 30).

Acyl-enzyme intermediates. Serine proteases are probably the most studied of any group of enzymes.[229] Early work was focused on the digestive enzymes. The pseudosubstrate, *p*-nitrophenyl acetate, reacts with chymotrypsin at pH 4 (far below the optimum pH for hydrolysis) with rapid release of *p*-nitrophenol and formation of acetyl derivative of the enzyme.



This acetyl enzyme hydrolyzes very slowly at pH 4 but rapidly at higher pH. These experiments suggested a double displacement mechanism:



(12-20)

Although the experiments with DFP suggested that the $-O^-$ group from Ser 195 might be the base $-B^-$ in this equation, there was reluctance to accept this deduction because of the very weak acidity of the $-CH_2OH$ group. Furthermore, the pH dependence of catalysis suggested an imidazole group of a histidine side chain as the attacking nucleophile B. Indeed, imidazoles catalyze the nonenzymatic hydrolysis of *p*-nitrophenyl acetate with formation of unstable *N*-acetyl imidazoles as intermediates. Thus, while the stable end products of reactions with pseudosubstrates were unquestionably derivatives of serine, the possibility remained that these were side products and that histidine was involved in transient, rapidly forming, and reacting intermediates. It remained for the results of the then newly developed science of X-ray crystallography to clarify this question.[230]

Three-dimensional structures. The structures of chymotrypsin,[199,230,231] trypsin,[232,233] elastase,[234,235] thrombin,[236] kallikrein,[237,238] and many other enzymes are similar, with the basic fold shown in Fig. 12-9.[199,228] Both Ser 195 and His 57 (or corresponding residues) are present in the active site (Figs. 12-9, 12-10). From the observed positions of competitive inhibitors occupying the active site, the modes of binding depicted in Fig. 12-10A for the chymotrypsin family and in Fig. 12-10B for the subtilisin family have been deduced. Bear in mind that the X-ray diffraction results do not

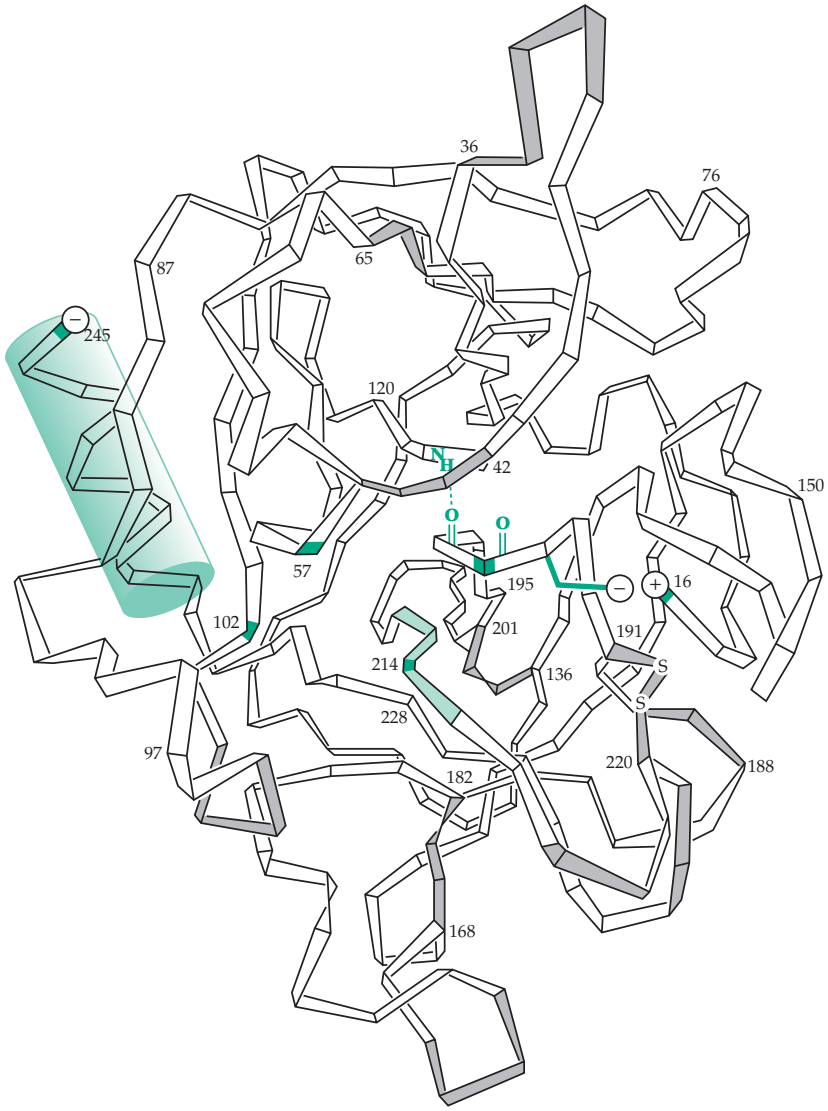


Figure 12-9 Alpha-carbon diagram of the three-dimensional structure of pancreatic elastase. A principal structural feature is a pair of β cylinders. One of these, at the top of the figure, is viewed end-on, while the other, at the bottom of the figure, is viewed from a side. The prominent interface between them is seen in the center. The α-carbon positions of the catalytic triad serine 195, histidine 57, and aspartate 102 are marked. As shown in Fig. 12-10 the catalytic triad is located across the interface between β cylinders, which may allow for easier conformational alterations during the action of the enzyme. The four disulfide bridges and the long C-terminal helix are also emphasized. The cross-hatched loop regions are residues present in elastase but not present in chymotrypsin. The green shaded strand (residues 214–216) is a segment that joins residues P_1 and P_2 of the substrate to the edge of the lower β cylinder in an extended β structure. The ion pair formed by aspartate 194 and isoleucine 16 during zymogen activation is also shown, as are two peptide carbonyl groups that protrude into the interface area, one forming a hydrogen bond across the interface. Modified from a drawing of Sawyer *et al.*[234] which was in turn based on the original chymotrypsin drawing of Annette Snazle.[230]

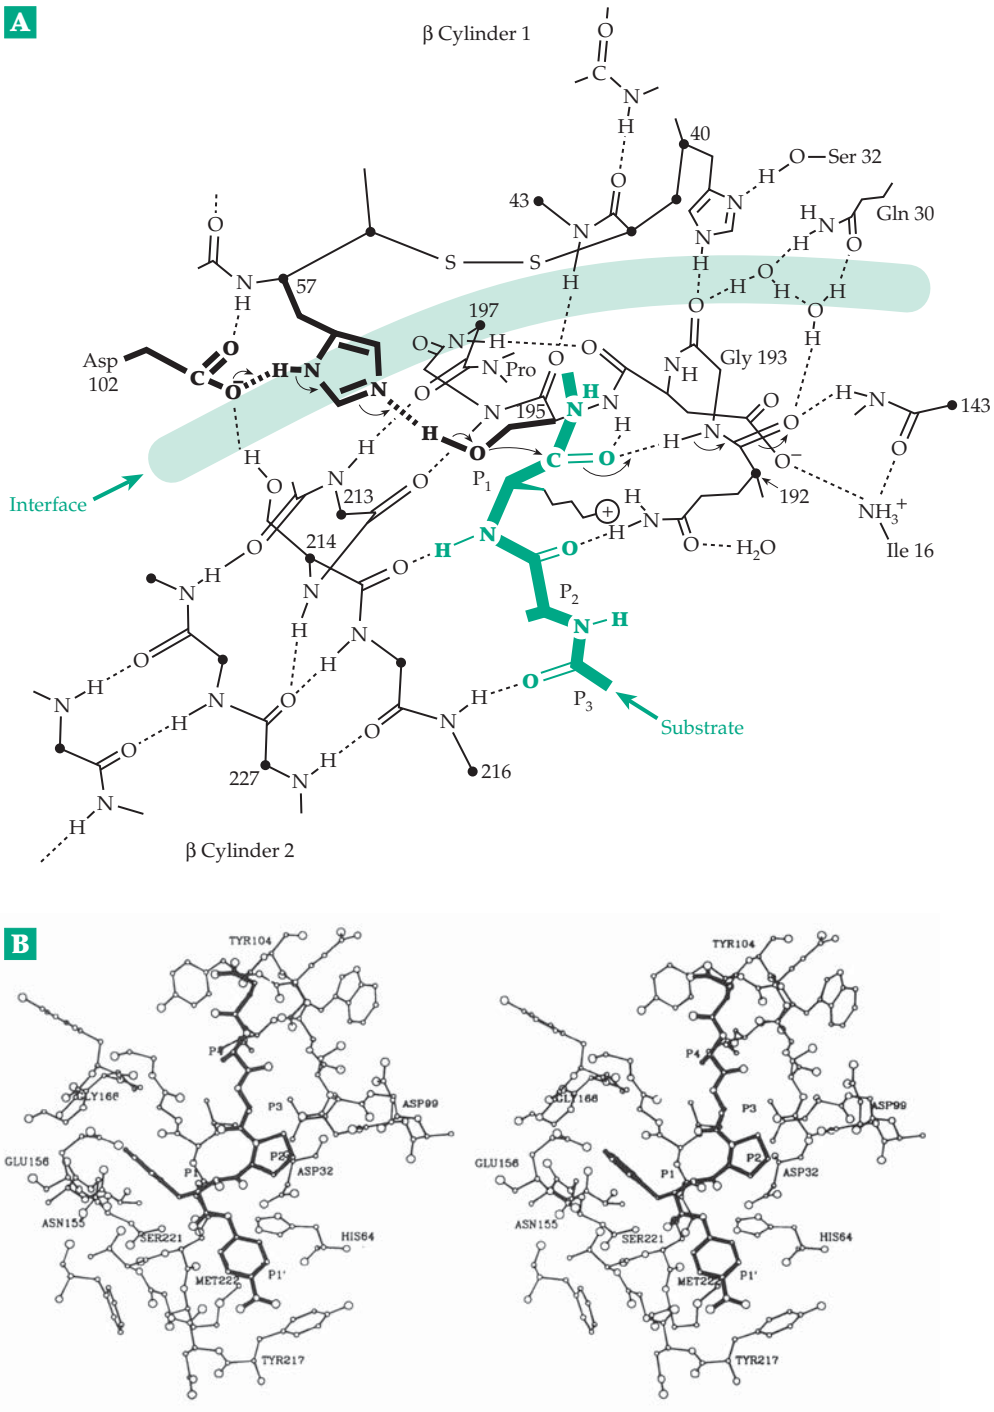

Figure 12-10 (A) Part of the hydrogen-bonding network of trypsin and other serine proteases with a bound trypsin substrate (green). Residues P_1 to P_3, as defined in Fig. 12-14, have been marked. The view is similar to that in Fig. 12-9 but some background lines have been omitted. Note the two competing hydrogen-bonded chains passing through C=O of residue 227 in β cylinder 2. One of these chains passes through the backbone of the substrate and the other through residues 214 and 195 across the interface between domains into β cylinder 2. Asp 102, His 57, and Ser 195 of the catalytic triad are emphasized. Arrows indicate probable movement of electrons from the negative charge of Asp 102 into the "oxyanion hole." After Metzler.[85] Based on papers of Sawyer *et al.*[234] and Huber and Bode.[240] (B) Stereoscopic view showing the model substrate *N*-succinyl-L-Ala-L-Ala-L-Pro-L-Phe-*p*-nitroanilide bound into the active site of subtilisin BPN′. Residues of the catalytic triad (Ser 221, His 64, Asp 32) and some others are labeled. Subsites P_1', P_1, P_2, P_3, and P_4 (see Fig. 12-14) are also labeled. Notice that site P_3, which is near the top in this drawing, is at the bottom in (A). Based on X-ray data of R. Bott and M. Ultsch at 0.2 nm resolution. From Wells and Estell.[223]

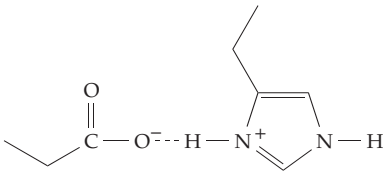
show where the hydrogen atoms are and that these have been added in Fig. 12-10. The imidazole group of His 57 is located next to the side chain –OH group of Ser 195 and is able to form an N---H–O hydrogen bond to it. The obvious conclusion is that His 57 acts as a general base catalyst that assists in removing the proton from the –OH of Ser 195, making that hydroxyl group more nucleophilic than it would be otherwise. This may happen after the –OH group has started to add to the substrate carbonyl.

The second nitrogen atom of His 57 is hydrogen bonded to the carboxylate group of Asp 102, which is in turn hydrogen bonded to two other groups. Aspartate 102 has one of the few carboxylate side chains that is buried inside the protein. To Blow,[230,231,239] the structure suggested a **charge-relay system** by which negative charges might move synchronously from Asp 102 to the imidazole which could then deprotonate the hydroxyl group of Ser 195, allowing the serine oxygen to add to the substrate carbonyl to form the tetrahedral

or **oxyanion** intermediate, which is depicted in step *b* of Fig. 12-11. The small arrows in Fig. 12-10 also indicate the movement of charge. Blow suggested that in the extreme case a *proton* might be transferred also from the His 57 imidazole to the Asp 102 carboxylate. However, a variety of experiments, including studies by ^{15}N NMR[241,242] and by neutron diffraction,[243] suggest that the imidazole does not transfer its proton to the carboxylate of Asp 102,[244,245] unless it does so transiently, e.g., in a transition state complex. Instead, the carboxylate and the imidazolium ions formed by protonation of His 57 probably exist as a tight ion pair:



Support for this concept is provided by ^1H NMR studies which have identified a downfield resonance of the hydrogen-bonded proton in this pair at ~18 ppm in chymotrypsinogen and chymotrypsin at low pH and at ~14.9–15.5 ppm at high pH values.[246,247] Similar resonances are seen in the α-lytic protease,[248] in subtilisin,[249] in adducts of serine proteases with boronic acids[250,251] or peptidyl trifluoromethyl ketones,[252] in alkylated derivative of the active site histidine,[253] and in molecular complexes that mimic the Asp-His pair in the active sites of serine proteases.[254]

The catalytic cycle. Figure 12-11 depicts the generally accepted sequence of reactions for a serine protease. If we consider both the formation and the subsequent hydrolysis of the acyl-enzyme intermediate with appropriate oxyanion intermediates, there are at least seven distinct steps. As indicated in this figure, His 57 not only accepts a proton from the hydroxyl

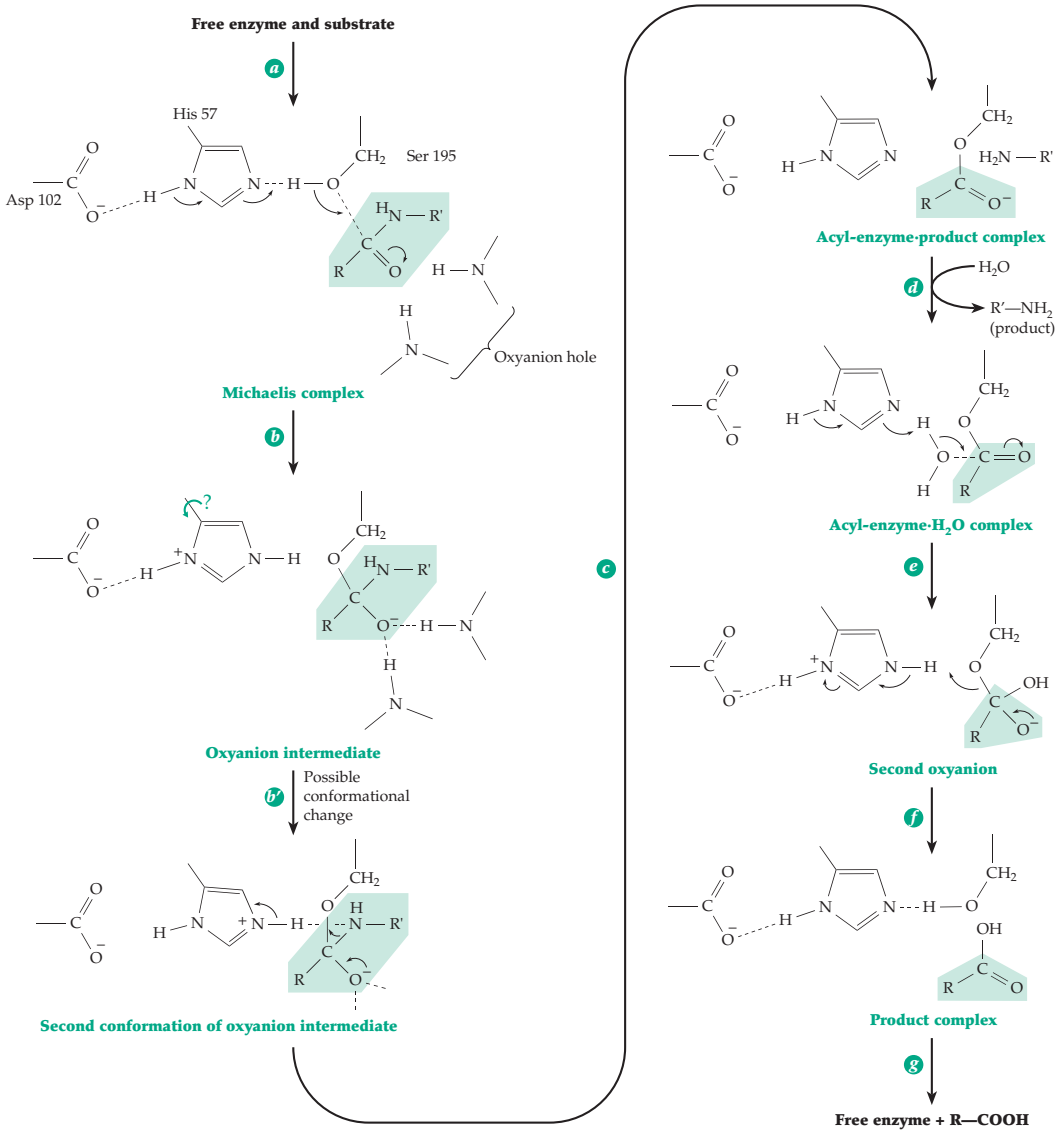


Figure 12-11 Sequence of chemical reactions involved in the action of a serine protease. The oxyanion hole structure has been omitted in the right-hand column. The imidazole ring may rotate, as indicated by the green arrow, to provide two different conformations.

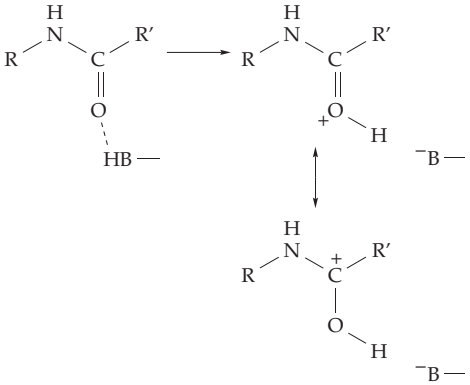
group of Ser 195 (step *b*) but probably also functions in protonation of the –NH–R′ leaving group (step *c*). An unprotonated –NH–R′ would be such a poor leaving group that the oxyanion intermediate would not go on to acyl-enzyme. However, donation of a proton to that leaving group from the protonated His 57 (general acid catalysis) permits elimination of H_2N–R′ (step *c*). The product of this step is the acyl-enzyme intermediate which must be hydrolyzed to complete the catalytic cycle. This is accomplished through steps *d*–*f* of Fig. 12-11. The product R′–NH_2 is replaced by H_2O, which, in steps paralleling steps *b* and *c*, is converted to an HO^- ion that serves as the attacking nucleophile to form (in step *e*) a second oxyanion intermediate which is cleaved to the second product R–COOH. The water molecule that enters in step *d*, and which participates in hydrolysis of the acyl enzyme, has apparently been observed directly by time-resolved Laue crystallography at low temperature.[255]

The catalytic triad. The significance of the charge-relay effect may not be fully understood but the importance of the Ser•His•Asp cluster, which has become known as the catalytic triad, cannot be doubted. It has evolved independently in several subfamilies of bacterial and plant proteases, a well-known example of "convergent evolution." This triad is also found throughout a broad range of many different kinds of enzymes and other proteins. In pancreatic enzymes the catalytic triad consists of Ser 195•His 57•Asp 102 but in the bacterial subtilisin it consists of Ser 221•His 64•Asp 32 and in a wheat serine carboxypeptidase it is Ser 146•His 397•Asp 338.[219] In all three cases the folding patterns of the polypeptides are entirely different but the geometry of the triad is the same. Another folding pattern is seen in a protease encoded by cytomegalovirus, which contains an active site Ser 132•His 63 pair.[256,257]

Investigation of a host of mutant proteins also demonstrates the importance of the catalytic triad. For example, if either the histidine or the serine of the triad of subtilisin was replaced by alanine the catalytic activity decreased by a factor of 2 x 10^6 and replacement of the aspartate of the triad by alanine decreased activity by a factor of 3 x 10^4.[229,258] When Asp 102 of trypsin is replaced by asparagine the catalytic activity falls by four orders of magnitude.[259] This may be in part because the histidine in this mutant is hydrogen bonded to Asn 102 as the tautomer with a proton on N^ε, the nitrogen that should serve as the catalytic base in step *b* (Fig. 12-11).[260] A mutant in which Ser 214 (see Fig. 12-10) was replaced with alanine is fully active but charged residues in this position interfere with catalysis.[261]

Does the "low-barrier hydrogen bond" in the catalytic triad play any special role in catalysis? Blow's suggestion of a charge relay from Asp 102 to Ser 195 of chymotrypsin is probably correct. Some theoretical calculations have indicated the possibility of synchronous movement of the two protons in the system during step *a* of the sequence shown in Fig. 12-11, with the proton in the strong hydrogen bond to Asp 102 moving away from His 57 and toward the midpoint distance of the hydrogen bond. Could the presumed high energy of the short hydrogen bond be harnessed to lower the transition state energy? A realistic possibility is that the hydrogen bond increases the polarizability of the catalytic triad, facilitating movement of the substrate to the transition state. Cassidy *et al.* suggested that the strong hydrogen bond may be formed by compression of the triad resulting from binding of substrate in the S_1 and S_2 subsites.[252] They suggested that this would raise the pK_a of His 57 from ~7 in the free enzyme to 10–12, high enough to enable it to remove the proton from the Ser 195 –OH group and low enough to allow the protonated form to be the proton donor to the leaving group (step *c*, Fig. 12-11).

The "oxyanion hole." A third mechanism by which an enzyme can assist in a displacement reaction on a carbonyl group is through protonation of the carbonyl oxygen atom by an acidic group of the enzyme (Eq. 12-21). This will greatly increase the positive charge on the carbon atom making attack by a nucleophile easier and will also stabilize the tetrahedral



(12-21)

intermediate. Although the carbonyl oxygen is very weakly basic, it can interact with a suitably oriented acidic group of the enzyme. In many serine proteases this acidic function is apparently fulfilled by NH groups of two amide linkages. In chymotrypsin these are the backbone NH groups of Ser 195 and Gly 193 (Figs. 12-10,12-12). No actual transfer of a proton to the carbonyl oxygen of the substrate is expected. However, the NH groups are positive ends of amide dipoles and can interact electrostatically with the negative charge that develops on the oxyanion. The fit of substrate into the **oxyanion hole** between the two

NH groups is apparently good only for the tetrahedrally bonded oxyanion intermediate,[262] a structure thought to be close to that of the transition state. The importance of the oxyanion hole for catalysis has been supported by theoretical calculations[245] and by the study of mutant enzymes.[263] In subtilisin, in which a side chain of asparagine forms part of the oxyanion hole, replacement of Asn with the isosteric Leu causes k_{cat} to fall by a factor of about 200 while K_m is unaffected.[264] It is also of interest that thiono ester substrates, in which the C=O of an oxygen ester has been replaced by C=S, bind with normal affinity to chymotrypsin but are not hydrolyzed at significant rates.[265]

The formation of the oxyanion intermediate during serine protease action is also supported by the existence of tetrahedral forms of enzymes inhibited by substrate-like aldehydes. The –OH group of Ser 195 can add to the carbonyl group to form hemiacetals. For example, a ^{13}C-enriched aldehyde whose carbonyl carbon had a chemical shift of 204 ppm gave a 94 ppm resonance as it formed the tetrahedral hemiacetal with one of the inhibitory aldehydes, *N*-acetyl-L-Leu-L-Leu-L-arginal (**leupeptin**; Box 12-C). A natural product from a species of *Streptomyces*, this aldehyde inhibits trypsin and several other enzymes strongly.[266] Adducts of wheat serine carboxypeptidases with aldehyde inhibitors have also been observed.[267] While the carbonyl group of the substrate amide linkage that is to be cleaved apparently can't form strong hydrogen bonds to the NH groups of the oxyanion hole, that of the acyl-enzyme intermediate can, as judged by resonance Raman spectroscopy.[268,269] The strength of the hydrogen bonding, as judged by the stretching frequency of the C=O group, is correlated with the reactivity of the acyl group.[269]

Chymotrypsinogen and related proenzymes have extremely low catalytic activity even though a major part of the substrate binding site as well as the catalytic triad system are already in place. However, the oxyanion hole is created during activation of the proenzyme by a subtle conformational change[197,262,271] that involves the chain segment containing Gly 193 (Fig. 12-12). This is further evidence of the importance of this part of the active site structure.

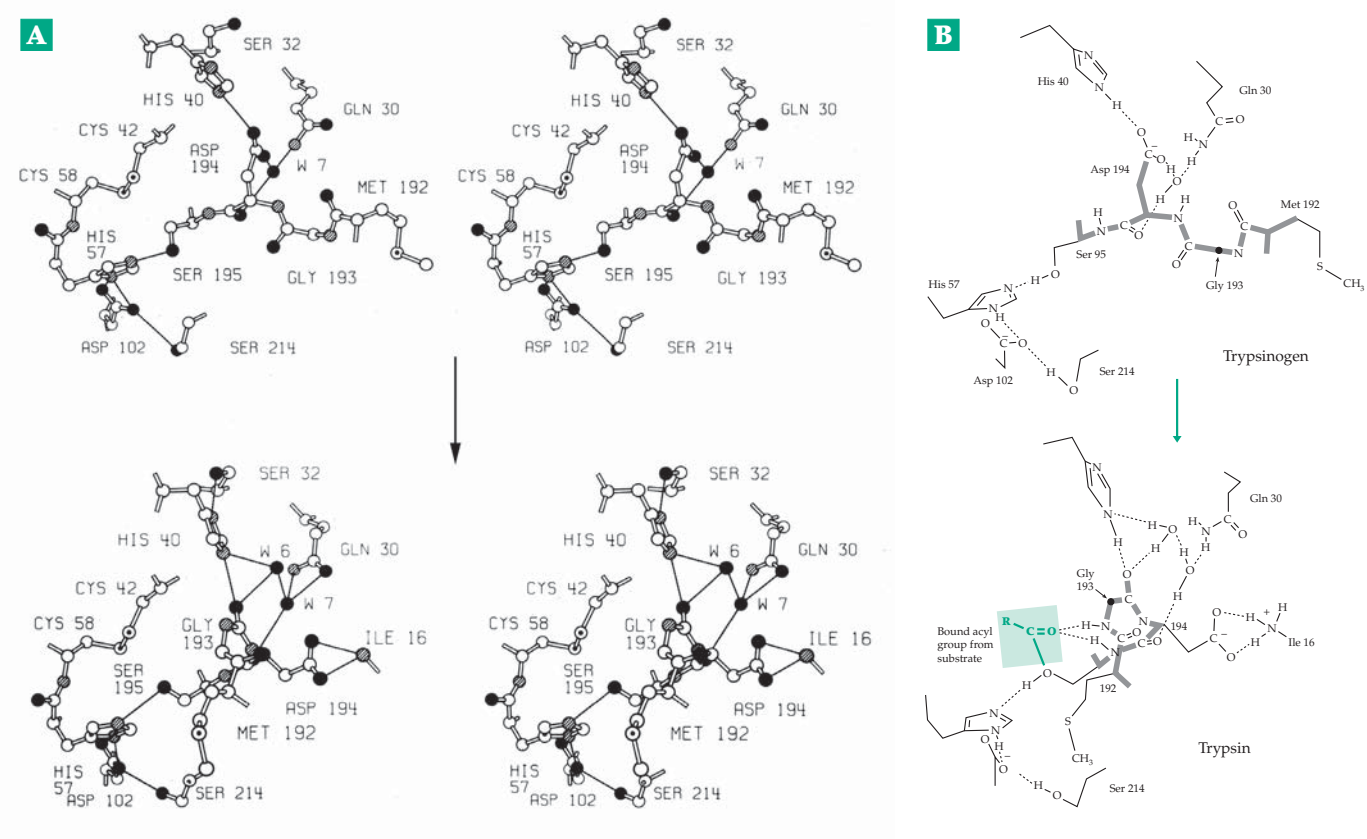


Figure 12-12 Formation of the oxyanion hole following cleavage of trypsinogen between Lys 15 and Ile 16. (A) Stereoscopic view. (B) Schematic representation. The newly created terminal $-NH_3^+$ of Ile 16 forms a hydrogen-bonded ion pair with the carboxylate of Asp 194. This breaks the hydrogen bond between Asp 194 and His 40 in trypsinogen, inducing the peptide segment 192–194 to shift from an extended conformation to a helical form in which the NH groups of Gly 193 and Ser 195 form the oxyanion hole. Notice that the positions and interactions of Asp 102, His 57, and Ser 195, the catalytic triad, are very little changed. From Birktoft *et al.*[270]

Stereoelectronic considerations. The amide group that is cleaved by a protease is a resonance hybrid of structures A and B of Fig. 12-13. The unshared pair of electrons on the nitrogen atom of structure A and the third unshared pair on the oxygen atoms of structure B (shaded orbitals) have been drawn in this figure in such a way that they are anti-periplanar to the entering serine oxygen. This is required in the transition state according to stereoelectronic theory. The newly created (shaded) electron pair on oxygen is one of those that hydrogen bonds to an NH group of the oxyanion hole. The tetrahedral intermediate has another unshared pair, which is not hydrogen bonded, and is antiperiplanar to the HN-R leaving group. Thus, it appears to be set up for easy elimination. Nevertheless, there is some doubt about the need for adherence to the stereoelectronic "rule" that two antiperiplanar lone pairs are necessary for elimination.

There is another complication. The leaving group –NH–R′ cannot be eliminated from the oxyanion until it is protonated, presumably by the imidazolium group of His 57. However, the proton on His 57 will be adjacent to the proton that is already on this nitrogen rather than to the unshared pair of electrons on the same nitrogen atom. A conformational change in which the tilt of the catalytic imidazole ring is altered (step *b′*, Fig. 12-11) or in which the ring rotates, may have to precede the protonation of the leaving group (step *c*, Fig. 12-11).[272–274b] This change may be assisted by the presence of positive charge on the protonated imidazole, but it still does not solve the problem. Bizzozero and Butler suggested that a rapid inversion of this chiral center on the –NH–R′ group may be required prior to protonation and elimination.[273] This would explain their observation that *N*-alkylated peptide linkages of otherwise fast substrates are not cleaved by chymotrypsin. A high-resolution structure determination demonstrated that a very slow elastase substrate that contains *N*-methylleucine at the cleavage site forms a normal ES complex.[275] However, inversion would be hindered by the *N*-methyl group. An alternative in inversion would be a torsional rearrangement of the substrate during binding.[276] The structure of an acyl-enzyme intermediate with elastase has been determined by crystallographic cryoenzymology. The intermediate was allowed to accumulate at –26°C, after which the temperature was lowered to –50°C and the structure determined. The structure shows the carbonyl group in the oxyanion hole as anticipated.[277]

pH dependence. A plot of k_{cat}/K_m for chymotrypsin is bell shaped with a maximum around pH 7.8 and pK_a values of 6.8 and 8.8. These represent pK_as of the free enzyme (Eq. 9-57). That of 6.8 has been shown to represent His 57. As the pH is lowered from the optimum the affinity for substrate falls off as His 57 becomes protonated. The high pK_a of 8.8 is thought to belong to the N-terminal amino group of Ile 16, a group that is generated during the conversion of the proenzyme to active enzyme.[278] The Ile 16 amino group forms an ion pair with Asp 194 (Fig. 12-12B) which is next to the serine at the active center. This salt linkage helps to hold the enzyme in the required conformation for reaction and its deprotonation at high pH causes a decrease in substrate affinity.[279]

The value of k_{cat} is also pH dependent and falls off at low pH around a pK_a value of from 6–7 depending upon the substrate. However, no higher pK_a affects k_{cat} in the experimentally accessible range. These results provide the basis for believing that an unprotonated His 57 is needed in the ES complex for catalysis to occur. Similar conclusions have been reached for other serine proteases.

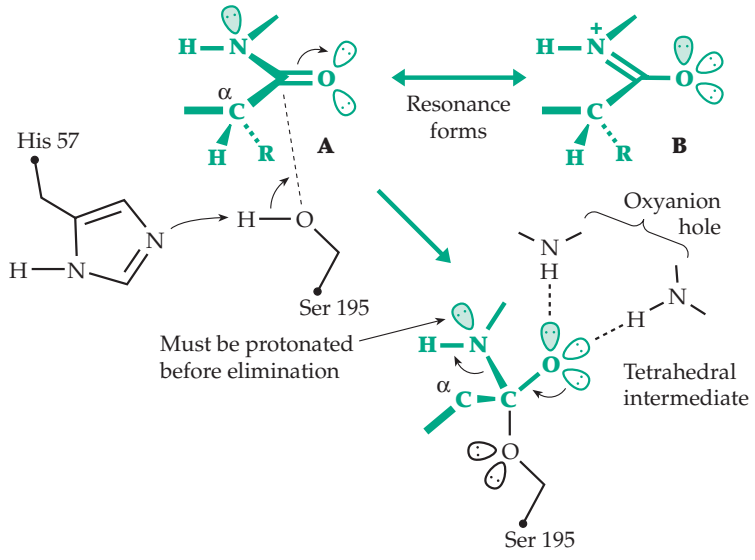

Figure 12-13 The stereochemistry of formation of a tetrahedral intermediate by a serine protease. The most probable orientation of groups as deduced by model building is shown. The shaded orbitals in A and B are antiperiplanar to the entering oxygen of Ser 195. See Polgár and Halász.[272]

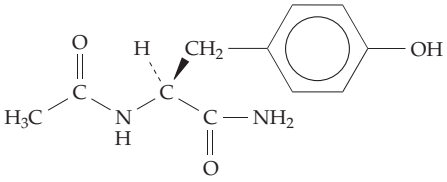
Substrate specificity. Like most other enzymes, proteases display distinct preferences for certain substrates. These are often discussed using the nomenclature of Fig. 12-14. The substrate residue contributing the carbonyl of the amide group to be cleaved is designated P_1 and residues toward the N terminus as P_2, P_3, etc., as is shown in Fig. 12-14. Residues toward the C terminus from the peptide linkage to be cleaved are designated P_1', P_2', etc. Chymotrypsin acts

most rapidly if the P_1 residue is one of the aromatic amino acids.[280] Thus, the S_1 part of the substrate binding site must bind preferentially to large, flat aromatic rings. The crystal structure of chymotrypsin showed this site to be composed of nonpolar side chain groups. On the other hand, in trypsin the specificity portion of the S_1 site is a deep "specificity pocket" containing a fixed negative charge provided by the carboxylate side chain group of Asp 189. This explains why trypsin acts only upon peptide linkages containing the positively charged arginine or lysine residues in the P_1 position. In elastase the specificity pocket is partly filled by nonpolar side chains and the enzyme can accommodate only small P_1 side chains such as the methyl group of alanine. Replacement of Asp 189 of trypsin by lysine led to the predicted loss of specificity for basic side chains. However, the mutant enzyme did not become specific for negatively charged side chains.[281] This is presumably because the lysine $-NH_3^+$ group was not located in the same position as the Asp 189 carboxylate as a result of a different packing of side chains between native and mutant enzymes. Residues P_1' and P_2' also have major effects on substrate binding by serine proteases.[282–284] Now many mutant forms of subtilisin[225,285] and other serine proteases are being made and are yielding a more sophisticated understanding of the basis of the specificity of these enzymes. An important factor that has emerged is flexibility of surface loops in allowing an enzyme to adjust its structure to give a better fit to some substrates.[286,287] The specificity of the serine proteases is also being exploited in the design of specific inhibitors (Box 12-D).

Many serine proteases react with *p*-nitrophenylacetate to give acetyl enzymes. However, its rate of hydrolysis to give acetate is orders of magnitude slower than that of acyl-enzymes derived from small substrates such as the chymotrypsin substrate *N*-acetyltyrosine amide.



N-Acetyltyrosine amide

In addition to the specificity-determining P_1 aromatic side chain, the amide groups of this substrate can form specific hydrogen bonds to the protein (Fig. 12-10). These hydrogen bonds presumably help the enzyme to recognize the compound, which is bound with K_m of ~0.03 M and is hydrolyzed (with liberation of NH_3)[288,289] with k_{cat} ~0.17 s^{-1}.

What happens when the length of the substrate is extended in the direction of the N terminus? The tyrosyl residue in the foregoing compound may be designated P_1. For extended substrates which contain P_2, P_3, and additional residues (this includes most natural substrates) the K_m values decrease very little from that of short substrates despite the larger number of "subsites" to which the substrate is bound. However, the maximum velocity is often much greater for the extended substrates than for short ones. Thus, for *N*-acetyltyrosyl-glycine amide K_m is 0.017 M, only a little less than for *N*-acetyltyrosine amide, but k_{cat} is 7.5 s^{-1}, 440 times greater than for the shorter substrate.[229,288,289] Other examples have been tabulated by Fersht.[279]

These observations suggest that *the binding energy that would be expected to increase the tightness of binding is, instead, causing an increase in* V_{max}[279,290] that is, it is reducing the Gibbs energy of activation. How can this be? Imagine that as the extended substrate binds, for example, into the subsite S_2 (which binds residue P_2), it must compress a spring in the enzyme. Could not the compressed spring now provide a source of energy for assisting in peptide bond cleavage? If this is the case, we must ask "what are the springs?" Are there amide linkages of the peptide backbone that are distorted when the substrate hydrogen bonds into the site? How is the distortion transmitted to the active site and how does it stabilize the transition

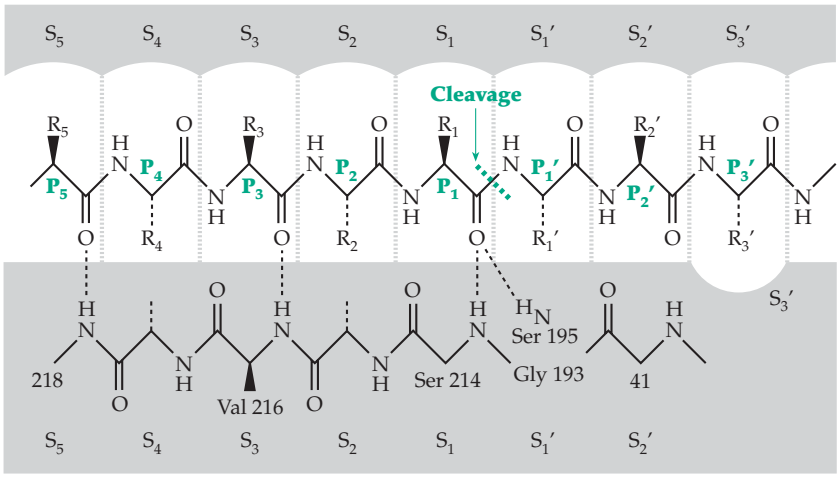


Figure 12-14 Standard nomenclature used to define the residues P_1, P_2 . . . toward the N terminus and P_1', P_2' . . . toward the C terminus of a peptide substrate for a protease. The corresponding subsites of the protease are designated S_1, S_2 . . . S_1', S_2'.

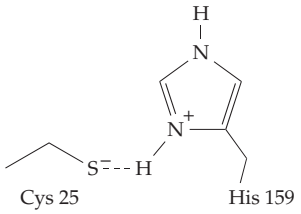
state? We are far from understanding the answers to these questions. However, it is of interest that one chain of H-bonds that passes through the amide between P_1 and P_2 also passes through a carbonyl group of a β bulge (Fig. 12-10). A second chain of H-bonds that connects to the same β bulge passes through the backbone amide of the active site Ser 195, across the interface between the two domains, and through the backbone of the second β cylinder.[85] Perhaps when substrate binds, the strengthening of the first H-bond chain weakens the second through competition at the β bulge, allowing some subtle rearrangement in the active site structure. We are talking here about the P_1–P_2 amide. What happens at P_2–P_3, and further along the chain in both directions? It is important to understand these effects; the phenomenon of increased reaction rate for longer, more specific substrates is observed with many proteases and other enzymes as well.

Another difference between small substrates and longer, more specific substrates has been found in studies of the effects of changing the solvent from pure H_2O to mixtures containing an increasing mole fraction of ^2H_2O. This is called a **proton inventory**.[291] For the serine proteases the rates are decreased as the ^2H content of the solvent increases, a fact that suggests that some step involving a proton transfer, for example, the deprotonation of Ser 195, is rate limiting. For simple substrates, the effect is directly proportional to the mole fraction of ^2H. However, for extended substrates, a quadratic dependence on the mole fraction of ^2H is observed. This suggests that a process involving synchronous transfer of two protons, as in the postulated charge relay system, may be more important in extended substrates than in simple ones and may account for the more rapid action on these substrates.[290,292] However, other interpretations of the data are possible, leaving this conclusion uncertain.[229,291]

2. The Cysteine Proteases (Thiol Proteases)

Papain from the papaya is one of a family of enzymes that includes **bromelain** of the pineapple, **ficin** of the fig, and **actinidin** of the kiwifruit.[293] Additional cysteine proteases[294] from the latex of the papaya tree *Carica papaya* are known as **caricain**, **chymopapain**,[294] and **glycyl endopeptidase**.[295] All are members of a large superfamily which includes at least 12 mammalian enzymes and many others from both eukaryotic and prokaryotic organisms.[296] All share with papain a characteristic structure which was determined by Drenth and coworkers in 1968.[297] The participating nucleophile in the active sites of these enzymes is an SH group, that of Cys 25 in papain. An adjacent imidazole from His 159 removes the proton from the SH group to form a thiolate-imidazolium pair.[298–300]



The close proximity of the imidazolium group greatly lowers the microscopic pK_a of the Cys 25 thiol group and the proximity of the resulting hydrogen-bonded S^- group greatly raises the microscopic pK_a of the imidazolium group.

Studies of the pH dependence of V_{max}/k_{cat} (Eq. 9-57) reveal a bell-shaped dependence on pH with pK_a values[301,302] of ~4 and ~9. However, the ion pair is formed at a pH below four with apparent pK_a values of 2.5, 2.9, and 3.3 for ficin, caricain, and papain, respectively.[302] These low values can be assigned principally to Cys 25 with only very small contributions from His 159 (see Eq. 6-75). A third pK_a, perhaps of a nearby carboxylate from Glu 50, affects the rate. For caricain the nearby Asp 158 (Fig. 12-15) has been implicated.[303,304]

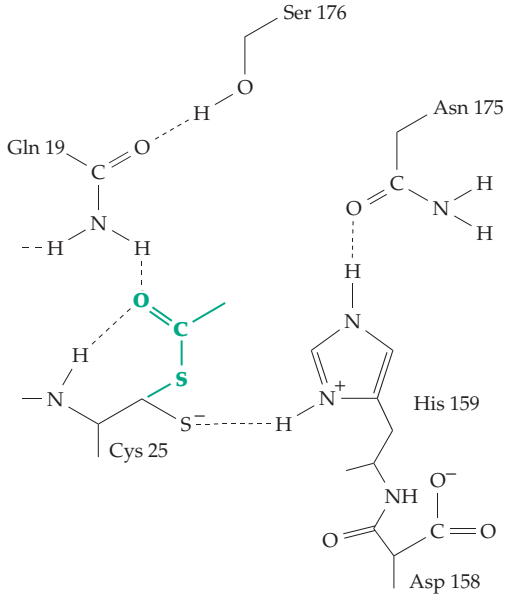


Figure 12-15 Schematic drawing of the active site of a cysteine protease of the papain family with a partial structure of an acyl-enzyme intermediate in green. The thiolate-imidazolium pair of Cys 25•His 159 lies deep in the substrate-binding cleft and bridges an interface between two major structural domains, just as the Ser•His pair does in serine proteases (Fig. 12-10). This may facilitate small conformational changes during the catalytic cycle. Asn 175 provides a polarizable acceptor for positive charge, helping to stabilize the preformed ion pair, and allows easy transfer of an imidazolium proton to the product of substrate cleavage. The peptide NH of Cys 25 and the side chain of Gln 19 form an oxyanion hole.

As shown in Fig. 12-15, the side chain of Asn 175 provides papain with a third member of a catalytic triad analogous to that of serine proteases.[305] Glutamine 19, together with the peptide backbone NH of Cys 25, provides an oxyanion hole.[306–308] Many studies, including structure determinations on bound aldehyde and other inhibitors, and observation by ^{13}C NMR[309] indicate that thiol proteases act by addition of the thiolate anion to the peptide carbonyl of the P_1 residue, just as in step *b* of Fig. 12-11 (see also Fig. 12-12) for serine proteases.[308,310] However, alternative sequences of proton transfer have been suggested.[311] A possible role for a strong hydrogen bond has also been proposed.[310] For a detailed discussion see Brocklehurst *et al.*[312]

Most of the lysosomal proteases called **cathepsins** are small 20- to 40-kDa glycoproteins found in all animal tissues.[313] Most are cysteine proteases which function best and are most stable in the low pH reducing environment of lysosomes. They resemble papain in size, amino acid sequence, and active site structures. Papain is nonspecific but most cathepsins have definite substrate preferences. Cathepsin B is the most abundant. There are smaller amounts of related cathepsins H (an aminopeptidase)[314] and L[315] and still less of cathepsins C, K, and others. Cathepsin B is both an endopeptidase and an exopeptidase.[316] It acts on peptides with arginine at either P_1 or P_2 but also accepts bulky hydrophobic residues in P_1 and prefers tyrosine at P_3.[317] Cathepsin S is less stable at higher pH than other cathepsins and has a more limited tissue distribution, being especially active in the immune system.[318,319]

Cathepsin K is especially abundant in the bone resorbing osteoclasts (Chapter 8). It is essential to normal bone structure and its absence is associated with the rare hereditary disease pycnodysostosis (pycno) which causes short stature, fragile bones, and skull and skeletal deformities.[320] It may also play a role in the very common bone condition osteoporosis. Cathepsin C is also called **dipeptidyl peptidase**. It removes N-terminal dipeptides from many intracellular proteins activating many enzymes, including some other cathepsins.[321,322] A **prohormone thiol protease** cleaves peptide chains between pairs of basic residues, e.g., in the brain peptide precursor proenkephalin (Chapter 30), and also on the N-terminal side of arginine residues.[323] **Pyroglutamate aminopeptidase** removes pyroglutamyl (5-oxoprolyl) groups from amino termini of some peptides and proteins (see Fig. 2-4).[324] Another cysteine protease cleaves **isopeptide** linkages such as those formed by transglutaminase or those involving ubiquitin (Box 10-C).[325] Another cysteine protease present in animal tissues was recognized by its ability to hydrolyze the anticancer drug bleomycin. This **bleomycin hydrolase** is a hexamer with a central channel lined with papainlike active sites as in the proteasome structure (Box 7-A)[326] The enzyme also binds to DNA.[327] Unfortunately, cancer tissues often contain high levels of the enzyme, whereas it is low in skin and lung tissues, which are damaged by bleomycin.

The Ca^{2+}-dependent neutral proteases called **calpains** are found within the cells of higher animals. The 705-residue multidomain peptide chain of a chicken calpain contains a papain-like domain as well as a calmodulin-like domain.[328] It presumably arose from fusion of the genes of these proteins. At least six calpains with similar properties are known.[329] Some have a preference for myofibrillar proteins or neurofilaments.[330] They presumably function in normal turnover of these proteins and may play a role in numerous calcium-activated cellular processes.[331–332a]

A group of **cysteinyl aspartate-specific proteases (caspases)** play an essential role in programmed cell death (apoptosis).[333–335] Recall that nematodes are cell-constant organisms. For maturation of *Caenorhabditis elegans* 131 programmed cell deaths must occur at specific stages of development. An essential gene for this process was identified and named ***CED-3***. Deletion of this gene completely blocked the death of these cells. *CED*-3 encodes a cysteine protease that is highly homologous to the mammalian **interleukin-1β-converting enzyme** (**ICE** or caspase 1) which cleaves the 31-kDa **pro-interleukin-1β** to form the active 175 kDa species of this cytokine (Chapter 30). At least ten caspases are known and many observations have confirmed their role in apoptosis (see also Chapter 32). In caspases 1 and 2 the side chains of Cys 285 and His 237 form the catalytic dyad and peptide NH groups of Cys 285 and Gly 238 form the oxyanion hole.[333]

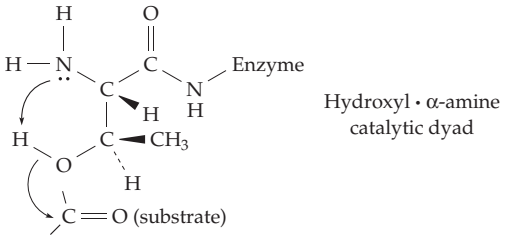
Parasites often use proteases in attacks on their hosts. The cysteine protease **cruzain** is secreted by the trypanosomes that cause Chagas' disease and is essential to their survival within the human body.[336,337] Cruzain is consequently an attractive target for development of drugs for treating this major disease.

Among cysteine proteases of bacteria is a papain-like enzyme from *Clostridium histolyticum* with a specificity similar to that of trypsin.[338] The anaerobic *Porphyromonas gingivalis*, which is implicated in periodental disease, produces both arginine- and lysine-specific cysteine proteases designated **gingipains**.[339,339a] Some virally encoded cysteine proteases, including one from the polio virus, have trypsin-like sequences with the serine of the catalytic triad replaced by cysteine.[340,341] A human adenovirus protease also has a Cys•His•Glu triad but a totally different protein fold.[342]

Zymogens of cysteine proteases usually have a long terminal extension which is removed, sometimes by autoactivation. Propapain has a 107-residue extension.[343] The 322-residue cathepsin B carries an unusually short 62-residue extension in its proenzyme form.[315,343,344] In every case the N-terminal extension folds into a domain, one of whose functions is to block the active site cleft.

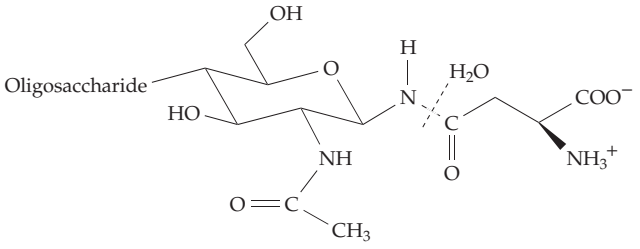
3. N-terminal Nucleophile Hydrolases and Related Enzymes

The most recently discovered group of proteases are the N-terminal threonine hydrolases of the **multicatalytic protease complex** (MPC) of proteasomes. The enzymes are arranged in a regular array inside proteasomal compartments as shown in Box 7-A. The active site is a catalytic dyad formed from the amino group at the N terminus of the β subunits.[345–346a]

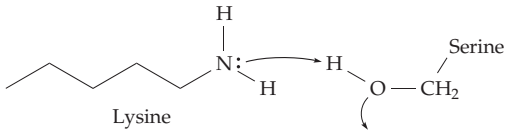


Proteasomes of *Thermoplasma* contain a single type of β subunit but eukaryotic proteasomes contain subunits with at least three distinct substrate preferences.[347–349c] They all appear to use the same hydrolytic mechanism but in their substrate specificities they are chymotrypsin-like, peptidylglutamyl-peptide hydrolyzing, branched chain amino acid preferring, and small neutral amino acid preferring based on the P_1 amino acid residue. In the spleen some of the β subunits of the proteasomes appear to have been replaced by proteins encoded by the major histocompatibility complex of the immune system (Chapter 31).[347] This may alter the properties of the proteasome to favor their function in antigen processing. Proteasomes are also ATP- and ubiquitin-dependent, as discussed in Section 6.

The enzyme glucosylasparaginase (aspartylglucosaminidase) is one of a group of other enzymes that use N-terminal threonyl groups as catalytic dyads.[346,350–353] It removes N-linked glycosyl groups from asparagine side chains of proteolytically degraded proteins and, as indicated on the accompanying structural formula, releases free aspartate and a 1-amino-*N*- acetylglucosamine-containing oligosaccharide. The amino group is then released as NH_3 from the product by acid catalysis in the lysosome.[350]

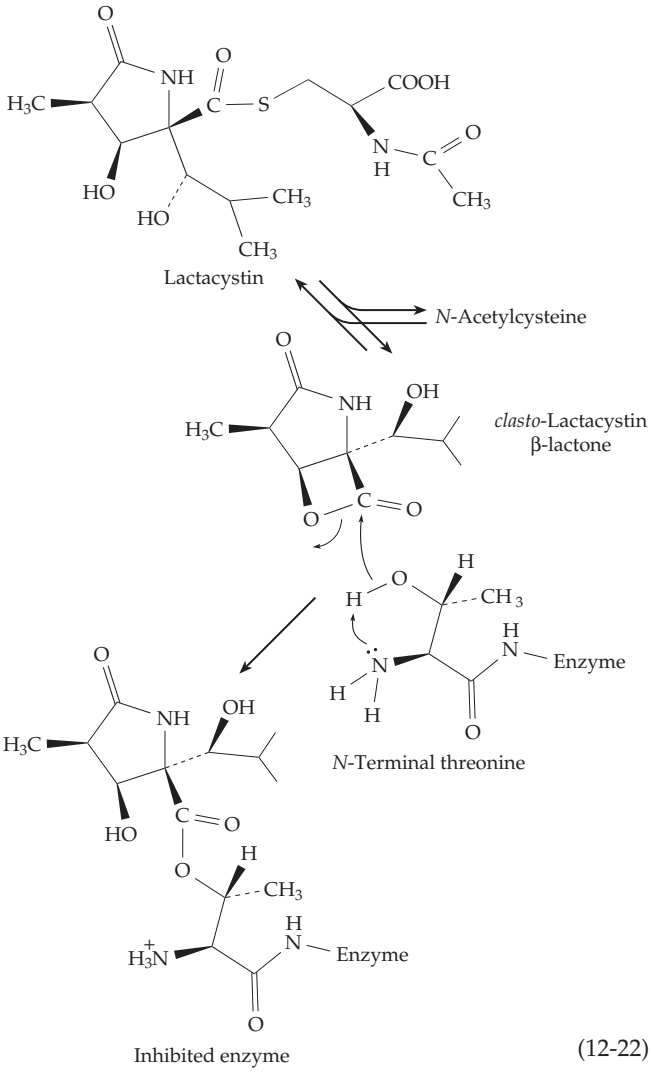


Glutamine PRPP amidotransferase (Fig. 25-15) and a penicillin acylase have similar active sites and overall structures.[354] The $-NH_2$ group is basic enough in the environment of the protein to remove the proton from the threonine –OH group, activating it as indicated below. Several serine proteases use an $-NH_2$ group of a lysine to form a serine•lysine dyad.[346]



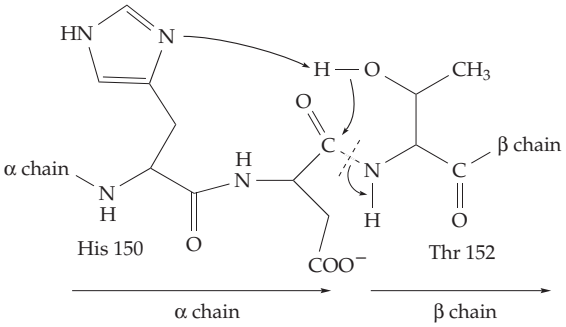
Among these are the well-known *E. coli* **leader peptidase**[355,356] and other signal peptidases.[357] These are integral membrane proteins that cleave N-terminal signal sequences from proteins incorporated into plasma membranes. Another enzyme of this class is the **lexA** repressor and protease discussed in Chapter 28.

A specific inhibitor of the major proteasomal activities is **lactacystin**, a compound formed by *Streptomyces*. Lactacystin is converted reversibly, by loss of *N*-acetylcysteine, into a β-lactone known as *clasto*-lactacystin. The N-terminal amino group attacks the reactive four-membered ring of the lactone (Eq. 12-22).[358,359]



(12-22)

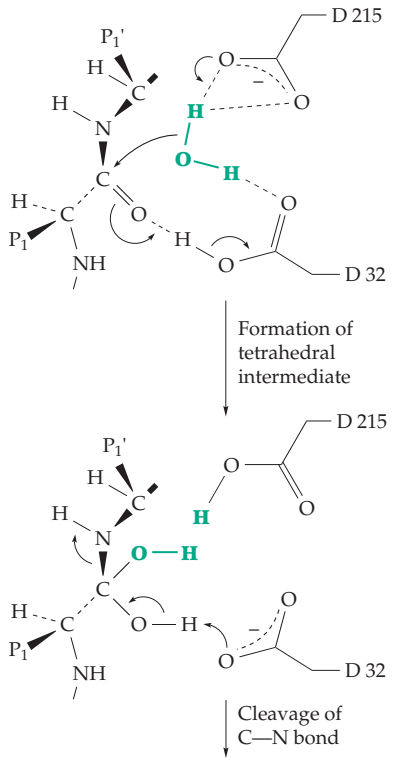
The active sites of the N-terminal nucleophile hydrolases are generated *autocatalytically*.[360–362] A single peptide chain is cleaved to form α and β chains as in the following diagram. An activating nucleophile such as histidine removes a proton from an adjacent threonine –OH and the resulting alkoxide ion attacks the adjacent peptide linkage, presumably via a tetrahedral intermediate, to form an ester linkage. Compare this sequence with reactions in Box 12-A and Eq. 14-41. Hydrolysis generates the N-terminal threonine as indicated:



4. The Aspartic Proteases

A fourth large group of protein-hydrolyzing enzymes consists of **pepsin** of the stomach[363] and related enzymes.[364] Each of these ~320-residue proteins is folded into two domains which associate with a pseudo-twofold axis of symmetry that passes through the active site.[365] A second human gastric aspartic proteinase is **gastricsin**.[365] The related **chymosin** (rennin),[366] which is obtained from the fourth stomach of the calf, causes a rapid clotting of milk and is widely used in manufacture of cheese. Pepsin has a broad specificity but cleaves preferentially between pairs of hydrophobic residues, converting proteins into soluble fragments. It is unusual in being able to cleave X-Pro peptide bonds.[367] Chymosin has a more restricted specificity, cutting the κ-casein of milk between a Phe–Met bond. This decreases the stability of the milk micelles, inducing clotting.[366] The serum protein **renin** (distinct from rennin), the lysosomal **cathepsins D** and **E**,[368–370] an **aspartyl aminopeptidase**,[371] and various fungal proteases are also closely related.[372–375] Renin,[376,377] which is synthesized largely in the kidneys, is involved in blood pressure regulation (Box 22-D). More distantly related aspartic proteases are encoded by retroviruses.

The pepsin family is most active in the low pH range 1–5. All of the enzymes contain two especially reactive aspartate carboxyl groups.[378] One of them (Asp 215 in pepsin) reacts with site-directed diazonium compounds and the other (Asp 32) with site-directed epoxides.[379] It is attractive to think that one of these carboxyl groups might be the nucleophile in a double displacement mechanism. The second carboxyl could then be the proton donor to the cleaving group. The acyl-enzyme would be an acid anhydride. However, X-ray studies on pepsin[363,380] and on related fungal enzymes such as **penicillopepsin**[381] and others[373,375] suggested a different possibility: A water molecule, hydrogen bonded to one of the active site Asp carboxylates or bridging between them, becomes the nucleophile. A proton, held by the carboxylate pair, protonates the substrate carbonyl to facilitate nucleophilic attack.[381] This is illustrated in Eq. 12-23 but without detail. Several intermediate sequences of reaction steps are possible.[382] At the beginning of the sequence one of the two symmetrically placed carboxylates is protonated while the other is not. Also notice that although the active site is symmetric, the substrate is bound asymmetrically as determined by its hydrogen bonding into an extended binding site.



(12-23)

A characteristic feature of catalysis by the aspartic proteases is a tendency, with certain substrates, to catalyze transpeptidation reactions of the following type.

Acetyl-Phe-Tyr + Acetyl-Phe* → Acetyl-Phe*-Tyr

(12-24)

Here Phe* is an isotopically labeled residue. Although such reactions suggested the possibility of some kind of activated amino group on the tyrosine that is cut off in the initial cleavage of the unlabeled substrate, it is more likely that the released tyrosine stays in the active site,[383] while the acetyl-Phe fragment exchanges with acetyl*-Phe.

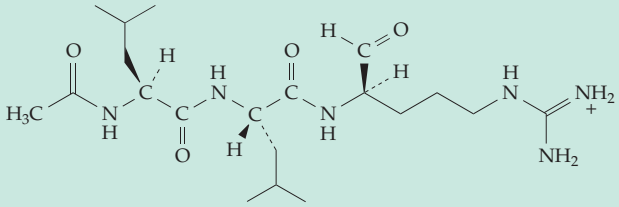
BOX 12-C SYNTHETIC PROTEASE INHIBITORS

One of the goals of synthetic medicinal chemistry is to design potent inhibitors of clinically important proteases. Elastase inhibitors may be useful for treatment of emphysema, pancreatitis, and arthritis,[a,b] while inhibitors of the angiotensinogen-converting enzyme or of renin (Box 22-D) can help control blood pressure. Inhibition of thrombin, factor Xa, or other blood clotting factors (Fig. 12-17) may prevent blood clots and inhibition of the cytosolic tryptase may provide a new treatment for asthma. Inhibition of the cysteine protease cathepsin K may help combat osteoporosis and inhibition of cysteine proteases of corona viruses may fight the common cold. Cysteine proteases of schistosomes are also targets for protease inhibitors.[c]

Many chemical approaches are used in designing inhibitors. Often, a naturally occurring inhibitor provides a starting point. The availability of high-resolution structures of the target enzymes and of various enzyme-inhibitor complexes assists in the rational design of tight-binding inhibitors. Use of combinatorial chemistry (Chapter 3)[d] is another source of potential inhibitors. To be of practical use in medicine many criteria of stability, solubility, and low toxicity must be met. While most inhibitors are disappointing as drugs, their use in laboratory experimentation has clarified a great deal of biochemistry.

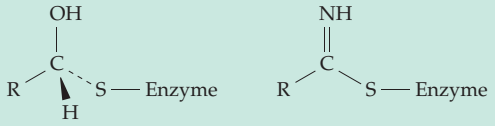
A straightforward approach is to hunt for short polypeptides that meet the specificity requirement of an enzyme but which, because of peculiarities of the sequence, are acted upon very slowly. Such a peptide may contain unusual or chemically modified amino acids. For example, the peptide **Thr-Pro-nVal-NMeLeu-Tyr-Thr** (nVal = norvaline; NMeLeu = *N*-methylleucine) is a very slow elastase substrate whose binding can be studied by X-ray diffraction and NMR spectroscopy.[e] Thiol proteases are inhibited by **succinyl-Gln-Val-Val-Ala-Ala-*p*-nitroanilide**, which includes a sequence common to a number of naturally occurring peptide inhibitors called **cystatins**.[f] They are found in various animal tissues where they inhibit cysteine proteases.

A group of inhibitors such as **leupeptin** have C-terminal aldehyde groups. Small oligopeptides with this structure and with appropriate specificity-determining side chains form tetrahedral hemiacetals, which may mimic transition state structures, at the active sites of the target enzymes.[g,h]



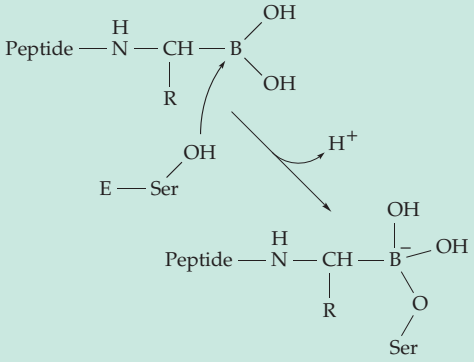
Leupeptin (*Actinomyces*)

Leupeptin is a slow, tight-binding inhibitor of trypsin. Some peptide aldehydes are potent, reversible inhibitors of cysteine proteases forming hemithioacetals with the active site cysteine.[i] Similarly, peptide nitriles form thioimidate adducts.[h]



Hemithioacetal Thioimidate

The peptide **boronic acids** form adducts with the active site serine of serine proteases.[j–l]



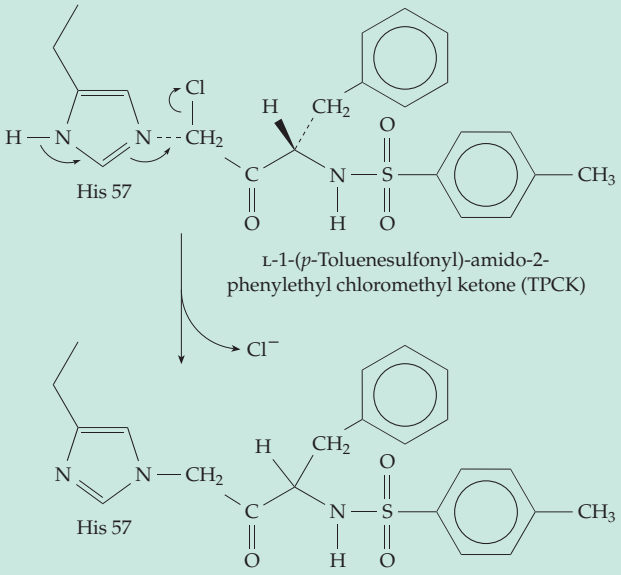
Adduct

However, both X-ray crystallography[m] and ^{11}B NMR[n] have shown that imidazole of the catalytic triad may also add to the boronic acid and that a tetrahedral adduct with both the serine oxygen and histidine nitrogen covalently bonded to boron can also be formed.[m] Thus, in reversibly inhibited enzymes a mixture of different chemical species may exist. Inhibitors can be designed to bind more tightly by providing additional bonding opportunities. For example, a suitably placed cyano group on a phenylalanine ring in the P_1 position of thrombin

BOX 12-C (continued)

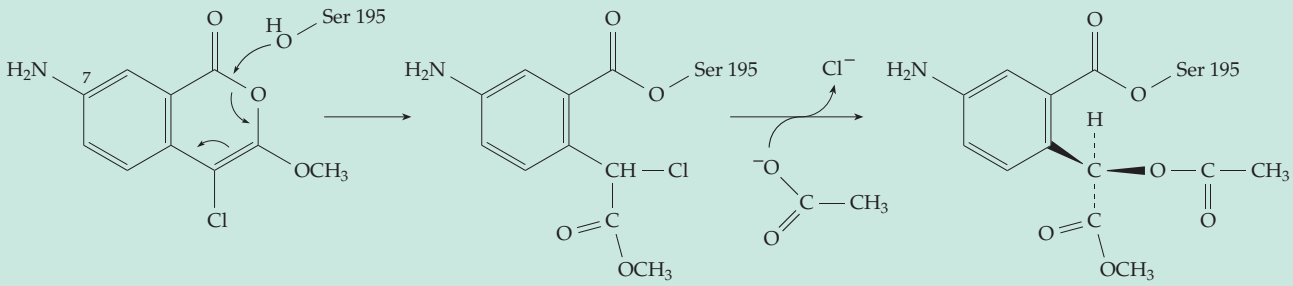
or other serine proteases can form a hydrogen bond to the peptide NH of Gly 219 (see Fig. 12-9).[o]

Numerous synthetic active-site directed or enzyme-activated irreversible inhibitors have been designed.[p] For example, the following chloroketone inhibits chymotrypsin but does not act on trypsin. The corresponding structure with a lysine side chain (TLCK) inhibits only trypsin. These **affinity labeling compounds** initially bind noncovalently at the active site.



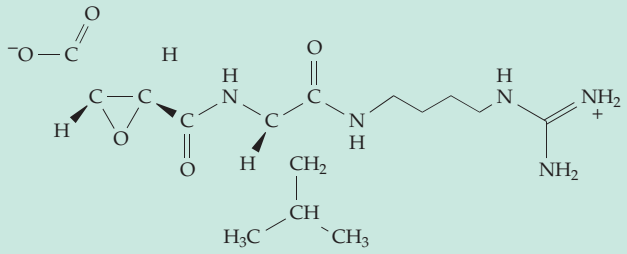
However, α-chloroketones are powerful alkylating agents and the bound inhibitor attacks His 57 of the catalytic triad system. The reaction is probably more complex than is indicated in the foregoing equation and may involve an epoxy ether intermediate.[q] Many other peptide chloromethyl ketone inhibitors have been devised.[q,r]

Isocoumarins inactivate many serine proteases. For example, 7-amino-4-chloro-3-methoxyisocoumarin acylates serine 195 of elastases as follows.[s]



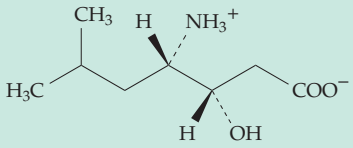
Many other enzyme-activated inhibitors are being developed.[c,d,t]

Epoxy groups, such as that of E-64, a compound isolated from the culture medium of a species of *Aspergillus*, react irreversibly with the active site thiolate group of cysteine proteases.[i,u,v] Related epoxides may become useful medications against abnormal cathepsin levels.



E-64, from *Aspergillus japonicum*

All of the aspartic proteases are inhibited by **pepstatin**, a peptide produced by some species of *Actinomyces* and which contains two residues of the unusual amino acid **statine** (**sta**).[w] Pepstatin has the sequence Isovaleryl-L-Val-L-Val-Sta-L-Ala-Sta.



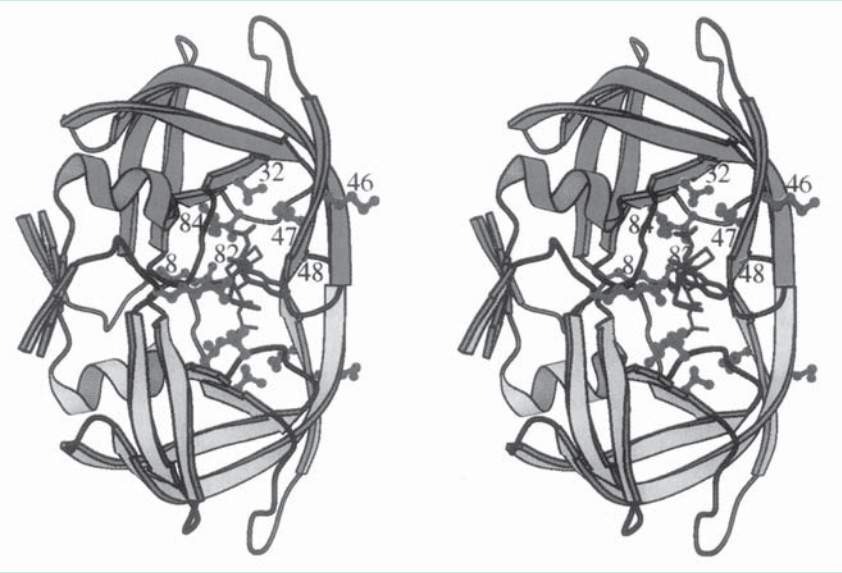
Statine (Sta)

The statine residue mimics the noncovalently bonded tetrahedral intermediate, permitting formation of a very tight complex. Pepstatin is a poor inhibitor of human renin but its existence has inspired the synthesis of numerous related compounds, some of which are effective renin inhibitors.[x,y] Some of these inhibitors use the human angiotensinogen sequence with a secondary alcohol group mimicking the tetrahedral intermediate.[x,z]

BOX 12-C SYNTHETIC PROTEASE INHIBITORS (continued)

These aspartic protease inhibitors are also "lead compounds" in the development of inhibitors of HIV protease.[aa–cc] As in statine-based inhibitors, the site of occupancy by the catalytic H_2O (green in Eq. 12-23) is occupied in the inhibitor by something that mimics a tetrahedral intermediate with –CHOH–, $-PO_2H-$, etc.[bb] Tremendous efforts are being expended in designing these inhibitors and considerable success has been achieved. However, the rapid development of mutant strains of the virus with drug-resistant proteases presents a major challenge.[cc,dd]

Mercaptans of suitable structure bind tightly to Zn^{2+} in the active sites of metalloproteases. For example, **captopril**[ee] is a tight-binding competitive inhibitor of the angiotensinogen-converting enzyme that is effective in lowering blood pressure and the first of many related inhibitors.[ff] As mentioned in the text, a variety of inhibitors that mimic the geometry of a tetrahedral intermediate or transition state are also potent inhibitors of metalloproteases.



Stereoscopic ribbon structure of the HIV-1 protease with the synthetic inhibitor Sequinivir[cc] bound in the active site. One of the two identical subunits (top) is shaded darker than the second (bottom). When mutated, the amino acid side chains shown in ball-and-stick form with residue numbers shown for the top subunit led to drug-resistant viruses. Pepsin is secreted as the inactive pepsinogen, which is activated by H^+ ions at a pH below 5. Determination of its crystal structure revealed that in the proenzyme the N-terminal 44-residue peptide segment lies across the active site, blocking it.[384] At low pH the salt bridges that stabilize the proenzyme are disrupted and the active site is opened up to substrates.

While the cellular aspartate proteases are over 300 residues in length, the retroviral proteases are less than one-half this size.[385–388] That of the human HIV-I protease contains only 99 residues. These enzymes are cut from a polyprotein (encoded by the viral ***gag*** and ***pol*** genes (Fig. 28-26). The *pol* gene encodes four other essential enzymes as well, and these are cut apart at eight different sites by action of the protease.[388] Despite its small size, it displays sequence homologies with the larger cellular aspartate proteases and has a related three-dimensional structure. Each chain has only one active site aspartate; the functional enzymes are dimers and the catalytic mechanism appears to be similar to that of pepsin.[388–392] A great deal of effort is being devoted to designing synthetic HIV protease inhibitors, which are used in the treatment of AIDS (Box 12-C).

5. Metalloproteases

The pancreatic **carboxypeptidases** are characterized by the presence of one firmly bound **zinc ion** in each molecule. The Zn^{2+} can be removed and can be replaced by other metal ions such as Co^{2+} and Ni^{2+}, in some cases with reconstitution of catalytic activity. The human pancreas synthesizes and secretes proenzymes for two forms of carboxypeptidase A, with a preference for C-terminal hydrophobic residues, as well as carboxypeptidases B, which prefer C-terminal basic residues. Additional A and B forms[393] as well as more specialized nondigestive carboxypeptidases are also known. In eukaryotic cells the latter participate in processing of proteins. Following removal of N-terminal signal sequences, processing often continues with removal of basic residues from the C termini by **carboxypeptidases N**, **H** (also called E or enkephalin convertase),[394] and **M**, all of which are metalloenzymes.[395,396] Carboxypeptidase N removes C-terminal arginines from many biologically important peptides. It also circulates in the plasma and protects the body by inactivating such potent inflammatory peptides as the kinins and anaphylotoxins.[397] Carboxypeptidase H is located in secretory granules, while carboxypeptidase M is membrane associated.[396] Dipeptidyl carboxypeptidase (**angiotensin-converting enzyme**) removes the C-terminal Pro–Phe dipeptide from angiotensinogen to generate the potent pressor agent angiotensin I (Box 22-D) and cleaves dipeptides from many other substrates as well.[398] A **D-alanyl-D-alanyl carboxypeptidase** cleaves D-alanine from the ends of cell wall peptides (Chapter 20).[399]

Another well-known zinc-containing enzyme is **thermolysin**, a nonspecific *endopeptidase* widely used in laboratories. Produced by a themophilic bacterium, it is unusually resistant to heat. It contains four bound calcium ions in addition to the active site zinc.[400–402] The active site structure resembles that of pancreatic carboxypeptidase A and the two enzymes appear to act by similar mechanisms.[401,403,404] The mammalian zinc endopeptidase **neprilysin**, an integral membrane protein involved in inactivation of enkephalins and other signaling peptides, also resembles thermolysin.[405] A related neutral endopeptidase is the product of a gene called *PEX* (phosphate-regulating gene with homologies to endopeptidases on the X chromosome). The absence of the *PEX* gene product causes **X-linked hypophosphatemic rickets** which leads to excessive loss of phosphate from the body with defective mineralization of bone.[406] The **mitochondrial processing peptidase**, which removes signal sequences from the N termini of mitochondrial proteins, also contains Zn^{2+} at its active site.[407,408] However, it is an αβ heterodimer and a member of an additional family of enzymes, one of which includes human insulin-degrading enzyme.

In both carboxypeptidase A and thermolysin the active site Zn^{2+} is chelated by two imidazole groups and a glutamate side chain (Fig. 12-16). In carboxypeptidase A, Arg 145, Tyr 248, and perhaps Arg 127 form hydrogen bonds to the substrate. A water molecule is also bound to the Zn^{2+} ion. The presence of the positively charged side chain of Arg 145 and of a hydrophobic pocket accounts for the preference of the enzyme for C-terminal amino acids with bulky, nonpolar side chains. The Zn^{2+} in thermolysin is also bound to two imidazole groups and that in D-alanyl-D-alanyl carboxypeptidase to three.

The presence of a zinc ion in the metalloproteases immediately suggested a role in catalysis. Unlike protons, which have a weak affinity for the oxygen of an amide carbonyl group, a metal ion can form a strong complex. If held in position by other ligands from the protein, a properly placed zinc ion might be expected to greatly enhance the electrophilic nature of the carbon atom of the C=O group. However, it has been difficult to establish the exact mechanism of action.[410] Carboxypeptidase A cleaves both peptides and ester substrates. For peptides, K_m is the same for various metals while k_{cat} changes, but the converse is true for ester substrates.[411] From its position Glu 270 (Glu 143 in thermolysin) seems to be the logical nucleophile to attack the substrate to form an acyl-enzyme intermediate, an anhydride. Using the following specific *ester* substrate, Makinen *et al.* showed that at very low temperatures of −40° to −60°C, in solvents such as 50:50 ethylene glycol:water, an acyl-enzyme intermediate can be detected spectroscopically. It could even be separated from free enzyme[412] by gel

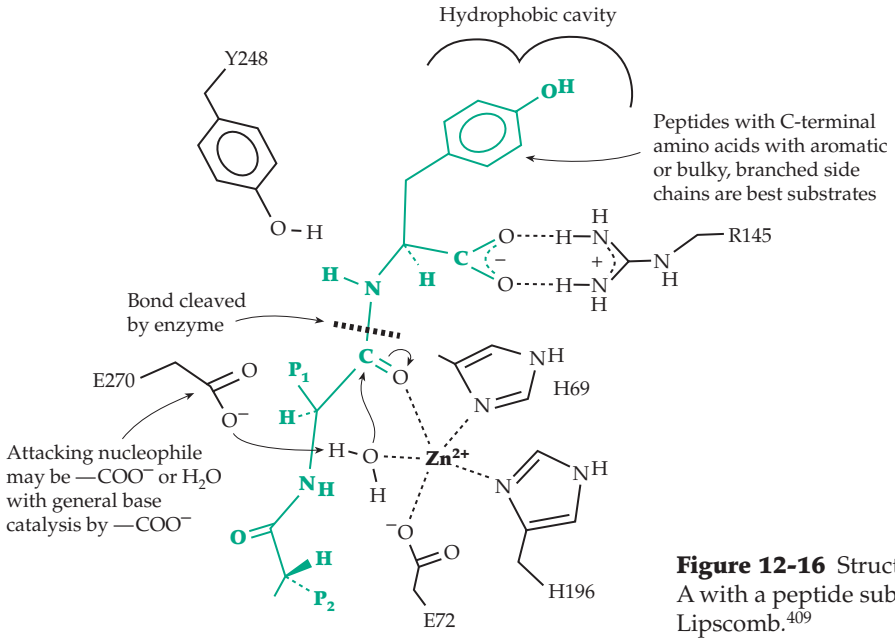

Figure 12-16 Structure of the active site of carboxypeptidase A with a peptide substrate present. See Christianson and Lipscomb.[409]

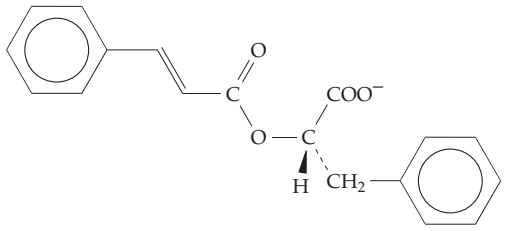
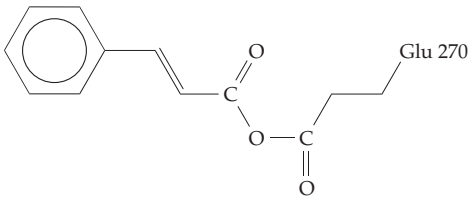
filtration at −60°C and its cyanoborohydride reduction product was characterized.[413]



O-(*trans*-*p*-cinnamoyl)-L-β-phenyllactate

The intermediate appears to be the acid anhydride formed by Glu-270.[414,415] The conformation of the intermediate was deduced by ENDOR spectroscopy and its formation and reaction interpreted according to stereoelectronic principles.[416]



If the anhydride mechanism is correct, the water molecule bound to the Zn^{2+} probably provides an HO^- ion necessary for the hydrolysis of the intermediate anhydride.[417]

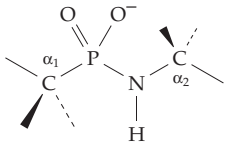
Although these results seem convincing there are objections.[410] The mechanism deduced for hydrolysis of an ester may be different than that for a peptide.[418] Furthermore, many observations favor an alternative mechanism. A hydroxide ion derived from a water molecule bound to the zinc ion may be the initial attacking nucleophile.[404,419–422] Both X-ray crystallographic studies and EPR investigations[403,414] show that the zinc in carboxypeptidases can coordinate at least five surrounding atoms. As shown in Fig. 12-16, the Zn^{2+} could hold the attacking water molecule and, at the same time, provide the positive charge for stabilizing the resulting tetrahedral intermediate. Glu 270 (or in thermolysin His 231) acts as a base to deprotonate the bound H_2O. Mock and Stanford argue that the H_2O is probably displaced when the peptide carbonyl binds and that the H_2O is then deprotonated and adds to the polarized carbonyl.[404]

The pH dependence of the action of carboxypeptidase A is determined by pK_a values of ~6 and ~9.5 for the free enzyme[422] and of ~6.4 and ~9 for k_{cat}.[420] For thermolysin the values for k_{cat} are ~5 and ~8.[404] Assignment of pK_a values has been controversial. They may all be composites of two or more microscopic constants but probably, at least for carboxypeptidase, the low pK_a is largely that of Glu 270 while the high one represents largely the dissociation of a proton from the zinc-bound H_2O.

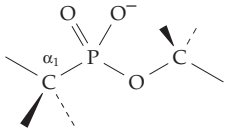
Earlier studies of carboxypeptidase had indicated that Tyr 248 moves its position dramatically upon substrate binding, and it was suggested that its phenolic –OH group protonates the leaving group in the acylation step. However, a mutant in which Tyr 248 was replaced by phenylalanine still functions well.[423]

Phosphonamidates,[424,425] phosphonate esters, and oxo-methylene substrate analogs, which presumably mimic the geometry of the tetrahedral intermediate or transition state of the intermediate or transition state

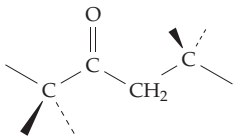
of the catalytic cycle, are effective inhibitors of zinc proteases. X-ray studies of complexes of such inhibitors with both thermolysin and carboxypeptidase A support the suggestion that the Zn^{2+} binds the carbonyl oxygen of the amide bond that is to be cleaved in a



Phosphonamidate



Phosphonate ester



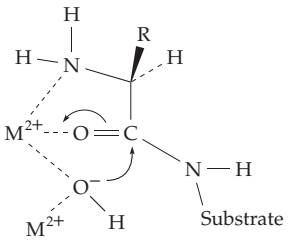
Oxo-methylene analog

substrate and that a glutamate side chain could activate a Zn^{2+}-bound water to form an attacking nucleophile. A similar conclusion was reached from the structure of a thermolysin–product complex.[426]

Another large group of zinc proteases are the **matrix metalloproteases** which act on proteins of the extracellular matrix, such as collagen, proteoglycans, and fibronectin.[427–429c] These enzymes have been classified as **collagenases**, **gelatinases** (which act on denatured collagen), **stromelysins** (which are activated in response to inflammatory stimuli),[430–432] and a membrane type. The group also includes the digestive enzyme **astacin**, from the crayfish,[433] and metalloproteases from snake venoms.[429,434] The matrix metalloproteases are essential to the remodeling of the extracellular matrix that occurs during wound healing, tissue growth, differentiation, and cell death. An example of tissue remodeling is the development of dental enamel (Box 8-G). The proteinaceous matrix formed initially must be digested away, perhaps by the metalloprotease **enamelysin**, and replaced by the dense mineral of enamel.[435] Excessive secretion of collagenase by fibroblasts is observed in **rheumatoid arthritis** and other inflammatory conditions.

At least 64 different matrix metalloproteins are known.[427] Each enzyme consists of three domains. An 80- to 90-residue N-terminal propeptide domain contains a cysteine whose $-S^-$ group binds to the active site zinc, screening it from potential substrates. The central catalytic domain is followed by a hinge region and a C-terminal domain that resembles the serum iron binding and transporting **hemopexin**.[427,436] The mechanism of action is probably similar to that of thermolysin.[430]

Many aminopeptidases are metalloenzymes.[437] Most studied is the cytosolic **leucine aminopeptidase** which acts rapidly on N-terminal leucine and removes other amino acids more slowly. Each of the subunits of the hexameric enzyme contains *two* divalent metal ions, one of which must be Zn^{2+} or Co^{2+}.[438,439] A methionine aminopeptidase from *E. coli* contains two Co^{2+} ions[440,441] and a proline-specific aminopeptidase from the same bacterium two Mn^{2+}.[442] In all of these enzymes the metal ions are present as dimetal pairs similar to those observed in phosphatases and discussed in Section D,4 and to the Fe–Fe pairs of hemerythrin and other diiron proteins (Fig. 16-20). A hydroxide ion that bridges the metal ions may serve as the nucleophile in the aminopeptidases.[438] A bound bicarbonate ion may assist.[438a]



A metalloenzyme **peptide deformylase** removes the formyl groups from the N termini of bacterial proteins. Although the active site is similar to that of thermolysin,[443] the Zn^{2+} form of peptide deformylase is unstable. Both Ni^{2+} and Fe^{2+} form active, stable enzymes.[444,445]

6. ATP-Dependent Proteases

Much of metabolism is driven by the Gibbs energy of hydrolysis of ATP so it shouldn't be surprising that ATP is sometimes rather directly involved in hydrolytic degradation of polypeptide chains. Much of protein processing occurs in the endoplasmic reticulum,[446] which also assists in sorting unneeded and defective proteins for degradation in the ubiquitin–proteasome system. Proteasomal degradation occurs in the cytosol, in the nucleus, and along the ER. However, the predominant location is the *centrosome*.[446a]

Polyubiquitination of proteins requires ATP (Box 10-C) and additional ATP is utilized in the proteasomes (Box 7-A) during the selection of polyubiquitinated proteins for hydrolysis.[447,448] With 28 subunits the 26S proteasome is complex and not fully understood.[448] The ATP-hydrolyzing subunits appear to all be in the cap regions. Is the ATP used to open and close the entry pores? To induce conformational changes in all subunits as part of a catalytic cycle? Or to unfold folded proteins to help them enter the proteasomes?[449]

Some answers may be obtained from smaller bacterial, mitochondrial, and chloroplast ATP-dependent proteases. Cells of *E. coli* contain at least nine proteases, which have been named after the musical scale as Do, Re, Mi, Fa, So, La, Ti, Di, and Ci.[450,451] Most are serine proteases but two, Ci and Pi, are metalloproteins. Protease **La** (**Lon protease**, encoded by gene ***lon***) has attracted particular attention because the hydrolysis of two molecules of ATP occurs synchronously with cleavage of a peptide linkage in the protein chain.[452] This enzyme, as well as protease **Ti** (more often called **Clp**, for caseinolytic protease),[451,453,454] is ATP-dependent.[451]

The Lon protease of *E. coli* is a large 88-kDa serine protease with the catalytic domain, containing active site Ser 679, in the C-terminal half. The N-terminal portion contains two ATP-binding motifs and a linker region.[455,456] A homologous protein known either as Lon or as PIM1 is present in mitochondria.[457,458] The *E. coli* proteases Clp (Ti) include ClpAP and ClpXP, which are heterodimers, each containing the catalytic subunit ClpP and either ATPase ClpA or ClpX. The active enzyme may be designated **ClpAP**.[459–461] A homolog of ClpP has been found in human mitochondria.[461a] The ATPase Clp forms seven-subunit rings resembling the rings of proteasomes (Box 7-A), while the catalytic subunit ClpA forms six-membered rings.[451,454] Despite the mismatch in symmetry and the fact that they are serine proteases, these enzymes appear similar to proteasomes. However, each catalytic subunit has an ATPase neighbor. Why is it needed? The related **ClpB** is both an ATPase and a chaperonin. It is essential for survival of *E. coli* at high temperatures.[461b]

Another ATP-dependent protease identified among heat shock proteins of *E. coli* is known as **Hs1V–Hs1U** or (ClpQ–ClpY). It has a threonine protease active site and is even more closely remeniscient of eukaryotic proteasomes.[462–463a] Also active in *E. coli* is another ring-like protease, a membrane-bound zinc endopeptidase **FtsH** (or HflB).[463b] Similar eukaryotic proteases also exist.[460]

7. The Many Functions of Proteases

Many of the enzymes considered in the preceding sections function within the *digestive* tract. Others function in the *processing* of newly formed peptide chains, while others act in the *intracellular degradation* of proteins. Yet others are secreted from cells and function in the external surroundings. Both processing and intracellular degradation can be viewed as parts of *biosynthetic loops* (Chapter 17) that synthesize mature proteins, and then degrade them when they have served their function or have become damaged. The pathways involved are varied and complex, a natural result of thousands of enzymes and other compounds acting on accessible and chemically appropriate parts of the proteins. Evolutionary selection has evidently led to the particular set of pathways that we observe for any organisms.

Because they must often cleave large **polyproteins**, many viruses encode processing proteases.[464–466b] For example, the entire RNA genome of the poliovirus encodes a large polyprotein which is cut by two virally encoded chymotrypsin-like cysteine proteases within Tyr-Gly and Gln-Gly sequences;[341,465] Asn-Ser sequences are also cut, apparently autocatalytically. As we have already seen, retroviruses encode their own aspartic protease. Most cellular and secreted proteins of bacteria or eukaryotes also undergo processing. This ranges from removal of *N*-formyl groups to cutting off signal peptides, addition or formation of prosthetic groups, internal cleavages, and modifications at the C termini. A variety of peptidases are required.

Degradation of proteins, which converts them back to amino acids as well as other products, takes place in part in the cytosol via the ubiquitin-protease system. Proteolysis also occurs in ER and external cell spaces through the action of membrane-bound and secreted proteases. Loosely folded proteins, which can arise in various ways, are subject to rapid degradation. For example, synthesis of a polypeptide chain on a ribosome may be accidentally disrupted with formation of a protein with a shorted chain. Mature proteins may become damaged. For example, certain histidine residues are readily attacked by oxidizing reagents. Oxidative damage may mark proteins for rapid degeneration.[450] In *E. coli*, proteases So and Re attack oxidized glutamine synthetase much more rapidly than the intact native enzyme.[450,467] In mammalian cells the proteasomes degrade oxidized as well as poorly folded proteins.[468] However, proteasomal digestion is not complete and peptide fragments may be secreted. Peptide fragments of proteins are also formed in the ER and may be secreted. Thus, a variety of small peptide hormones and other biologically active peptides are both generated and inactivated in or around cells.[469–471] Some receptors are activated by proteases.[471a]

Circulating proenzymes of the blood clotting factors, of the complement system (Chapter 31), represent a specialized group of secreted **signaling proteins** that are able to initiate important defensive cascades. Proteases also act more directly in defense systems of the body. For example, serine proteases cause lysis of the target cells of cytotoxic T lymphocytes[472] (Chapter 31) and activated neutrophils[473] (Chapter 18). At the same time, pathogenic bacteria often secrete proteases that assist in attack on their hosts[474] and schistosomes secrete an elastase that helps them penetrate skin and invade their hosts.[475]

8. Protease Inhibitors of Animals and Plants

Premature conversion of proenzymes such as trypsinogen into active proteases in the pancreas would be disastrous. To prevent this, the pancreas also produces inhibitors. The complex cascades that control blood clotting would also be unstable were it not for the presence in blood of numerous inhibitory proteins. Indeed, inhibitors of proteases are found everywhere in animals, plants, and microorganisms.[476–478] They are usually proteins but small antibiotic protease inhibitors are also produced by microorganisms. Protein inhibitors are usually specific for a given type of enzyme: The **serpins** inhibit serine proteases, and the **cystatins** inhibit cysteine proteases.[479–483] Other inhibitors block the action of metalloproteases[484–486] and aspartic proteases. Inhibitors help not only host organisms but also parasites. For example, *Ascaris suum*, a very large nematode that is thought to infect 1/4 of the human population of the earth and nearly all of the pigs, secretes a pepsin inhibitor.[487] However, the large 720-kDa serum **α-macroglobulins** (Box 12-D) inhibit all classes of proteases.

About 20 families of protein inhibitors of proteases have been described.[488] The egg white **ovomucoids** comprise one family. Turkey ovomucoid is a three-domain protein whose 56-residue third domain is a potent inhibitor of most serine proteases.[488,489] The 58-residue **pancreatic trypsin inhibitor**[490] is a member of another family of small proteins. A 36-residue insect (locust) protease inhibitor is even smaller.[491]

Inhibitors that block the action of trypsin and other proteases are found in many plants. The inhibitor activity is usually highest in seeds and tubers, but synthesis of inhibitors can be induced in other parts of plants e.g. tomato and potato by wounding.[492] See also Chapter 31. Legumes contain small 60- to 76-residue inhibitors (Bowman–Birk inhibitors) each containing seven disulfide linkages, and they are relatively stable toward cooking and toward acid denaturation in the stomach.[493,494] Although they interfere with protein digestion they seem to have an anticarcinogen effect.[493] Soybeans also contain a larger 181-residue trypsin inhibitor (Kunitz type).[495]

Several inhibitor–protease complexes have been crystallized and details of their interactions are known. For example, the pancreatic trypsin inhibitor binds at the active site of trypsin with $K_f > 10^{13}$ M^{-1} at neutral pH.[496] The two molecules fit snugly together,[490,497] the inhibitor being bound as if it were a peptide substrate with one edge of the inhibitor molecule forming an antiparallel β structure with a peptide chain in the enzyme. Lysine 15, which forms part of this β structure, enters the specific P_1 binding site for a basic amino acid in a substrate. Thus, the protease inhibitor is a modified substrate which may actually undergo attack at the active site. However, the fit between the two molecules is so tight that it is hard for a water molecule to enter and complete the catalytic act. The complex reacts very slowly, keeping the enzyme inactive. There is not enough inhibitor to interfere with the large amounts of trypsin formed from trypsinogen in the small intestine so that trypsin can function there.

Most protease inhibitors act by mechanisms similar to that of the pancreatic trypsin inhibitor. They are very slow substrates with a **reactive loop** that carries suitable P_1, P_2, and P_1' residues that meet the specificity requirements of the enzyme. Additional noncovalent interactions prevent dissociation and make the energy barrier for hydrolysis so high that the reaction is extremely slow.[488,494,495]

The serpins are larger ~400-residue proteins.[498–500] They also form complexes in which hydrolysis and release of the serpin occurs very slowly. However, structural analysis before reaction and after release showed that a major rearrangement occurs in the serpin structure. The P_1 through ~P_{15} residues of the cleaved reactive loop are inserted into the center of the main β sheet of the serpin, leaving the P_1 and P_1' residues ~7 nm apart.[499,500] It seems likely that the rearrangement begins during formation of the tight inhibited complex, which cannot be dissociated by boiling in a sodium dodecyl sulfate (SDS) solution and which may be an acyl-enzyme.[501,502] A serpin molecule can act only once.

Blood contains several serpins. They are abundant, accounting for about 10% of the total protein of human plasma.[478,500] The most abundant is the **α1-protease inhibitor** or α_1-antitrypsin, a 394-residue glycoprotein component of the α-globulin fraction of blood serum.[500a] There is no trypsin in tissues, but this inhibitor blocks the action of other serine proteases, including cathepsin G and **leukocyte elastase**.[503] Hereditary absence of α_1-protease inhibitor often leads to severe **pulmonary emphysema** at an early age. Elastase released by neutrophils at sites of inflammation degrades many components of connective tissue including elastin, collagen, and proteoglycans. Without the presence of protease inhibitor too much damage is done to surrounding tissue. A lack of this inhibitor is one of the commonest genetic defects among persons of European ancestry, affecting 1 in 750 persons born.[504–506] The most serious known mutation is a replacement of guanine by adenine at a specific point in the DNA and a resultant replacement of Glu 342 with lysine in the protease inhibitor. This in some manner adversely affected the processing and secretion of the protein.

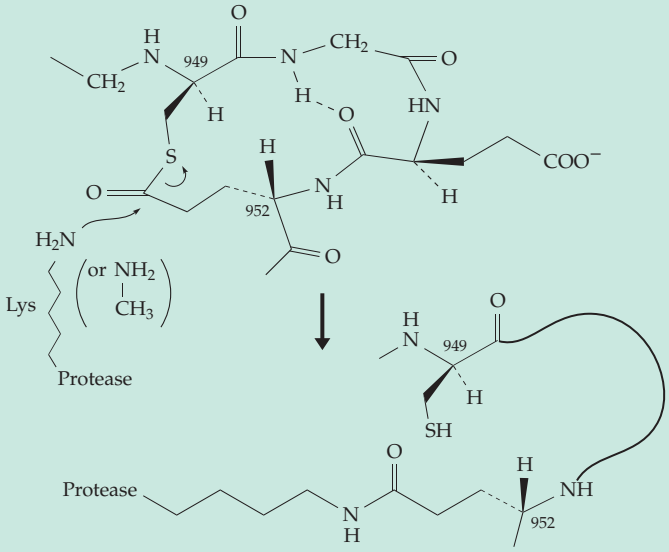
At its reactive site the α_1-protease inhibitor has the sequence

Ala-Ile-Pro-Met*-Ser-Ile-Pro-Pro,

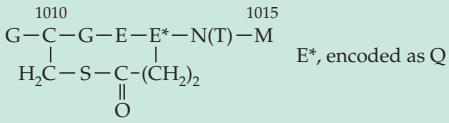
the Met-Ser pair marked by the asterisk fitting into the P_1-P_1' sites (Fig. 12-14). The methionine (Met 358) in

BOX 12-D MOLECULAR MOUSETRAPS

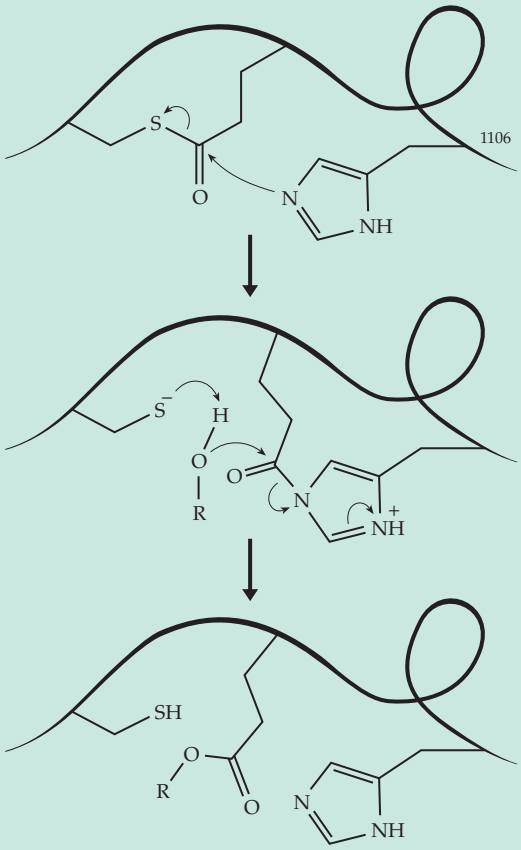
The large 720-kD α_2-macroglobulin of human serum, as well as related proteins of vertebrate and invertebrate circulatory systems and of egg whites of birds and reptiles, is a trap for proteases.[a–f] Human macroglobulin is a homotetramer consisting of two pairs of identical 180-kDa subunits, each pair being held together in an antiparallel configuration by two disulfide bridges. Each subunit contains a "bait region" with cleavage sites appropriate for nearly all known endoproteases[f] and also a thioester linkage as explained later. Electron microscopic reconstructions of the native protein and its complexes with proteases show that a major structural transformation occurs.[e,f] The macroglobulin traps two protease molecules of the size of trypsin, or one larger one such as plasmin, in an internal cavity. The internal thioesters, which are formed between Cys 949 and Gln 952 (with loss of NH_3) in each subunit, become reactive[g] and form covalent bonds with ε-amino groups of various lysine side chains of the trapped proteases.



The serum proteins C3 and C4, members of the complement system (Chapter 31), are converted into their active forms, C3b and C4b, by proteolytic removal of short N-terminal peptide fragments. Both C3b and C4b bind tightly to cell surfaces, a feature that helps to direct the complement system's attack to the surfaces of invading organisms. This tight binding also involves covalent attachment of macromolecules by reaction with a preformed thioester just as with α_2-macroglobulin.[h–j] In fact, the thioester linkage was first discovered in the complement proteins. Both C3 and C4 contain the thioester within the following sequence, which is the same as that in α_2-macroglobulin:



Here the side chains have been added for the thioester-forming cysteine and glutamate and the sequence numbers are for C3. The thioester-forming glutamate is labeled E* because it is not encoded as glutamate but as glutamine, suggesting a mechanism of thioester formation. Protein C4 exists as two subforms, C4A and C4B. Both C3 and C4A react predominately with lysine amino groups, but C4B reacts with –OH groups of cell surface polysaccharides.[h] It has a histidine at position 1106. There is good evidence that it is adjacent to the C=O group of the thioester and reacts to form an acyl-imidazole which is more reactive with hydroxyl groups than is a thioester:



Activation of C3 and C4 apparently allows the preformed thioester, which is buried in the interior

BOX 12-D (continued)

of these proteins, to become exposed on the external surface where it can react. The high group transfer potential of the thioester ensures that the reaction will go to completion.

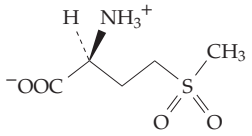
this sequence, as well as another nearby methionine residue, is very susceptible to oxidation to sulfoxides:



Methionine sulfoxide

The oxidation, which may be caused by such agents as myeloperoxidase (Chapter 16) released from leukocytes,[507] inactivates the inhibitor. This may be physiologically important in permitting the proteases to be *uninhibited* in the immediate vicinity of the leukocyte. Cigarette smoke also inactivates α_1-protease inhibitor by oxidation of the same methionine residues and the lungs of smokers contain the oxidized inhibitor.[508] However, the major cause of emphysema among smokers appears to be an increase in released neutrophil elastase.[509] One approach to the treatment of emphysema involves weekly intravenous injection of α_1-antitrypsin.[510] This treatment may be improved by use of genetically engineered oxidation-resistant variants of the antitrypsin such as Met 385→Val.[504,511] Efforts are also being made to introduce an α_1-antitrypsin gene into lung epithelial cells.[510,512]

Blood plasma also contains at least nine other protease inhibitors. One of these, the thrombin inhibitor **antithrombin III** (Section 9), contains the sequence Arg-Ser-Leu at the P_1, P_1', and P_2' sites. A tragic case of a person born with a Met 385 → Arg mutation in α_1-antitrypsin has been reported.[513] This converted the antitrypsin to an antithrombin causing a bleeding disorder that was eventually fatal.

9. Coagulation of Blood

The clotting of blood following injury and the subsequent dissolving of the clot are familiar phenomena that involve several cascades of proteolytic enzymes together with a number of accessory **cofactors**.[514–516] The first step in clotting results from "activation" of blood platelets which aggregate to form a platelet plug that slows bleeding.[514,517] The clot, which is formed by the insoluble **fibrin**, grows on the platelet surfaces and strengthens the plug. The initial rapid formation of a clot occurs via the **tissue factor pathway** (or extrinsic pathway; right side of Fig. 12-17) which is triggered by the exposure in injured tissues of **tissue factor** (TF), a transmembrane glycoprotein[518–522] and a member of the cytokine receptor superfamily.[518] Human TF is a 263-residue protein with a single membrane-spanning region and a small 20-residue C-terminal cytoplasmic domain. The 219-residue extracellular domain consists largely of two IgG-like domains (Fig. 12-18).[519,523] This protein stimulates the conversion of fibrinogen[524–526] into the insoluble fibrin through the action of three proteases–factor VIIa, factor Xa, and thrombin. These enzymes are generated from proenzymes VII, X, and prothrombin, respectively in a cascade mechanism.

Factor VII binds tightly to TF,[527,527a,b] which also binds Ca^{2+} and phospholipid of the cell membranes. Within this complex a plasma protease, such as thrombin or factor VIIa or Xa, cleaves a single Arg-Ile bond in VII to form active VIIa.[528–530] The TF•VIIa complex is a very active protease which cleaves a specific peptide bond in factor X to form Xa[531–533] which continues the cascade. Notice that there are autocatalytic features: VII can be converted to the active VIIa by the action of Xa and the accessory factor Va is generated from the precursor, factor V, in part through the action of thrombin.[514,534–535] Factors Xa and Va together with Ca^{2+} and phospholipid form the active **prothrombinase** complex which attacks prothrombin to form the active enzyme thrombin.[536,537] The roles of factor Va and Ca^{2+} appear to be to hold the prothrombin and the activated protease Xa together on the phospholipid surface.[538] This localizes the clotting. Factor Xa is unusually specific, cleaving only after arginine in the sequence. Its activation of prothrombin results from cleavage of two

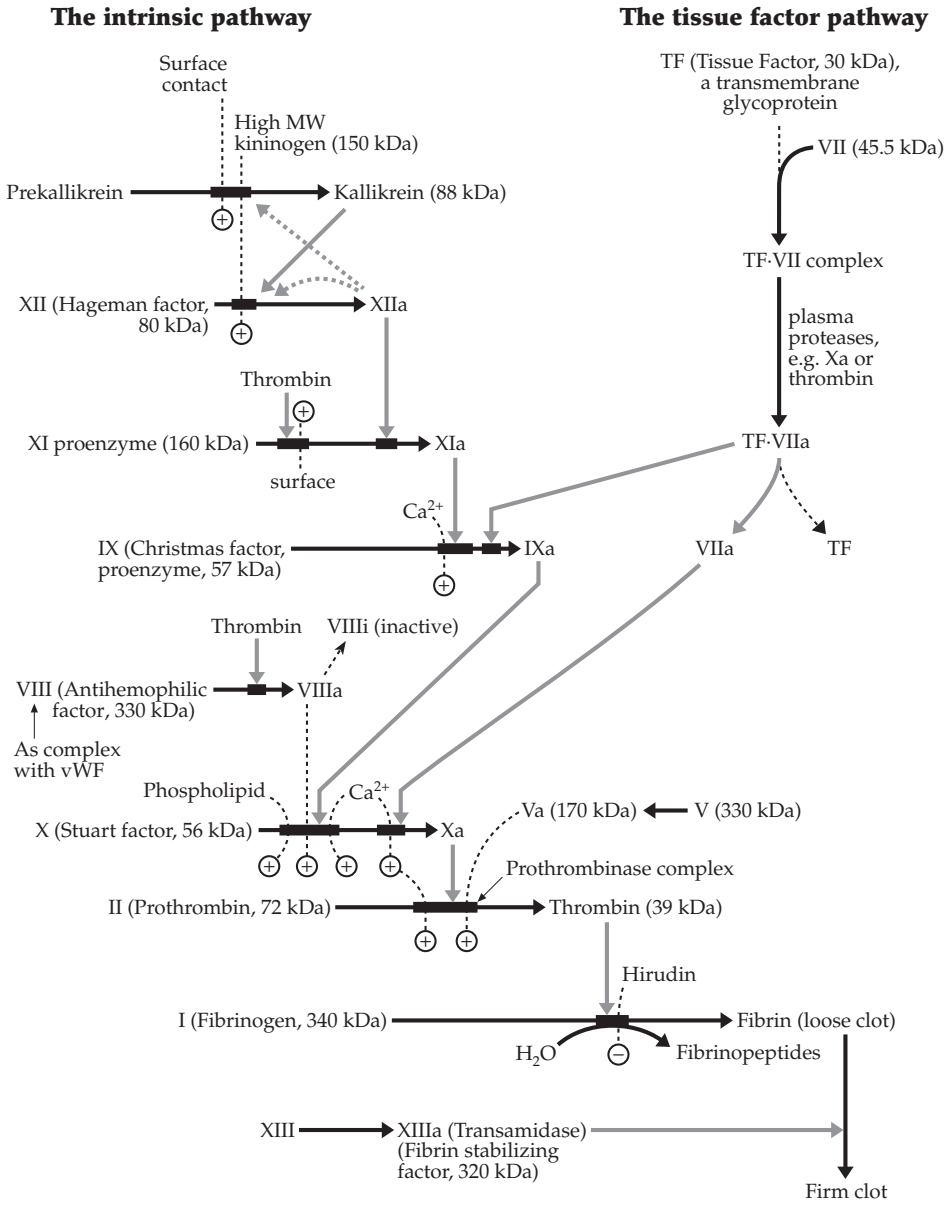


Figure 12-17 Major components of the human blood clotting cascades. The site of action of the leech anticoagulant protein hirudin is also indicated.

peptide bonds, which releases the 39-kDa thrombin from the much larger, immobilized 72-kDa proenzyme.[236,531]

Thrombin, like most other clotting factors, is also a serine protease. However, the clotting factors are multidomain proteins that are more elaborate and more specific[539] than the digestive enzymes. Prothrombin, as well as factors VII, IX, and X and the anticoagulant protein C, contain at their N-terminal ends several residues of γ-carboxyglutamate (Gla), an amino acid generated in a posttranslational modification that depends upon vitamin K (Chapter 15). In human prothrombin there are ten of these in the following N-terminal sequence, where E* represents Gla. Since many of these enzymes are also dependent upon activation by calcium ions (see Fig. 12-17), it is thought that the function of Gla is to assist in the binding of

```

Ca^{2+} which helps to tie these proteins to the phospholipids of platelet surfaces. In factors VII, IX, X, and protein C this Ca^{2+}-binding domain is followed by two epidermal growth factor (EGF)-like domains, each containing one residue of *erythro*-β-hydroxyaspartate or hydroxyasparagine formed by hydroxylation of an aspartate or asparagine residue in the first EGF-like domain.[540,540a,b] The C-terminal catalytic domain of each enzyme contains the protease active site.

Fibrinogen is an elongated molecule with an $(\alpha\beta\gamma)_2$ structure.[524,541,541a] Thrombin cleaves specific Arg-Gly bonds in the α and β chains releasing short (14- to16-residue) "fibrinopeptides" from the N termini of the peptide chains. This leaves Gly-Pro-Arg "knobs" at

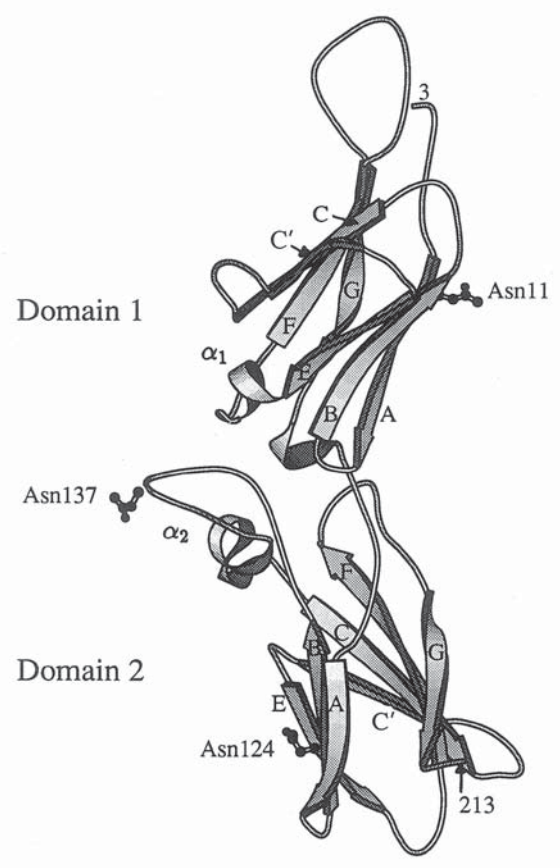

Figure 12-18 A ribbon drawing of the three-dimensional structure of the extracellular region (residues 3 to 213) of human tissue factor. Strands of domain 1 and 2 are labeled A to G. Two helices are labeled α_1, and α_2 and the three asparagines that provide the glycosylation sites are also marked. MolScript drawing from Harlos *et al.*[520]

the N termini of the α-chains and these fit into complementary "holes" in the γ chains to form noncovalently linked aggregates.[542–544] The clot that forms is unstable, but it is soon crosslinked by the action of the **transamidase** (transglutaminase or **factor XIIIa**; Eq. 2-23).[545,546] The fibrin monomers, von Willebrand factor (discussed in following paragraphs), fibronectin, collagen, and other proteins all become crosslinked.

The slower **intrinsic mechanism** first described in 1964[547,548] consists of a cascade involving six proteases (Fig. 12-17, left side). Again, autocatalytic cycles are present in the activation by XIIa of both prekallikrein[549] and XII and in activation by thrombin of factors XI and VIII. This intrinsic pathway is initiated by the serine protease proenzymes prekallikrein and factor XII together with the accessory protein high-molecular-mass-H- kininigen.[549] Activation occurs when blood contacts surfaces such as glass or kaolin (a clay).[547,548,550] Factor XI can also be activated by thrombin. Heredity absence of factor XI leads to bleeding problems, especially after surgery, but absence of XII does not. This fact suggests that direct activation of XI by thrombin is important and that the kallikrein–factor XII pathway is usually less important.

Factor IX (Christmas factor) is next in the intrinsic mechanism cascade. It can be activated either by XIa or by VIIa of the tissue factor pathway. The absence of a functional factor IX leads to the inherited X-linked bleeding disorder **hemophilia B** which affects 1 in 30,000 males. The condition can be mild or very serious[551,552] and may be caused by a variety of mutations or by incorrect splicing of the messenger RNA for the 416-residue factor IX. The level of factor IX in blood increases with age, almost doubling by old age.[552a]

Factor IXa causes a rapid activation of factor X only if Ca^{2+}, phospholipid,[553,554] and the accessory factor VIIIa[555] are present. The IXa•VIIIa complex acts on X about 2×10^5 times faster than does IXa alone. This complex cleaves the same bonds in X as does the VIIa•Va complex formed in the tissue factor pathway.[514] The 2332-residue factor VIII and factor V have similar structures that include three repeats of a domain homologous to the blue copper-containing plasma protein **ceruloplasmin** (Chapter 16).[556–559] Tyrosine 1680 of VIII apparently must be converted to a sulfate ester for full activity.[560]

The absence of factor VIII in about 1/10,000 males born, leads to the severe X-linked bleeding disorder **hemophilia A**. Human factor VIII is encoded by a 186-kb gene containing 26 coding exons. Severe cases of hemophilia are usually a result of point mutations that produce stop codons in this gene and therefore a shortened protein. Milder cases may result from an amino acid substitution.[561] Factor VIII circulates in the plasma as a complex with the **von Willebrand factor**, (vWF), a large multimeric protein derived by proteolytic cleavage, glycosylation, and sulfation of a 2813-residue precursor.[562–566] The mature 2050-residue vWF stabilizes factor VIII in the blood. Another important function of vWF is to bind platelets to damaged endothelial surfaces.[567,568] Like fibrinogen, vWF contains RGD sequences specific for binding to adhesion receptors.[569,570] It also binds to collagen. A serious inherited bleeding disorder caused by deficiency of vWF was first discovered among inhabitants of islands in the Gulf of Bothnia, Finland, in 1926 by von Willebrand.[563,571] If mild forms of the disease are included, vWD deficiency is the commonest bleeding problem. However, abnormalities have been identified in almost every one of the proteins in the coagulation cascades.[514]

Until recently, these bleeding diseases were treated by regular injections of the appropriate factors isolated from human plasma. This was both costly and carried a high risk of infection by HIV, hepatitis, or other contaminating viruses. Now, cloned genes are used for commercial production of the factors.[572,573] Experiments in animals, designed to lead to eventual gene

replacement therapy, have been somewhat successful.[573,574] It is of interest to compare the relative concentrations of several of the clotting factors in plasma and to compare these with their positions in the cascade of the tissue factor (extrinsic) pathway.[515]

	mg / L	Mass kDa	μM
VII	0.5	45.5	0.01
V	10.0	330	0.03
Prothrombin	150	72	2.1
Fibrinogen	3,000	340	8.8

Why do we have the intrinsic pathway when the tissue factor pathway provides rapid clot formation? The answer seems to be that the tissue factor pathway is needed immediately after injury but that it is turned off quickly by the **anticoagulation systems** of the body. As a result the protease **plasmin** begins to dissolve (lyse) the clot within a few hours. The intrinsic pathway is apparently needed to maintain the clot for a longer period.[514]

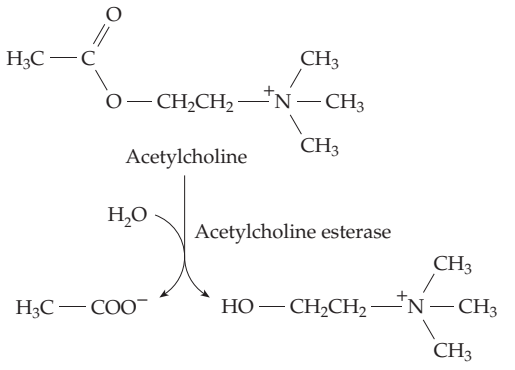
What prevents the clotting mechanism, with its autocatalytic cycles, from running out of control? In part the answer lies in the localization of the enzymatic activation to tissue surfaces near a wound. The flow of blood rapidly dilutes components that escape into the general circulation and liver cells take up and destroy the active proteases. A variety of circulating antiproteases including the **tissue factor pathway inhibitor**[575] act on these escaped enzymes. Two anticoagulation systems that are localized on vessel walls[576] also come into action very quickly. The circulating polysaccharide heparin (Chapter 4) forms a complex with the serpin **antithrombin**. Antithrombin traps thrombin as an inactive complex or compound[577,578a] and heparin greatly accelerates the inactivation.[578] Kallikrein and factors IXa, Xa, XIa, and XIIa are also inhibited.

Thrombin is an allosteric protein which exists as a mixture, in nearly equal amounts, of a fast-acting form that cleaves fibrinogen and is stabilized by Na^+, and a slow-acting form that initiates the second anticoagulant cascade.[579] The slow acting form, bound to **thrombomodulin**,[527a,540b,580,580a,b,581] an endothelial cell surface protein, attacks the proenzyme of another serum protease called **protein C**.[582,582a] Activated protein C (APC) inactivates the accessory clotting factors Va and VIIIa. The accessory factor **protein S**[583] is also needed for rapid inactivation. A blood clot is temporary and its dissolution begins as soon as it is formed, largely through the action of plasmin, a protease derived from the circulating 791-residue **plasminogen**[584–588] through the action of yet other proteases. Plasminogen often becomes crosslinked to cell surface proteins by transglutaminase.[586] Plasminogen activators include **urokinase**,[589] a protease present in kidney tissue and urine, and **tissue plasminogen activator** (tPA),[590,591] a 527-residue protease which is now produced by recombinant DNA technology. It is sometimes used to dissolve blood clots in emergency situations, such as myocardial infarction and pulmonary embolism,[592] but can also cause serious bleeding problems. Plasmin is inhibited by the plasma **α_2 antiplasmin** and is inactivated by action of clotting factor XIIa. Likewise, tPA is inhibited by several protease inhibitors present in tissues and in plasma. One is a fast-acting serpin called plasminogen activator inhibitor.[593] Another anticoagulant compound of medical interest is **hirudin**, a 65-residue peptide from the leech. It binds very tightly to thrombin (K_d = 1 pM) preventing its action.[594–596] Insects also produce antithrombin.[597,598] Ticks[599,600] and some insects[598] inject proteins that inhibit Xa selectively.[599] Anticoagulants are of great medical importance and much effort is being devoted to the design of better inhibitors of thrombin,[601–603] factor Xa,[604] and other components of the blood coagulation cascade.

Inherited deficiencies of the anticoagulant pathways with associated problems of thrombosis are known. These include problems with protein C,[576,605] plasminogen,[606] and antithrombin.[607,608]

10. Esterases and Lipases

A group of esterases hydrolyze simple oxygen esters. Some of these are designed to hydrolyze a particular ester or small group of esters, while others have a more nonspecific action. **Acetylcholinesterase**[609–611a] is specific for acetylcholine (Eq. 12-25), a neurotransmitter that is released at many nerve synapses and neuromuscular junctions (Chapter 30). The acetylcholine, which is very toxic in excess, must be destroyed rapidly to prepare the synapse for transmission of another impulse:



(12-25)

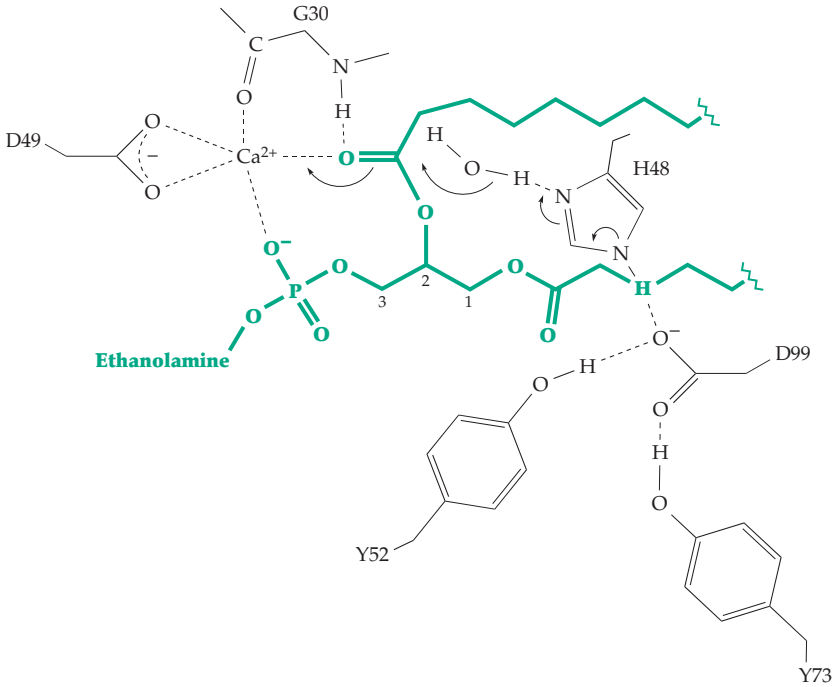
The more widely distributed **butyrylcholinesterase**[612] is less specific but prefers butyrylcholine. Acetylcholinesterase is a very efficient catalyst:[613–615] $k_{cat} = 1.6 \times 10^4\ s^{-1}$

and $k_{cat}/K_m = 2 \times 10^8\ M^{-1}s^{-1}$ at 25°C. It exists as a series of molecular forms containing varying numbers of 68-kDa catalytic subunits, 100-kDa structural subunits and subunits with triple-helical ~120-kDa collagen-like "tails."[609,616] The subunits are joined by disulfide bridges to give aggregates that range from simple dimers of catalytic subunits to tailed forms containing 8–12 catalytic subunits and non-collagenous structural subunits as well. The tailed forms are secreted from cells and may be designed to take up residence in the basal lamina of synapses, whereas the dimers are apparently attached to phosphatidylinositol anchors in the membranes (Fig. 8-13).[617] Human liver **carboxylesterases** are relatively nonspecific enzymes that hydrolyze ester groups of various drugs and toxins including cocaine and heroin. Products are often excreted in the urine.[618] **Thioesterases** function in biosynthesis of fatty acids, polyketides (Chapter 21), and many other substances.[619]

Lipases[620,621] hydrolyze triacylglycerols. The pancreatic digestive lipase[622,623] acts faster on emulsified fats than on glycerol esters in true solution but requires the cooperation of a small 10-kDa **colipase**.[624] **Cholesterol esterase** hydrolyzes not only cholesterol esters but also esters of fat-soluble vitamins, phospholipids, and triacylglycerols.[625,626] Other lipases include gastric[627] and hepatic lipases and a **lysosomal acid lipase**[628] which also attacks neutral lipids. Plasma **lipoprotein lipase**[629,630] digests fats in the chylomicrons and from the very low-density lipoproteins of blood. **Hormone-sensitive lipase** hydrolyzes stored triacylglycerols in the cytosol in response to catecholamines, ACTH, and other hormones.[631] The **phospholipases** attack phospholipids, while **cutinase**,[632] produced by some fungi, cleaves the ester linkages in the cutin (Chapter 21) of plant surfaces. Fungal lipases are important industrial commodities. Numerous structural and mechanistic studies have been made with them.[620,629,633–635] The gene for a lipase from *Candida rugosa* has been synthesized using codons that maximize its expression in *Saccharomyces cerevisiae* and which allow for further genetic engineering of the lipase.[636]

All of these esterases appear to act by mechanisms closely related to those of proteases. Acetylcholinesterase contains an active site serine that reacts with organophosphorus compounds (Box 12-E) and is part of an Asp-His-Ser catalytic triad which lies in a deep "gorge" as well as an oxyanion hole.[637] A surprise is the absence of an essential carboxylate group that might bind the positively charged trimethylammonium group of acetylcholine. Instead, the lining of the gourge is rich in aromatic side chains which may interact with the methyl groups of the substrate and by their polarizability stabilize the charge.[611,638] Most lipases, including cutinase, also have an Asp-His-Ser or Glu-His-Ser triad as well as some form of oxyanion hole.[620,632,639] Like the serine proteases, the lipases have bell-shaped pH optima.

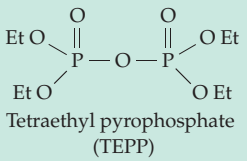
Phospholipase A_2 cleaves the ester linkage at the 2 position in phospholipids.[640–642] One isoenzyme form is secreted by the pancreas as a proenzyme whose N-terminal seven residues are removed by trypsin to give an active 125-residue enzyme. Phospholipase A_2 of a similar type is abundant in venoms of reptiles and bees. The venom and pancreatic enzymes have closely similar three-dimensional structures.[643–645] Although the folding pattern is different from that of chymotrypsin, imidazole (His 48) and carboxylate (Asp 99) groups are present in the active site in an orientation resembling that of the catalytic triad of serine protease. The enzyme requires calcium ions, one of which binds at an appropriate point for complexation with the substrate carbonyl as it is converted to an oxyanion intermediate. The backbone NH of Gly 30 may also serve as an oxyanion ligand. However, in most phospholipases there is no active site serine. Instead, a water molecule is positioned to serve as the attacking nucleophile in formation of the oxyanion as is indicated in the following scheme, which shows a truncated phosphatidylethanolamine as the substrate.[643] Phospholipase A_2 is up to 1000 or more times as active on phospholipids in micelles as on dissolved substrates.[621,646,647] Apparently, the



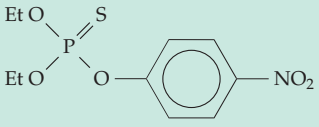
BOX 12-E INSECTICIDES

Over 200 organic insecticides, designed to kill insects without excessive danger to humans and animals, are presently in use.[a–e] Many of these compounds act by inhibiting cell respiration; others uncouple ATP synthesis from electron transport. The chlorinated hydrocarbons such as DDT act on nerves in a manner that is still not fully understood. One of the largest classes of insecticides acts on the enzyme acetylcholinesterase of nerve synapses. Like chymotrypsin, it contains an active site serine residue that reacts with organophosphorus compounds. The extreme toxicity of esters of pyrophosphate and of dialkylphosphonofluoridates was recognized in the 1930s and led to their development in Germany and in England as insecticides and as nerve gases. Among the most notorious is diisopropylphosphonofluoridate (diisopropylfluorophosphate; DFP), for which the LD_{50} (dose lethal to 50% of the animals tested) is only 0.5 mg kg^{-1} intravenously. This exceedingly dangerous compound can cause rapid death by absorption through the skin.

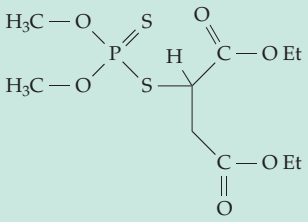
The following structures are a few of the organophosphorus compounds and other acetylcholinesterase inhibitors that are selectively toxic to insects.



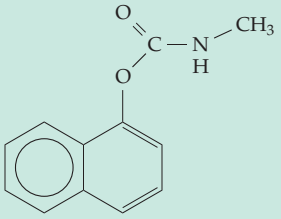
Tetraethyl pyrophosphate (TEPP)



Parathion



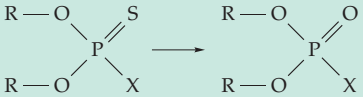
Malathion



Carbaryl

The characteristic high group transfer potential of a phospho group in pyrophosphate linkage, which makes ATP so useful in cells, also permits tetraethyl pyrophosphate to phosphorylate active sites of acetylcholinesterases. While TEPP is very toxic, it is rapidly hydrolyzed; all harmful residues are gone within a few hours after use.

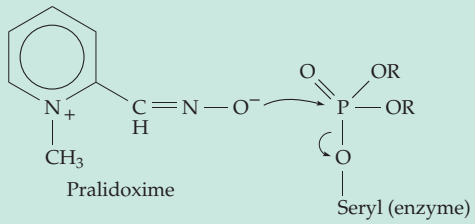
Two insecticides that have been used widely are **parathion** and **malathion**. They are less toxic than DFP or TEPP and do not become effective insecticides until they undergo bioactivation during which conversion from a P = S to a P = O compound occurs:



Highly toxic

The desulfuration reaction involves microsomal oxidases of the liver, the sulfur being oxidized ultimately to sulfate.[f] The reactivity of parathion with cholinesterases depends upon the high group transfer potential imparted by the presence of the excellent leaving group, the *p*-nitrophenolate anion. If the P– O linkage to this group is hydrolyzed before the desulfuration takes place, the phosphorus compound is rendered harmless. Thus, the design of an effective insecticide involves finding a compound which insects activate rapidly but which is quickly degraded by higher animals. Other factors, such as rate of penetration of the insect cuticle and rate of excretion from the organism, are also important.

The phosphorylated esterases formed by the action of organophosphorus inhibitors are very stable, but some antidotes can reverse the inhibition. The oxime of 2-formyl-1-methylpyridinium ion (pralidoxime) is very effective.[g] Its positive charge permits it to bind to the site normally occupied by the quarternary nitrogen of acetylcholine and to displace the dialkylphospho group:



Pralidoxime Seryl (enzyme)

Carbaryl, a widely used methyl carbamate, is a pseudosubstrate of acetylcholinesterase that reacts 10^5 to 10^6 times more slowly than do normal substrates. The carbamoylated enzyme formed is not as stable as the phosphorylated enzymes and the inhibition is reversible.

A basic problem is that most insecticides are designed to attack the central nervous system of the insect, the system that depends heavily upon acetylcholine. However, in human beings the readily accessible peripheral nervous system also depends upon acetylcholine, e.g., in neuronuscular junctions. The danger of poisoning is great. Another approach is to attack the glutamate-dependent peripheral system in insects, e.g., with inhibitors of glutamate decarboxylase. Glutamate functions as a neurotransmitter in the human body but only in the well-

BOX 12-E (continued)

protected central nervous system.

Another important problem is the development of insects resistant to insecticides. This often arises as a result of increased levels of carboxylesterases which hydrolyze both organophosphates and carbaryl.[h,i] A mutation that changed a single active site glycine to aspartate in a carboxylesterase of a blowfly changed the esterase to an organophosphorus hydrolase which protected the fly against insecticides.[j]

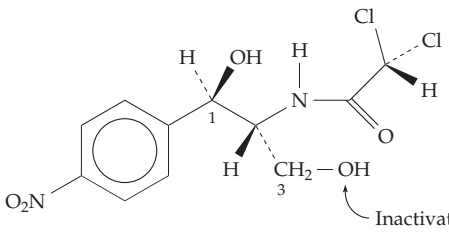
substrate-binding cavity of the protein is designed to accommodate phospholipid molecules in the preferred conformation found in the micelles.[643] Most of the other lipases have lids which close over the active sites and impede access of substrates. Binding to a phospholipid surface apparently induces a conformational change that opens the lid. This allows substrate to enter from the lipid surface.[620,621,646] Cutinases, which do not display interfacial activation, do not have lids. Phospholipase A_2 activity is stimulated by an applied electrical field, a result that suggests that its activity *in vivo* may be regulated in part by the membrane potential.[648]

11. Other Acyltransferases

Acyl groups are frequently transferred from amides or esters to various acceptors in biosynthetic reactions. Among the many known acyltransferases are the ribosomal **peptidyl transferases** (Chapter 29), a transacylase involved in bacterial peptidoglycan synthesis (Chapter 20), transglutaminase (Eq. 2-23),[649,650] γ-glutamylcyclotransferase (Box 11-B), and transacylation reactions involving acyl-CoA derivatives. Examples of the latter are *N*-acetylation[651] or myristoylation (Chapter 8) of proteins, the formation of acetylcholine from choline[652] and of acetylcarnitine from carnitine (Eq. 17-4), and acetylation of the antibiotic chloramphenicol. The high group transfer potential of thioesters ensures that these reactions proceed to completion. **Chloramphenicol acetyltransferase** (**CAT**),[653] the enzyme that catalyzes acetylation and inactivation of the antibiotic by bacteria, is much used in studies of gene expression (Chapter 28). A catalytic histidine removes the proton from the 3-OH group and a serine hydroxyl provides an oxyanion hole to accommodate the anticipated tetrahedral intermediate.[652,654] The steroidal antibiotic fusidic acid (Chapter 22, Section G) is a competitive inhibitor.[655] A related transferase is aspartate carbamoyltransferase (Fig. 7-20; Chapter 24).



Chloramphenicol, a broad-spectrum *Streptomyces* antibiotic

Penicillin and related antibiotics are inactivated by β-lactamases (Box 20-G), some of which resemble serine proteases in forming acyl enzymes with active site serine side chains.[656,657] Others are zinc metallogenzymes.[658,659] **Amidohydrolases** such as **asparaginase** and **glutaminase,**[660,661] deacetylases,[662] and many other hydrolases can also be described as acyltransferases.

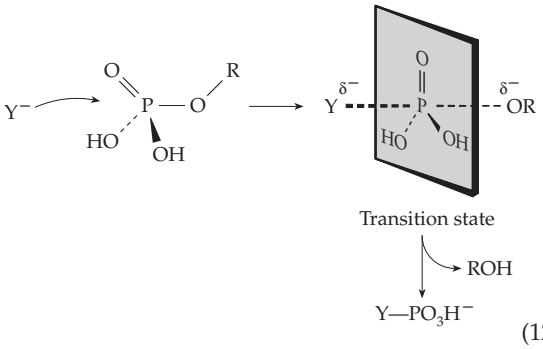
D. Displacement on a Phosphorus Atom

Nucleophilic displacements on phosphorus (Table 10-1, reaction type 1C) are involved in virtually every aspect of cellular energetics and in many aspects of biosynthesis. One large group of such enzymes are **phosphotransferases**, which transfer **phospho** (also called **phosphono** or, traditionally in biochemistry, **phosphoryl**) groups from one nucleophilic center to another. When transfer is to water the enzymes are called **phosphatases**, and when from one group in a molecule to another in the same molecule, **mutases**.

Enzymes that transfer a phospho group from ATP to water are **ATPases** and those that transfer the phospho group from ATP to some other nucleophile are **kinases**. Substituted phospho groups can also be transferred. Thus, **nucleases**, members of a larger class of **phosphodiesterases**, hydrolyze nucleic acids by transfer of nucleotidyl groups to a hydroxyl group of water. **Polynucleotide polymerases** transfer nucleotidyl groups to growing polynucleotide chains. An intramolecular nucleotidyl transferase is adenylate cyclase. **Topoisomerases** carry out a sequence of phosphotransferase reactions.

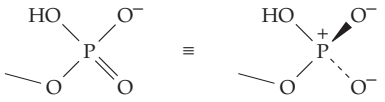
1. Questions about Mechanisms

Consider the following general equation for transfer to nucleophile Y^- of a phospho group attached in an ester or an anhydride linkage to form ROH, which could be an alcohol, carboxylic acid, or a phosphoric acid such as ATP.



(12-26)

This equation could also represent a half-reaction in a double-displacement process. As with displacements on saturated carbon atoms, two basic mechanisms can be imagined. The first is S_N2-like or **associative**.[663–667] The transition state might be represented where the bonds from the phosphorous atom to Y and to O are approximately equally formed. In an **in-line** displacement, where Y, P, and –OR are colinear, this mechanism leads to inversion if a chiral phospho group is used. There is another possibility for the associative mechanism. Whereas a carbon atom can form only four stable covalent bonds, phosphorus is able to form five. While nucleophilic attack on carbon leads to a *transient* five-bonded transition state (Eq. 12-2), attack on phosphorus could produce a relatively long-lived pentacovalent intermediate (Eq. 12-27). Notice that two transition states are involved. Remember that our conventional way of drawing phosphate esters with a double bond from phosphorus to one of the oxygens is misleading. All of the P–O bonds share some of the double-bond character and the phosphate group has many characteristics of a completely single-bonded structure:

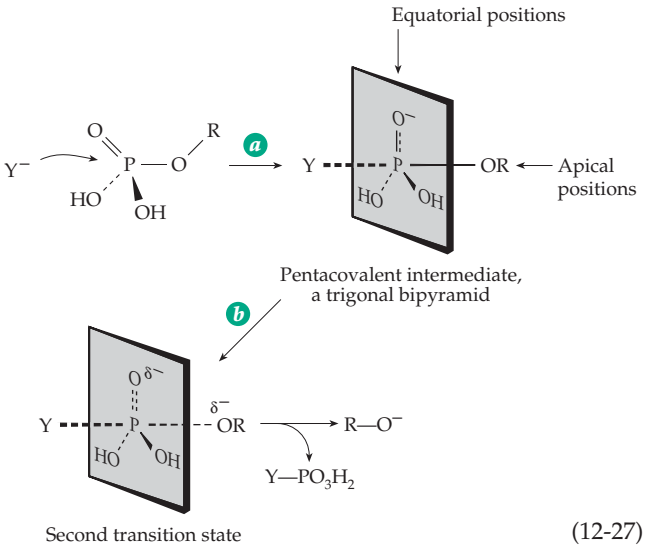


Likewise, in the transition state structures of Eq. 12-27, step *b*, the P–O bonds, except for that to –OR, are equivalent and all have partial double-bond character.

Geometric complexities. The geometry of the pentacovalent intermediate in Eq. 12-27 is that of a **trigonal bipyramid**. In this structure the bond angles in the **equatorial** plane are 120°, whereas all of the angles between any of those bonds and the two that attach to the groups in the **apical** positions are 90°. This disparity arises naturally from the fact that it is impossible to place five points on the surface of a sphere all equidistant one from the other. The attack of Y^- from the side opposite O–R (an in-line attack) leads to a trigonal bipyramid in which –O–R and –Y occupy the two apical positions. However, if Y^- attacks a face opposite one of the other oxygens (**adjacent** attack), –O–R will take an equatorial position.

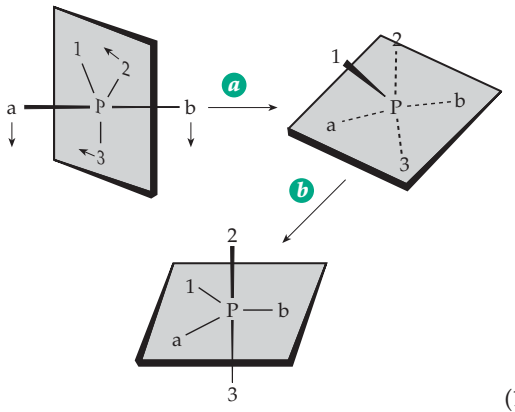
The chemical reactivities of groups in the apical and equatorial positions of pentacovalent intermediates are different.[664] In particular, elimination of a nucleophilic group to form a tetrahedral phosphate is easier from an apical position than from an equatorial position. For the in-line displacement of Eq. 12-27 elimination of RO^- should be easy. However an adjacent attack would leave –OR in an equatorial position. Before it could be eliminated, the intermediate would probably have to undergo a **permutational rearrangement** by which –OR would be transferred from an equatorial to an apical position.

One type of permutational rearrangement, known as **pseudorotation**, can be visualized as in Eq. 12-28.[668,669] The axial groups a and b move back while equatorial groups 2 and 3 move forward, still in the same equato-



(12-27)

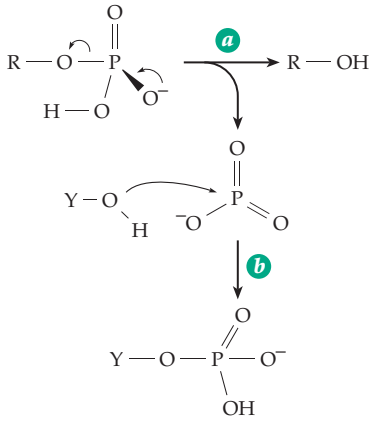
rial plane. Equatorial group 1 does not move. This decreases the 120° bond angles between the equatorial groups and increases the bond angles between group 1 and the axial groups until all four bond angles to group 1 are equivalent. The resulting **square pyramid** is a high-energy transition state structure in the pseudorotation process and can either revert to the original structure or, by continued motion of the groups in the same directions as before, to the structures shown at



(12-28)

the bottom of Eq. 12-28. In the final structure, groups 2 and 3 are axial and the original axial groups a and b are equatorial. Pseudorotation is slow enough that it could be rate limiting in enzymatic reactions. Stereoelectronic effects could also affect these rates.[670,671] However, much evidence indicates that enzymes almost always avoid these complexities by using in-line mechanisms.

Metaphosphate ions. An alternative to an associative mechanism is an S_N1-like or **dissociative** mechanism which can occur by elimination of a **metaphosphate ion** (Eq. 12-29, step *a*). A nucleophilic reagent can then add to the eliminated metaphosphate in step *b*. The formation of metaphosphate is analogous to formation of carbocation during the action of lysozyme (Eq. 12-11). This dissociative mechanism could lead either to racemization or to inversion of a chiral phosphate. Metaphosphate ions have been shown to exist. They are generated in certain nonenzymatic elimination reactions in aprotic solvents[672–674] and they are reactive electrophiles able to react as in Eq. 12-29. However, there is some doubt that they can exist free in aqueous media.[675] Jencks and associates concluded from studies of linear Gibbs energy relationships that in the transition state for nonenzymatic phospho transfer reactions there is a large amount of bond breaking and a small amount of new bond formation in the transition state[676] but no free metaphosphate. There is a large dependence of the rate on the pK_a of the leaving group, but there is still a small dependence on the pK_a of the entering nucleophile. Thus, we have *a*



(12-29)

dissociative mechanism but without free metaphosphate. The concept is supported by studies of kinetic isotope effects.[677,678]

Coping with negative charges. We visualize phospho group transfers as involving attack by a nucleophile bearing at least a partial negative charge. However, phospho groups also carry one or two negative charges and that in ATP even more. Therefore, it does not seem surprising that many phosphotransferases are metalloenzymes, sometimes containing bound Zn^{2+} which neutralizes some of the negative charge. Furthermore, enzymes usually accept ATP as a substrate only when it is accompanied by a divalent metal ion,[679] usually Mg^{2+}. Another way in which enzymes deal with the negative charges on phospho groups is to have arginine side chains in appropriate positions to interact by forming strong ion paired-hydrogen bonds. It is often assumed that it is essential to neutralize the charge on the phospho group to avoid electrostatic repulsion from a partial or complete negative charge on the attacking nucleophilic center. However, with a dissociative mechanism and a metaphosphate-like intermediate the transition state may be reached without charge neutralization.[679,680] Interactions of Mg^{2+} with phosphorus-containing substrates, like those of fixed positive charges in the protein may also be essential for binding the substrate correctly to an enzyme.

2. Magnetic Resonance Studies

There have been many investigations of phosphotransferases by NMR and EPR methods.[681,682] One approach is to use paramagnetic ions such as Mn^{2+}, Cu^{2+}, or Cr^{3+} to induce nuclear relaxation in substrate and coenzyme molecules at active sites of enzymes. Flavin radicals and specifically introduced nitroxide spin labels can serve as well. Paramagnetic ions greatly increase the rate of magnetic relaxation of nearby nuclei (Chapter 3, Section I). Thus, small amounts of

Mn^{2+} in a sample lead to broadening of lines in ordinary ^{1}H, ^{13}C, and ^{31}P NMR spectra.

Useful information about enzymes can sometimes be obtained by observing effects of paramagnetic ions on the NMR signal of protons in the solvent water. The relaxation time of solvent protons is usually greater than 1 s. However, in the ion $Mn(H_2O)_6^{2+}$ the protons of the coordinated water molecules relax much more rapidly, both T_1 and T_2 being $\sim 10^{-1}$ s. Since the coordinated water molecules usually exchange rapidly with the bulk solvent, a small number of manganese ions can cause a significant increase in relaxation rate for all of the water protons. Broadening of the proton band is observed and differences in T_1 and T_2 can be measured by appropriate methods. Paramagnetic relaxation effects usually increase as the inverse sixth power of the internuclear distance. Knowing the Mn^{2+}–H distance to be 0.287 ± 0.005 nm for hydrated Mn^{2+}, it has been possible to relate the effects on T_1 and T_2 to the number of H_2O molecules coordinated at any one time to a protein-bound metal ion and to their rate of exchange with the bulk solvent.

Relaxation effects on ^{1}H, ^{13}C, and ^{31}P, while more difficult to observe, can provide geometric information about active sites. The theory is complex, but under some conditions the paramagnetically induced relaxation can be described adequately by Eq. 12-30.

$$r = C[T_{1M} f(\tau_c)]^{1/6} \qquad (12\text{-}30)$$

Here r is the internuclear distance, C is a combination of physical constants, and T_{1M} is the longitudinal relaxation time. The complex function $f(\tau_c)$ depends upon the correlation time τ_c, the resonance frequency of the nucleus being observed, and the frequency of precession of the electron spins at the paramagnetic centers. The value of τ_c can be estimated (Chapter 3) and, in turn, the distance r according to Eq. 12-30.

Such studies on creatine kinase (Eq. 12-31) utilized both a bound Mn^{2+} ion and a nitroxide spin label to estimate distances of various protons from the nitroxide.[683] Together with EPR measurements (Box 8-C), which gave the Mn^{2+}–nitroxide distance, a model of the ATP•Mn^{2+} complex in the active site was constructed. Additional EPR experiments on Mn^{2+} complexes with ATP and ADP containing ^{17}O in the α, β, or γ phospho groups showed that in the enzyme•ATP• creatine complex the metal ion is bound to all three phospho groups of ATP. It remained coordinated with the two phospho groups of ADP and also that of the phosphocreatine product in the enzyme•ADP•creatine-*P* complex as well as in the transition state, which is pictured occurring via a metaphosphate ion.[684]

$$\text{Creatine-}P + \text{ADP} \underset{k_r}{\overset{k_f}{\rightleftharpoons}} \text{ATP} + \text{creatine} \qquad (12\text{-}31)$$

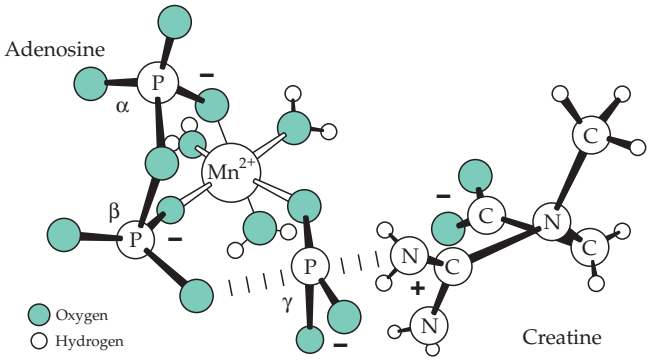


Figure 12-19 Proposed transition state structure formed from Mn^{2+}, ATP, and creatine bound in the active site of muscle creatine kinase. Based on EPR spectroscopy with regiospecifically ^{17}O-labeled substrates. The electrical charges have been added in one possible constellation. However, hydrogen atoms bound to phospho groups are not shown. After Leyh *et al.*[684]

Phosphorus-31 NMR has been used to measure **internal equilibrium constants** within enzyme-substrate (ES) complexes.[663,685–687] By having both substrate and product concentrations high enough to saturate the enzyme, all of the enzyme exists as ES and enzyme–product (EP) complexes in equilibrium with each other. For a phosphotransferase at least one substrate and one product contain phosphorus. Although the NMR resonances are broadened by binding to the large, slowly tumbling protein, their areas can be measured satisfactorily and can be used to calculate an equilibrium constant such as that for Eq. 12-32:

$$\text{ES} \underset{k_r}{\overset{k_f}{\rightleftharpoons}} \text{EP}$$

$$K' = [\text{EP}]/[\text{ES}] \qquad (12\text{-}32)$$

An example is illustrated in Fig. 12-20. In this experiment[685] the relative areas of the ^{31}P signals of ADP (one for free ADP and one, slightly more intense, for MgADP) and of the signal for phosphoenolpyruvate (PEP) were measured in the absence of enzyme and in the presence of a catalytic amount of pyruvate kinase (Fig. 12-20A). The results verified that the equilibrium constant for the overall reaction (Eq. 12-33) is very high (3300).

$$\text{Phosphoenolpyruvate (PEP)} + \text{ADP} \rightarrow \text{ATP} + \text{pyruvate} \qquad (12\text{-}33)$$

However, with an excess of enzyme (Fig. 12-20B) the internal constant was estimated as

$$K' = \frac{[E \bullet MgATP \bullet pyruvate]}{[E \bullet MgADP \bullet PEP]} = 0.5 - 1.0 \qquad (12\text{-}34)$$

This is a difficult measurement and reinvestigation by another group[686] indicated that the amount of the PEP-containing complex had been overestimated and that K′=10.

If the rates of the forward and backward reactions in Eq. 12-34 are of the same order as the spin-lattice relaxation times (T_1) of the ^{31}P in the bound substrate and product, the rate constants k_f and k_r can be evaluated by **saturation-transfer NMR**.[688] This is done by irradiating one resonance, e.g., that of the γ-P of ATP, and observing whether this causes a loss of intensity of the resonance for the product which is receiving its phospho group from ATP. This technique was used to observe the creatine kinase reaction (Eq. 12-31) in living muscle in both relaxed and contracting states. For resting muscle the observed forward flux was 1.7×10^{-3} M s^{-1} and the backward flux 1.2×10^{-3} M s^{-1}. Thus, this reaction, which supplies ATP for contraction of the muscle from stored phosphocreatine, appears to be operating at or near equilibrium. This had been assumed but had previously been difficult to prove. Two-dimensional NMR techniques can now be used for this kind of measurement.[689]

When ^{31}P is bonded to ^{18}O the chemical shift of the ^{31}P is altered by 0.0206 ppm from that when the phosphorus is bonded to ^{16}O. This allows ^{18}O labels introduced into phospho groups to serve as tracers which can be followed continuously during reactions.[683] The technique is useful in studies of stereochemistry (see Section 2) and for examination of **positional isotope exchange**.[690] This latter technique is often used with ATP containing ^{18}O in the β,γ-bridge position. If an enzyme transfers the terminal (γ) phospho group to an acceptor via a phosphoenzyme but without loss of the ADP, we may expect positional isomerization. The ^{18}O will move between the β,γ-bridge position and a nonbonding position as the phospho group is repeatedly transferred back and forth between ATP and the acceptor and as the phospho group rotates.[682,690]

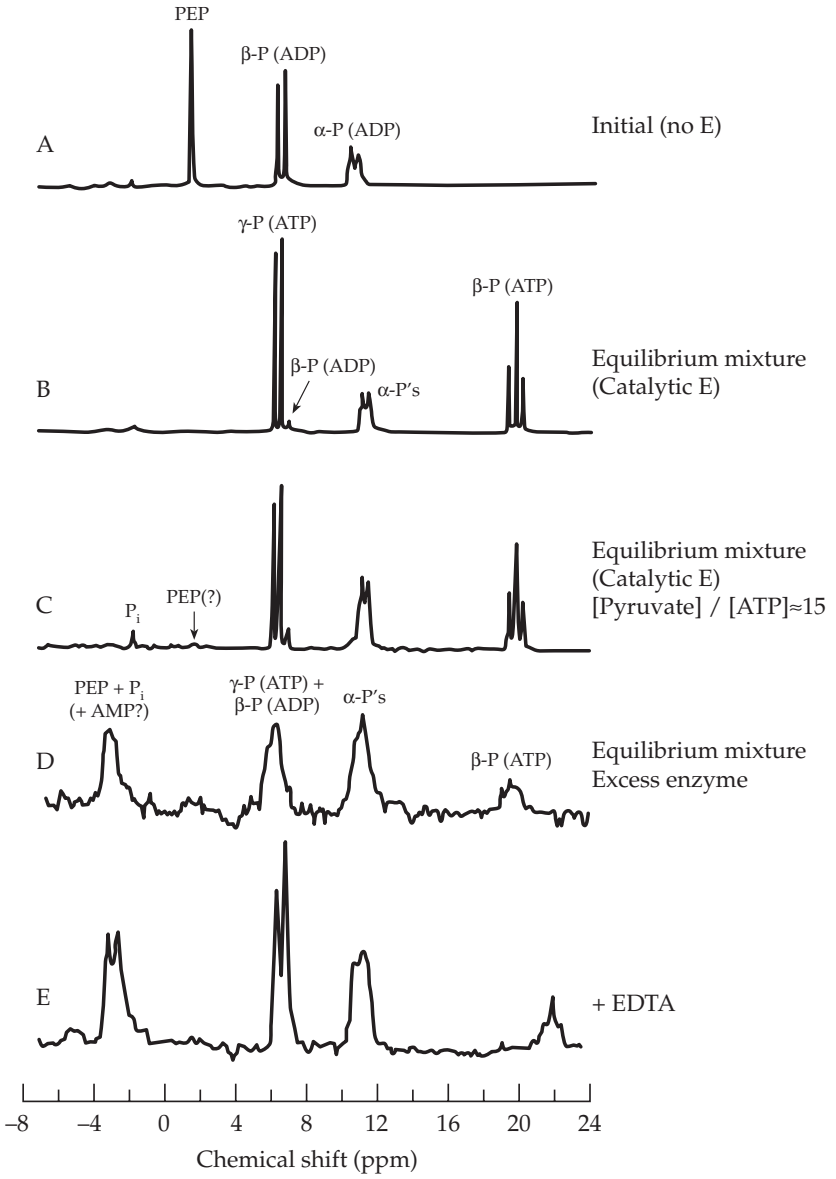

Figure 12-20 Equilibria in pyruvate kinase reaction as studied by ^{31}P NMR at 40.3 MHz, pH 8.0, 15°C. (A–C) Equilibria with low enzyme in levels ~15% ^2H_2O. (A) ^{31}P NMR spectrum of 1.5 ml of reaction mixture; PEP, 13.3 mM; ADP, 14.1 mM; $MgCl_2$, 20 mM; potassium Hepes buffer, 100 mM; KC, 50 mM without enzyme. (B) Equilibrium mixture after the addition of ~1 mg of pyruvate kinase to the reaction mixture. (C) Equilibrium after the addition of potassium pyruvate (final concentration of 200 mM) to the sample of the spectrum in (B). (D,E) Equilibrium with enzyme concentrations in excess of the substrates. Sample volumes ~1.1 ml with 10% ^2H_2O. (D) Equilibrium mixture set up with enzyme (2.8 mM active sites); 2.8 mM PEP; 2.4 mM ADP; 5.7 mM $MgCl_2$; 100 mM potassium Hepes; 100 mM KCl. (E) Spectrum after the addition of 50 µl of 400 mM EDTA (pH readjusted to 8.0) to the sample of spectrum D. The EDTA removes metal ions, stopping the catalytic reactions and sharpening the resonances. From Nageswara Rao *et al.*[685]

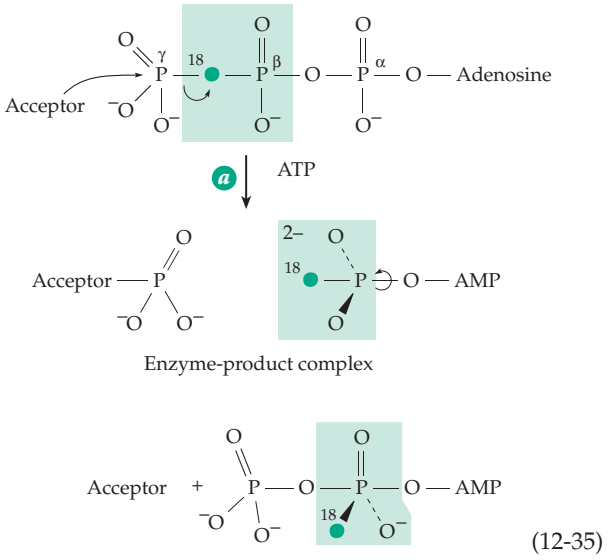
Equation 12-35 shows one part of this isomerization. The negative oxygens have been omitted here to avoid implying a known state of protonation or a localization of charge.

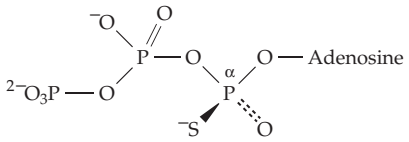


(12-35)

Figure 12-21 illustrates the use of the technique in investigating the possible participation of metaphosphate in a nonenzymatic reaction.

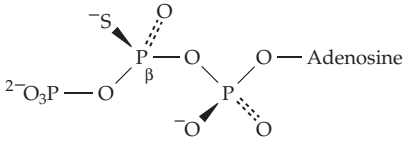
3. Stereochemistry

Evidence for an in-line S_N2-like mechanism of most enzymatic phospho group transfer reactions comes largely from study of chiral phospho groups.[663,692–695] A chiral phosphate can be introduced at either the α or β phosphorus of ATP by substitution of one of the oxygen atoms by sulfur. A chiral phospho group in the β position can be formed by substituting one oxygen by S and a second by ^{18}O.

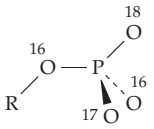


ATP αS (*R* configuration at P)

Notice that the negative charge is largely localized on sulfur in these phosphorothioate compounds.[696] More general is the use of ^{17}O and ^{18}O to form a chiral phospho group:



ATP βS (*S* configuration at P)



An ester chiral at the phosphorus atom; *R* configuration

Considerable ingenuity was required in both the synthesis of these chiral compounds[695,697] and the stereochemical analysis of the products formed from them by enzymes.[698–700] In one experiment the phospho group was transferred from chiral phenyl phosphate to a diol acceptor using *E. coli* alkaline phosphatase as a catalyst (Eq. 12-36). In this reaction transfer of the phospho group occurred without inversion. The chirality of the product was determined as follows. It was cyclized by a nonenzymatic in-line displacement to give equimolar ratios of three isomeric cyclic diesters. These were methylated with diazomethane to a mixture of three pairs of diastereoisomers triesters. These diastereoisomers were separated and the chirality was determined by a sophisticated mass spectrometric analysis.[692] A simpler analysis employs ^{31}P NMR spectroscopy and is illustrated in Fig. 12-22. Since alkaline phosphatase is relatively nonspecific, most phosphate esters produced by the action of phosphotransferases can have their phospho groups transferred without inversion to 1,2-propanediol and the chirality can be determined by this method.

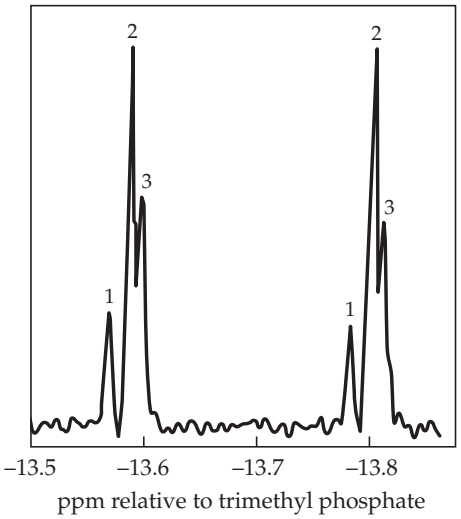


Figure 12-21 The ^{31}P NMR spectrum at 101.2 MHz of P_α of isotopically labeled ADP. This was recovered from an experiment in which ADP containing 87 atom % of ^{18}O in all four oxygens around P_β was allowed to undergo partial (~20%) nonenzymatic hydrolysis to AMP and P_i. Peaks 1 represent the species containing no ^{18}O bonded to P_α. Peaks 2 represent all species with ^{18}O in the P_α–O–P_β bridge, and peaks 3 represent species with ^{18}O in nonbridging positions at P_α. These have undergone positional isotope exchange. From Lowe and Tuck.[691]

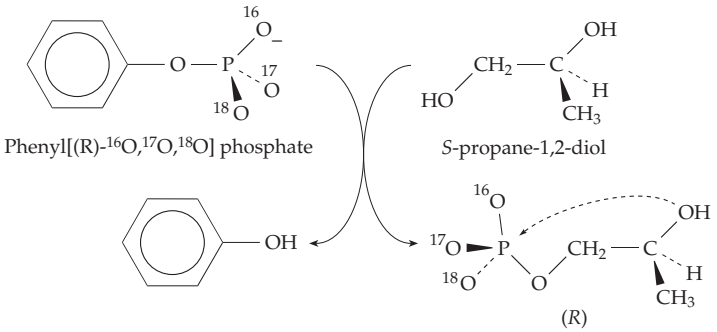
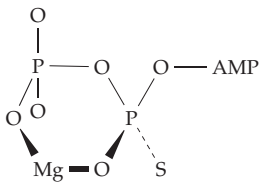


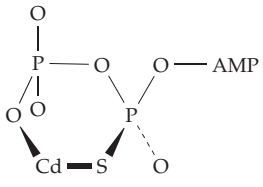
(12-36)

Although inversion was not observed with the *E. coli* alkaline phosphatase, it has been observed for ribonucleases and many other hydrolytic enzymes and for most kinases transferring phospho groups from ATP. The difference lies in the existence of a phosphoenzyme intermediate in the action of alkaline phosphatase (see Eq. 12-38). Each of the two phosphotransferase steps in the phosphatase action apparently occurs with inversion. The simplest interpretation of all the experimental results is that *phosphotransferases usually act by in-line S_N2-like mechanisms which may involve metaphosphate-ion-like transition states that are constrained to react with an incoming nucleophile to give inversion*. An adjacent attack with pseudorotation would probably retain the original configuration and is therefore excluded.

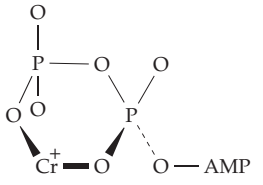
The substrate for many phosphotransferases is MgATP. Which of the possible isomers of this chelate complex is utilized by these enzymes? Since Mg^{2+} associates and dissociates rapidly from the complexes there are several possibilities: a tridentate complex with oxygens from α, β, and γ phospho groups coordinated with the metal ion, an α,β-bidentate, a β,γ-bidentate, or a monodentate complex. Most evidence suggests that β,γ-bidentate complexes of the following types are the true substrates.



Mg–ATP βS complex with Λ screw sense, *R* configuration at P



Cd–AT βS complex with Λ screw sense, *S* configuration at P

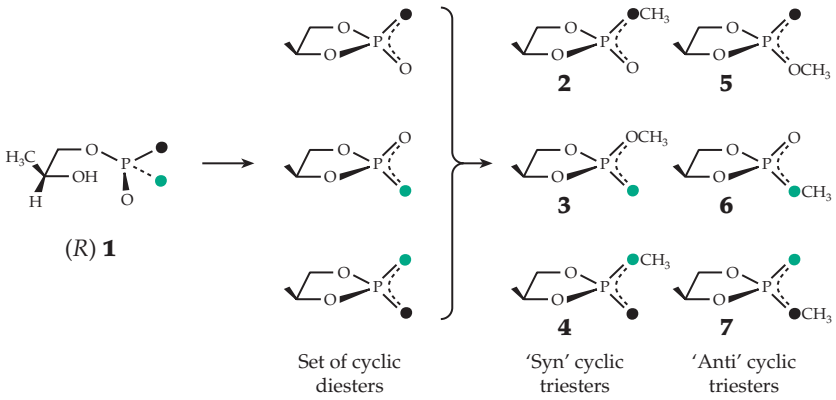


Cr–ATP complex with Δ screw sense

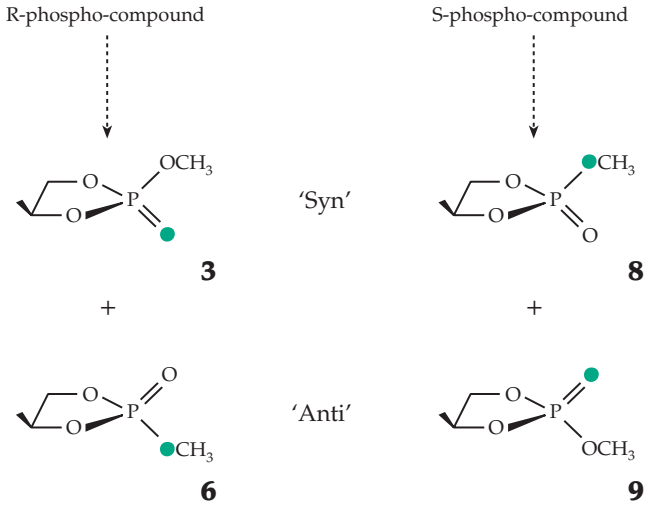
The first structure drawn is for a Mg–ATP *S* complex with a chiral β-phosphothioate group. The Mg^{2+} is expected to bond to oxygen. However, in the second complex, in which Cd^{2+} has been substituted for Mg^{2+}, it is expected that the Cd^{2+} will bond to sulfur. Therefore, the stereochemically equivalent structure will be obtained only when the compound has the *S* configuration at the phosphorus. In the third of the foregoing complexes, Mg^{2+} has been replaced by Cr^{3+} to give an **exchange-inert** complex of ATP in which the Cr^{3+} will remain attached firmly to the same two oxygen atoms under most experimental conditions. Notice also that in this complex, the AMP portion occupies a different position than in the first two complexes. It is called the Δ **screw-sense isomer**,[702] while the upper two complexes are Λ screw-sense isomers. We may reasonably expect that an enzyme, which may provide additional ligands to the metal ions, will prefer one or the other of these screw-sense isomers. For α,β-bidentate ATP complexes both α and β phosphorous atoms become chiral centers and even more isomers are possible.

The use of exchange inert Cr^{3+} and Co^{3+} complexes of ATP has been developed by Cleland and associates.[702–705] The β,γ-bidentate chromium complexes were separated into the Λ and Δ isomers.[704] Each was separated further into a pair of "ring-puckering isomers". These metal complexes are all competitive inhibitors of MgATP and both ring puckering isomers of the Δ screw sense are very slow substrates of various kinases. The Λ isomers serve as very slow substrates for pyruvate kinase, adenylate kinase, and fructose-6-phosphate kinase.[703] The Δ exo isomer is the strongest inhibitor of creatine kinase, suggesting this same conformation for the MgATP substrate. The disastereoisomers of ATPαS and ATPβS have also been tested with kinases in the presence of either Mg^{2+} or Cd^{2+}. With creatine kinase[695,706] the isomers with the R configuration at phosphorus are preferred in the presence of Mg^{2+} but those with the *S* configuration are preferred in the presence of Cd^{2+}. This might be related to the previously mentioned preferences of the metals for O vs. S ligands, and would suggest that this enzyme prefers the Λ isomer (see foregoing structures). However, EPR studies with the corresponding Mn^{2+} complexes suggest that the Δ isomer is preferred by the enzyme.[693] There are 12 isomers of monoammine Cr(III)ATP. Their use has provided information about the location of water molecules in metal complexes of kinases.[707]

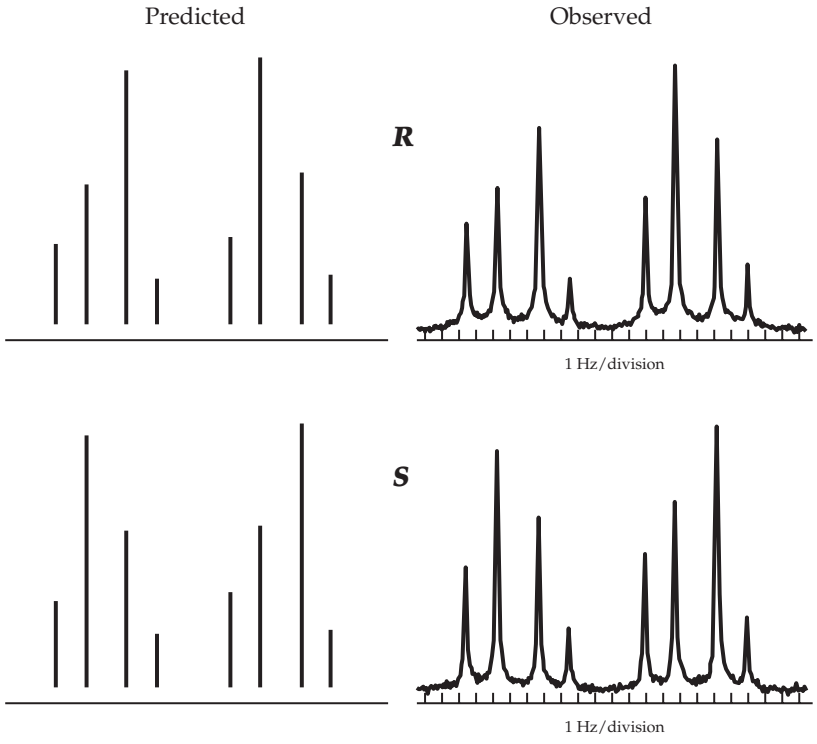
In the following sections we will consider several individual phosphotransferases.



The product 1-phospho-(*S*)-propane-1,2-diol **1** (here shown as *R* at phosphorus) is converted by in-line ring closure to an equimolar mixture of three cyclic diesters. These are methylated to give six cyclic triesters. Of these, only **3** and **6** give sharp ^{31}P resonance because the ^{17}O in the others broadens the lines.



Two cyclic triesters **3** and **6** from an *R*-phospho compound and two others **8** and **9** from an *S*-phospho compound will give sharp ^{31}P NMR resonances.

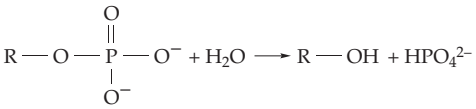


Predicted and observed ^{31}P NMR spectra of the mixtures of syn and anti cyclic triesters derived from labeled samples of 1 phospho-(*S*)-propane-1,2-diols that are *R* and *S* at phosphorus.

Figure 12-22 Method for determining chirality of phospho groups containing ^{16}O, ^{17}O, and ^{18}O. From Buchwald and Knowles.[701]

4. Phosphatases

The phosphatases catalyze hydrolysis of phosphate esters to produce inorganic phosphate:[667]

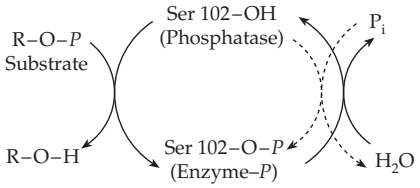


(12-37)

The **acid phosphatases** and **alkaline phosphatases** are nonspecific and cleave many different phosphate esters, whereas **glucose-6-phosphatase**, **fructose-1,6-bisphosphatase**, and many others are specific for single substrates. The nonspecific phosphatases may provide inorganic phosphate ions in places where they are needed, e.g., in mineralizing bone. All phosphatases help to drive metabolic cycles (Chapter 17).

The alkaline phosphatases are found in bacteria, fungi, and higher animals but not in higher plants. In *E. coli* alkaline phosphatase is concentrated in the periplasmic space. In animals it is found in the brush border of kidney cells, in cells of the intestinal mucosa, and in the osteocytes and osteoblasts of bone. It is almost absent from red blood cells, muscle, and other tissues which are not involved extensively in transport of nutrients.

The alkaline phosphatase of *E. coli* is a dimer of 449-residue subunits which requires Zn^{2+}, is allosterically activated by Mg^{2+}, and has a pH optimum above 8.[667,708–711] At a pH of ~4, incubation of the enzyme with inorganic phosphate leads to formation of a phosphoenzyme. Using ^{32}P-labeled phosphate, it was established that the phosphate becomes attached in ester linkages to serine 102. The same active site sequence Asp-Ser-Ala is found in mammalian alkaline phosphatases. These results, as well as the stereochemical arguments given in Section 2, suggest a double-displacement mechanism of Eq. 12-38:



(12-38)

The active site contains two Zn^{2+} ions and one Mg^{2+} ion which are held by imidazole and carboxylate groups. The inorganic phosphate in an enzyme–product complex is bound to both zinc ions (Fig. 12-23). The Ser 102 side chain is above one Zn. In the enzyme-*P* intermediate it would be linked to the phospho group as an ester which would then be hydrolyzed, reversibly, by a water molecule bound to Zn.[712–713a] This water presumably dissociates to Zn^{+}–OH and its bound hydroxyl ion carries out the displacement. This reaction may be preceded by a proton transfer to an oxygen atom of the phospho group.[714]

Acid phosphatases, which have pH optima of ~5 and are inhibited by fluoride ion, occur in bacteria, fungi, plants, and animals. In bone, the acid phosphatase content is high in the osteoclasts which function in the resorption of calcium from bone. The highest content of acid phosphatase in humans is in the prostate and an elevated serum level has long been used as a diagnostic indicator of prostatic cancer.[715] Acid phosphatase is a periplasmic enzyme in *E. coli*.[716] Phosphoenzymes have been trapped from both plant and animal acid phosphatases.[717] For example, a brief incubation with ^{32}P-labeled *p*-nitrophenyl phosphate followed by rapid denaturation in an alkaline medium gave a covalently labeled protein from which ^{32}P-containing N δ-phosphohistidine was isolated. In agreement with kinetic evidence that a phosphoenzyme is a true intermediate, there is no inversion of chiral phospho groups by liver or prostate acid phosphatases.[718]

Some acid phosphatases from animals and plants are violet in color and contain iron (Chapter 16) and an Mn^{3+}-containing acid phosphatase has been isolated from sweet potatoes.[720] These enzymes have dimetal centers, often containing one Zn^{2+} and one Fe^{3+} with bridging carboxylate and hydroxide ions between the metals. Imidazole, tyrosinate, and carboxylate side chains hold the metals as in Fig. 16-20. A water molecule bound to the Fe^{3+} is thought to dissociate with a low pK_a of 4.8 to give an $Fe^{3+} \bullet {}^{-}OH$ complex. The hydroxyl ion can then attack the phospho groups, one

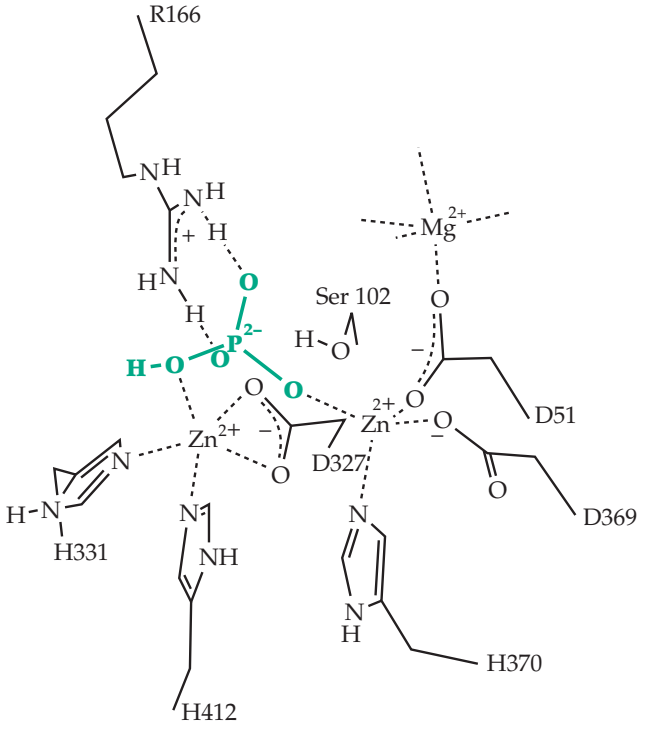


Figure 12-23 Schematic drawing of the product inorganic phosphate bound in the active site of *E. coli* alkaline phosphatase. See Ma and Kantrowitz.[719]

of whose oxygen atoms is coordinated with the Zn^{2+}.

The mechanism resembles that proposed for a **phosphotriesterase** (Fig. 12-24). The triesterase catalyzes detoxification of organophosphorus toxins such as parathion (Box 12-E) and seems to have evolved rapidly from a homologous protein of unknown function.[721] The phosphotriesterase contains two Zn^{2+} ions in a dimetal center. An unusual structural feature is a carbamate group, formed from Lys 169 and CO_2, which provides a bridging ligand for the metal pair.[721–725] A carbamylated lysine also functions in ribulose bisphosphate carboxylase (Fig. 13-11).

Phosphatases specific for such substrates as glucose-6-phosphate, fructose-1,6-bisphosphate, and phosphoglycolate help to drive metabolic cycles (Chapter 17). The 335-residue **fructose-1,6-bisphosphatase** associates to form a tetramer with D_2 symmetry.[726–730] The allosteric enzyme exists in two conformational states (see Chapter 11). Activity is dependent upon Mg^{2+} or other suitable divalent cation, e.g., Mn^{2+} or Zn^{2+}, and is further enhanced by K^+ or NH_3^+. While the dimetal sites depicted in Figs. 12-23 and 12-24 are quite rigid and undergo little change upon formation of complexes with substrates or products, the active site of fructose-1,6-bisphosphatase is more flexible. There are three metal-binding sites but they contain no histidine side chains and have been seen clearly only in a product complex.[727,728] Perhaps because of the need for flexibility involved in allosteric changes, the active site is not fully formed until the substrate binds. **Fructose-2,6-bisphosphatase** forms one domain of a bifunctional kinase-phosphatase (Chapter 11). It has two imidazole rings, as well as side chains from a glutamate and two arginine residues at the catalytic and substrate-binding site.[728a]

The 357-residue mammalian glucose-6-phosphatase plays an important role in metabolism (Chapter 17). Defects in the enzyme cause a glycogen storage disease (Box 20-D) and severe disruption of metabolism.[731] However, the molecular basis of its action is not well-known. Furthermore, the active site of the enzyme is located in the lumen of the endoplasmic reticulum[732] and glucose-6-phosphate must pass in through the plasma membrane. An additional glucose-6-phosphate transporter subunit may be required to allow the substrate to leave the cytoplasm.[73]

Pyrophosphatases, which are present in all cells, and catalyze hydrolysis of inorganic pyrophosphate (PP_i) to orthophosphate (P_i) (see Chapter 6, Section D), also drive metabolic sequences. The very active pyrophosphatase of *E. coli* has a turnover number of over $2 \times 10^4\ s^{-1}$ at 37°C. The 1000 molecules per cell are sufficient to immediately hydrolyze any pyrophosphate produced by bacterial metabolism.[733] The much studied soluble pyrophosphatases of *E. coli*,[734,735] yeast,[736] and other organisms[736a,b] are metalloenzymes that are most active with Mg^{2+}. Two Mg^{2+} ions are held, mostly by carboxylate side chains, while a third apparently enters the active site as magnesium pyrophosphate, perhaps $MgP_2O_7^-$. As with other metallohydrolases, a metal-bound hydroxyl ion may serve as the attacking nucleophile.

At least three distinct families of **protein phosphatases** remove phosphate groups from serine, threonine, and tyrosine side chains in proteins.[737] Their role in control of numerous biochemical processes has been discussed in Chapter 11, Section C,2. The catalytic domains or subunits of the protein phosphatases act together with regulatory domains or separate regulatory subunits to control thousands of reactions. For example, protein phosphatase 1 (PP1) together with a glycogen-targeting subunit dephosphorylates inactive glycogen kinase (see Fig. 11-4). Belonging to the same family is **calcineurin** (PP2B), a phosphatase activated by Ca^{2+} through binding to calmodulin (Box 6-D). There are two families of Ser/Thr phosphatases. Their polypeptide folding patterns differ, but the active sites have similar dimetal centers resembling those in Figs. 12-24 and 16-20 with $Mn^{2+} + Fe^{2+}$, $Zn^{2+} + Fe^{3+}$, and probably other pairs of metals.[737–740] The family containing PP1 has weak sequence homology with the purple acid phosphatases.[740] Another common feature of these enzymes is a conserved His-Asp dyad (His 125 and Asp 95 in PP1) which is thought to be a proton donor, protonating the leaving group ($-O^-$) in a manner

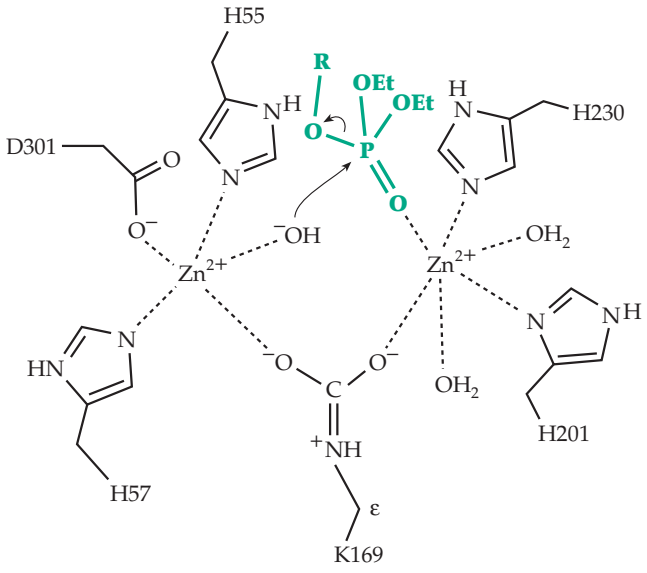

Figure 12-24 Hypothetical event in the action of a phosphotriesterase. A carbamylated lysine (lower center), as well as a water molecule, bridge the two Zn^{2+} ions, which are held by imidazole and aspartate carboxylate groups. The bound H_2O can be deprotonated to give the HO^- complex shown. The substrate may displace the HO^- ion from the right-hand zinc and thereby move close to the bound HO^- which attacks as indicated. Based on Cd^{2+}-containing structure and discussion by Benning *et al.*[722]

reminiscent of the serine proteases. The reaction is evidently initiated by attack of an $^{-}$OH ion held by the dimetal center. This would resemble the mechanism pictured in Fig. 12-24 except that the phospho group would carry two negative charges.

The protein tyrosine phosphatases also exist as several families with numerous functions in control of transcription, growth, differentiation, and metabolism.[741–743] These enzymes function by a double-displacement mechanism, as in Eq. 12-38, but with a cysteine side chain rather than serine. The cysteine is present in the conserved sequence (H/V)**C**X_5**R**(S/T). The arginine binds the phospho group and helps to stabilize the transition state, which probably is metaphosphate-like.[742]

5. Ribonucleases (RNases)

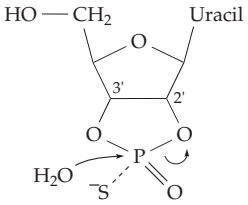
Many hydrolases act on phosphodiester linkages, which abound in nature.[725,744] Some are digestive enzymes but others serve more specific metabolic functions. **Ribonuclease A** (**RNase A**), the pancreatic digestive enzyme responsible for breakdown of RNA, was one of the first enzymes for which a structure was deduced. By 1963 Moore and Stein and their associates, who had earlier developed ion exchange methods for separating amino acids and peptides (Fig. 3-6), had determined the sequence of the 124-residue bovine enzyme.[745] They observed that Lys 41 was unusually reactive with dinitrofluorobenzene and that photooxidation of His 12 and His 119, which are almost at opposite ends of the peptide chain, inactivates the enzyme. They concluded that both histidines are at the active site, a conclusion that was later substantiated by X-ray crystallography.[746–748] A segment 12 nucleotides in length can fit into the cleft in the enzyme that contains the active site. The negatively charged phosphates of the RNA backbone form 8 – 9 electrostatic bonds to lysine and arginine side chains of the enzyme.[749,750] However, the only close interactions of the nucleic acid bases with the enzyme occur at the site of cleavage as shown in Fig. 12-25. The four residues His 12, Lys 41, Thr 45, and His 119 are strictly conserved in the RNAse A superfamily.[749] The carboxylate of Asp 121 apparently helps to orient the proper tautomer of His 119 for catalysis.[751]

Ribonuclease A was the first enzyme to be synthesized in the laboratory. Fully active ribonuclease has been synthesized,[752] as have new modified enzymes. For example a 63-residue peptide made up of five segments of the native RNase sequence retained measurable catalytic activity.[753] Using total synthesis, unnatural amino acids, such as 4-fluorohistidine, have been incorporated at specific positions in RNAse.[752]

Cleavage of a phosphodiester linkage in the substrate chain occurs in two steps. In the first or *transesterification* step, the hydroxyl group on the 2' position of the ribose ring is thought to be deprotonated by attack of either the imidazole of His 12, as shown in Fig. 12-25, or by the adjacent amino group of Lys 41. (In the latter case His 12 would have to remove a proton from the $-NH_3^+$ group of Lys 41 before it could attack.) In either case the positive charge of Lys 41 would help to neutralize the negative charge on the phosphate. The deprotonation of the 2'–OH may occur synchronously with its attack on the adjacent 3' phospho group. An in-line displacement of the oxygen attached to the 5' carbon of the next nucleotide unit is thought to be assisted by His 119. Its protonated imidazolium group may transfer a proton to a phosphate oxygen atom prior to or synchronously with formation of the new P–O bond in step *a* (Fig. 12-25).[754] The intermediate formed in step *a* is a cyclic 2', 3'-diphosphate which then undergoes hydrolysis by attack of a water molecule in step *b* to give the free nucleoside 3'-phosphate. The overall reaction is a two-step double-displacement, analogous to that with chymotrypsin, except that a neighboring group in the substrate rather than an amino acid side chain is the nucleophilic catalyst. The pH dependence of the enzyme is in agreement with this mechanism because there are two pK_a values of ~5.4 and ~6.4 which regulate the catalytic activity. Microscopic pK_a values of His 12 and His 119 have been measured by NMR spectroscopy as ~ 6.1 and ~ 6.3 and are shifted somewhat by binding of nucleotides.

A bacterial peptidase splits a 20-residue fragment containing His 12 from the N-terminal end of RNase A. This "S-peptide" can be recombined with the rest of the molecule, which is inactive, to give a functional enzyme called ribonuclease S. In a similar way, residues 119–124 of RNase A can be removed by digestion with carboxypeptidase to give an inactive protein which lacks His 119. In this case, a synthetic peptide with the sequence of residues 111 – 124 of RNase A forms a complex with the shortened enzyme restoring full activity.[755]

Stereochemical studies support in-line mechanisms for both the transesterification and hydrolysis steps of ribonuclease catalysis. For example, chiral uridine 2',3'-cyclic phosphorothioates are hydrolyzed with inversion of configuration, with the diastereoisomer shown yielding a 2'-monophosphothioate of the *R* configuration at phosphorus.



Uridine 2',3'-cyclic phosphorothioate

Transesterification step is also in-line[757] as it is shown in Fig. 12-25. Study of kinetic isotope effects in H_2O–D_2O mixtures suggested that two protons may move synchronously as the enzyme–substrate complex passes through the transition state.[758] Although RNase A is one of the most studied of all enzymes, there are still uncertainties about the mechanism. Is a proton removed first by His 12 (Fig. 12-25), as has long been assumed, or is a proton transferred first from His 119 to the oxygen of the phospho group?[759,760] Is the reaction concerted, as suggested by kinetic isotope effects,[761] or is there a pentacovalent intermediate?

The specificity of RNase A for a pyrimidine on the 3' side of the phosphodiester bond that is cleaved is evidently ensured by the pair of hydrogen bonds from O-2' of the pyrimidine to the backbone NH of Thr 45 and a second from the N-4' proton to the side chain OH of the same threonine (Fig. 12-25). Other nucleases, such as ribonuclease T_2,[762] with different specificities also make use of hydrogen bonding of the base at the 3' side of the cleavage point with backbone amide groupings.

Various bacterial ribonucleases as well as the fungal ribonucleases T_1, U_1, and U_2 (see also Fig. 5-43) have amino acid sequences related to that of RNase A[763,764,764a] but with distinctly different three-dimensional structures. The active sites contain Glu, His, and Arg side chains. For RNase T_1, Glu 58 and His 92 appear to provide acid–base catalysis with assistance from Tyr 38, Arg 77, and His 40.[763,765] A glutamate carboxylate also appears to be the catalytic base in the related RNase, called **barnase**, from *Bacillus amyloliquefaciens*.[766]

In addition to extracellular digestive enzymes, the RNase family contains many intracellular enzymes that are involved in turnover of RNA.[767,768] RNase H digests away RNA primers during DNA synthesis (Chapter 27). RNase H activity is also present in a domain of viral reverse transcriptases and is absolutely essential for the replication of HIV and other retroviruses.[769] The structures of the reverse transcriptase RNase H domain and of the *E. coli* enzyme are similar.[769–771] Unlike RNase A, the RNases H are metalloenzymes which apparently contain two Mg^{2+} ions held by carboxylate groups and utilize a metal bound HO^- ion as in previously discussed phosphatases. Secreted RNases sometimes have specific functions. For example, the 123-residue **angiogenin** is homologous to pancreatic RNases but acts to induce formation of new blood vessels (angiogenesis).[772–774] This is essential to growth of solid cancers as well as for normal growth. The enzyme is a very poor catalyst but its RNase activity appears essential for its biological function. Mutation of any of the catalytic residues His 13, Lys 40, or His 114 abolishes all angiogenic activity. A neurotoxin secreted by eosinophils[775] is one of a group of selectively toxic RNases.[776,777] Intracellular RNases are often found as complexes of specific inhibitor proteins.[778]

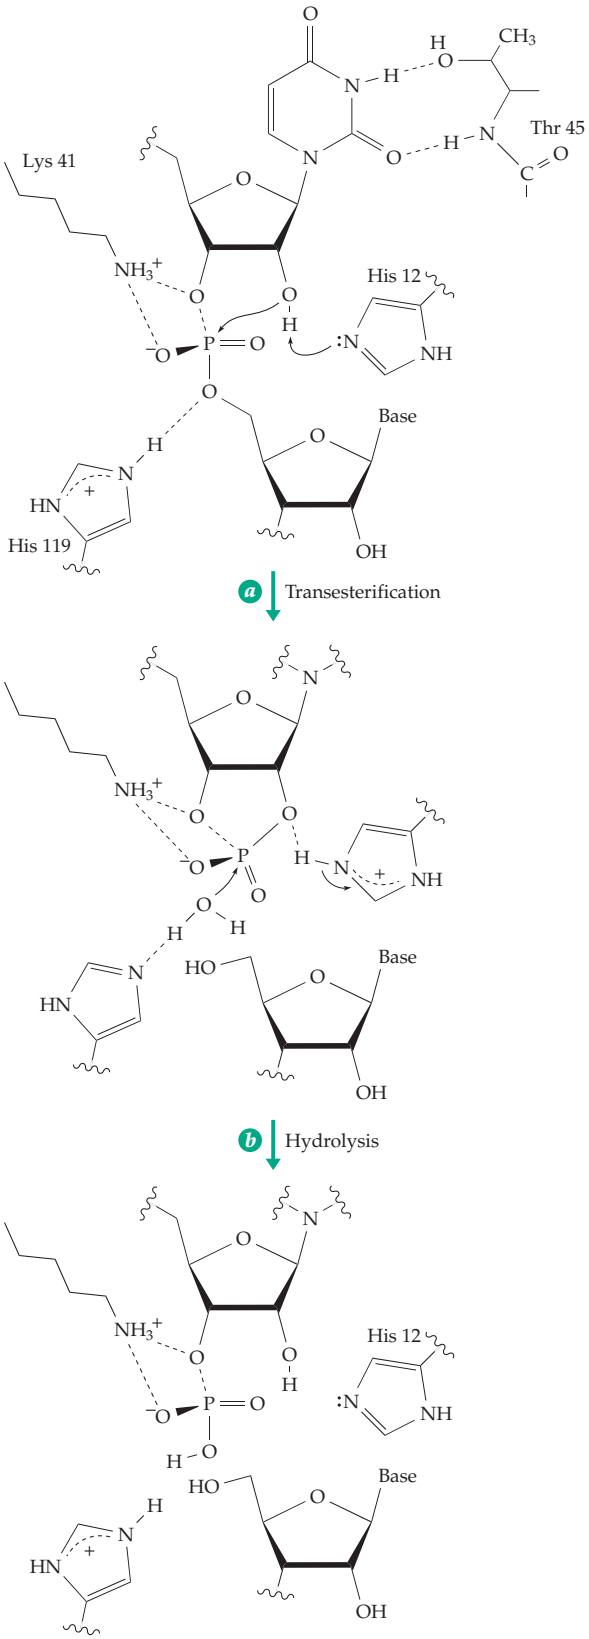


Figure 12-25 Proposed two-step in-line reaction mechanism for ribonuclease A. The hydrogen bonding that provides recognition of the pyrimidine base at the 3' end created by the cleavage is also shown. See Wladkowski *et al.*[756]

6. Ribonuclease P, Ribozymes, and Peptidyl Transferase

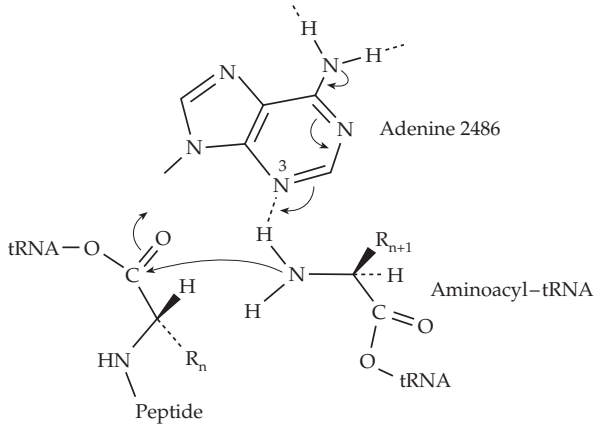
A very different ribonuclease participates in the biosynthesis of all of the transfer RNAs of *E. coli*. **Ribonuclease P** cuts a 5' leader sequence from precursor RNAs to form the final 5' termini of the tRNAs. Sidney Altman and coworkers in 1980 showed that the enzyme consists of a 13.7-kDa protein together with a specific 377-nucleotide RNA component (designated M1 RNA) that is about five times more massive than the protein.[779] Amazingly, the M1 RNA alone is able to catalyze the ribonuclease reaction with the proper substrate specificity.[780–782a] The protein apparently accelerates the reaction only about twofold for some substrates but much more for certain natural substrates. The catalytic center is in the RNA, which functions well only in a high salt concentration. A major role of the small protein subunit may be to provide counterions to screen the negative charges on the RNA and permit rapid binding of substrate and release of products.[783] Eukaryotes, as well as other prokaryotes, have enzymes similar to the *E. coli* RNase P. However, the eukaryotic enzymes require the protein part as well as the RNA for activity.[784]

Thomas Cech and associates independently discovered another class of catalytic RNA molecules. These are **self-splicing RNAs** that cut out intervening sequences from themselves to generate ribosomal RNA precursors (see Chapter 28).[785–787] They act only once and are therefore not enzymes. However, the introns that are cut out during self-splicing are **ribozymes** which, like the RNA from ribonuclease P, can act catalytically and have properties similar to those of protein enzymes. They exhibit the kinetic properties of enzymes and are denatured by heat. The RNAs are folded into compact structures resembling those of globular proteins. Like tRNA, they contain loops and hydrogen-bonded stems. Phylogenetic comparisons (Chapter 29) of the M1 RNA of ribonuclease P isolated from various species have allowed prediction of precise secondary structures.[783,788,789] A simplified M1 RNA consisting of 263 nucleotides from conserved regions of the molecule is catalytically effective.[783] Tetrahymena ribozyme also has a complex structure with a 247-nucleotide catalytic core formed by two structural domains (Fig. 12-26).[790,791] The crystal structure of a third ribozyme, one found in the RNA of the human pathogen hepatitis delta virus (HDV), has also been determined.[792] It is a smaller 72-nucleotide self-cleaved molecule with a very different structure from that in Fig. 12-26. It makes use of a double pseudoknot (see Fig. 5-29) to bind the RNA into a compact, tightly hydrogen-bonded structure with a deep active site cleft. It is the fastest known naturally occurring self-cleaving RNA and is able to react at a rate of more than 1 s^{-1} at its optimum temperature of 65°C.

Smaller self-cleaving RNAs have been found among plant viruses and viroids. Many of them have a common catalytic core which can be converted into 30- to 40-nucleotide ribozymes. Only 17 nucleotides and three hydrogen-bonded helical stems are required to form the self-cleaving "hammerhead" domain, which has a structural similarity to the catalytic core of the *Tetrahymena* ribozyme. The **hammerhead ribozymes** (Fig. 12-27) represent one form of small ribozyme.[793–797] Another is the **hairpin ribozyme** shown in Fig. 12-28,[798,801] which also shows the even smaller lead-dependent "**leadzyme**," a ribozyme that doesn't occur in nature.

In an intact viral self-cleaving RNA the entire catalytic center is formed from a single strand. Stems II and III of the hammerhead ribozyme (Fig. 12-27C) are closed by large loops. In the ribozyme shown, loop III has been cut off and stem II has been closed by a tight loop to form a compact catalytic RNA that will cut a substrate having a suitable nucleotide sequence for binding to the ribozyme. Only 12 bases in this ribozyme are highly conserved. By varying the sequences in the ribozyme half of stems I and III, catalysts that cleave after any sequence GUX, where X=A, C, or V, can be designed. Such catalysts are useful in the laboratory and potentially also in medicine.

What groups of a ribozyme bind to substrates and what groups participate in catalysis? Like peptides, RNAs have amide groups that can hydrogen bond to substrates. Adenine and cytosine can supply protonated amino groups which could participate in acid–base catalysis. This is evidently the case in the **peptidyl transferase** centers of ribosomes. The RNA in these centers catalyzes a transesterification in which an aminoacyl group is transferred from an aminoacyl-tRNA anto the growing polypeptide chain attached to a second tRNA molecule. The reaction is evidently catalyzed by a universally conserved adenine ring located at position 2486 in the *Haloarcula marismortii* 23S RNA (position 2451 in *E. coli*). There are no protein groups within 1.8 nm of the location of peptide bond synthesis.[798a] The active site adenine appears to be much more basic than normal. A high pK_a of 7.6 controls the peptidyl transferase, and also controls the methylation of the active site adenine by dimethylsulfate.[798b] The site of protonation is thought to be largely N3 of adenine 2486, which is probably the basic center involved in catalysis. The peptidyltransferase reaction may be initiated as follows.[798a]



A similar catalytic mechanism is probably used by the small 85-nucleotide hepatitis delta virus ribozyme whose catalytic base is thought to be N3 of cytosine 75, which is associated with a pK_a of ~6.1.[798c] Both this HDV ribozyme and the ribosomal RNA resemble serine proteases with histidine as the catalytic base. However, the self-splicing RNA of *Tetrahymena* initiates a nucleophilic attack with the 3'–OH group of a guanosine molecule that is bound to a site in the P7 region (Fig. 12-16A) and which acts as a cofactor (see Fig. 28-18). Ribonuclease P and all group I and II self-cleaving introns also use an external nucleophile such as a guanosine –OH and form 3'-OH and *O*-phosphate or

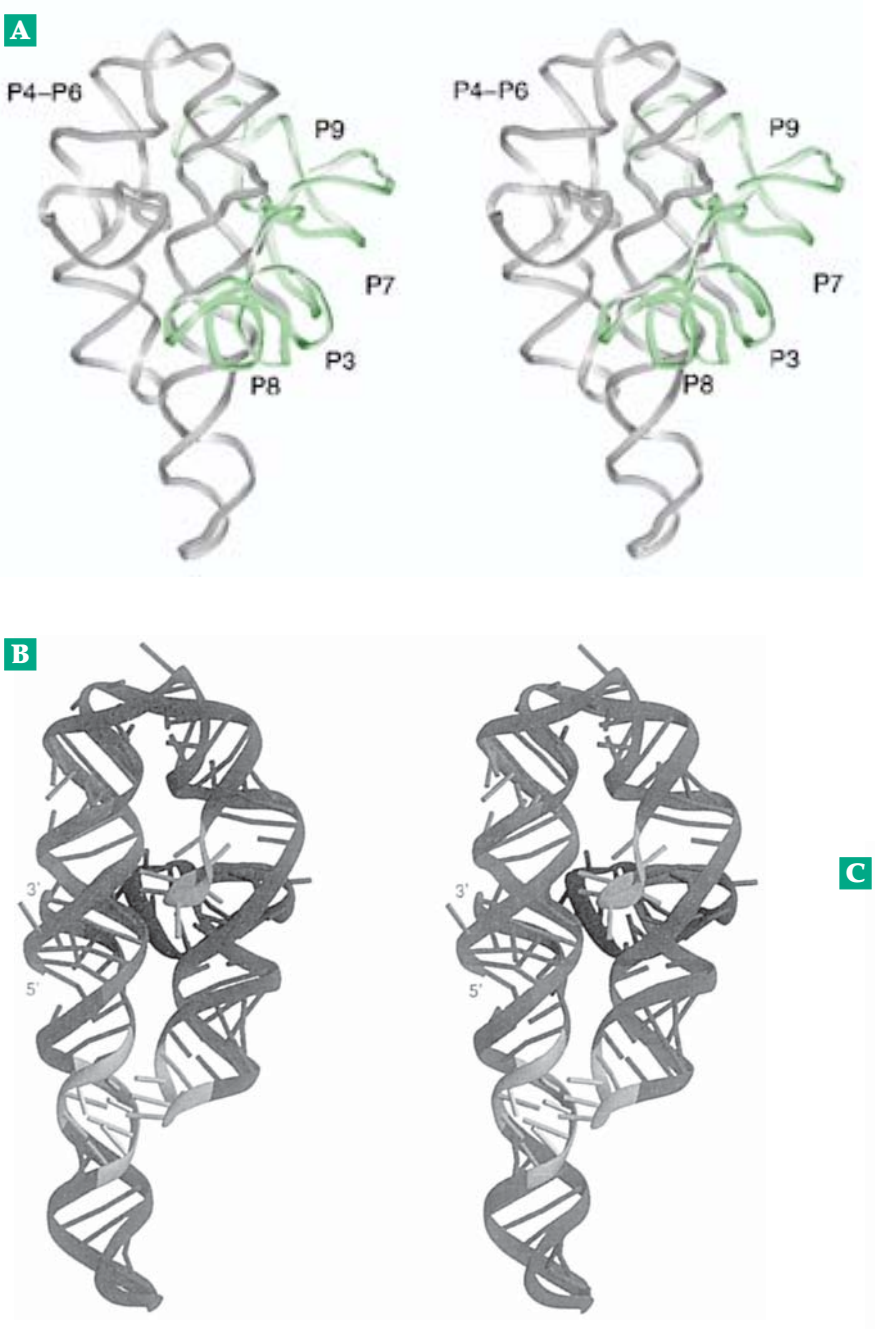


Figure 12-26 (A,B) Stereoscopic views of the *Tetrahymena* ribozyme. (A) Ribbon tracing of the phosphodiester backbone. The successive conserved structural elements, from the 5' and 3' ends are designated P1 to P9. The P4 – P6 region forms one major domain, while the P3 and P5 – P9 regions form a second domain which folds around the first. From Golden *et al.*[790] (B) Structure of the P4 – P6 domain viewed from the back side as pictured in (A). From Cate *et al.*[791] The active site lies between this domain and the larger one which folds over it leaving the active site in a deep crevice.[790] The active site is centered above the "tetraloop" GAAA (residues G150 to A153), which is shown with lighter shading (in B) near the upper center of the P4 – P6 domain. (C). Details of one of three layers of hydrogen-bonded interactions between purine and pyrimidine bases involved in interaction of the tetraloop with the adjacent helix in the P5 region. Cleavage occurs in the P1 domain, which folds into the active site and is not shown in these drawings. Courtesy of Thomas Cech.

From Baidya and Uhlenback.[793] (C) Diagram of a hammerhead ribozyme with standard numbering of nucleotides. The three helical stems are labeled I, II, and III. From Bevers *et al.*[796] (D) Simplified cleavage mechanism which resembles step *a* of Fig. 12-25 and ignores the known participation of metal ions.

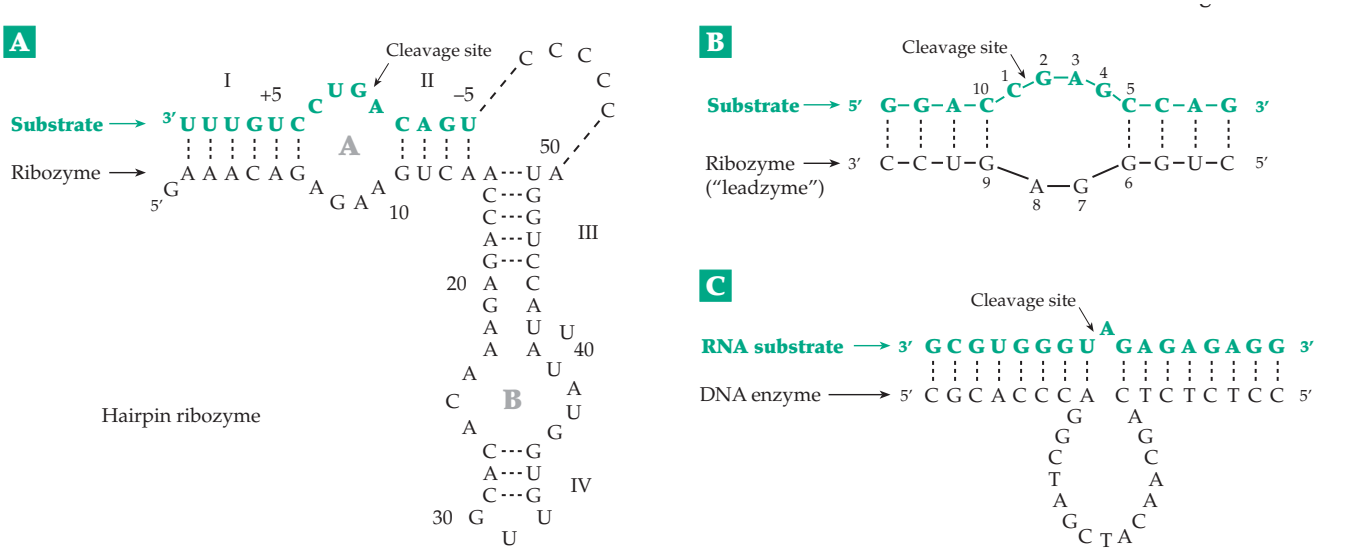

Figure 12-28 (A) A hairpin ribozyme formed from the minus strand of a satellite RNA associated with tobacco ringspot virus. On the basis of hydroxyl radical footprinting (see Fig. 5-50), to identify protected areas a folding pattern that brings domains A and B together to form a compact catalytic core has been proposed.[798] (B) A "leadzyme," a ribozyme dependent upon Pb^{2+} for cleavage of RNA.[802,803] (C) An RNA-cleaving DNA enzyme.[804]

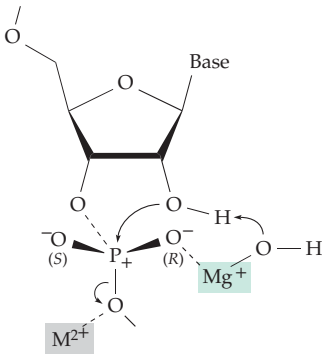
phosphodiester ends at the cleavage points. Hammerhead ribozymes utilize the 2'-OH of the ribose at the cleavage site to form a 2',3'-cyclic phosphate ester as in step *a* of the ribonuclease A reaction (Fig. 12-25) and as indicated in Fig. 12-27D. Ribozymes act by in-line mechanisms, causing inversion of the configuration at the phosphorus.[799,800]

Most ribozymes, as well as RNase P,[805,806] require one or two metal ions for activity.[807] Magnesium ions predominate and many Mg^{2+} ions are bound at distinct sites in crystalline ribozymes. Hammerhead and hairpin ribozymes work reasonably well with monovalent ions. One proposed mechanism is for an HO^- ion bound to the Mg^{2+} to remove H^+ from the 2'– OH of the ribose ring as follows:



When the *pro-R* oxygen of the phospho group (labeled *R* in the accompanying structure) was replaced by sulfur the rate of cleavage decreased 10^3-fold. However, the rate was restored fully when Cd^{2+} was added, presumably because of the high affinity of cadmium ions for sulfur ligands.[808] This supports the possibility of a dual role for Mg^{2+} in activating a water molecule to provide HO^- and in stabilizing negative charges on the phospho group by interaction with the *pro-R* oxygen in the transition state. Several investigators have suggested that *two* metal ions may be needed. One possibility is for a mechanism similar to that proposed for alkaline phosphatase (Fig. 12-25) and other phosphotransferases.[809,810] The *Tetrahymena* ribozyme functions best if both Mg^{2+} and Mn^{2+} are present.[811] A second metal may act as a Lewis acid facilitating loss of the 5'-OH as indicated by M^{2+} (in gray) in the preceding diagram. Metal ions may also participate in conformational changes as well as have structural functions in ribozymes.[812,813] Studies of the kinetics of action of hammerhead ribozymes have suggested that the intrinsic ribozyme-substrate binding energy is utilized for catalysis.[814] This may be possible because the ribozyme is only partially folded in the ground state but it folds into a tighter conformation in the transition state.[815]

Methods have been devised for generating enormous numbers of RNA molecules with random sequences and for selecting those with unusual catalytic activities.[816–819] Among the new catalysts produced in this way are very small ribozymes that cleave RNA specifically in the presence of Pb^{2+} (Fig. 12-28B).[802,803] The leadzyme is more active with neodymium (Nd^{3+}) + Pb^{2+} than with lead alone, suggesting a two-metal mechanism.[820] Other artificial ribozymes include RNA ligases,[817] acyltransferases,[821] and DNA hydrolases.[822,823] Is it possible to find a DNA enzyme? Without the 2'–OH of ribose to form hydrogen bonds it seemed doubtful, but an RNA-cleaving DNA enzyme has been selected from a population of ~10^{14} different small DNA molecules. The DNA enzyme (Fig. 12-28C) will cleave RNA, whose sequence fulfills the base pairing requirements of two 8-deoxynucleotide recognition domains. Cleavage occurs between an unpaired purine and a paired pyrimidine using a metal-dependent mechanism that gives a 2',3'-cyclic phosphate as in ribonuclease A cleavage.[804]

7. Deoxyribonucleases (DNases)

A multitude of nucleases cleave DNA, single- or double-stranded. They range from the pancreatic digestive enzyme DNase I through specialized nucleases that function during DNA repair and the hundreds of restriction endonucleases that have become so valuable in modern laboratory work. Some nucleases leave a 3'-phosphate ester at a cut end in a DNA chain, while others leave a 5'-phosphate end.[824] Many nucleases are dealt with in later chapters. Only a few will be mentioned here.

One of the most studied enzymes of this group is the 149-residue micrococcal (staphylcoccal) nuclease from *Micrococcus* which cleaves either RNA or single- or double-stranded DNA. The relatively nonspecific enzyme cuts nearly randomly at the 5' side of the phosphodiester linkages, leaving 3'-phosphate groups. It enhances the uncatalyzed hydrolysis rate at least 10^{16}-fold.[825–827] The crystal structure showed that the majority of the acidic and basic side chains of the protein interact with each other through clusters of hydrogen bonds. At the active site the side chains of both Arg 35 and Arg 87 form pairs of hydrogen bonds to the 5'-phosphate group of the specific inhibitor deoxythymidine 3',5'-diphosphate (Fig. 12-29). While Arg 87 appears to be in a position to protonate the leaving group $-O^-$, ^{13}C NMR experiments showed that all of the arginine side chains had pK_a values above 11.6. However, Tyr 85 has a pK_a of 9.5, which appears to control k_{cat}/K_m.[828] A Y85F mutant lacks this pK_a. The X-ray structure also suggests that Glu 43 may be the attacking nucleophile and that it may deprotonate a water molecule bound to the Glu 43 carboxylate. The resulting HO^- probably carries out a direct in-line attack as shown in Fig. 12-29. Mutants such as E43D, E43Q, and E43S have greatly decreased activity,[829] in

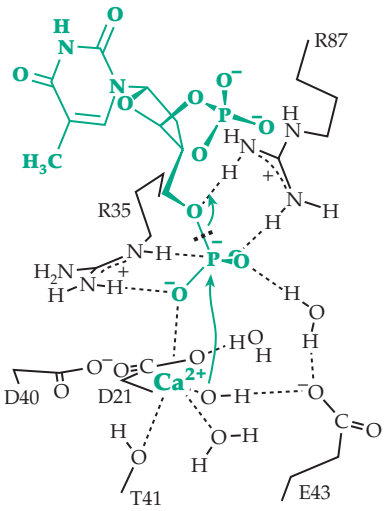


Figure 12-29 Drawing showing the hydrogen-bonding interactions between the guanidinium ions of arginines 35 and 87 of the micrococcal (staphylococcal) nuclease with the 5'-phosphate of the inhibitor thymidine 3',5'-diphosphate in the complex of E + I + Ca^{2+}. A possible mechanism is illustrated. A hydroxyl ion bound to Ca^{2+} carries out an in-line attack on the phosphorus. See Libson *et al.*[826]

agreement with this mechanism. The nearby Ca^{2+} is essential. For this nonspecific nuclease there is no hydrogen bonding of a purine or pyrimidine base of the substrate to the enzyme.

The digestive enzyme, pancreatic DNAse I, makes single-stranded cuts in double-stranded (ds) DNA. An exposed strand of peptide chain from the enzyme binds into the minor groove of B-type DNA.[830] Because this groove becomes too narrow in long (A+T) rich sequences, they are cleaved slowly. Certain hypersensitive sites are cleaved very rapidly, perhaps because the DNA at these regions is bent or is able to bend to give a very good fit to the enzyme active site. A histidine which is hydrogen bonded to a nearby carboxylate of a glutamate side chain appears to be a catalytic base that acts upon a water molecule as in phospholipase A (Section D,10), displacing the 3' oxygen of the phosphodiester linkage. An imidazolium group from a second histidine is hydrogen bonded to an aspartate carboxylate and a tyrosine –OH to form a catalytic triad that can protonate the 3' $-O^-$ as it is displaced.[831] Two Mg^{2+} ions are also required. Both are held by different carboxylate side chains and may also interact with oxygen atoms of the phospho group to neutralize charge and stabilize the transition state.

In contrast to DNAse I, the **restriction endonucleases**, which are discussed in Chapter 5, Section H,2 and in Chapter 26, have precise substrate sequence specificities. Three of the best known restriction endonucleases are called *Eco*RI,[832–834] an enzyme which binds to and cuts both strands of the palindromic sequence 5'-GAATTC; *Eco*RV,[835] which cuts both strands in the center of the sequence 5'-GATATC; and *Bam*H1, which binds to the sequence 5'-GGATCC and cleaves after the 5' G on each strand.[836] A high-resolution structure is also known for *Cfr*10I, which recognizes the less strict sequence 5'-PuCCGGPy and cleaves both strands after the 5' Pu.[837] All of these enzymes require Mg^{2+} and have active sites containing carboxylate groups. Two-metal mechanisms have been suggested.

Restriction endonuclease *Eco*RI is able to cut a chain in dsDNA which has a chiral phophorothioate group at the specific cleavage site.[838] The reaction occurs with inversion of configuration at phosphorus, suggesting direct in-line attack by a hydroxyl ion generated from H_2O.

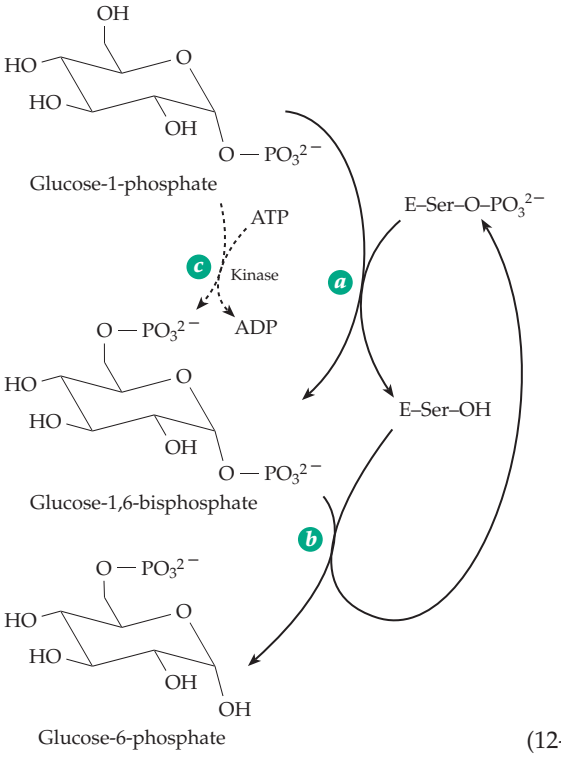
Attempts are being made to design semisynthetic restriction endonucleases specific for single-stranded DNA or RNA. For example, an oligonucleotide with a sequence complementary to a sequence adjacent the linkage that is to be cut can be covalently linked to a relatively nonspecific nuclease. Such an enzyme derived from micrococal nuclease cuts a single-stranded chain of either DNA or RNA adjacent to the double-stranded region of the ES complex.[839]

8. Mutases

Phosphotransferases that shift phospho groups from one position within a substrate to another are often called **mutases**. For example, **phosphoglucomutase** catalyzes the interconversion of glucose 1-phosphate and glucose 6-phosphate, an important reaction that bridges glycogen metabolism and glycolysis (Fig. 11-2). This 561-residue protein operates through formation of an intermediate **phosphoenzyme**.[840–842] The phospho group becomes attached to the OH of Ser 116 and can be transferred either to the 6 or the 1 position of a glucose phosphate (step *a* and reverse of step *b* in Eq. 12-39).

The two-step reaction accomplishes the reversible isomerization of glucose 1-phosphate and glucose 6-phosphate via **glucose 1,6-bisphosphate**. Evidently, the glucose bisphosphate, without leaving the enzyme is reoriented to allow transfer of the phospho group to either the 1- or 6-position.[841] The phospho enzyme is relatively unstable and can undergo hydrolysis to free enzyme and P_i. To prevent loss of active enzyme in this way, a separate reaction (catalyzed by a kinase; Eq. 12-39, step *c*)[843] generates glucose 1,6-bisphosphate, which rephosphorylates any free enzyme formed by hydrolysis of the phospho enzyme. The glucose 1,6-bisphosphate can be regarded as a cofactor or **cosubstrate** for the reaction.

Phosphoglycerate mutase, which interconverts 2-phosphoglycerate and 3-phosphoglycerate in glycolysis (Fig. 10-3, step *c*), functions by a similar mecha-



(12-39)

nism.[843–845] However, the enzyme-bound phospho group is carried on an imidazole group. The essential cosubstrate required by some phosphoglycerate mutases is 2,3-bisphosphoglycerate.[845] It is formed from the glycolytic intermediate 1,3-bisphosphoglycerate (Fig. 10-3) by action of another mutase, **bisphosphoglycerate mutase**.[843,846]

1,3-bisphosphoglycerate → 2,3-bisphosphoglycerate (12-40)

This is also the pathway for synthesis of 2,3-biphosphoglycerate in red blood cells where it serves as an important allosteric regulator (Chapter 7). Two human phosphoglycerate mutase isoenzymes are known. One is found in muscle and the other in brain and other tissues.[844] A hereditary lack of the muscle type enzyme is one of the known types of glycogen storage diseases (Box 20-D).

Human **phosphomannomutase**, which catalyzes the interconversion of mannose 1- and 6- phosphates, appears to carry the phospho group on an aspartate side chain in the sequence **D**XDX (T/V), which is conserved in a family of phosphomutases and phosphatases.[847] The first aspartate in the sequence is phosphorylated during the enzymatic reaction.

9. Molecular Properties of Kinases

Kinases transfer phospho groups from polyphosphates such as ATP to oxygen, nitrogen, or sulfur atoms of a second substrate.[848] Examples include **hexokinase**, the enzyme responsible for synthesis of glucose 6-phosphate from free glucose and ATP (Fig. 11-2, step *a*); **phosphofructokinase**, which forms fructose 1,6 bisphosphate in the glycolysis pathway (Fig. 11-2, step *b*); and **phosphoglycerate kinase**, and **pyruvate kinase**, both of which form ATP from ADP in the glycolysis pathway (Fig. 10-3, steps *b*, *c*, and *f*). There are many others. Kinases vary greatly in size and in three-dimensional structure. For example, a small **adenylate kinase**, which phosphorylates AMP to ADP (Eq. 6-65), is a 22-kDa monomer of 194 residues. Pyruvate kinase is a tetramer of 60-kDa subunits and muscle phosphofructokinases are tetramers of 75- to 85-kDa subunits. The three-dimensional structures also vary. While all kinases consist of two domains built around central β sheets (Fig. 12-30), there are several different folding patterns.[849] The two-domain structures all have deep clefts which contain the active sites. Both adenylate kinase (Fig. 12-30) and hexokinase crystallize in two or more forms with differing conformations.[850] This and other evidence suggests that as a kinase binds and recognizes its two correct substrates, the active site cleft closes by a hinging action that brings together the reacting molecules in the correct orientation.[851–853] In the crystal structure shown in Fig. 12-30 both ADP and AMP are bound in a nonproductive complex. If the ADP were replaced with ATP (or the AMP with a second ADP) to form a productive complex the two reacting phospho groups would be ~0.8 nm apart. A reaction could not occur without further closing of the active site cleft.[854] Evidence for domain closure has been obtained for many other kinases. For example, substrate complexes of phosphoglycerate kinase have been crystallized in both "open" forms and "closed" forms in which a 30° hinge-bending movement has brought the ligands together for an in-line phospho group transfer.[855]

For many enzymes an ATP binding site has been revealed by study of nonhydrolyzable analogs of ATP such as "AMP-PNP" whose structure is shown in Fig. 12-31.[856] AMP-PNP has been used in thousands of investigations of ATP-dependent processes.[857] For example, the structure of a phosphoglycerate • Mg^{2+} • AMP-PNP complex in the active site of phosphoglycerate kinase has been determined.[858] Modeling of a transition state complex indicates that all three negatively charged oxygens of the ATP portion of structure are stabilized by hydrogen bonding.[852] Related analogs such as AMP-PCH_2P (Fig. 12-3) have been used in similar ways.[859] Another analog Mg^{2+} • Ap_5A (Fig. 12-31) is a bisubstrate inhibitor which binds to adenylate kinases, fixing the enzymes in a closed conformation that is thought to resemble the transition state.[859,860]

The Mg^{2+} complex of ATP is regarded as the true substrate for kinases. The metal usually also binds both to the phospho groups of ATP and to groups on

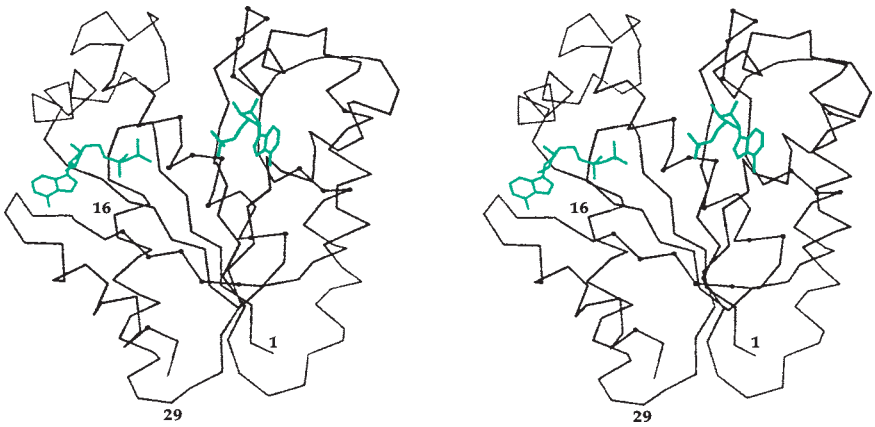


Figure 12-30 Stereoscopic α-carbon plots of a 194-residue subunit of adenylate kinase from the archaebacterium *Sulfolobus acidocaldarius* with ADP (left side) and AMP (right side) bound into the active site. From Vonrheim *et al.*[854] Courtesy of G. E. Schulz.

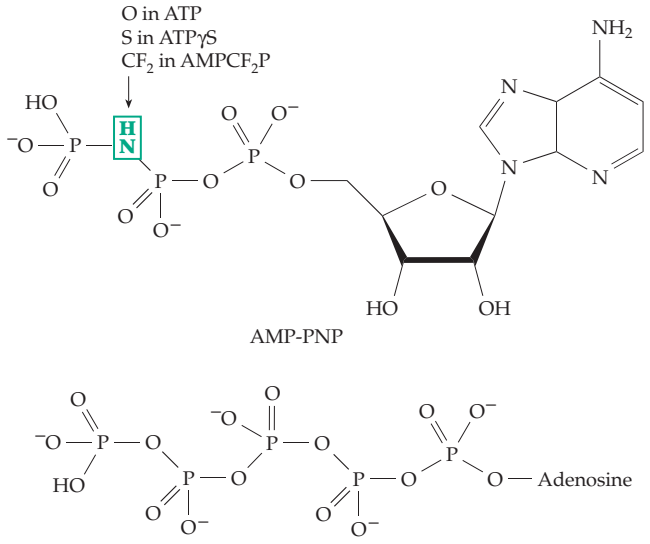

Figure 12-31 Some useful analogs of ATP.

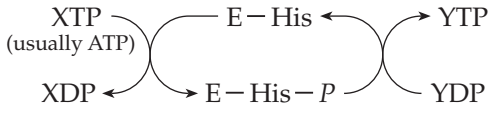
the enzyme. Crystallographic investigations as well as studies with exchange-inert ATP complexes (Section 2) have suggested that the metal ion is bound initially to the terminal (γ) and adjacent (β) phospho groups of ATP. However, this metal bridge could prevent rather than assist the reaction. For some phosphotransferase reactions with exchange-inert complexes the product appears to be the α,β-bidentate complex of ADP (see Section 2) suggesting that movement of the metal ion from the β,γ- to the α,β-bidentate ATP complex may occur either prior to or during transfer of the phospho group. Theoretical calculations also suggest a movement in the metal complexation as the reaction progresses.[861] EPR studies that involved observation of hyperfine coupling between ^{17}O in substrates and Mn^{2+} in the active site led Reed and Leyh to conclude that the activating metal ion is bound to all three phospho groups in the transition state.[849]

Adenylate kinase performs the essential function of recovering AMP formed by many enzymatic processes and converting it to ADP (Eq. 6-65) which can be reconverted to ATP by oxidative or substrate level phosphorylation. The enzyme is present in all organisms. In vertebrates different isoenzymes function in the cytosol, mitochondrial intermembrane space, and mitochondrial matrix.[862,863] A group of other **nucleotide** and **deoxynucleotide kinases** convert nucleoside monophosphates into diphosphates.[864,865] Some of them, e.g., **uridylate kinase** are similar in structure and properties to adenylate kinase.[866,867] Another member of the adenylate kinase family is phosphoribulokinase, an important photosynthetic enzyme (see Fig. 17-14, step *a*).[868]

Most kinases transfer chiral phospho groups with inversion and fail to catalyze partial exchange reactions that would indicate phosphoenzyme intermediates. However, **nucleoside diphosphate kinase** contains an active site histidine which is phosphorylated to form a phosphoenzyme.[869] The enzyme catalyzes phosphorylation of nucleoside diphosphates other than ADP by a nucleotide triphosphate, usually ATP.



(12-41)

Here, X is usually adenosine and Y is any ribonucleoside or deoxyribonucleoside. This enzyme supplies all of the nucleotide triphosphates except ATP for use in the many cellular processes that require them.[870–872] The enzyme aligns the substrate, holding the phospho group with a pair of arginines and a magnesium ion. The phospho group is aligned for an in-line displacement by N^{δ} of His 122, part of a hydrogen-bonded His–Glu dyad. Formation of the phosphoenzyme occurs in less than 1 ms without significant conformational change other than a 30° rotation of the histidine ring.[870,873]

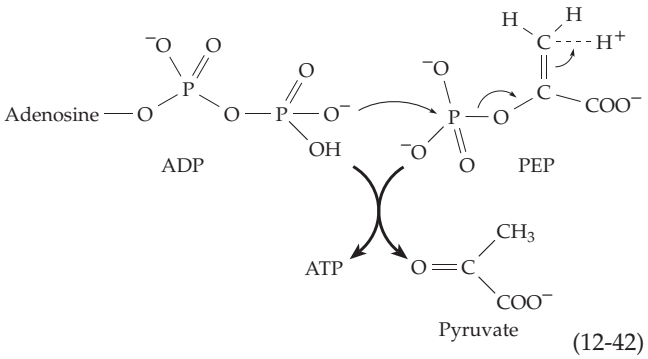
Hexokinase, the enzyme that phosphorylates glucose to glucose 6-phosphate, exists as four isoenzymes in mammals. Hexokinases I, II, and III are large ~ 100-kDa monomers with similar amino acid sequences, a single active site, and complex allosteric regulatory properties. The three-dimensional structure is known for hexokinase I, which is the pacemaker of glycolysis in the brain.[874,875] Hexokinase IV (glucokinase) is a 50-kDa protein that is found in liver and in the β cells of the pancreas. It has a low K_m and is not inhibited by glucose 6-phosphate, properties that allow for rapid uptake of glucose after a meal.[876] Its properties are similar to those of a major isoenzyme of yeast,[877] a dimer of identical 50-kDa subunits whose structure is also known.[878] The glucose-binding residues are conserved in yeast hexokinase, in glucokinase, and in brain hexokinase. The sequence of the latter suggests that it may have arisen by a doubling of a shorter hexokinase gene.[879]

Fructose 6-phosphate kinase (phosphofructokinase) has attracted much attention because of its regulatory properties (Chapter 11).[880–882] Prokaryotic forms are somewhat simpler.[883] The related fructose 6-phosphate 2-kinase is a component of a bifunctional kinase-phosphatase (Fig. 11-2, steps *d* and *e*) and has a structure similar to that of adenylate kinase.[884]

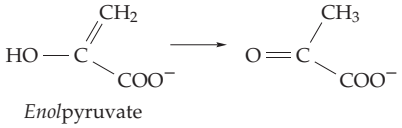
Phosphoglycerate kinase is encoded by the mammalian X chromosome. Several mutant forms are associated with hemolytic anemia and mental disorders.[885,886] Mutation of Glu 190, which is in the hinge region far from the active site, to Gln or Asn markedly reduces enzymatic activity.[887]

Creatine kinase transfers a phospho group to a nitrogen atom of the quanidinium group of creatine (Eq. 12-31 and Fig. 12-19). Several isoenzymes participate in its function of buffering the ATP level in tissues such as muscle fibers, neurons, photoreceptors, and spermatozoa which experience high and fluctuating energy needs.[888] A form from the mitochondrial intermembrane space of chicken heart is an octomer of 380-residue subunits.[889] The structurally and mechanistically similar **arginine kinase** has an analogous function in many invertebrates, e.g., in the horseshoe crab, which provided enzyme for a structure determination.[890]

The ~500-residue subunits of **pyruvate kinase** consist of four domains,[891] the largest of which contains an 8-stranded barrel similar to that present in triose phosphate isomerase (Fig. 2-28). Although these two enzymes catalyze different types of reactions, a common feature is an enolic intermediate. One could imagine that pyruvate kinase protonates its substrate phosphoenolpyruvate (PEP) synchronously with the phospho group transfer (Eq. 12-42). However, the enzyme catalyzes the rapid conversion of the enolic form of pyruvate to the oxo form (Eq. 12-43) adding the proton sterospecifically to the *si* face. This and other evidence favors the enol as a true intermediate



(12-42)



(12-43)

and a product of the phosphotransfer step.[891] Pyruvate kinase requires not only two equivalents of a divalent cation such as Mg^{2+} or Mn^{2+} but also a monovalent cation, usually K^+. However, Li^+, Na^+, NH_4^+, Rb^+, Tl^+, and others can substitute. The monovalent cation induces an essential conformational change. Using ^{205}Tl NMR it was found that the thallium ion binds about 0.6 nm from Mn^{2+} that is also present in the active site.[892] All three metals interact directly with the γ phospho group of ATP.[891] Pyruvate kinase is a regulated allosteric enzyme present in four isoenzymic forms in mammals.[893–894a]

Protein kinases, which were discussed in Chapter 11, phosphorylate selected – OH groups of serine, threonine, and tyrosine side chains in proteins. Examination of the sequences in the complete genome of yeast (*Saccharomyces cerevisiae*) indicates the presence of at least 113 protein kinase genes, which account for ~ 2% of the total DNA.[895] Higher eukaryotes have more. While structures of these enzymes vary widely, they share a common two-domain catalytic core structure.[896,897] The best known, and one of the simplest of them, is the catalytic subunit of cyclic AMP-dependent protein kinase.[897,898] The substrate MgATP binds into the active site cleft with the γ-phospho group protruding to meet the appropriate site of a bound protein substrate (Fig. 12-32). Most protein kinases are regulated by an "activation loop" that must be correctly placed before the ES complex can be formed. As discussed in Chapter 11, regulation of the cAMP-dependent kinase depends upon inhibition by a regulatory subunit. In the cAMP-dependent kinases and many other protein kinases the activation loop (not shown in Fig. 12-32), which helps to form the substrate site, contains a phosphothreonine residue which is essential for activity. It is a stable feature of the cAMP-activated kinase, incorporated at position 197, but for some tyrosine kinases it is generated by autophosphorylation.[899]

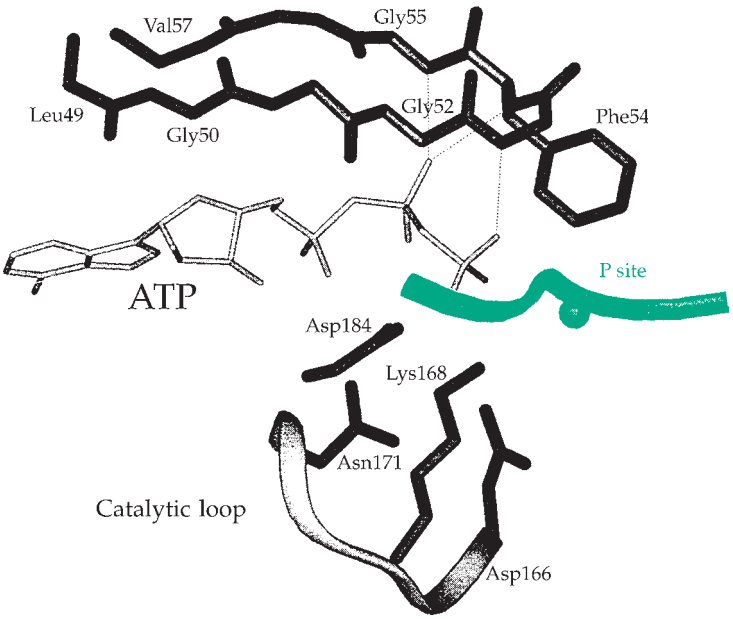


Figure 12-32 The active site of cyclic AMP-dependent protein kinase with bound ATP and a segment of an inhibitory peptide (green) blocking the substrate site. The small ball is an alanine side chain; it would be Ser or Thr in a substrate. The ATP is clamped by the glycine-rich loop at the top of the figure. Hydrogen bonds from peptide NH groups bind the β and γ phospho groups of ATP. A magnesium ion (not shown) also binds to the β and γ phosphate oxygens and to the invariant Asp 184. The Asp 166 carboxylate is probably the catalytic base for deprotonation of the substrate –OH. From Grant *et al.*[896] Courtesy of Susan S. Taylor.

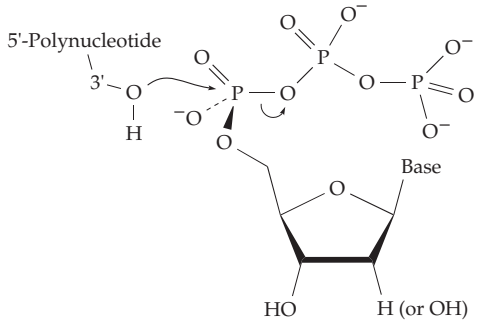
For the enzyme to be activated the phosphothreonine must form a hydrogen-bonded ion pair with Lys 189 and be hydrogen bonded to His 87, tying together critical regions of the catalytic domain. The regulatory subunits, unless occupied by cAMP (Chapter 11) are competitive inhibitors of the substrates.[900] Cyclic GMP-activated kinases also have distinct functions.[901] In **tryosine kinases**[902–904] C-terminal src-homology domains (Fig. 7-30 and Chapter 11) fold over and interact in an inhibitory fashion until an appropriate activating signal is received (see Fig. 11-13).

A relative of the kinases is **adenylate cyclase**, whose role in forming the allosteric effector 3',5'-cyclic AMP (cAMP) was considered in Chapter 11. This enzyme catalyzes a displacement on P_α of ATP by the 3'-hydroxyl group of its ribose ring (see Eq. 11-8 , step *a*). The structure of the active site is known.[905] Studies with ATPαS suggest an in-line mechanism resembling that of ribonuclease (step *a*, Eq. 12-25). However, it is Mg^{2+} dependent, does not utilize the two-histidine mechanism of ribonuclease A, and involves an aspartate carboxylate as catalytic base.[906] All isoforms of adenylate cyclase are activated by the α subunits of some G proteins (Chapter 11). The structures[907] of $G_{s\alpha}$ and of its complex with adenylate kinase[905] have been determined. The $G_{s\alpha}$ activator appears to serve as an allosteric effector.

Guanylate cyclases, which form cyclic GMP, occur in particulate and soluble forms.[908] The latter have been of great interest because they are activated by nitric oxide (NO). The soluble guanylate cyclases are αβ heterodimers. The C-terminal regions of both α and β subunits are homologous to the catalytic domain of adenylate cyclase. The N-terminal domain of the α subunits contains heme whose Fe atom is coordinated by a histidine imidazole.[908,908a] This iron atom is apparently the receptor for NO, a major gaseous hormone, which is discussed in Chapter 18.

10. Nucleotidyl Transferases

An important group of enzymes transfer substituted phospho groups, most often nucleotidyl groups. The nucleases, ATPases, and GTPases, which have already been discussed, belong to this group as do the nucleic acid synthesizing enzymes, the **DNA** and **RNA polymerases**,[909–911] **reverse transcriptase**,[912] and **topoisomerases**. As with other phosphotransferases, the nucleotidyl transfers occur with inversion[913,913a] and crystallographic investigations also support in-line mechanisms as illustrated in the following scheme. Two metal ions assist.



The inorganic pyrophosphate formed is hydrolyzed to inorganic phosphate by pyrophosphatase. Specific information about the polymerases and topoisomerases is given in Chapters 27 and 28.

E. The Adenylate Kinase Fold, the P Loop, and ATPases and GTPases

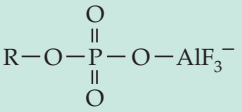
A magnesium–ATP-binding fragment consisting of ~40 residues at the N terminus of adenylate kinase contains sequences homologous to those in the GTP-binding "G proteins" such as the protooncogenes *ras* (Fig. 11-7A) and also to sequences in myosin and in mitochondrial ATP synthase.[914] This includes the glycine-rich "P loop" which extends from Gly 15 to Gly 22 in the porcine cytosolic enzyme and contains a highly conserved lysine [Lys 21 of porcine adenylate

BOX 12-F THE TOXICITY OF ALUMINUM

Aluminum, in the form of oxides and silicate minerals, is the most abundant element in the earth's crust. Yet it appears to be actively excluded from most living organisms. It seems surprising that a naturally occuring Al^{3+}-dependent enzyme hasn't been found, but there is no evidence that Al is an essential element. Until recently, it was usually regarded as harmless. The aluminum salts known as alums are used in baking powders and have been added to pickles and other foods. Aluminum sulfate is often used as a coagulant to clarify turbid drinking water. Because of the insolubility of $Al(OH)_3$ and of aluminum phosphate the concentration of Al^{3+} is very low at neutral pH. However, small amounts of $AlOH^{2+}$, $Al(OH)_2^+$, and $Al(OH)_4^-$ are present in water. Fluoride complexes such as AlF^{2+} may also be present. Soluble complexes, such as that with citrate, may permit some Al^{3+} to be absorbed by the body.[a,b]

The toxicity of aluminum has been recognized most clearly by the development of bone disease caused by deposition of Al in bones of patients on hemodialysis[a–c] and in infants on intravenous therapy.[d,e] Excessive Al in the water used for dialysis may also cause brain damage. Dietary aluminum may be one cause of Alzheimer's disease,[f–h] but this is controversial as is a possible role of aluminum in vaccines in causing inflammation in muscle.[i,j] Solubilization of soil aluminum by acid rain has been blamed for the decline of forests in Europe and North America,[j] for the death of fish in acid waters,[k] and for very large reductions in yield for many crops.[l,m] An aluminum-resistant strain of buckwheat makes and secretes from its roots large amounts of oxalate which binds and detoxifies the Al^{3+} ions.[m]

Al^{3+} has a radius somewhat less than that of Fe^{3+} (Table 6-10) and it may sometimes occupy empty Fe^{3+} binding sites. Thus, the transferrin[n] in blood carries some Al^{3+}, although citrate is probably a more important carrier.[o] Al^{3+} binds preferentially to oxygen ligands and can compete with Mg^{2+}. However, the slower rate of ligand exchange reactions with Al^{3+} may interfere with the proper functioning of the metal. Brain hexokinase is strongly inhibited[p] by Al^{3+} and the binding of Al^{3+} to tubulin decreases the rates of GTP hydrolysis and of Ca^{2+}-induced depolymerization of microtubules.[q] Aluminofluoride ions, such as AlF_4^-, react with phosphates to form ions such as,



which may be potent competitive inhibitors of enzymes acting on ATP, GTP, or other phosphate-containing substrate.[r,s] However, Fe^{3+} can be replaced by Al^{3+} in a purple acid phosphatase (Chapter 16) with retention of good catalytic activity.[t]

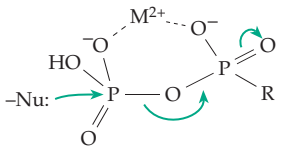
kinase and Lys 17 of the archaeal enzyme (Fig. 12-30)] and of the *ras* oncogene product).[915] The lysine side chain appears to interact with the β and / or γ phospho group of ATP or GTP. The peptide chain of the P loop wraps around the β phospho group as the chain turns from the first β strand into the first helix. This can be seen in Fig. 12-30, in which the P loop surrounds the β phospho group of ADP. Two peptide NH groups also bind to the β phospho group on a side opposite to that occupied by Mg^{2+}. A similar loop in the dinucleotide-binding domain of a dehydrogenase can be seen hydrogen bonded to the P_α and P_β phospho groups of NAD^+ in Fig. 2-13. Consensus sequences for three groups of glycine-rich loops are:[896]

Dinucleotide-binding	G X G X X G
P loop	G X X X X G K (S/T)
Protein kinase	G X G X X G X V

The protein kinase loop is seen at the top of Fig. 12-32 and extends from Gly 50 to Val 57. These conserved loops help to hold the ATP in place and to orient it correctly. Do they have any other significance? The answer is not clear. These glycine-rich loops fold across the β–γ diphosphate linkage that is broken when ATP or GTP is hydrolyzed. Cleavage of both of these molecules is associated with movement. Kinases close around ATP, and parts of G proteins (Fig. 11-7) move when these regulatory devices function.[915,916] Cleavage of ATP causes movement in the ATPase heads of muscle myosin, providing the force for muscular contraction (Chapter 19). Somewhat the opposite occurs in mitochondrial ATP synthase (Chapter 18) when movement in the synthase heads snaps ADP and inorganic phosphate together to form ATP. Common to all of these processes is a movement of charge within the ATP (or its cleavage products) from the attack nucleophile into the neighboring phospho group, as is indicated by the arrows in the following diagram.



Not shown in this diagram is an accompanying flow of positive charge which may include movement of a metal ion, addition and loss of protons, and which may induce conformational changes.[914] The latter are essential not only to muscle contraction and ATP synthesis but also to many other processes that depend upon the Gibbs energy of cleavage of ATP and related compounds. This includes the pumping of ions against concentration gradients (Chapter 8), the action of **topoisomerases** (Chapter 27) which function to alter the supercoiling in DNA, and the functioning of the phosphotransferase system by which sugars and other compounds are brought into bacterial cells (Chapter 8).

F. Displacements on Sulfur Atoms

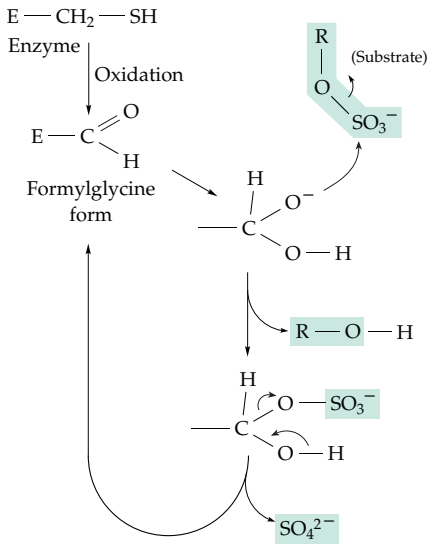
Nucleophilic displacement reactions occur on sulfur atoms in various oxidation states. A common reaction is **thiol–disulfide** exchange (Eqs. 10-9, 11-7), a reaction in which a nucleophilic thiolate anion attacks one of the sulfur atoms of a disulfide. Proteins such as **thioredoxin** of *E. coli* and **thioltransferases** (Box 15-C), which contain internal disulfide bridges, can be reduced by disulfide exchange with thiols such as glutathione (Box 11-B). The reduced proteins may then undergo similar exchange reactions that cleave disulfide linkages in other molecules. An example is glutathione reductase (Fig. 15-12). Thioltransferases may also serve as **protein disulfide isomerases** (Chapter 10, Section D,3). Nucleophilic displacements on sulfur or on selenium atoms are steps in a variety of enzymatic reactions. Among these are glutathione peroxidase (Eq. 15-59) and thiosulfate: cyanide sulfotransferase (Eq. 24-45).

While esters of sulfuric acid do not play as central a role in metabolism as do phosphate esters, they occur widely. Both oxygen esters ($R–O–SO_3^-$, often referred to as **O-sulfates**) and derivatives of sulfamic acid ($R–NH–SO_3^-$, **N-sulfates**) are found, the latter occurring in mucopolysaccharides such as heparin. Sulfate esters of mucopolysaccharides and of steroids are ubiquitous and sulfation is the most abundant known modification of tyrosine side chains. Choline sulfate and ascorbic acid 2-sulfate are also found in cells. Sulfate esters of phenols and many other organic sulfates are present in urine.

Sulfotransferases[917–920a] transfer sulfo groups to O and N atoms of suitable acceptors (reaction type 1D, Table 10-1). Usually, transfer is from the "active sulfate," **3'-phosphoadenosine 5'-phosphosulfate** (**PAPS**),[921] whose formation is depicted in Eq. 17-38. **Sulfatases** catalyze hydrolysis of sulfate esters. The importance of such enzymes is demonstrated by the genetic **mucopolysaccharidoses**. In four of these disease-specific sulfatases that act on iduronate sulfate, heparan *N*-sulfate, galactose-6-sulfate, or *N*-acetylglucosamine-4-sulfate are absent. Some of these, such as heparan *N*-sulfatase deficiency, lead to severe mental retardation, some cause serious skeletal abnormalities, while others are mild in their effects.[922]

Sulfatases are unusual in having a residue of **formylglycine** at the active site. This is generated oxidatively from cysteine in human enzymes[923,923a] and from serine in some bacterial sulfatases.[924,924a] Absence of this modification results in a multiple sulfatase deficiency disease. A probable mechanism of sulfatase

based on a crystal structure determination is given by Eq. 12-44.[923]



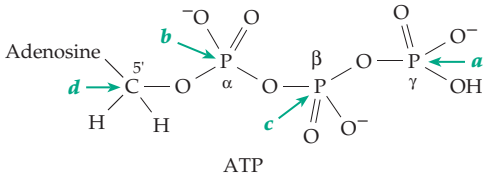
(12-44)

G. Multiple Displacement Reactions and the Coupling of ATP Cleavage to Endergonic Processes

A combination of successive displacement reactions of two types is required in many enzymatic reactions, including most of those by which the cleavage of ATP is coupled to biosynthesis. To harness the group transfer potential of ATP to drive an endergonic metabolic process there must be a mechanism of **coupling**. Otherwise, hydrolysis of ATP within a cell would simply generate heat. *An essential part of the coupling mechanism usually consists of a nucleophilic displacement on phosphorus followed by displacement on carbon.* Likewise, the synthesis of ATP and related compounds often begins with a displacement on carbon followed by one on phosphorus.

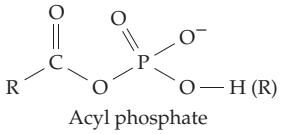
1. Transfer of Phospho, Pyrophospho, and Adenylyl Groups from ATP

The first step in coupling ATP cleavage to any process is transfer of part of the ATP molecule to a nucleophile Y, usually by displacement on one of the three phosphorus atoms. The nucleophilic attack may be (*a*) on the terminal phosphorus (P_γ) with displacement of ADP or (*b*) on the internal phosphorus (P_α) with displacement of inorganic pyrophosphate. In the first case, $Y{-}PO_3H^-$ is formed; in the latter, **Y-adenylyl** (sometimes shortened to Y-adenyl) is formed. More rarely, displacement occurs (*c*) on the central phosphorus (P_β) with transfer of a pyrophospho group to the nucleophile. Still less frequent (*d*) is a displacement on C-5' as shown in Eq. 17-37. If the nucleophile Y in any of these displacement reactions is H_2O, the resulting hydrolysis tends to go to completion, i.e., the phospho, adenylyl, and pyrophospho groups of ATP all have high group transfer potentials (Table 6-6). If Y is an –OH group in an ordinary alcohol the transfer reaction also tends to go to completion because the group transfer potential of a simple phosphate ester is relatively low. Consequently, phosphorylation by ATP is often used as a means of introducing an essentially irreversible step in a metabolic pathway.

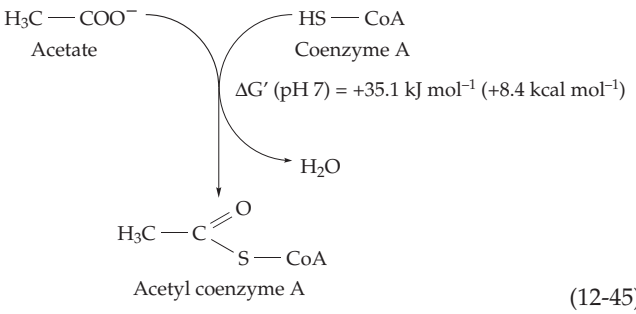


2. Acyl Phosphates

Transfer of a phospho or adenylyl group from ATP to the oxygen atom of a carboxylate group yields an **acyl phosphate**, a type of metabolic intermediate of special significance. Acyl phosphates are mixed anhydrides of carboxylic and phosphoric acids in which *both the acyl group and the phospho group have high group transfer potentials.* As a consequence, acyl phosphates can serve as metabolic intermediates through which the group transfer potential of ATP is transferred into other molecules and is harnessed to do chemical work.



A typical example is the synthesis of acetyl coenzyme A (Eq. 12-45). See Fig. 14-1 for the complete structure of –SH group-containing coenzyme A.

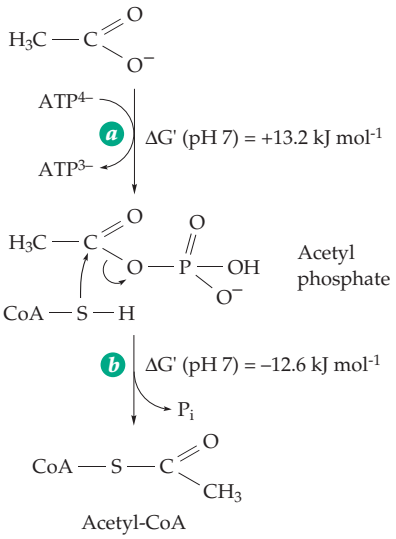


(12-45)

Because the acetyl group in the product also has a high group transfer potential, $\Delta G'$ for this reaction is highly positive and the formation of acetyl-CoA will not occur spontaneously. However, the sum of $\Delta G'$ for the reaction in Eq.12-45 plus that for the hydrolysis of ATP (Eq. 12-46) is nearly zero (+ 0.6kJ mol^{-1}).

$$ATP^{4-} + H_2O \rightarrow ADP^{3-} + HPO_4^{2-} + H^+$$
$$\Delta G' = -34.5 \text{ kJ mol}^{-1} (-8.3 \text{ kcal mol}^{-1}) \quad (12\text{-}46)$$

Coupling of the two reactions is accomplished by first letting an oxygen atom of the nucleophilic carboxylate group attack P_γ of ATP to form acetyl phosphate (Eq. 12-47, step *a*). In the second step (step *b*) the sulfur atom of the –SH group of coenzyme A (often abbreviated CoA–SH) attacks the carbon atom of the acetyl phosphate with displacement of the good leaving group P_i. While $\Delta G'$ for Eq. 12-47, step *a*, is moderately positive (meaning that a relatively low concentration of acetyl phosphate will accumulate unless the [ATP] / [ADP] ratio is high), the equilibrium in Eq. 12-47, step *b*, favors the products.

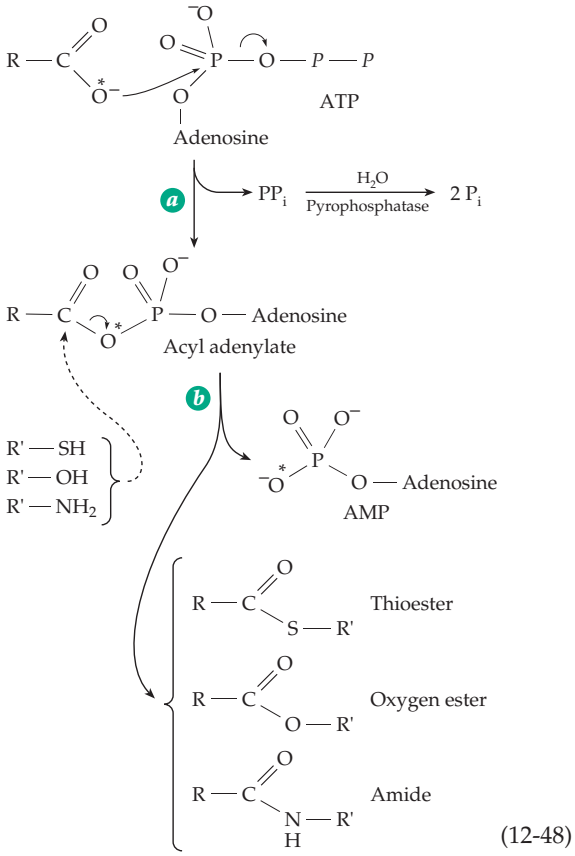


(12-47)

The two reactions of Eq. 12-47 are catalyzed by **acetate kinase**[925] and an ***S*-acetyltransferase**, respectively. The sequence represents an essential first stage in bacterial utilization of acetate for growth. It is also used in a few bacteria in reverse as a way of *generating* ATP in fermentation reactions. On the other hand, most eukaryotic cells make acetyl-CoA from acetate by coupling the synthesis to cleavage of ATP to AMP and P_i. A single enzyme **acetyl-CoA synthetase** (acetate thiokinase) catalyzes both steps in the reaction (Eq. 10-1). The sequence parallels that of Eq. 12-47, but the initial displacement is on P_α of ATP to form **acetyl adenylate**. This intermediate remains tightly bound to the enzyme until the second step in the sequence takes place. When ^{18}O is present in the acetate (designated by the asterisks in Eq. 12-48) it appears in the phospho group of AMP as expected for the indicated mechanism.

3. General Mechanism of Formation of Thioesters, Esters, and Amides

The sequences of Eqs. 12-47 and 12-48 are general ones used by cells for linking carboxylic acids to –OH, –SH, and – NH_2 groups to form oxygen esters, thioesters, or amides, respectively. ATP can be cleaved at either P_α or P_γ. If cleavage is at P_α (Eq. 12-48) the hydrolysis of inorganic pyrophosphate (PP_i) to P_i provides an additional coupling of ATP cleavage to biosynthesis as is discussed in Chapter 17, Section H.

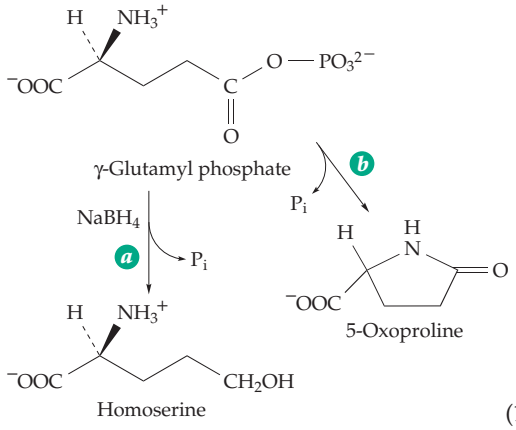


(12-48)

An enzyme catalyzing a reaction similar to that of acetyl-CoA synthetase is **succinyl-CoA synthetase** (succinate thiokinase).[926,927] The enzyme from *E. coli* has been studied most. The first step is formation of a phosphoenzyme by transfer of the γ phospho group from ATP to N^ε of histidine 246 in the α subunit of the 140-kDa $\alpha_2\beta_2$ tetramer.[926] The phospho group is then transferred to succinate to form succinyl phosphate, which reacts with coenzyme A, as in step *b*, Eq. 12-48,

to form succinyl-CoA. Crystallographic studies suggest that for this step the succinyl phosphate and the coenzyme A may be bound to opposite α subunits in the tetramer.[926] However, in some bacteria and in eukaryotes the enzyme appears to operate as an αβ heterodimer.[927]

Glutamine synthetase,[928,929] a large enzyme containing 12 identical 468-residue subunits with 622 symmetry (as in Fig. 7-12), has a major regulatory function in nitrogen metabolism, which is discussed in Chapter 24. Apparently, the intermediate acyl phosphate (γ-glutamyl phosphate) has a transient existence and all three reactants–glutamate, NH_4^+, and ATP–must be bound to the enzyme concurrently before the active site becomes functional. Early evidence for the acyl phosphate[930,931] included reduction by sodium borohydride to an alcohol (Eq. 12-49*a*) and isolation of the internal amide of glutamic acid **5-oxoproline** (Eq. 12-49*b*).



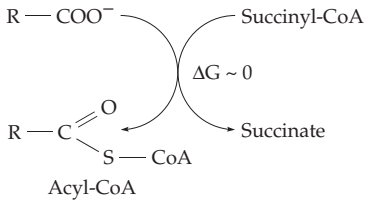
(12-49)

Ammonium ions appear to be bound at a specific site and to be deprotonated by the Asp 50 carboxylate.[929]

The **aminoacyl-tRNA synthetases** join amino acids to their appropriate tRNA molecules for protein synthesis. They have the very important task of selecting both a specific amino acid and a specific tRNA and joining them. The enzymes differ in size and other properties. However, they all appear to function by a common basic chemistry that makes use of cleavage of ATP at P_α (Eq. 12-48) via an intermediate aminoacyl adenylate and that is outlined also in Eq. 17-36. These enzymes are discussed in Chapter 29 .

4. Coenzyme A Transferases

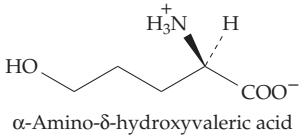
The following problem in energy transfer arises occasionally: A thioester, such as succinyl-CoA, is available to a cell and the energy available in its unstable linkage is needed for synthesis of a different thioester. It would be possible for a cell to first form ATP or GTP, using a synthetase reaction in reverse; then the ATP or GTP formed could be used to make the new linkage by the action of another acyl-CoA synthetase. However, special enzymes, the **CoA transferases**, function more directly (Eq. 12-50). The mechanism is not obvious.



(12-50)

How can the CoA be transferred from one acyl group to another while still retaining the high group transfer potential of the acyl group?

The following experiments shed some light. Kinetic studies of **succinyl-CoA–acetoacetate CoA transferase** indicate a ping-pong mechanism. The enzyme alternates between two distinct forms, one of which has been shown to contain bound CoA.[932–934] The E-CoA intermediate formed from enzyme plus acetoacetyl-CoA was reduced with ^3H-containing sodium borohydride and the protein was completely hydrolyzed with HCl. Tritium-containing α-amino-δ-hydroxyvaleric acid was isolated. Since thioesters (as well as oxygen esters) are cleaved in a two-step process



to alcohols by reduction with borohydride, it was concluded that the intermediate E-CoA is a thioester of the Glu 344 side chain. In exchange reactions ^{18}O from labeled succinate entered both the E-CoA intermediate and the carboxyl group of acetoacetate.

A mechanism involving formation of a transient anhydride is similar to reactions discussed in preceding sections.[717,720] The student should be able to write out the step-by-step detail. Does this mechanism explain the ^{18}O exchange data? A second possibility is a **4-center reaction** (Eq. 12-51). However, mechanisms of this type have not been demonstrated for enzymatic reactions.

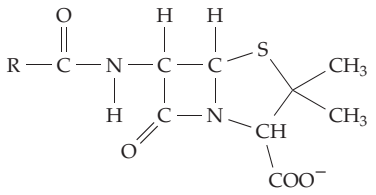
Study Questions

1. Outline the reactions by which glyceraldehyde 3-phosphate is converted to 3-phosphoglycerate with coupled synthesis of ATP in the glycolysis pathway. Show important mechanistic details.

2. Papain is a protein-hydrolyzing (proteolytic) enzyme with an –SH group and an imidazole group at the active site. Write a reasonable structure for a "tetrahedral intermediate" that would be expected to arise during formation of an acyl enzyme intermediate.

3. Adenylate kinase catalyzes the interconversion of ATP, AMP, and ADP.
   a) Draw a reasonable structure for a penta-covalent intermediate derived from ATP and AMP.
   b) Draw a reasonable structure for the transition state leading from ATP + AMP to two molecules of ADP in an S_N2-like reaction.

4. Penicillin inhibits a D-alanyl-D-alanine transpeptidase that catalyzes the reaction



Penicillin

$$\text{R}'\text{-D-alanyl-D-alanine} + \text{H}_2\text{N-R} \rightarrow \text{R}'\text{-D-alanyl-NH-R} + \text{D-alanine}$$

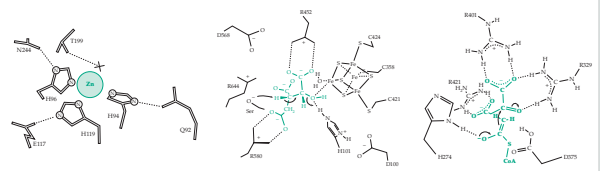
   where R and R′ are different parts of a bacterial peptidoglycan. Write a step-by-step mechanism for this reaction and indicate how penicillin may inhibit the enzyme by combining with it irreversibly. See Strynodka *et al., Nature* **359**, 700–705, 1992, for related reaction of penicillin with a penicillinase.

5. Write out step-by-step chemical mechanisms for the following enzymatic reaction. Use small arrows to indicate directions of electron flow. Remember to have all electrons move in the same direction in any single structure.

$$\text{Amino acid} + \text{tRNA} + \text{ATP} \rightarrow \text{Aminoacyl-tRNA} + \text{AMP} + \text{PP}_\text{i}$$

6. Trypsin in which Asp 102 has been replaced by Asn has 10^4 times less catalytic activity than natural trypsin at neutral pH. From the crystal structure of the mutant enzyme it appears that the imidazole group of His 57 is held by the Asn side chain in the wrong tautomeric form for catalysis. Explain. Compare this incorrect tautomeric form with that in the initial structure shown in Fig. 12-11.

7. A recent discovery in biochemistry is that RNA can act as an enzyme in chemical reactions, usually reactions involving RNA hydrolysis. Discuss the features of RNA structure that might favor evolution of enzymes composed entirely of a single polyribonucleotide chain, and describe a proposed mechanism for RNA-catalyzed hydrolysis of RNA molecules.

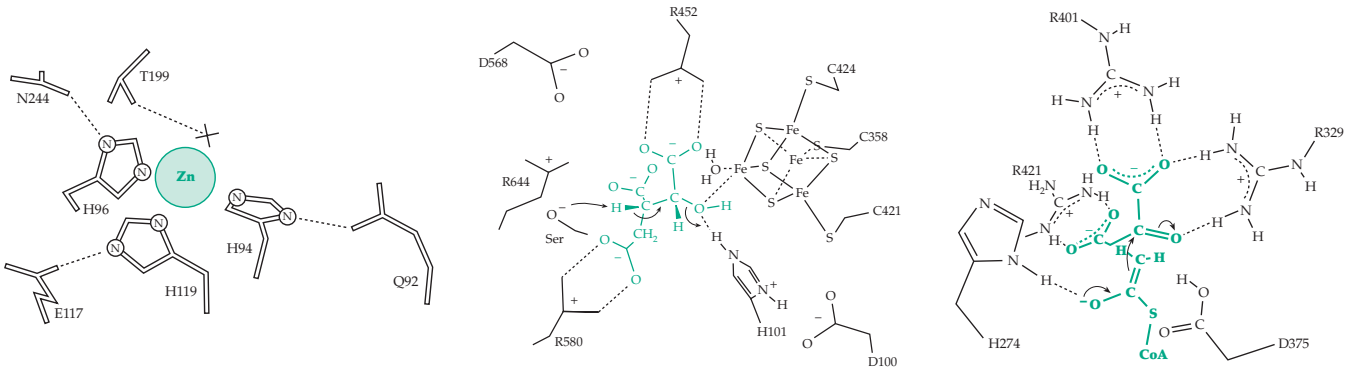


One of the simplest biochemical addition reactions is the hydration of carbon dioxide to form carbonic acid, which is released from the zinc-containing **carbonic anhydrase** (left, Fig. 13-1) as HCO_3^-. **Aconitase** (center, Fig. 13-4) is shown here removing a water molecule from isocitrate, an intermediate compound in the citric acid cycle. The H_2O that is removed will become bonded to an iron atom of the Fe_4S_4 cluster at the active site as indicated by the black H_2O. An enolate anion derived from acetyl-CoA adds to the carbonyl group of oxaloacetate to form citrate in the active site of **citrate synthase** (right, Fig. 13-9) to initiate the citric acid cycle.

Contents

Enzymatic Addition, Elimination, Condensation, and Isomerization: Roles for Enolate and Carbocation Intermediates

13

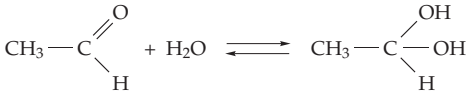


In Chapter 12 we considered reactions by which living cells are able to transfer groups from one molecule to another using nucleophilic displacements. We also showed how transfer reactions can be utilized by ligases to join two molecules together with the Gibbs energy of cleavage of ATP or of a related molecule driving the reaction. In this chapter we will examine addition reactions, which provide a simple way of joining two molecules by means of C–O, C–N, C–S, or C–C bonds. Among these are the aldol and Claisen-type condensations by which C–C bonds are formed. We will also consider elimination reactions and decarboxylations, which are the reverse of addition and condensation reactions, as well as mechanistically related isomerizations. Many reactions of these types occur in the major pathways of metabolism.

A. Addition of R–OH, R–NH_2, and R–SH to Polarized Double Bonds

Next to nucleophilic displacement, the commonest mechanistic processes in enzymatic catalysis are addition to double bonds and elimination to form double bonds. These often involve addition of a nucleophile together with a proton to a highly polarized double bond such as C=O or C=N–. In other reactions, which are discussed in Section C,2, the nucleophile attacks one end of a C=C bond that is polarized by conjugation with C=O or C=N.

Alcohols, amines, and thiols add readily to the electrophilic carbon of the carbonyl group to form **hemiacetals**, **carbinolamines, hemiketals,** and **hemimercaptals**. An example is the formation of ring structures of sugars (Eq. 4-1). Water can also add to carbonyl groups and most aliphatic carbonyl compounds exist in water as an equilibrium mixture with a covalent hydrate (Eq. 13-1). For example, acetaldehyde in aqueous solution consists of a mixture of about 50% free aldehyde and 50% hydrate in rapidly reversible equilibrium[1,2] and formaldehyde is over 99.9% hydrated.[3]

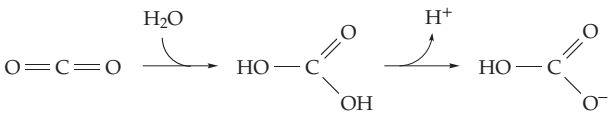


(13-1)

Addition reactions often occur as parts of more complex reactions. For example, a thiol group of glyceraldehyde-3-phosphate dehydrogenase reacts with the aldehyde substrate to form a hemimercaptal, which is subsequently oxidized to a thioester (see Fig. 15-6).

1. Carbonic Anhydrase

Another simple addition reaction is the hydration of CO_2 to form the bicarbonate ion. Without catalysis the reaction may require several seconds,[4,5] the apparent first-order rate constant being ~0.03 s^{-1} at 25°C. Cells must often hasten the process. The specific catalyst carbonic anhydrase is widespread in its distribution



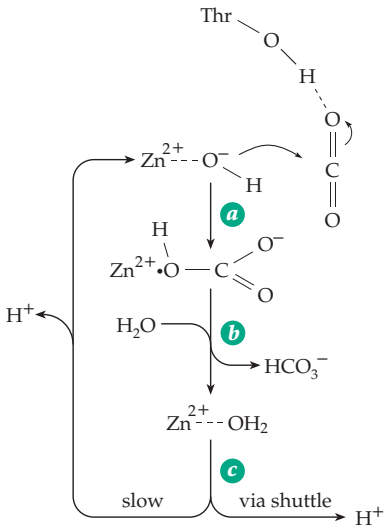
(13-2)

and is especially active in tissues (e.g., red blood cells, and lungs) that are involved in respiration. One liter of mammalian blood contains 1–2 g of this enzyme, a monomeric 30-kDa protein containing ~260 amino acids and one tightly bound ion of Zn^{2+}. Erythrocytes contain two isoenzymes (I and II) of carbonic anhydrase and the human body contains at least eight distinct isoenzymes (I – VIII).[5–8] They are found wherever there is a high demand for CO_2 or bicarbonate. Isoenzyme I, II, III, and VII are cytosolic. Carbonic anhydrase I is specific to erythrocytes, while isoenzyme II is present in most cells. Hereditary lack of carbonic anhydrase II is associated with **osteopetrosis** (marble bone disease), a condition involving failure of bone resorption and the calcification of other tissues.[9] The generation of acidity according to Eq. 13-2 is presumably required for dissolution of bone by the osteoclasts.

Isoenzymes III and VII have a more specialized distribution. Carbonic anhydrase III is abundant in adipocytes which use bicarbonate in fatty acid synthesis.[7] Isoenzyme V is present in the mitochondrial matrix and is also abundant in both adipocytes and liver.[7,8] Isoenzyme IV is a larger membrane-associated form, while VI is secreted into the saliva.[10] Carbonic anhydrase has also been identified in *E. coli*.,[11] in a methanobacterium,[12] and in green plants.[13,13a] A 60-kDa carbonic anhydrase called **nacrein** is found in the organic matrix of the nacreous layer of the pearl oyster, the layer that forms aragonite (orthorhombic calcium carbonate) in the shell and in pearls.[14]

X-ray studies of carbonic anhydrases I and II, from human blood, revealed that both have an ellipsoidal shape of dimensions ~4.1 x 4.1 x 4.7 nm.[15,16] The zinc atom in each molecule lies in a deep pocket ~1.2 nm from the surface and is surrounded by three histidine side chains and one H_2O or OH^- ion, the four ligands forming a distorted tetrahedron (Fig. 13-1). The coordinating imidazole group from His 119 is hydrogen bonded to a carboxylate group of Glu 117, a feature reminiscent of the charge-relay system of serine protease. This carboxylate group is also bound into a more extended hydrogen-bonded network, part of which is indicated in Fig. 13-1. The other imidazole groups also form hydrogen bonds to protein groups and the zinc-bound H_2O is involved in an extensive hydrogen-bonded network with several other bound water molecules and protein side chains.[17a] Most of these structural features are conserved in the other mammalian isoenzymes.[5] However, from X-ray absorption spectroscopy (EXAFS) it appears that spinach carbonic anhydrase contains one or more sulfur ligands to the zinc,[13] while the enzymes from the archaeon *Methanosarcina thermophila* have a left-handed β helix structure (see Figs. 2-17 and 13-3).[12] Nevertheless, this enzyme has the same three-histidine Zn–OH structure found in the mammalian enzymes.

Carbonic anhydrase II is among the most rapid enzymes known, with the turnover number at 25°C for hydration of CO_2 being ~10^6 s^{-1}. The same enzyme catalyzes hydration of acetaldehyde (Eq. 13-1) but at a 1000-fold slower rate. A pK_a of ~7 controls the activity. This appears to represent the loss of H^+ from the Zn^{2+}–OH_2 complex[18] to give Zn^+–OH. The latter is in effect a stabilized hydroxide ion existing at a pH at which OH^- is normally not present in quantity. It is this hydroxide ion that adds to the CO_2 or to the aldehyde substrate (Eq. 13-3, step *a*).[18–20] In step *b* a water molecule replaces the departing bicarbonate.[17] A variety of data



(13-3)

indicate that proton transfers mediated by the enzyme are essential parts of the carbonic anhydrase mechanism.[18–19b,21–23] One proposal is that the nearby imidazole group of His 64 (not shown in Fig. 13-1) deprotonates the bound H_2O via a hydrogen-bonded network of bound water molecules (Eq. 13-3, step *c*). The side chain of Thr 199 may function in a cyclic proton transfer in step *c*.[19] The proton generated in step *c* is released to the solvent in a process that is catalyzed by buffer anions or by amines such as histamine. The latter binds at the edge of the active site and forms an additional hydrogen-bonded pathway to the zinc-bound H_2O.[24] A different proton shuttle pathway has been proposed for the slower carbonic anhydrase III.[25]

Related to the reaction catalyzed by carbonic anhydrase is the addition of an amino group to CO_2 (Eq. 2-21) to form a carbamino group (–NH–COO^-). This reaction is essential to the functioning of hemoglobin, which must carry large amounts of CO_2, as carbamino groups, from tissues to the lungs, (Eq. 7-47) and to some enzymes such as ribulose bisphosphate carboxylase (Figs. 13-10, 13-11).

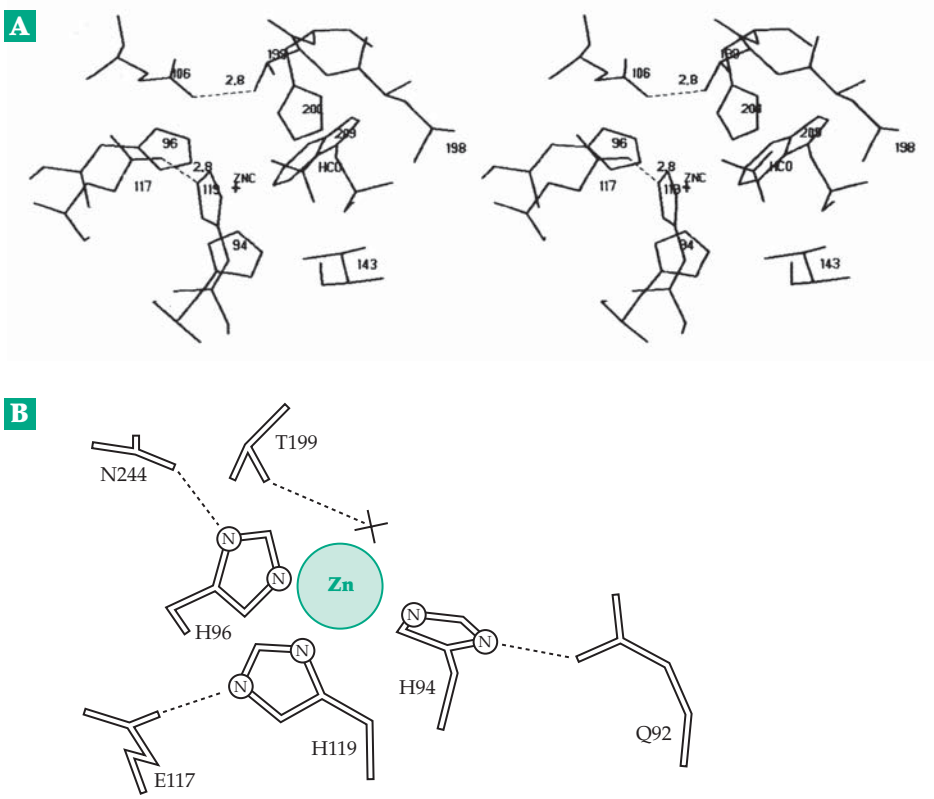


Figure 13-1 (A) Stereoscopic view showing the binding pocket for HCO_3^- in the active site of human carbonic acid anhydrase I. Also shown are the hydrogen-bonded pairs E117–H119 and E106–T199. ZNC, zinc ion; HCO, bicarbonate. From Kumar and Kannan.[16] (B) View of the active site of carbonic anhydrase II. The orientation is a little different than in (A). The location of H_2O or ^-OH bound to the zinc ion is marked X. Hydrogen bonds from the three histidines that form coordinate bonds to the zinc, Q92, E117, the backbone carbonyl of N244, and the hydrogen bond from the zinc-bound hydroxyl to the T199 side chain are shown as dashed lines. From Kiefer *et al.*[17]

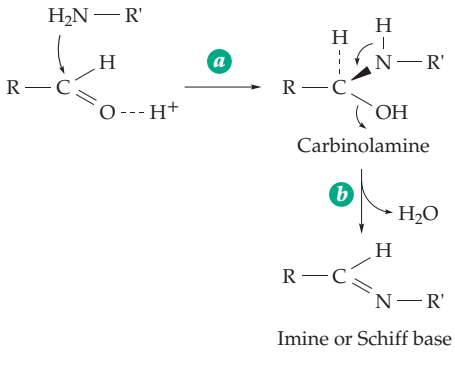
2. Imines (Schiff Bases)

As we have seen already, many enzymatic reactions depend upon formation of **imines**, which are commonly called Schiff bases. The two-step formation of Schiff bases consists of addition of an amino group to a carbonyl group to form a carbinolamine followed by elimination of water (Eq. 13-4).[26] One group of **aldolases** (Section D) have, at their active centers,



(13-4)

lysine side chains which form Schiff bases with the ketone substrates prior to the principal reaction of breaking or forming a C – C bond. Similarly, the initial reaction of the aldehyde coenzyme **pyridoxal phosphate** with amino acid substrates is the formation of Schiff bases (Fig. 14-4). Indeed, *the groups C=O and H_2N– are inherently complementary* and their interaction through imine formation is extremely common.

Schiff bases often form within a fraction of a second, but one or both steps of Eq. 13-4 may require catalysis to achieve enzymatic velocities.[27] The reaction is usually completely reversible and formation constants are often low enough that a carbonyl compound present in small amounts will not react extensively with an amine unless the two are brought together on an enzyme surface. If the amino group is hydrogen bonded to the enzyme, the proton may remain on the Schiff base nitrogen, enhancing the electron-accepting properties of the C=N group. The pK_a values of Schiff bases with aliphatic aldehydes are usually 1–2 units lower than those of the corresponding primary amines. However, the local environment may sometimes cause the pK_a to be increased. Most Schiff bases are reduced readily by sodium borohydride or sodium cyanoborohydride to form secondary amines in which the original aldehydes are bound covalently to the original amino groups (Eq. 3-34). This provides a method for locating sites of Schiff base formation in enzymes. An isotopically substituted aldehyde or amine can be employed, or an isotopic label can be introduced, by using ^2H- or ^3H-containing sodium borohydride in the reduction.

3. Stereochemistry of Addition to Trigonal Carbon Atoms

Adducts formed by enzymatic addition of nucleophiles to carbonyl groups are usually chiral. For example, addition of an amino group to the "front" side of the carbonyl carbon in Eq. 13-5 (the *si* face as defined in Chapter 9) creates a carbinolamine of the *S* configuration. Addition of the amino group from behind the plane of the paper (the *re* face) would lead to a carbinolamine of the *R* configuration.

BOX 13-A ZINC

The average human ingests 10–15 mg of zinc a day.[a] Although it is poorly absorbed, the concentrations of zinc in tissues are relatively high and the metal plays an essential role in a multitude of enzymes. The total zinc content of a 70-kg person is 1.4–2.3 g. A typical tissue concentration of Zn^{2+} is 0.3–0.5 mM; an unusually high content of ~15 mM is found in the prostate gland.

Zinc ion is much more tightly bound to most organic ligands than is Mg^{2+} (Table 6-9). It has a filled 3*d* shell and tends to form four ionic bonds with a tetrahedral geometry, often with nitrogen- or sulfur-containing ligands.[b] Unlike Mg^{2+}, which interacts rapidly and reversibly with enzymes, Zn^{2+} tends to be tightly bound within over 300 **metalloenzymes**.[c–e] A common feature is the surrounding of the Zn^{2+} at the active center by three imidazole groups, the fourth coordination position being free for interaction with substrate. The second nitrogen of the imidazole ring in many instances is hydrogen bonded to a main chain carbonyl group of the peptide, a feature that is also shared by histidines in other metalloproteins.

The most important chemical function of Zn^{2+} in enzymes is probably that of a Lewis acid providing a concentrated center of positive charge at a nucleophilic site on the substrate.[f] This role for Zn^{2+} is discussed for carboxypeptidases (Fig.12-16) and thermolysin,[g] alkaline phosphatase (Fig. 12-23),[h] RNA polymerases, DNA polymerases, carbonic anhydrase (Fig. 13-1),[i] class II aldolases (Fig. 13-7), some alcohol dehydrogenases (Fig. 15-5), and superoxide dismutases (Fig.16-22). Zinc ions in enzymes can often be replaced by Mn^{2+}, Co^{2+}, and other ions with substantial retention of catalytic activity.[f,j]

In addition to its function in catalysis, zinc often plays an important structural role, e.g., in the **zinc finger** transcriptional regulators (Fig. 5-38).[k] Zinc ions bind to insulin and stabilize its hexameric structure (Fig. 7-18).[l] Six Zn^{2+} ions are present in the hexagonal tail plate of the T-even bacteriophage (Box 7-C) and appear to be essential for invasion of bacteria.[m] In carnivores, the **tapetum**, the reflecting layer behind the retina of the eye of many animals, contains crystals of the Zn^{2+}–cysteine complex. Since zinc ions have no color their presence has often been overlooked. Zinc ions will doubtless be found in many more places within cells. Zinc is usually the major component of the bound metals in the **metallothioneins** (Box 6-E). These small 6.6-kDa proteins which contain ~33% cysteine and bind as many as six ions of Cd^{2+}, Hg^{2+}, Cu^{2+}, or Zn^{2+} per molecule are present in all animal tissues as well as in plants and some bacteria.[j]

From a nutritional viewpoint, Cu^{2+} competes with zinc ion, as does the very toxic Cd^{2+}. The latter accumulates in the cortex of the kidney. Dietary cadmium in concentrations less than those found in human kidneys shortens the lives of rats and mice. However, some marine diatoms contain a cadmium-dependent carbonic anhydrase.[n] Although zinc deficiency was once regarded as unlikely in humans, it is now recognized as occurring under a variety of circumstances[o,p] and is well-known in domestic animals.[q] Consumption of excessive amounts of protein as well as alcoholism, malabsorption, sickle cell anemia, and chronic kidney disease can all be accompanied by zinc deficiency.

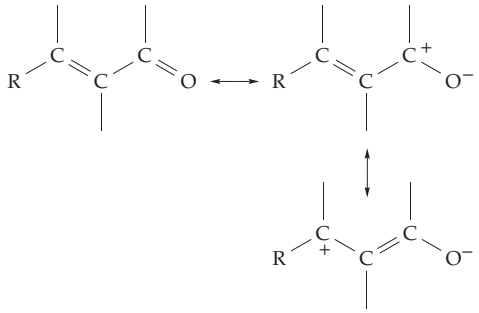
Addition from "front" (*re* face of the carbonyl carbon) — *S* configuration (13-5)

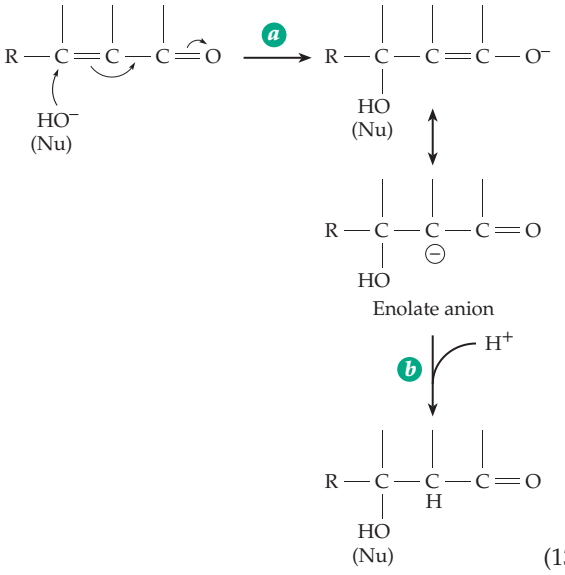
4. Addition to Carbon–Carbon Double Bonds, Often Reversible Reactions

Most of the reactions that we will consider in this chapter involve addition of a proton to a carbon atom or removal of a proton attached to a carbon atom. A frequent metabolic reaction is addition of water to a carbon–carbon double bond that is conjugated with a carbonyl group. This transmits the polarization of the carbonyl group to a position located two carbon atoms further along the chain.



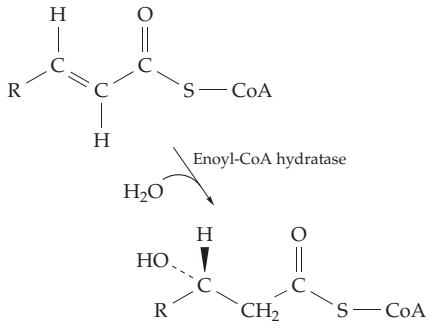
Because of this effect bases can add to a carbon–carbon double bond in a position β to the carbonyl group as in Eq. 13-6, step *a*. The product of addition of HO^- is the anion of an **enol** in which the negative charge is distributed by resonance between the oxygen of the carbonyl group and the carbon adjacent to the carbonyl. A stable product results if a proton adds to the latter position (Eq. 13-6, step *b*). Many nucleophilic groups (Nu in Eq. 13-6) other than HO^-, may add, the reaction being known as a **Michael addition**. If a neutral nucleophile Nu adds, the product may lose a proton, or transfer it to the adjacent carbon in Eq. 13-6, step *b*, to give a neutral end product. The reverse of an addition reaction of this type is also known as an **elimination reaction**.

Enzymatic reactions involving addition to a C=C bond adjacent to a carbonyl group (or in which elimination occurs α,β to a carbonyl) are numerous. Except for some enzymes acting by free radical mechanisms, the nucleophilic group always adds at the β position suggesting that the mechanism portrayed by Eq. 13-7 is probable. It is noteworthy that *frequently in a metabolic sequence a carbonyl group is deliberately introduced to facilitate elimination or addition at adjacent carbon atoms*. The carbonyl may be formed by oxidation of a hydroxyl group or it may be provided by a thioester formed with coenzyme A or with an **acyl carrier protein** (Chapter 14).



(13-6)

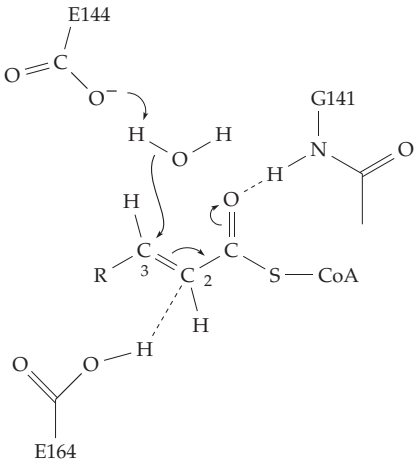
Enoyl-CoA hydratase. A specific example of the reaction in Eq. 13-6 is the addition of water to *trans*-α,β-unsaturated CoA derivatives (Eq. 13-7). It is catalyzed by enoyl–CoA hydratase (crotonase) from mitochondria and is a step in the β oxidation of fatty acids (Fig. 10-4).



L-β-Hydroxyacyl-CoA (13-7)

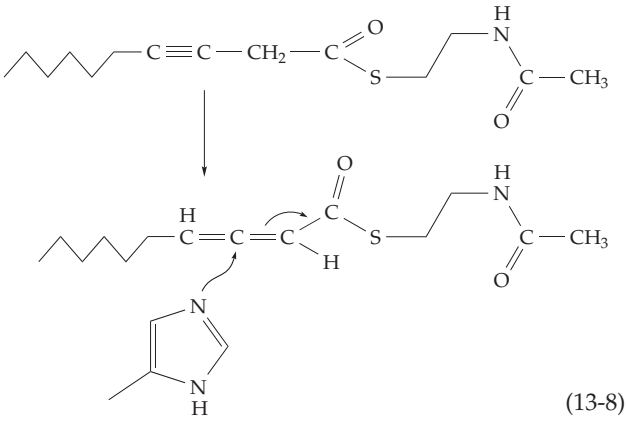
The enzyme is a hexamer, actually a dimer of trimers made up of 291-residue polypeptide chains.[28] Acetoacetyl-CoA is a competitive inhibitor which binds into the active site and locates it. From the X-ray structure of the enzyme–inhibitor complex it can be deduced that the carboxylate group of E144 abstracts a proton from a water molecule to provide the hydroxyl ion that binds to the β position (Eq. 13-6, step *a*) and that the E164 carboxyl group donates a proton to the intermediate enolate anion in step *b*.[28] The hydroxyl group

and the proton enter from the same side of the double bond in a *syn* addition. The X-ray structure shows that the E144 and E164 side chains are on the same side of the double bond, accounting for this stereochemistry.[28,28a]



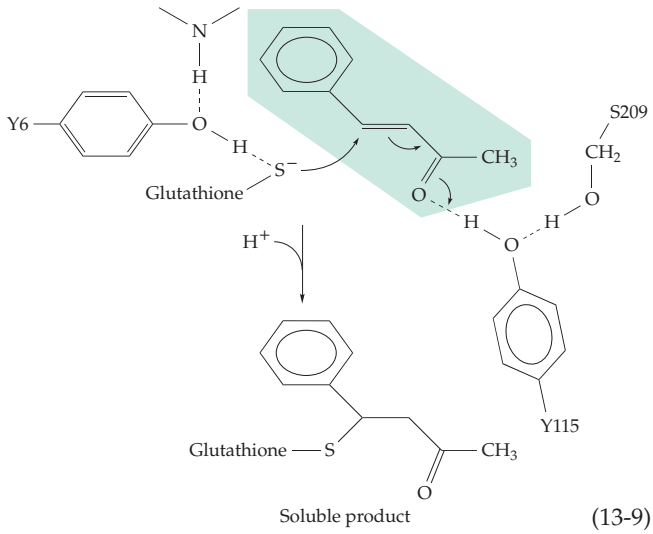
Cinnamoyl-CoA thiol esters (R = phenyl in the foregoing structure) contain a good light-absorbing group (chromophore). Binding to the protein induces distinct shifts in the ultraviolet absorption spectrum and also in ^{13}C NMR and Raman spectra. These shifts suggest that binding induces an enhanced positive charge at C-3 and formation of a strong hydrogen bond to the carbonyl group.[29] The X-ray studies indicate that this bond is to the G141 peptide nitrogen as shown. These results favor an enolate anion intermediate as in Eq. 13-6. However, kinetic isotope effects[30] as well as studies of proton exchange have suggested a concerted mechanism with water adding at the same time that a proton binds at C-2.[30–31a]

A closely related *E. coli* protein is a 79-kDa multifunctional enzyme that catalyzes four different reactions of fatty acid oxidation (Chapter 17). The amino-terminal region contains the enoyl hydratase activity.[32] A quite different enzyme catalyzes dehydration of thioesters of β-hydroxyacids such as 3-hydroxydecanoyl-acyl carrier protein (see Eq. 21-2) to both form and isomerize enoyl-ACP derivatives during synthesis of unsaturated fatty acids by *E. coli*. Again, a glutamate side chain is the catalytic base but an imidazole group of histidine has also been implicated.[33] This enzyme is inhibited irreversibly by the *N*-acetylcysteamine thioester of 3-decynoic acids (Eq. 13-8). This was one of the first enzyme-activated inhibitors to be studied.[34]



(13-8)

Glutathione S-transferases. Addition of glutathione (Box 11-B) to a large variety of different substrates containing electrophilic centers, such as that at the β position in an α,β-unsaturated ketone (Eq. 13-9), is catalyzed by the ubiquitous group of enzymes called glutathione *S*-transferases. There are six classes of

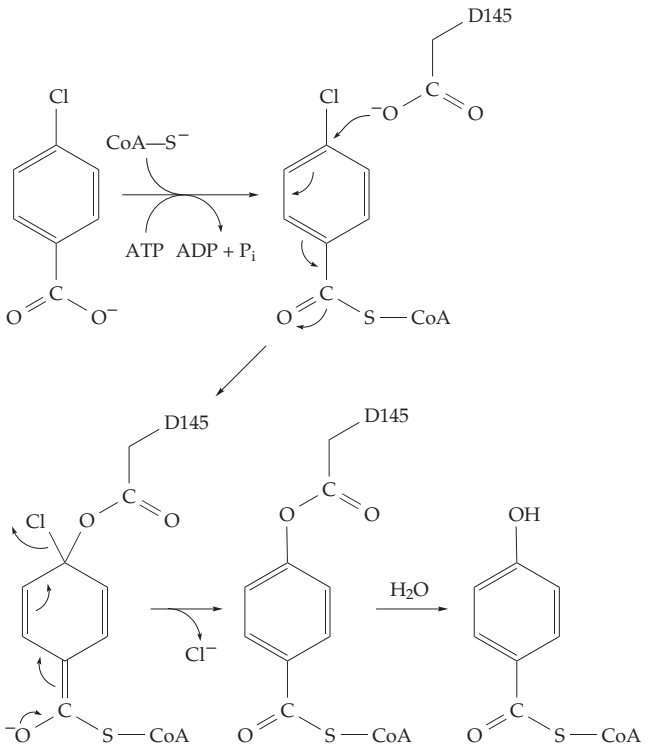


(13-9)

eukayotic glutathione *S*-transferases—one membrane-associated microsomal[35] and five cytosolic.[36–40] They play an important role in detoxifying many xenobiotics and other relatively hydrophobic compounds by converting them to more soluble compounds that can be degraded and excreted easily (see Box 11-B). A pair of tyrosines appear to participate in catalysis, as is indicated in Eq. 13-9.[38,41] Glutathione *S*-transferases have attracted attention because of their role in detoxifying anticancer drugs. Cancer cells can become resistant to drugs as a result of excessive synthesis of these detoxifying enzymes. At the same time glutathione transferases protect human patients from drugs. In plants these enzymes may provide protection from insecticides and herbicides.[41a] Glutathione transferases of pathogenic organisms such as schistosomes are appropriate targets for new drugs as well as for vaccines.[42] Nonenzymatic Michael addition of glutathione to such compounds as **4-hydroxynonenal**, a product of peroxidation of the polyunsaturated arachidonate (see Eq. 21-15) are also biochemically important.

Chlorobenzoyl-CoA dehalogenase. The enzymatic release of chloride ion from 4-chloroxybenzoyl-CoA

would be hard to explain by a simple nucleophilic displacement by HO^-. However, *addition* of HO^-, followed by elimination of Cl^-, would be chemically reasonable. Nevertheless, single-turnover studies revealed a more complex mechanism involving formation of a covalent adduct with the enzyme.[43,44] A carboxylate group adds and Cl^- is eliminated to form of an oxygen ester, which is then hydrolyzed to the final product (Eq. 13-10). Studies of mutant enzymes[45] together with X-ray crystallography[46] support this mechanism. As with enoyl-CoA hydratase, binding of substrate to chlorobenzoyl-CoA dehalogenase causes alterations in ultraviolet, NMR, and Raman spectra that can be interpreted as indicating enhanced polarization of the benzoyl group.[47,48] For example, changes in the C = O stretching frequency suggest that the bond is elongated, presumably as a result of hydrogen bonding to the N – H of G114, which lies at the N terminus of an α helix and experiences the additional polarizing effect of the helix dipole (Fig. 2-20).[48,49] This effect can be compared with that mentioned previously for enoyl-CoA hydratase.

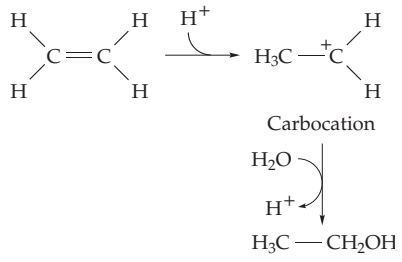


(13-10)

In fact, close sequence and structural homologies show that chlorobenzoyl-CoA dehalogenase, enoyl-CoA hydratase, and a variety of other hydratases, isomerases, synthases, lyases, and hydrolases belong to a large family of related proteins.[49a,49b,49c]

5. Addition to Double Bonds Adjacent to Carboxylate Groups

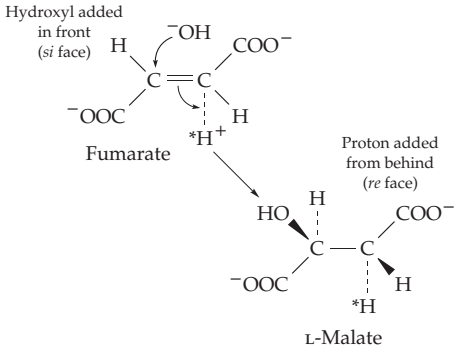
Biochemical reactions often involve addition to C = C bonds that are not conjugated with a true carbonyl group but with the poorer electron acceptor $-COO^-$. While held on an enzyme a carboxylate group may be protonated, making it a better electron acceptor. Nevertheless, there has been some doubt as to whether the carbanion mechanism of Eq. 13-6 holds for these enzymes. Some experimental data suggested a quite different mechanism, one that has been established for the nonenzymatic hydration of alkenes. An example is the hydration of ethylene by hot water with dilute sulfuric acid as a catalyst (Eq. 13-11), an industrial method of preparation of ethanol. The electrons of the double bond form the point of attack by a proton, and the resulting carbocation readily abstracts a hydroxyl



(13-11)

ion from water. Direct addition of OH^- to ethylene to form a carbanion is not favored, because there is no adjacent carbonyl group to stabilize the negative charge.

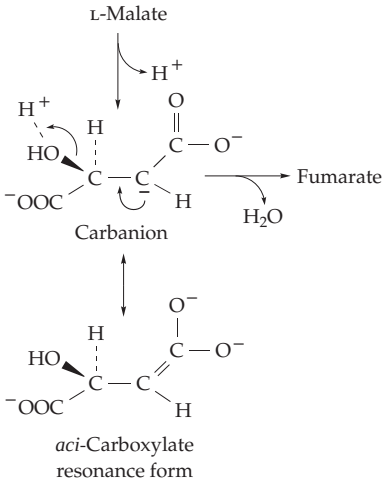
Fumarate hydratase. The most studied enzyme of this group is probably the porcine mitochondrial fumarate hydratase (fumarase; see also Chapter 9), a tetramer of 48.5-kDa subunits[50] with a turnover number of ~2 x 10^3 s^{-1}. It accelerates the hydration reaction more than 10^{15}-fold.[51] A similar enzyme, the 467-residue **fumarase C** whose three-dimensional structure is known,[52,53] is found in cells of *E. coli* when grown aerobically. The product of the fumarate hydratase reaction is L-malate (*S*-malate). The stereospecificity is extremely high. If the reaction is carried out in ^2H_2O an atom of ^2H is incorporated into the *pro-R* position, i.e., the proton is added strictly from the *re* face of the trigonal carbon (Eq. 13-12). To obtain L-malate the hydroxyl must have been added from the opposite side of the double bond. Such *anti* (*trans*) addition is much more common in both nonenzymatic and enzymatic reactions than is addition of both H and OH (or –Y) from the same side (*syn*, *cis*, or adjacent addition).[54] For concerted addition it is a natural result of stereoelectronic control. Almost *all* enzymatic addition and elimination reactions involving free carboxylic acids are anti with the proton entering from the *re* face,



(13-12)

suggesting that there has been conservation throughout evolution of a single basically similar mechanism.[54,55]

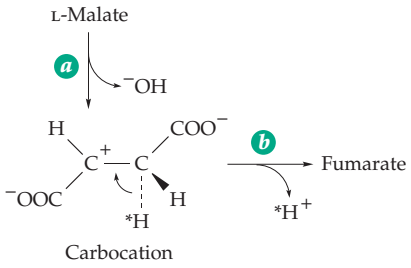
The pH dependence of the action of fumarate hydratase indicates participation of both an acidic and a basic group with pK_a values of 5.8 and 7.1.[56] See Chapter 9 for additional information. However, either anion or carbocation mechanisms might be possible. That the cleavage of the C–H bond is not rate limiting is suggested by the observation that malate containing ^{2}H in the *pro-R* position is dehydrated at the same rate as ordinary malate. If the anion mechanism (Eq. 13-13) is correct, the ^{2}H from the *pro-R* position of specifically labeled malate might be removed rapidly, while the loss of OH^- could be slower. If so, the ^{2}H would be "washed out" of L-malate faster than could happen by conversion to fumarate followed by rehydration to malate. In fact, the opposite was observed.



(13-13)

The hydroxyl group was lost rapidly and the ^{2}H more slowly. This result suggested the carbocation ion mechanism of Eq. 13-14.

While no *primary* isotope rate effect was observed, when the hydrogen at C-2 or the *pro-S* hydrogen at C-3 of malate was replaced by ^{2}H or ^{3}H distinct secondary isotope effects were seen. Thus, k(^{1}H) / k(^{2}H) = 1.09 for both the *pro-S* and the C-3 hydrogen atoms.[57] These findings appeared to support the carbocation

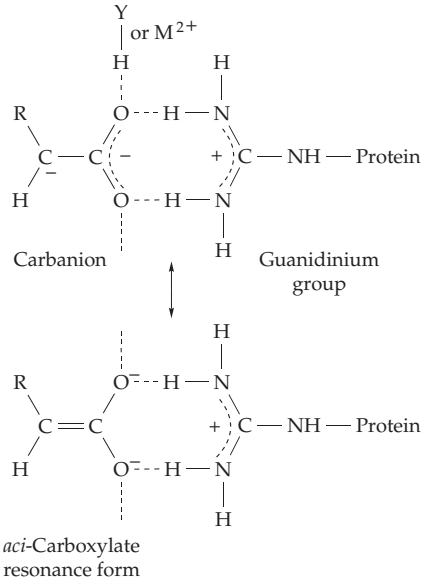


(13-14)

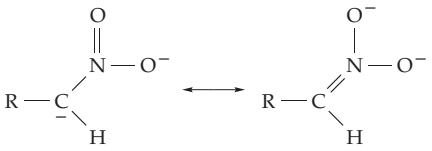
mechanism for the reasons considered in Chapter 12 and suggested that step *b* of Eq. 13-14 is rate limiting. The relative values of V_{max} for hydration of fumarate, fluorofumarate, and difluorofumarate (104, 410, and 86 mol ml^{-1} min^{-1} mg^{-1}) also seemed to support the carbocation mechanism.[58]

However, it has become clear that protons removed from a substrate to a basic group in a protein need not exchange rapidly with solvent (see Eq. 9-102). In fact, the proton removed by fumarate hydratase from malate is held by the enzyme for relatively long periods of time. Its rate of exchange between malate and solvent is slower than the exchange of a bound fumarate ion on the enzyme surface with another substrate molecule from the medium.[59] Thus, the overall rate is determined by the speed of dissociation of products from the enzyme and we cannot yet decide whether removal of a proton precedes or follows loss of OH^-.

Two new lines of evidence suggest that proton abstraction comes first. A careful study of both ^{18}O and ^{2}H isotope effects[60] supports the carbanion intermediate, as does the strong inhibition by anions of 3-nitropropionate and 3-nitro-2-hydroxypropionate.[61] To provide a good electron sink the carboxylate group adjacent to the proton that is removed by fumarate hydratase must either be actually protonated in the enzyme–substrate (ES) complex or paired with and hydrogen bonded to a positively charged group.



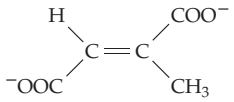
The anion formed by removal of the 3-H is analogous to the enolate anion of Eq. 13-6 and has a strong structural similarity to the readily formed anions of organic nitro compounds. The nitronate anions may, perhaps, be regarded as transition state inhibitors.



Nitronate anion

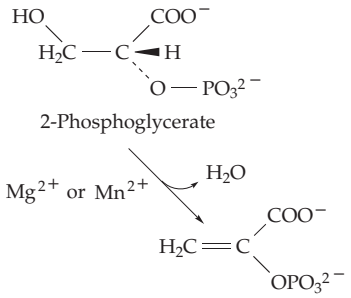
There is still a third possible mechanism for the fumarate hydratase reaction. The proton and hydroxyl groups may be added *simultaneously* in a concerted reaction.[62] However, observed kinetic isotope effects are not consistent with this mechanism.[60] In 1997 the structure of fumarase C of *E. coli* was reported.[52,53] Each active site of the tetrameric enzyme is formed using side chains from three different subunits. The H188 imidazole is hydrogen bonded to an active site water molecule and is backed up by the E331 carboxylate which forms a familiar catalytic pair. However, these results have not clarified the exact mode of substrate binding nor the details of the catalytic mechanism. Structural studies of fumarate hydratase from yeast[53a] and the pig[53b] are also in progress.

Some other fumarate-forming reactions. Other enzymes that catalyze elimination reactions that produce fumarate are **aspartate ammonia-lyase** (aspartase),[63] **argininosuccinate lyase** (Fig. 24-10, reaction *g*),[64,65] and **adenylosuccinate lyase** (Fig. 25-15). In every case it is NH_3 or an amine, rather than an OH group, that is eliminated. However, the mechanisms probably resemble that of fumarate hydratase. Sequence analysis indicated that all of these enzymes belong to a single **fumarase-aspartase family**.[64,65] The three-dimensional structure of aspartate ammonia-lyase resembles that of fumarate hydratase, but the catalytic site lacks the essential H188 of fumarate hydratase. However, the pK_a values deduced from the pH dependence of V_{max} are similar to those for fumarase.[64] **3-Methylaspartate lyase** catalyzes the same kind of reaction to produce ammonia plus *cis*-mesaconate.[63] Its sequence is not related to that of fumarase and it may contain a dehydroalanine residue (Chapter 14).[66]



cis-Mesaconate

Enolase. A key reaction in the metabolism of sugars is the dehydration of 2-phosphoglycerate to form **phosphoenolpyruvate** (PEP), the phospho derivative of the enolic form of pyruvic acid:



(13-15)

A carbanionic intermediate has often been suggested for this enzyme.[67,68] However, despite measurements of kinetic isotope effects and many other experiments it has been difficult to establish a detailed mechanism.[68]

Enolase has a complex metal ion requirement,[68a,69] usually met by Mg^{2+} and Mn^{2+}. From NMR studies of the relaxation of water protons, it was concluded that a Mn^{2+} ion coordinates two rapidly exchangeable water molecules in the free enzyme. When substrate binds, one of these water molecules may be immobilized and may participate in an addition reaction that forms phosphoenolpyruvate (reverse of reaction 13-15). A tightly bound "conformational" metal ion is located in the known three-dimensional structure in such a

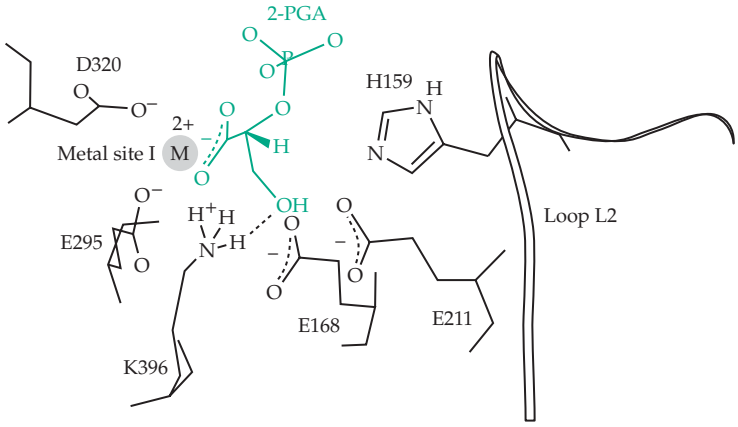


Figure 13-2 View of the active site of yeast enolase containing a bound molecule of 2-phospho-D-glycerate. The catalytic magnesium ion is at the left but the "conformational" metal is not visible here. The imidazole group of His 159 serves as the catalytic base and the $-NH_3^+$ of Lys 396 or Lys 345[73b] as the catalytic acid. From Vinarov and Nowak.[69]

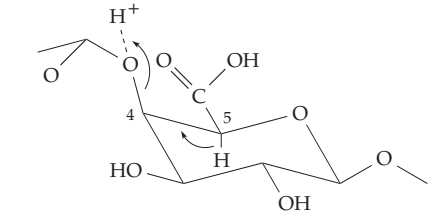
way that it might function in this manner. A more loosely bound "catalytic" metal ion is also essential.[69–72]

Figure 13-2 shows a view of the active site of yeast enolase occupied by a molecule of bound 2-phosphoglycerate. Histidine 159 is probably the catalytic base that removes the α-proton to form an *aci*-anion which is stabilized by interaction with the catalytic Mg^{2+} ion. A protonated lysine 396 amino group may be the catalytic acid.[68a,69] The active site is surrounded by a complex hydrogen-bonded network.[73] As is discussed in Section B, a large number of other enzymes belong to an **enolase superfamily** of enzymes. Among them is **glucarate dehydratase**, which initiates a pathway for catabolism of D-glucarate and galactarate in *E. coli*.[73a]

Pectate lyase and related enzymes. A group of polysaccharide lyases cleave the chains of polymers of uronic acids with 1,4 linkages such as pectins, hyaluronan, heparin,[74,75] and dermatan sulfate (Fig. 4-11). These bacterial enzymes also employ an elimination mechanism.[76] The geometry of the β-linked galacturonic acid units of pectin is favorable for *anti* elimination of the 5-H and the *O*-glycosyl group in the 4 position (Eq. 13-16). However, the corresponding **hyaluronate lyase** (hyaluronidase) acting on glucuronic acid residues causes a *syn* elimination. These results suggest the formation of anionic intermediates which can eliminate a substituent from either the equatorial or axial position of the sugar ring. Hyaluronate lyase from the pathogenic *Streptococcus pneumoniae* apparently utilizes an imidazole group as the catalytic base and a tyrosine side chain as the proton donor in the reaction.[76a,76b]

Pectate lyase C from the plant pathogen *Erwinia*, which causes soft-rot in many different plants, has a parallel β barrel structure (Fig. 13-3)[77] which is similar to that of the tailspike protein shown in Fig. 2-17 and represents what may be a very large structural family of proteins.[78] The location of the active site is not



Galacturonic acid unit of pectin

obvious from the structure but on the basis of the effects of a large number of mutations, it is thought to be near the Ca^{2+}- binding site labeled in Fig. 13-3. Replacement of any of three Asp or Glu and three Lys residues in this region leads to loss of or reduction in catalytic activity.[79]

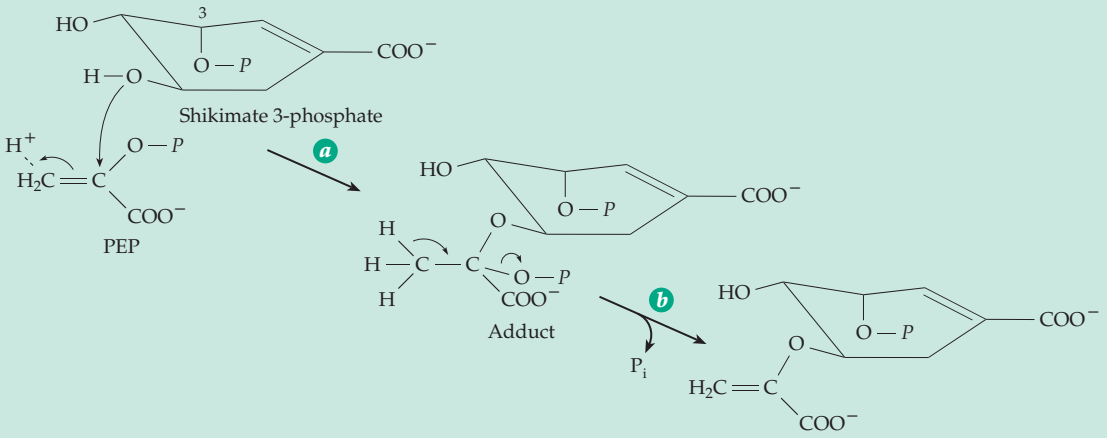
6. Aconitase and Related Iron – Sulfur Proteins

Two consecutive reactions of the citric acid cycle (Fig. 10-6), the dehydration of citrate to form *cis*-aconitate and the rehydration in a different way to form isocitrate (Eq. 13-17), are catalyzed by aconitase (aconitate hydratase). Both reactions are completely stereospecific. In the first (Eq. 13-17, step *a*), the *pro-R* proton from C-4 (stereochemical numbering) of citrate is removed and in step *c* isocitrate is formed. Proton addition is to the *re* face in both cases.

As with fumarate hydratase, the enzyme holds the abstracted proton (for up to 7×10^{-5} s) long enough so that a *cis*-aconitate molecule sometimes diffuses from the enzyme and (if excess *cis*-aconitate is present) is replaced by another. The result is that the new *cis*-aconitate molecule sometimes receives the proton (intermolecular proton transfer). The proton removed

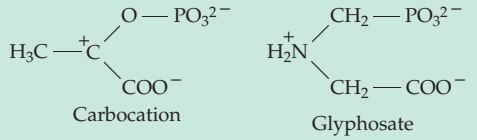
BOX 13-B EPSP SYNTHASE AND THE HERBICIDE GLYPHOSATE

The reversible reaction of phosphoenolpyruvate (PEP) with shikimate 3-phosphate is a step in the synthesis of the aromatic amino acids (see Fig. 25-1). The chemical mechanism indicated



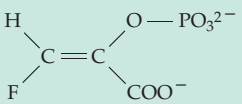
5-Enolpyruvoylshikimate-3-phosphate (EPSP)

was proposed by Leaven and Sprinson in 1964.[a] Step *a* is unusual[b] because it involves protonation on the methylene carbon of PEP and addition of a nucleophile at C-2, the opposite of the addition in the enolase reaction (Eq. 13-15, reverse). It is likely that formation of a cationic intermediate precedes that of the adduct shown. However, the structure of the adduct has been confirmed by isolation from the active site and by synthesis[c] and it has been observed in the active site by NMR spectroscopy.[d] The three-dimensional structure of EPSP synthase is known.[e,m] It is inhibited by the commercial herbicide **glyphosate** [*N*-(phosphonomethyl) glycine] whose structure is somewhat similar to that of the proposed carbocation that arises from PEP. The inhibitor (*Z*)-3-fluorophosphoenolpyruvate is a pseudosubstrate that reacts in step *a* to give a stable adduct unable to go through step *b* to form a



Carbocation

Glyphosate



(*Z*)-3-Fluorophosphonoenolypyruvate

A related mechanism is utilized in the biosynthesis of UDP-muramic acid (Eq. 20-6).[j] There is an enolpyruvoyl adduct analogous to that of EPSP synthase; a proposed enolpyruvoyl-enzyme adduct with Cys 115 is not on the major path.[k,l] However, this enzyme is not inhibited by glyphosate.[i]

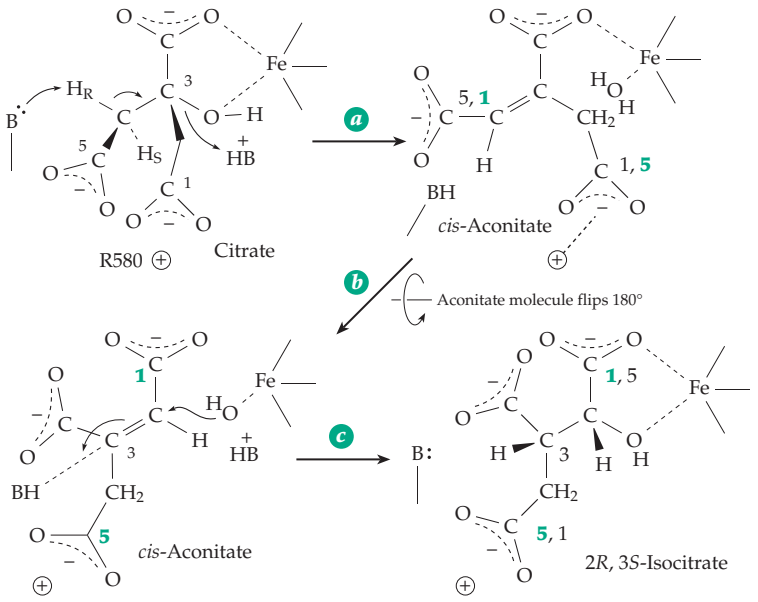
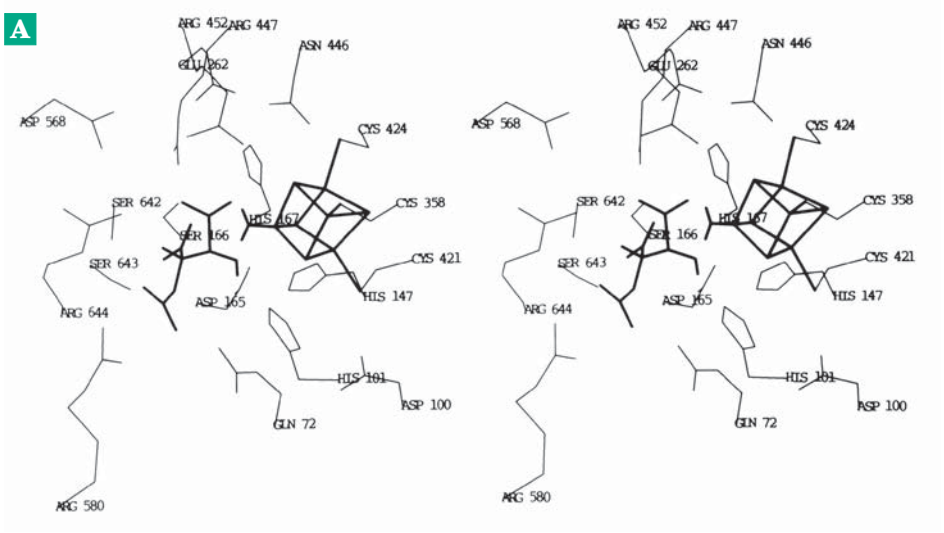
from citrate is often returned to the molecule in Eq. 13-17, step *b*, but the position of reentry is different from that of removal. Apparently, after the initial proton removal, the *cis*-aconitate that is formed "flips over" so that it can be rehydrated (Eq. 13-17, step *c*) with participation of the same groups involved in dehydration but with formation of the new product.[80,80a]

Aconitase contains iron in the form of an Fe_4S_4 iron-sulfur cluster (Fig. 13-4).[81–83] However, the enzyme is usually isolated in a form that does not show its maximum activity until it has been incubated with ferrous iron (Fe^{2+}). The inactive form of the enzyme is thought to contain an Fe_3S_4 cluster (Chapter 16) which is converted back to the Fe_4S_4 cluster by the incubation



(13-17)



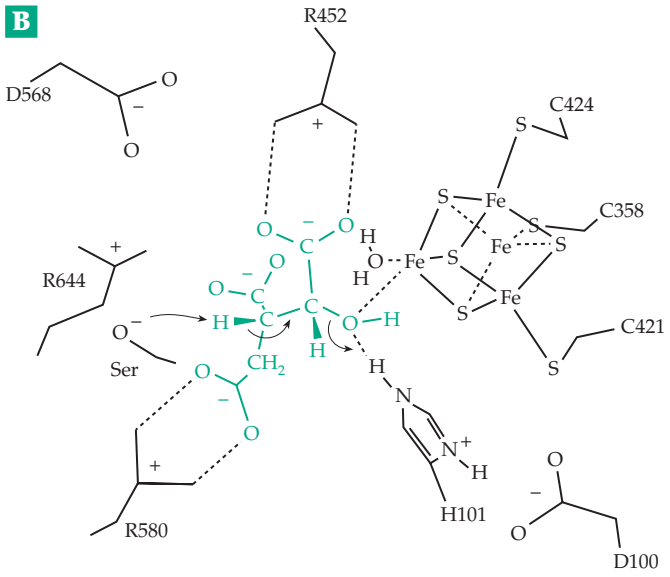


Figure 13-4 (A) Stereoscopic view of the active site of mitochondrial aconitase with a molecule of L-isocitrate placed by modeling next to the Fe_4S_4 cluster. This cluster still has a water molecule bound to one iron atom as in the free enzyme.[83] Courtesy of C. D. Stout. (B) Interpretive diagram.

with Fe^{2+}.[84–87] From Mössbauer spectroscopy it was deduced that the iron atom that is lost upon inactivation is the binding site for the –OH group of citrate or isocitrate and of an adjacent carboxylate.[87] Since iron can engage in oxidation–reduction processes, aconitase could act by a mechanism different from others discussed here. However, an Fe–OH group could act much as does the Zn–OH of carbonic anhydrase (Eq. 13-4). Any redox chemistry may be involved in control of the enzyme.

X-ray studies have confirmed the proximity of the Fe_4S_4 cluster to bound substrate analogs.[83,88] The isocitrate shown in Fig. 13-4 was fitted into the active site by modeling. It shows the water molecule bound to the Fe_4S_4 cluster as observed for the free enzyme.[83] Notice that this cluster is held by three cysteine side chains (C358, C421, and C424) rather than the usual four (Chapter 16). The fourth iron atom is free to bind to water. When the enzyme acts on isocitrate this water must be displaced by the one generated from the substrate. The Fe probably acts as a polarizing electrophile that assists in the elimination but it is apparently the histidine–aspartate pair (H101–D100) that serves as the catalytic acid in generating the H_2O. What is the catalytic base? The only candidate seen in the structure is the Ser 642 –OH, dissociated to $-O^-$. Can this be correct? Mutational analysis supports the essential role of this side chain.[80a] The peptide NH and guanidinium groups of R644 appear to provide an "oxyanion hole" (Chapter 12) that stabilizes the negative charge.[86] Mutations also support the role of the His-Asp pair.[88,89] Another His–Asp pair (H167–D165) is located directly behind the bound substrate and Fe–OH_2 in Fig. 13-4A and is apparently also essential.[88]

Aconitase exists as both mitochondrial and cytosolic isoenzyme forms of similar structure. However, the cytosolic isoenzyme has a second function. In its apoenzyme form, which lacks the iron–sulfur cluster, it acts as the much-studied **iron regulatory factor**, or iron-responsive element binding protein (IRE-BP). This protein binds to a specific stem-loop structure in the messenger RNA for proteins involved in iron transport and storage (Chapter 28).[86,90]

Other enzymes in the aconitase family include **isopropylmalate isomerase** and **homoaconitase** enzymes functioning in the chain elongation pathways to leucine and lysine, both of which are pictured in Fig. 17-18.[90] There are also iron–sulfur dehydratases, some of which may function by a mechanism similar to that of aconitase. Among these are the two fumarate hydratases, **fumarases A and B,** which are formed in place of fumarase C by cells of *E. coli* growing anaerobically.[91,92] Also related may be bacterial L-serine and L-threonine dehydratases. These function without the coenzyme pyridoxal phosphate (Chapter 14) but contain iron–sulfur centers.[93–95] A **lactyl-CoA dehydratase** and some related iron-sulfur enzymes (pp. 861-862) may act via a mechanism related to that of vitamin B_{12}.

7. Addition to or Formation of Isolated Double Bonds

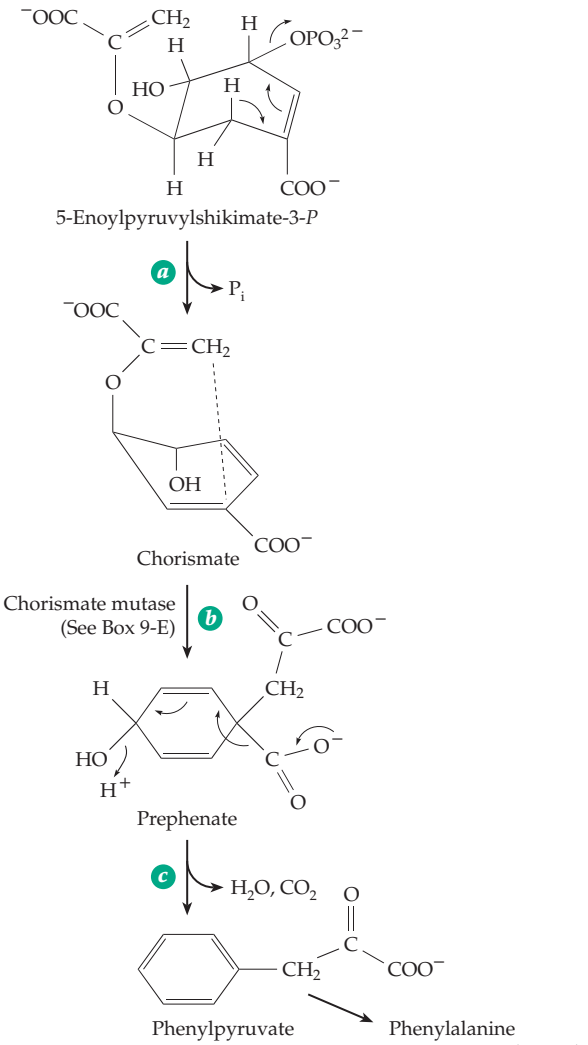
Only a few examples are known in which an enzyme induces addition to a double bond that is *not conjugated* with a carbonyl or carboxyl group. Pseudomonads have been observed to catalyze stereospecific hydration of oleic acid to D-10-hydroxystearate.[96] The addition is *anti* and the proton enters from the *re* face.

8. Conjugative and Decarboxylative Elimination Reactions

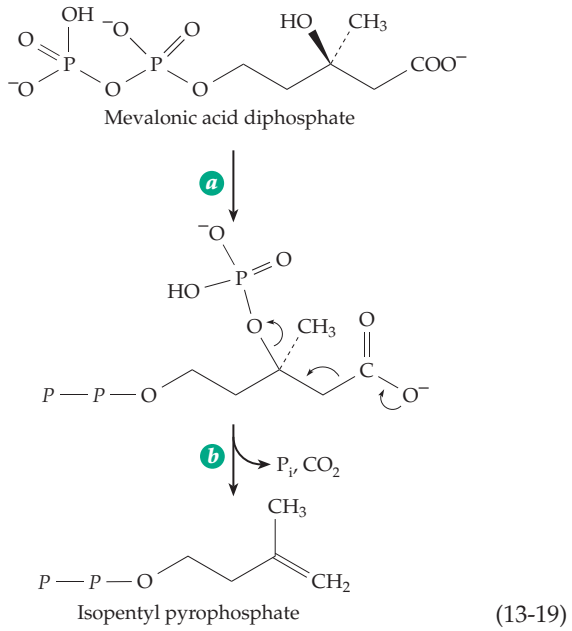
Elimination can occur if the electrophilic and nucleophilic groups to be removed are located not on adjacent carbon atoms but rather are separated from each other by a pair of atoms joined by a double bond. Such a conjugative elimination of phosphate is the last step in the biosynthesis of **chorismate** (Eq. 13-18, step *a*). Chorismate is converted to **prephenate** (see Box 9-E) which undergoes a conjugative and decarboxylative elimination (Eq. 13-18, step *c*) with loss of both water and CO_2 to form **phenylpyruvate**, the immediate biosynthetic precursor of phenylalanine. These reactions provide a good example of how *elimination reactions can be used to generate aromatic groups*. In fact, this is the usual method of synthesis of aromatic rings in nature.

Notice the stereochemistry of Eq. 13-18, step *a*. Orbital interaction rules predict that if the elimination is a concerted process it should be syn. The observed anti elimination suggests a more complex mechanism involving participation of a nucleophilic group of the enzyme.[97]

Elimination usually involves loss of a proton together with a nucleophilic group such as –OH, $-NH_3^+$, phosphate, or pyrophosphate. However, as in Eq. 13-18, step *c*, electrophilic groups such as $-COO^-$ can replace the proton. Another example is the conversion of **mevalonic acid-5-pyrophosphate** to **isopentenyl pyrophosphate** (Eq. 13-19): This is a key reaction in the biosynthesis of isoprenoid compounds such as cholesterol and vitamin A (Chapter 22). The phosphate ester formed in step *a* is a probable intermediate and the reaction probably involves a carbocationic intermediate generated by the loss of phosphate prior to the decarboxylation.



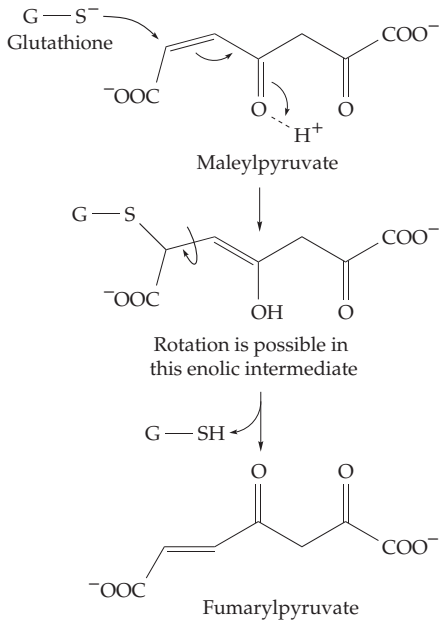
(13-18)



(13-19)

9. Isomerization Assisted by Addition

An interesting use is made of addition to a double bond by glutathione-dependent ***cis–trans* isomerases**.[76] One of them converts **maleate** to fumarate with a turnover number of 300 s^{-1}. Similar enzymes, which participate in bacterial breakdown of aromatic compounds (Fig. 25-7), isomerize **maleylacetoacetate** and **maleylpyruvate** to the corresponding fumaryl derivatives (Eq. 13-20). The – SH group of bound glutathione is thought to add to the double bond. Rotation can then occur in the enolic intermediate. Thiocyanate ion catalyzes the isomerization of maleic acid nonenzymatically, presumably by a similar mechanism.



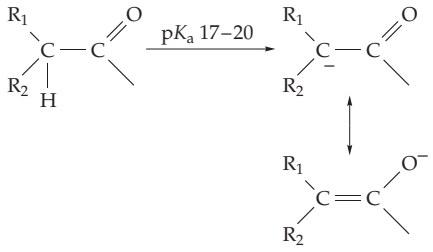
(13-20)

10. Reversibility of Addition and Elimination Reactions

Many addition and elimination reactions, e.g., the hydration of aldehydes and ketones, and reactions catalyzed by lyases such as fumarate hydratase are strictly reversible. However, biosynthetic sequences are often nearly irreversible because of the elimination of inorganic phosphate or pyrophosphate ions. Both of these ions occur in low concentrations within cells so that the reverse reaction does not tend to take place. In decarboxylative eliminations, carbon dioxide is produced and reversal becomes unlikely because of the high stability of CO_2. Further irreversibility is introduced when the major product is an aromatic ring, as in the formation of phenylpyruvate.

B. Enolic Intermediates in Enzymatic Reactions

Enzymologists have freely proposed enolate anions, enols, and enamines as intermediates for many years. Such intermediates have been demonstrated for some nonenzymatic acid- or base-catalyzed reactions, but how can enzymes form enolates at pH 7 without the use of strong acids or bases? The microscopic pK_a value of an α-hydrogen in a ketone or aldehyde is about 17–20.[72,98,99]



(13-21)

It will be similar for an acyl-CoA. However, for a carboxylic acid, protonated on oxygen, the pK_a will be much higher (~22–25) and for carboxylate anions even higher (~29–32).[100]

1. Mandelate Racemase and Related Enzymes

The degradation of mandelic acid by the bacterium *Pseudomonas putida* (Chapter 25) is initiated by mandalate racemase, another $(\alpha/\beta)_8$-barrel protein.[101] X-ray structures of bound inhibitors together with modeling suggest that the side chain of Lys 264 is the catalytic base that abstracts the α-H from *S*-mandelate (Fig. 13-5) and that the catalytic pair of His 297 and Asp 270 acts as proton donor, or, in the reverse direction, as catalytic base for deprotonation of *R*-mandelate.[102–104] The enzyme is structurally a member of the enolase superfamily[105] and requires Mg^{2+} for activity. The pH dependence of the reaction velocity k_{cat} reveals two pK_a values in the ES complex; ~6.4 and ~10.0. These are the same for *S*- and *R*- isomers. How can the pK_a values be assigned? Do they each belong in part to His 297 and in part to Lys 166? Do other adjacent groups also share? In the K166R mutant the lower pK_a is raised to 8.0. The D270N mutant has lost all but 0.01% of its catalytic activity.[104]

The carboxylate group of the mandelate interacts with side chains of E317, K264, and a Mg^{2+} ion (Fig. 13-5). These may serve both to protonate the carboxylate and also to help stabilize an *aci* anion formed upon dissociation of the α-hydrogen (Eq. 13-22). Both pK_a values for mandelic acid and its enolic form and the equilibrium constants for enolization in water are known[107] and are given beside the arrows in Eq. 13-22. It is difficult to imagine how a base with a pK_a near neutrality could remove an α-proton with a pK_a of 22.0, which is 14 pK units away from the pK_a of the catalytic base. This corresponds to a thermodynamic barrier (Eq. 9-97) of 14 x 5.7 = 80 kJ/mol, making the reaction impossibly slow. In addition to this thermodynamic barrier the *rates* of dissociation of carbon acids are known to be slow, presumably because of the lack of hydrogen bond formation between the C–H proton and the catalytic base (Eq. 9-97). This *intrinsic* barrier (Chapter 9) for simple ketones has been estimated as 45 kJ/mol for a total barrier of ~125 kJ. However, the observed $\Delta G^{\ddagger}$ as estimated from Eq. 9-81 is only ~57 kJ/mol. The enzyme must catalyze the reaction by lowering the very high thermodynamic barrier and perhaps also by lowering the intrinsic barrier.[72,108]

Protonation of the carboxylate greatly decreases the microscopic pK_a for loss of the α-hydrogen as a proton to form the enolic *aci* acid (Eq. 13-22). Double protonation, although depending upon a pK_a of –8,

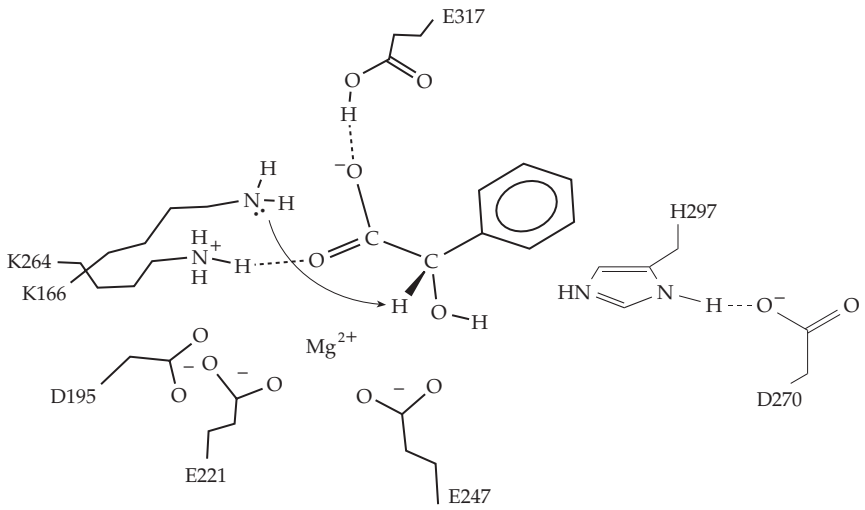


Figure 13-5 An *S*-mandelate ion in the active site of mandelate racemase. Only some of the polar groups surrounding the active site are shown. The enzyme has two catalytic acid–base groups. Lysine 166 is thought to deprotonate *S*-mandelate to form the *aci* anion, while His 297 deprotonates *R*-mandelate to form the same anion.[106]

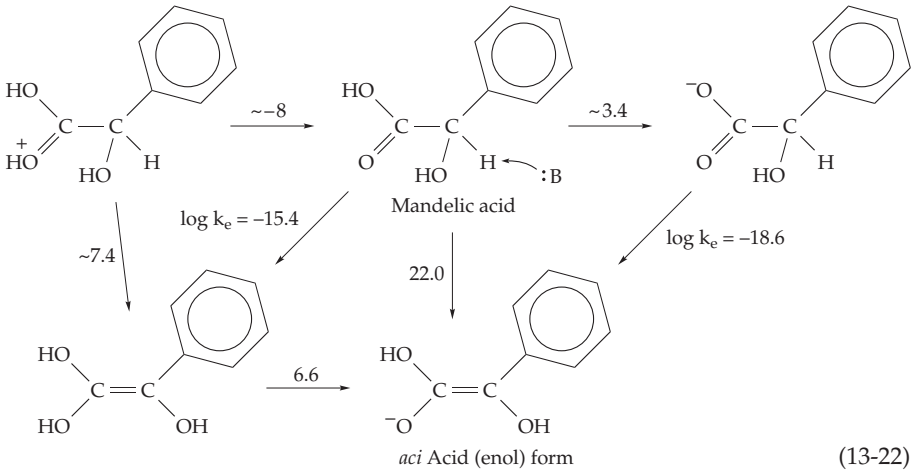
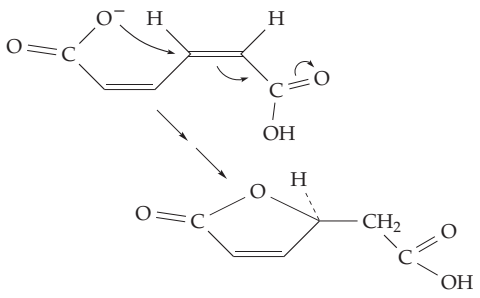


(13-22)

would reduce the pK_a of the α-hydrogen to ~ 7.4, making it very easy to enolize[109] and solving the thermodynamic problem. However, what forces could keep the substrate molecule in this unlikely state of protonation? Gerlt and Gassman proposed formation of a strong, short hydrogen bond to a carboxylate oxygen.[110] Formation of such a bond would lead to an increased positive charge on the alpha carbon, lowering the pK_a and therefore the thermodynamic barrier. It could also lower the intrinsic barrier,[108] for example, by permitting, to some extent, the formation of a C—H---N hydrogen bond in the transition state.[111] Polarization by the Mg^{2+} ion may also be involved. The very strong electrostatic forces within the active site may be sufficient to explain the formation of enolate anions or enols as intermediates in many different enzymes.[108,112]

A number of other racemases and epimerases may function by similar mechanisms. While some amino acid racemases depend upon pyridoxal phosphate (Chapter 14), several others function without this coenzyme. These include racemases for aspartate,[113] glutamate,[114–115a] proline, phenylalanine,[116] and diaminopimelate epimerase.[117] Some spiders are able to interconvert D and L forms of amino acid residues in intact polypeptide chains.[118,119]

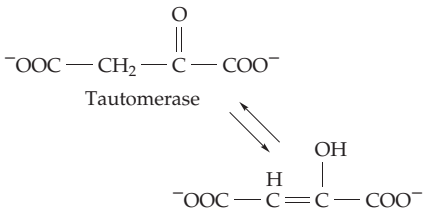
Another enzyme of the mandelate pathway of degradation of aromatic rings (Fig. 25-8) is the ***cis,cis*-muconate lactonizing enzyme** which catalyzes the reaction of Eq. 13-23. It has a three-dimensional structure almost identical to that of mandelate racemase but has incorporated an additional feature that allows formation, by addition, of the intermediate *aci*-acid.[101,105]



(13-23)

2. Isomerases

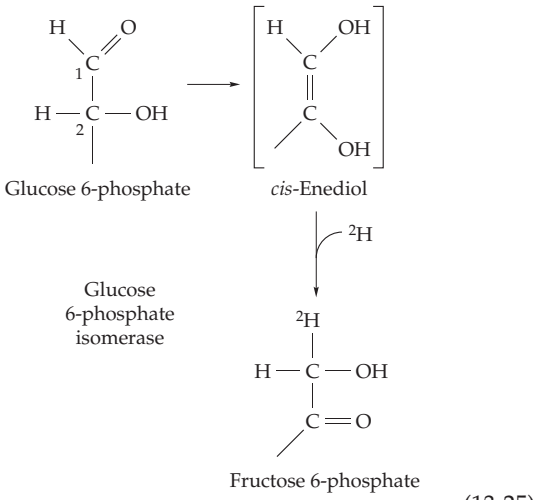
The isomerases that catalyze the simplest reactions are **tautomerases** that promote the oxo-enol (keto-enol) transformation. The widely distributed oxaloacetate tautomerase (Eq. 13-24) is especially active in animal tissues.[97,120] Oxaloacetate exists to a substantial extent in the enolic form: at 38°, ~ 6% enol, 13% oxo, and ~ 81% covalent hydrate.[120,121] A mammalian **phenylpyruvate tautomerase** has also been investigated.[122]



(13-24)

The oxidation of one functional group of a molecule by an adjacent group in the same molecule is a feature of many metabolic sequences. In most cases an enolic intermediate, formed either from a ketone as in Eq. 13-25 or by a dehydration reaction (see Eq. 13-32), is postulated.

Aldose–ketose interconversions. A metabolically important group of enzymes catalyze the interconversion of aldose sugars with the corresponding 2-ketoses (Table 10-1, reaction 4C). Several sugar phosphates undergo rapid isomerization. **Glucose 6-phosphate isomerase** (Eq. 13-25) appears to function in all cells with a high efficiency.[123–125a] The 132 kDa dimeric protein from muscle converts glucose 6-phosphate to



(13-25)

fructose 6-phosphate with a turnover number of ~ 10^3 s^{-1}. Hereditary defects in this enzyme cause a variety of problems that range from mild to very severe.[126] **Mannose 6-phosphate isomerase** also forms fructose 6-phosphate, while **ribose 5-phosphate isomerase**[127] interconverts the 5-phosphates of D-ribose and D-xylulose in the pentose phosphate pathways (Chapter 17). Other enzymes, most often metalloenzymes, catalyze the isomerization of free sugars.

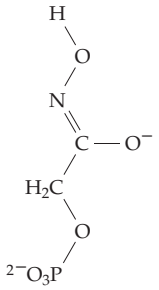
These enzymes vary widely in secondary and tertiary structure.[127a] Mannose-6-phosphate isomerase is a 45 kDa Zn^{2+}-containing monomer. The larger 65 kDa **L-fucose isomerase**, which also acts on D-arabinose, is a hexameric Mn^{2+}-dependent enzyme.[127a] **L-Arabinose isomerase** of *E. coli*, which interconverts arabinose and L-ribulose, is a hexamer of 60-kDa subunits[128] while the **D-xylose isomerase** of *Streptomyces* is a tetramer of 43-kDa subunits.[129] The nonenzymatic counterpart of the isomerization catalyzed by the enzyme is the base-catalyzed **Lobry deBruyn–Alberda van Ekenstein transformation** (Eq. 13-25).[130]

In 1895, Emil Ficher proposed an enediol intermediate for this isomerization. As would be expected, the enzyme-catalyzed isomerization of glucose-6-phosphate in ^2H_2O is accompanied by incorporation of deuterium into the product fructose 6-phosphate at C-1. In the reverse reaction ^2H-containing fructose 6-phosphate was found to react at only 45% of the rate of the ^1H-containing compound. Thus, the primary deuterium isotope effect expected for a rate-limiting cleavage of the C–H bond was observed (see Chapter 12, Section B,3).

When fructose 6-phosphate containing both ^2H and ^{14}C in the 1 position was isomerized in the presence of a large amount of nonlabeled fructose 6-phosphate, the product glucose 6-phosphate contained not only ^{14}C but also ^2H, and the distribution indicated that the ^2H had been transferred from the C-1 position into the C-2 position.[123] It was concluded that in over half the turnovers of the enzyme, ^2H removed from C-1 is put back on the same molecule at C-2. This intramolecular transfer of a proton suggests a syn transfer, the proton being removed and put back on the same side of the molecule. The carrier of the proton may be a histidine side chain.[131] This result, together with the known configuration of glucose at C-2, indicates that the intermediate is the *cis*-enediol and that addition of a proton at either C-1 or C-2 of the enediol is to the *re* face. However, mannose-6-phosphate isomerase catalyzes addition to the *si* face.

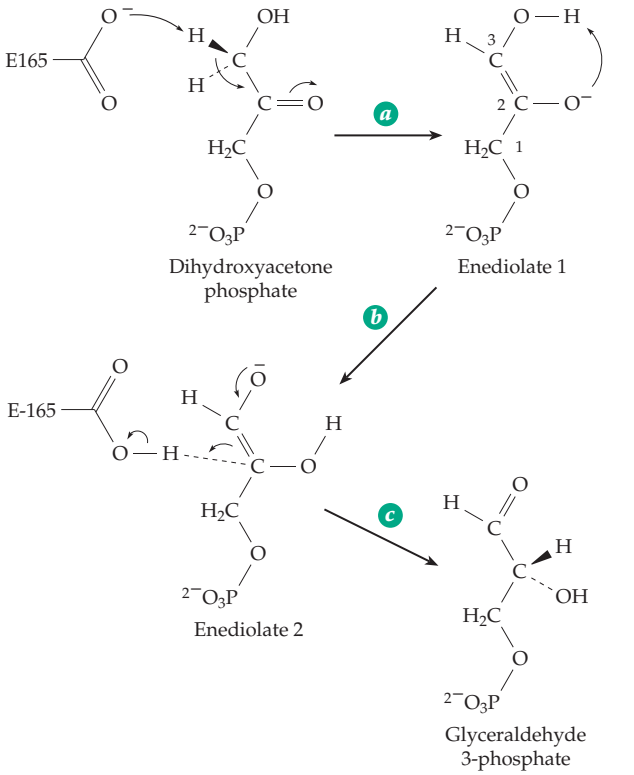
Catalysis of ring opening by isomerases. Glucose-6-phosphate isomerase catalyzes a second reaction, namely, the opening of the ring of the α-anomer of glucose 6-phosphate (one-half of the mutarotation reaction; Eq. 10-88). Noltmann suggested a concerted acid–base catalysis by two side chain groups as is indicated in Eq. 9-90. An NMR study showed that the isomerization of the α anomer occurs at least ten times faster than that of the β. Thus, β-glucose 6-phosphate is first converted to α-glucose 6-phosphate before it can be isomerized to fructose 6-phosphate.[132]

Triose phosphate isomerase. This dimeric 53-kDa enzyme interconverts the 3-phosphate esters of glyceraldehyde and dihydroxyacetone and is the fastest enzyme participating in glycolysis. Its molecular activity at 25° is ~2800 s^{-1} in the direction shown in Eq. 13-26 and ~250 s^{-1} in the reverse direction (the predominant direction in metabolism)[133] and is thought to operate at the diffusion-controlled limit (Chapter 9).[133] Each of the identical subunits consists of a striking $(\alpha/\beta)_8$ barrel (Fig. 13-6) with an active site at the carboxyl ends of the β strands.[134–137] Structures of the enzyme containing bound inhibitors such as phosphoglycolohydroxamate have also been determined (Fig. 13-6).[138] Triose phosphate isomerase is also one of the most investigated of all enzymes. Not only are its catalytic properties unusual but also there are known defects in the human enzyme[137] and it is also a potential target for antitrypanosomal drugs.[139]



Phosphoglycolohydroxamate (PGH), a tight-binding inhibitor (K_d = 15μM) that resembles enediolate 1 of Eq. 13-26

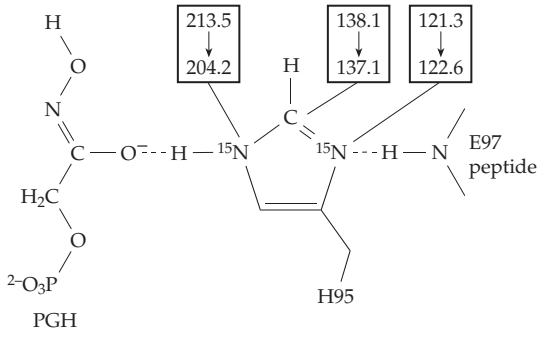
Although its high catalytic activity might favor intramolecular transfer of the proton removed by triose phosphate isomerase, little such transfer has



(13-26)

been observed.[140] This suggested that a relatively weak base such as a carboxylate group might serve as the proton acceptor at the C-3 position of dihydroxyacetone phosphate. Covalent labeling experiments and later X-ray studies have implicated Glu 165, whose carboxylate group is thought to remove the *pro-R* hydrogen atom from the hydroxymethyl group of dihydroxyacetone phosphate as indicated in Eq. 13-26. When this residue is replaced by Asp, most activity is lost.[141] Kinetic studies suggest that this carboxyl group has a pK_a of ~3.9 in the free enzyme. However, k_{cat} is independent of pH up to pH 10.[140] The pK_a of the phosphate also affects the binding (K_m), with only the phosphate dianion being a substrate. Study of the infrared spectrum of dihydroxyacetone bound to the enzyme revealed a shift of the carbonyl bands at 1733 cm^{-1} by about 20 cm^{-1} to ~1713 cm^{-1}. This might indicate a polarization and stretching of the carbonyl group by a positively charged histidine or lysine side chain of the protein.[142] The His 95 side chain is appropriately placed (Fig. 13-6) to function in this way[143] and its replacement by glutamine decreases catalytic activity by a factor of 400.[144] The $-NH_3^+$ group of lysine 12, another essential residue, is apparently needed for substrate binding.[136,145] After product is released, an isomerization within the enzyme is usually required to prepare it for acceptance of a new substrate. This may involve movement of protons between side chain groups or a conformational change or both. In the case of triose phosphate isomerase, a very rapid isomerization requiring about ~ 1 ms has been detected.[146]

To investigate further the function of His 95, Lodi and Knowles recorded the ^{13}C and ^{15}N NMR spectra of the three histidine rings[148] both in unligated enzyme and in the phosphoglycolohydroxamate (PGH) complex. The results were a surprise. The His 95 resonances



did not change at all when the pH was changed from below 5 to 9.9, and the chemical shift values (shown above) indicate clearly that the ring is **unprotonated** in both free enzyme and in the complex. The key chemical shift values are shown on the diagram to the

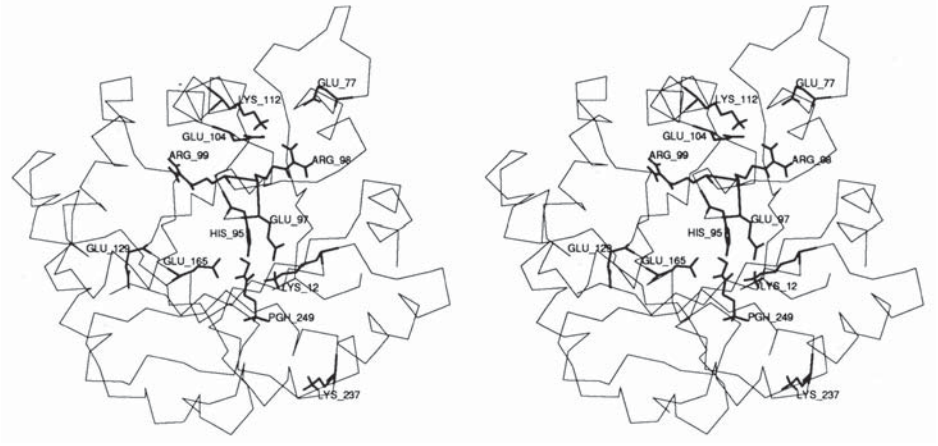


Figure 13-6 Stereoscopic view into the active site of triose phosphate isomerase showing side chains of some charged residues; PGH, a molecule of bound phosphoglycolohydroxamate, an analog of the substrate enolate.[138] The peptide backbone, as an alpha-carbon plot, is shown in light lines.[147] The $(\alpha / \beta)_8$-barrel structure is often called a TIM barrel because of its discovery in this enzyme. Courtesy of M. Karplus.

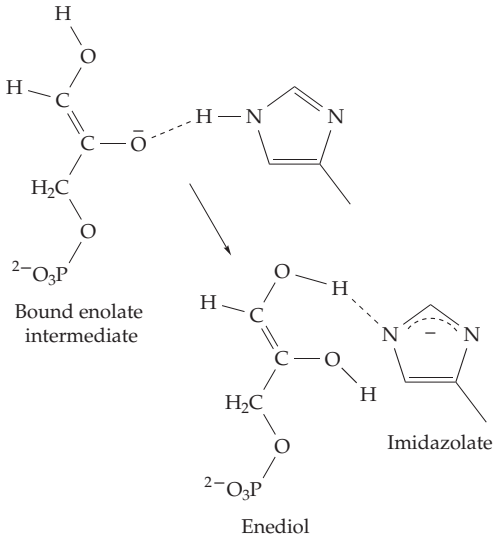
left; the arrows indicate the changes upon formation of the PGH complex. These results suggest that H95 is never protonated and that if it acts as the catalytic acid it does so by dissociating to an imidazolate ion (Eq. 13-27).[148]

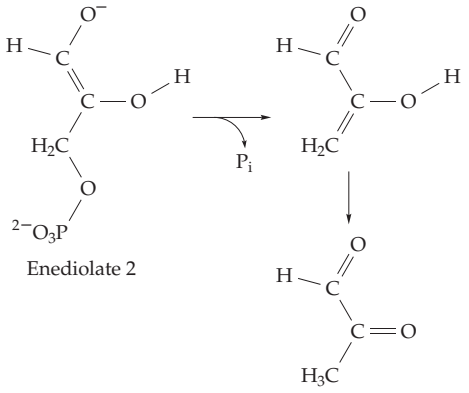


(13-27)

The imidazole would donate a proton to the enolate ion and then remove a proton from the resulting enediol. Although the proposed chemistry is unusual, it is argued that the high pK_a of the neutral imidazole acting as a proton donor would be matched with the high pK_a of the enol, permitting rapid reaction.[148] Nevertheless, two other possibilities exist. Theoretical calculations support the idea that the proton transfer between the two oxygens in the enediolate may occur *without catalysis by a proton donor*[149] as indicated in step *b* of Eq. 13-26. Another possibility is that a transient protonation of H95 by the adjacent E97 carboxyl group occurs and allows the histidine to participate in the proton transfer. Study of kinetic isotope effects has indicated coupled motion of protons and proton tunneling.[143]

Another detail should be mentioned. The active site of triose phosphate isomerase is formed by a series of loops connecting the α helices and β strands of the barrel. One of those loops, consisting of residues 167–176, folds over the active site after the substrate is bound to form a hinged lid that helps to hold the substrate in the correct orientation for reaction.[150–152] When the lid, which can be seen in Fig. 13-6, closes, the peptide NH of G171 forms a hydrogen bond to a phosphate oxygen atom of the substrate. This is only one of many known enzymes with deeply buried active sites that close in some similar fashion before a rapid reaction occurs.

Although enzymes tend to be extremely specific they are not always completely able to avoid side reactions. Triose phosphate isomerase releases small amounts of **methylglyoxal** (Eq. 13-28), presumably as

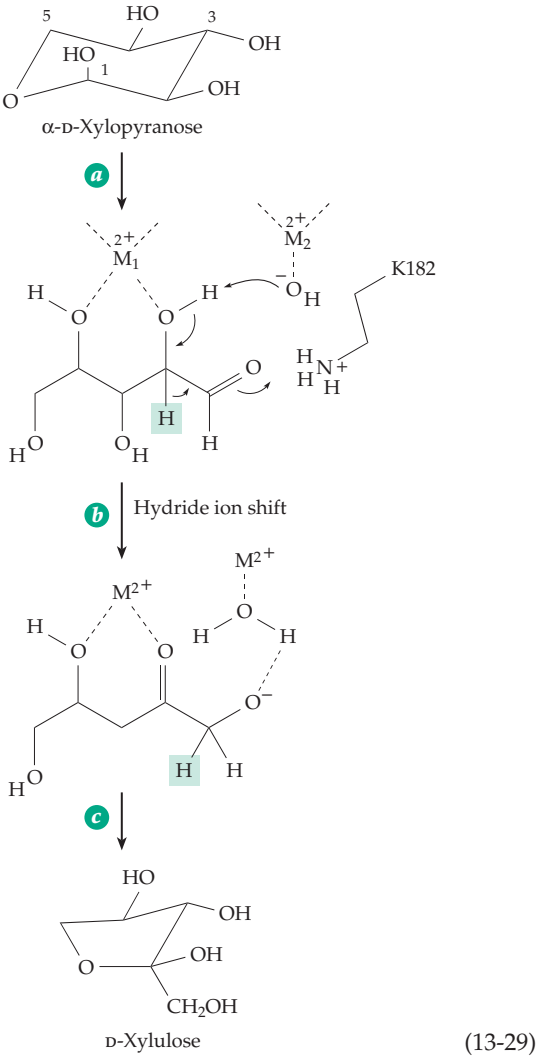


(13-28)

a result of elimination of phosphate from enediolate 2 of Eq. 13-26. Deletion of four residues from the hinged lid produced an enzyme in which this side reaction was increased 5.5-fold.[146]

Xylose isomerase and the hydride shift mechanism. This bacterial enzyme, which isomerizes D-xylose to D-xylulose, has an $(\alpha/\beta)_8$ barrel similar to that of triose phosphate isomerase. It is of industrial importance because it also catalyzes isomerization of D-glucose to the sweeter sugar D-fructose, a reaction used in preparation of high-fructose syrup. For this purpose the isomerase is often immobilized on an insoluble matrix such as diethylaminoethyl cellulose.[153] This enzyme, as well as other isomerases that act on free sugars, requires a metal ion such as Mg^{2+}, Co^{2+}, or Mn^{2+}. The three-dimensional structures, solved in several different laboratories,[129,154–158] show that there are two metal ions (ordinarily Mg^{2+}) about 0.5 nm apart and held by an array of glutamate and aspartate side chains. One glutamate carboxylate forms short ionic bonds to both metal ions and an essential histidine is also coordinated with metal ion 2. The three-dimensional structure is superficially similar to that of triose phosphate isomerase but there are major differences in properties. Xylose isomerase requires metal ions, acts on unphosphorylated non-ionic substrates, and does not catalyze detectable exchange of protons with the solvent. Furthermore, *X-ray structures do not show the presence of any catalytic base that could initiate formation of an intermediate enolate ion.* These facts suggested an alternative isomerization mechanism, one involving a hydride ion shift and well-known from studies of the Cannizarro reaction.[159] Because the non-ionic substrates and inhibitors bind weakly it has been difficult to obtain a clear picture of events in the active site. The substrate is the α-anomer of D-xylopyranose[155] and the enzyme catalyzes the opening of the sugar ring (step *a*, Eq. 13-29).[157] The details of this process are not clear but acid-base catalysis as in Eq. 9-87 is probable.

There is a consensus[156–158] that the open form of

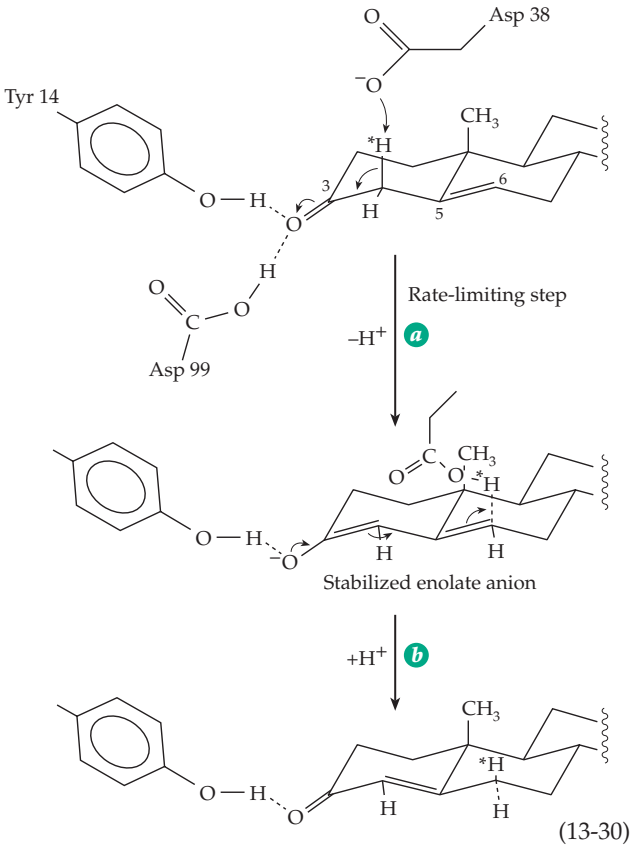


(13-29)

the sugar is bound to one of the two metal ions as shown in Eq. 13-29 and that a bound hydroxide ion on the second metal provides the catalytic base to remove a proton from the –OH at position 2. The isomerization occurs with the shaded hydrogen atom being shifted as H^- to the carbon atom of the carbonyl group. During the reaction metal ion 2 moves apart from metal ion 1 by ~0.09 nm,[129,157,158] another fact that has made analysis of X-ray data difficult. Protonation of the alkoxide ion at C-2 is followed by ring closure (step *c*, Eq. 13-29).

3-Oxosteroid isomerases. Cholesterol serves in the animal body as a precursor of all of the steroid hormones, including the 3-oxosteroids progesterone and testosterone (Chapter 22). The 3-hydroxyl group of cholesterol is first oxidized to an oxo group. This is followed by an essentially irreversible migration of the double bond in the 5,6-position into conjugation with the carbonyl group (Eq. 13-30) catalyzed by a 3-oxo-Δ^5-steroid isomerase. The small 125-residue enzyme from the bacterium *Pseudomonas testosteroni* has been studied by a great variety of methods.[160–164] The subunits associate as dimers or higher oligomers. The enzyme has a high content of nonpolar amino acid residues and is soluble in high concentrations of ethanol. This property is compatible with the location of the eukaryotic enzyme in the endoplasmic reticulum. The substrate binding site is a hydrophobic cavity.

Oxosteroid isomerase has a remarkably high molecular activity (~0.75 x 10^5 s^{-1}). Substrates containing ^2H in the 4 position react only one-fourth as rapidly as normal substrates. The large isotope effect suggested that cleavage of the C–H bond to form an enzyme-stabilized enolate anion is rate limiting (Eq. 13-30, step *a*).[160] The proton in the axial position at C-4 is removed preferentially but without complete stereospecificity.[165] The abstracted proton must be carried by a group on the enzyme and returned to the 6 position of the substrate, again in an axial orientation (Eq. 13-30, step *b*), a suprafacial transfer. Studies of the binding of spin-labeled substrate analogs, molecular modeling, and directed mutation indicate that Asp 38 is this proton carrier.[164,166] Little exchange of the proton with solvent is observed, presumably because of the extreme rapidity of the isomerase action. However, competitive inhibitors such as nortestosterone, whose double-bond arrangement is that of the product in Eq. 13-30, undergo exchange of one of the hydrogens at C-4 with the medium. The ultraviolet absorption band of the inhibitor at 248 nm is shifted to 258 nm upon combination with the enzyme, presumably as a result of formation of the

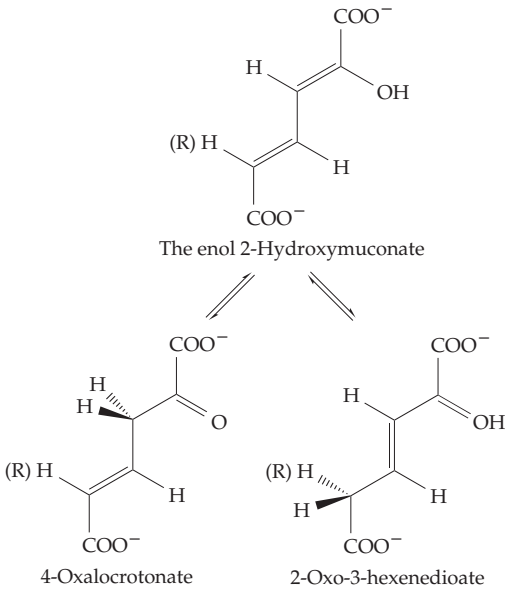


(13-30)

enolate anion. Tyrosine 14 has been identified as the catalytic acid, able to stabilize the enolate anion as depicted in Eq. 13-30.[161,162] A high-resolution NMR structure[167] and X-ray crystal structures[167a,b] have revealed an adjacent Asp 99 side chain that may assist.[167c]

Enzymatic isomerization of *cis*-aconitate to *trans*-aconitate apparently also involves proton abstraction,[165] with resonance in the anion extending into the carboxylic acid group. Its mechanism may be directly related to that of the oxosteroid isomerase. However, there are other 1,3-proton shifts in which neither a carbonyl nor a carboxyl group is present in the substrate (Eqs. 13-55, 13-56).

4-Oxalocrotonate tautomerase. This bacterial enzyme, which functions in the degradation of toluene (Chapter 25), is actually an isomerase. It catalyzes rapid interconversion of an unconjugated unsaturated α-oxoacid such as 4-oxalocrotonate with an intermediate enol (which may leave the enzyme) and the isomeric conjugated oxoacid (Eq. 13-31).[168–170] A related 5-carboxymethyl-2-hydroxymuconate isomerase



(13-31)

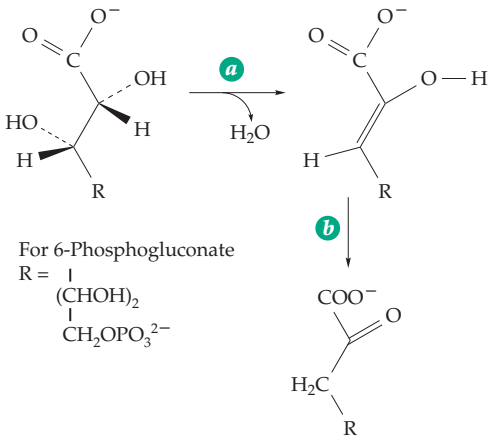
catalyzes the same reaction when R = $-CH_2COO^-$ in Eq. 13-31. It is an unusually small enzyme consisting of only 62 amino acid residues. The pH dependence reveals pK_a values of 6.2 and 9.0 in the free enzyme and 7.7 and 8.5 in the ES complex.[171]

The pK_a of 6.2 has been associated with the amino-terminal proline 1.[172] 4-Oxalocrotonate tautomerase is one of a small group of enzymes that have been synthesized nonenzymatically with both L amino acids and as a mirror image constructed with D amino acids.[173]

3. Internal Oxidation–Reduction by Dehydration of Dihydroxyacids

When a carboxylic acid contains hydroxyl groups in both the α and β positions, dehydration leads to formation of an enol that can tautomerize to 2-oxo-3-deoxy derivatives of the original acid (Eq. 13-32). Thus, phosphogluconate dehydratase yields 2-oxo-3-deoxyphosphogluconate as the product. When the reaction is carried out in ^2H_2O the ^2H is incorporated with a random configuration at C-3, indicating that the enzyme catalyzes only the dehydration and that the tautomerization of the enol to the ketone is nonenzymatic.

The reaction of Eq. 13-32 initiates a unique pathway of sugar breakdown, the Entner–Douderoff pathway (Eq. 17-18), in certain organisms. The 6-phosphogluconate is formed by oxidation of the aldehyde group of glucose 6-phosphate. This pattern of oxidation of a sugar to an aldonic acid followed by dehydration according to Eq. 13-32 occurs frequently in metabolism. A related reaction is the dehydration of 2-phosphoglycerate by enolase (Eq. 13-15). In this case the product is phosphoenolpyruvate, a stabilized form of the enolic intermediate of Eq. 13-32 (when R = H).



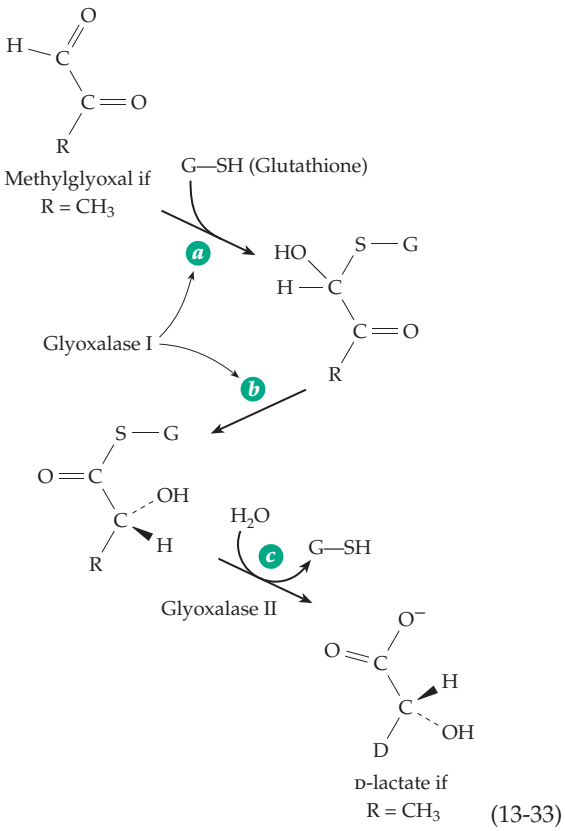
(13-32)

4. Formation and Metabolism of Methylglyoxal (Pyruvaldehyde)

The rather toxic methylglyoxal is formed in many organisms and within human tissues.[174] It arises in part as a side reaction of triose phosphate isomerase (Eq. 13-28) and also from oxidation of acetone (Eq. 17-7) or aminoacetone, a metabolite of threonine (Chapter 24).[175] In addition, yeast and some bacteria, including *E. coli*, have a **methylglyoxal synthase** that converts dihydroxyacetone to methylglyoxal, apparently using a mechanism similar to that of triose phosphate isomerase. It presumably forms enediolate 2 of Eq. 13-26, which eliminates inorganic phosphate to yield methyl-

glyoxal as in Eq. 13-28.[176,176a] Methylglyoxal is converted to D-lactate by the two-enzyme **glyoxalase** system (Eq. 13-33).[177] The combined action of methylglyoxal synthase and the glyoxalases provides a bypass to the usual glycolysis pathway (Fig. 10-3). Although it does not provide energy to the cell, it releases inorganic phosphate from sugar phosphates that may accumulate under conditions of low phosphate because the free P_i concentration is too low to support the glyceraldehyde 3-phosphate dehydrogenase reaction (step *a* of Fig. 10-3).

Glyoxalase acts not only on methylglyoxal but also on other α-oxo-aldehydes. It is thought to be an important enzyme system that protects cells against these potentially dangerous metabolites. Glyoxalase consists of a pair of enzymes, **glyoxalase I** and **glyoxalase II**, which catalyze the reactions of Eq. 13-33. Each subunit of the 183-residue human glyoxalase I contains one tightly bound Zn^{2+} ion.[178] However, the *E.coli* enzyme[178a] is inactive with Zn^{2+} and maximally active with Ni^{2+}. The enzyme requires glutathione as a cofactor, and in step *a* of the reaction (Eq. 13-33) the glutathione adds to form a thiohemiacetal[179] which is then isomerized in step *b*. During this step retention of the abstracted proton is so complete that it was earlier thought to function by an intramolecular hydride ion shift as in xylose isomerase. More recent evidence favors an enolate anion intermediate. However, the three-dimensional structure is not related to that of other isomerases and the exact mechanism remains uncertain. Glyoxylase II, which catalyzes step *c* of Eq. 13-33, is an esterase.[175,180]

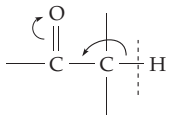


(13-33)

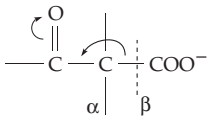
C. Beta Cleavage and Condensation

In Chapter 12 and in the preceding sections of this chapter we examined displacement and addition reactions involving nucleophilic centers on O, N, or S. Bonds from carbon to these atoms can usually be broken easily by acidic or basic catalysis. The breaking and making of C–C bonds does not occur as readily and the "carbon skeletons" of organic molecules often stick together tenaciously. Yet living cells must both form and destroy the many complex, branched carbon compounds found within them.

A major mechanistic problem in cleavage or formation of carbon–carbon bonds is the creation of a nucleophilic center on a carbon atom. The problem is most often solved by using the *activating influence of a carbonyl group to generate a resonance-stabilized enolate anion*. Just as the presence of a carbonyl group facilitates cleavage of an adjacent C–H bond, so it can also assist the cleavage of a C–C bond. The best known reactions of this type are the **aldol cleavage** and the



Cleavage of C—H bond facilitated by a carbonyl group



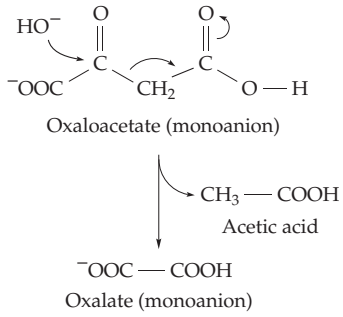
β Cleavage with release of CO_2

decarboxylation of **β-oxo acids**. The latter has been referred to as β decarboxylation and its reverse as β carboxylation. In this book these terms have been extended to include other reactions by which bonds between the α and β carbon atoms of a carbonyl compound are broken or formed, and these will be referred to as **β cleavage and β condensation**.

The β *condensation* reactions consist of displacement or addition reactions in which an enzyme-bound enolate anion acts as the nucleophile. We can group these condensation reactions into three categories as indicated by reaction types 5A, 5B, and 5C of Table 10-1.

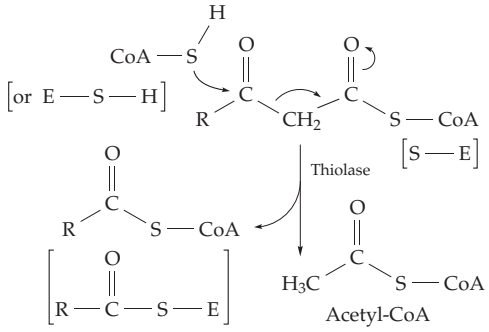
1. Displacement on a Carbonyl Group

A β-oxo acid, with proper catalysis, is susceptible to hydrolysis by attack of water on the carbonyl group. An example is the reaction catalyzed by **oxaloacetate acetylhydrolase** which has been isolated from *Aspergillus niger* (Eq. 13-34). A related cleavage is catalyzed by ribulose bisphosphate carboxylase (see Eq. 13-48).



(13-34)

The **thiolases**[181] are lyases that cleave β-oxoacyl derivatives of CoA by displacement with a thiol group of another CoA molecule (Eq. 13-35). This is the chain cleavage step in the β oxidation sequence by which fatty acid chains are degraded (Fig. 10-4). Biosynthetic thiolases catalyze the condensation of two molecules of acetyl-CoA to form acetoacetyl-CoA, (see Eq. 17-5), a precursor to cholesterol and related compounds and to poly-β-hydroxybutyrate (Box 21-D). Because acetyl-CoA is a thioester, the reaction is usually described as a **Claisen condensation**. A related reaction, involving decarboxylation of malonyl-CoA, is a step in fatty acid synthesis. Since the thiolases are inhibited by –SH reagents it has been suggested that a thiol group in the enzyme reacts initially with the β-carbonyl group as in Eq. 13-35 to give an enzyme-bound *S*-acyl intermediate. The acyl group is then transferred to CoA in a second step.



(13-35)

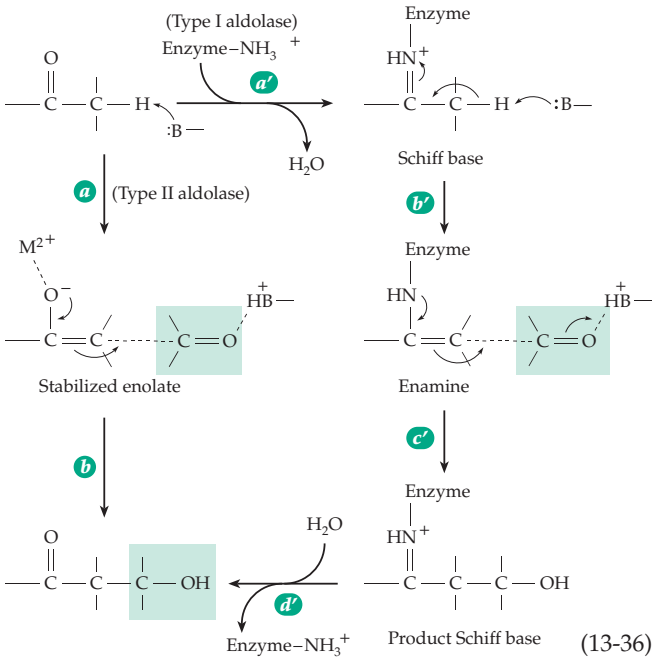
A very similar reaction is catalyzed by 3-hydroxy-3-methylglutaryl-CoA lyase (HMG-CoA lyase), which functions in the formation of acetoacetate in the human body (Eq. 17-5, step *c*) and also in the catabolism of leucine (Fig. 24-18)[182,183] and in the synthesis of **3-hydroxy-3-methylglutaryl-CoA**, the presursor of cholesterol (Eq. 17-5, step *b*)[183a]

2. Addition of an Enolate Anion to a Carbonyl Group or an Imine; Aldolases

The **aldol condensation** (Eq. 13-36), which is also illustrated in Box 10-D, is one of the more common reactions by which C–C bonds are formed[183b] and, in the reverse reaction, cleaved in metabolism. Aldolases are classified into two major types. The type II aldolases are metal-ion dependent, the metal ion stabilizing the intermediate enolate ion (Eq. 13-36, steps *a* and *b*). Type I aldolases, which include the most studied mammalian enzymes, have a more complex mechanism involving intermediate Schiff base forms (Eq. 13-36, steps *a′*, *b′*, *c′*, *d′*).[184] The best known members of this group are the **fructose bisphosphate aldolases** (often referred to simply as aldolases), which cleave fructose-1,6-P_2 during glycolysis (Fig. 10-2, step *e*).

These enzymes have been found in all plant and animal tissues examined and are absent only from a few specialized bacteria. Three closely related isoenzymes are found in vertebrates.[185,186] The much studied rabbit muscle aldolase A is a 158-kDa protein tetramer of identical peptide chains.[186,187] Aldolase B, which is lacking in hereditary fructose intolerance, predominates in liver and isoenzyme C in brain.[185]

Treatment with sodium borohydride of the enzyme-substrate complex of aldolase A and dihydroxyacetone phosphate leads to formation of a covalent linkage between the protein and substrate. This and other evidence suggested a Schiff base intermediate (Eq. 13-36). When ^{14}C-containing substrate was used, the borohydride reduction (Eq. 3-34) labeled a lysine side chain in the active site. The radioactive label was followed through the sequence determination and was found on Lys 229 in the chain of 363 amino acids.[186,188–188b] The enzyme is another $(\alpha / \beta)_8$-barrel protein and the side chain of Lys 229 projects into the interior of the barrel which opens at the C-terminal ends of the strands. The conjugate base form of another lysine, Lys 146, may represent the basic group B in Eq. 13-36,

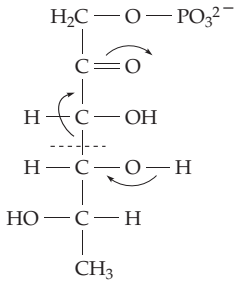


(13-36)

step *b*. Another possibility is that the adjacent phosphate group of the substrate acts as the acid–base catalyst for this step.[189] Aldolase A has been altered by mutations into a monomeric form that retains high catalytic activity,[190] something that has not often been accomplished for oligomeric enzymes.

The **type II aldolases** are not inactivated by sodium borohydride in the presence of substrate. A probable function of the essential metal ion is to polarize the carbonyl group as indicated in Eq. 13-36. In both yeast and *E. coli* aldolase the Zn^{2+} is held by 3 imidazole groups.[191,191a] An arginine side chain is a conserved residue involved in substrate binding in several class II aldolases.[192] Some blue-green algae contain both types of aldolase, as do the flagellates *Euglena* and *Chlamydomonas*.

The catabolism of L-fucose by *E. coli* requires cleavage of L-fuculose-1-phosphate to form dihydroxyacetone phosphate and D-lactaldehyde by a class II aldolase.[193]



L-Fuculose-1-phosphate

The mechanism of chain cleavage proposed on the basis of the structure and modeling[193] is illustrated in Fig. 13-7.

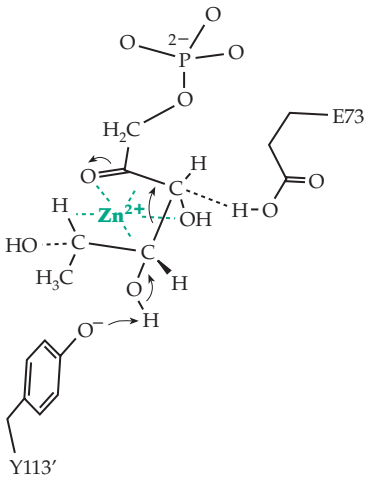


Figure 13-7 Interaction of the bound zinc ion of L-fuculose-1-phosphate aldolase and catalytic side chains with the substrate in the active site of the enzyme as revealed by X-ray crystallography and modeling. See Dreyer and Schulz.[193]

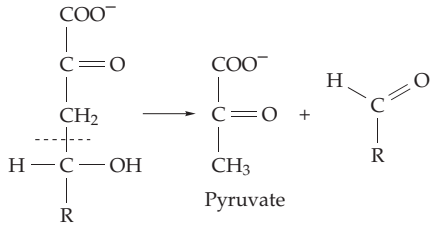
Special aldolases of both classes cleave and form C–C bonds throughout metabolism. Several of them act on 2-oxo-3-deoxy substrates forming pyruvate as one product (Eq. 13-37). The aldehyde product varies. In the Entner–Doudoroff pathway of carbohydrate metabolism (Chapter 21) 3-deoxy-2-oxo-6-phosphogluconate (KDPG) is cleaved to pyruvate and 3-phosphoglyceraldehyde.[194] The same products arise from the corresponding phosphogalactonate derivative.[195] The subunits of the trimeric KDPG aldolase have an $(\alpha/\beta)_8$-barrel structure similar to that of eukaryotic fructose 1,6-bisphosphate aldolase.[194] The 8-carbon sugar acid "KDO" of bacterial cell walls (Fig. 4-26) is cleaved by another aldolase. The catabolism of hydroxyproline leads to 4-hydroxy-2-oxoglutarate, which is cleaved to pyruvate and glyoxylate.[196] In the catabolism of deoxynucleotides, another aldolase converts 2-deoxyribose 5-phosphate to acetaldehyde and glyceraldehyde 3-phosphate.[197]



(13-37)

Closely related to aldolases is **transaldolase**, an important enzyme in the pentose phosphate pathways of sugar metabolism and in photosynthesis. The mechanism of the transaldolase reaction (Eq. 17-15) is similar to that used by fructose-1,6-bisphosphate aldolase with a lysine side chain forming a Schiff base and catalytic aspartate and glutamate side chains.[198]

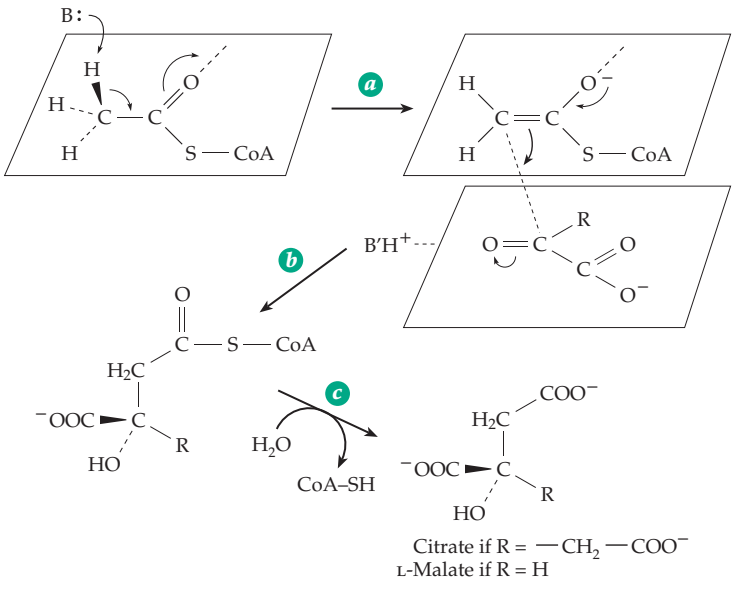
Polycarboxylic acid synthases. Several enzymes, including **citrate synthase,** the key enzyme which catalyzes the first step of the citric acid cycle, promote condensations of acetyl-CoA with ketones (Eq. 13-38). An α-oxo acid is most often the second substrate, and a thioester intermediate (Eq. 13-38) undergoes hydrolysis to release coenzyme A.[199] Because the substrate acetyl-CoA is a thioester, the reaction is often described as a Claisen condensation. The same enzyme that catalyzes the condensation of acetyl-CoA with a ketone also catalyzes the second step, the hydrolysis of the CoA thioester. These polycarboxylic acid synthases are important in biosynthesis. They carry out the initial steps in a *general chain elongation process* (Fig. 17-18). While one function of the thioester group in acetyl-CoA is to activate the methyl hydrogens toward the aldol condensation, the subsequent hydrolysis of the thioester linkage provides for overall irreversibility and "drives" the synthetic reaction.

TABLE 13-1
Products Arising from Reactions of Acetyl-CoA with a Second Substrate with Catalysis by a Polycarboxylate Synthase

Ketone substrate	Product	Further metabolites
 Glyoxylate	 L-Malate	Carbohydrates, etc., via glyoxylate pathway
 Oxaloacetate	*Si*-Citrate synthase  Citrate	2-Carbon unit from acetyl-CoA occupies *pro-S* position
 2-Oxoglutarate	 Homocitrate	Lysine via α-aminoadipic acid
 2-Oxoisovalerate	 α-Isopropylmalate	Leucine
 Acetoacetyl-CoA	 *S*-3-Hydroxy-3-methylglutaryl-CoA (HMG-CoA)	Free acetoacetate Isoprenoid compounds

The stereochemistry of the reaction is also illustrated in Eq. 13-38. These enzymes may be classified by designating the face of the carbonyl group to which the enolate anion adds. The *si* face is up in Eq. 13-38. The common citrate synthase of animal tissues[200] and that of *E. coli*[201] condense with the *si* face and are designated (*si*)-citrate synthases. A few anaerobic bacteria use citrate (*re*)-synthase having the opposite stereochemistry.[202] Many citrate synthases are ~100-kDa dimers[203,204] but some are hexamers[203,205] and are allosterically inhibited by NADH. The second substrates and products of several related reactions of acetyl-CoA are summarized in Table 13-1.

The *si*-citrate synthase of pigs is a dimer of 437-residue chains, each of which is organized into a large rigid domain and a smaller



(13-38)

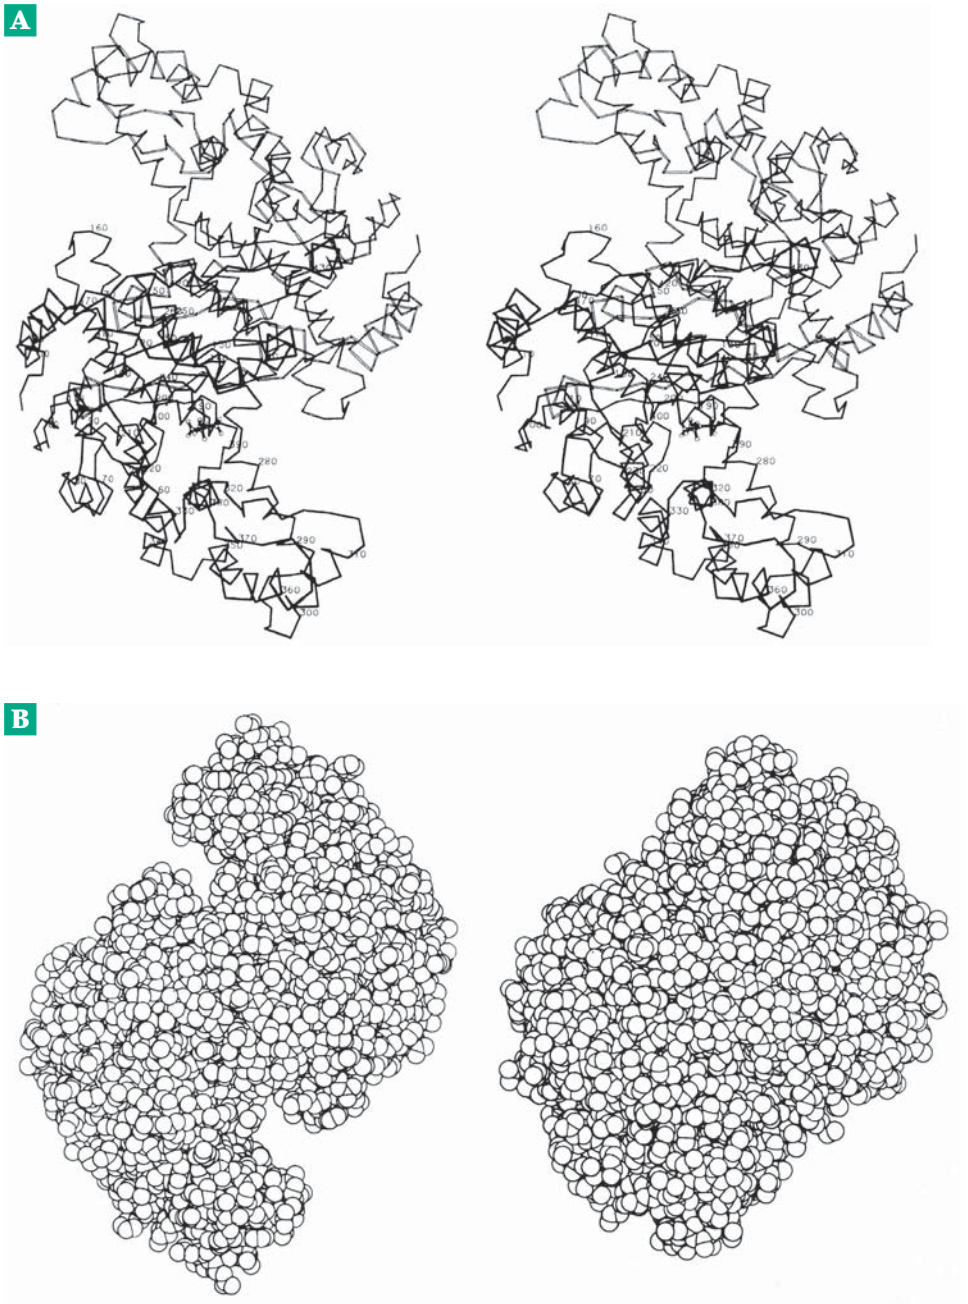


Figure 13-8 Three-dimensional structure of citrate synthase. (A) Stereoscopic alpha carbon trace of the dimeric pig enzyme in its open conformation.[209] A molecule of citrate is shown in the lower subunit. The view is down the two-fold axis. Courtesy of Robert Huber. (B) Space-filling representation of the open (left) and closed (right) forms of the same enzyme.[200] Courtesy of Stephen J. Remington.

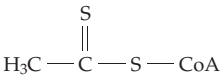
flexible domain. The active site lies between the domains.[206] When oxaloacetate binds into the cleft the smaller domain undergoes a complex motion that closes the enzyme tightly around the substrate (Fig. 13-8).[200,207,208] The bound oxaloacetate is shown in Fig. 13-9. It is surrounded by a large number of polar side chains, including several from histidine and arginine residues. Of these, Arg 401 and Arg 421 of the second subunit bind the substrates' two carboxylate groups. In this tight complex the imidazole of His 320 is in the correct position to protonate the carbonyl oxygen of the oxaloacetate. The domain movement has also brought the groups that bind the acetyl-CoA into their proper position creating, by "induced fit," the acetyl-CoA binding site. This conformational change also accounts for the observation of an ordered kinetic mechanism with oxaloacetate binding before acetyl-CoA. The imidazole of His 274 is correctly oriented to abstract a proton from the methyl group of acetyl-CoA to generate the intermediate enolate anion. When oxaloacetate alone is bound into the active site the carbonyl stretching frequency, observed by infrared spectroscopy, is shifted from 1718 cm^{-1} for free oxaloacetate to 1697 cm^{-1}. This decrease of 21 cm^{-1} suggests a strong polarization of the C = O bond by its interaction with His 320 in the ground state.[211] This interaction is seen also in the ^{13}C NMR spectrum, the carbonyl resonance being shifted downfield by 6.8 ppm upon

binding to the protein.[212] The enolate anion mechanism is also supported by kinetic isotope effects.[213]

The methyl protons of dithia-acetyl-CoA are much more reactive than those of acetyl-CoA (pK_a ~12.5 vs ~20). When citrate acts on this acetyl-CoA analog together with oxaloacetate, the expected enolate anion

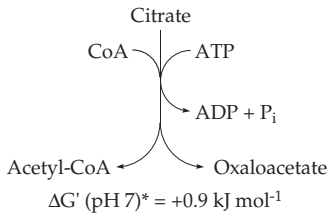


Dithia-acetyl-CoA

forms rapidly as is indicated by the appearance of a 306 nm absorption band. However, it condenses very slowly with the oxaloacetate.[214] The binding equilibria, kinetics, and X-ray structures of complexes for a variety of other analogs of acetyl-CoA have also been studied.[210,215-216a] It appears that Asp 375 and His 274 work together to generate the enolate anion (Fig. 13-9). NMR measurements indicate formation of an unusually short hydrogen bond, but its significance is uncertain.[216a,216b] Malate synthase (Table 13-1) operates with a very similar mechanism but has an entirely different amino acid sequence and protein fold.[216c]

Other Claisen condensations are involved in synthesis of fatty acids and polyketides[217] (Chapter 21) and in formation of 3-hydroxy-3-methylglutaryl-CoA, the precursor to the polyprenyl family of compounds (Chapter 22). In these cases the acetyl group of acetyl-CoA is transferred by a simple displacement mechanism onto an –SH group at the active site of the synthase to form an acetyl-enzyme.[218,219] The acetyl-enzyme is the actual reactant in step *b* of Eq. 17-5 where this reaction, as well as that of HMG-CoA lyase, is illustrated.

Citrate cleaving enzymes. In eukaryotic organisms the synthesis of citrate takes place within the mitochondria, but under some circumstances citrate is exported into the cytoplasm. There it is cleaved by **ATP-citrate lyase**. To ensure that the reaction goes to completion, cleavage is coupled to the hydrolysis of ATP to ADP and inorganic phosphate (Eq. 13-39). The value of *G'* given here is extremely dependent upon the concentration of Mg^{2+} as a result of strong chelation of Mg^{2+} by citrate.[220] The reaction sequence is complex but can be understood in terms of an initial ATP-dependent synthesis of



ΔG' (pH 7)* = +0.9 kJ mol^{-1} (13-39)

citryl-CoA using a mechanism similar to that in Eq. 12-47. There is evidence for both phosphoenzyme and citryl enzyme intermediates (Eq. 13-40).[221] Native ATP-citrate lyase is a tetramer of 110-kDa subunits. It usually contains some phosphoserine and phosphothreonine residues but they apparently have little effect on activity.[222] Phosphorylation is catalyzed by cAMP-dependent and by insulin-dependent protein kinases.[223,224] A related reaction is the ATP-dependent cleavage of malate to acetyl-CoA and glyoxylate. It requires two enzymes, malyl-CoA being an intermediate.[225]

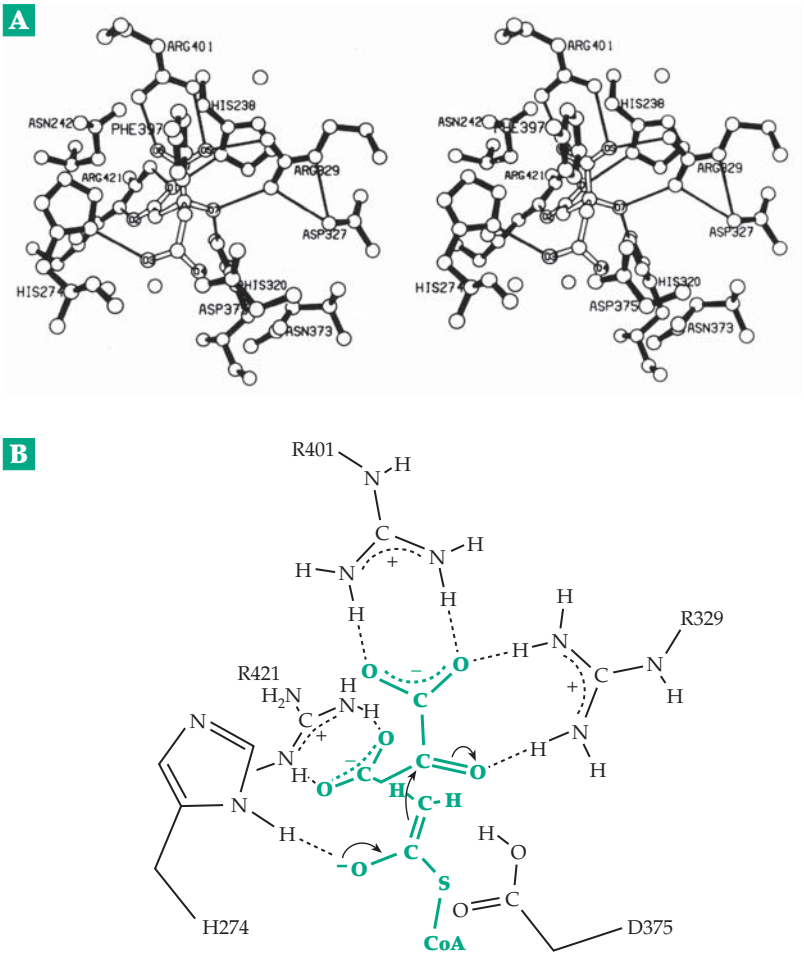


Figure 13-9 Active site of pig citrate synthase. (A) Stereoscopic view with a molecule of citrate in the active site.[200] Courtesy of Stephen J. Remington. (B) Interpretive view of the enolate anion of acetyl-CoA and oxaloacetate bound in the active site. Based on work by Kurz *et al.*[210]

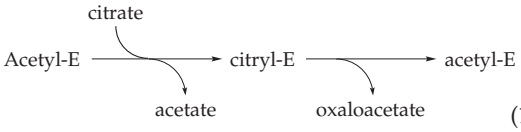
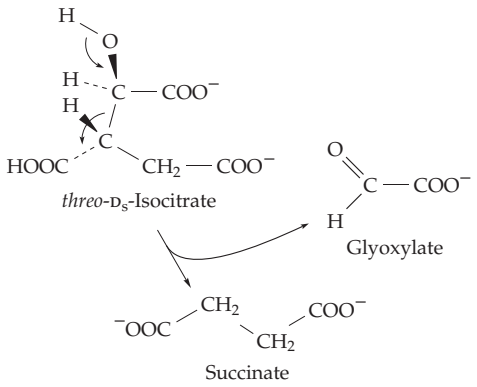
A substrate-induced citrate lyase found in bacteria such as *E. coli* and *Klebsiella* promotes the anaerobic dissimilation of citrate splitting it to oxaloacetate and acetate.[226] The large ~585-kDa protein from *Klebsiella*[225] has the composition $(\alpha\beta\gamma)_6$, where the α, β, and γ subunits have masses of ~ 55-, 30-, and 10-kDa, respectively. The subunit carries an unusual covalently bound derivative of coenzyme A[227] (see also Chapter 14). The 10-kDa γ subunit serves as an **acyl-carrier protein**, the –SH of its prosthetic group being acetylated by a separate ATP-dependent ligase. The resulting acetyl-enzyme undergoes an acyl exchange (analogous to a CoA-transferase reaction; Eq. 12-50) to form a citryl enzyme before the aldol cleavage takes place (Eq. 13-40).



(13-40)

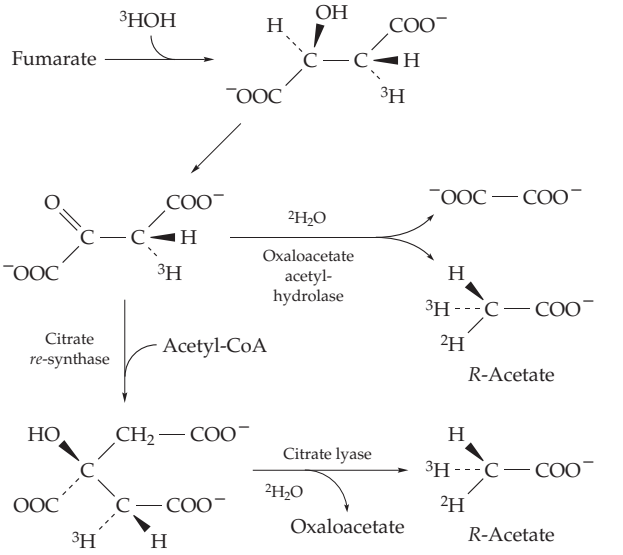
The first unique enzyme of the important glyoxylate pathway (Chapter 17), **isocitrate lyase**, cleaves isocitrate to succinate and glyoxylate (Eq. 13-41).[228] The carboxylate group that acts as electron acceptor would presumably be protonated by the enzyme.



(13-41)

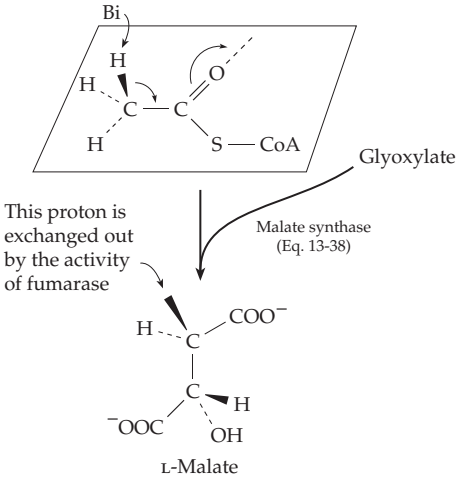
3. Chiral Acetates and Their Use in Stereochemical Studies

Consider the series of enzyme-catalyzed reactions shown in Eq. 13-42. Fumarate is hydrated in ^{3}H-containing water to malate which is oxidized to oxaloacetate. Hydrolysis of the latter with oxaloacetate acetylhydrolase (Eq. 13-34) in ^2H_2O gives oxalate and chiral (*R*) acetate. The identical product can be obtained by condensing oxaloacetate with acetyl-CoA using citrate (*re*)-synthetase. The resulting citrate is cleaved in ^2H_2O using a citrate lyase having the *si* specificity.[229,230] Acetate of the opposite chirality can be formed enzymatically beginning with [2,3-^{3}H]fumarate hydrated by fumarate hydratase in ordinary water. Chiral acetates have also been prepared nonenzymatically,[229] and their configuration has been established unequivocally.



(13-42)

During the action of both oxaloacetate acetylhydrolase and citrate lyase (Eq. 13-42) inversion of configuration occurs about the carbon atom that carries the negative charge in the departing enolate anion. That inversion also occurs during catalysis by citrate (*re*)-synthase and other related enzymes has been demonstrated through the use of chiral acetates.[229,230] The findings with malate synthase[199] are illustrated in Eq. 13-38. Presumably, a basic group B of the enzyme removes a proton to form the planar enolate anion. The second substrate glyoxylate approaches from the other side of the molecule and condenses as is shown. Since any one of the three protons in either *R* or *S* chiral acetyl-CoA might have been abstracted by base B, several possible combinations of isotopes are possible in the L-malate formed. One of the results of the experiment using chiral (*R*) acetyl-CoA is illustrated in Eq. 13-43. The reader can easily tabulate the results of removal of the ^{2}H or ^{3}H. However, notice that if the base –B: removes ^{2}H (D) or ^{3}H (T) the reaction will be much slower because of the kinetic isotope effects which are expected to be $^{H}k/^{D}k \approx 7$ and $^{H}k/^{T}k \approx 16$. A second important fact is that the *pro-R* hydrogen at C-3 in malate is specifically exchanged out into water by the action of fumarate hydratase. From the distribution of tritium in the malate and fumarate formed using the two chiral acetates, the inversion by malate synthase was established. See Kyte[231] for a detailed discussion.

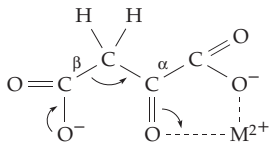


(13-43)

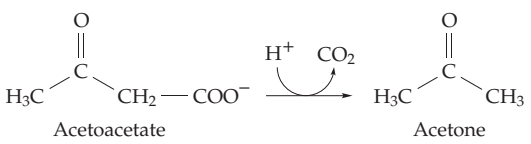
4. Addition of an Enolate Ion to Carbon Dioxide and Decarboxylation

The addition of an enolate anion to CO_2 to form a β-oxoacid represents one of the commonest means of incorporation of CO_2 into organic compounds. The reverse reaction of **decarboxylation** is a major mechanism of biochemical formation of CO_2. The equilibrium constants usually favor decarboxylation but the cleavage of ATP can be coupled to drive carboxylation when it is needed, e.g., in photosynthesis.

Decarboxylation of β-oxoacids. Beta-oxoacids such as oxaloacetic acid and acetoacetic acid are unstable, their decarboxylation being catalyzed by amines, metal ions, and other substances. Catalysis by amines depends upon Schiff base formation,[232] while metal ions form chelates in which the metal assists in electron withdrawal to form an enolate anion.[233–235]



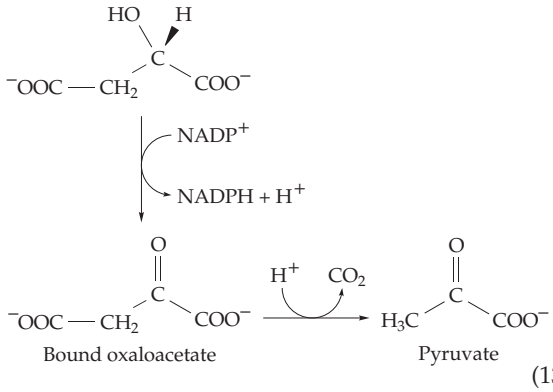
Can we apply any of this information from nonenzymatic catalysis to decarboxylating enzymes? Some decarboxylases do form Schiff bases with their substrates, and some are dependent on metal ions.[235] The acetone-forming fermentation of *Clostridium acetobutylicum* requires large amounts of acetoacetate decarboxylase (Eq. 13-44).



(13-44)

The enzyme is inactivated by borohydride in the presence of substrate, and acid hydrolysis of the inactivated enzyme yielded ε-*N*-isopropyllysine. Decarboxylation occurs from a Schiff base by a mechanism analogous to that of the aldol cleavage shown in Eq. 13-36.[236] Mechanistically related is 4-oxalocrotonate decarboxylase.[236a]

Linked oxidation and decarboxylation. Metabolic pathways often make use of oxidation of a β-hydroxy acid to a β-oxoacid followed by decarboxylation in the active site of the same enzyme. An example is conversion of L-malate to pyruvate (Eq. 13-45). The Mg^{2+} or Mn^{2+}-dependent decarboxylating malic dehydrogenase that catalyzes the reaction is usually called **the malic enzyme**. It is found in most organisms.[237–240] While a concerted decarboxylation and dehydrogenation may sometimes occur,[241–242] the enzymes of this group appear usually to operate with bound oxoacid intermediates as in Eq. 13-45.

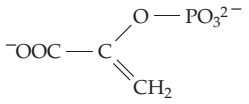


(13-45)

Other reactions of this type are the oxidation of isocitrate to 2-oxoglutarate in the citric acid cycle (Fig. 17-4, steps *d* and *e*),[243] oxidation of 6-phosphogluconate to ribulose 5-phosphate (Eq. 17-12),[244] and corresponding reactions of isopropylmalate dehydrogenase[245,246] and tartrate dehydrogenase.[247,248] Crystallographic studies of isocitrate dehydrogenase using both photolabile "caged" isocitrate[247] and slow mutant forms[243] with polychromatic Laue crystallography (Chapter 3) have demonstrated the rapid formation of the anticipated intermediate **oxalosuccinate**.

Phosphoenolpyruvate, a key metabolic intermediate. A compound of central importance in metabolism is the phosphate ester of the enol form of pyruvate, commonly known simply as phosphoenolpyruvate (PEP).[249] It is formed in the glycolysis pathway by dehydration of 2-phosphoglycerate (Eq. 13-15) or by decarboxylation of oxaloacetate. Serving as a preformed enol from which a reactive enolate anion can be released for condensation reactions,[250,251] PEP

is utilized in metabolism in many ways.



Phosphoenolpyruvate (PEP)

In animals and in many bacteria, PEP is formed by decarboxylation of oxaloacetate. In this reaction, which is catalyzed by **PEP carboxykinase** (PEPCK), a molecule of GTP, ATP, or inosine triphosphate captures and phosphorylates the enolate anion generated by the decarboxylation (Eq. 13-46).[252] The stereochemistry is such that CO_2 departs from the *si* face of the forming enol.[253] The phospho group is transferred from GTP with inversion at the phosphorus atom.[254] The enzyme requires a divalent metal ion, preferably Mn^{2+}. In fact, kinetic studies of the GTP-dependent avian mitochondrial enzyme indicate two metal-binding sites, one on the polyphosphate group of the bound GTP and one on carboxylate side chains of the protein.[252,255] The three-dimensional structure of the ATP-dependent *E. coli* enzyme reveals a nucleotide binding site similar to the ATP site of adenylate kinase (Fig. 12-30).[256] A definite binding site for CO_2 is also present in the enzyme.[257]

PEPCK is also activated by low concentrations of Fe^{2+} and this activation depends upon a protein that has been identified as glutathione peroxidase (Eq. 15-58). By destroying H_2O_2 the latter may allow the Fe^{2+} to prevent oxidation of an SH group on PEP carboxykinase.[258] Synthesis of PEPCK is stimulated by glucagon, evidently through a direct action of cAMP on transcription of the structural gene.[259] Transcription is also stimulated by glucocorticoids and thyroid hormone and is inhibited by insulin.

In some organisms, such as the parasitic *Ascaris suum*, PEPCK functions principally as a means of synthesis of oxaloacetate by reaction of PEP with CO_2 and GDP. These organisms lack pyruvate kinase, which allows for buildup of the high PEP concentration needed to drive this reaction.[260] In a similar way PEP can be converted to oxaloacetate by **PEP carboxytransphosphorylase**, an enzyme found only in propionic acid bacteria and in *Entamoeba*. The reaction (Eq. 13-47) is accompanied by synthesis of inorganic pyrophosphate which may be cleaved to "pull" the reaction in the indicated direction.

PEP

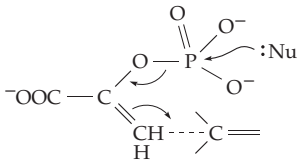
re Face is toward reader

(13-46)

$$PEP + CO_2 + P_i \rightarrow PP_i + \text{oxaloacetate} \qquad (13\text{-}47)$$

Oxaloacetate is also decarboxylated without phosphorylation of the enolate anion formed but with release of free pyruvate. Both pyruvate kinase and PEPCK can act as oxaloacetate decarboxylases.[261]

In the important reactions discussed in the following sections enolate ions are intermediates in carbon-carbon bond formation. Other examples are given in Eqs. 20-7 and 20-8, and Fig. 25-1, in which C–C bonds are formed by action of PEP as a carbon nucleophile,



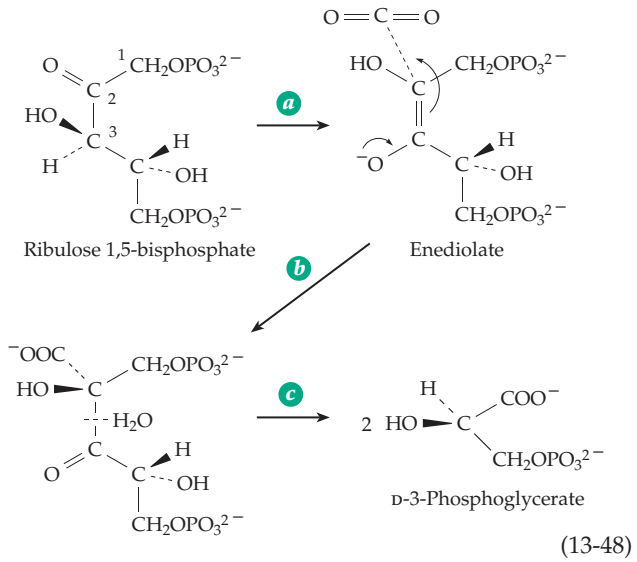
e.g., in aldol-like condensations.[242a] Yet another unusual type of reaction, involving formation of an enol ether linkage is illustrated in Box 13-B and in Eq. 25-3.

Ribulose bisphosphate carboxylase. The major route of incorporation of CO_2 into organic compounds is via photosynthesis. When ^{14}C-labeled CO_2 enters chloroplasts of green plants, the first organic ^{14}C-containing compound detected is 3-phosphoglycerate. Two molecules of this compound are formed through the action of **ribulose-1,5-bisphosphate carboxylase** (abbreviated **rubisco**), an enzyme present in chloroplasts and making up 16% of the protein of spinach leaves. This enzyme, whose structure is illustrated in Fig. 13-10, is thought to be the most abundant protein on earth. Because O_2 competes with CO_2 as a substrate, the enzyme also catalyzes an "oxygenase" reaction. It is therefore often called **ribulose-1,5-bisphosphate carboxylase/oxygenase**.[262] The rubisco from most plants is a 500- to 560-kDa L_8S_8 oligomer as shown in Fig. 13-10. The large subunit is encoded in the chloroplast DNA. However, a family of nuclear genes encode the small subunits, which are synthesized as larger precursors, with N-terminal extensions being removed to give the mature subunits.[263,264] Two types of small subunits occupy different positions in the

quasi-symmetric spinach rubisco.[264] In *Euglena* the small subunit is synthesized as a polyprotein precursor containing eight copies of the subunit.[265] Rubisco from the hydrogen-oxidizing bacterium *Alcaligenes eutrophus* has a similar quaternary structure,[266] but the enzyme from *Rhodospirillum rubrum* is a simple dimer.[267] In dinoflagellates the rubisco gene is present in nuclear DNA rather than in the chloroplasts.[268]

The carboxylation reaction catalyzed by rubisco differs from others that we have considered in that the carboxylated product is split by the same enzyme (Eq. 13-48). The mechanism shown in Eq. 13-48 was suggested by Bassham *et al*.[271] Ribulose bisphosphate, for which the enzyme is absolutely specific, is first converted to its enolic form, a 2,3-enediol. Loss of a proton from the 3-OH group forms the endiolate anion needed for the carboxylation in step *b*. The product of this step is a β-oxoacid which undergoes enzyme-catalyzed hydrolytic cleavage (Eq. 13-48, step *c*; see also Eq. 13-34). Support for this mechanism came from the observation that 2-carboxyarabinitol bisphosphate (Fig. 13-11B) is a potent inhibitor, possibly a transition state analog.[272] This inhibitor, bound into the active site of the enzyme from spinach, is seen in both Figs. 13-10B and 13-11A. An expanded version of Eq. 13-48 is given in Fig. 13-12, which is based upon modeling together with a variety of X-ray structures including that shown in Fig. 13-11.

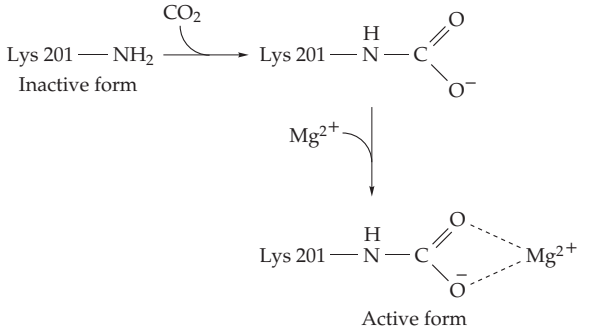
An essential Mg^{2+} ion is held by carboxylates of D203 and E204 and by modified K201. It also coordinates three molecules of H_2O in the free enzyme.[272a] Catalytic roles for the H294 and H327 imidazole groups are still being elucidated.[272b] Lysine 175 protonates C2 of the aci anion generated by C–C bond cleavage (step *e*, Fig. 13-12).[272c,276] Like many enzymes, rubisco exists in two major conformational states: open and closed.[272d]



(13-48)

Chemical studies also support the indicated mechanism. For example, the β-oxoacid intermediate formed in step *b* of Eq. 13-48 or Fig. 13-12 has been identified as a product released from the enzyme by acid denaturation during steady-state turnover.[273,274] Isotopic exchange with ^3H in the solvent[275] and measurement of ^{13}C isotope effects[277] have provided additional verification of the mechanism. The catalytic activity of the enzyme is determined by ionizable groups with pK_a values of 7.1 and 8.3 in the ES complex.[278]

The apparent value of K_m for total CO_2 (CO_2 + HCO_3^-) is high, 11–30 mM, but for the true substrate CO_2 it is only 0.45 mM. In intact chloroplasts the affinity for substrate is distinctly higher, with the K_m for total CO_2 dropping to ~0.6 mM. The difference appears to result largely from a regulatory reaction of CO_2 in which the side chain amino group of lysine 201 of the large subunit forms a carbamate (Eq. 13-49). Although carbamylation is spontanous, it is enhanced by an ATP-dependent process catalyzed by **rubisco activase.**[279] The carbamylation converts the side chain of Lys 201 into a negatively charged group that binds to an essential divalent metal, usually Mg^{2+}, in the active center[282] as is shown in Fig. 13-11, A and B. The nature of the reaction is uncertain. One possibility is that the activase is a chaperonin.[280] It appears to assist the enzyme in removing inhibitory sugars that arise by side reactions in the active site.[281] Rubisco is also regulated by the level of a natural inhibitor which has been identified as 2-carboxyarabinitol 1-phosphate. This is the same as the inhibitor shown in Fig. 13-11 but with one less phosphate group and consequent weaker binding.[273a]



(13-49)

In most plants photosynthesis is also strongly inhibited by O_2. This observation led to the discovery that O_2 competes directly for CO_2 at the active site of rubisco in a process called **photorespiration**. Chloroplasts inhibited by oxygen produce **glycolate** in large amounts[282a] as a result of the reaction of the intermediate enediolate ion formed in step *b* of Eq. 13-48 with O_2

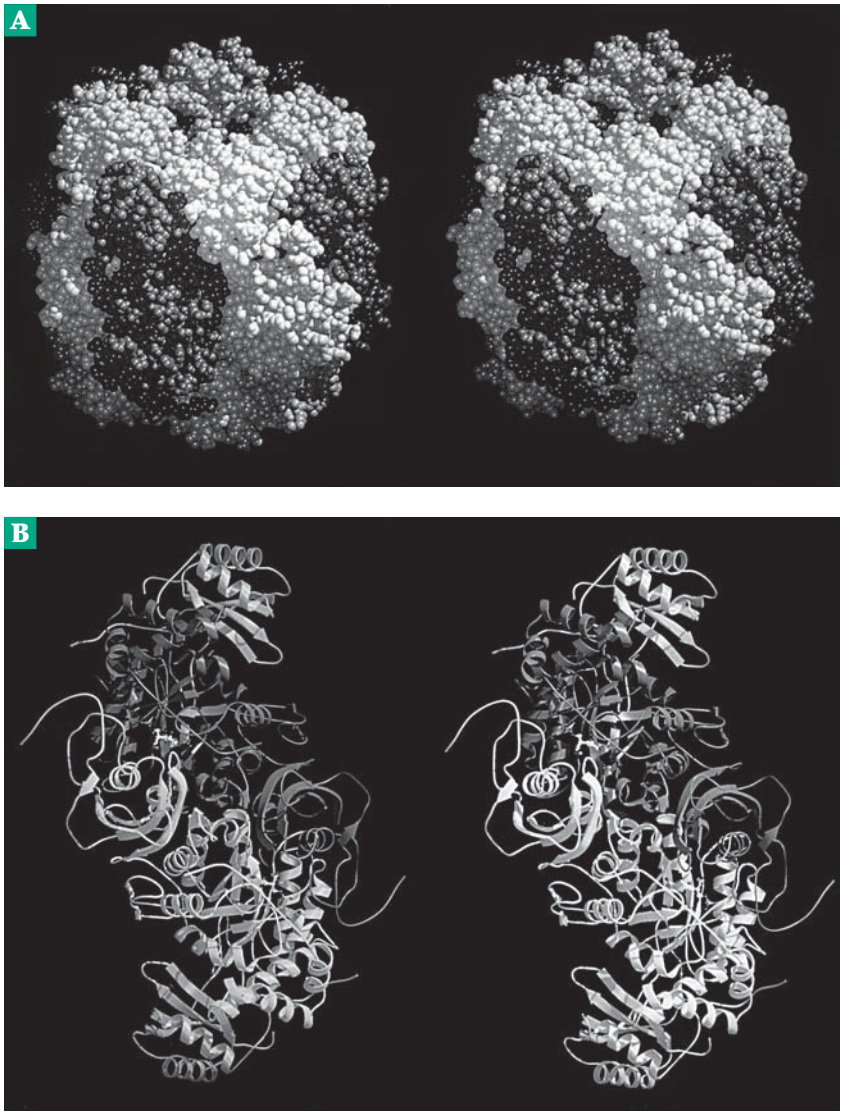


Figure 13-10 Stereoscopic view of ribulose bisphosphate carboxylase (rubisco) from spinach. (A) The symmetric L_8S_8 molecule contains eight 475-residue large subunits (in two shades of gray) and eight 123-residue small subunits (lighter gray in upper half of image). (B) One L_2S_2 substructure containing two active sites shared between adjacent large subunits with the bound inhibitor 2-carboxy-D-arabinitol 1,5-bisphosphate.[269] In the upper LS unit the S subunit (top) is light and the L subunit is dark. Courtesy of Inger Andersson. Similar structures have been determined for enzymes from tobacco[269a] and from the cyanobacterium *Synechoccus*.[270]

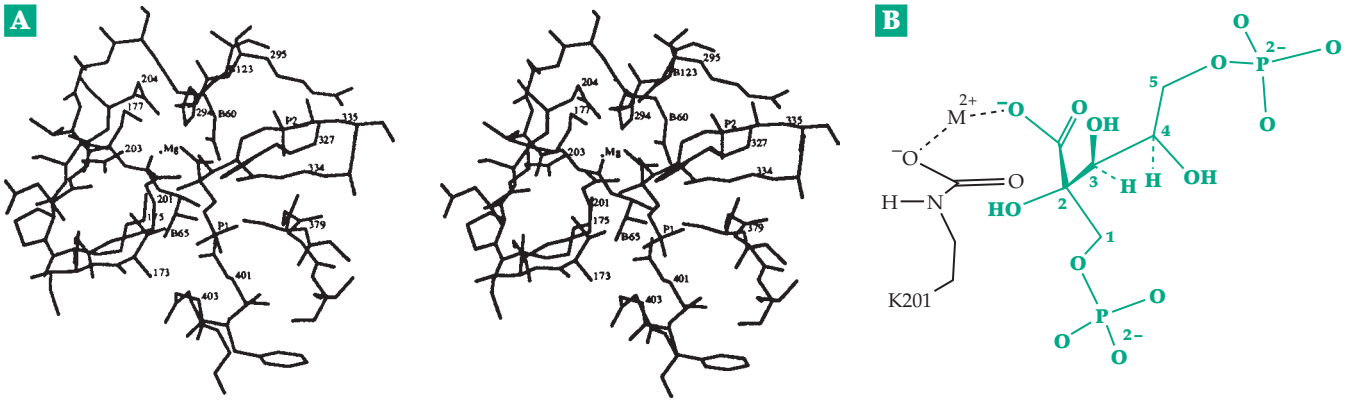

Figure 13-11 (A) Overview of the active site of spinach rubisco showing bound 2-carboxy-D-arabinitol 1,5-bisphosphate and Mg^{2+} and residues within hydrogen-bonding distance of these ligands. The hydroxyl groups at C2 and C3 of the inhibitor are in *cis* conformation. [269] Courtesy of Inger Andersson. (B) Structure of the inhibitor 2-carboxy-D-arabinitol 1,5-bisphosphate. A part of the carbamylated lysine 201 and the essential metal ion are also shown.

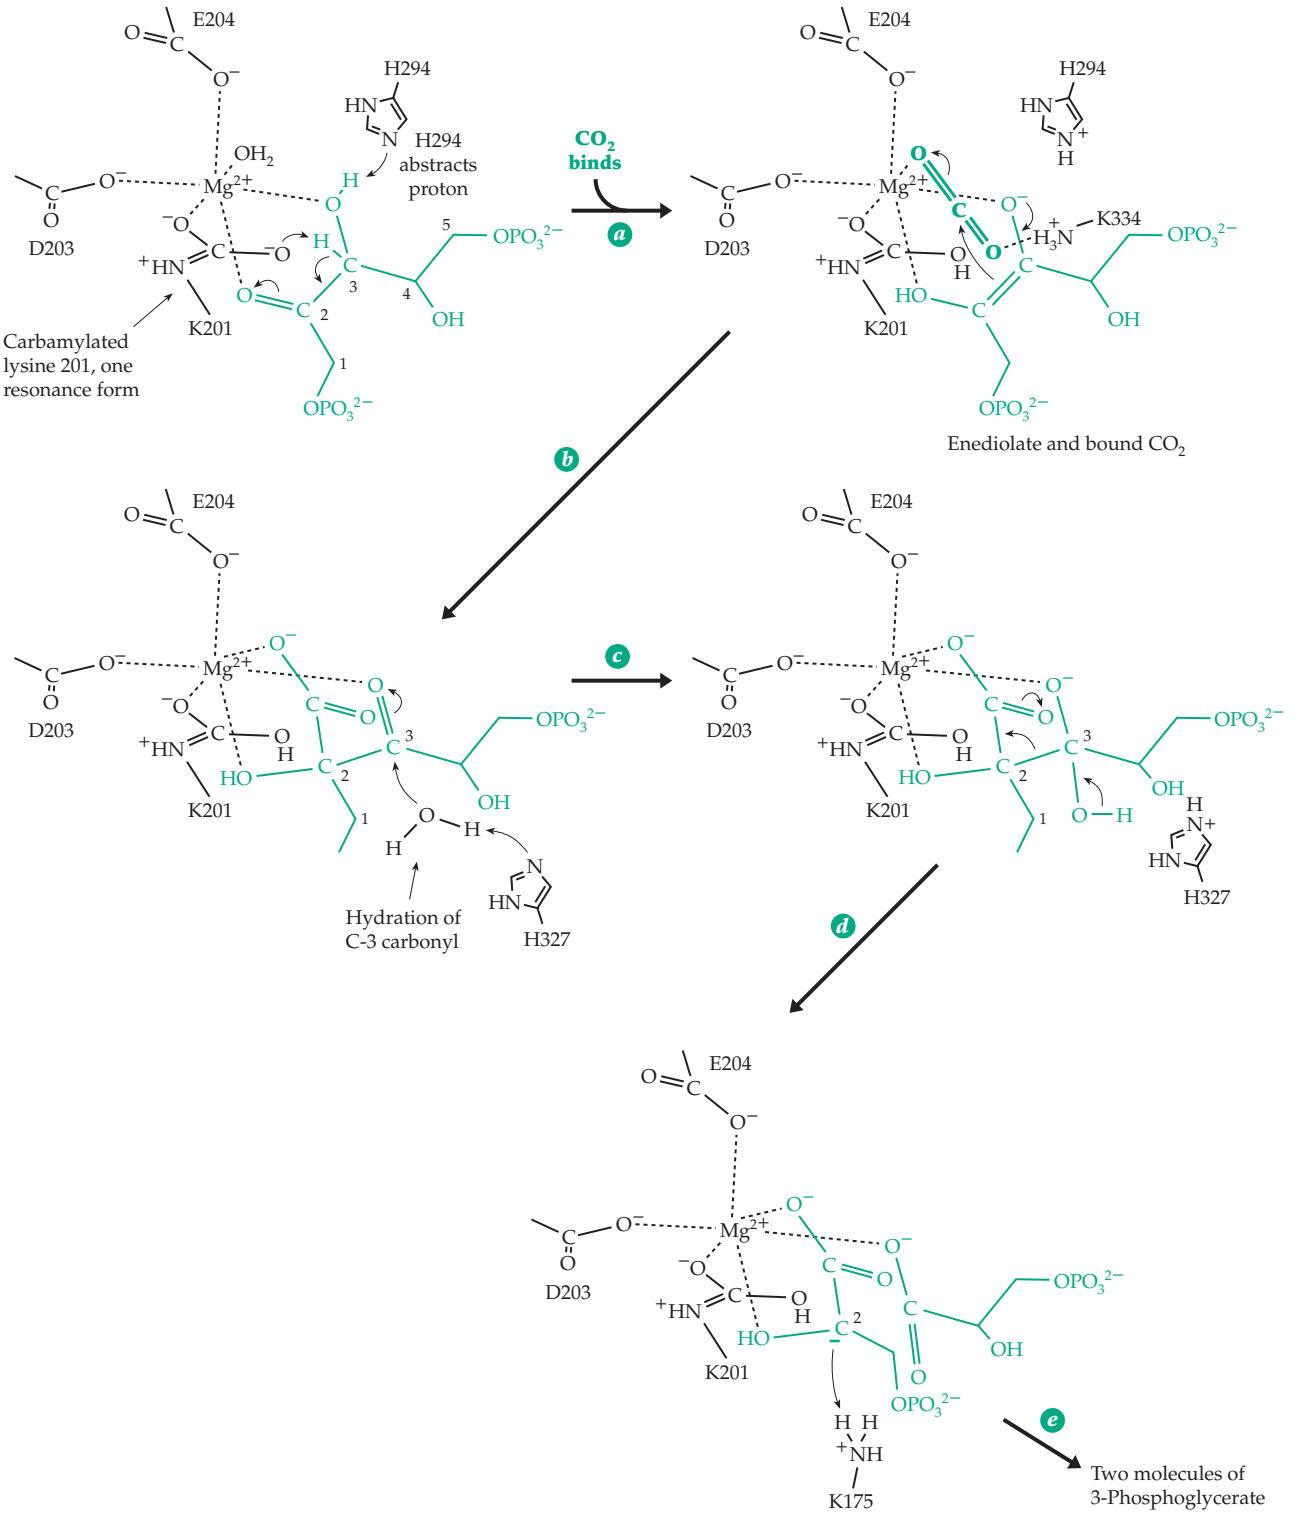

Figure 13-12 Proposed mechanism of action of ribulose bisphosphate carboxylase (rubisco). This is an abbreviated version of the mechanism as presented by Taylor and Andersson.[276] The binding of ribulose 1,5-bisphosphate occurs after carbamylation of lysine 201 and binding of a magnesium ion. Formation of an enediolate intermediate in step *a* is probably catalyzed by the carbamate group as indicated. Removal of a proton from the 3-OH, perhaps by H294, and addition of a proton to form an –OH group at C2 are also necessary. The CO_2 may bind to the Mg^{2+} and be polarized by interaction with other side chains prior to reaction. Carboxylation occurs by addition of the enediolate to CO_2 in step *b*. The hydration of the resulting 3-oxo group (step *c*) is necessary for cleavage of the C–C bond in step *d*. The participation of the newly formed carboxylate as an *aci* anion coordinated to Mg^{2+} is presumably involved. Protonation, with stereochemical inversion, is thought to involve K175, as shown. The two product molecules dissociate in step *e*.

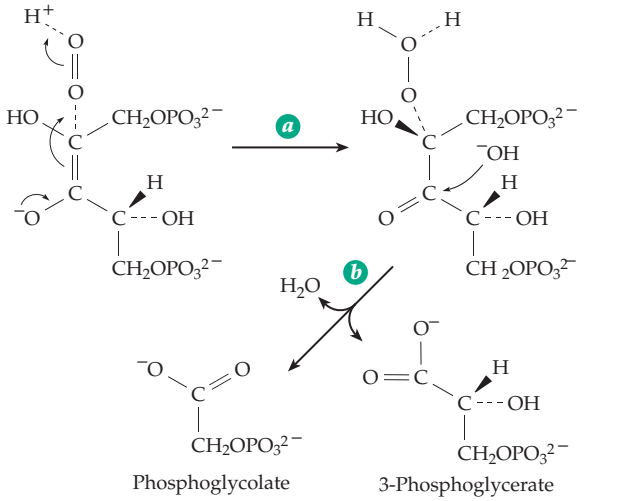
(Eq. 13-50, step *a*). The peroxide formed in this way breaks up under the hydrolytic action of the enzyme to form phosphoglycolate and 3-phosphoglycerate (Eq. 13-50, step *b*).

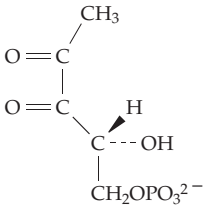


(13-50)

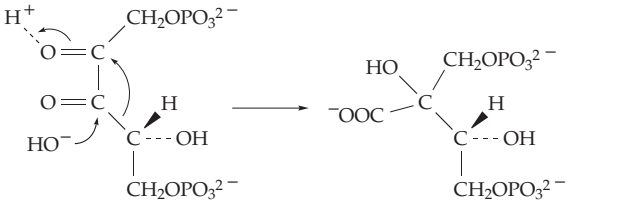
Molecular oxygen usually reacts rapidly with only those organic substrates, such as dihydroflavins, that are able to form stable free radicals. However, the endiolate anion of Eq. 13-50 may be able to donate a single electron to O_2 to form a superoxide–organic radical pair prior to formation of the peroxide (see also Eq. 15-30). Similar oxygenase side reactions have been observed for a variety of other enzymes that utilize carbanion mechanisms.[283] The reaction of rubisco with O_2 is of both theoretical and practical interest, the latter because of its significance in lowering the yield in photosynthesis (Chapter 23).

The simpler dimeric rubisco from *Rhodospirillum* is very inefficient in carboxylation and catalyzes much more oxygenation than do rubiscos of higher plants.[283a] Mutant enzymes that have impaired carboxylase and enhanced oxygenase are also known.[284,284a]

The small subunits of rubisco may help suppress undesirable side reactions.[285] For example, the following deoxypentodiulose phosphate can be formed by β elimination from the second intermediate of Eq. 13-48.

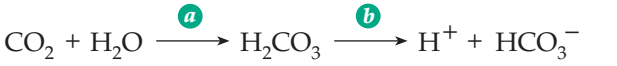


Some side products of the normal oxgenase reaction arise by elimination of a peroxide ion from the first intermediate of Eq. 13-50. The resulting dicarbonyl bisphosphate can rearrange to give a carboxytetritol bisphosphate (Eq. 13-51).[284]



(13-51)

Carbon dioxide or bicarbonate ion? An important question in the consideration of carboxylation and decarboxylation reactions is whether the reactant or the product is CO_2 or HCO_3^-. An approach to answering the question was suggested by Krebs and Roughton,[286]



(13-52)

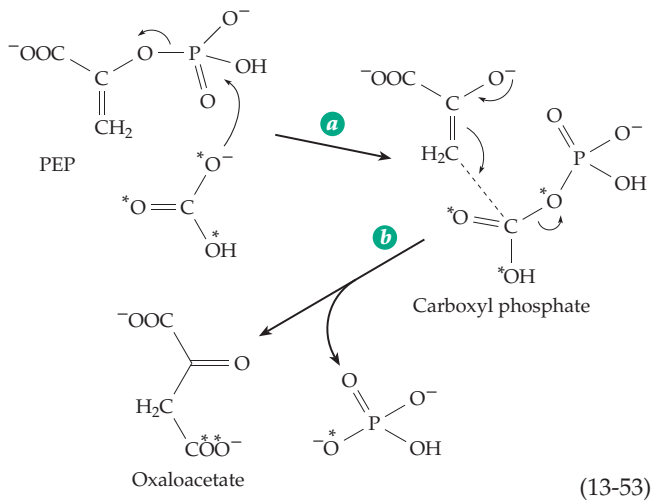
who pointed out that the attainment of equilibrium between free CO_2 and HCO_3^- (Eq. 13-52) may require several seconds. If an enzyme produces CO_2 as a product and progress of the reaction is followed manometrically, the pressure will rise higher than the equilibrium value as the CO_2 is evolved. Later when substrate is exhausted and the CO_2 equilibrates with bicarbonate, the pressure will fall again. The addition of carbonic anhydrase, which catalyzes Eq. 13-52, step *a*, abolishes the "overshoot." If bicarbonate is the primary product of a decarboxylation, there is a lag in the appearance of free CO_2.

A second approach is to use [^{18}O]bicarbonate and to follow the incorporation of ^{18}O into a carboxylated substrate. If CO_2 is the primary substrate only two labeled oxygen atoms enter the compound, whereas if HCO_3^- is the reactant three are incorporated.[287] A third technique is measurement of the rate of incorporation of CO_2 or bicarbonate in the carboxylated product. Over a short interval of time, e.g., 1 min, different kinetics will be observed for the incorporation of CO_2 and of bicarbonate.[288] Using these methods, it was established that the product formed in Eq. 13-46 and the reactant in Eq. 13-47 is CO_2. However, the carboxylation enzymes considered in the next section use bicarbonate as the substrate.

5. Incorporation of Bicarbonate into Carboxyl Groups

An important enzyme with a biosynthetic function in many bacteria and in all higher plants is **PEP carboxylase**,[289] which catalyzes the reaction of Eq. 13-53. This enzyme, in effect, accomplishes the reverse of Eq. 13-46 by converting the three-carbon PEP, by reaction with bicarbonate, into the four-carbon oxaloacetate. The latter is needed for "priming" of the citric acid cycle and for biosynthesis of such amino acids as aspartate and glutamate. That the enzyme functions in this way is indicated by the fact that mutants of *Salmonella* defective in the enzyme do not grow unless oxaloacetate or some other intermediate in the citric acid cycle is added to the medium. The enzyme from *S. typhimurium* is a 400-kDa tetramer with complex regulatory properties. The corresponding enzyme from spinach has 12 subunits and 12 bound Mn^{2+} ions. The enzyme also has a special function in the C_4 plants,[290] in which it is a component of a carbon dioxide concentrating system (Chapter 23).

When [^{18}O]bicarbonate is a substrate, two labeled oxygen atoms enter the oxaloacetate, while the third appears in P_i. A concerted, cyclic mechanism could explain these results. However, study of kinetic isotope effects,[291] use of a substrate with a chiral thiophospho group,[292] and additional ^{18}O exchange studies[293] have ruled out this possibility. A transient carboxyl phosphate (Eq. 13-53) is evidently an intermediate.[294,295] The incorporation of the ^{18}O from bicarbonate into phosphate is indicated by the asterisks. The carboxyl group enters on the *si* face of PEP. However, there is another possibility.[295,296] The carboxyl phosphate, while in the active site adjacent to the enolate anion, may eliminate phosphate, the enolate ion adding to the resulting CO_2 to form the final product. According to this mechanism the group transfer potential of the phosopho group in PEP is

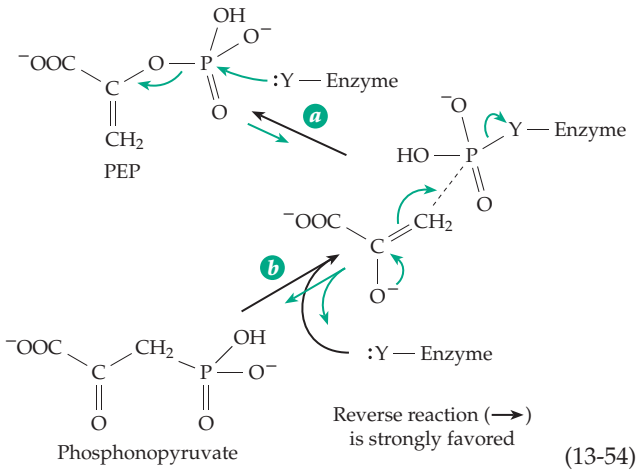


(13-53)

utilized to concentrate the CO_2 and to localize it next to the enolate anion generated by the same process.

PEP carboxylase is lacking from animal tissues and fungi. In these creatures PEP is converted to pyruvate, which is then carboxylated to oxaloacetate with coupled cleavage of ATP by the action of **pyruvate carboxylase** (Eq. 14-3), an enzyme that not only utilizes bicarbonate ion but also contains **biotin**. However, there are mechanistic similarities between its action and that of PEP carboxylase.

PEP mutase and the synthesis of phosphonates. The lipids of some organisms, such as *Tetrahymena*, contain aminoethylphosphonate, a compound with a C–P bond (Chapter 8). There are also many other naturally occurring phosphono compounds and huge quantities of synthetic phosphonates, present in detergents, herbicides, and insecticides, are metabolized by bacteria.[297] Here we will consider only one step in the biosynthesis of phosphonates, the conversion of PEP into phosphonopyruvate (Eq. 13-54), a reaction catalyzed by **PEP mutase**. The phospho group is moved



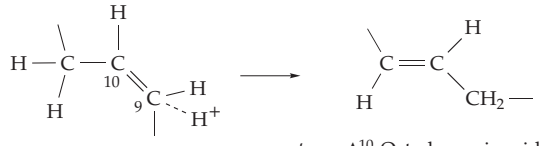
(13-54)

from the oxygen atom of PEP to the methylene carbon atom. When attached to carbon the phospho group is designated **phosphono**. The reaction occurs with retention of the configuration around phosphorus and a phosphoenzyme intermediate seems to be involved[298,299] as shown in Eq. 13-54. The equilibrium in this reaction strongly favors PEP. One further product formed from phosphonopyruvate is phosphonoethylamine, a component of phosphonolipids.[300] It is easy to imagine a synthetic route involving transamination followed by decarboxylation. Another mutase, similar to PEP mutase, shifts the carboxyphospho group $^-OOC–PO_2^-$– exactly as in Eq. 13-54 as part of the biosynthetic pathway of a natural herbicide formed by *Streptomyces hygroscopicus*.[301,302] Soil bacteria contain specialized enzymes that catalyze the hydrolytic cleavage of P–C bonds.[302a]

D. Some Isomerization and Rearrangement Reactions

A few metabolic reactions do not fit into any of the categories discussed so far and apparently do not depend upon a coenzyme. Some of these involve transfer of alkyl groups or of hydrogen atoms from one carbon to another. The hydrogen atoms move by direct transfer without exchange with the medium. All of the reactions could involve carbocations but there is often more than one mechanistic possibility.

A simple 1,3-proton shift is shown in Table 10-1 as reaction type 6A. An example is the isomerization of oleic acid to *trans*-Δ^{10}-octadecenoic acid (Eq. 13-55) catalyzed by a soluble enzyme from a pseudomonad.[303]

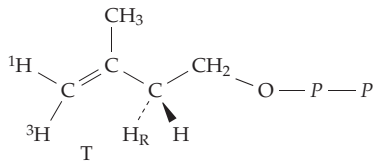


Oleic acid
(*cis*-Δ^9-octadecenoic acid)

trans-Δ^{10}-Octadecenoic acid

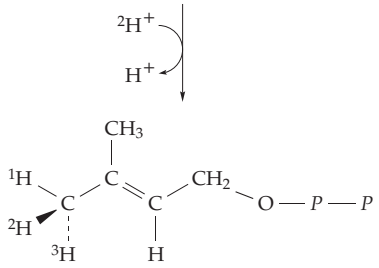
(13-55)

A second example is isomerization of **isopentenyl diphosphate** to **dimethylallyl diphosphate** (Eq. 13-56).[304–307] The stereochemistry has been investigated using the ^{3}H-labeled compound shown in Eq. 13-56. The *pro-R* proton is lost from C-2 and a proton is added to the *re* face at C-4. When the reaction was carried out in ^2H_2O a chiral methyl group was produced as shown.[304] A concerted proton addition and abstraction is also possible, the observed *trans* stereochemistry being expected for such a mechanism. However, the fact that the enzyme is strongly inhibited by the cation of 2-(diethylamino) ethyl pyrophosphate, an analog of a probable carbocation intermediate. Cysteine and glutamate side chains are essential.[307]



T

Isopentenyl diphosphate

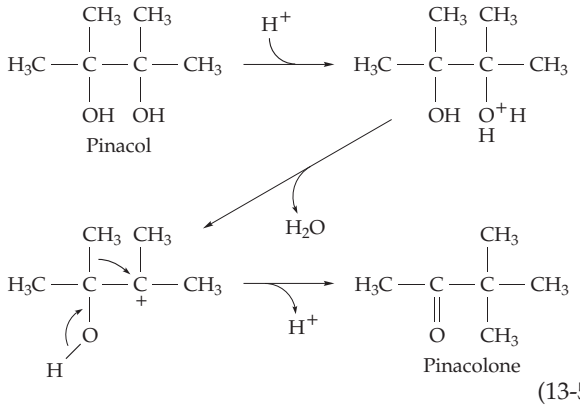


Dimethylallyl diphosphate

(13-56)

Reaction type 6B of Table 10-1 is allylic rearrangement with simultaneous condensation with another molecule. The reaction, which is catalyzed by **prenyltransferases**,[307a] occurs during the polymerization of polyprenyl compounds (Fig. 22-1,Eqs. 22-2, 22-3). Experimental evidence favors a carbocation mechanism for all of these reactions.[308,309] See Chapter 22.

Reaction type 6C (Table 10-1) occurs during the biosynthesis of leucine and valine (Fig. 24-17). The rearrangement is often compared with the nonenzymatic acid-catalyzed pinacol–pinacolone rearrangement in which a similar shift of an alkyl group takes place (Eq. 13-57). The enzyme-catalyzed rearrangement



Pinacol

Pinacolone

(13-57)

presumably gives the structure drawn in brackets in Table 10-1. The same enzyme always catalyzes reduction with NADH to the diol, the Mg^{2+}-dependent enzyme being called **acetohydroxy acid isomeroreductase**. Rearrangement has never been observed without the accompanying reduction.[310–313] More complex rearrangements that occur during biosynthesis of sterols are described in Chapter 22.

Study Questions

1. Discuss the role of carbonyl groups in facilitating reactions of metabolism.

2. Write a step-by-step sequence showing the chemical mechanisms involved in the action of a type I aldolase that catalyzes cleavage of fructose 1,6-bisphosphate. The enzyme is inactivated by sodium borohydride in the presence of the substrate. Explain this inactivation.

3. Some methylotrophic bacteria dehydrogenate methanol to formaldehyde. The latter undergoes an aldol condensation to form a hexulose-6-phosphate:

   Write a reasonable cycle of biochemical reactions (utilizing this compound) by which three molecules of methanol can yield one molecule of glyceraldehyde 3-phosphate, a compound that can be either catabolized for energy or utilized for biosynthesis.

4. Malate is formed in the glyoxylate pathway by reaction of glyoxylate with Acetyl-CoA. Indicate the chemical mechanism of the reactions involved and structure of an intermediate species.

5. Acetyl-CoA is condensed with acetoacetyl-CoA to give an intermediate which is eventually converted to mevalonate.
   a) Show the sequence of reactions leading from acetyl-CoA to mevalonate with the structures of important intermediates.
   b) Mevalonate is an important intermediate on the pathway leading to what *class* of compounds?

6. a) Show the structures of the reactants for the 3-hydroxy-3-methylglutaryl-CoA synthase reaction.
   b) Free coenzyme A is liberated in the above reaction. From which of the two reactants did it come? Explain the metabolic significance of the liberation of free CoA.

7. Phosphoenolpyruvate carboxykinase catalyzes the following reaction:

   Oxaloacetate + GTP→ CO_2 + phosphoenolpyruvate + GDP

   Illustrate the probable mechanism of the reaction.

8. Write a complete step-by-step mechanism for the action of ATP-citrate lyase which catalyzes the following reaction (Eq. 13-39):

   ATP + citrate + CoA – SH → Acetyl – CoA + oxaloacetate + ADP + P_i

9. Malonyl-CoA synthetase forms its product from free malonate and MgATP. Both phospho-enzyme and malonyl-enzyme intermediates have been detected. Suggest a sequential mechanism of action. See Kim, Y. S., and Lee, J. K. (1986) *J. Biol. Chem.* **261**, 16295–16297.

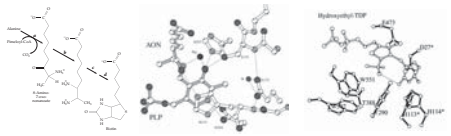
10. The carboxylation of acetone with HCO_3^- to form acetoacetate (the reverse of Eq. 13-44) is not a thermodynamically spontaneous process ($\Delta G°'$ ~17 kJ mol^{-1}). An anaerobic strain of *Xanthobacter* couples this reaction to the cleavage of ATP to AMP + 2 P_i. Suggest possible mechanisms. See Sluis, M. K., and Ensign, S. A. (1997) *Proc. Natl. Acad. Sci. U.S.A.* **94**, 8456–8461.

11. The reaction of Eq. 10-11 begins with a hydroxylation, which can be viewed as insertion of an oxygen atom into a C–H bond. Draw the probable intermediate formed in this reaction and indicate how it can be converted to the final products.

12. Cyanase from *E. coli* decomposes cyanate (NCO^-) to ammonia and CO_2. Isotopic labeling studies show that the second oxygen atom in the product CO_2 comes not from H_2O but from a second substrate, bicarbonate ion. The correct equation for the enzymatic process is:

   $NCO^- + H^+ + HCO_3^- \rightarrow NH_2 - COO^- + CO_2$

   Propose a sequence of steps for this enzymatic reaction, which has been investigated by Anderson and coworkers. Johnson, W. V., and Anderson, P. M. (1987) *J. Biol. Chem.* **262**, 9021–9025 and Anderson, P. M., Korte, J. J., Holcomb, T. A., Cho, Y.-g, Son, C.-m, and Sung, Y.-c. (1994) *J. Biol. Chem.* **269**, 15036–15045.



The vitamin **biotin** is formed in nature (left) by condensation of L-alanine with pimeloyl-CoA to form 8-amino-7-oxononanoate (AON). This compound is seen at the upper left of the center structure joined as a Schiff base with the coenzyme **pyridoxal phosphate** (PLP). This is a product complex of the enzyme AON synthase (see Webster *et al., Biochemistry* **39**, 516-528, 2000) Courtesy of D. Alexeev, R. L. Baxter, and L. Sawyer. Biotin synthesis requires three other enzymes (steps *b*, *c*, *d*). Step *b* is catalyzed by a PLP-dependent transaminase. At the left is **thiamin diphosphate**, in the form of its 2-(1-hydroxyethyl) derivative, an intermediate in the enzyme pyruvate decarboxylase (Dobritzsch *et al., J. Biol. Chem.* **273**, 20196-20204, 1998). Courtesy of Guoguang Lu. Thiamin diphosphate functions in all living organisms to cleave C–C bonds adjacent to C=O groups.

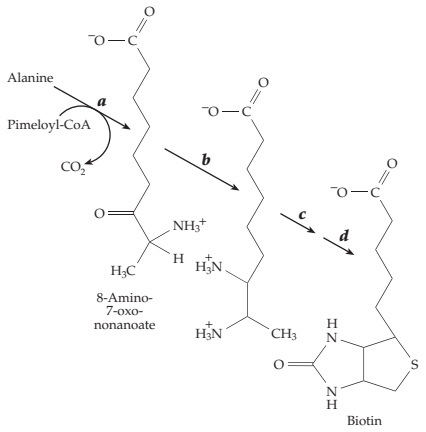
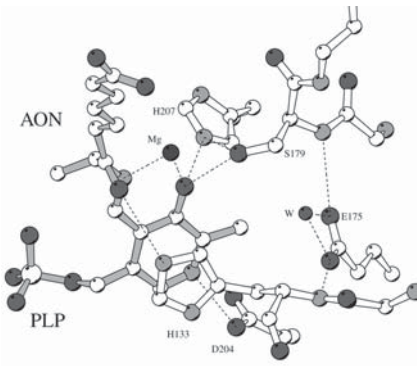
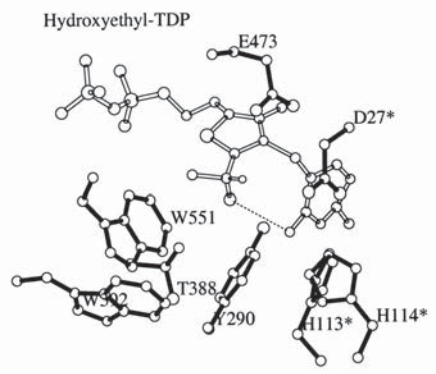
Coenzymes: Nature's Special Reagents

14







Most of the reactions discussed in Chapters 12 and 13 are catalyzed by enzymes that contain only those functional groups found in the side chains of the constituent amino acids. **Coenzymes** are nonprotein molecules that function as essential parts of enzymes. Coenzymes often serve as "special reagents" needed for reactions that would be difficult or impossible using only simple acid–base catalysis. In many instances, they also serve as **carriers**, alternating catalysts that accept and donate chemical groups, hydrogen atoms, or electrons. Coenzymes will be considered here in three groups:

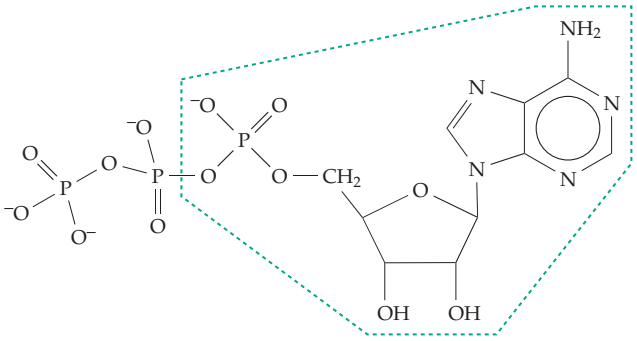
1. Compounds of high group transfer potential such as ATP and GTP that function in energy coupling within cells. Because it is cleaved and then dissociates from the enzyme to which it is bound, ATP may be regarded as a substrate rather than a coenzyme. However, as a phosphorylated form of ADP it may also be viewed as a carrier of high-energy phospho groups.

2. Compounds, often derivatives of **vitamins** that, while in the active site of the enzyme, alter the structure of a substrate in a way that permits it to react more readily. Coenzyme A, pyridoxal phosphate, thiamin diphosphate, and vitamin B_{12} coenzymes fall into this group.

3. Oxidative coenzymes with structures of precisely determined oxidation–reduction potential. Examples are NAD^+, $NADP^+$, FAD, and lipoic acid. They serve as carriers of hydrogen atoms or of electrons. Some of these coenzymes, such as NAD^+ and $NADP^+$, can usually dissociate rapidly and reversibly from the enzymes with which they function. Others, including FAD, are much more tightly bound and rarely if ever dissociate from the protein catalyst. Heme groups are covalently linked to proteins such as cytochrome *c* and cannot be dissociated without destroying the enzyme. Very tightly bound coenzyme groups are often called **prosthetic groups**, but there is no sharp line that divides prosthetic groups from the loosely bound coenzymes. For example, NAD^+ is bound weakly to some proteins but tightly to others. Oxidative coenzymes are discussed in Chapter 15.

A. ATP and the Nucleotide "Handles"

The role of ATP in "driving" biosynthetic reactions has been considered in Chapter 12, where attention was focused on the polyphosphate group which undergoes cleavage. What about the adenosine end? Here is a shapely structure borrowed from the nucleic acids. What is it doing as a carrier of phospho groups? At least part of the answer seems to be that the adenosine monophosphate (AMP) portion of the molecule is a "handle" which can be "grasped" by catalytic proteins. For some enzymes, such as acetyl-CoA synthetase (Eq. 12-45), the handle is important because the intermediate acyl adenylate must remain bound to the protein. Without the large adenosine group, there would be little for the protein to hold onto.



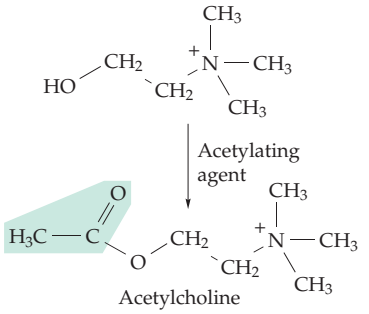
The AMP "handle" in ATP

AMP is only one of several handles to which nature attaches phospho groups to form di- and triphosphate derivatives. Like AMP, the other handles are nucleotides, the monomer units of nucleic acids. Thus, one enzyme requiring a polyphosphate as an energy source selects ATP, another CTP, or GTP. The nucleotide handles not only carry polyphosphate groups but also are present in other coenzymes, such as CoA, NAD^+, $NADP^+$, and FAD. In addition, they serve as carriers for small organic molecules. For example, **uridine diphosphate glucose** (UDP-Glc) Chapter 10, is a carrier of active glucosyl groups important in sugar metabolism and **cytidine diphosphate choline** is an intermediate in synthesis of phospholipids.

Recalling that acetyl adenylate (acetyl-AMP) is an intermediate in synthesis of acetyl-CoA, and comparing the biosynthesis of sugars, phospholipids, and acetyl-CoA, we see that in each case the enzyme involved requires a different nucleotide handle. The handle may provide a means of recognition which can help an enzyme to pick the right bit of raw material out of the sea of molecules surrounding it. Figure 5-6 shows the shapes of the four purine and pyrimidine bases forming the most common nucleotide handles. The distinctive differences both in shape and in hydrogen bond patterns are obvious. In binding to proteins, the hydrogen bond-forming groups in the purine and pyrimidine bases sometimes interact with precisely positioned groups in the protein. However, in some enzymes the "handle" is not precisely bound. This seems to be the case for adenine, which makes surprisingly few hydrogen bonds to proteins.[1] Hydroxyl groups of the ribose or deoxyribose ring also often form hydrogen bonds and the negatively charged oxygen atoms of the 5'-phosphate may interact with positively charged protein side chains.

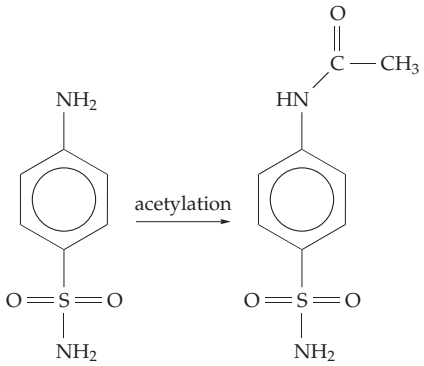
B. Coenzyme A and Phosphopantetheine

The existence of a special coenzyme required in biological acetylation was recognized by Fritz Lipmann in 1945.[2–3a] The joining of acetyl groups to other molecules is a commonplace reaction within living cells, one example being the formation of the neurotransmitter **acetylcholine**. In the laboratory acetylation is carried out with reactive compounds such as acetic anhydride or acetyl chloride.



Acetylcholine (14-1)

Lipmann wondered what nature used in their place. His approach in seeking the biological "active acetate" is one that has been used successfully in solving many biochemical problems. He first set up a test system to examine the ability of extracts prepared from fresh liver tissue to catalyze the acetylation of sulfanilamide (Eq. 14-2). A specific color test was available for quantitative determination of very small amounts of the



Sulfanilamide (14-2)

product. The rate of acetylation of sulfanilamide under standard conditions was taken as a measure of the activity of the biochemical acetylation system. Lipmann soon discovered that the reaction required ATP and that the ATP was cleaved to ADP concurrently with the formation of acetyl-sulfanilamide. He also found that dialysis or ultrafiltration rendered the liver extract almost inactive in acetylation. Apparently some essential material passed out through the semipermeable dialysis membrane. When the dialysate or ultrafiltrate was concentrated and added back, acetylation activity was restored. The unknown material was not destroyed by boiling, and Lipmann postulated that it was a new coenzyme which he called **coenzyme A** (CoA). Now the test system was used to estimate the amount of the

BOX 14-A DISCOVERY OF THE VITAMINS

Several mysterious and often fatal diseases which resulted from vitamin deficiencies were prevalent until the past century. Sailors on long sea voyages were often the victims. In the Orient, the disease **beriberi** was rampant and millions died of its strange paralysis called "polyneuritis." In 1840, George Budd predicted that the disease was caused by the lack of some organic compound that would be discovered in "a not too distant future."[a] In 1893, C. Eijkman, a Dutch physician working in Indonesia, observed paralysis in chicks fed white rice consumed by the local populace. He found that the paralysis could be relieved promptly by feeding an extract of rice polishings. This was one of the pieces of evidence that led the Polish biochemist Casimir Funk to formulate the "vitamine theory" in about 1912. Funk suggested that the diseases **beriberi**, **pellagra**, **rickets**, and **scurvy** resulted from lack in the diet of four different vital nutrients. He imagined them all to be amines, hence the name **vitamine**.

In the same year in England, F. G. Hopkins announced that he had fed rats on purified diets and discovered that amazingly small amounts of **accessory growth factors**, which could be obtained from milk, were necessary for normal growth.[b] By 1915, E. V. McCollum and M. Davis at the University of Wisconsin had recognized that rat growth depended on not one but at least two accessory factors. The first, soluble in fatty solvents, they called **A**, and the other, soluble in water, they designated **B**. Factor B cured beriberi in chicks. Later, when it was shown that vitamine A was not an amine, the "e" was dropped and **vitamin** became a general term.

Progress in isolation of the vitamins was slow, principally because of a lack of interest. According to R. R. Williams, when he started his work on isolation of the antiberiberi factor in 1910 most people were convinced that his efforts were doomed to failure, so ingrained was Pasteur's idea that diseases were caused only by bacteria. In 1926, Jansen isolated a small amount of thiamin, but it was not until 1933 that Williams, working almost without financial support, succeeded in preparing a large amount of the crystalline compound from rice polishings. Characterization and synthesis followed rapidly.[c,d]

It was soon apparent that the new vitamin alone would not satisfy the dietary need of rats for the B factor. A second thermostable factor (B_2) was required in addition to thiamin (B_1), which was labile and easily destroyed by heating. When it became clear that factor B_2 contained more than one component, it was called **vitamin B complex**. There was some confusion until relatively specific animal tests for each one of the members had been devised. **Riboflavin** was found to be most responsible for the stimulation of rat growth, while **vitamin B_6** was needed to prevent a facial dermatitis or "rat pellagra." **Pantothenic acid** was especially effective in curing a chick dermatitis, while **nicotinamide** was required to cure human pellagra. **Biotin** was required for growth of yeast.

The antiscurvy (antiscorbutic) activity was called **vitamin C**, and when its structure became known it was called **ascorbic acid**. The fat-soluble factor preventing rickets was designated **vitamin D**. By 1922, it was recognized that another fat-soluble factor, **vitamin E**, is essential for full-term pregnancy in the rat. In the early 1930s **vitamin K** and the **essential fatty acids** were added to the list of fat-soluble vitamins. Study of the human blood disorders "tropical macrocytic anemia" and "pernicious anemia" led to recognition of two more water-soluble vitamins, **folic acid** and **vitamin B_{12}**. The latter is required in minute amounts and was not isolated until 1948. Have all the vitamins been discovered? Rats can be reared on an almost completely synthetic diet. However, there is the possibility that for good health humans require some as yet undiscovered compounds in our diet. Furthermore, it is quite likely that we receive some essential nutrients that we cannot synthesize from bacteria in our intestinal tracts. An example may be the pyrroloquinoline quinone (PQQ).[e]

Why do we need vitamins? Early clues came in 1935 when nicotinamide was found in NAD^+ by H. von Euler and associates and in $NADP^+$ by Warburg and Christian. Two years later, K. Lohman and P. Schuster isolated pure **cocarboxylase**, a dialyzable material required for decarboxylation of pyruvate by an enzyme from yeast. It was shown to be thiamin diphosphate (Fig. 15-3). Most of the water-soluble vitamins are converted into coenzymes or are covalently bound into active sites of enzymes. Some lipid-soluble vitamins have similar functions but others, such as vitamin D and some metabolites of vitamin A, act more like hormones, binding to receptors that control gene expression or other aspects of metabolism.

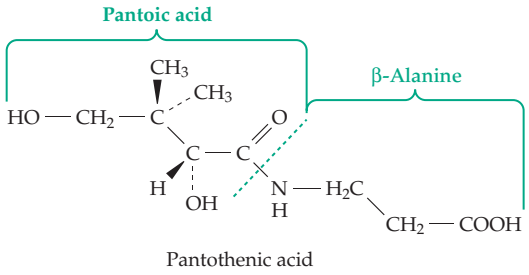
coenzyme in a given volume of dialysate or in any other sample. When small amounts of CoA were supplied to the test system, only partial restoration of the acetylation activity was observed and the amount of restoration was proportional to the amount of CoA. With test system in hand to monitor various fractionation methods, Lipmann soon isolated the new coenzyme in pure form from yeast and liver.

Coenzyme A (Fig. 14-1) is a surprisingly complex molecule. The handle is AMP with an extra phospho group on its 3'-hydroxyl. The phosphate of the 5'-carbon is linked in anhydride (pyrophosphate) linkage to another phosphoric acid, which is in turn esterified with **pantoic acid**. Pantoic acid is linked to **β-alanine** and the latter to **β-mercaptoethylamine** through amide linkages, the reactive SH group being attached to a long (1.9-nm) semi-flexible chain. Coenzyme A can be cleaved by hydrolysis to **pantetheine** (Fig. 14-1), **pantetheine 4'-phosphate**, and **pantothenic acid**. These three compounds are all **growth factors**.

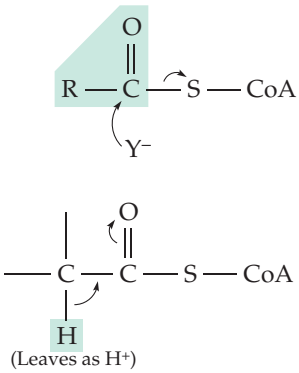
Pantothenic acid is a vitamin, which is essential to human life. Its name is derived from a Greek root that reflects its universal occurrence in living things. The bacterium *Lactobacillus bulgaricus*, which converts milk



to yogurt, needs the more complex pantetheine for growth. It finds a ready supply of pantetheine in milk and has lost its ability to synthesize this compound. However, it can convert pantetheine to CoA. Pantetheine 4'-phosphate is required for growth of *Acetobacter suboxydans*. While it is not a dietary essential for most organisms, it is found in a covalently bound form in several enzymes.

While CoA was discovered as the "acetylation coenzyme," it has a far more general function. It is required, in the form of acetyl-CoA, to catalyze the synthesis of citrate in the citric acid cycle. It is essential to the β oxidation of fatty acids and carries propionyl and other acyl groups in a great variety of other metabolic reactions. About 4% of all known enzymes require CoA or one of its esters as a substrate.[4]

Coenzyme A has two distinctly different biochemical functions, which have already been considered briefly in Chapters 12 and 13 and can be summarized as follows:



These functions depend, to a considerable extent, on the fact that the properties of the carbonyl group of a thioester are closely similar to those of an isolated carbonyl group in a ketone.[5]

Synthesis of fatty acids in bacteria requires a small **acyl carrier protein (ACP)** whose functions are similar to those of CoA. However, it contains pante-

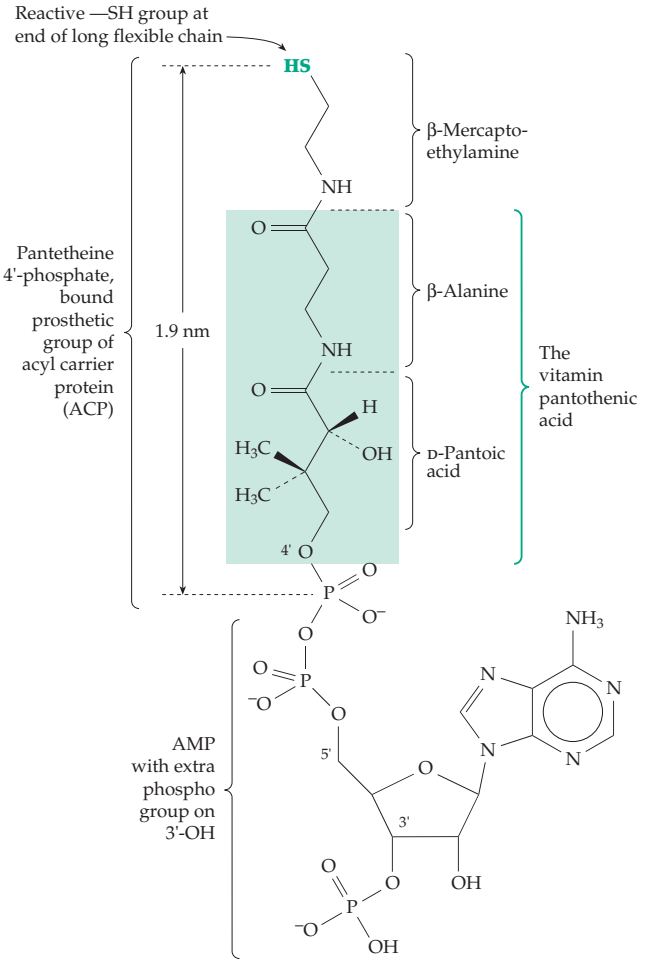


Figure 14-1 Coenzyme A, an acyl-activating coenzyme containing the vitamin pantothenic acid.

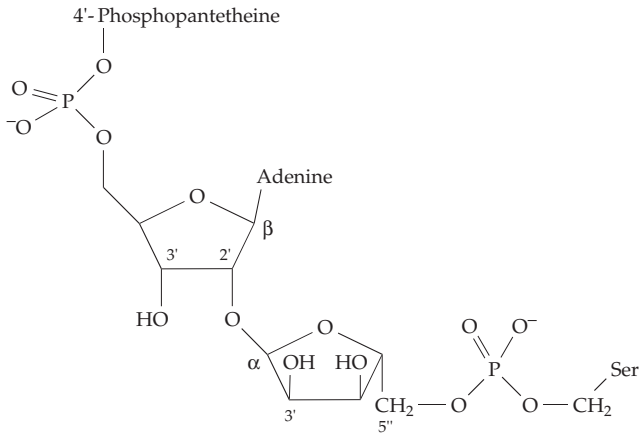
theine 4'-phosphate covalently bonded through phosphodiester linkage to a serine side chain. In *E. coli* this is at position 36 in the 77-residue protein.[6,7] Here the nucleotide handle of CoA has been replaced with a larger and more complex protein which can interact in specific ways with the multiprotein fatty acid synthase complex described in Chapter 21. In higher organisms ACP is usually not a separate protein but a domain in a large synthase molecule. Bound phosphopantetheine is also found in enzymes involved in synthesis of peptide antibiotics (Chapter 29)[8,9] and polyketides (Chapter 21).[10,11] It is also present in subunits of cytochrome oxidase and of ATP synthase of *Neurospora* but appears to play only a structural role, being needed for proper assembly of these multimeric proteins.[12] In a citrate-cleaving enzyme, and in a bacterial malonate decarboxylase, phosphopantethine is attached to a serine side chain as 2′-(5″-phosphoribosyl)-3′-dephospho-CoA.[13–14a]

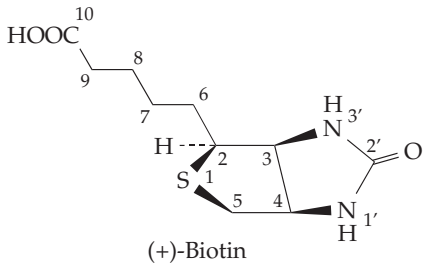


Attachment of phosphopantetheine to proteins is catalyzed by a phosphotransferase that utilizes CoA as the donor. A phosphodiesterase removes the phosphopantetheine, providing a turnover cycle.[15–15b] A variety of synthetic analogs have been made.[4,16] The reactive center of CoA and phosphopantetheine is the SH group, which is carried on a flexible arm that consists in part of the β-alanine portion of pantothenic acid. A mystery is why pantoic acid, a small odd-shaped molecule that the human body cannot make, is so essential for life. The hydroxyl group is a potential reactive site and the two methyl groups may enter into formation of a "trialkyl lock" (p. 485), part of a sophisticated "elbow" or shoulder for the SH-bearing arm.

When it binds to citrate synthase acetyl-CoA appears to bind only after the enzyme has undergone a conformational change that closes the enzyme around its other substrate oxaloacetate (Fig. 13-8). The adenine ring of the long CoA handle is tightly bonded to the protein through hydrophobic interactions and hydrogen-bond recognition interactions. Additional specific hydrophobic interactions allow the enzyme to hold the acetyl group in a precise position where it can be acted upon by the catalytic groups. In the case of CoA transferase (Eq. 12-50) smaller thiols can replace CoA but with much lower catalytic rates. The acyl-CoA derivatives are weakly bound, the expected intrinsic binding energy of the pantetheine portion of the molecule apparently being used to increase k_{cat}.[17] From a study of kinetics and equilibria it was concluded that the binding energy of the interaction of the nucleotide portion of coenzyme A with the enzyme is utilized to increase the rate of formation and to stabilize the covalently linked E-CoA (see Eq. 12-50). On the other hand, binding of the pantoic acid part of the molecule decreases the stability of the transition state for breakup of the complex by ~40 kJ/mol, which corresponds to a 10^7-fold increase in the reaction rate.[16]

C. Biotin and the Formation of Carboxyl Groups from Bicarbonate

By 1901 it was recognized that yeast required for its growth an unknown material which was called **bios**. This was eventually found to be a mixture of pantothenic acid, inositol, and a third component which was named **biotin**. Biotin was also recognized as a factor promoting growth and respiration of the clover root nodule organism *Rhizobium trifolii* and as vitamin H, a material that prevented dermatitis and paralysis in rats that were fed large amounts of uncooked egg white. Isolation of the pure vitamin was a heroic task accomplished by Kögl in 1935. In one preparation 250 kg of dried egg yolk yielded only 1.1 mg of crystalline biotin.[18]

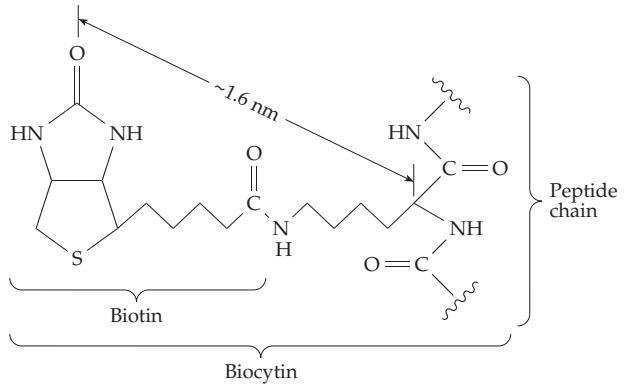


Biotin contains three chiral centers and therefore has eight stereoisomers.[18,19] Of these, only one, the dextrorotatory (+)-biotin, is biologically active.[19,20] The vitamin is readily oxidized to the sulfoxide and sulfone. The sulfoxide can be reduced back to biotin by a molybdenum-containing reductase in some bacteria (see also Chapter 16, Section H).[20a] Biotin is synthesized from pimeloyl-CoA (see chapter banner, p. 719 and Eq. 24-39). Four enzymes are required. Two of them, a

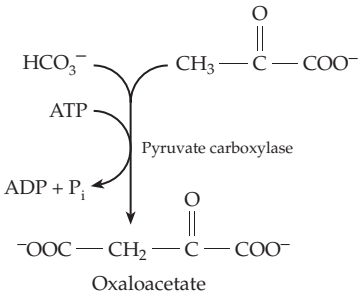
synthase that catalyzes step *a* (banner) and a transaminase that catalyzes step *b*, contain the coenzyme pyridoxal phosphate (PLP).[20b] The final step is insertion of a sulfur atom from an iron-sulfur center.

1. Biotin-Containing Enzymes

Within cells the biotin is covalently bonded to proteins, its double ring being attached to a 1.6-nm flexible arm. The first clue to this fact was obtained from isolation of a biotin-containing material **biocytin**, ε-N-biotinyl-L-lysine, from autolysates (self-digests) of rapidly growing yeast.[21] It was subsequently shown that the lysine residue of the biocytin was originally present in proteins at the active sites of biotin-containing enzymes usually within the sequence AMKM[22] or VMKM.[23] Other conserved features also mark the attachment site.[24]

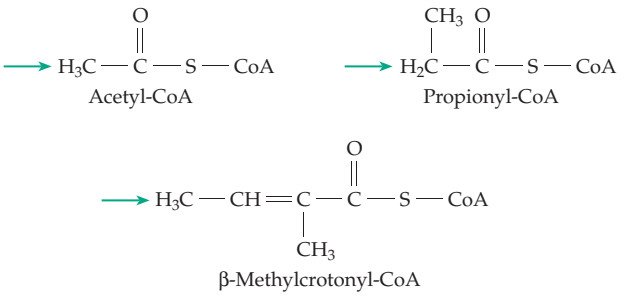


Biotin acts as a **carboxyl group carrier** in a series of carboxylation reactions, a function originally suggested by the fact that aspartate partially replaces biotin in promoting the growth of the yeast *Torula cremonis*. Aspartate was known to arise by transamination from oxaloacetate, which in turn could be formed by carboxylation of pyruvate. Subsequent studies showed that biotin was needed for an enzymatic ATP-dependent reaction of pyruvate with bicarbonate ion to form oxaloacetate (Eq. 14-3). This is a β carboxylation coupled to the hydrolysis of ATP.



(14-3)

In addition to pyruvate carboxylase, other biotin-requiring enzymes act on **acetyl-CoA**, **propionyl-CoA**, and **β-methylcrotonyl-CoA**, using HCO_3^- to add carboxyl groups at the sites indicated by the arrows in the accompanying structures. Because of the presence of the C=C double bond conjugated with the carbonyl group, the carboxylation of β-methylcrotonyl-CoA is electronically analogous to β carboxylation.



Human cells, as well as those of other higher eukaryotes, carry genes for all four of these enzymes.[25–29] Acetyl-CoA carboxylase is a cytosolic enzyme needed for synthesis of fatty acids but the other three enzymes enter mitochondria when they function. The biotin-dependent carboxylases, which are listed in Table 14-1, have a variety of molecular sizes and subunits but show much evolutionary conservation in their sequences and chemical mechanisms.[22,25] In higher eukaryotes all of the catalytic apparatus of the enzymes is present in single large 190- to 200-kDa subunits. The 251-kDa subunit of yeast acetyl-CoA carboxylase consists of 2337 amino acid residues.[30] That of rats contains 2345[31] and that of the alga *Cyclotella* 2089.[32] Human cytosolic acetyl-Co carboxylase has 2347 residues while a mitochondria-associated form has an extra 136 residues, most of them in a hydrophobic N-terminal extension.[32a,b] Plants have two forms of the enzyme, one cytosolic and one located in plastids. In wheat, they have 2260 and 2311 residues, respectively.[32c,32d] Animal and fungal pyruvate carboxylases are also large ~500-kDa tetramers.[32e] The yeast enzyme consists of 1178-residue monomers.[33] In contrast, the 560-kDa human propionyl-CoA carboxylase is an $\alpha_4\beta_4$ tetramer.[34,35]

In bacteria and in at least some plant chloroplasts,[36,37] acetyl-CoA carboxylase consists of three different kinds of subunit and four different peptide chains. The much studied *E. coli* enzyme is composed of a 156-residue **biotin carboxyl carrier protein**,[38] a 449-residue **biotin carboxylase**, whose three-dimensional structure in known,[39,39a] and a **carboxyltransferase** subunit consisting of 304 (α)- and 319 (β)- residue chains. These all associate as a dimer of the three subunits (eight peptide chains).[40–42]

Biotin becomes attached to the proper ε-amino groups at the active centers of biotin enzymes by the action of **biotin holoenzyme synthetase** (biotinyl

protein ligase), which utilizes ATP to form an intermediate biotinyl-AMP.[43–47a] Hereditary deficiency of this enzyme has been observed in a few children and has been treated by administration of extra biotin.[48] The *E. coli* biotin holoenzyme synthetase, whose three-dimensional structure is known, has a dual function. It is also a repressor of transcription of the biotin biosynthetic operon.[45] Intracellular degradation of biotin-containing proteins yields biotin-containing oligopeptides as well as biocytin. These are acted on by **biotinidase** to release free biotin.[49,50] The action of this enzyme in recycling biotin may be a controlling factor in the rate of formation of new biotin-dependent enzymes.

2. The Mechanism of Biotin Action

It may seem surprising that a coenzyme is needed for these carboxylation reactions. However, unless the cleavage of ATP were coupled to the reactions, the equilibria would lie far in the direction of decarboxylation. For example, the measured apparent equilibrium constant K' for conversion of propionyl-CoA to *S* methylmalonyl-CoA at pH 8.1 and 28°C[51] is given by Eq. 14-4.

$$K' = \frac{[\text{ADP}][\text{P}_i][\text{methylmalonyl–CoA}]}{[\text{ATP}][\text{HCO}_3^-][\text{propionyl–CoA}]} = 5.7$$

$$\Delta G' = -4.36 \text{ kJ mol}^{-1} \qquad (14\text{-}4)$$

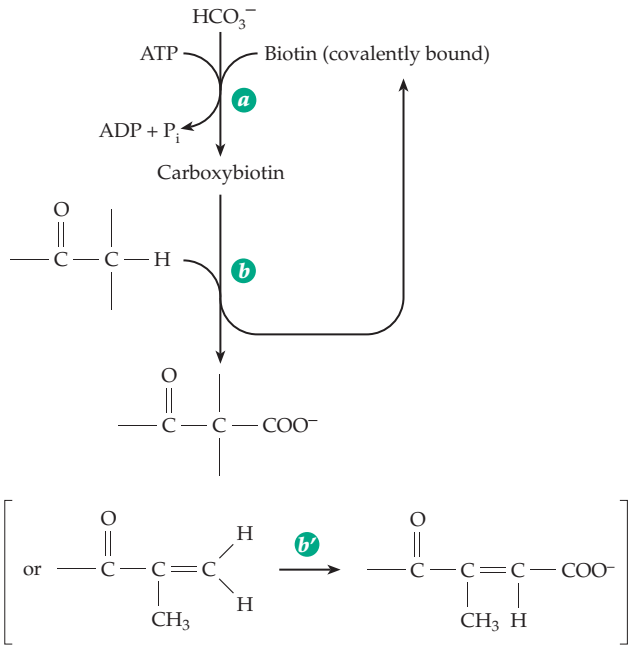
4. Other

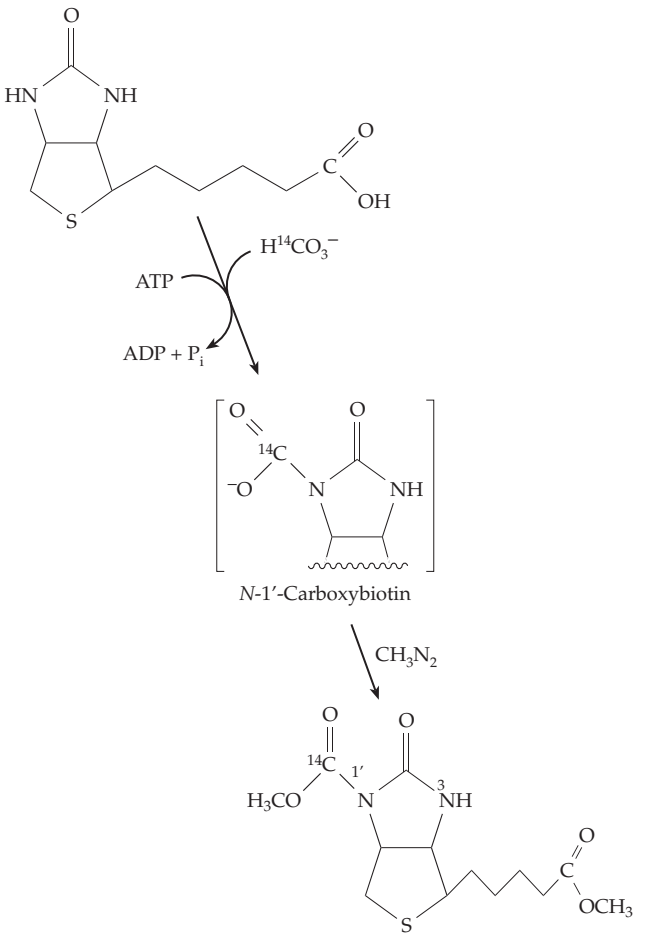
   Malonate decarboxylase
   Urea carboxylase

The function of biotin is to mediate the coupling of ATP cleavage to the carboxylation, making the overall reaction exergonic. This is accomplished by a two-stage process in which a **carboxybiotin** intermediate is formed (Eq. 14-5). There is *one known biotin-containing enzyme that does not utilize ATP*. Propionic acid bacteria contain a **carboxyltransferase** which transfers a carboxyl group reversibly from methylmalonyl-CoA to pyruvate to form oxaloacetate and propionyl-CoA (see Fig. 17-10). This huge enzyme consists of a central hexameric core of large 12S subunits to which six 5S dimeric subunits and twelve 123-residue biotinylated peptides are attached.[25,52] No ATP is needed because free HCO_3^- is not a substrate. However, biotin serves as the carboxyl group carrier in this enzyme too.



(14-5)

Carboxybiotin. The structure of biotin suggested that bicarbonate might be incorporated reversibly into its position 2'. However, this proved not to be true and it remained for F. Lynen and associates to obtain a clue from a "model reaction." They showed that purified β-methylcrotonyl-CoA carboxylase promoted the carboxylation of *free* biotin with bicarbonate ($H^{14}CO_3^-$) and ATP. While the carboxylated biotin was labile, treatment with diazomethane (Eq. 14-6) gave a stable dimethyl ester of ***N*-1'-carboxybiotin**.[53,54] The covalently bound biotin at active sites of enzymes was also successfully labeled with $^{14}CO_2$. Treatment of the labeled enzymes with diazomethane followed by hydrolysis with trypsin and pepsin gave authentic *N*-1'-carboxybiocytin. It was now clear that the cleavage of ATP is required to couple the CO_2 from HCO_3^- to the biotin to form carboxybiotin. The enzyme must

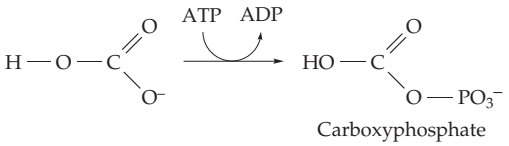


(14-6)

then transfer the carboxyl group from carboxybiotin to the substrate that is to be carboxylated. Enzymatic transfer of a carboxyl group from chemically synthesized carboxybiotin onto specific substrates confirmed the proposed mechanism.[55]

The biotin carboxyl carrier subunit of *E. coli* acetyl-CoA carboxylase contains the covalently bound biotin.[55a,b] The larger biotin carboxylase subunit catalyzes the ATP-dependent attachment of CO_2 to the biotin and the carboxyltransferase subunit catalyzes the final transcarboxylation step (Eq. 14-5, step *b*) by which acetyl-CoA is converted into malonyl-CoA. The biotin, which is attached to the carrier protein, is presumably able to move by means of its flexible arm from a site on the carboxylase to a site on the transcarboxylase.

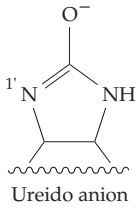
Carboxyphosphate. During the initial carboxylation step ^{18}O from labeled bicarbonate enters the P_i that is split from ATP. This suggested transient formation of **carboxyphosphate** by nucleophilic attack of HCO_3^- on ATP (Eq. 14-7). The carboxyl group of this reactive mixed anhydride[56] could then be transferred to biotin. This mechanism is supported by the fact that biotin carboxylase catalyzes the transfer of a



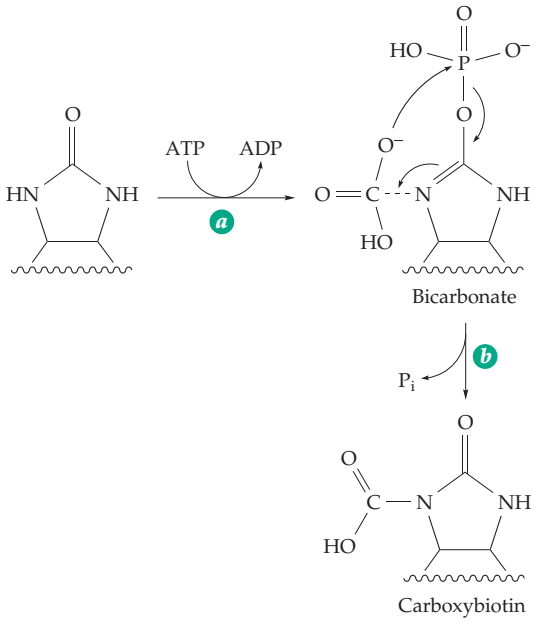
(14-7)

phospho group to ADP from carbamoyl phosphate, an analog of carboxyphosphate in a reaction that is analogous to the reverse of that in Eq. 14-7 and also by a slow bicarbonate-dependent ATPase activity that does not depend upon biotin.[57,58,58a]

The simplest mechanism for transfer of the carboxyl group of carboxyphosphate to biotin would appear to be nucleophilic displacement of the phosphate leaving group by N1' of biotin. The enzyme could presumably first catalyze removal of the N1' hydrogen to form a ureido anion.[59] Another reasonable possibility would be for the terminal phospho group of ATP to be transferred to biotin to form an *O*-phosphate[60,61]

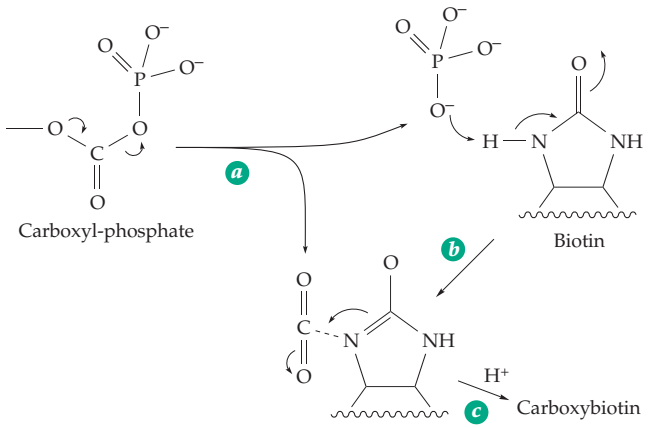


(Eq. 14-8, step *a*) which could react with bicarbonate as in Eq. 14-8, step *b*. Cleavage of the enol phosphate by attack of HCO_3^- would simultaneously create a nucleophilic center at N1' and carboxyphosphate ready to react with N1'. However, this could not easily explain the ATPase activity in the absence of biotin.



(14-8)

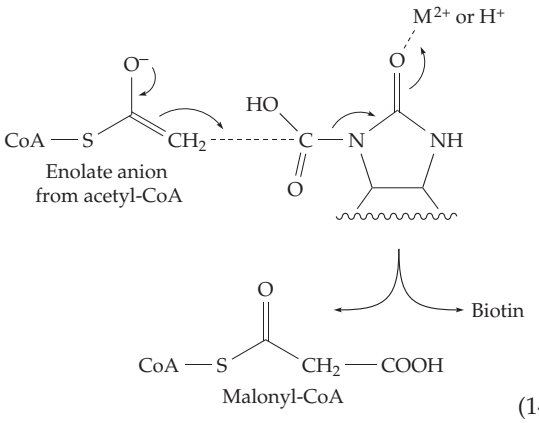
Either of the foregoing mechanisms requires that the ureido anion of biotin attack the rather unreactive carbon atom of carboxyphosphate. Another alternative, which is analogous to that suggested for PEP carboxylase (Eq. 13-53) is for carboxyphosphate to eliminate inorganic phosphate to give the more electrophilic CO_2 (Eq. 14-9, step *a*). The very basic inorganic phosphate trianion PO_4^{3-} that is eliminated could remove the proton from N1' of biotin to create the biotin ureido anion (step *b*), which could then add to CO_2 (step *c*).[22]



(14-9)

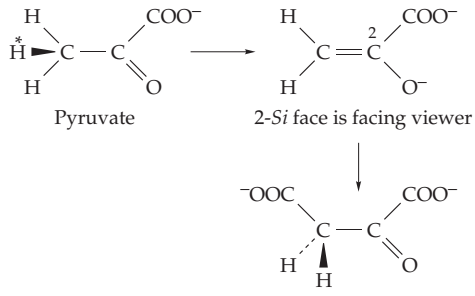
Have we checked all of the possibilities for the mechanism of biotin carboxylation? Kruger and associates[62,63] suggested that biotin, as a ureido anion, might add to bicarbonate to form a highly unstable intermediate which, however, could be phosphorylated by ATP (Eq. 14-10, steps *a* and *b*). This intermediate could undergo elimination of inorganic phosphate (step *c*), driving the reaction to completion. The observed transfer of isotope from ^{18}O-containing bicarbonate into ADP would be observed.

The β carboxylation step. Once formed, the carboxybiotin "head group" could swing to the carboxyltransferase site where transfer of the carboxyl group into the final product takes place. This might occur either by nucleophilic attack of an enolate anion on the carbonyl carbon (Eq. 14-11) or on CO_2 generated by reversal of the reactions of Eq. 14-9, steps *b* and *c*.

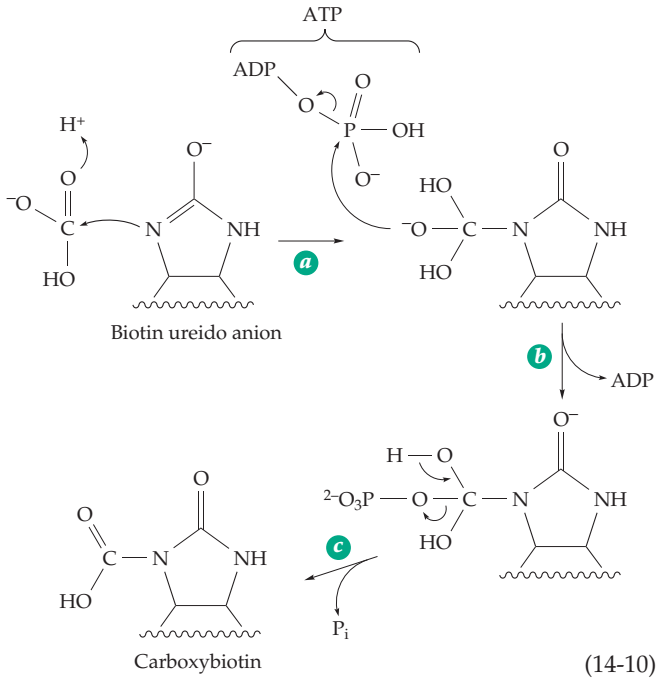


(14-11)

When pyruvate with a chiral methyl group is carboxylated by pyruvate carboxylase the configuration at C-3 is retained. The carboxyl enters from the 2-*si* side, the same side from which the proton (marked H*) was removed to form the enolate anion (Eq. 14-12). Comparable stereochemistry has been established for other biotin-dependent enzymes.[64,65]



(14-12)



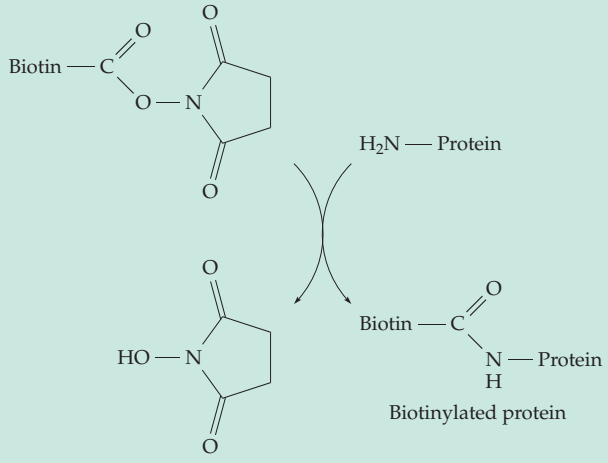
(14-10)

These enzymes do not catalyze any proton exchange at C-3 of pyruvate or at C-2 of an acyl-CoA unless the biotin is first carboxylated. This suggested that removal of the proton to the biotin oxygen and carboxylation might be synchronous. However, ^{13}C and ^{2}H kinetic isotope effects and studies of ^{3}H exchange[66] support the existence of a discrete enolate anion intermediate as shown in Eq. 14-11.[65,67] This mechanism is also consistent with the observation that propionyl-CoA

BOX 14-B THE BIOTIN-BINDING PROTEINS AVIDIN AND STREPTAVIDIN

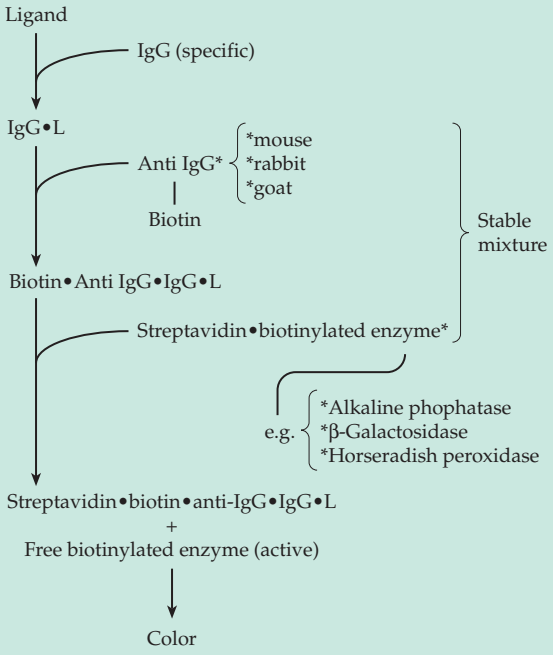
A biochemical curiosity is the presence in egg white of the glycoprotein **avidin**.[a,b] Each 68-kDa subunit of this tetrameric protein binds one molecule of biotin tenaciously with $K_f \sim 10^{15}\ M^{-1}$. Nature's purpose in placing this unusual protein in egg white is uncertain. Perhaps it is a storage form of biotin, but it is more likely an antibiotic that depletes the environment of biotin. A closely similar protein **streptavidin** is secreted into the culture medium by *Streptomyces avidinii*.[c] Its sequence is homologous to that of avidin. It has a similar binding constant for biotin and the two proteins have similar three-dimensional structures.[a,d–j] Biotin binds at one end of a β barrel formed from antiparallel strands and is held by multiple hydrogen bonds and a conformational alteration that allows a peptide loop to close over the bound vitamin.

Historically, avidin was important to the discovery of biotin. The bonding between avidin and biotin is so tight that inclusion of raw egg white in the diet of animals is sufficient to cause a severe biotin deficiency. Avidin has also been an important tool to enzymologists interested in biotin-containing enzymes. Avidin invariably inhibits these enzymes and inhibition by avidin is diagnostic of a biotin-containing protein. Recently, avidin and streptavidin have found widespread application in affinity chromatography, in immunoassays, and in the staining of cells and tissues.[d,k–p] These uses are all based on the ability to attach biotin covalently to side chain groups of proteins, polysaccharides, and other substances. The carboxyl group of the biotin "arm," which lies at the surface of the complex with avidin or streptovidin, can be converted to any of a series of reactive derivatives. For example, *p*-nitrophenyl or *N*-hydroxysuccinimide esters of biotin can be used to attach biotin to amino groups of proteins to form biotinylated proteins.



Other reactive derivatives can be used to attach biotin to phenolic, thiol, or carbonyl groups.

The affinity of avidin or streptavidin for the resulting biotinylated materials is still very high. This fact has permitted the application of this "biotin–avidin technology" to numerous aspects of research and diagnostic medicine. For example, a specific antibody (IgG) can be utilized for immunoassay of a hormone or other ligand. A second antibody, specific for the IgG–ligand complex, can be produced in a biotinylated form. A steptavidin complex of a biotinylated enzyme such as alkaline phosphatase, β-galactosidase, or horseradish peroxidase, for which a sensitive colorimetric assay is available, is allowed to react with the biotin•anti-IgG•IgG•ligand complex. The streptavidin now releases enzyme in proportion to the amount of ligand originally present. Since the biotinylated anti IgG and streptavidin•biotinylated enzyme can be stored as a stable mixture, the assay is simple and fast.



Avidin technology can also be applied to the isolation of proteins and other materials from cells. Because the irreversibility of the binding of biotin may be a problem, photocleavable biotin derivatives have been developed.[q] In the following structure, the biotin derivative has been joined to a protein (as in the first equation in this box) and is ready for separation, perhaps on a column containing immobilized avidin or streptavidin. After separation the biotin together with the linker and photocleavable group are cut off by a short irradiation with ultra-

BOX 14-B (continued)

violet light, leaving the protein in a free form.

carboxylase and transcarboxylase both catalyze elimination of HF from β-fluoropropionyl-CoA to form the unsaturated acrylyl-CoA.[67] The elimination presumably occurs via an enolate anion intermediate as in Eq. 13-28.

A bound divalent metal ion, usually Mn^{2+}, is required in the transcarboxylation step. A possible function is to assist in enolization of the carboxyl acceptor. However, measurement of the effect of the bound Mn^{2+} on ^{13}C relaxation times in the substrate for pyruvate carboxylase indicated a distance of ~0.7 nm between the carbonyl carbon and the Mn^{2+}, too great for direct coordination of the metal to the carbonyl oxygen.[68] Another possibility is that the metal binds to the carbonyl of biotin as indicated in Eq. 14-11. Pyruvate carboxylase utilizes two divalent metal ions and at least one monovalent cation.[68a]

What is the role of the sulfur atom in biotin? Perhaps it interacts with CO_2, helping to hold it in a correct orientation for reaction. Perhaps it helps to keep the ureido ring of biotin planar, or perhaps it has no special function.[69]

3. Control Mechanisms

Most pyruvate carboxylases of animal and of yeast are allosterically activated by acetyl-CoA, but those of bacteria are usually not. The enzyme from chicken liver has almost no activity in the absence of acetyl-CoA, which appears to increase greatly the rate of formation of carboxyphosphate and to slow the side reaction by which carboxyphosphate is hydrolyzed to bicarbonate and phosphate.[70] The acetyl-CoA carboxylases of rat or chicken liver aggregate in the presence of citrate to form ~8000-kDa rods. Citrate is an allosteric activator for this enzyme but it acts only on a phosphorylated form and the primary control mechanism.[71,72] This enzyme in plants is a target for a group of herbicides that are selectively toxic to grasses.[73]

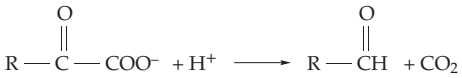
4. Pumping Ions with the Help of Biotin

Biotin-dependent **decarboxylases** act as sodium ion pumps in *Klebsiella*[74] and in various anaerobes.[22,75] For example, oxaloacetate is converted to pyruvate and bound carboxybiotin.[74,74a] The latter is decarboxylated

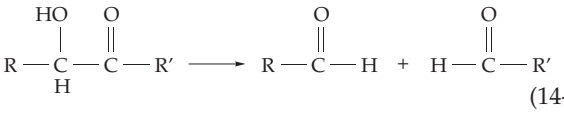
to CO_2 at the same time that two Na^+ ions are transported from the inside to the outside of the cell. The function of this pump, like that of the Na^+, K^+-ATPase (Fig. 8-25) is to provide an electrochemical gradient that drives the transport of other ions and molecules through the membrane. Similar ion pumps are operated by decarboxylation of methylmalonyl-CoA[76] and glutaconyl-CoA.[77] Yeast (*Saccharomyces cerevisiae*) cannot make biotin and requires an unusually large amount of the vitamin when urea, allantoin, allantoic acid, and certain other compounds are supplied as the sole source of nitrogen for growth. The reason is that in this organism urea must first be carboxylated by the biotin-containing **urea carboxylase**[78] (see Eq. 24-25) before it can be hydrolyzed to NH_3 and CO_2.

D. Thiamin Diphosphate

In Chapter 13 we considered the breaking of a bond between two carbon atoms, one of which is also bonded to a carbonyl group. These β cleavages are catalyzed by simple acidic and basic groups of the protein side chains. On the other hand, the decarboxylation of 2-oxo acids (Eq. 14-13) and the cleavage and formation of α-hydroxyketones (Eq. 14-14) depend upon thiamin diphosphate (**TDP**).[79–85] These reactions represent a second important method of making and breaking carbon–carbon bonds which we will designate **α condensation and α cleavage**. The common feature of all thiamin-catalyzed reactions is that the bond broken (or formed) is *immediately adjacent to the carbonyl group*, not one carbon removed, as in β cleavage reactions. No simple acid–base catalyzed mechanisms can be written; hence the need for a coenzyme.



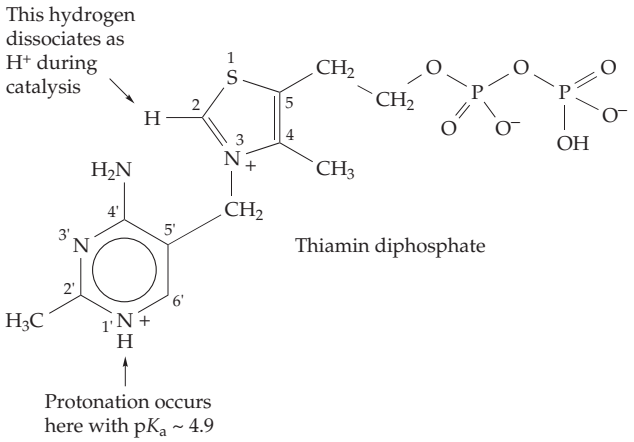
(14-13)



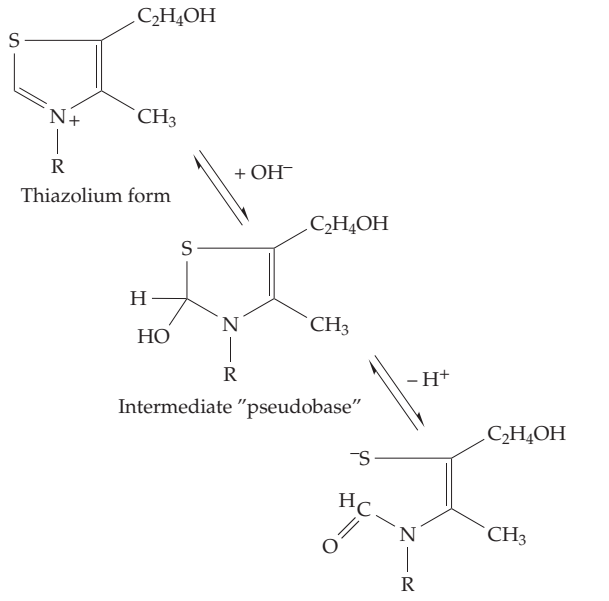
(14-14)

1. Chemical Properties of Thiamin

The weakly basic portion of thiamin or of its coenzyme forms is protonated at low pH, largely on N-1 of the pyrimidine ring.[86–88] The pK_a value is ~ 4.9. In basic solution, thiamin reacts in two steps with an opening of the thiazole ring (Eq. 14-15) to give the anion of a thiol form which may be crystallized as the sodium salt.[79,84] This reaction, like the competing reaction described in Eq. 7-19, and which leads to a yellow unstable form of the thiamin anion, is an example of a cooperative two-proton dissociation with linked structural changes. A very low concentration of the



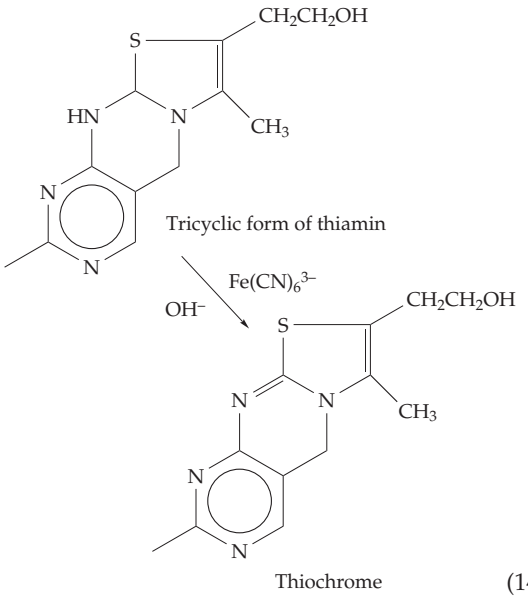
intermediate "pseudobase" is present during the titration. This property, which is unusual among small molecules, was instrumental in leading Williams *et al.* to the correct structure for the vitamin.[89] A still unanswered question is, What biological significance is associated with these reactions? Perhaps the thiol form depicted in Eq. 14-15 or the "yellow form" (Eq. 7-19) becomes attached to active sites of some proteins through disulfide linkages.



(14-15)

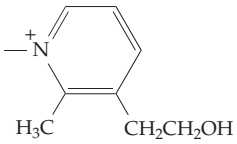
Thiamin is unstable at high pH[90,91] and is destroyed by the cooking of foods under mildly basic conditions. The thiol form undergoes hydrolysis and oxidation by air to a disulfide. The tricyclic form (Eq. 7-19) is oxidized to **thiochrome**, a fluorescent compound

whose formation from thiamin by treatment with alkaline hexacyanoferrate (III) (ferricyanide; Eq. 14-16) is the basis of a much used fluorimetric assay.



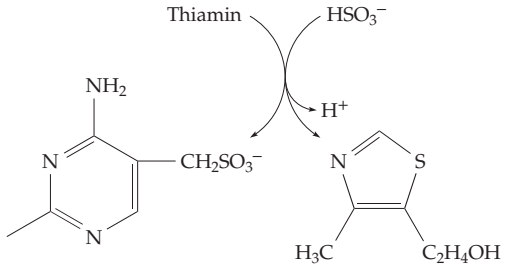
(14-16)

Treatment of thiamin with boiling 5N HCl deaminates it to the hydroxy analogue **oxythiamin**, a potent antagonist. **Pyrithiamin**, another competitor containing



in place of the thiazolium ring, is very toxic especially to the nervous system.

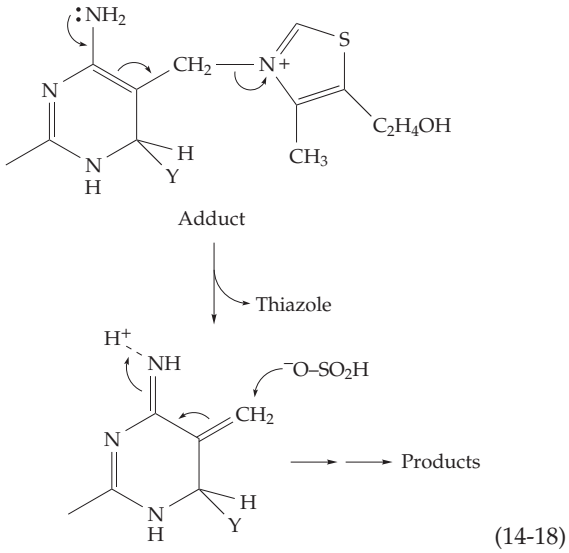
In a solution of sodium sulfite at pH 5, thiamin is cleaved by what appears to be a nucleophilic displacement reaction on the methylene group to give the free thiazole and a sulfonic acid.



(14-17)

In fact the mechanism of the reaction is more complex and is evidently initiated by addition of a nucleophile Y, such as $^{-}$OH or bisulfite, followed by elimination of the thiazole (Eq. 14-18).

A similar cleavage is catalyzed by thiamin-degrading enzymes known as thiaminases which are found in a number of bacteria, marine organisms, and plants. In a bacterial thiaminase, group Y of Eq. 14-18 is a cysteine –SH.[92,92a]

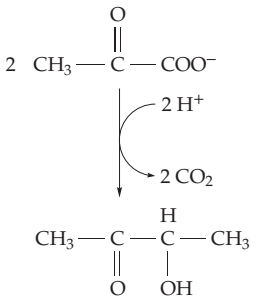


(14-18)

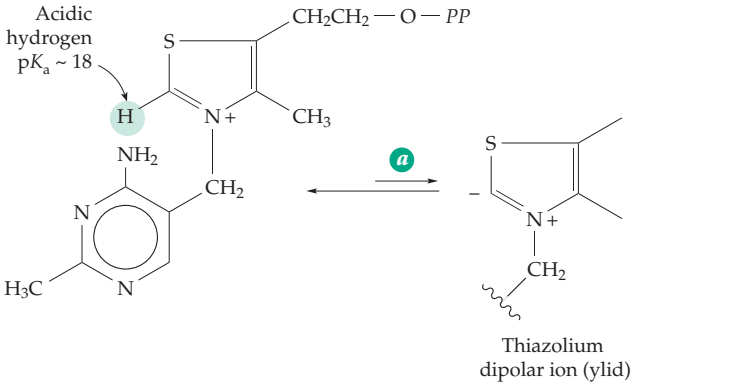
Thiamin is synthesized in bacteria, fungi, and plants from 1-deoxyxylulose 5-phosphate (Eq. 25-21), which is also an intermediate in the nonmevalonate pathway of polyprenyl synthesis. However, thiamin diphosphate is a coenzyme for synthesis of this intermediate (p. 736), suggesting that an alternative pathway must also exist. Each of the two rings of thiamin is formed separately as the esters 4-amino-5-hydroxymethylpyrimidine diphosphate and 4-methyl-5-(β-hydroxyethyl) thiazole monophosphate. These precursors are joined with displacement of pyrophosphate to form thiamin monophosphate.[92b] In eukaryotes this is hydrolyzed to thiamin, then converted to thiamin diphosphate by transfer of a diphospho group from ATP.[92b,c] In bacteria thiamin monophosphate is converted to the diphosphate by ATP and thiamin monophosphate kinase.[92b]

2. Catalytic Mechanisms

The first real clue to the mechanism of thiamin-dependent cleavage came in about 1950 when Mizuhara showed that at pH 8.4 thiamin catalyzes the nonenzymatic conversion of pyruvate into acetoin (Eq. 14-19).[93] Following Mizuhara's lead, Breslow investigated the same reaction using the then new NMR method.[94] He made the surprising discovery that the hydrogen atom in the 2 position of the thiazolium ring, between the sulfur and the nitrogen atoms, exchanged easily with deuterium of $^{2}H_2O$. The pK_a of this proton has been estimated as ~18, low enough to permit rapid

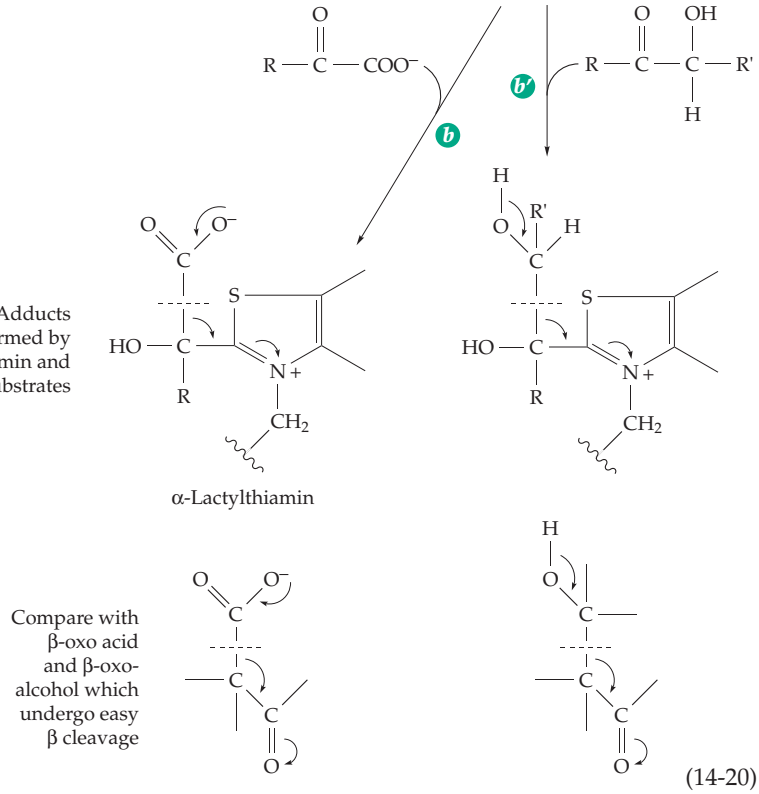


(14-19)



dissociation and replacement with ^2H.[84,95,96] The resulting **thiazolium dipolar ion** (or **ylid**) formed by this dissociation (Eq. 14-20, step *a*) is stabilized by the electrostatic interaction of the adjacent positive and negative charges. Breslow suggested that this dipolar ion is the key intermediate in reactions of thiamin-dependent enzymes.[94,97] The anionic center of the dipolar ion can react with a substrate such as an 2-oxo acid or 2-oxo alcohol by addition to the carbonyl group (Eq. 14-20, step *b* or 14-20, step *b'*). The resulting adducts are able to undergo cleavage readily, as indicated by the arrows showing the electron flow toward the =N$^+$– group.

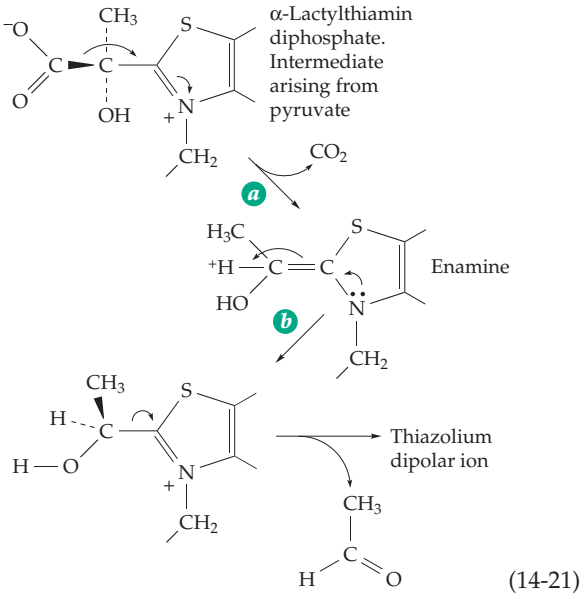
Below the structures of the adducts in Eq. 14-20 are those of a 2-oxo acid and a β-ketol with arrows indicating the electron flow in decarboxylation and in the aldol cleavage. The similarities to the thiamin-dependent cleavage reaction are especially striking if one remembers that in some aldolases and decarboxylases the substrate carbonyl group is first converted to an N-protonated Schiff base before the bond cleavage.



(14-20)

We see that *the essence of the action of thiamin diphosphate as a coenzyme is to convert the substrate into a form in which electron flow can occur from the bond to be broken into the structure of the coenzyme*. Because of this alteration in structure, a bond breaking reaction that would not otherwise have been possible occurs readily. To complete the catalytic cycle, the electron flow has to be reversed again. The thiamin-bound cleavage product (an enamine) from either of the adducts in Eq. 14-20 can be reconverted to the thiazolium dipolar ion and an aldehyde as shown in step *b* of Eq. 14-21 for decarboxylation of pyruvate to acetaldehyde.

The adducts α-lactylthiamin and α-lactylthiamin diphosphate have both been synthesized.[84,98–100] As long as α-lactylthiamin is kept as a dry solid or at low pH, it is stable. However, it decarboxylates readily in neutral solution (Eq. 14-21). Decarboxylation is much

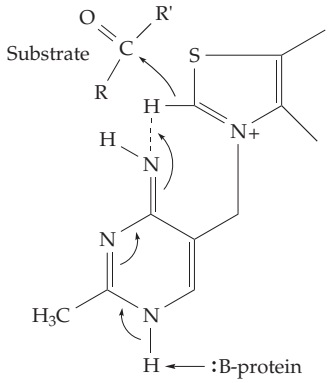


(14-21)

more rapid in methanol, a fact that was predicted by Lienhard and associates.[101] They suggested that decarboxylation is easier in a solvent of low polarity because the transition state has a lower polarity than does lactylthiamin. An enzyme could assist the reaction by providing a relatively nonpolar environment.

The crystal structures of thiamin-dependent enzymes (see next section) as well as modeling[102,103] suggest that lactylthiamin pyrophosphate has the conformation shown in Eq. 14-21. If so, it would be formed by the addition of the ylid to the carbonyl of pyruvate in accord with stereoelectronic principles, and the carboxylate group would also be in the correct orientation for elimination to form the enamine in Eq. 14-21, step *b*.[82–83a] A transient 380- to 440-nm absorption band arising during the action of pyruvate decarboxylase has been attributed to the enamine.

What is the role of the pyrimidine portion of the coenzyme in these reactions? The pyrimidine ring has a large inductive effect on the basicity of the thiazolium nitrogen and may increase the rate of dissociation of the C-2 proton somewhat.[104] More significant is the fact that the $-NH_2$ group is properly placed to function as a basic catalyst in the generation of the thiazolium dipolar ion. However, the amino group of thiamin is not very basic ($pK_a \sim 4.9$) and the site of protonation at low pH is largely N-1 of the pyrimidine ring. In the protonated form the $-NH_2$ group is even less basic because of electron withdrawal into the ring. Studies of thiamin analogs suggested another possibility. Schellenberger[105] found pyruvate decarboxylase inactive when TDP was substituted by analogs with modified aminopyrimidine rings, e.g., with methylated or dimethylated amino groups or with N1 of the ring replaced by carbon (an aminopyridyl analog). More recently the experiment has been repeated with additional enzymes[106] and X-ray studies have shown that the analogs bind into the active site of transketolase in a normal way.[107] Of the compounds studied *only an aminopyridyl analog of TDP having a nitrogen atom at 1'* (but CH at 3') *had substantial catalytic activity.* Jordan and Mariam showed that *N*-1'-methylthiamin is a superior catalyst in nonenzymatic catalysis.[108] These results are consistent with the speculative scheme illustrated in the following drawing from the first edition of this book.[109] The $-NH_2$ group of the N1-protonated aminopyrimidine has lost a proton to form a normally *minor tautomer* in which the resulting imino group would be quite basic. Assisted by a basic group from the protein, it could abstract the proton from the thiazolium ring to form the ylid.



Crystallographic studies show that the catalytic base (:B-protein) is the carboxylate group of a conserved glutamate side chain (E59' in Fig. 14-2). Kern *et al*. used NMR spectroscopy of thiamin diphosphate present in native and mutant pyruvate decarboxylase and transketolase to monitor the exchange rates of the C2-H proton of the thiazolium ring.[109a] The results confirmed the importance of the conserved glutamate side chain for dissociation of the C2-H proton. Participation of other catalytic groups from the enzyme may also be important. However, these groups are not conserved in the whole family of enzymes. For example, glutamine 122, which is within hydrogen-bonding distance of both the substrate and thiamin amino group, is replaced by histidine in transketolase.[110] A variety of kinetic studies involving mutants,[111,111a] alternative substrates,[112,113] and isotope effects in substrates[114–116] and solvent[117,118] have not yet resolved the details of the proton transfers that occur within the active site.

3. Structures of Thiamin-Dependent Enzymes

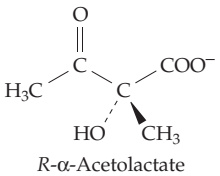
By 1998, X-ray structures had been determined for four thiamin diphosphate-dependent enzymes: (1) a bacterial pyruvate oxidase,[119,120] (2) yeast and bacterial pyruvate decarboxylases,[121–122c] (3) transketolase,[110,123,124] and (4) benzoylformate decarboxylase.[124a] The reactions catalyzed by these enzymes are all quite different, as are the sequences of the proteins. However, the thiamin diphosphate is bound in a similar way in all of them. A conserved pattern of hydrogen bonds holds the diphosphate group to the protein and also provides ligands to a metal ion. This is normally Mg^{2+}, which is held in nearly perfect octahedral coordination by two phosphate oxygen atoms, a conserved aspartate carboxylate, a conserved asparagine amide, and a water molecule. The thiamin rings are in a less polar region. The amino group of the pyrimidine is adjacent to the 2–CH of the thiazole and N1' of the pyrimidine is apparently protonated and hydrogen bonded to the carboxylate group of a conserved glutamate side

chain. This is shown in Fig. 14-2. Substitution of the corresponding glutamate 51 of yeast pyruvate decarboxylase by glutamine or alanine greatly reduced or eliminated catalytic activity.[125]

4. The Variety of Enzymatic Reactions Involving Thiamin

Most known thiamin diphosphate-dependent reactions (Table 14-2) can be derived from the five half-reactions, *a* through *e*, shown in Fig. 14-3. Each half-reaction is an α cleavage which leads to a thiamin- bound enamine (center, Fig. 14-3) The decarboxylation of an α-oxo acid to an aldehyde is represented by step *b* followed by *a* in reverse. The most studied enzyme catalyzing a reaction of this type is yeast **pyruvate decarboxylase,** an enzyme essential to alcoholic fermentation (Fig. 10-3). There are two ~250-kDa isoenzyme forms, one an α_4 tetramer and one with an $(\alpha\beta)_2$ quaternary structure. The isolation of α-hydroxyethylthiamin diphosphate from reaction mixtures of this enzyme with pyruvate[52] provided important verification of the mechanisms of Eqs. 14-14, 14-15. Other decarboxylases produce aldehydes in specialized metabolic pathways: indolepyruvate decarboxylase[126] in the biosynthesis of the plant hormone **indole-3-acetate** and benzoylformate decarboxylase in the mandelate pathway of bacterial metabolism (Chapter 25).[124a,127]

Formation of α-ketols from α-oxo acids also starts with step *b* of Fig. 14-3 but is followed by condensation with another carbonyl compound in step *c*, in reverse. An example is decarboxylation of pyruvate and condensation of the resulting active acetaldehyde with a second pyruvate molecule to give *R*-α-acetolactate, a reaction catalyzed by **acetohydroxy acid synthase** (acetolactate synthase).[128] Acetolactate is the precursor to valine and leucine. A similar ketol condensation, which is catalyzed by the same synthase, is



R-α-Acetolactate

required in the biosynthesis of isoleucine (Fig. 24-17). Since this

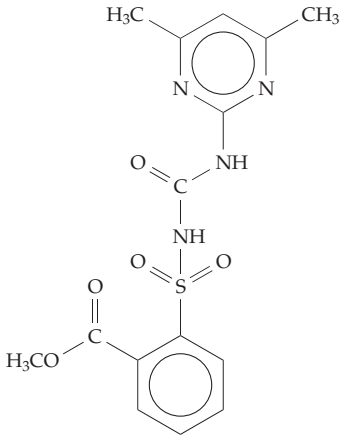
TABLE 14-2
Enzymes Dependent upon Thiamin Diphosphate as a Coenzyme

1. Nonoxidative
   - Pyruvate decarboxylase*
   - Indolepyruvate decarboxylase
   - Benzoylformate decarboxylase*
   - Glyoxylate carboligase
   - Acetohydroxy acid synthase (acetolactate synthase)
   - 1-Deoxy-D-xylulose 5-phosphate synthase
   - Transketolase*
   - Phosphoketolase
2. Oxidative decarboxylase
   - Pyruvate oxidase (FAD)*
   - Pyruvate dehydrogenase (Lipoyl, FAD, NAD^+) multienzyme complex
   - Pyruvate:ferredoxin oxidoreductase
   - Indolepyruvate:ferredoxin oxidoreductase

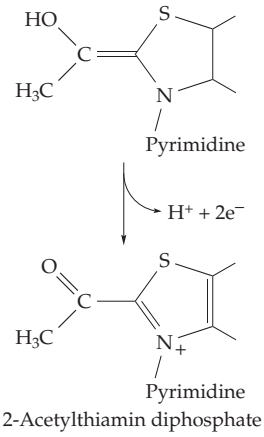
* Three-dimensional structures for these enzymes had been determined by 1998.

synthase is not present in mammals it is a popular target for herbicides.[129,130] It is inhibited by many of the most widely used herbicides including sulfometuron methyl, whose structure is shown here.



Sulfometuron methyl

Acetolactate is a β-oxo acid and is readily decarboxylated to acetoin, a reaction of importance in bacterial fermentations (Eq. 17-26). Acetoin, of both *R* and *S*



(14-22)

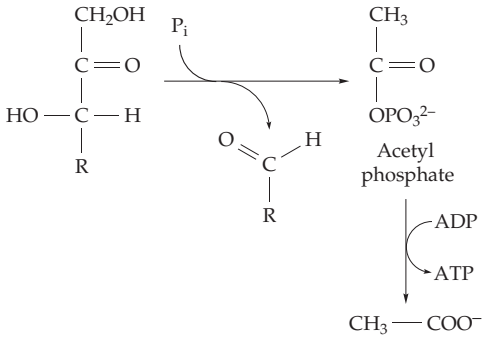
configurations, is also formed by pyruvate decarboxylases acting on acetaldehyde.[103,131] The ketol condensation of two molecules of glyoxylate with decarboxylation to form tartronic semialdehyde (see Fig. 17-6) is an important reaction in bacterial metabolism. It is catalyzed by **glyoxylate carboligase,**[132] another thiamin diphosphate-dependent enzyme. Formation of 1-deoxy-D-xylulose 5-phosphate, an intermediate in the nonmevalonate pathway of isoprenoid synthesis, is formed in a thiamin diphosphate-catalyzed condensation of pyruvate with glyceraldehyde 3-phosophate (Fig. 22-2)[132a] However, there is an unresolved problem. As previously mentioned, the same intermediate is thought to be a precursor to thiamin diphosphate (Eq. 25-21). This suggests the presence of an alternative pathway.

Ketols can also be formed enzymatically by cleavage of an aldehyde (step *a*, Fig. 14-3) followed by condensation with a second aldehyde (step *c*, in reverse). An enzyme utilizing these steps is **transketolase** (Eq. 17-15),[132b] which is essential in the pentose phosphate pathways of metabolism and in photosynthesis. α-Diketones can be cleaved (step *d*) to a carboxylic acid plus active aldehyde, which can react either via *a* or *c* in reverse. These and other combinations of steps are often observed as side reactions of such enzymes as pyruvate decarboxylase. A related thiamin-dependent reaction is that of pyruvate and acetyl-CoA to give the α-diketone, **diacetyl**, $CH_3COCOCH_3$.[133] The reaction can be viewed as a displacement of the CoA anion from acetyl-CoA by attack of thiamin-bound active acetaldehyde derived from pyruvate (reverse of step *d*, Fig. 14-3 with release of CoA).

5. Oxidative Decarboxylation and 2-Acetylthiamin Diphosphate

The oxidative decarboxylation of pyruvate to form acetyl-CoA or acetyl phosphate plays a central role in the metabolism of our bodies and of most other organisms. This reaction is usually formulated as the reverse of step *e* of Fig. 14-3, which shows the cleavage of an **acyl-dihydrolipoyl** derivative. However, there is a possibility that the lipoyl group functions not as shown in Fig. 14-3 but as an oxidant that converts the TDP enamine to 2-acetylthiamin diphosphate (Eq. 14-22)[134,135] and only after that as an acyl group carrier. A related reaction that is known to proceed through acetyl-TDP is the previously mentioned bacterial pyruvate oxidase. As seen in Fig. 14-2, this enzyme has its own oxidant, FAD, which is ready to accept the two electrons of Eq. 14-22 to produce bound acetyl-TDP. The electrons may be able to jump directly to the FAD, with thiamin and flavin radicals being formed at an intermediate stage.[135a] The electron transfers as well as other aspects of oxidative decarboxylation are discussed in Chapter 15, Section C.

A reaction that is related to that of transketolase but is likely to function via acetyl-TDP is **phosphoketolase**, whose action is required in the energy metabolism of some bacteria (Eq. 14-23). A product of phosphoketolase is acetyl phosphate, whose cleavage can be coupled to synthesis of ATP. Phosphoketolase presumably catalyzes an α cleavage to the thiamin-containing enamine shown in Fig. 14-3. A possible mechanism of formation of acetyl phosphate is elimination of H_2O from this enamine, tautomerization to 2-acetylthiamin, and reaction of the latter with inorganic phosphate.



(14-23)

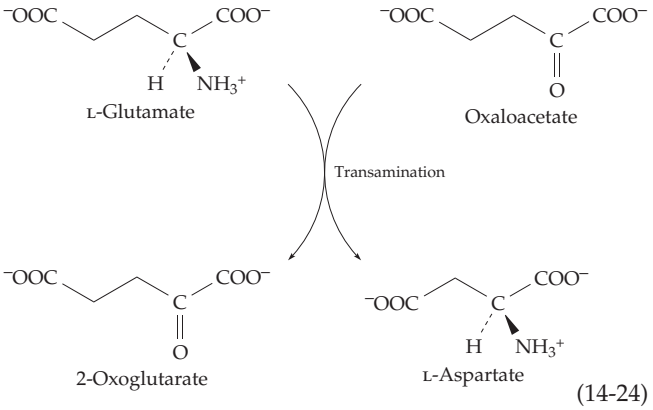
6. Thiamin Coenzymes in Nerve Action

The striking paralysis caused by thiamin deficiency together with studies of thiamin analogs as metabolites suggested a special action for this vitamin in nerves.[136] The thiamin analog **pyrithiamin** (p. 731) both induces paralytic symptoms and displaces thiamin from nerve preparations. The nerve poison **tetrodotoxin** (Chapter 30) blocks nerve conduction by inhibiting inward diffusion of sodium, but it also promotes release of thiamin from nerve membranes. Evidence for a metabolic significance of thiamin triphosphate comes from identification of soluble and membrane-associated thiamin triphosphatases[137] as well as a kinase that

forms protein-bound thiamin triphosphate in the brain.[138] Mono-, tri-, and tetraphosphates also occur naturally in smaller amounts. One might speculate about a possible role for the rapid interconversion of cationic and yellow anionic forms of thiamin via the tricyclic form (Eq. 7-19) in some aspect of nerve conduction.

E. Pyridoxal Phosphate

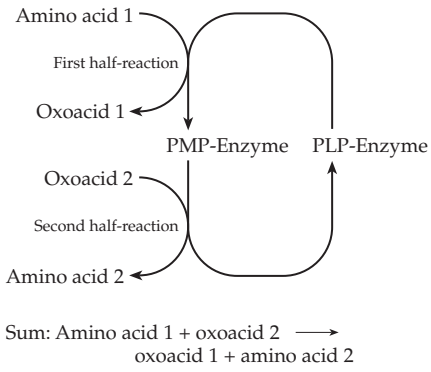
The phosphate ester of the aldehyde form of vitamin B_6, **pyridoxal phosphate** (pyridoxal-*P* or PLP), is required by many enzymes catalyzing reactions of amino acids and amines. The reactions are numerous, and pyridoxal phosphate is surely one of nature's most versatile catalysts. The story begins with biochemical **transamination**, a process of central importance in nitrogen metabolism. In 1937, Alexander Braunstein and Maria Kritzmann, in Moscow, described the transamination reaction by which amino groups can be transferred from one carbon skeleton to another.[139,140] For example, the amino group of glutamate can be transferred to the carbon skeleton of oxaloacetate to form aspartate and 2-oxoglutarate (Eq. 14-24).



(14-24)

This transamination reaction is a widespread process of importance in many aspects of the nitrogen metabolism of organisms. A large series of **transaminases** (**aminotransferases**), for which glutamate is most often one of the reactants, have been shown to catalyze the reactions of other oxoacids and amino acids.[141–143]

In 1944, Esmond Snell reported the nonenzymatic conversion of pyridoxal into pyridoxamine (Box 14-C) by heating with glutamate. He recognized that this was also transamination and proposed that pyridoxal might be a part of a coenzyme needed for aminotransferases and that these enzymes might act via two half-reactions that interconverted pyridoxal and pyridoxamine (Eq. 14-25). The hypothesis was soon verified and the coenzyme was identified as pyridoxal 5'-phosphate or pyridoxamine 5'-phosphate (Fig. 14-5).[144,145]



(14-25)

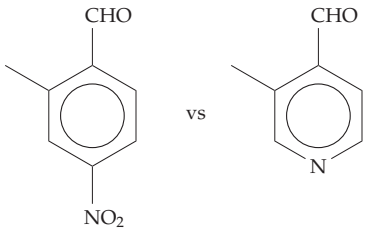
At about the same time, Gunsalus and coworkers noticed that the activity of **tyrosine decarboxylase** produced by lactic acid bacteria was unusually low when the medium was deficient in pyridoxine. Addition of pyridoxal plus ATP increased the decarboxylase activity of cell extracts.[146] PLP was synthesized and was found to be the essential coenzyme for this and a variety of other enzymes.[147]

1. Nonenzymatic Models

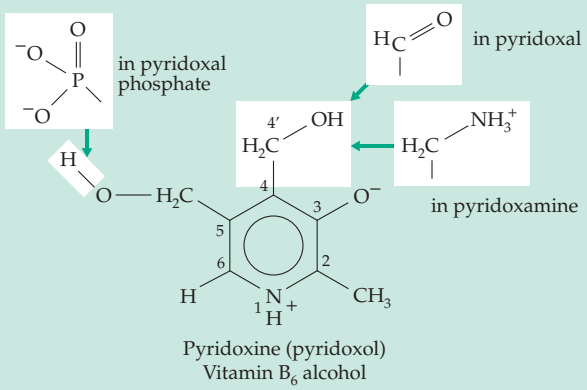
Pyridoxal or PLP, in the complete absence of enzymes, not only undergoes slow transamination with amino acids but also catalyzes many other reactions of amino acids that are identical to those catalyzed by PLP-dependent enzymes. Thus, *the coenzyme itself can be regarded as the active site of the enzymes* and can be studied in nonenzymatic reactions. The latter can be thought of as *models* for corresponding enzymatic reactions. From such studies Snell and associates drew the following conclusions.[148]

a. The aldehyde group of PLP reacts readily and reversibly with amino acids to form Schiff bases (Fig. 14-4) which react further to give products.

b. For an aldehyde to be a catalyst, a strong electron-attracting group, e.g., the ring nitrogen of pyridine (as in PLP), must be *ortho* or *para* to the –CHO group. A nitro group, also strongly electron attracting, can replace the pyridine nitrogen in model reactions.



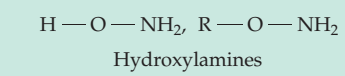
BOX 14-C THE VITAMIN B_6 FAMILY: PYRIDOXINE, PYRIDOXAL, AND PYRIDOXAMINE



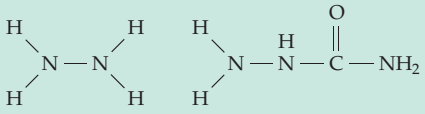
Pyridoxine (pyridoxol)
Vitamin B_6 alcohol

Pyridoxine, the usual commercial form of vitamin B_6, was isolated and synthesized in 1938. However, studies of bacterial nutrition soon indicated the existence of other naturally occurring forms of the new vitamin which were more active than pyridoxine in promoting growth of certain lactic acid bacteria. The amine **pyridoxamine** and the aldehyde **pyridoxal** were identified by Snell, who found that pyridoxal could be formed from pyridoxine by mild oxidation and that pyridoxamine could be formed from pyridoxal by heating in a solution with glutamic acid via a transamination reaction. These simple experiments also suggested the correct structures of the new forms of vitamin B_6. Animal tissues contain largely pyridoxal, pyridoxamine, and their phosphate esters. The lability of the aldehyde explains the ease of destruction of the vitamin by excessive heat or by light. On the other hand, plant tissues contain mostly pyridoxine, which is more stable. Kinases use ATP to form the phosphate esters, which are interconvertible within cells.[a–e] Pyridoxine 5'-phosphate can be oxidized to PLP[d,e,f] and the latter may undergo transamination to PMP. The acid–base chemistry and tautomerism of pyridoxine were discussed in Chapter 6, Section E,2.

Many poisonous substances as well as useful drugs react with PLP-requiring enzymes. Thus, much of the toxic effect of the "carbonyl reagents" hydroxylamine, hydrazine, and semicarbazide stems from their formation of stable derivatives analogous to Schiff bases with PLP.

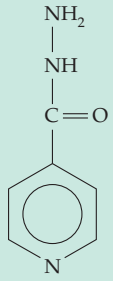


Hydroxylamines



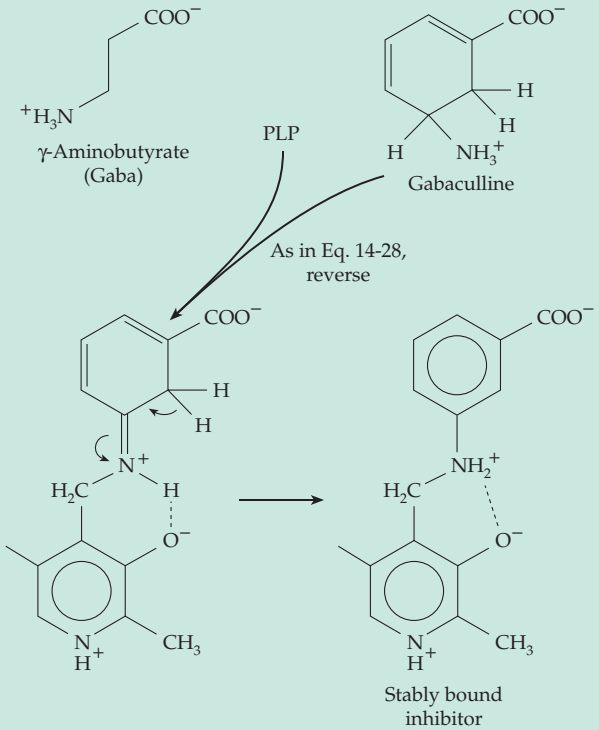
Hydrazine Semicarbazide

Isonicotinyl hydrazide (INH), one of the most effective drugs against tuberculosis, is inhibitory to pyridoxal kinase, the enzyme that converts pyridoxal to PLP.[c] Apparently, the drug reacts with pyridoxal to form a hydrazone which blocks the enzyme. Pyridoxal kinase is not the primary target of INH in mycobacteria. However, patients on long-term isonicotinyl hydrazide therapy sometimes suffer symptoms of vitamin B_6 deficiency.[g]



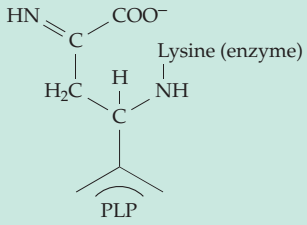
Isonicotinyl hydrazide
(isoniazid)

PLP-dependent enzymes are inhibited by a great variety of enzyme-activated inhibitors that react by several distinctly different chemical mechanisms.[h] Here are a few. The naturally occurring **gabaculline** mimics γ-aminobutyrate (Gaba) and inhibits γ-aminobutyrate aminotransferase as well as other PLP-dependent enzymes. The inhibitor follows the normal catalytic pathway as far as the ketimine. There, a proton is lost from the inhibitor permitting formation of a stable benzene ring and leaving the inhibitor stuck in the active site:



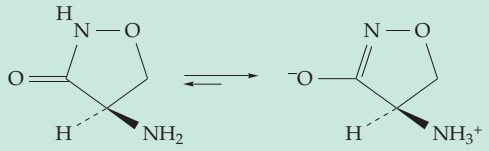
BOX 14-C (continued)

Beta-chloroalanine and serine *O*-sulfate can undergo β elimination (as in Eq. 14-29) in active sites of glutamate decarboxylase or aspartate aminotransferase. The enzymes then form free aminoacrylate, a reactive molecule that can undergo an aldol-type condensation with the external aldimine to give the following product.[i]



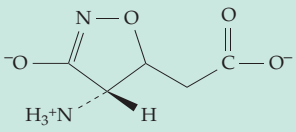
Nucleophilic groups from enzymes can add to double bonds, e.g., in an aminoacrylate Schiff base, or to multiple bonds present in the inhibitor. An example is γ-vinyl γ-aminobutyrate (4-amino-5-hexenoic acid), another inhibitor of brain γ-aminobutyrate aminotransferase which is a useful anticonvulsant drug.

Another enzyme-activated inhibitor is the streptomyces antibiotic **D-cycloserine** (oxamycin), an antitubercular drug that resembles D-alanine in structure. A potent inhibitor of alanine racemase, it also inhibits the non-PLP, ATP-dependent, **D-alanyl-D-alanine synthetase** which is needed in the biosynthesis of the peptidoglycan of bacterial cell walls.

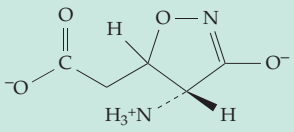


D-Cycloserine

L-Cycloserine inhibits many PLP enzymes and is toxic to humans. This observation led Khomutov *et al.* to synthesize the following more specific "cycloglutamates," structural analogs of glutamic acid with fixed conformations.[j,k] Nature apparently anticipated the synthetic chemist, because it has been reported that the mushroom *Tricholoma muscarium* contains one of the same compounds. It is said to impart two interesting properties to the mushroom: a delicious flavor and a lethal action on flies that alight on the mushroom's surface![l]

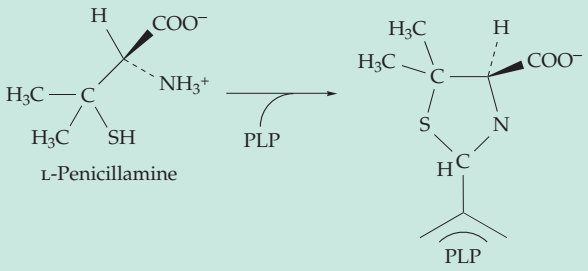


A cycloglutamate that inhibits aspartate aminotransferase



An isomeric cycloglutamate tricholomic acid found in certain mushrooms

The substituted cysteine derivative L-penicillamine causes convulsions and low glutamate decarboxylase levels in the brain, presumably because the Schiff base formed with PLP can then undergo cyclization, the SH group adding to the C=N to form a stable thiazolidine ring.



L-Penicillamine

Toxopyrimidine, the alcohol derived from the pyrimidine portion of the thiamin molecule, is a structural analog of pyridoxal. When fed to rats or mice it induces running fits which can be stopped by administration of vitamin B_6. Phophorylation of toxopyrimidine by pyridoxal kinase may produce an antagonistic analog of PLP. In a similar fashion, 4-deoxypyridoxine, which was tested as a possible anticancer drug, caused convulsions and other symptons of vitamin B_6 deficiency in humans. A host of synthetic PLP derivatives have been made, some of which are effective in blocking PLP enzymes.[h]

c. The presence of an – OH group adjacent to the – CHO group greatly enhances the catalytic activity. Since certain metal ions, such as Cu^{2+} and Al^{3+}, increase the rates in model systems and are known to chelate with Schiff bases of the type formed with PLP, it was concluded that either a metal ion or a proton formed a chelate ring and helped to hold the Schiff base in a planar conformation (Fig. 14-6). *However, such a function for metal ions has not been found in PLP-dependent enzymes.*

d. In model systems the 5-hydroxymethyl and 2-methyl groups are not needed for catalysis. However, in enzymes the 5-CH_2OH group is essential for attachment of the phosphate handle. The 2-CH_3 group is usually not necessary for coenzymatic activity.

Many investigations of nonenzymatic reactions of PLP and related compounds have been and are still being conducted[149,150]

2. A General Mechanism of Action of PLP

Based upon consideration of the various known PLP-dependent enzymes of amino acid metabolism, Braunstein and Shemyakin in 1952 proposed a general mechanism of PLP action[151,152] which, in most details, was the same as the one proposed independently by Snell and associates on the basis of the nonenzymatic reactions.[148] The general mechanism, which has been verified by studies of many enzymes, can be stated as follows: *Pyridoxal phosphate reacts to convert the amino group of a substrate into a Schiff base that is electronically the equivalent of an adjacent carbonyl* (Fig. 14-4). However, a Schiff base of an amino acid with a simple aldehyde (for example, acetaldehyde) has the opposite polarity from that of C=O (see the following structures). Such an imine could not substitute for a carbonyl group in activating an α-hydrogen nor in facilitating C–C bond cleavage in the amino acid. It is necessary to have the strongly electron-attracting pyridine group conjugated with the C=N group in such a way that electrons can flow from the substrate into the coenzyme.

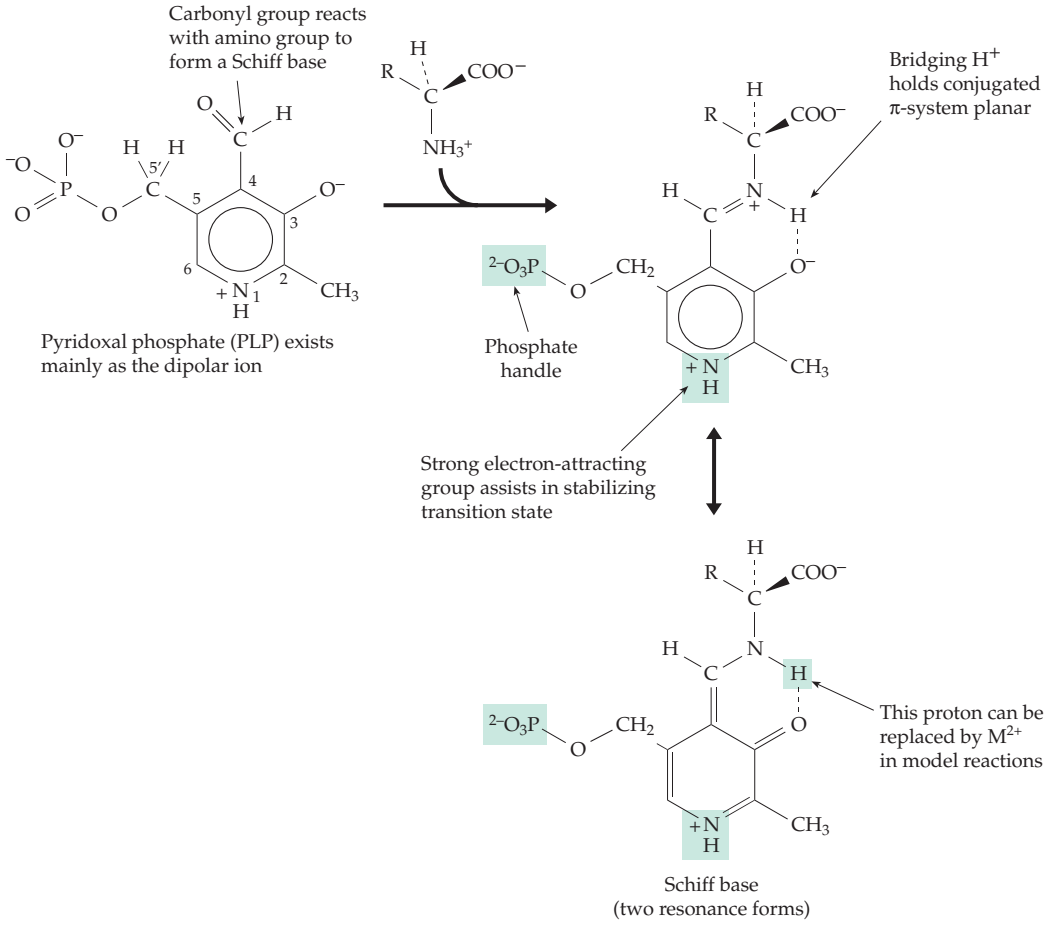

Figure 14-4 Pyridoxal 5'-phosphate (PLP), a special coenzyme for reactions of amino acids.

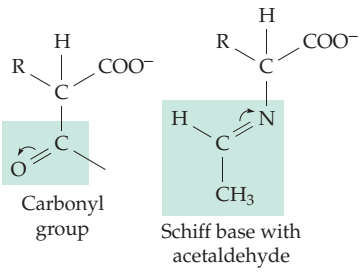
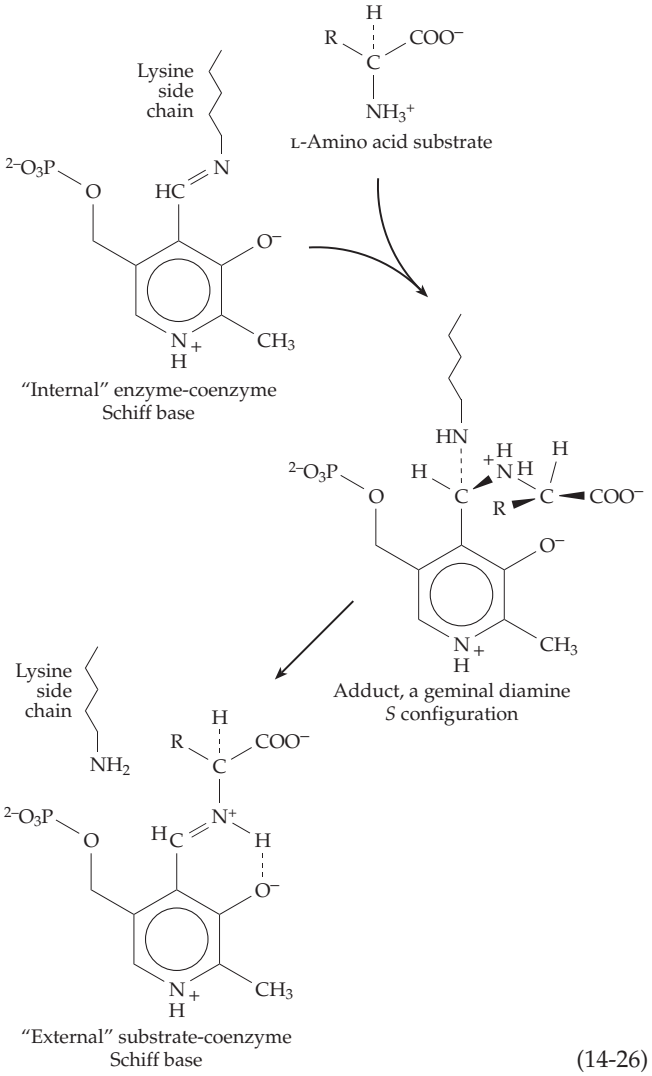


Before discussing the reactions of Schiff bases of PLP we should consider one fact that was not known in 1952. PLP is bound into an enzyme's active site as a Schiff base with a specific lysine side chain before a substate binds . This is often called the **internal aldimine**. When the substrate binds it reacts with the internal Schiff base by a two-step process called **transimination** (Eq. 14-26) to form the substrate Schiff base, which is also called the **external aldimine**.



(14-26)

3. The Variety of PLP-Dependent Reactions

In Fig. 14-5 the reactions of PLP-amino acid Schiff bases are compared with those of β-oxo-acids. Beta-hydroxy-α-oxo acids and Schiff bases of PLP with β-hydroxy-α-amino acids can react in similar ways. The reactions fall naturally into three groups (*a*,*b*,*c*) depending upon whether the bond cleaved is from the α-carbon of the substrate to the hydrogen atom, to the carboxyl group, or to the side chain. A fourth group of reactions of PLP-dependent enzymes (*d*) also involve removal of the α-hydrogen but are mechanistically more complex. Some of the many reactions catalyzed by these enzymes are listed in Table 14-3.

***Loss of the α-hydrogen* (Group *a*).** Dissociation of the α-hydrogen from the Schiff base leads to a **quinonoid–carbanionic intermediate** whose structure in depicted in Fig. 14-5. The name reflects the characteristics of the two resonance forms drawn. Like an enolate anion, this intermediate can react in several ways (1-4).

(1) **Racemization**. A proton can be added back to the original alpha position but without stereospecificity. A racemase which does this is important to bacteria. They must synthesize D-alanine and D-glutamic acid from the corresponding L-isomers for use in formation of their peptidoglycan envelopes.[153–154a] The combined actions of alanine racemase plus D-alanine aminotransferase, which produces D-glutamate as a product, provide bacteria with both D amino acids. A fungal alanine racemase is necessary for synthesis of the immunosuppresant cyclosporin (Box 9-F).[155,155a] High concentrations of free D-alanine are found in certain regions of the brain and also in various glands.[156]

The carboxyl group of an amino acid can also activate the α-hydrogen. This may be the basis for an aspartate racemase and other racemases that are *not* dependent upon PLP.[156–158] See also Chapter 13, Section B,4.

(2) **Cyclization**. A second kind of reaction is represented by the conversion of *S*-adenosylmethionine to **aminocyclopropanecarboxylic acid**, a precursor to the plant hormone **ethylene** (see Chapter 24).[159] The quinonoid intermediate cyclizes with elimination of methylthioadenosine to give a Schiff base of the product (Eq. 14-27).[160–161a] The cyclization step appears to be a simple S_N2-like reaction.[162]

(3) **Transamination**. A proton can add to the carbon attached to the 4 position of the PLP ring (Fig. 14-5) to form a second Schiff base, often referred to as a **ketimine** (Eq. 14-28). The latter can readily undergo hydrolysis to **pyridoxamine phosphate** (PMP) and an α-oxo acid. This sequence represents one of the

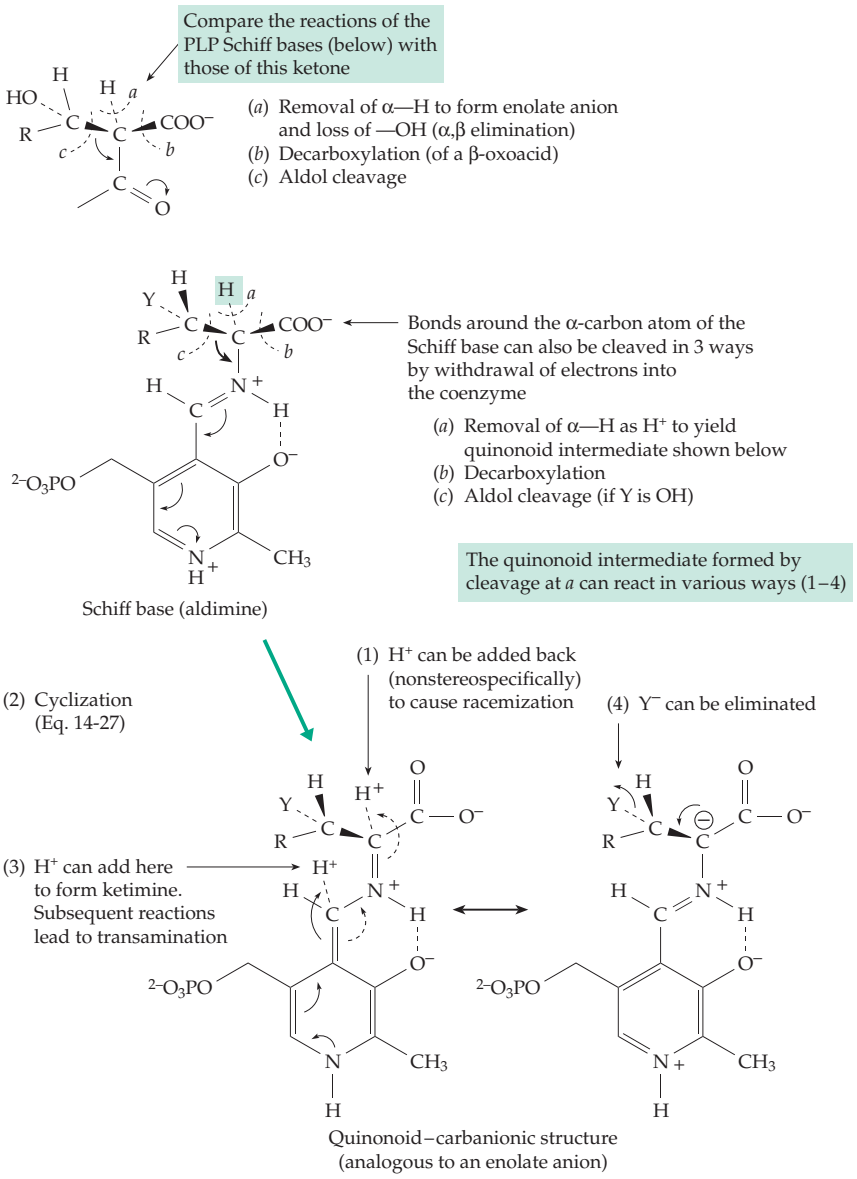


Figure 14-5 Some reactions of Schiff bases of pyridoxal phosphate. (*a*) Formation of the quinonoid intermediate, (*b*) elimination of a β substituent, and (*c*) transamination. The quinonoid–carbanionic intermediate can react in four ways (1–4) if enzyme specificity and substrate structure allow.

two half-reactions (Eqs. 14-24 and 14-25) required for enzymatic transamination.

Transaminases participate in metabolism of most of the amino acids, over 60 different enzymes have been identified.[142,163] Best studied are the **aspartate aminotransferases**, a pair of cytosolic and mitochondrial isoenzymes which can be isolated readily from animal hearts. Their presence in heart muscle and brain in high concentration is thought to be a result of their functioning in the malate–aspartate shuttle (Chapter 18). The sequences of the two proteins differ greatly, with only 50% of the residues being the same in both isoenzymes. However, these differences are largely on the outside surface, the folding pattern (Fig. 2-6) and internal structure (Fig. 14-6) are almost identical.[142,163–167a] Three-dimensional structures of aspartate aminotransferases of *E. coli*, yeast, chickens, and mammals are extremely similar, even though sequence identity may be as low as 20%.[167a] Most other transaminases also use the L-gutamate–oxoglutarate pair as one of the product–reactant pairs but a few prefer smaller substrates with uncharged side chains. An example is serine: pyruvate (or alanine:glyoxylate) aminotransferase, an important mitochondrial and peroxisomal enzyme in both animals and plants.[168] Other specialized aminotransferases act on aromatic amino acids,[168a] the branched chain amino acids valine, leucine, and isoleucine,[168b,c] and D-amino acids.[168d] Many of them are highly specific for individual amino acids such as phosphoserine,[168e] ornithine,[168f,g] *N*-acetylornithine,[168h,i] and 8-amino-7-oxononanoate (see banner, p. 719).[168j] An apparently internal transamination, which requires PMP and PLP, converts glutamate-1-semialdehyde into δ-aminolevulinate (see Eq. 24-44) in the pathway of porphyrin biosynthesis used by bacteria and plants.[168k]

(4) **Elimination and β replacement**. When a good leaving group is present in the β position of the amino acid it can be eliminated (Fig. 14-5, Eq. 14-29).[170] A large number of enzymes catalyze such reactions. Among them are **serine** and **threonine dehydratases,** which eliminate OH^- as H_2O;[171–173a] **tryptophan indole-lyase** (tryptophanase) of bacteria, which eliminates indole;[174–176c] **tyrosine phenol-lyase** (elimination of phenol);[177–178a] and **alliinase** of garlic (elimination of 1-propenylsulfenic acid).[179,180] Cystathionine, a precursor to methionine, eliminates L-homocysteine through the action of **cystathionine β lyase** (cystathionase).[181,182] Ammonia is eliminated from the β position of 2,3-diaminopropionate by a bacterial lyase.[183]

TABLE 14-3
Some Enzymes That Require Pyridoxal Phosphate as a Coenzyme

(*a*) Removing alpha hydrogen as H^+
- (1) Racemization
  - Alanine racemase*
- (2) Cyclization
  - Aminocyclopropane carboxylate synthase
- (3) Amino group transfer
  - Aspartate aminotransferase*
  - Alanine aminotransferase
  - D-Amino acid aminotransferase*
  - Branched chain aminotransferase
  - Gamma-aminobutyrate aminotransferase
  - ω-Amino acid:pyruvate aminotransferase*
  - Tyrosine aminotransferase
  - Serine:pyruvate aminotransferase
- (4) Beta elimination or replacement
  - D- and L- Serine dehydratases (deaminases)
  - Tryptophan indole-lyase (tryptophanase)*
  - Tyrosine phenol-lyase*
  - Alliinase
  - Cystathionine β-lyase (cystathionase)*
  - *O*-Acetylserine sulfhydrylase (cysteine synthase)
  - Cystathionine β-synthase
  - Tryptophan synthase*

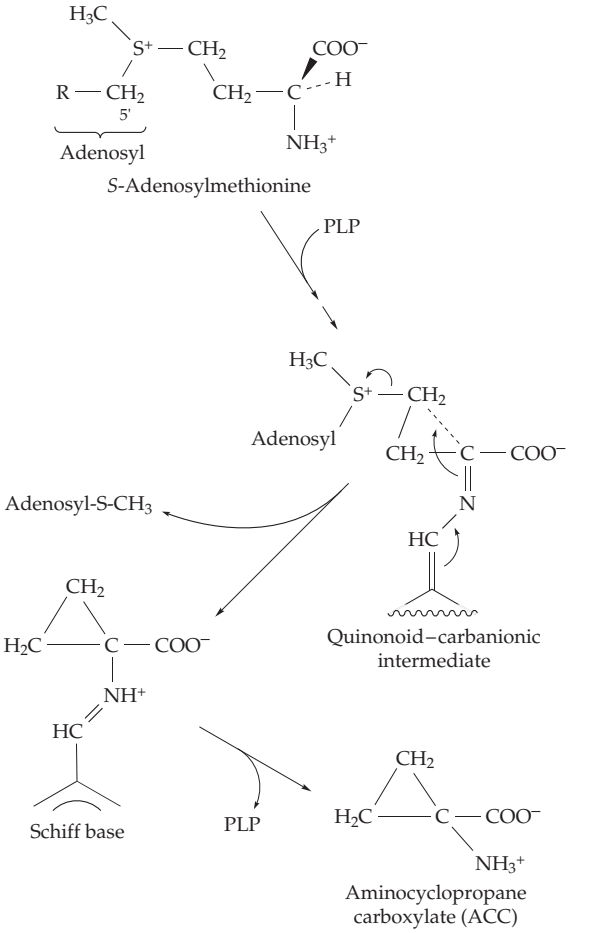
(*b*) Removal of alpha carboxylate as CO_2
- Diaminopimelate decarboxylase
- Glycine decarboxylase (requires lipoyl group)
- Glutamate decarboxylase
- Histidine decarboxylase
- Dopa decarboxylase
- Ornithine decarboxylase*
- Tyrosine decarboxylase
- Dialkylglycine decarboxylase (a decarboxylating transaminase)*

(*c*) Removal or replacement of side chain (or –H) by aldol cleavage
- Serine hydroxymethyltransferase
- Threonine aldolase
- δ-Aminolevulinate synthase
- Serine palmitoyltransferase
- 2-Amino-3-oxobutyrate-CoA ligase

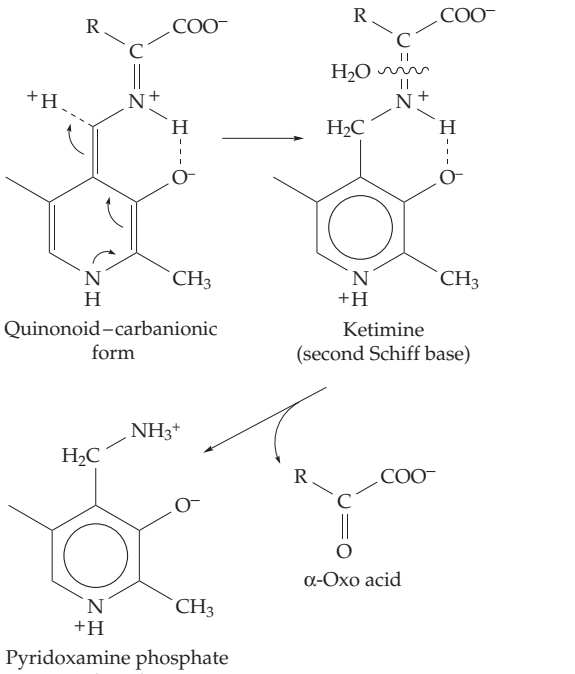
(*d*) Reactions of ketimine intermediates
- Aspartate γ-decarboxylase
- Selenocysteine lyase
- *Nif S* protein of nitrogenase
- Gamma elimination and replacement
  - Cystathionine γ-synthase
  - Cystathionine γ-lyase
  - Threonine synthase

(*e*) Other enzymes
- Lysine 2,3-aminomutase
- Glycogen phosphorylase*
- Pyridoxamine phosphate (PMP) in synthesis of 3,6-dideoxy hexoses

* The three-dimensional structures of these and other PLP-dependent enzymes were determined by 2000.



(14-27)



(14-28)

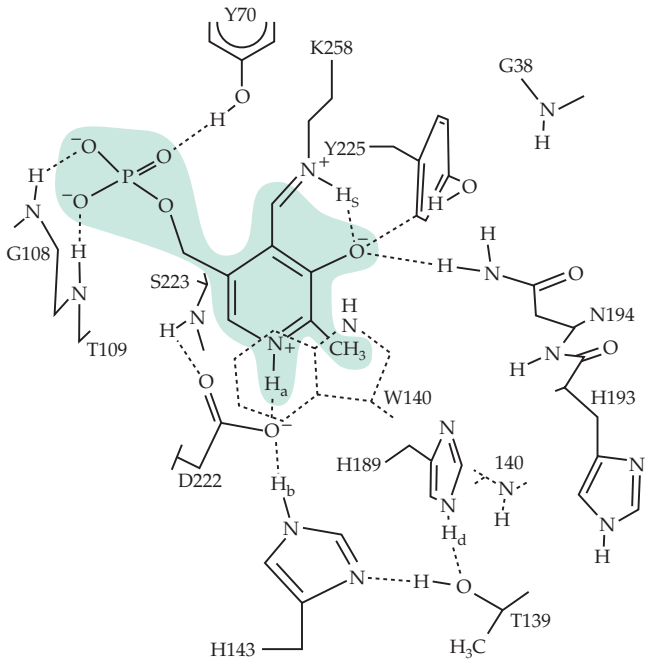


Figure 14-6 Drawing showing pyridoxal phosphate (shaded) and some surrounding protein structure in the active site of cytosolic aspartate aminotransferase. This is the low pH form of the enzyme with an *N*-protonated Schiff base linkage of lysine 258 to the PLP. The tryptophan 140 ring lies in front of the coenzyme. Several protons, labeled H_a, H_b, and H_d, are represented in ^1H NMR spectra by distinct resonances whose chemical shifts are sensitive to changes in the active site.[169]

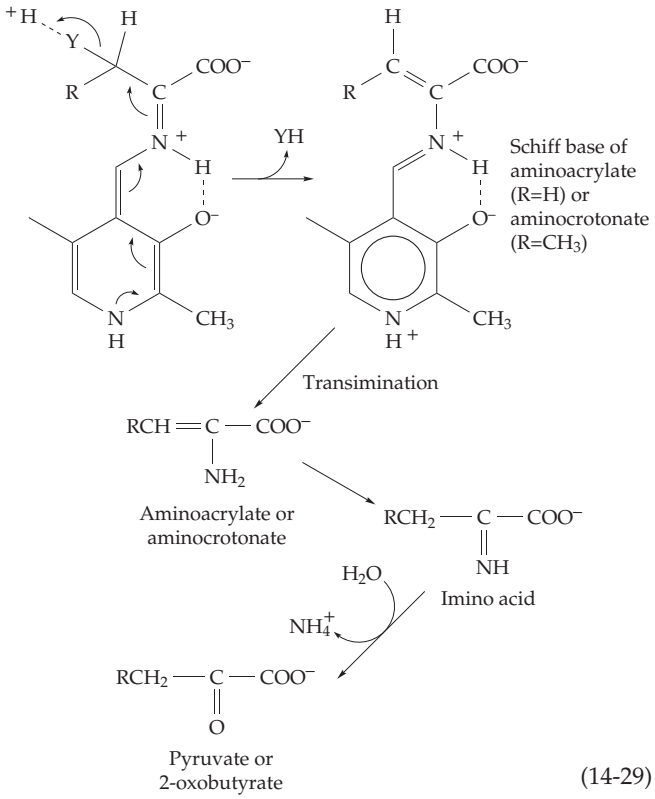
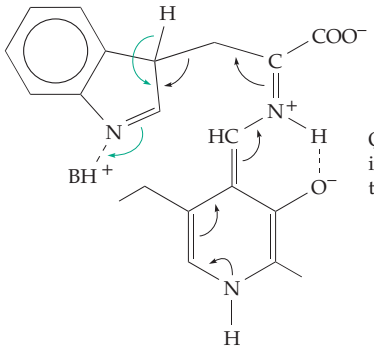


(14-29)

Beta replacement is catalyzed by such enzymes of amino acid biosynthesis as **tryptophan synthase** (Chapter 25),[184] ***O*-acetylserine sulfhydrylase** (cysteine synthase),[185–186a] and **cystathionine β-synthase** (Chapter 24).[187–188c] In both elimination and β replacement an unsaturated Schiff base, usually of aminoacrylate or aminocrotonate, is a probable intermediate (Eq. 14-29). Conversion to the final products is usually assumed to be via hydrolysis to free aminoacrylate, tautomerization to an imino acid, and hydrolysis of the latter, e.g., to pyruvate and ammonium ion (Eq. 14-29). However, the observed stereospecific addition of a



Quinonoid–carbanionic intermediate with tautomerized indole ring

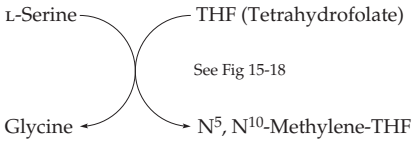
proton at the β-C atom of 2-oxobutyrate[189] suggests that these steps may occur with the participation of groups from the enzyme. Before indole can be eliminated by tryptophan indolelyase the indole ring must presumably be tautomerized to the following form of the quinonoid intermediate. The same species may be created by tryptophan synthase upon addition of indole to the enzyme-bound aminoacrylate. The green arrows on the structure indicate the tautomerization that would occur to convert the indole ring to the structure found in tryptophan. The three-dimensional structure of tryptophan synthase is shown in Fig. 25-3. It is a complex of two enzymes with a remarkable tunnel through which the intermediate indole can pass.[184,190] An unusual PLP-dependent β replacement is used to synthesize a transfer RNA ester of **selenocysteine** prior to its insertion into special locations in a few proteins (Chapter 15, Section G, and Chapter 29).

***Decarboxylation* (Group *b*).** The bond to the carboxyl group of an amino acid substrate is broken in reactions catalyzed by **amino acid decarboxylases**.[191,192] These also presumably lead to a transient quinonoid-carbanionic intermediate. Addition of a proton at the original site of decarboxylation followed by breakup of the Schiff base completes the sequence. Decarboxylation of amino acids is nearly irreversible and frequently appears as a final step in synthesis of amino compounds. For example, in the brain glutamic acid is decarboxylated to **γ-aminobutyric acid** (Gaba),[193–196b] while 3,4-dihydroxyphenylalanine (dopa) and 5-hydroxy-

tryptophan are acted upon by an **aromatic amino acid decarboxylase** to form, respectively, the neurotransmitters **dopamine** and **serotonin**.[197–199b] Histidine is decarboxylated to **histamine**.[200–202] However, not all histidine decarboxylases use PLP as a coenzyme (Section F).

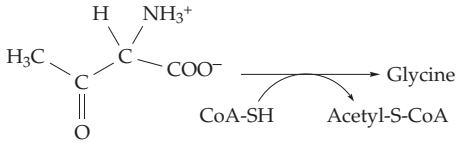
Arginine is converted by a PLP-dependent decarboxylase to agmatine (Fig. 24-12) which is hydrolyzed to **1,4-diaminopropane**.[191] This important cell constituent is also formed by hydrolysis of arginine to **ornithine** (Fig 24-10) and decarboxylation of the latter.[203–206c] **Lysine** is formed in bacteria by decarboxylation of *meso*-diamino-pimelic acid (Fig. 24-14). **Glycine** is decarboxylated oxidatively in mitochondria in a sequence requiring lipoic acid and tetrahydrofolate as well as PLP (Fig. 15-20).[207–209b] A **methionine** decarboxylase has been isolated in pure form from a fern.[210] The bacterial **dialkylglycine** decarboxylase is both a decarboxylase and an aminotransferase which uses pyruvate as its second substrate forming a ketone and L-alanine as products (See Eq. 14-37)[210a, 210b]

***Side chain cleavage* (Group *c*).** In a third type of reaction the side chain of the Schiff base of Fig. 14-5 undergoes aldol cleavage. Conversely, a side chain can be added by β condensation. The best known enzyme of this group is **serine hydroxymethyltransferase**, which converts serine to glycine and formaldehyde.[211–213b] The latter is not released in a free form but is transferred by the same enzyme specifically to **tetrahydrofolic acid** (Eq. 14-30), with which it forms a cyclic adduct.



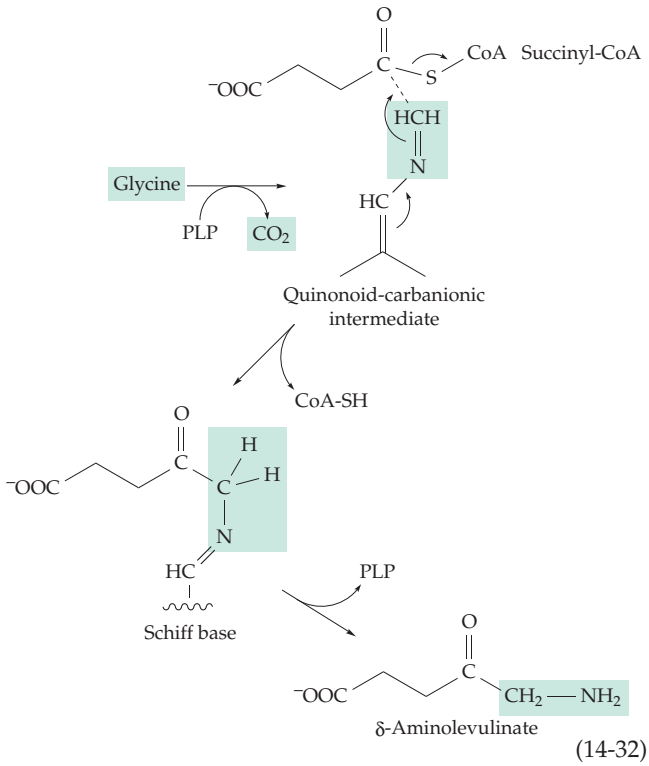
(14-30)

Threonine is cleaved to acetaldehyde by the same enzyme. A related reaction is indicated in Fig. 24-27 (top). In a more important pathway of degradation of threonine the hydroxyl group of its side chain is dehydrogenated to form 2-amino-3-oxobutyrate which is cleaved by a PLP-dependent enzyme to glycine and acetyl-CoA (Eq. 14-31).[214,215]



(14-31)

Conversely, ester condensation reactions join acyl groups from CoA derivatives to Schiff bases derived from glycine or serine. Succinyl-CoA is the acyl donor



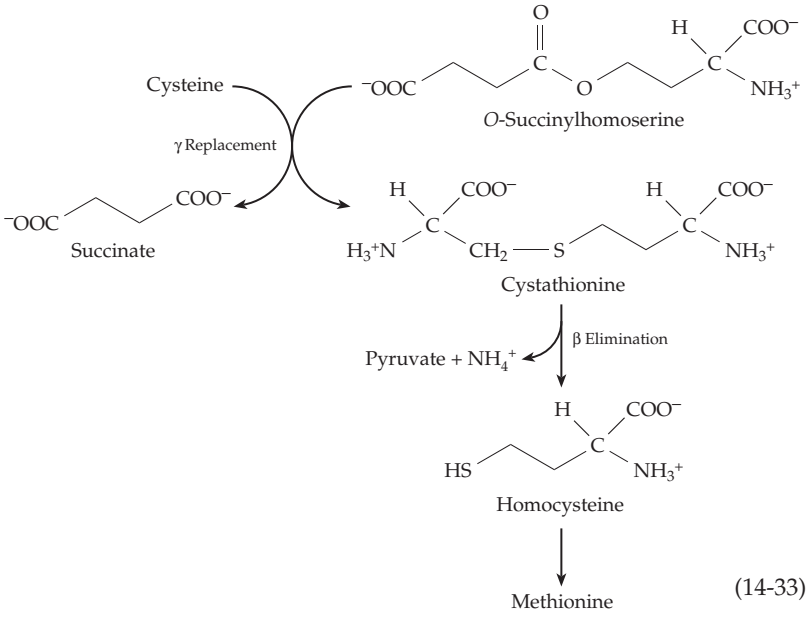
(14-32)

in Eq. 14-32 for the second known pathway for biosynthesis of **δ-aminolevulinic acid**, an intermediate in porphyrin synthesis (Chapter 24).[216–218b] The enzyme does not catalyze decarboxylation of glycine in the absence of succinyl-CoA, and the decarboxylation probably follows the condensation as indicated in Eq. 14-32.[219] In a similar reaction in the biosynthesis of **sphingosine** serine is condensed with palmitoyl-CoA and decarboxylated to form an aminoketone intermediate (Fig. 21-6).[219a] 8-Amino-7-oxonanonoate synthase forms a precursor of biotin (see banner, p. 719).[220]

***Ketimine intermediate as electron acceptor* (Group *d*).** The fourth group of PLP-dependent reactions are thought to depend upon formation of the ketimine intermediate of Eq. 14-28. In this form the original α-hydrogen of the amino acid has been removed and the C=NH$^+$ bond of the ketimine is polarized in a direction that favors electron withdrawal from the amino acid into the imine group. This permits another series of enzymatic reactions analogous to those of the β-oxo acid shown at the top of Fig. 14-5. Both elimination and C–C bond cleavage α,β to the C=N group of the ketimine can occur.

Enzymes of this group catalyze elimination of γ substituents from amino acids as illustrated in Fig. 14-7. Eliminated groups may be replaced by other substituents, either in the α or the β positions. The ketimine formed initially by such an enzyme (step *a*) undergoes elimination of the γ substituent (β with respect to the C=N group) along with a proton from the β position of the original amino acid to form an

unsaturated intermediate which can react in one of three ways, depending upon the enzyme. Addition of HY′ leads to γ replacement (step *c*), while addition of a proton at the α position leads, via reaction step *d*, to an α,β-unsaturated Schiff base. The latter can react by addition of HY′ (β replacement, step *e*) or it can break down to an α-oxo acid and ammonium ion (step *f*), just as in the β elimination reactions of Eq. 14-29. An important γ replacement reaction is conversion of *O*-acetyl-, *O*-succinyl-, or *O*-phosphohomoserine to cystathionine (Eq. 14-33). This **cystathionine γ-synthase** reaction[220a] lies on the pathway of biosynthesis of methionine by bacteria, fungi, and



(14-33)

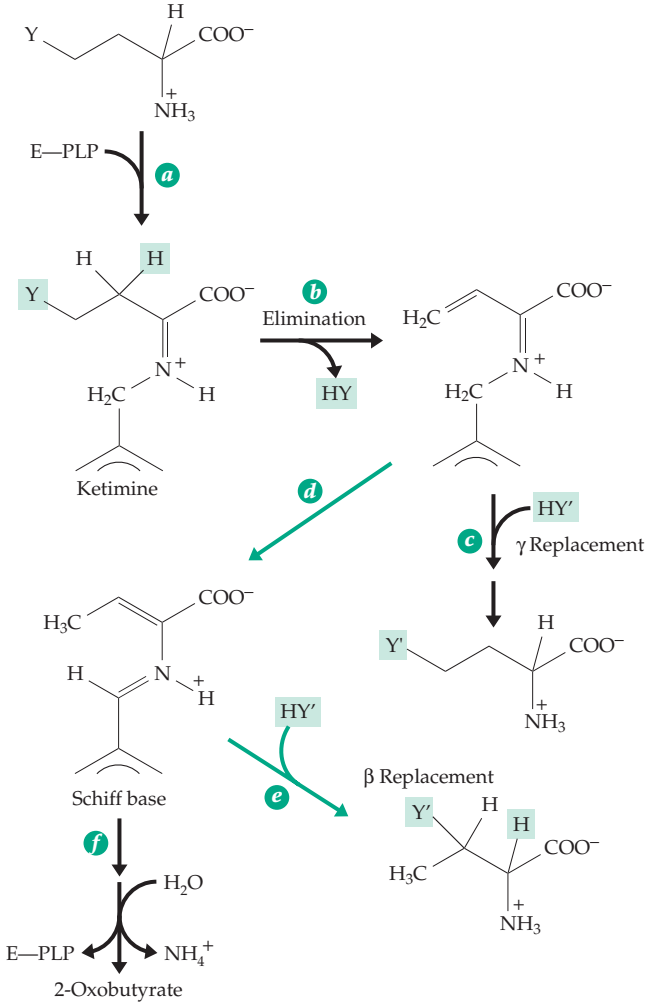


Figure 14-7 Some PLP-dependent reactions involving elimination of a γ substituent. Replacement by another γ substituent or by a substituent in the β position is possible, as is deamination to an α-oxo acid.

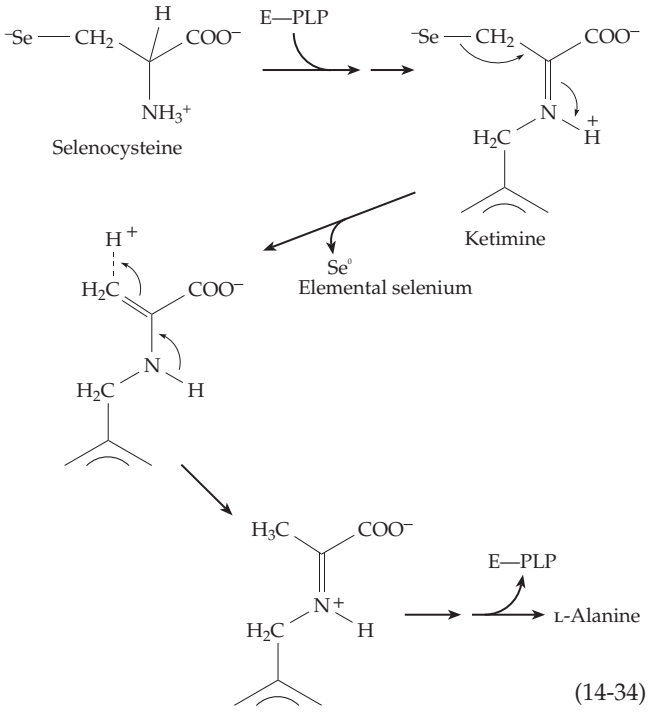
higher plants. Subsequent reactions include β elimination from cystathionine of **homocysteine**[220b] which is then converted to methionine (Eq. 14-33). Threonine is formed from ***O*-phosphohomoserine** via γ elimination followed by β replacement with HO^-, a reaction catalyzed by **threonine synthase** (Fig. 24-13).[220c]

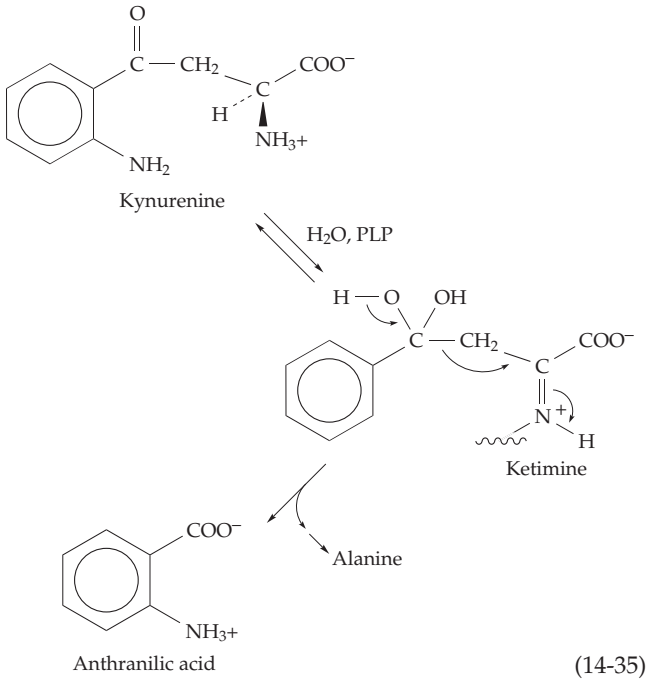
The loss of a β-carboxyl group as CO_2 can also occur through a ketimine or quinonoid intermediate. For example, the bacterial **aspartate β-decarboxylase**[221] converts aspartate to alanine and CO_2. **Selenocysteine** is utilized to create the active sites of several enzymes (Chapter 15). Excess selenocysteine is degraded by the PLP-dependent **selenocysteine lyase**,[222–223b] which evidently eliminates elemental selenium from a ketimine or quinonoid state of an intermediate Schiff base (Eq. 14-34). A similar reaction may occur in the biosynthesis of iron–sulfur clusters. The **Nif S** protein is essential for formation of Fe_4S_4 clusters in the nitrogen-fixing enzyme nitrogenase. This enzyme is in some way involved in transferring the sulfur atom of cysteine into an iron–sulfur cluster.[224] Alanine is the other product suggesting transfer of S^0 into the cluster using the sequence of Eq. 14-34.

Another related reaction that goes through a ketimine is the conversion of the amino acid **kynurenine** to alanine and anthranilic acid.[225] It presumably depends upon hydration of the carbonyl group prior to β cleavage (Eq. 14-35). An analogous thiolytic cleavage utilizes CoA to convert 2-amino-4-ketopentanoate to acetyl-CoA and alanine.[226]

Glycogen phosphorylase. While PLP is ideally designed to catalyze reactions of amino compounds it was surprising to find it as an essential cofactor for glycogen phosphorylase (Fig. 11-5). The PLP is linked as a Schiff base in the same way as in other PLP-depen-



(14-34)

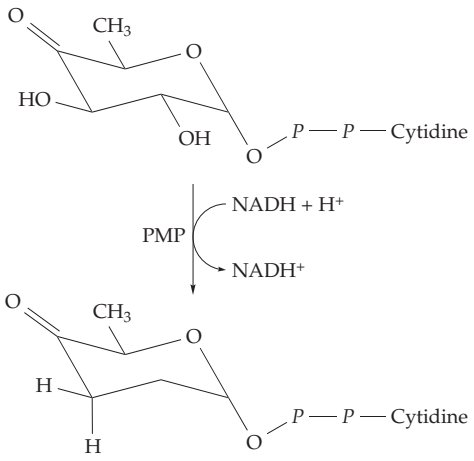


(14-35)

dent enzymes, but there is no obvious function for the coenzyme ring. As suggested in Chapter 12, the phosphate group probably acts as an acid–base catalyst. It has been estimated that 50% of the vitamin B_6 in our body is present as PLP in muscle phosphorylase.[227] Studies of vitamin B_6-deficient rats suggest that PLP in phosphorylase serves as a reserve supply, much of which can be taken for other purposes during times of deficiency.

4. Pyridoxamine Phosphate as a Coenzyme

If PLP is a cofactor designed to react with amino groups of substrates, might not pyridoxamine phosphate (PMP) act as a coenzyme for reactions of carbonyl compounds? An example of this kind of function has been found[228–230] in the formation of 3,6-dideoxyhexoses needed for bacterial cell surface antigens (Fig. 4-15). Glucose (as cytidine diphosphate glucose; CDP-glucose) is first converted to 4-oxo-6-deoxy-CDP-glucose. The conversion of the latter to 3,6-dideoxy-CDP-glucose (Eq. 14-36) requires PMP as well as NADH or NADPH.



(14-36)

The student may find it of interest to propose a mechanism for this reaction, taking into account the expected direct transfer of a hydrogen from NADH as described in Chapter 15, before consulting published papers. Part of the reaction cycle appears to involve a free radical derived from the PMP. This is discussed further in Chapter 20 together with free radical-forming PLP enzymes

5. Stereochemistry of PLP-Requiring Enzymes

According to stereoelectronic principles, the bond in the substrate amino acid that is to be broken by a PLP-dependent enzyme should lie in a plane perpendicular to the plane of the cofactor–imine π system (Fig. 14-8). This would minimize the energy of the transition state by allowing maximum σ–π overlap between the breaking bond and the ring–imine π system. It also would provide the geometry closest to that of the planar quinonoid intermediate to be formed, thus minimizing molecular motion in the approach to the transition state. Figure 14-8 shows three orientations of an amino acid in which the α-hydrogen, the carboxyl group, and the side chain, respectively, are positioned for cleavage. For each orientation shown, another geometry suitable for cleavage of the same bond is

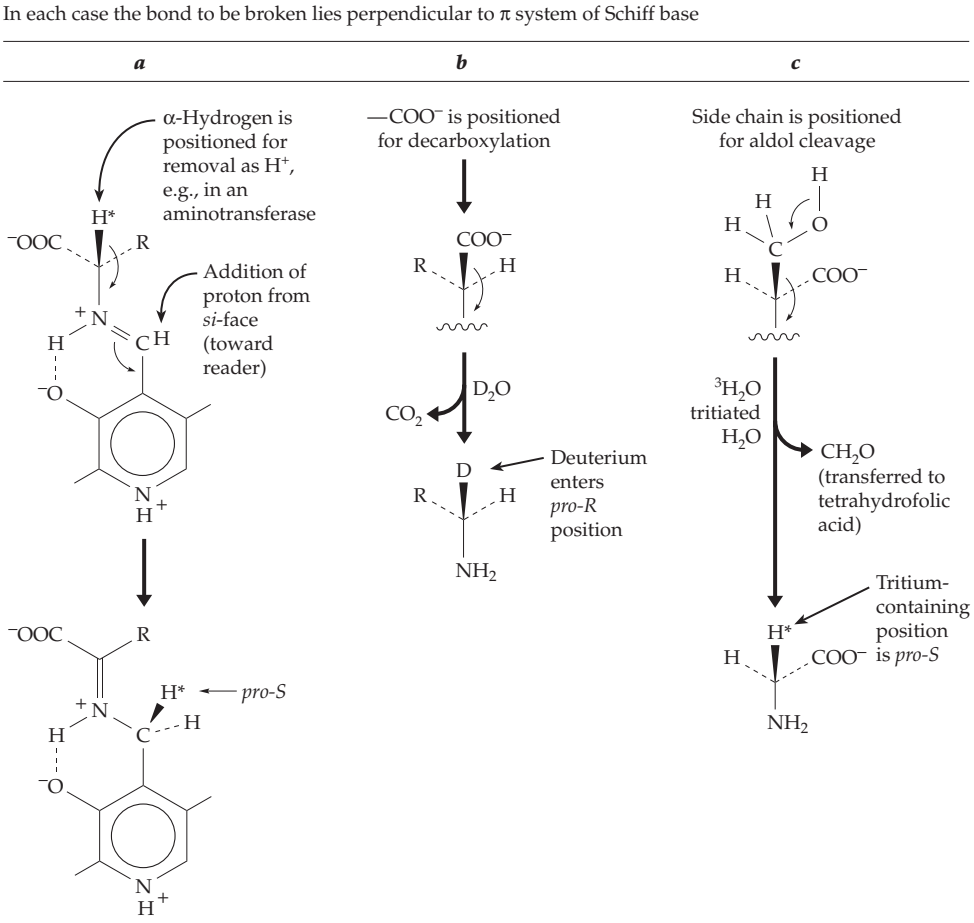


Figure 14-8 Some stereochemical aspects of catalysis of PLP-requiring enzymes.

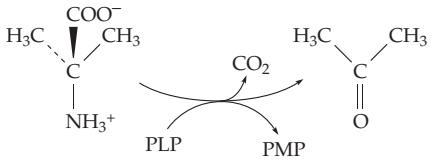
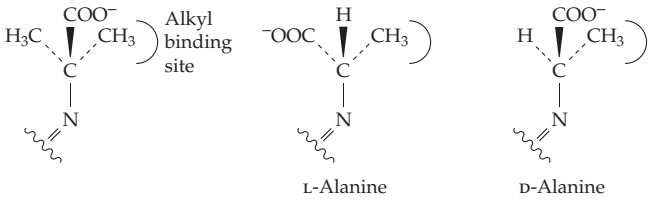
obtained by rotating the amino acid through 180°.

Dunathan suggested that this stereoelectronic requirement explains certain side reactions observed with PLP-requiring enzymes. The idea also received support from experiments with a bacterial α-dialkylglycinedecarboxylase.[231,232] The enzyme ordinarily catalyzes, as one half-reaction, the combination decarboxylation–transamination reaction shown in Eq. 14-37. It also acts on both D- and L-alanine, decarboxylating the former but catalyzing only removal of the α-H



(14-37)

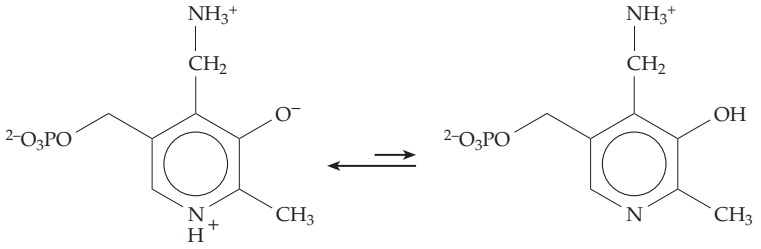
from L-alanine. The results can be rationalized by assuming that the enzyme possesses a definite site for one alkyl group but that the position of the second alkyl group can be occupied by –H or –COO^- and that the group labilized lies perpendicular to the π system:



Glycine is unreactive, suggesting that occupation of the alkyl binding site is required for catalysis.

According to Dunathan's postulate, there are only two possible orientations of the amino acid substrate in an aminotransferase. One is shown in Fig. 14-8. In the other, the amino acid is rotated 180° so that the α-hydrogen protrudes *behind* the plane of the paper. Dunathan studied **pyridoxamine:pyruvate aminotransferase**, an enzyme closely related to PLP-requiring aminotransferases and which catalyzes the transamination of pyridoxal with L-alanine to form pyridoxamine and pyruvate. The same reaction is catalyzed by the apoenzyme of aspartate aminotransferase. In both cases, when the alanine contained ^2H in the α position the ^2H was transferred stereospecifically into

the *pro-S* position at C-4' of the pyridoxamine (indicated by asterisks in Fig. 14-8).[233] The results suggested that a group from the protein abstracts a proton from the α position and transfers it on the same side of the π system (**suprafacial transfer**), adding it to the *si* face of the C=N group as shown in Fig. 14-8. Later, the same stereospecific proton transfer was demonstrated for the PLP present in the holoenzyme.[234] Not surprisingly, the D-amino acid aminotransferase adds the proton to the *re* face of the C=N group.[235]



Dipolar ionic form
I 327 nm
II 253 nm
III 217 nm

Minor non-dipolar ionic tautomer
I 283 nm

(14-38)

When a decarboxylase acts on an amino acid in ^2H_2O, an atom of ^2H is incorporated in the *pro-R* position, the position originally occupied by the carboxyl group (Fig. 14-8). Cleavage of serine by serine hydroxymethyltransferase in ^3H-containing water leads to incorporation of ^3H in the *pro-S* position. Stereospecific introduction of ^2H or ^3H has been observed in the β position of 2-oxobutyrate formed in β or γ elimination reactions. Conversion of serine to tryptophan by tryptophan synthetase occurs without inversion at C-3.[236] These and many other observations on PLP-dependent enzymes[189,237,238] can be generalized by saying that enzymatic reactions of PLP Schiff bases usually take place on only one face of the relatively planar structure. This is the *si* face at C-4' of the coenzyme (see Fig. 14-8). This result is expected if a single acid–base group serves as proton acceptor in one step and as proton donor in a later step. This leads naturally to the observed retention of configuration in steps involving replacement and the suprafacial transfer of protons from one position on that face to another.

6. Seeing Changes in the Optical Properties of the Coenzyme

The absorption of light in the ultraviolet and visible regions is a striking characteristic of many coenzymes. It can be measured accurately and displayed as an absorption spectrum and may also give rise to circular dichroism and to fluorescence (Chapter 23). The optical properties of the vitamin B_6 coenzymes are sensitive to changes both in environment and in the state of protonation of groups in the molecule. For example, PMP in the neutral dipolar ionic form, which exists at pH 7, has three strong light absorption bands centered at 327, 253, and 217 nm.[239] The other ionic forms of PMP and other derivatives of vitamin B_6 also each have three absorption bands spaced at roughly similar intervals, but with varying positions and intensities. The minor tautomer of PMP containing an uncharged ring (Eq. 14-38) has its low-energy (long-wavelength) band at 283 nm. When both the ring nitrogen and phenolic oxygen are protonated, the band shifts again to 294 nm and if both groups are deprotonated the resulting anion absorbs at 312 nm. Thus, observation of the absorption spectrum of the coenzyme bound to an enzyme surface can tell us whether particular groups are protonated or unprotonated. The peak of bound PMP at 330 nm in aspartate aminotransferase (Fig. 14-9) is indicative of the dipolar ionic form (Eq. 14-38). However, the 5-nm shift from the position of free PMP suggests a distinct change in environment.

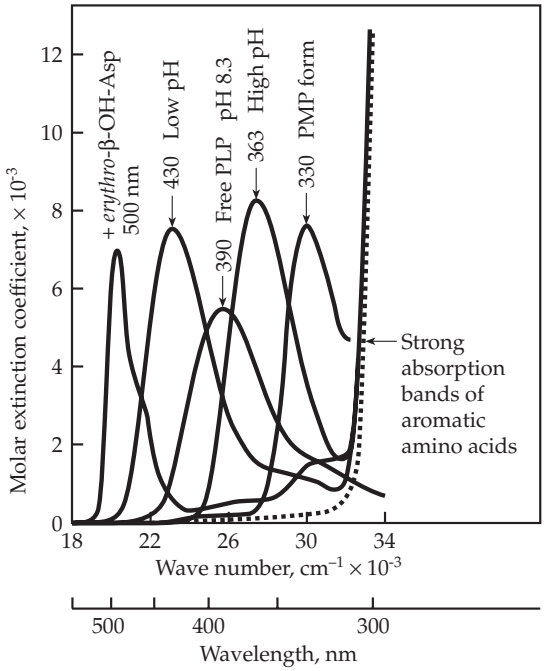


Figure 14-9 Absorption spectra of various forms of aspartate aminotransferase compared with that of free pyridoxal phosphate. The low pH form of the enzyme observed at pH <5 is converted to the high pH form with $pK_a \sim 6.3$. Addition of *erythro*-3-hydroxyaspartate produces a quinonoid form whose spectrum here is shown only 1/3 its true height. The spectrum of free PLP at pH 8.3 is also shown . The spectrum of the apoenzyme (**- - -**) contains a small amount of residual absorption of uncertain origin in the 300- to 400-nm region.

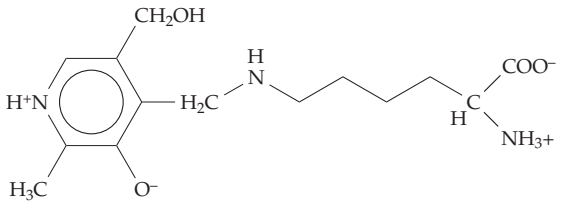
Pyridoxal phosphate exists in an equilibrium between the aldehyde and its covalent hydrate (as in Eq. 13-1). The aldehyde has a yellow color and absorbs at 390 nm (Fig. 14-9), while the hydrate absorbs at nearly the same position as does PMP. The absorption bands of Schiff bases of PLP are shifted even further to longer wavelengths, with N-protonated forms absorbing at 415–430 nm. Forms with an unprotonated C=N group absorb at shorter wavelengths.[149,240]

Imine groups in free enzymes. When, in 1957, W. T. Jenkins examined one of the first highly purified aspartate aminotransferase preparations he noted a surprising fact: The bound coenzyme, at pH 5, absorbed not at 390 nm, as does PLP, but at 430 nm, like a Schiff base (Fig. 14-9). When the pH was raised, the absorption band shifted to 363 nm. The result suggests dissociation of a proton (with a pK_a of ~ 6.3) from the hydrogen-bonded position in a Schiff base of the type shown in Fig. 14-6. It was quickly demonstrated for this enzyme and for many other PLP-dependent enzymes that reduction with sodium borohydride caused the spectrum to revert to one similar to that of PMP and fixed the coenzyme to the protein. After complete HCl digestion of such borohydride-reduced proteins a fluorescent amino acid containing the reduced pyridoxyl group was obtained and in every case was identified as ε-pyridoxyl-lysine. Thus, PLP-containing enzymes in the absence of substrates usually exist as Schiff bases with lysine side chains of the proteins. Even the PLP in glycogen phosphorylase is joined in this way. However, its absorption maximum at 330 nm shows



ε-Pyridoxyllysine

that in phosphorylase it is present as the nondipolar ionic tautomer with a 3-OH group on the ring as in Eq. 14-38.

Absorption bands at 500 nm. With many PLP enzymes certain substrates and inhibitors cause the appearance of intense and unusually narrow bands at ~500 nm. Such a band is observed with aspartate aminotransferases acting on *erythro*-3-hydroxyaspartate (Fig. 14-9). This substrate undergoes transamination very slowly, and the 500-nm absorbing form which accumulates is probably an intermediate in the normal reaction sequence. A similar spectrum is produced by tryptophan indole-lyase acting on the competitive inhibitor L-alanine. Under the same conditions the enzyme promotes a rapid exchange of the α-hydrogen of the alanine with ^2H of ^2H_2O. Serine hydroxymethyltransferase gives a 495- to 500-nm band with both D-alanine and the normal product glycine.[241] Similar spectra have been produced in nonenzymatic model reactions[242] and probably represent the postulated quinonoid–carbanionic intermediates.

7. Atomic Structures

The three-dimensional structures of aspartate aminotransferases from *E. coli* to humans are very similar.[163–167a] The folding pattern (Fig. 2-6) and active site structure (Figs. 14-6 and 14-10) are completely conserved. The major domain of the protein contains a central β sheet surrounded by helices with coenzyme attached to a lysine at the C terminus of one of the β strands. The protein is a dimer with the two major domains held together by both polar and nonpolar interactions. The two active sites are located at the interface between the subunits and residues from both subunits participate in forming the active site (Fig. 14-10). The internal Schiff base is formed with Lys 258. The protonated ring nitrogen of the dipolar ionic PLP forms an ion pair with the carboxylate of Asp 222 which protrudes from a central seven-stranded β sheet. The phenolic $-O^-$ forms a hydrogen bond with the –OH of Tyr 225. The interactions of Asp 222 and Tyr 225 fix the ring as the dipolar ionic tautomer.

The phosphate group of the coenzyme, which ^{31}P NMR shows to be predominantly dianionic,[243] forms an ion pair with the side chain of Arg 266 and hydrogen bonds to a backbone N–H at the N terminus of a long helix where it can interact with the positive end of the helix dipole. In addition, the phosphate forms hydrogen bonds to four OH groups of Ser, Thr, and Tyr side chains. In front of the coenzyme ring are two guanidinium groups from the side chains of Arg 386 and of Arg 292* (from the second subunit). These have been shown by X-ray crystallography to bind the two carboxylate groups of a substrate such as glutamate, 2-oxoglutarate, aspartate, oxaloacetate, or cysteine sulfinate; of quasi-substrates such as 2-methylaspartate and *erythro*-β-hydroxyaspartate; or of dicarboxylic inhibitors (Fig. 14-10).

Comparison of amino acid sequences suggests that many other PLP-dependent enzymes have folding patterns similar to those of aspartate aminotransferase but that there are four or more additional different folding patterns.[205,243a,b] Among the enzymes resembling aspartate aminotransferase are ω-amino acid: pyruvate aminotransferase,[244] 2,3-dialkylglycine decarboxylase,[232] tyrosine phenol-lyase,[177] a bacterial ornithine decarboxylase,[182,204] and cystathionine β-lyase.[182] The tryptophan synthase β subunit has a second folding pattern,[184] while alanine racemase[153] and eukaryotic

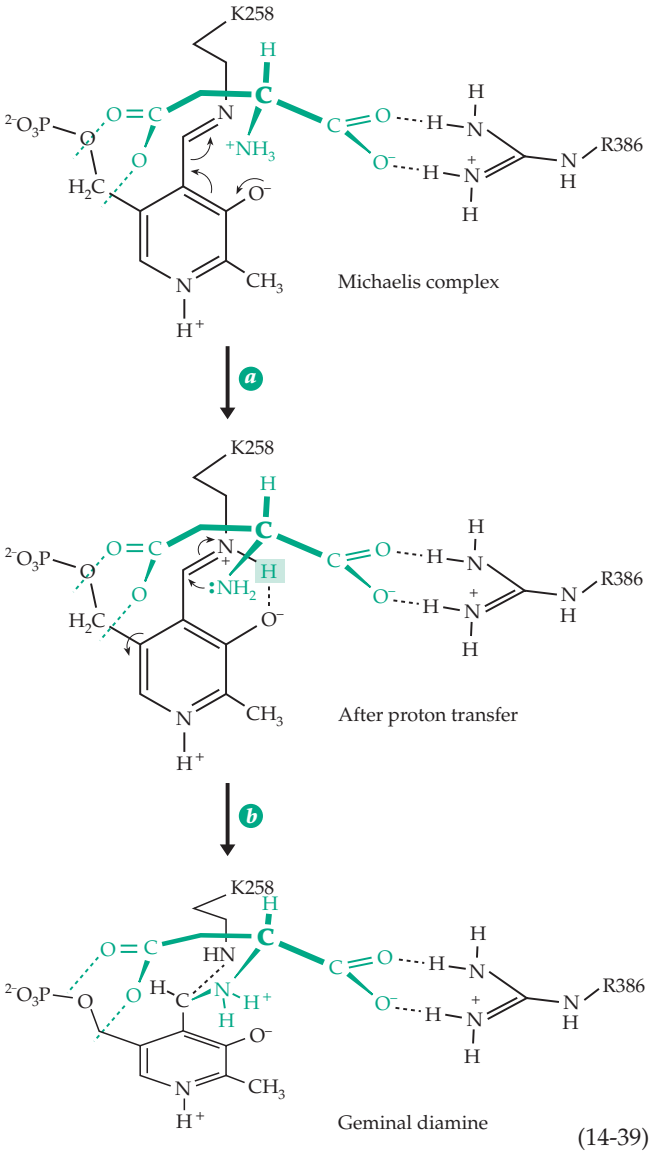
ornithine decarboxylases[205] have $(\alpha\beta)_8$-barrel structures resembling that in Fig. 2-28. A fourth structural pattern is that of D-amino acid aminotransferase.[235] It is anticipated that the branched-chain aminotransferase[245] will have a similar stucture. Glycogen phosphorylase (Fig 11-5) has a fifth folding pattern.

8. Constructing a Detailed Picture of the Action of a PLP Enzyme

Consider the number of different steps that must occur in about one-thousanths of a second during the action of an aminotransferase. First, the substrate binds to form the "Michaelis complex." Then the transimination (Eq. 14-26) takes place in two steps and is followed by the removal of the α-hydrogen to form the quinonoid intermediate. An additional four steps are needed to form the ketimine, to hydrolyze it, and to release the oxoacid product to give the PMP form of the enzyme. The reaction sequences in some of the other enzymes are even more complex. How can one enzyme do all this?

The first step in the sequence is the binding of the substrate to form the "Michaelis complex." The positive charges on Arg 386 and Arg 292 doubtless attract the carboxylate groups of the substrate and aid in guiding it toward a correct fit. In a similar manner the $-O^-$ of the coenzyme, which is distributed by resonance into the $-C=N$ of the Schiff base linkage, attracts the $-NH_3^+$ of the substrate. When a substrate or inhibitor binds to the two guanidinium groups a small structural domain of the enzyme moves and closes around the substrate which now has very little contact with the external solvent. In the initial "Michaelis complex" the $-NH_3^+$ group of the substrate lies directly in front of the C-4' carbon of the coenzyme (Fig. 14-10), where it can initiate the transimination reaction of Eq. 14-26. However, before this can happen a proton must be removed to convert the $-NH_3^+$ to $-NH_2$.

Long before the three-dimensional structures were known, Ivanov and Karpeisky[246] suggested that in the free enzyme the positively charged group (Arg 386) that binds the α-carboxylate of the substrate interacts electrostatically with the $-O^-$ of the coenzyme. This is one of the factors that keeps the pK_a of the $-CH=N^+H-$ that is conjugated with this $-O^-$ at a low value of ~6.3 (at 0.1 M anion concentration). However, in the Michaelis complex this interaction of the + charge of Arg 386 with the imine group must be weakened because of the pairing of the $\alpha-COO^-$ of the substrate with the + charge. This will increase the basicity of the imine nitrogen and will also cause a decrease in the pK_a of the substrate $-NH_3^+$, making is easier for a proton to jump from the $-NH_3^+$ to the imine group. This proton transfer is shown in Eq. 14-39, step *a*. Thus, the nucleophilic $-NH_2$ group is generated by a



(14-39)

process that at the same time increases the electrophilic properties of the carbon atom of the imine group. This favors the immediate addition of $-NH_2$ to $-C=N^+H-$ to give the adduct a **geminal diamine** (Eq. 14-39, step *b*), which is shown in three dimensions in Fig. 14-10B.

Notice that each step in the overall sequence changes the electronic or steric characteristics of the complex in a way that facilitates the next step.[246] This is an important principle that is applicable throughout enzymology: *For an enzyme to be an efficient catalyst each step must lead to a change that sets the stage for the next*. These consecutive steps often require proton transfers, and each such transfer will influence the subsequent step in the sequence. Some steps also require alterations in the conformation of substrate, coenzyme, and enzyme. One of these is the transimination sequence (Eqs. 14-26, 14-39). On the basis of the observed loss of circular dichroism in the external aldimine, Ivanov and Karpeisky suggested that a

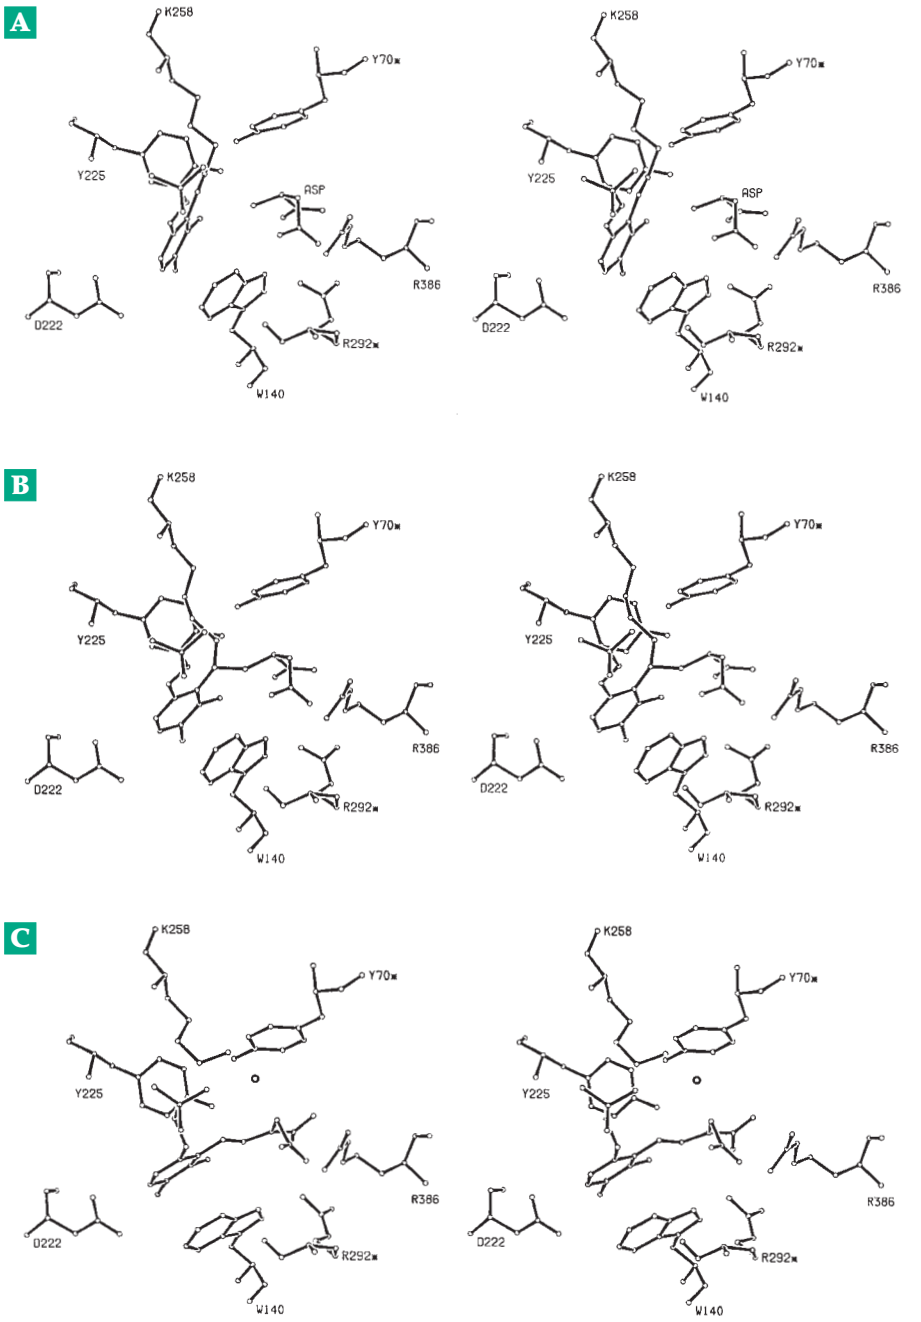


Figure 14-10 Models of catalytic intermediates for aspartate aminotransferase in a half-transamination reaction from aspartate to oxalocetate. For clarity, only a selection of the active site groups are shown. (A) Michaelis complex of PLP enzyme with aspartate. (B) Geminal diamine. (C) Ketimine intermediate. The circle indicates a bound water molecule. See Jansonius and Vincent in Jurnak and McPherson.[163] Courtesy of J.N. Jansonius.

rotation of the coenzyme occurs as the $-NH_2$ of the substrate adds to the C = N bond during transimination (Eq. 14-39, step *b*). This accomplishes the essential shortening by ~0.15 nm of the distance between C-4' and the N atom from a van der Waals contact distance to a covalent bond distance while the carboxylate groups of the substrate remain bound in their initial positions.

That the coenzyme really does change its orientation was suggested by a dramatic change in the absorption spectrum of a crystal recorded with plane polarized light (linear dichroism) when 2-methylaspartate was soaked into a crystal (Fig. 23-9).[247] X-ray crystallography confirmed rotation of the ring by ~30°.[163,242,247] To complete the transimination sequence, which is shown only partially by Eq. 14-39, another proton transfer is needed to move the positive charge on the substrate $-N^+H_2-$ to that of lysine 258, whose amino group is then eliminated. This requires additional tilting of the ring. The crystal structure of the external aldimine with α-methylaspartate has been determined[248] as have those of ketimines with glutamate and aspartate,[249,250] a carbinolamine,[251] and quinonoid complexes of related enzymes.[212a]

The ε-amino group, which is eliminated in Eq. 14-26, is basic and functions in the next several steps of catalysis, including the abstraction of the α-hydrogen and in its transfer to the 4'-carbon (Eq. 14-28). This amino group can be seen in Fig. 14-10C, where it is positioned beside a water molecule that is needed to hydrolyze the ketimine. From this figure it can be seen that the group is able to move from site to site on one side of the planar external aldimine, quinonoid–carbanionic, and nearly planar ketimine forms. If the Lys 258 amino group is the catalytic base for these reactions it must be present at pH 7. What is its pK_a? And why doesn't this pK_a show up in the plot of V_{max} vs pH as in Fig 9-9? In fact, the maximum velocity of aspartate aminotransferase and many other PLP-dependent enzymes is independent of pH over a broad range. The answer is probably that the pK_a's of both the $-NH_2$ groups of Lys 258 and the amino acid in the Michalis complex are high when there is no positive charge on the adjacent Schiff base $-C=N-$ but

very low when the Schiff base is protonated (–C=NH^+–). This is a result of the large electrostatic effect of a closely adjacent charge in a medium of low dielectric constant (see Chapter 7, Section A). When the Schiff base is unprotonated, as in the first structure of Eq. 14-39, the adjacent amino group has a *high* pK_a and is mostly protonated. However, the proton can jump as in step *a* of that equation to give a protonated Schiff base. Now the unprotonated $-NH_2$ group has a very *low* pK_a, but it is still strongly nucleophilic and can readily add to the Schiff base double bond in step *b* of Eq. 14-39. In a similar fashion the amino group of Lys 258 will alternately be unprotonated and then protonated, its microscopic pK_a alternating between low and high, as it catalyzes the steps of abstracting the α-hydrogen and forming and hydrolyzing the ketimine. Only two microscopic pK_a values, one very high and one very low appear in the V_{max} vs pH profile. This alternation of microscopic pK_a values may be a common characteristic of enzymes that bind ionized substrates and can make good use of the strong electrostatic effects that arise in the active sites to facilitate essential proton transfers.

Aspartate aminotransferases are distinguished from most other PLP-dependent enzymes including transaminases by the relatively low pK_a of ~6.3 for the *free* enzyme. The unprotonated Schiff base in the free enzyme can then react with the protonated amino group of the substrate. How can other PLP enzymes react with amino acids when they have protonated Schiff bases even at relatively high pH? A logical answer is that some basic group with a low pK_a is close to the Schiff base and acts to deprotonate the substrate $-NH_3^+$ so that transimination can occur. Clausen *et al*. suggested that in cystathionine β-lyase this is probably tyrosine (Y111), which is adjacent to the Schiff base –C=NH^+– of the external aldimine and is thought to be ionized in the active enzyme.[182] NMR evidence suggests that protonation of an adjacent catalytic base occurs upon substrate binding in D-serine dehydratase as well.[252] Many other variations in active site environments are seen among PLP-dependent enzymes. As with aspartate aminotransferases, there is often an essential carboxylate group that holds a proton onto the pyridine ring of the coenzyme. However, in alanine racemase a guanidinium group from arginine is hydrogen bonded to the coenzyme ring.[153]

Below the active site of aspartate aminotransferase, as shown in Fig. 14-6, is a cluster of three buried histidine side chains in close contact with each other. The imidazole of H143 is hydrogen bonded to the D222 carboxylate, the same carboxylate that forms an ion pair with the coenzyme. This system looks somewhat like the catalytic triad of the serine proteases in reverse. As with the serine proteases, the proton-labeled H_b in Fig. 14-6 can be "seen" by NMR spectroscopy (Fig. 3-30). So can the proton H_a on the PLP ring. These protons act as built-in sensors able to detect small changes in the electronic environment. For example, when the Schiff base proton dissociates around the pK_a of ~6.2 the NMR resonance of H_a shifts upfield from 17.2 to 15.2 ppm as a result of donation of electons into the ring from the $-O^-$ of the coenzyme.[169] This shift illustrates the reality of the strong electrostatic forces that operate across heterocyclic aromatic rings within active sites of proteins. In alanine racemase a different histidine cluster is present beneath the active site and constitutes part of the "solvent" in which the catalyzed reaction takes place. At least in the case of aspartate aminotransferase, none of the histidines are absolutely essential for activity but the hydrogen-bonded network, which can be altered in mutant forms, may be important.

The detailed description of a reaction sequence given here has to be altered for each specific enzyme. A vast amount of work, only a little of which is cited here, has been done on PLP enzymes.[253–254a] These studies involve calorimetry,[255] kinetics,[210,256–259] crystallography, optical spectroscopy,[188,260,261] NMR,[243,262–264] and genetic engineering and chemical modification.[178,185,186,265]

F. Pyruvoyl Groups and Other Unusual Electrophilic Centers

A few enzymes that might be expected to have PLP at their active sites have instead a prosthetic group consisting of pyruvic acid bound by an amide linkage, a **pyruvoyl group** (Table 14-4). These and several apparently related enzymes are the subject of this section.

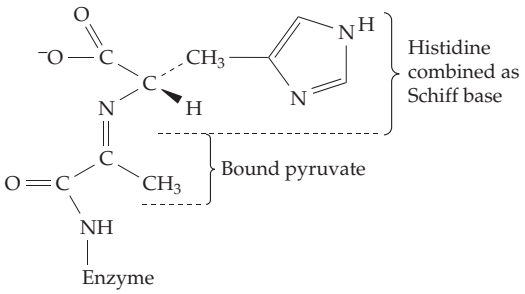
TABLE 14-4
Some Pyruvoyl Enzymes

Decarboxylases	Product
Histidine (bacterial)	
S-Adenosylmethionine	
Aspartate α- decarboxylase	β-Alanine
Phosphatidylserine	Phosphatidyl-ethanolamine
4' - Phosphopantothenylcysteine	4' - Phosphopan-tetheine
Reductases (clostridial)	
Proline	
Glycine	

Adapted from van Peolje and Snell.[267]

1. Decarboxylases

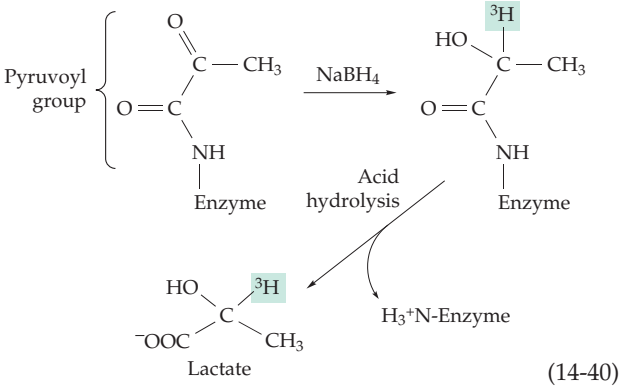
Mammalian **histidine decarboxylase** contains PLP but the enzyme from many bacteria contains a pyruvoyl group, as do a few other decarboxylases both of bacterial and eukaryotic origin.[266,267] These enzymes are inhibited by carbonyl reagents and by borohydride. When ^3H-containing borohydride was used to reduce the histidine decarboxylase of *Lactobacillus*, ^3H was incorporated and was recovered in lactic acid following hydrolysis. This suggested the presence of a pyruvoyl group attached by an amide linkage and undergoing the chemical reactions that are shown in Eq. 14-40. Reduction in the presence of the substrate histidine resulted in covalent binding of the histidine to the bound pyruvate. Thus, as with the PLP-containing decarboxylases, a Schiff base is formed with the substrate. Decarboxylation is presumably accomplished by using the electron-attracting properties of the carbonyl group of the amide:



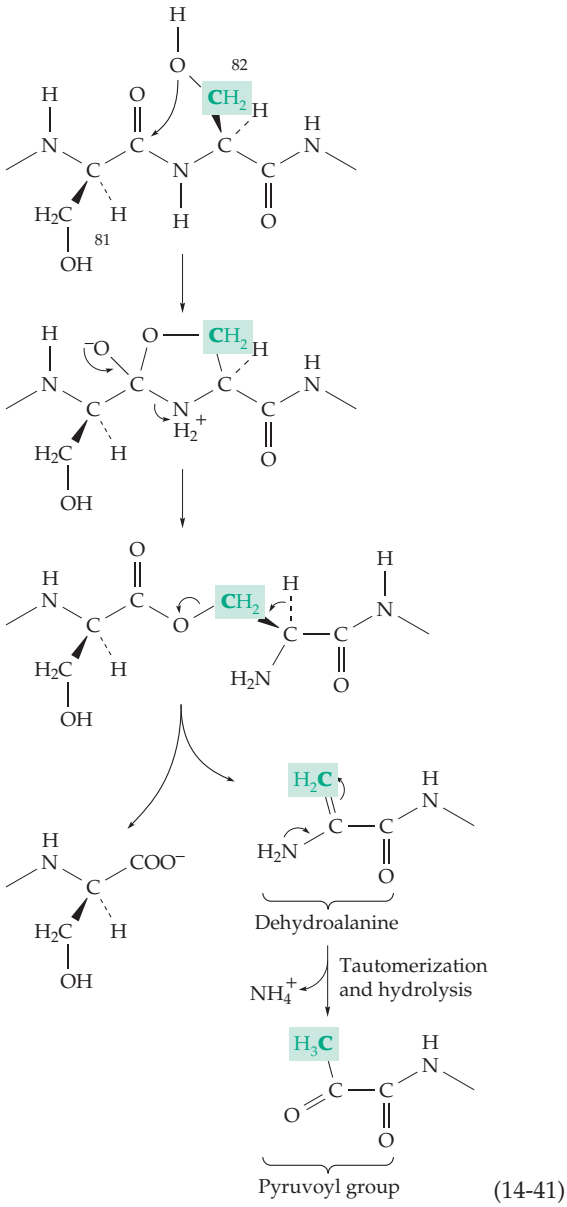
When ^{14}C-labeled serine was fed to organisms producing histidine decarboxylase, ^{14}C was incorporated into the bound pyruvoyl group (Fig. 14-11). Thus, serine is a precursor of the bound pyruvate. The enzyme is manufactured in the cell as a longer 307-residue proenzyme which associates as hexamers (designated π_6). The active enzyme was found to be formed by cleavage of the π chains between Ser 81 and Ser 82 to form 226-residue α chains and 81-residue β chains which associate as $(\alpha\beta)_6$.[270,271] The α chains carry the N-terminal pyruvoyl group, which was formed from Ser 82. The activation occurs spontaneously by incubations of the proenzyme for 24–48 h at pH ~7 in the presence of divalent metal ions.

Substituted serine residues under mildly alkaline conditions readily undergo α,β elimination to form **dehydroalanine** residues. When prohistidine decarboxylase containing ^{18}O in its serine side chains was activated ^{18}O was found in the carboxylate group of Ser 81 of the β chains. It was shown that it had been transferred from the side chain of Ser 82. This suggested the formation of an intermediate oxygen ester of Ser 81 during formation of the pyruvoyl group (Eq. 14-41).[272]

***S*-Adenosylmethionine decarboxylase** is the first enzyme in the biosynthetic pathway to spermidine (Chapter 24). Whether isolated from bacteria, yeast, animals, or other eukaryotes, this enzyme always contains a bound pyruvoyl group.[273–274b] Both the



(14-40)



(14-41)

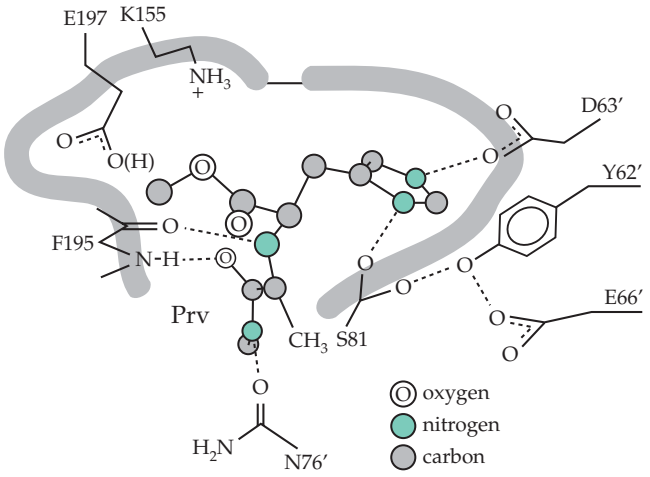


Figure 14-11 Schematic diagram of the active site of the pyruvoyl enzyme histidine decarboxylase showing key polar interactions between the pyruvoyl group and groups of the inhibitor *O*-methylhistidine and surrounding enzyme groups. Aspartate 63 appears to form an ion pair with the imidazolium group of the substrate.[268] Hydrogen bonds are indicated by dotted lines. See Gallagher *et al.*[269]

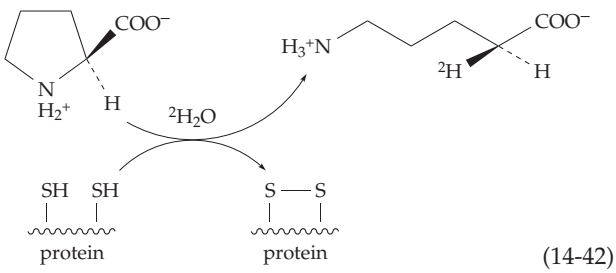
mammalian enzyme and that from *E. coli* are $(\alpha\beta)_4$ tetramers formed in a manner similar to that of bacterial histidine decarboxylase. Other pyruvoyl decarboxylases are **phosphatidylserine decarboxylase**,[275,276] an intrinsic membrane protein used to form phosphatidylethanolamine, **aspartate α-decarboxylase**,[277] which forms β alanine needed for biosynthesis of coenzyme A, and **4'-phosphopantethenoylcysteine decarboxylase**,[278] the second of two decarboxylases required in the synthesis of coenzyme A. Because of the lack of a primary amino group, its mechanism must be somewhat different from that of other enzymes in this group.[267]

2. Proline and Glycine Reductases

An enzyme required in the anaerobic breakdown of proline by clostridia utilizes a dithiol-containing protein to reductively open the ring (Eq. 14-42).[279,280]



(14-42)

This enzyme also contains an N-terminal pyruvoyl residue as does one subunit of a selenium-containing glycine reductase which utilizes a dithiol to convert glycine into acetate with coupled formation of ATP:

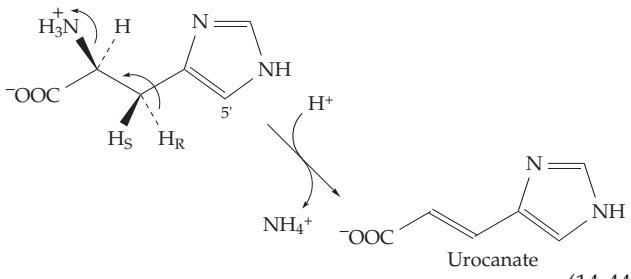
$$\text{Glycine} + \text{ADP} + P_i + 2\,e^- \rightarrow \text{acetate}^- + NH_4^+ + \text{ATP} \qquad (14\text{-}43)$$

In both cases it has been proposed that the pyruvoyl group forms a positively charged Schiff base with the substrate. The bond-breaking mechanisms are not obvious but some ideas have been proposed.[281–283a] The ATP may arise from reaction with an intermediate acetyl phosphate.[282] See Eq. 15-61.

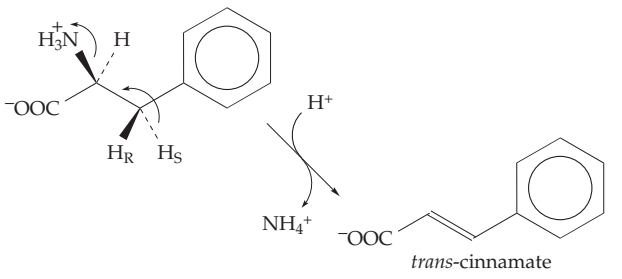
3. Dehydroalanine and Histidine and Phenylalanine Ammonia-Lyases

Catabolism of histidine in most organisms proceeds via an initial elimination of NH_3 to form **urocanic acid** (Eq. 14-44). The absence of the enzyme **L-histidine ammonia-lyase** (histidase) causes the genetic disease histidinemia.[284,285] A similar reaction is catalyzed by the important plant enzyme **L-phenylalanine ammonia-lyase**. It eliminates $-NH_3^+$ along with the *pro-S* hydrogen in the β position of phenylalanine to form *trans*-cinnamate (Eq. 14-45). Tyrosine is converted to *p*-coumarate by the same enzyme. Cinnamate and coumarate are formed in higher plants and are converted into a vast array of derivatives (Box 21-E, Fig. 25-8).

The reactions of Eqs. 14-44 and 14-45 are unusual because the nucleophilic substituent eliminated is on the α-carbon atom rather than the β. There is nothing in the structures of the substrates that would permit an



(14-44)



(14-45)

easy elimination of the α-amino group. Thus, it should not be surprising that both enzymes contain a special active center. When ^2H is introduced into the β position of phenylalanine, no isotope effect on the rate is observed. Rather, the rate-limiting step appears to be the release of ammonia from the coenzyme group. It appears that the enzyme must in some way make the amino group a much better leaving group than it would be otherwise.

Both enzymes are inhibited by sodium borohydride and also by nitromethane. After reduction with NaB^3H_4 and hydrolysis, ^3H-containing alanine was isolated. This suggested that they contain **dehydroalanine**, which could arise by dehydration of a specific serine residue.[286,287] For phenylalanine ammonia-lyase from *Pseudomonas putida* this active site residue has been identified as S143. Replacement by cysteine in the S143C mutant also gave active enzyme while S143A

BOX 14-D DIETARY REQUIREMENTS FOR B VITAMINS

It is difficult to determine the amounts of vitamins needed for good health and they may differ considerably from one individual to another. The quantities listed below are probably adequate for most young adults but must be increased during pregnancy and lactation and after very strenuous exercise.

Pantothenic acid: 10–15 mg/day. Deficiency causes apathy, depression, impaired adrenal function, and muscular weakness. ω-Methylpantothenic acid is a specific antagonist. The calcium salt, calcium pantothenate, is the usual commercial form.

Biotin: 0.15–0.3 mg/day. The discovery that biotin deficiency in young chickens can lead to sudden death resulted in a recommendation to supplement infant formulations with biotin.[a] **Desthiobiotin**, in which the sulfur has been removed and replaced by two hydrogen atoms, can replace biotin in some organisms and appears to lie on one pathway of biosynthesis.[b,c] **Oxybiotin,** in which the sulfur has been replaced by oxygen, is active for many organisms and partially active for others. No evidence for conversion to biotin itself has been reported, and oxybiotin may function satisfactorily in at least some enzymes.

Thiamin: 0.23 mg or more per 1000 kcal of food consumed and a minimum total of 0.8 mg/day. Replacement of the methyl group on the pyrimidine ring by ethyl, propyl, or isopropyl gives compounds with some vitamin activity, but replacement by hydrogen cuts activity to 5% of the original. The butyl analog is a competitive inhibitor.

Vitamin B_6: 1.5–2 mg/day; 0.4 mg/day for infants. Vitamin B_6 is widely distributed in foods, and symptoms of severe deficiency are seldom observed. However, a number of cases of convulsions have been attributed to partial destruction of vitamin B_6 in infant liquid milk formulas. Convulsions occurred when the vitamin B_6 content was reduced to about one-half that normally present in human milk.

Several cases of children with an abnormally high vitamin B_6 requirement (2–10 mg/day) have been reported, and rare metabolic diseases are known[d–f] in which specific enzymes, such as cystathionine synthase, have a reduced affinity for PLP. Patients with these diseases also benefit from a higher than normal intake of the vitamin. Excessive excretion of the vitamin may also occur, an example being provided by a strain of laboratory mice that require twice the normal amount of vitamin B_6 and which die in convulsions after a brief period of vitamin B_6 depletion.[d] Dietary supplementation with large amounts of vitamin B_6 for treatment of medical conditions such as carpal tunnel syndrome has been controversial.[g] Amounts of pyridoxine over 50 mg per day may damage peripheral nerves, probably because of the chemical reactivity of pyridoxal and PLP.

Nicotinamide: About 7.5 mg/day. Tryptophan can substitute to some extent. See also Box 15-A.

Riboflavin: About 1.5 mg/day. See also Box 15-B.

Folic acid: About 0.2–0.4 mg/day. See also Box 15-D.

Vitamin B_{12}: About 2 μg/day. See also Box 16-B.

Vitamin C (ascorbic acid): 50–200 mg/day. See also Box 18-D.

was inactive.[288,289] These results support the formation of dehydroalanine. One proposed mechanism of action of the enzymes involved addition of the substrate amino group to the C = C bond of the dehydroalanine followed by elimination (Eq. 14-46). Dissociation of the C – H bond in this step would be assisted by the electron-accepting properties of the adjacent aromatic ring. However, the proposed chemistry was not convincing. Noting that a 5-nitro substituent on the histidine greatly enhances the rate of reaction, Langer *et al.* proposed that the histidine reacts with the electrophilic carbon in the pyruvoyl center as in Eq. 14-47.[290,291] However, this chemistry, too, was unprecedented in enzymology. Determination of the three-dimensional structure of histidine ammonia-lyase[292] led to the discovery of a new prosthetic group and a solution to the problem. Two dehydration steps, (Eq. 14-47) convert an Ala-Gly-Ser sequence within the protein into **4-methylidine-imidazole-5-one (MIO)**, a modified dehydroalanine with enhanced electron-accepting properties. The proposed mechanism of action is portrayed in Eq. 14-48.

Study Questions

1. Discuss the role of biotin in metabolism and the chemical mechanism of its action. Illustrate with examples.

2. Biotin has been shown to be an essential component of a bacterial oxaloacetate *decarboxylase* that pumps two sodium ions out of a cell for each oxaloacetate molecule decarboxylated. Propose a chemical mechanism for the functioning of biotin and also any ideas that you may have for the operation of the sodium pump.

3. Write out the equation by which **acetyl-CoA** and **pyruvate** can be converted into **L-glutamate**, which can be observed in living animals by ^{13}C NMR. If [2-^{13}C] sodium acetate were injected into the animal what labeling pattern could be anticipated in the L-glutamate?

4. Compare mechanisms and coenzyme requirements for biological decarboxylation of the following three groups of compounds:

   β-oxoacids
   α-oxoacids
   α-amino acids

5. Illustrate, using structural equations, the chemical mechanisms of the following biochemical reactions.

   a) Pyruvate → acetaldehyde + CO_2
   b) 2-Pyruvate → α-acetolactate + CO_2
   c) Pyruvate + NAD^+ + CoA-SH → acetyl-CoA + NADH + H^+ + CO_2
   d) Fructose 6-*P* + glyceraldehyde-3-*P* → xylulose-5-*P* + erythrose-4-*P*

6. 3-Fluoropyruvate is converted quantitatively by pyruvate decarboxylase from wheat germ into acetate, fluoride (F^-), and carbon dioxide. Propose a reaction mechanism. See Gish, G., Smyth, T., and Kluger, R. (1988) *J. Am. Chem. Soc.* **110**, 6230-6234.

7. In *E. coli* **L-cysteine** is formed from L-serine and the sulfide ion S^{2-} in a reaction that also requires acetyl-CoA and is catalyzed by the consecutive action of an acyl transferase and cysteine synthase. Outline the mechanism of this conversion indicating participation of any essential coenzymes.

8. Illustrate, using structural equations, the chemical mechanisms of the following biochemical reactions.

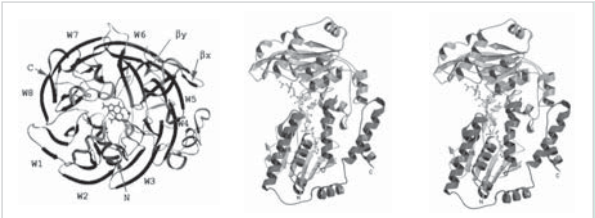
   a) L-Glutamate + oxaloacetate → 2-oxoglutarate + L-aspartate
   b) L-Serine → pyruvate + NH_4^+
   c) L-Serine + indole (from cleavage of indole-3-glycerol phosphate) → L-tryptophan
   d) L-Serine + tetrahydrofolate → glycine + N^5, N^{10}-methylene-tetrahydrofolate
   e) L-Selenocysteine → L-alanine + Se^0

9. Threonine is formed by *E. coli* from homoserine via the intermediate γ-phosphohomoserine. Write out an abbreviated reaction sequence for its conversion to L-threonine by the action of threonine synthase.

10. Write out a plausible step-by-step mechanism by which 1-aminocyclopropane-1-carboxylate synthase (ACC synthase) of plant tissues can form ACC from *S*-adenosylmethionine. This reaction requires a specific cofactor

11. Tissues of the mammalian central nervous system contain a pyridoxal phosphate-dependent glutamate decarboxylase that catalyzes conversion of Glu to γ-aminobutyrate (GABA), an inhibitory synaptic transmitter. GABA is degraded by transimination with α-oxoglutarate as the acceptor to yield succinic semialdehyde, which then is oxidized to succinate by an NAD-linked dehydrogenase.

    a) Show how these reactions can operate as a shunt pathway that allows the citric acid cycle to function without the enzymes α-oxoglutarate dehydrogenase and succinate thiokinase.
    b) Is the shunt more or less efficient than the normal cycle from the standpoint of energy recovery? Explain.



Biological oxidation-reduction reactions rely upon many organic coenzymes and transition metal ions. Left, a molecule of the hydrogen carrier pyrroloquinoline quinone (**PQQ**, Fig. 15-23) is seen at the bottom of a 7-bladed β propeller of a bacterial methanol dehydrogenase. In adrenodoxin reductase (right) the reducing power of **NADPH** is passed to **FAD** and then to the small redox protein adrenodoxin. In this stereoscopic view the pyridine ring of the oxidized coenzyme NADP$^+$ and the tricyclic flavin ring of FAD are seen stacked against each other in the center; the adenylate ends stretching toward the top and bottom of the complex. From Ziegler and Schulz, (2000) *Biochemistry* **39**, 10986-10995.

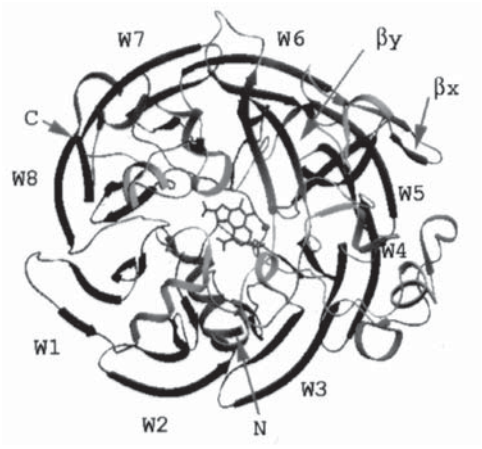
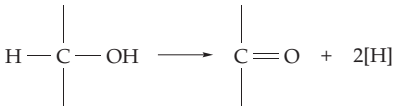
Coenzymes of Oxidation–Reduction Reactions

15

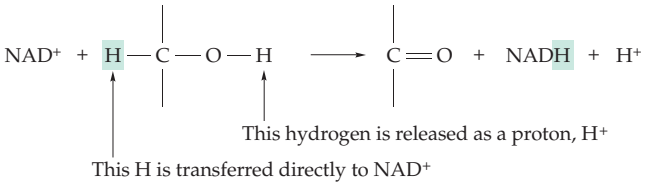


The **dehydrogenation** of an alcohol to a ketone or aldehyde (Eq. 15-1) is one of the most frequent biological oxidation reactions. Although the hydrogen atoms removed from the substrate are often indicated simply as 2[H], it was recognized early in the twentieth century that they are actually transferred to hydrogen-carrying coenzymes such as NAD^+, $NADP^+$, FAD, and **riboflavin 5'-phosphate** (FMN). This chapter deals with these coenzymes and also with a number of other organic oxidation–reduction coenzymes. They may be considered either as carriers of hydrogen or as carriers of electrons ($H = H^+ + e^-$) in metabolic reactions.



(15-1)

When NAD^+ becomes reduced by dehydrogenation of an alcohol, one of the hydrogen atoms removed from the alcohol becomes firmly attached to the NAD^+, converting it to NADH. The other is released as a proton (Eq. 15-2). Study of ^2H-labeled alcohols and their oxidation by NAD^+ has shown that *dehydrogenases catalyze direct transfer to NAD^+ of the hydrogen that is attached to carbon in the alcohol*. There is never any exchange of this hydrogen atom with protons of the medium. At the same time, the hydrogen attached to the oxygen of the alcohol is released into the medium as H^+:



(15-2)

The foregoing observations suggested that these biological dehydrogenations may be viewed as removal of a hydride ion (H^-) together with a proton (H^+) rather than as removal of two hydrogen atoms. NAD^+ and $NADP^+$ are regarded as hydride ion-accepting coenzymes. However, it has been impossible to establish conclusively that the hydrogen atom and electron are transferred simultaneously as H^-. Transfer of the hydrogen atom to or from these coenzymes may conceivably be followed by or preceded by transfer of an electron. The situation is even less clear for the flavin coenzymes FAD and riboflavin phosphate for which intermediate **free radical** oxidation states are known to exist. However, regardless of the actual mechanism, it is convenient to classify most hydrogen transfer reactions of metabolism as if they occurred by transfer of a hydride ion. *The hydride ion can be regarded as a nucleophile which can add to double bonds or can be eliminated from substrates in reactions of types that we have already considered.* Some of these reactions are listed in Table 15-1.

Why are there *four* major hydrogen transfer coenzymes, NAD^+, $NADP^+$, FAD, and riboflavin phosphate (FMN), instead of just one? Part of the answer is that the **reduced pyridine nucleotides** NADPH and NADH are more powerful reducing agents than are reduced **flavins** (Table 6-7). Conversely, flavin coenzymes are more powerful oxidizing agents than are

NAD^+ and $NADP^+$. This difference reflects the chemical difference between the vitamins **riboflavin** and **nicotinamide** which form the oxidation–reduction centers of the coenzymes. Another difference is that NAD^+ and $NADP^+$ tend to be present in free forms within cells, diffusing from a site on one enzyme to a site on another. These coenzymes are *sometimes* tightly bound but flavin coenzymes are *usually* firmly bound to proteins, fixed, and unable to move. Thus, they tend to accept hydrogen atoms from one substrate and to pass them to a second substrate while attached to a single enzyme.

The oxidation–reduction potential of a pyridine nucleotide coenzyme system is determined by the standard redox potential for the free coenzyme (Table 6-8) together with the ratio of concentrations of oxidized to reduced coenzyme ([NAD^+] / [NADH], Eq. 6-64). If these concentrations are known, a redox

TABLE 15-1
Some Biochemical Hydrogen Transfer Reactions[a]

Reaction	Example (oxidant)
A Dehydrogenation of an alcohol 	Alcohol dehydrogenase (NAD^+)
B Dehydrogenation of an amine 	Amino acid dehydrogenases, amine oxidases (NAD^+ or flavin)
C Dehydrogenation of adduct of thiol and aldehyde 	Glyceraldehyde 3-phosphate dehydrogenase (NAD^+ or $NADP^+$)
D Dehydrogenation of acyl-CoA, acyl-ACP, or carboxylic acid  (Y = —S—CoA or —OH)	Acyl-CoA dehydrogenases (Flavin) Succinic dehydrogenase (Flavin) Opposite: enoyl reductase (NADPH)
E Reduction of desmosterol to cholesterol by NADPH 	Reduction of desmosterol to cholesterol by NADPH

[a] Reaction type 9 A,B of Table on the inside cover at the end of the book: A hypothetical hydride ion H^- is transferred from the substrate to a coenzyme of suitable reduction potential such as NAD^+, $NADP^+$, FAD, or riboflavin 5′-phosphate. The reverse of hydrogenation is shown for E. Many of the reactions are reversible and often go spontaneously in the reverse direction from that shown here.

potential can be defined for the NAD^+ system within a cell. This potential may vary in different parts of the cell because of differences in the $[NAD^+]$ / [NADH] ratio, but within a given region of the cell it is constant. On the other hand, the redox potentials of flavoproteins vary. Since the flavin coenzymes are not dissociable, two flavoproteins may operate at very different potentials even when they are physically close together.

Why are there two pyridine nucleotides, NAD^+ and $NADP^+$, differing only in the presence or absence of an extra phosphate group? One important answer is that they are members of two different oxidation–reduction systems, both based on nicotinamide but functionally independent. The experimentally measured ratio $[NAD^+]$ / [NADH] is much higher than the ratio $[NADP^+]$ / [NADPH]. Thus, these two coenzyme systems also can operate within a cell at different redox potentials. A related generalization that holds much of the time is that *NAD^+ is usually involved in pathways of catabolism, where it functions as an oxidant, while NADPH is more often used as a reducing agent in biosynthetic processes.* See Chapter 17, Section I for further discussion.

A. Pyridine Nucleotide Coenzymes and Dehydrogenases

In 1897, Buchner discovered that "yeast juice," prepared by grinding yeast with sand and filtering, catalyzed fermentation of sugar. This was a major discovery which excited the interest of many other biochemists.[1] Among them were Harden and Young, who, in 1904, showed that Buchner's cell-free yeast juice lost its ability to ferment glucose to alcohol and carbon dioxide when it was dialyzed. Apparently, fermentation depended upon a low-molecular-weight substance that passed out through the pores of the dialysis membrane. Fermentation could be restored by adding back to the yeast juice either the concentrated dialysate or boiled yeast juice (in which the enzyme proteins had been destroyed). The heat-stable material, which Harden and Young called **cozymase**, was eventually found to be a mixture of inorganic phosphate ions, thiamin diphosphate, and NAD^+. However, characterization of NAD^+ was not accomplished until 1935.

Pure $NADP^+$ was isolated from red blood cells in 1934 by Otto Warburg and W. Christian, who had been studying the oxidation of glucose 6-phosphate by erythrocytes.[1a] They demonstrated a requirement for a dialyzable coenzyme which they characterized and named **triphosphopyridine nucleotide** (TPN^+, but now officially $NADP^+$; Fig. 15-1). Thus, even before its recognition as an important vitamin in human nutrition, nicotinamide was identified as a component of $NADP^+$.

Warburg and Christian recognized the relationship of $NADP^+$ and NAD^+ (then called DPN^+) and proposed that both of these compounds act as hydrogen carriers through alternate reduction and oxidation of the pyridine ring. They showed that the coenzymes could be reduced either enzymatically or with sodium dithionite $Na_2S_2O_4$.

$$S_2O_4^{2-} + NAD^+ + H^+ \rightarrow NADH + 2\,SO_2 \qquad (15\text{-}3)$$

The reduced coenzymes NADH and NADPH were characterized by a new light-absorption band at 340 nm. This is not present in the oxidized forms, which absorb maximally at 260 nm (Fig. 15-2). The reduced forms are stable in air, but their reoxidation was found

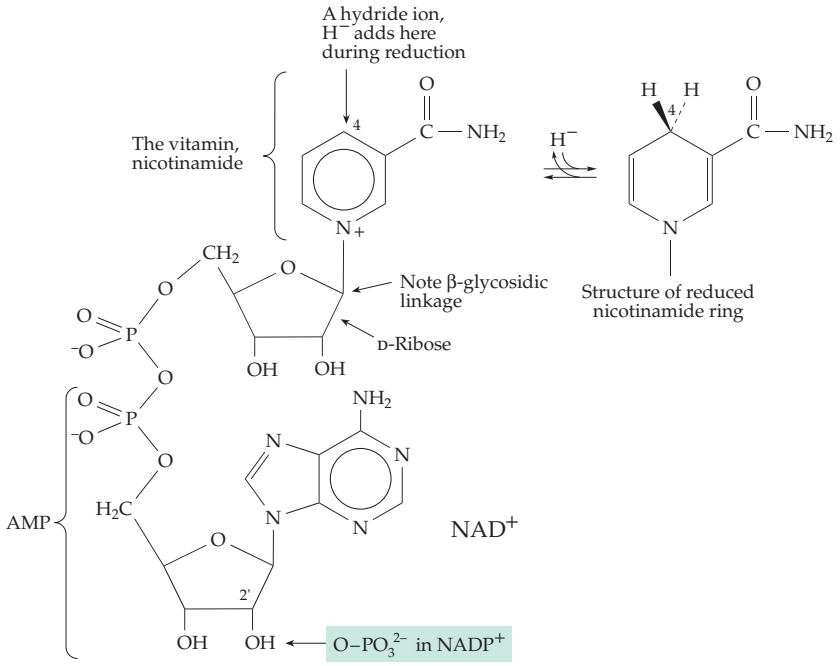


Figure 15-1 The hydrogen-carrying coenzymes NAD^+ (nicotinanide adenine dinucleotide) and $NADP^+$ (nicotinamide adenine dinucleotide phosphate). We use the abbreviations NAD^+ and $NADP^+$, even though the net charge on the entire molecule at pH 7 is negative because of the charges on oxygen atoms of the phospho groups.

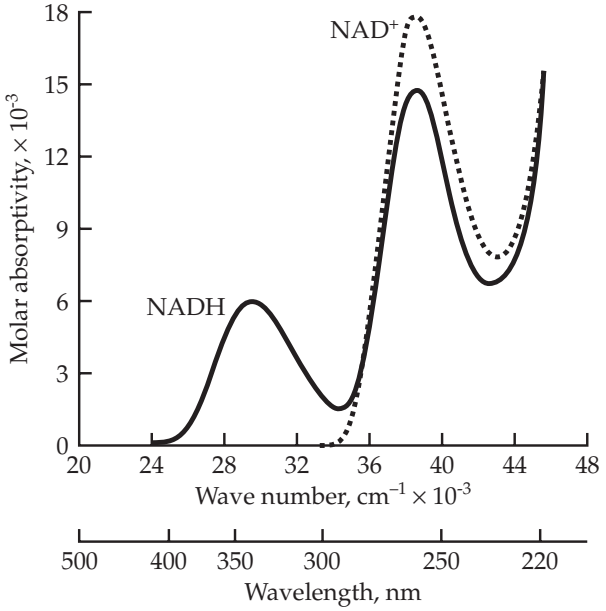

Figure 15-2 Absorption spectra of NAD^+ and NADH. Spectra of $NADP^+$ and NADPH are nearly the same as these. The difference in absorbance between oxidized and reduced forms at 340 nm is the basis for what is probably the single most often used spectral measurement in biochemistry. Reduction of NAD^+ or $NADP^+$ or oxidation of NADH or NADPH is measured by changes in absorbance at 340 nm in many methods of enzyme assay. If a pyridine nucleotide is not a reactant for the enzyme being studied, a **coupled assay** is often possible. For example, the rate of enzymatic formation of ATP in a process can be measured by adding to the reaction mixture the following enzymes and substrates: hexokinase + glucose + glucose-6-phosphate dehydrogenase + $NADP^+$. As ATP is formed, it phosphorylates glucose via the action of hexokinase. $NADP^+$ then oxidizes the glucose 6-phosphate that is formed with production of NADPH, whose rate of appearance is monitored at 340 nm.

to be catalyzed by certain yellow enzymes which were later identified as flavoproteins.

1. Three-Dimensional Structures of Dehydrogenases

Most NAD^+- or $NADP^+$- dependent dehydrogenases are dimers or trimers of 20- to 40-kDa subunits. Among them are some of the first enzymes for which complete structures were determined by X-ray diffraction methods. The structure of the 329-residue per subunit muscle (M_4) isoenzyme of **lactate dehydrogenases** (see Chapter 11) from the dogfish was determined to 0.25 nm resolution by Rossmann and associates in 1971.[2–4] More recently, structures have been determined for mammaliam muscle and heart type (H_4) isoenzymes,[5] for the testicular (C_4) isoenzyme from the mouse,[6] and for bacterial lactate dehydrogenases.[6–8] In all of these the polypeptide is folded nearly identically. The structures of the homologous cytosolic and mitochondrial isoenzymes of **malate dehydrogenase** are also similar,[9–11] as are those of the bacterial enzyme.[12,13] All of these proteins consist of two structural domains and the NAD^+ is bound to the nucleotide-binding domain in a similar manner as is shown in Fig. 2-13 for glyceraldehyde phosphate dehydrogenase. The coenzyme-binding domains of the dehydrogenases of known structures all have this nearly constant structural feature (often called the Rossmann fold) consisting of a six-stranded parallel sheet together with several α helical coils[14] (Figs. 2-13 and 2-27).

The coenzyme molecule curls around one end of the nucleotide-binding domains in a "C" conformation with the nicotinamide ring lying in a pocket (Figs. 2-13, 15-3). Even before the crystal structure of lactate dehydrogenase was known, the lack of pH dependence of coenzyme binding from pH 5 to 10 together with observed inactivation by butanedione suggested that the pyrophosphate group of NAD^+ binds to a guanidinium group of an arginine residue. This was identified by X-ray diffraction studies as Arg 101. This ion pairing interaction, as well as the hydrogen bond between Asp 53 and the 2' oxygen atom of a ribose ring (Fig. 15-3), is present in all of the lactate and malate dehydrogenases.

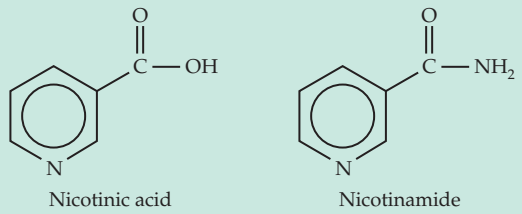
The adenine ring of the coenzyme is bound in a hydrophobic pocket with its amino group pointed out into the solvent. A second structural domain holds additional catalytic groups needed to form the active site.

2. Stereospecificity and Mechanism

When NAD^+ is reduced in ^2H_2O by dithionite (Eq. 15-3) an atom of ^2H is introduced into the reduced pyridine. Chemical degradation showed the ^2H to be present at the 4 position of the ring para to the nitrogen atom[15] (see Fig. 15-1). As shown by Westheimer and associates, during enzymatic reduction of NAD^+ by deuterium-containing ethanol, $CH_3–C^2H_2OH$, one of the ^2H atoms is transferred into the NADH formed, thus establishing the *direct transfer of a hydrogen atom*.[16,17] When the NAD^2H formed in this way is reoxidized enzymatically with acetaldehyde, with regeneration of NAD^+ and ethanol, the ^2H is completely removed.

This was one of the first recognized examples of the ability of an enzyme to choose between two identical atoms at a *pro*-chiral center (Chapter 9). The two sides of the nicotinamide ring of NAD were designated A and B and the two hydrogen atoms at the 4 position of NADH as H_A (now known as *pro-R*) and H_B (*pro-S*). Alcohol dehydrogenase always removes the *pro-R* hydrogen. Malate, isocitrate, lactate, and D-glycerate dehydrogenases select the same hydrogen. However,

BOX 15-A NICOTINIC ACID AND NICOTINAMIDE



Nicotinic acid Nicotinamide

Nicotinic acid was prepared in 1867 by oxidation of nicotine. Although it was later isolated by Funk and independently by Suzuki in 1911–1912 from yeast and rice polishings, it was not recognized as a vitamin. Its biological significance was established in 1935 when nicotinamide was identified as a component of NAD^+ by von Euler and associates and of $NADP^+$ by Warburg and Christian.[a] Both forms of the vitamin are stable, colorless compounds highly soluble in water.

In 1937, Elvehjem and coworkers demonstrated that nicotinic acid cured canine "blacktongue." In the same year it was found to cure human **pellagra**, a terrible disease characterized by weakness, indigestion, and loss of appetite followed by dermatitis, diarrhea, mental disorders, and eventual death. At that time pellagra was common in the United States, especially in the south. The U.S. Public Health Service estimated that during 1912–1916 there were 100,000 victims and 10,000 deaths a year.[b,c]

The daily requirement for an adult is about 7.5 mg. The amount is decreased by the presence in the diet of tryptophan, which can be converted partially to nicotinic acid (Chapter 25).[d,e] Tryptophan is about 1/60 as active as nicotinic acid itself. The one-time prevalence of pellagra in the southern United States was a direct consequence of a diet high in maize whose proteins have an unusually low tryptophan content.

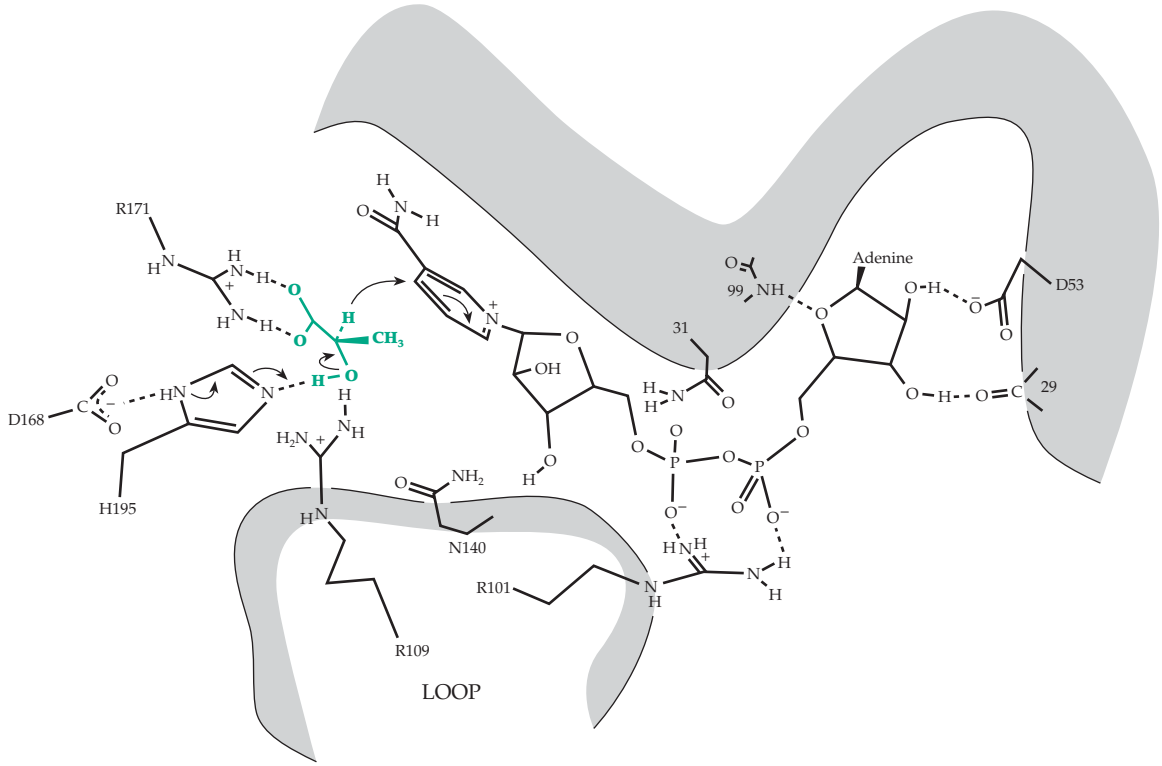

Figure 15-3 Diagrammatic structure of NAD^+ and L-lactate bound into the active site of lactate dehydrogenase. See Eventhoff *et al.*[5]

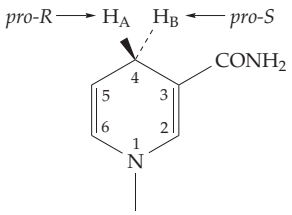
dehydrogenases acting on glucose 6-phosphate, glutamate, 6-phosphogluconate, and 3-phosphoglyceraldehyde remove the *pro-S* hydrogen. By 1979 this stereospecificity had been determined for 127 dehydrogenases, about half of which were found A-specific and half B-specific.[18] Isotopically labeled substrates



have usually been used for this purpose but a simple NMR method has been devised.[19,20]

How complete is the stereospecificity? Does the enzyme sometimes make a mistake? *Lactate dehydrogenase displays nearly absolute specificity*, transferring a proton into the "incorrect" *pro-S* position no more than once in 5×10^7 catalytic cycles.[21] This suggests a difference in transition-state energies of about 40 kJ / mol for the two isomers. X-ray structural studies suggested that a major factor determining this stereoselectivity might be the location of hydrogen-bonding groups that hold the $-CONH_2$ group of the nicotinamide. If these are located in such a way that the nicotinamide ring has a *syn* orientation with respect to the ribose ring to which it is attached (Fig. 15-4), the A face of the coenzyme will be against the substrate undergoing oxidation or reduction. If the ring has an *anti* conformation, the B side will be against the substrate.[18,22] However, the explanation cannot be this simple. High specificity is still retained when NADH is modified, for example, by replacement of the $-CONH_2$ on the pyridine ring with $-COCH_3$ or $-CHO$ or by use of α-NADH, in which the ribose–nicotinamide linkage is α instead of β as in normal NADH.[23]

An intriguing idea is that the enzyme selectively stabilizes one of the boat conformations of NADH or NADPH. According to stereoelectronic principles the axially oriented hydrogen in such a boat structure (*pro-R* in Fig. 15-4) will be the most readily transferred. On the basis of this principle, together with the idea that enzymes adjust the Gibbs energies of intermediate states to achieve optimum catalytic rates, the following prediction was made by Benner and associates:[24] *The thermodynamically most easily reduced carbonyl compounds will react by enzymatic transfer of the hydride ion from the pro-R position of NADH.* Conversely, the most difficultly reduced carbonyl compounds will receive the hydride ion from the *pro-S* position of NADH. The proposal has been controversial and it has been argued that evolutionary relationships play a dominant role in determining stereoselectivity.[23] Theoretical computations suggest that the boatlike puckering of the ring is flexible, raising some doubts about the rigidity of the reactants in the active site.[12,25] Nevertheless, it is likely that the coenzyme as well as bound substrates must assume very specific conformations before the enzyme is able to move to the transition state for the reaction. A great deal of effort has been expended in trying to understand other factors that may explain the high stereospecificity of dehydrogenases.[12,22,26–28]

When a hydrogen atom is transferred by an enzyme from the 4 position of NADH or NADPH to an aldehyde or ketone to form an alcohol, the placement of the hydrogen atom on the alcohol is also stereospecific. Thus, alcohol dehydrogenase acting on NAD^2H converts acetaldehyde to (*R*)-mono-[^{2}H]ethanol (Eq. 9-73). Pyruvate is reduced by lactate dehydrogenase to L-lactate, and so on. Even mutations that disrupt the binding of the carboxylate of lactate, e.g., substitution of arginine 171 (see Fig. 15-3) by tryptophan or phenylalanine and introduction of a new arginine on the other side of the active site, do not alter the L-stereospecificity. However, the specificity for lactate is lost.[29]

One step or two-step transfer? Another major question about dehydrogenases is whether the hydrogen atom that is transferred moves as a hydride ion, as is generally accepted, or as a hydrogen atom with separate transfer of an electron and with an intermediate NAD or NADPH free radical. In one study para-substituted benzaldehydes were reduced with NADH and NAD^2H using yeast alcohol dehydrogenase as a catalyst.[30] This permitted the application of the Hammett equation (Box 6-C) to the rate data. For a series of benzaldehydes for which σ^+ varied widely, a value

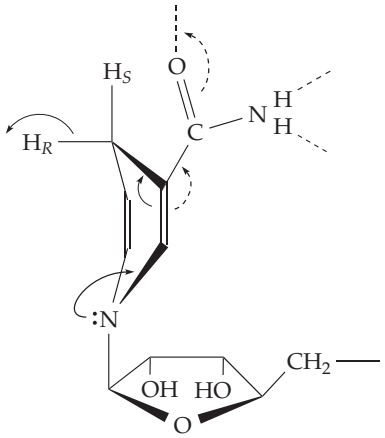


Figure 15-4 The nicotinamide ring of NADH in a *syn* boat conformation suitable for transfer of an axially oriented *pro-R* hydrogen atom from its A face as H^-. The flow of electrons is shown by the solid arrows. The dashed arrows indicate competing resonance which favors planarity of the ring and opposes the H^- transfer. Hydrogen bonds from the protein to the carboxamide group (dashed lines) affect both this tendency and the conformation of the nucleotide.

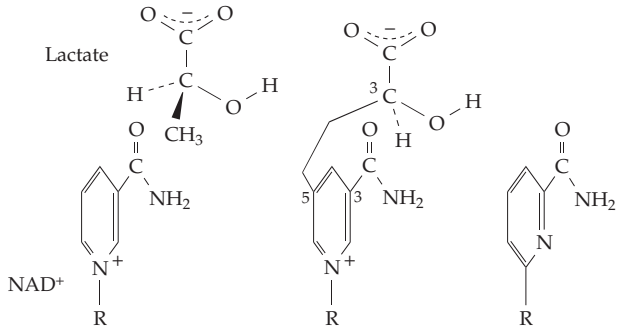
of ρ = +2.2 was observed for the rate constant with both NADH and NAD²H. Thus, electron-accepting substituents in the para position hasten the reaction. While the significance of this observation is not immediately obvious, the relatively low value of ρ is probably incompatible with a mechanism that requires complete transfer of a single electron from NADH to acetaldehyde in the first step. A primary isotope effect on the rates was $k_H/k_D = 3.6$, indicating that the C–H bond in NADH is broken in the rate-limiting step. The fact that the isotope effect is the same for all of the substituted benzaldehydes also argued in favor of a hydride ion transfer.

Studies of the kinetics of nonenzymatic model reactions of NADH with quinones[31,32] have also been interpreted to favor a single-step hydride ion transfer. Application of Marcus theory (Chapter 9, Section D,4) to data from model systems also supports the hydride transfer mechanism.[33,34] Quantum mechanical tunneling may be involved in enzymatic transfer of protons, hydride ions, and electrons.[35–36] Tunneling is often recognized by unusually large primary or secondary kinetic isotope effects. According to semi-classical theory (Chapter 12), the maximum effects for deuterium and tritium are given by the following ratios:

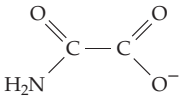
$$(k_{2_H}/k_{1_H}) = (k_{3_H}/k_{2_H})^{3.3} \approx 7.$$

Higher ratios, which suggest tunneling, are frequently observed for dehydrogenases.[36a,b] Tunneling is apparently coupled to fluctuations in motion within the enzyme-substrate complex. Study of effects of pressure on reactions provides a new approach that can aid interpretation.[36c,36d]

Coenzyme and substrate analogs. The structures of enzyme•NAD⁺•substrate complexes (Fig. 15-3) may be studied by X-ray crystallography under certain conditions or can be inferred from those of various stable enzyme-inhibitor complexes or from enzyme reconstituted with NAD⁺ that has been covalently linked to the substrate. In the following diagram,[27] NAD⁺ (I) is shown with L-lactate lying next to its A face, ready to transfer a hydride ion to the *pro-R* position in NADPH. Also shown (II) is 5-(*S*)-lac-NAD⁺, with the covalently linked lactate portion in nearly the same position as in diagram I. This NAD derivative was used to obtain the first 0.27-nm structure with a bound substrate-like molecule in lactate dehydrogenase.[37] Since then the structures of many complexes with a variety of dehydrogenases have been studied. In coenzyme analog III the ring is bound to ribose with a C–C bond and it lacks the positive charge on the nicotinamide ring in NAD⁺. It does not react with substrate. However, it binds to the coenzyme site of alcohol dehydrogenase and forms with ethanol a ternary complex whose structure has been solved.[38]



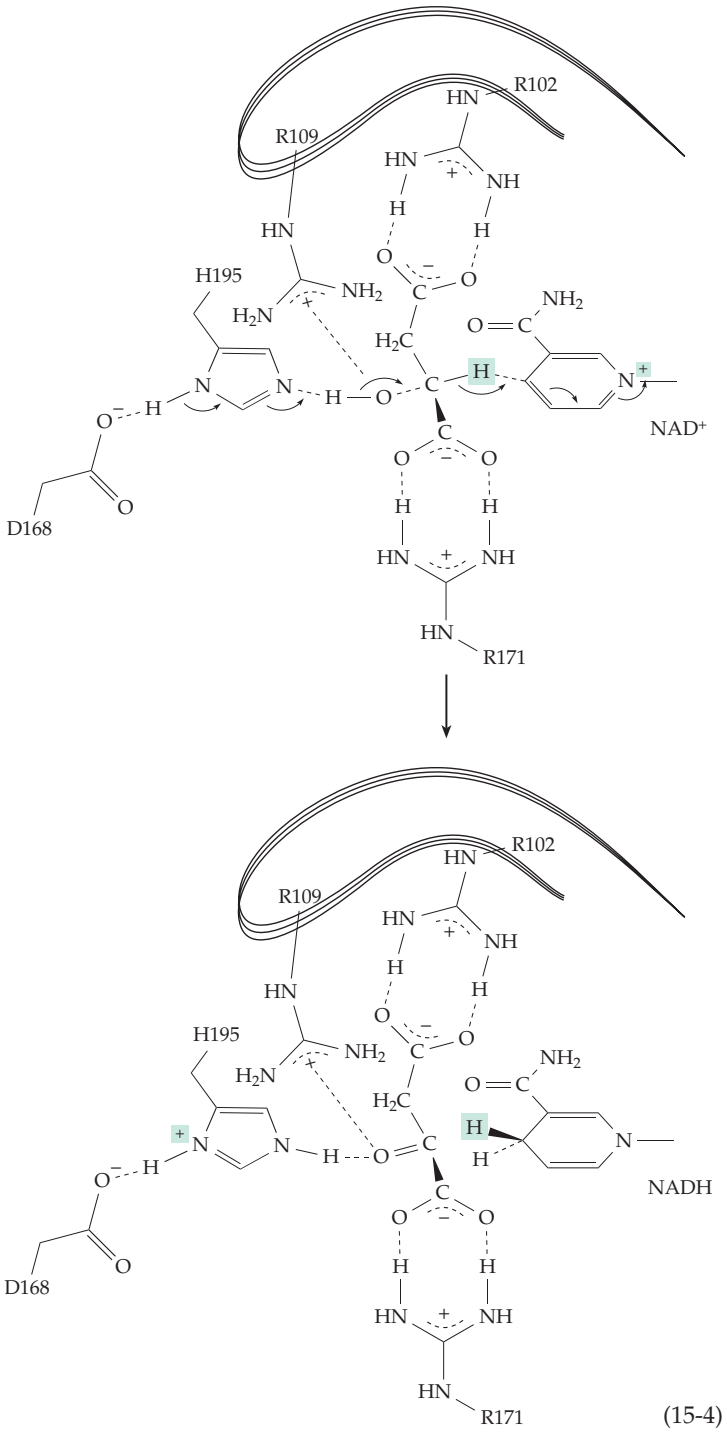
A related approach is to study complexes formed with normal NAD⁺ but with an unreactive second substrate. An example is oxamate, which binds well to lactate dehydrogenase to form stable ternary complexes for which equilibrium isotope effects have been studied.[39]



Oxamate

In the structure of the lactate dehydrogenase active site shown in Fig. 15-3, the lactate carboxylate ion is held and neutralized by the guanidinium group of Arg 171, and the imidazole group of His 195 is in position to serve as a general base catalyst to abstract a proton from the hydroxyl group of the substrate (Eq. 15-4). This imidazole group is also hydrogen bonded to the carboxylate of Asp 168 as in the "charge-relay" system of the serine proteases (Fig. 12-10). The same features are present in the active site of malate dehydrogenases and have been shown essential by study of various mutant forms.[11,40–42] The His:Asp pair of the dehydrogenases is not part of the nucleotide-binding domain but is present in the second structural domain, the "catalytic domain." This is another feature reminiscent of the serine proteases. A bacterial D-glycerate dehydrogenase also has a similar structure and the same catalytic groups. However, the placement of the catalytic histidine and the arginine that binds the α-carboxylate group of the substrate is reversed, allowing the enzyme to act on the D-isomer.[43]

Conformational changes during dehydrogenase action. Dehydrogenases bind coenzyme and substrate in an ordered sequence. The coenzyme binds first, then the oxidizable or reducible substrate. The binding of the coenzyme to lactate dehydrogenase is accompanied by a conformational change by which a loop, involving residues 98–120 and including one helix,



(15-4)

folds over the coenzyme like a lid.[41,44] This conformational change must occur during each catalytic cycle, just as in the previously discussed cases of citrate synthase (Chapter 13) and aspartate aminotransferase (Chapter 14). One effect of folding of the loop is to bring the side chain of Arg 109 into close proximity to His 195 and to the OH group of the bound lactate (Eq. 15-4). The closing of the loop also forces the positively charged nicotinamide ring more deeply into a relatively nonpolar pocket. This may induce a movement of the positive charge toward the 4' carbon of the ring, assisting in the transfer of the hydride ion (Eq. 15-4).[41] At the end of this transfer both Arg 109 and His 196 are positively charged and electrostatic repulsion between them may help to move the loop and release the products. If the reaction proceeds in the opposite direction the presence of two positive charges will assist in the hydride ion transfer. The importance of Arg 109 is demonstrated by the fact that a mutant with glutamine in place of Arg 109 has a value of k_{cat} only 1/400 that of native enzyme.[45]

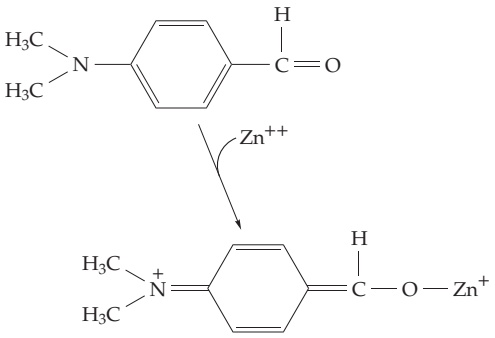
The loop closure also causes significant changes in the Raman spectra of the bound NAD^+, especially in vibrational modes that involve the carboxamide group of the nicotinamide ring. These have been interpreted as indicating an increased ridigity of binding of the coenzyme in the closed conformation.[46] As with many other enzymes acting on polar substrates, a characteristic of the pretransition state complex appears to be formation of a complex with a network of hydrogen bonds extending into the protein, exclusion of most water molecules, and tight packing of protein groups around the substrate. It is also significant that an overall net electrical charge on the ES complexes must be correct for tight binding of substrates to occur for lactate or malate dehydrogenase.[44] Positive and negative charges are balanced except for one excess positive charge which may be needed for catalysis.

Zinc-containing alcohol dehydrogenases. Liver alcohol dehydrogenase is a relatively nonspecific enzyme that oxidizes ethanol and many other alcohols. The much studied horse liver enzyme[47–60] is a dimer of 374-residue subunits, each of which contains a "catalytic" Zn^{2+} ion deeply buried in a crevice between the nucleotide-binding and catalytic domains. The enzyme also contains a "structural" Zn^{2+} ion[48] that is bound by four sulfur atoms from cysteine side chains but does not represent a conserved feature of all alcohol dehydrogenases. The catalytic Zn^{2+} is ligated by sulfur atoms from cysteines 46 and 174 and by a nitrogen atom of the imidazole group of His 67 (Fig. 15-5). In the free enzyme a water molecule is thought to occupy the 4th coordination position and its dissociation to form the $Zn^+–HO^-$ complex (Eq. 15-5) may account for a pK_a of 9.2 in the free enzyme and of 7.6 in the NAD^+ complex.[48] The apparent pK_a drops further to about 6.4 in the presence of the substrate

$$Zn^{2+}–OH_2 \rightarrow Zn^+–OH + H^+ \qquad (15\text{-}5)$$

ethanol. The assignment of this pK_a value has been controversial.[48,49] Histidine 51 (Fig. 15-5), Glu 68 and Asp 49 have side chains close to the zinc and, as we have seen (Chapter 7), macroscopic pK_a values of proteins can be *shared* by two or more closely placed groups.

Substrate binding also induces a conformational change in this enzyme. When both coenzymes and substrate bind the "closed" conformation of the enzyme is formed by a rotation of the catalytic domains of the two subunits relative to the coenzyme-binding domains.[50–51a] Structures of ternary complexes with inhibitors and with substrates have also been established. For example, liver alcohol dehydrogenase was crystallized as the enzyme•NAD^+• *p*-bromobenzyl alcohol complex with saturating concentrations of substrates in an equilibrium mixture[51b] and studied at low resolution. Transient kinetic studies or direct spectroscopic determinations led to the conclusion that the internal equilibrium (E•NAD^+•alcohol = E•NADH•aldehyde) favors the NAD^+•alcohol complex.[52] Subsequently, the complex was studied at higher resolution, and the basic structural features were confirmed with a



(15-6)

structure of the enzyme complexed with NAD^+ and 2,3,4,5,6-pentafluorobenzyl alcohol.[53] From the crystal structures of the NAD^+ • *p*-bromobenzyl alcohol complex and the previously mentioned complex with ethanol and analog III it appears that the oxygen of the alcohol substrate coordinates with the Zn^{2+}, displacing the bound water. Binding of the chromophoric aldehyde 4-*trans*-(*N*, *N*-dimethylamino) cinnamaldehyde shifts the wavelength of maximum absorbance by 66 nm, suggesting that Zn^{2+} binds directly to the oxygen of this ligand (Eq. 15-6).[54] Resonance-enhanced Raman spectroscopy (Chapter 23) of the complex of dimethylaminobenzaldehyde with alcohol dehydrogenase also supports an intermediate in which the Zn^{2+} becomes coordinated directly with the substrate oxygen (Eq. 15-6).[55] Rapid scanning spectrophotometry of complexes with another chromophoric substrate, 3-hydroxy-4-nitrobenzyl alcohol, also suggested that the alcohol first formed a complex with an undissociated alcoholic – OH group (Eq. 15-7, step *a*) and then lost a proton to form a zinc alcoholate complex (step *b*)[56] which could react by hydride ion transfer (step *c*).

Eklund *et al.* suggested that the side chains of Ser 48 and His 51 act as a proton relay system to remove the proton from the alcohol, in step *b* of Eq. 15-7, leaving the transient zinc-bound alcoholate ion, which can then transfer a hydride ion to NAD^+, in step *c*.[52] The shaded hydrogen atom leaves as H^+. The role of His 51 as a base is supported by studies of the inactivation of the horse liver enzyme by diethyl pyrocarbonate[57] and by directed mutation of yeast and liver enzymes. When His 51 was substituted by Gln the pK_a of 7 was abolished and the activity was decreased ten-fold.[58]

The functioning of zinc ions in enzymes has been controversial and other mechanisms have been proposed. Makinen *et al.* suggested a transient pentacoordinate Zn^{2+} complex on the basis of EPR measurements on en-

(15-7)

zyme containing Co^{2+}. Such a complex, in which the side chain of nearby Glu 68 would participate, would allow the coordinated water molecule to act as the base in deprotonation of the alcohol.[59] Molecular dynamics calculations indicate that Glu 68 can coordinate the zinc ion in this fashion, but Ryde suggests that its function may be to assist the exchange of ligands, i.e., the release of an alcohol or aldehyde product.[60] A variety of kinetic and spectroscopic studies have provided additional information that makes alcohol dehydrogenase one of the most investigated of all enzymes.

Liver alcohol dehydrogenase is important to the metabolism of ethanol by drinkers. Human beings exhibit small individual differences in their rates of alcohol metabolism which may reflect the fact that there are several isoenzymes and a number of genetic variants whose distribution differs from one person to the next as well as among tissues.[61–64] Inhibition of these isoenzymes by *uncompetitive* inhibitors, discussed in Chapter 9, is a goal in treatment of poisoning by methanol or ethylene glycol. Inhibition of the dehydrogenases slows the two-step oxidation of these substrates to toxic carboxylic acids.[65]

Yeast contains two cytosolic alcohol dehydrogenase isoenzymes.[66] Alcohol dehydrogenase I, present in large amounts in cells undergoing fermentation, functions to reduce acetaldehyde in the fermentation process. Alcohol dehydrogenase II is synthesized by cells growing on such carbon sources as ethanol itself and needing to oxidize it to obtain energy. A third isoenzyme is present in mitochondria. An alcohol dehydrogenase isoenzyme of green plants is induced by anaerobic stress such as flooding. It permits ethanolic fermentation to provide energy temporarily to submerged roots and other tissues.[67] Some bacteria contain an $NADP^+$-dependent, Zn^{2+}-containing alcohol dehydrogenase.[67a]

Other alcohol dehydrogenases and aldo-keto reductases. The oxidation of an alcohol to a carbonyl compound and the reverse reaction of reduction of a carbonyl group are found in so many metabolic pathways that numerous specialized dehydrogenases exist. A large group of "short-chain" dehydrogenases and reductases had at least 57 known members by 1995.[68–69a] Their structures and functions are variable. Most appear to be single-domain proteins with a large β sheet, a nucleotide-binding pocket, and a conserved pair of residues: Tyr 152 and Lys 156. These may function in a manner similar to that of the His-Asp pair in lactate dehydrogenase. A possible role of a cysteine side chain has been suggested for another member of this group, 3-hydroxyisobutyrate dehydrogenase, an enzyme of valine catabolism.[70]

Dehydrogenases often act primarily to reduce a carbonyl compound rather than to dehydrogenate an alcohol. These enzymes may still be called dehydrogenases. For example, in the lactic acid fermentation lactate is formed by reduction of pyruvate but we still call the enzyme lactate dehydrogenase. In our bodies this enzyme functions in both directions. However, some enzymes that act mainly in the direction of reduction are called reductases. An example is **aldose reductase**, a member of a family of **aldo-keto reductases**[71–73] which have $(\alpha/\beta)_8$-barrel structures.[74–76]

The normal physiological function of aldose reductase is uncertain but it can cause a problem in diabetic persons by reducing glucose to sorbitol (glucitol), ribose to ribitol, etc. The resulting sugar alcohols accumulate in the lens and are thought to promote cataract formation and may also be involved in the severe damage to retinas and kidneys that occurs in diabetes mellitus. Inhibitors of aldose reductase delay development of these complications in animals but the compounds tested are too toxic for human use.[76]

The active sites of aldo-keto reductases contain an essential tyrosine (Tyr 48) with a low pK_a value. The nearby His 110, Asp 43, and Lys 77 may also participate in catalysis.[76,77] The kinetics are unusual. Both NAD^+ and NADH are bound tightly and the overall rate of reduction of a substrate is limited by the rate of dissociation of NAD^+.[78] Citrate is a natural uncompetitive inhibitor of aldose reductase.[79]

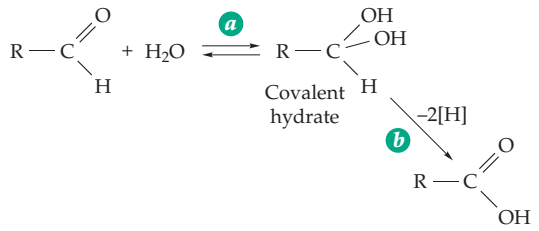
3. Dehydrogenation of Amino Acids and Amines

The dehydrogenation of an amine or the reverse reaction, the reduction of a Schiff base (Table 15-1, reaction type B), is another important pyridine nucleotide-dependent process. **Glutamate dehydrogenase,** a large oligomeric protein whose subunits contain 450 or more residues, is the best known enzyme catalyzing this reaction. An intermediate Schiff base of 2-oxoglutarate and NH_3 is a presumed intermediate.[80,81] Similar reactions are catalyzed by dehydrogenases for alanine,[82,83] leucine,[84] phenylalanine,[85] and other amino acids.[83,86,87]

4. Glyceraldehyde-3-Phosphate Dehydrogenase and the Generation of ATP in Fermentation Reactions

The oxidation of an aldehyde to a carboxylic acid, a highly exergonic process, often proceeds through a thioester intermediate whose cleavage can then be coupled to synthesis of ATP. This sequence is of central importance to the energy metabolism of cells (Chapters 10 and 17) and is shown in Fig. 15-6.

The best known enzyme catalyzing the first step of this reaction sequence is glyceraldehyde 3-phosphate dehydrogenase which functions in the glycolytic sequence (steps *a* and *b* of Fig. 10-3). It is present in both prokaryotes and eukaryotes as a tetramer of identical 36- to 37-kDa subunits. Three-dimensional structures have been determined for enzyme from several species, including lobster,[47,88] *E. coli*,[89] the thermophilic bacterium *Bacillus stearothermophilus* (Fig. 2-13),[90–90a] and trypanosomes.[91] Recall that aldehydes are in equilibrium with their covalent hydrates (Eq. 15-8, step *a*). Dehydrogenation of such a hydrate yields an acid (Eq. 15-8, step *b*) but such a mechanism offers no possibility of conserving the energy available from the reaction. However, during catalysis by glyceraldehyde-phosphate dehydrogenase the SH group of Cys 149, in the first step (step *a*, Fig. 15-6), adds to the substrate carbonyl group to form an adduct, a thiohemiacetal. This adduct is oxidized by NAD^+ to a thioester, an *S*-acyl enzyme (step *b*), which is then cleaved by the same enzyme through a displacement on carbon by an oxygen atom of P_i (phosphorolysis; step *c*). The sulfhydryl group of the enzyme is released simultaneously and the product, the acyl phosphate **1,3-bisphosphoglycerate**, is formed. The imidazole group of His 176 may catalyze both steps *a* and *b*.[89,92] A separate enzyme then transfers the phospho group from the 1 position of 1,3-bisphosphoglycerate to ADP to form ATP and 3-phosphoglycerate (step *d*). The overall sequence of Fig. 15-6 is the synthesis of one mole of ATP coupled to the oxidation of an aldehyde



(15-8)

to a carboxylic acid and the conversion of NAD^+ to NADH.

In green plants and in some bacteria an $NADP^+$-dependent cytoplasmic glyceraldehyde 3-phosphate dehydrogenase *does not* use inorganic phosphate to form an acyl phosphate intermediate but gives 3-phosphoglycerate with a free carboxylate as in Eq. 15-8.[93,93a] Because it doesn't couple ATP cleavage to the dehydrogenation, it drives the [NADPH] / [$NADP^+$] ratio to a high value favorable to biosynthetic processes (see Chapter 17).

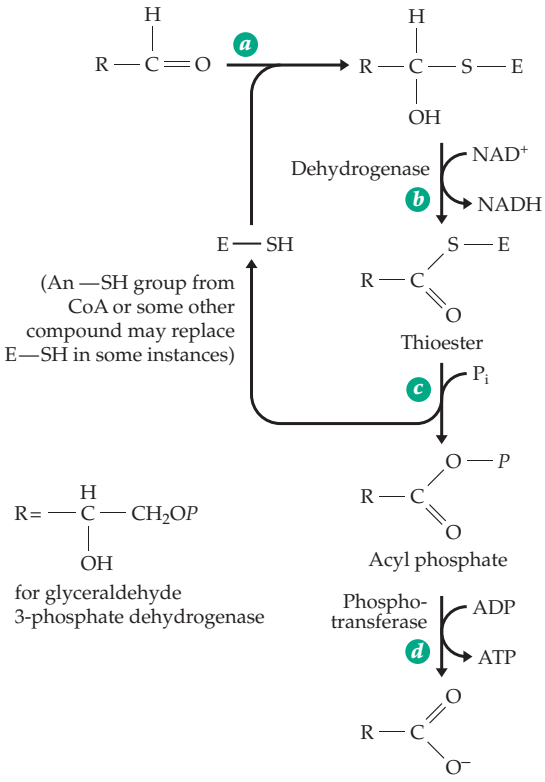


Figure 15-6 Generation of ATP coupled to oxidation of an aldehyde to a carboxylic acid. The most important known example of this sequence is the oxidation of glyceraldehyde 3-phosphate to 3-phosphoglycerate (Fig. 10-3, steps *a* and *b*). Other important sequences for "substrate-level" phosphorylation are shown in Eq. 14-23 and in Fig. 15-16.

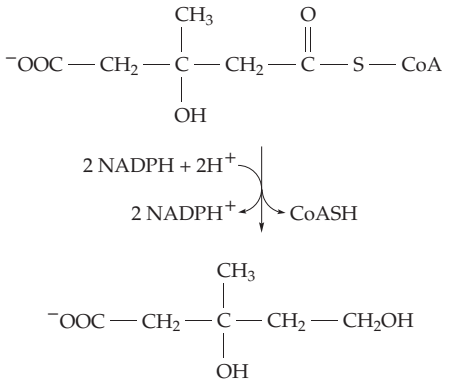
Animal tissues also contain aldehyde dehydrogenases of a nonspecific type which are thought to act to remove toxic aldehydes from tissues.[94,95] Like glyceraldehyde 3-phosphate, these enzymes form thioester intermediates as in Fig. 15-6 but which are hydrolyzed rather than being converted to acyl phosphates. A mutation (E487K) in the mitochondrial enzyme occurs in about 50% of the Asian population. Although the structural alteration is not at the active site, the enzyme activity is low. Individuals carrying the mutation are healthy but have an aversion to alcohol, whose consumption causes an elevated blood level of acetaldehyde, facial flushing, dizziness, and other symptoms. A similar effect is exerted by the drug disulfiram (Antabuse), which has been used to discourage drinking and whose metabolites are thought to inhibit aldehyde dehydrogenase.[95]

Alcohol dehydrogenases also oxidize aldehydes, probably most often as the geminal diol forms, according to Eq. 15-8. No ATP is formed. The same enzymes can catalyze the dismutation of aldehydes, with equal numbers of aldehyde molecules going to carboxylic acid and to the alcohol.[96–98]

5. Reduction of Carboxyl Groups

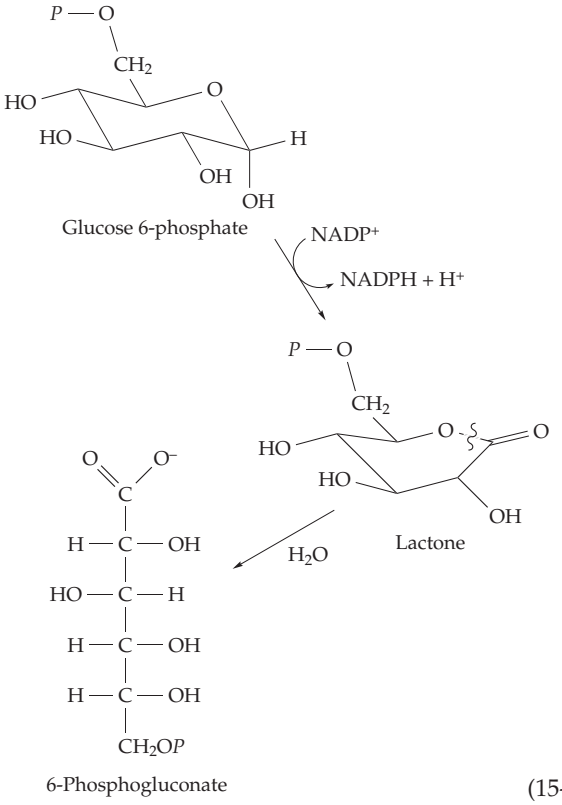
The last two reaction steps in Fig. 15-6, steps *c* and *d*, are in essence the reverse of the sequence used for synthesis of a thioester such as a fatty acyl coenzyme A. Thus, the chemistry by which ATP is generated during glycolysis and that by which it is utilized in biosynthesis is nearly the same. Furthermore, a standard biochemical method for reduction of carboxyl groups to aldehyde groups is conversion, in an ATP-requiring process, to a thioester followed by reduction of the thioester (Table 15-1, reaction type C). For example, the sequence of Fig. 15-6 is reversed during gluconeogenesis (see Fig. 17-17). The carboxyl group of the side chain of aspartate can be reduced in two steps to form the alcohol homoserine (Figs. 11-3; 24-13).

The aldehyde generated by reduction of a thioester is not always released from the enzyme but may be converted on to the alcohol in a second reduction step.[99] This is the case for **3-hydroxy-3-methylglutaryl-CoA reductase** (HMG-CoA reductase), a large 887-residue protein that synthesizes mevalonate (Eq. 15-9).[100–102] This highly regulated enzyme controls the rate of synthesis of cholesterol and is a major target of drugs designed to block cholesterol synthesis. The structure of a smaller 428-residue bacterial enzyme is known.[103,104] Aspartate 766 is a probable proton donor in both reduction steps and Glu 558 and His 865 may act as a catalytic pair that protonates the sulfur of coenzyme A.[100]



(15-9)

A related oxidation reaction is catalyzed by **glucose-6-phosphate dehydrogenase**, the enzyme that originally attracted Warburg's attention and led to the discovery of $NADP^+$. The substrate, the hemiacetal ring form of glucose, is oxidized to a lactone which is then hydrolyzed to 6-phosphogluconate (Eq. 15-10).[104a] This oxidation of an aldehyde to a carboxylic acid is not linked directly to ATP synthesis as in Fig. 15-6. The ring-opening step ensures that the reaction goes to completion. This reaction is a major supplier of NADPH for reductive biosynthesis and the large Gibbs energy decrease for the overall reaction ensures that the ratio [NADPH] / [$NADP^+$] is kept high within cells. This is the only source of NADPH for mature erythrocytes and a deficiency of glucose 6-phosphate dehydrogenase is a common cause of drug- and food-

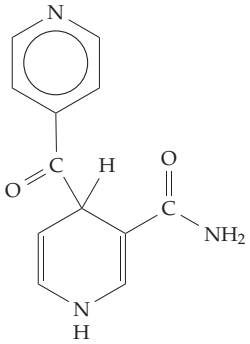


(15-10)

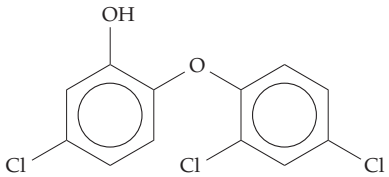
induced hemolytic anemia in human beings. About 400 variant forms of this enzyme are known.[105] Like the sickle cell trait (Box 7-B) some mutant forms of glucose-6-phosphate dehydrogenase appear to confer resistance to malaria.

6. Reduction of Carbon–Carbon Double Bonds

Neither $NADP^+$ nor NAD^+ is a strong enough oxidant to carry out the dehydrogenation of an acyl-CoA (reaction type D of Table 15-1). However, NADPH or NADH can participate in the opposite reaction. Thus, NADPH transfers a hydride ion to the β-carbon of an unsaturated acyl group during the biosynthesis of fatty acids (Chapter 17) and during elongation of shorter fatty acids (Chapter 21).[106–107b] A discovery of medical importance is that isonicotinyl hydrazide (INH), the most widely used antituberculosis drug, forms an adduct (of an INH anion or radical) with NAD^+ of long-chain **enoyl-acyl carrier protein reductase** (enoyl-ACP reductase).[133a,b] This enzyme utilizes NADH in reduction of a C=C double bond during synthesis of mycolic acids. The same enzyme is blocked by **triclosan**, an antibacterial compound used widely in household products such as antiseptic soaps, toothpastes, cosmetics, fabrics, and toys.[133c–e]

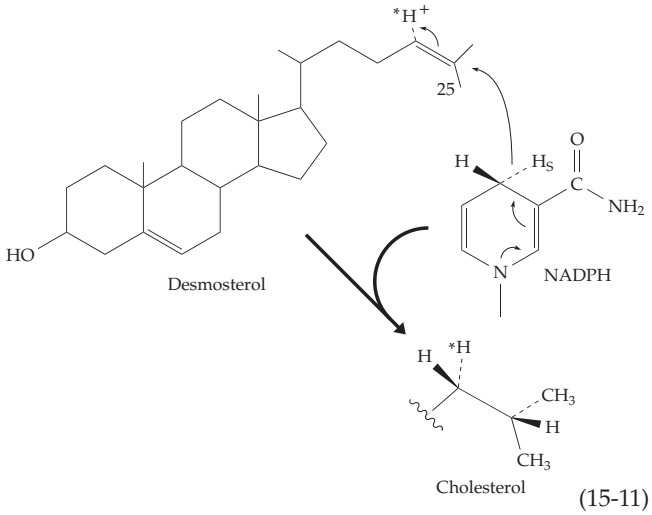


Adduct of isonicotinyl hydrazide anion with NAD^+



Triclosan

Less frequently NADPH is used to reduce an *isolated double bond*. An example is the hydrogenation of **desmosterol** by NADPH (Eq. 15-11), the final step in one of the pathways of biosynthesis of cholesterol (Fig. 22-7). In this and in other reactions of the same



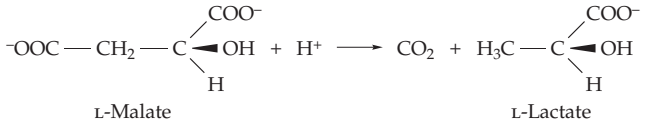
Desmosterol Cholesterol (15-11)

type, hydrogen transfer has been shown to be from the *pro-S* position in NADPH directly to C-25 of the sterol. The proton introduced from the medium (designated by the asterisks in Eq. 15-11) enters *trans* to the H^- ion from NADPH. The proton always adds to the more electron-rich terminus of the double bond, i.e., it follows the Markovnikov rule. This result suggests that protonation of the double bond may precede H^- transfer.[108]

Additional pyridine nucleotide-dependent dehydrogenases include **glutathione reductase** (Figs. 15-10, 15-12), **dihydrofolate reductase** (Fig. 15-19), isocitrate dehydrogenase, ***sn*-glycerol-3-phosphate dehydrogenase** (Chapter 21), L-3-hydroxyacyl-CoA dehydrogenase (Chapter 21), **retinol dehydrogenase** (Chapter 23), and a bacterial quinone oxidoreductase.[109] Some of these also contain a flavin coenzyme.

7. Transient Carbonyl Groups in Catalysis

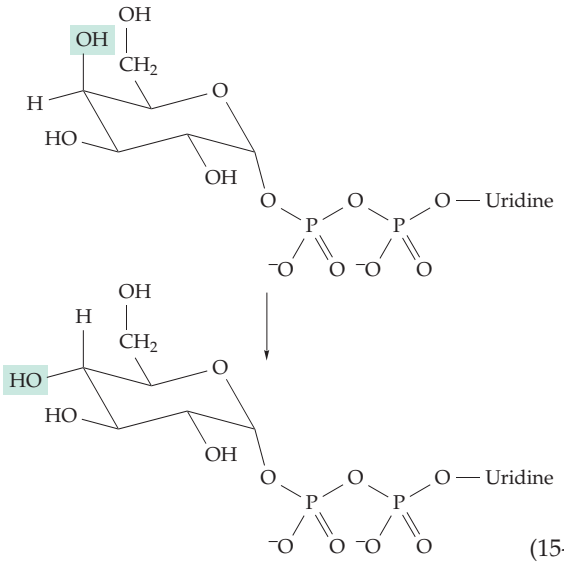
Some enzymes contain bound NAD^+ which oxidizes a substrate alcohol to facilitate a reaction step and is then regenerated. For example, the **malolactic enzyme** found in some lactic acid bacteria and also in *Ascaris* decarboxylates L-malate to lactate (Eq. 15-12). This reaction is similar to those of isocitrate dehydrogenase,[110–112] 6-phosphogluconate dehydrogenase,[113] and the malic enzyme (Eq. 13-45)[114] which utilize free NAD^+ to first dehydrogenate the substrate to a bound oxoacid whose β carbonyl group facilitates decarboxylation. Likewise, the bound NAD^+ of the malolactic



L-Malate L-Lactate (15-12)

enzyme apparently dehydrogenates the malate to a bound oxaloacetate which is decarboxylated to pyruvate.[115] The latter remains in the active site and is reduced by the bound NADH to lactate which is released from the enzyme.

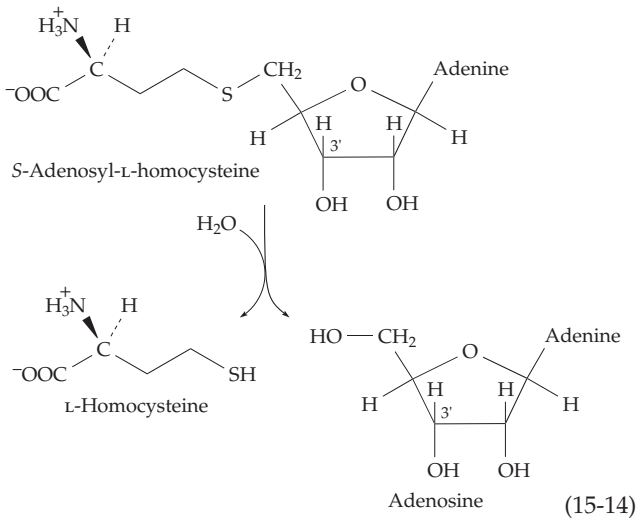
Another reason for introducing a carbonyl group is to form a symmetric intermediate in a reaction that inverts the configuration about a chiral center. An example is **UDP-galactose 4-epimerase**, an enzyme that converts UDP-galactose to UDP-glucose (Eq. 15-13; Chapter 20) and is essential in the metabolism of galactose in our bodies. The enzyme contains bound NAD^+ and forms a transient 4-oxo intermediate and bound NADH. Rotation of the intermediate allows nonstereospecific reduction by the NADH, leading to epimerization.[116–117a]



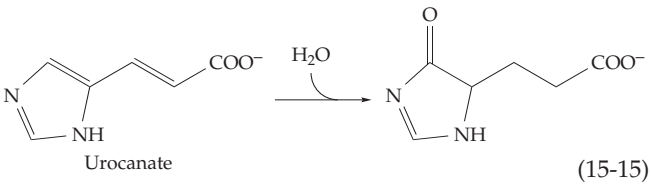
(15-13)

The enzyme is a member of the short-chain dehydrogenase group with a catalytic Tyr–Lys pair in the active site.[118] Another way that formation of an oxo group can assist in epimerization of a sugar is through enolization with nonstereospecific return of a proton to the intermediate enediol. A third possible mechanism of epimerization is through aldol cleavage followed by aldol condensation, with inversion of configuration. In each case the initial creation of an oxo group by dehydrogenation is essential.

Bound NAD^+ is also present in **S-adenosylhomocysteine hydrolase**,[119,120] which catalyzes the irreversible reaction of Eq. 15-14. Transient oxidation at the 3 position of the ribose ring facilitates the reaction. The reader can doubtless deduce the function that has been established for the bound NAD^+ in this enzyme. However, the role of NAD in the **urocanase** reaction (Eq. 15-15) is puzzling. This reaction, which is the second step in the catabolism of histidine, following Eq. 14-44, appears simple. However, there is no obvious



(15-14)

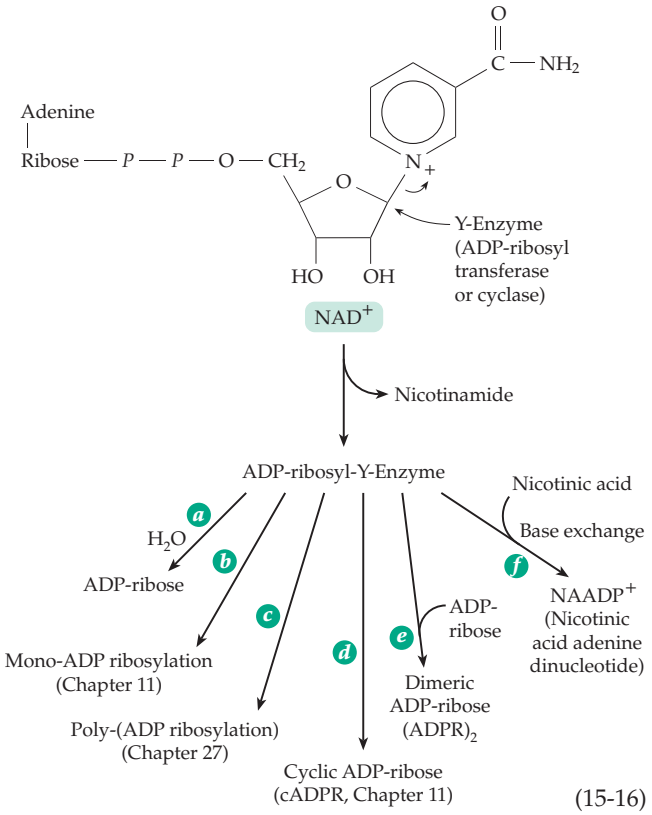


(15-15)

mechanism and no obvious role for NAD^+. See Frey for a discussion.[117]

8. ADP Ribosylation and Related Reactions of NAD^+ and $NADP^+$

The linkage of nicotinamide to ribose in NAD^+ and $NADP^+$ is easily broken by nucleophilic attack on C-1 of ribose. In Chapter 11 enzyme-catalyzed ADP ribosylation, which can be shown as in Eq. 15-16, is discussed briefly. The nucleophilic group –Y from an ADP-ribosyltransferase carries the ADP-ribosyl group which can then be transferred by a second displacement onto a suitable nucleophilic acceptor group.[121,122] Hydrolysis (Eq. 15-16, step *a*) gives free ADP-ribose.[123] Other known products of enzymatic action are indicated in steps *c*–*f*. Poly-(ADP ribosylation) is discussed in Chapter 27. The structure of cyclic ADP-ribose (cADPR)[124] is shown in Chapter 11, Section E,2. The acceptor nucleophile is N-1 of the adenine ring which is made more nucleophilic by electron donation from the amino group. A similar reaction with ADP ribose (Eq. 15-16, step *e*) produces a dimeric ADP-ribose $(ADPR)_2$[125] while reaction with free nicotinic acid (step *f*) yields, in an overall base exchange, nicotinic acid adenine dinucleotide ($NAADP^+$).[126,127] Some of these compounds, e.g., cADPR, $NAADP^+$, and $(ADPR)_2$, are involved in signaling with calcium ions.[124]

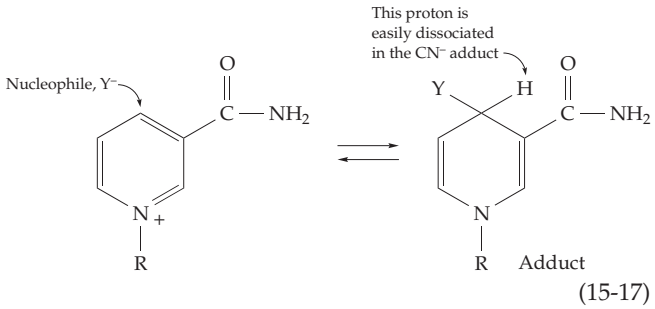


(15-16)

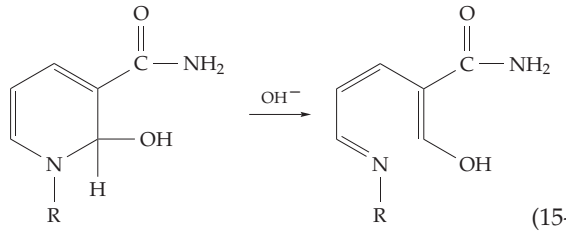
9. The Varied Chemistry of the Pyridine Nucleotides

Despite the apparent simplicity of their structures, the chemistry of the nicotinamide ring in NAD^+ and $NADP^+$ is surprisingly complex.[128,129] NAD^+ is extremely unstable in basic solutions, whereas NADH is just as unstable in slightly acidic media. These properties, together with the ability of NAD^+ to undergo condensation reactions with other compounds, have sometimes caused serious errors in interpretation of experiments and may be of significance to biological function.

Addition to NAD^+ and $NADP^+$. Many nucleophilic reagents add reversibly at the para (or 4) position (Eq. 15-17) to form adducts having structures resembling those of the reduced coenzymes. Formation of the cyanide adduct, whose absorption maximum is at 327 nm, has been used to introduce deuterium into the para position of the pyridine nucleotides. In the adduct, the hydrogen adjacent to the highly polarized C – N bond is easily dissociated as a proton. Thiolate anions and bisulfite also add. Dithionite ion, $S_2O_4^{2-}$, can lose SO_2 and acquire a proton to form the sulfoxylate ion HSO_2^- which also adds to the 4 position of the NAD^+ ring.[130] The resulting adduct is unstable and loses SO_2 to give NADH + H^+. Addition can also occur at the two ortho positions. The adducts of HO^- to the 4 position of NAD^+ are stable but those to the 2 position undergo ring opening (Eq. 15-18) in base-catalyzed reactions which are followed by further degradation.[128,131]

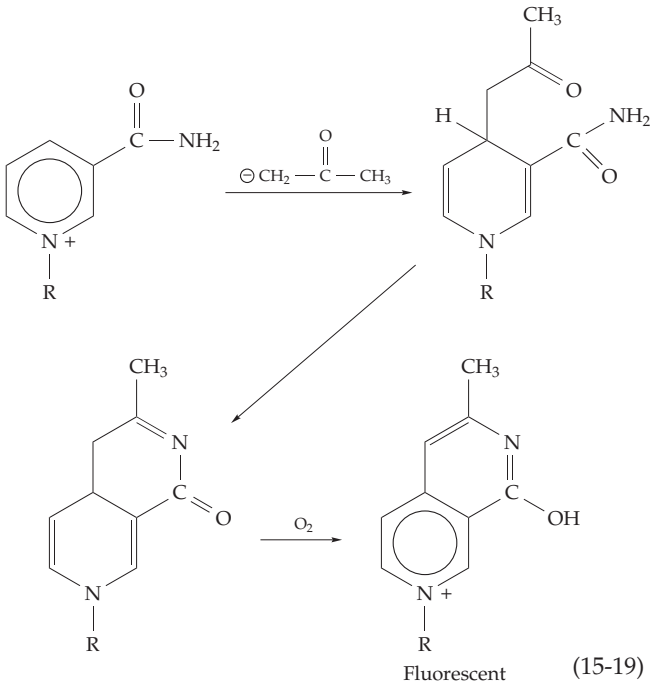


(15-17)



(15-18)

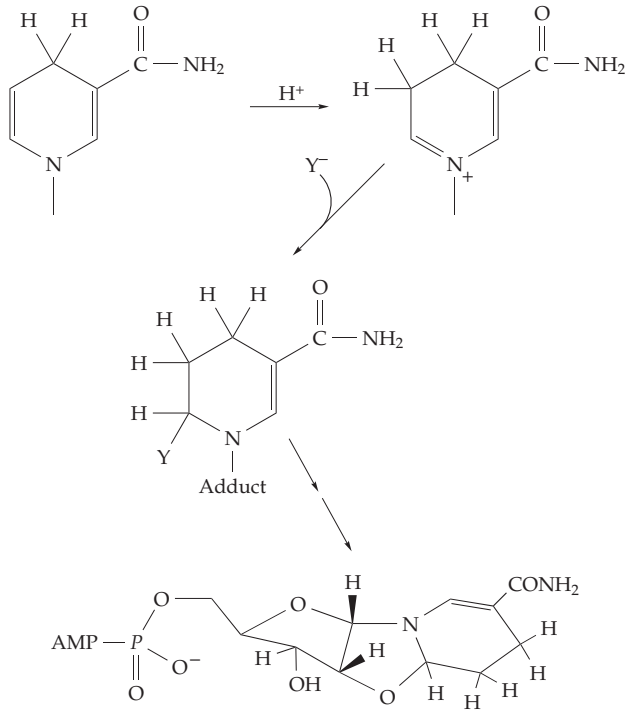
Another base-catalyzed reaction is the addition of enolate anions derived from ketones to the 4 position of the pyridine nucleotides (Eq. 15-19). The adducts undergo ring closure and in the presence of oxygen are converted slowly to fluorescent materials. While forming the basis for a useful analytical method for determination of NAD^+ (using 2-butanone), these reactions also have created a troublesome enzyme inhibitor from traces of acetone present in commercial NADH.[132]



(15-19)

The reactions of Eq. 15-19 occur nonenzymatically only under the influence of strong base but dehydrogenases often catalyze similar condensations relatively rapidly and reversibly. Pyruvate inhibits lactate dehydrogenase, 2-oxoglutarate inhibits glutamate dehydrogenase, and ketones inhibit a short-chain alcohol dehydrogenase in this manner.[133,69a]

Modification of NADH in acid. Reduced pyridine nucleotides are destroyed rapidly in dilute HCl and more slowly at pH 7 in reactions catalyzed by buffer acids.[128,131,134] Apparently the reduced nicotinamide ring is first protonated at C-5, after which a nucleophile Y^- adds at the 6 position (Eq. 15-20). The nucleophile may be OH^-, and the adduct may undergo further reactions. For example, water may add to the other double bond and the ring may open on either side of the nitrogen. The glycosidic linkage can be isomerized from β to α or can be hydrolytically cleaved. The early steps in the modification reaction are partially reversible, but the overall sequence is irreversible. One of the products, which has been characterized by crystal structure determination, is shown in Eq. 15-20.[128,135] It can arise if the group Y of Eq. 15-20 is the C-2' hydroxyl of the ribose ring and if the configuration of the glycosidic linkage is inverted (anomerized).

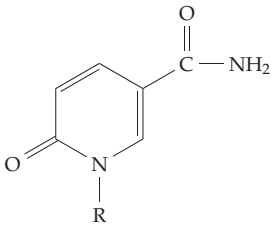


An acid modification product from NADH (15-20)

The foregoing reactions have attracted interest because glyceraldehyde-3-phosphate dehydrogenase, in a side reaction, converts NADH to a substance referred to as NADH-X which has been shown to be the 6(*R*) adduct of Eq. 15-20, where Y is –OH. In an ATP-dependent reaction an enzyme from yeast reconverts NADH-X to NADH.[136]

Mercury (II) ions can add in place of H^+ in the first step of Eq. 15-20 and subsequent reactions similar to those promoted by acid can occur.[137]

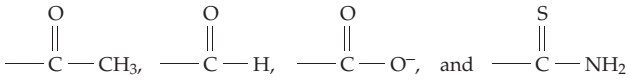
Other reactions of pyridine nucleotides. Alkaline hexacyanoferrate (III) oxidizes NAD^+ and $NADP^+$ to 2-,4-, and 6-pyridones. The 6-pyridone of *N*-methylnicotinamide is a well-known excretion product of nicotinic acid in mammals. Reoxidation of NADH and NADPH to NAD^+ and $NADP^+$ can be accomplished with hexacyanoferrate (III), quinones, and riboflavin



6-Pyridone

but not by H_2O_2 or O_2. However, O_2 does react at neutral pH with uptake of a proton to form a peroxide derivative of NADH.[138] When heated in 0.1 N alkali at 100°C for 5 min, NAD^+ is hydrolyzed to nicotinamide and adenosine-diphosphate-ribose.

Treatment of NAD^+ with nitrous acid deaminates the adenine ring. The resulting deamino NAD^+ as well as synthetic analogs containing the following groups in place of the carboxyamide have been used



widely in enzyme studies. In fact, almost every part of the coenzyme molecule has been varied systematically and the effects on the chemical and enzymatic properties have been investigated.[139–141] "Caged" NAD^+ and $NADP^+$ have also been made.[142] These compounds do not react as substrates until they are released ("uncaged") by photolytic action of a laser beam (see Chapter 23).

B. The Flavin Coenzymes

Flavin adenine diphosphate (**FAD**, flavin adenine dinucleotide) and **riboflavin 5'-monophosphate** (**FMN**, flavin mononucleotide), whose structures are shown in Fig. 15-7, are perhaps the most versatile of all

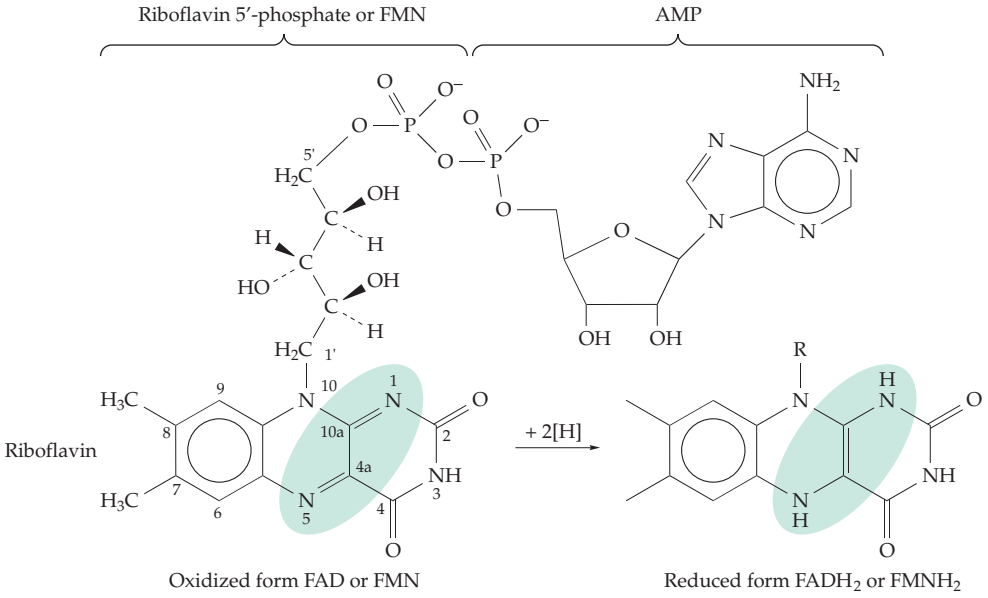


Figure 15-7 The flavin coenzymes flavin adenine dinucleotide (FAD) and riboflavin 5'-phosphate (FMN). Dotted lines enclose the region that is altered upon reduction.

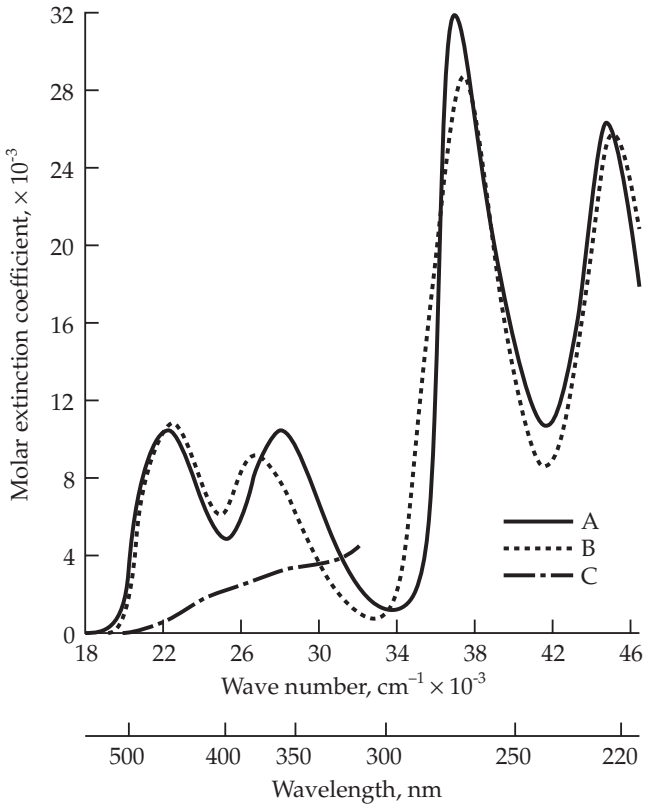

Figure 15-8 Absorption spectrum of neutral, uncharged riboflavin (A), the riboflavin anion (B), and reduced to the dihydro form (Fig. 15-7) by the action of light in the presence of EDTA (C). A solution of 1.1 x 10^{-4} M riboflavin containing 0.01 M EDTA was placed 11.5 cm from a 40-W incandescent lamp for 30 min.

the oxidation coenzymes. The name flavin adenine dinucleotide is not entirely appropriate because the D-ribityl group is not linked to the riboflavin in a glycosidic linkage. Hemmerich suggested that FAD be called flavin adenine diphosphate.[143]

The attention of biochemists was first attracted to flavins as a result of their color and fluorescence. The study of spectral properties of flavins (Fig. 15-8) has been of importance in understanding these coenzymes. The biochemical role of the flavin coenzymes was first recognized through studies of the "old yellow enzyme"[144,145] which was shown by Theorell to contain riboflavin 5'-phosphate. By 1938, FAD was recognized as the coenzyme of a different yellow protein, **D-amino acid oxidase** of kidney tissue. Like the pyridine nucleotides, the new flavin coenzymes were reduced by dithionite to nearly colorless dihydro forms (Figs. 15-7 and 15-8) revealing the chemical basis for their function as hydrogen carriers.

Flavins are also among the natural light receptors and display an interesting and much studied photochemistry (Fig. 3-5).[143] Flavins may function in some photoresponses of plants, and they serve as light emitters in bacterial bioluminescence (Chapter 23).[146,147]

Three facts account for the need of cells for both the flavin and pyridine nucleotide coenzymes: (1) Flavins are usually stronger oxidizing agents than is NAD^+. This property fits them for a role in the electron transport chains of mitochondria where a sequence of increasingly more powerful oxidants is needed and makes them ideal oxidants in a variety of other dehydrogenations. (2) Flavins can be reduced either by one- or two-electron processes. This enables them to participate in oxidation reactions involving free radicals and in reactions with metal ions. (3) Reduced flavins

are "autooxidizable," i.e., they can be reoxidized directly and rapidly by O_2, a property shared with relatively few other organic substances. For example, NADH and NADPH are not spontaneously reoxidized by oxygen. Autooxidizability allows flavins of some enzymes to pass electrons directly to O_2 and also provides a basis for the functioning of flavins in hydroxylation reactions.

1. Flavoproteins and Their Reduction Potentials

Flavin coenzymes are usually bound tightly to proteins and cycle between reduced and oxidized states while attached to the same protein molecule. In a free unbound coenzyme the redox potential is determined by the structures of the oxidized and reduced forms of the couple. Both riboflavin and the pyridine nucleotides contain aromatic ring systems that are stabilized by resonance. Part of this resonance stabilization is lost upon reduction. The value of $E°'$ depends in part upon the varying amounts of resonance in the oxidized and reduced forms. The structures of the coenzymes have apparently evolved to provide values of $E°'$ appropriate for their biological functions.

The relative strengths of binding of oxidized and reduced flavin coenzymes to a protein also have strong effects upon the reduction potential of the coenzyme.[148] If the oxidized form is bound weakly, but the reduced form is bound tightly, a bound flavin will have a greater tendency to stay in the reduced form than it did when free. The reduction potential $E°'$ will be less negative than it is for the free flavin-dihydroflavin couple. On the other hand, if the oxidized form of the flavin is bound more tightly by the protein than is the reduced form, $E°'$ will be more negative and the flavoenzyme will be a less powerful oxidizing agent. In fact, the values of $E°'$ at pH 7 for flavoproteins span a remarkably wide range from – 0.49 to +0.19 V. The state of protonation of the reduced flavin when bound to the enzyme will also have a major effect on the oxidation–reduction potential. For example, acyl-CoA dehydrogenases are thought to form an anionic species of reduced FAD ($FADH^-$) which is tightly bound to the protein.[149]

Every flavoprotein accepts electrons from the substrate that it oxidizes and passes these electrons on to another substrate, an oxidant. In the following sections we will consider for several enzymes how the electrons may get into the flavin from the oxidizable substrate and how they may flow out of the flavin into the final electron acceptor.

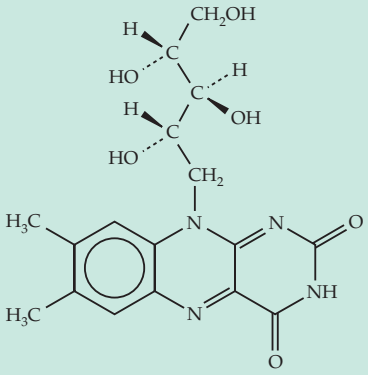
2. Typical Dehydrogenation Reactions Catalyzed by Flavoproteins

The functions of flavoprotein enzymes are numerous and diversified.[151–153a] A few of them are shown in Table 15-2 and are classified there as follows: (A) oxidation of hemiacetals to lactones, (B) oxidation of alcohols to aldehydes or ketones, (C) oxidation of amines to imines, (D) oxidation of carbonyl compounds or carboxylic acids to α,β-unsaturated compounds, (E) oxidation of NADH and NADPH in electron transport chains, and (F) oxidation of dithiols to disulfides or the reverse reaction. Three-dimensional structures are known for enzymes of each of these types.

Reactions of types A–C could equally well be catalyzed by pyridine nucleotide-requiring dehydrogenases. Recall that D-glucose-6-phosphate dehydrogenase uses $NADP^+$ as the oxidant (Eq. 15-10). The first product is the lactone which is hydrolyzed to 6-phosphogluconic acid. The similar reaction of free glucose (Table 15-2, reaction type A) is catalyzed by fungal **glucose oxidase**, a 580-residue FAD-containing enzyme.[154–155] A bacterial cholesterol oxidase has a similar structure.[156] The important plant enzyme **glycolate oxidase** is a dimer containing riboflavin 5'-phosphate.[157–159] It catalyzes a reaction of type B, which plays an important role in photorespiration (Chapter 23). **Amino acid oxidases** (reaction type C) are well-known. The peroxisomal D-amino acid oxidase from kidney was the source from which Warburg first isolated FAD and has been the subject of much investigation of mechanism and structure.[153,160–163] Many snake venoms contain an active 140-kDa L-amino-acid oxidase which contains FAD. Flavin-dependent **amine oxidases**, important in the human body, catalyze the related reaction with primary, secondary, or tertiary amines and in which a carboxyl group need not be present.[164–166a] Reduced flavin produced by all of these oxidases is reoxidized with molecular oxygen and hydrogen peroxide is the product. Nature has chosen to forego the use of an electron transport chain (Fig. 10-5), giving up the possible gain of ATP in favor of simplicity and a more direct reaction with oxygen. In some cases there is specific value to the organism in forming H_2O_2 (see Chapter 18).

In contrast to the flavin oxidases, flavin dehydrogenases pass electrons to carriers within electron transport chains and the flavin does *not* react with O_2. Examples include a bacterial **trimethylamine dehydrogenase** (Fig. 15-9) which contains an iron–sulfur cluster that serves as the immediate electron acceptor[167–169] and yeast **flavocytochrome b_2**, a lactate dehydrogenase that passes electrons to a built-in heme group which can then pass the electrons to an external acceptor, another heme in cytochrome *c*.[170–173] Like glycolate oxidase, these enzymes bind their flavin coenzyme at the ends of 8-stranded αβ barrels similar

BOX 15-B RIBOFLAVIN



The bright orange-yellow color and brilliant greenish fluorescence of riboflavin first attracted the attention of chemists. Blyth isolated the vitamin from whey in 1879 and others later obtained the same fluorescent, yellow compound from eggs, muscle, and urine. All of these substances, referred to as **flavins** because of their yellow color, were eventually recognized as identical. The structure of riboflavin was established in 1933 by R. Kuhn and associates, who had isolated 30 mg of the pure material from 30 kg of dried albumin from 10,000 eggs. The intense fluorescence assisted in the final stages of purification. The vitamin was synthesized in 1935 by P. Karrer.[a]

Riboflavin, a yellow solid, has a low solubility of ~100 mg / l at 25°C. Three crystalline forms are known. One of these, the "readily soluble form," is ten times more soluble than the others and can be used to prepare metastable solutions of higher concentration. One crystalline form is platelike and occurs naturally in the tapetum (Box 13-C) of the nocturnal lemur.

Discovery of the role of riboflavin in biological oxidation was an outgrowth of biochemists' interest in respiration. In the 1920s Warburg provided evidence that oxygen reacted with an iron-containing respiration catalyst and it was shown that the dye **methylene blue** could often substitute for oxygen as an oxidant (Box 18-A). Oxidation of glucose 6-phosphate by methylene blue within red blood cells required both a "ferment" (enzyme) and a "coferment," later identified as $NADP^+$. A yellow protein, isolated from yeast, was found to have the remarkable property of being decolorized by the reducing system of glucose 6-phosphate plus the protein and coferment from red blood cells.

Warburg and Christian showed that the color of this **old yellow enzyme** came from a flavin and proposed that its cyclic reduction and reoxidation played a role in cellular oxidation. When $NADP^+$ was isolated the proposal was extended to encompass a **respiratory chain**. The two hydrogen carriers $NADP^+$ and flavin would work in sequence to link dehydrogenation of glucose to the iron-containing catalyst that interacted with oxygen. While we still do not know the physiological function of the old yellow enzyme,[b] the concept of respiratory chain was correct.

Human beings require about 1.5 mg of riboflavin per day. Because of its wide distribution in food, a deficiency, which affects skin and eyes, is rarely seen. Riboflavin is produced commercially in large quantities by fungi such as *Eremothecium asbyii* which, apparently because of some metabolic anomaly, produce the vitamin in such copious amounts that it crystallizes in the culture medium.

When taken up by the body, riboflavin is converted into its coenzyme forms (Chapter 25) and any excess is quickly excreted in the urine. Urine also contains smaller amounts of metabolites. The ribityl group may be cut by the action of intestinal bacteria acting on riboflavin before it is absorbed. The resulting 10-hydroxyethyl flavin may sometimes be a major urinary product.[c,d] The related 10-formylmethyl flavin is also excreted,[c] as are small amounts of 7α- and 8α- hydroxyriboflavins, apparently formed in the body by hydroxylation. These may be degraded farther to the 7α- and 8α- carboxylic acids of lumichrome (riboflavin from which the ribityl side chain is totally missing).[e] A riboflavin glucoside has also been found in rat urine.[f]

The choroid layer of the eye (behind the retina) in many animals contains a high concentration of free riboflavin. Cats' eyes also contain a large amount of 7 α-hydroxyriboflavin (nekoflavin), as do their livers.[g] Nekoflavin is also present in human blood.[h] Hen egg white contains a 219-residue riboflavin-binding protein whose functions are thought to be storage of the vitamin and delivery to the developing embryo.[i–k] Most of the riboflavin in human blood is bound to proteins such as albumin and immunoglobulins. However, during pregnancy a riboflavin-binding protein similar to that of the chicken appears, apparently to carry riboflavin to the fetus.[j]

Riboflavin is stable to heat but is extremely sensitive to light, a fact of some nutritional significance. Do not leave bottled milk in the sunshine (see Fig. 15-8)! Many products of photolysis are formed (Fig. 3-5). Among them is lumichrome.

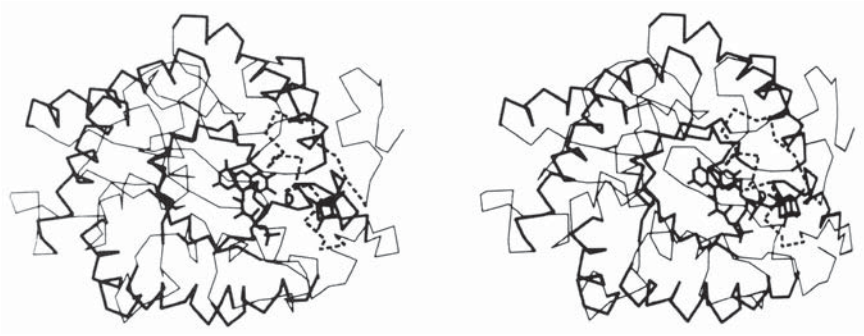

Figure 15-9 Stereoscopic view of the large domain (residues 1–383) of trimethylamine dehydrogenase from a methylotrophic bacterium. The helices and β strands of the $(\alpha\beta)_8$ barrel are drawn in heavy lines as are the FMN (center) and the Fe_4S_4 iron–sulfur cluster at the lower right edge. The α/β loop to which it is bound is drawn with dashed lines. The 733-residue protein also contains two other structural domains. From Lim *et al.*[150] Courtesy of F. S. Mathews.

to that of triose phosphate isomerase (Fig. 2-28). Flavocytochrome b_2 has an additional domain which carries the bound heme. Two additional domains of trimethylamine dehydrogenase have a topology resembling that of the FAD- and NADH-binding domains of glutathione reductase shown in Fig. 15-10. A bacterial **mandelate dehydrogenase** is structurally and mechanistically closely related to the glycolate oxidase family.[173a]

Reaction type D of Table 15-2, the dehydrogenation of an acyl-coenzyme A (CoA), could not be accomplished by a pyridine nucleotide system because the reduction potential ($E°'$, pH 7 = −0.32 V) is inappropriate. The more powerfully oxidizing flavin system is needed. (However, the reverse reaction, hydrogenation of a C=C bond, is often carried out biologically with a reduced pyridine nucleotide.) Dehydrogenation reactions of this type are important in the energy metabolism of aerobic cells. For example, the first oxidative step in the β oxidation of fatty acids (Fig. 17-1) is the α,β dehydrogenation of fatty acyl-CoA derivatives. The *pro-R* hydrogen atoms are removed from both the α- and β-carbon atoms to create the double bond (Table 15-2, type C).

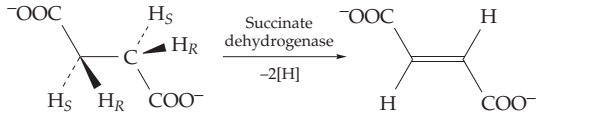
Figure 15-10 The three-dimensional structure of glutathione reductase. Bound FAD is shown. NAD^+ binds to a separate domain below the FAD. The two cysteine residues forming the reducible disulfide loop are indicated by dots. From Thieme *et al.*[182]

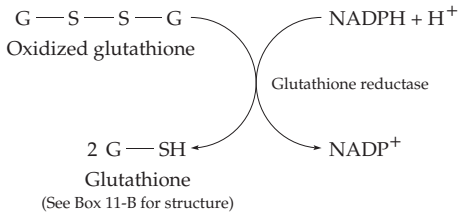
Animal mitochondria contain several different **acyl-CoA dehydrogenases** with differing preferences for chain length or branching pattern.[174–177] A related reaction that occurs in the citric acid cycle is dehydrogenation of succinate to fumarate by **succinate dehydrogenase** (Eq. 15-21).[177a] The dehydrogenation also involves *trans* removal of one of the two hydrogens, one *pro-S* hydrogen and one *pro-R*.[178] The enzyme has a large 621-residue flavoprotein subunit and a smaller 27-kDa iron–sulfur protein subunit.[179–181]



(15-21)

Neither the acyl-CoA dehydrogenases nor succinate dehydrogenase react with O_2. Acyl-CoA dehydrogenases pass the electrons removed from substrates to another flavoprotein, a soluble electron transferring flavoprotein (p. 794), which carries the electrons to an iron–sulfur protein embedded in the inner mitochondrial membrane where they enter the electron-transport chain. Succinate dehydrogenase as well as NADH dehydrogenase (Table 15-2, reaction E)[183] are embedded in the same membrane and also pass their electrons to iron–sulfur clusters and eventually to oxygen through the electron transport chain of the mitochondria (Chapter 18). **Fumarate reductase**[184] has properties similar to those of succinate dehydrogenase but catalyzes the opposite reaction in "anaerobic respiration" (Chapter 18),[184] as do similar reductases of bacteria[185] and of some eukaryotes.[186]

Dihydrolipoyl dehydrogenase (lipoamide dehydrogenase), **glutathione reductase**, and human **thioredoxin reductase**[187–190] belong to a subclass of flavoproteins that act on dithiols or disulfides. The reaction catalyzed by the first of these is illustrated in Table 15-2 (reaction type F). The other two enzymes usually promote the reverse type of reaction, the reduction of a disulfide to two SH groups by NADPH (Eq. 15-22). Glutathione reductase splits its substrate into two halves while reduction of the small 12-kDa protein **thioredoxin** (Box 15-C) simply opens a loop in its peptide chain. The reduction of lipoic acid opens the small disulfide-containing 5-membered ring in that molecule. Each of these flavoproteins also contains within its structure a reducible disulfide group that participates in catalysis.

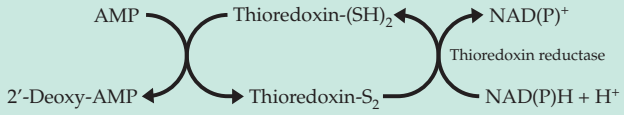


(15-22)

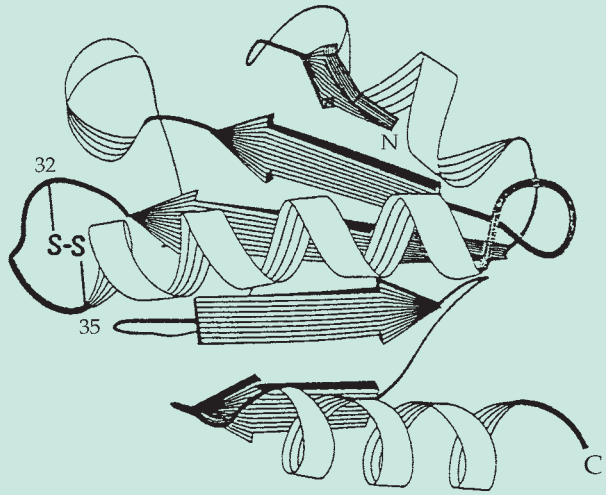
Each 50-kDa chain of the dimeric glutathione reductase is organized into three structural domains (Fig. 15-10).[191–193] Two of the domains each contain a nucleotide-binding motif resembling those of the NAD^+-dependent dehydrogenases. One of these domains binds NADPH and the other FAD. The latter domain also contains the reducible disulfide which is formed from Cys 58 and Cys 63. It serves as an intermediate hydrogen carrier which can in turn reduce oxidized glutathione. A **trypanothione reductase** from trypanosomes and related flagellated protozoa has a similar structure and acts on trypanothione, which replaces glutathione in these organisms.[188,194-196] Because it is unique to trypanosomes, this enzyme is a target for design of drugs against these organisms

BOX 15-C THIOREDOXIN AND GLUTAREDOXIN

The small proteins thioredoxin and glutaredoxin are present in relatively high concentrations in bacteria, plants, and animals. For example, thioredoxin has a concentration of 15 μM in *E. coli*. Both proteins were discovered by their role as reducing agents in conversion of the ribonucleotides AMP, GMP, CMP, and UMP to the corresponding 2-deoxyribonucleotides which are needed for synthesis of DNA:[a,b]



The redox group in thioredoxin is a **disulfide loop** located on a protrusion at one end of the molecule. In the 108-residue *E. coli* thioredoxin, as well as in the 105-residue human thioredoxin,[c] it is formed by cysteines 32 and 35 which are present in the conserved sequence CGPC. The –SH groups of these two interacting cysteines have pK_a values of ~6.9 and 7.5, the former belonging predominantly to the more exposed Cys 32.[d] The buried Asp 26 carboxyl group, which may be a proton donor to Cys 35 during reduction of the disulfide form,[e] forms a salt bridge with the Lys 57 $-NH_3^+$ and has a high pK_a of ~7.4.[e–g]

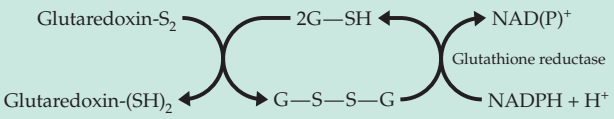


Oxidized *E. coli* thioredoxin. From Langsetmo *et al.*[f]

The pK_a assignments, which have been controversial, are discussed in Chapter 7. This disulfide loop is reduced by NADPH through the action of the flavoprotein enzyme **thioredoxin reductase**. The resulting thiol pair of the reduced thioredoxin is the reductant used for ribonucleotide reductase (Chapter 16). The standard redox potential $E°'$ of *E. coli* thioredoxin is –0.27 V, appropriately low for coupling to the NADPH / $NADP^+$ system.

Reduced thioredoxin has a variety of functions.[h] It is the reductant for conversion of methionine sulfoxide to methionine in bacteria, for reduction of sulfate in yeast, and for additional specific enzymatic reactions.[b,h] However, its major function may be to reduce disulfide linkages in various proteins.[i] Several photosynthetic enzymes are activated by reduction of disulfide linkages via photosynthetically generated reduced ferredoxin and thioredoxin[j,k] (Chapter 23). Reduced thioredoxin may also play a similar role in nonphotosynthetic cells. It may reduce mixed disulfides such as those formed between glutathione and proteins (Box 11-B).[l–n] Thioredoxin may participate in regulation of the level of nitric oxide (NO) in tissues[m] and it is needed in the assembly of filamentous bacteriophages.[b,o] For reasons that are not clear, thioredoxin is also an essential subunit for a virus-induced DNA polymerase formed in *E. coli* following infection by bacteriophage T7 (see Chapter 27).

It was a surprise to discover that a mutant of *E. coli* lacking thioredoxin can still reduce ribonucleotides. In the mutant cells thioredoxin is replaced by glutaredoxin, whose active site disulfide linkage is reduced by glutathione rather than directly by NADPH. Oxidized glutathione is, in turn, reduced by NADPH and glutathione reductase. Thus, the end result is the same with respect to ribonucleotide reduction.



However, the two proteins have significantly different specificities and functions. The disulfide loop in glutaredoxin, whose eukaryotic forms are often called **thioltransferases**,[p] has the sequence CPYC. Although glutaredoxins are weaker reductants of mixed disulfides of proteins with glutathione than are thioredoxins,[q–s] they are more specific.

Both thioredoxin and glutaredoxin are members of a larger group of thiol:disulfide oxidoreductases which are found in all known organisms. In *E. coli* there are one thioredoxin, three different glutaredoxins,[h,t] and the periplasmic protein disulfide

BOX 15-C (continued)

isomerases DsbA and DsbC, which were discussed in Chapter 10.[u–w] Similar enzymes are found in the endoplasmic reticulum of eukaryotic cells.[u,x] Like thioredoxins, they contain disulfide loops which contain the sequences CGHC and CGYC as well as CPHC. Thioredoxin reductase itself also can keep cytoplasmic bacterial proteins reduced.[y] Redox potentials vary within this family of proteins:[n,s,z,aa]

	$E^{\circ\prime}$, pH 7
Thioredoxins	–.27 V
Glutaredoxins	–.20 to –.23 V
Protein disulfide isomerase	–.18 V
DsbA	–.09 to –.12 V

These differences are correlated with differing functions. The intracellular reduced thioredoxins are thermodynamically the best reductants of disulfide linkages in proteins and they help keep intracellular proteins reduced. Glutaredoxin can be reduced efficiently by reduced glutathione or by NADPH and glutathione reductase and can, in turn, reduce cysteine and the oxidized form of vitamin C, **dehydroascorbic acid** (Box 18-D).[bb,cc] The periplasmic bacterial proteins DsbA and DsbC have the highest redox potentials and an unusually low first pK_a for the dithiol pair in their thioredoxinlike domains.[aa] The basis for these properties has been hard to understand but is consistent with their role in assisting formation of disulfide bridges in extracellular proteins and with the role of the related protein disulfide isomerase in the ER.[u,dd–ff] These disulfide exchanges are nucleophilic displacement reactions (Chapter 12).

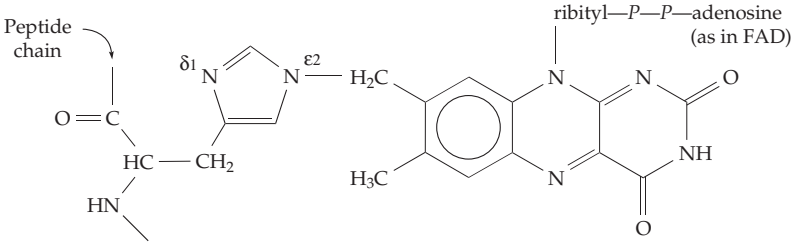
which cause such terrible diseases as African sleeping sickness and Chagas disease.[195,197]

Another flavoprotein constructed on the glutathione reductase pattern is the bacterial plasmid-encoded **mercuric reductase** which reduces the highly toxic Hg^{2+} to volatile elemental mercury, Hg^0. A reducible disulfide loop corresponding to that in glutathione reductase is present in this enzyme but there is also a second pair of cysteines nearby. All of these may participate in binding and reduction of Hg^{2+}.[198–199a]

3. More Flavoproteins

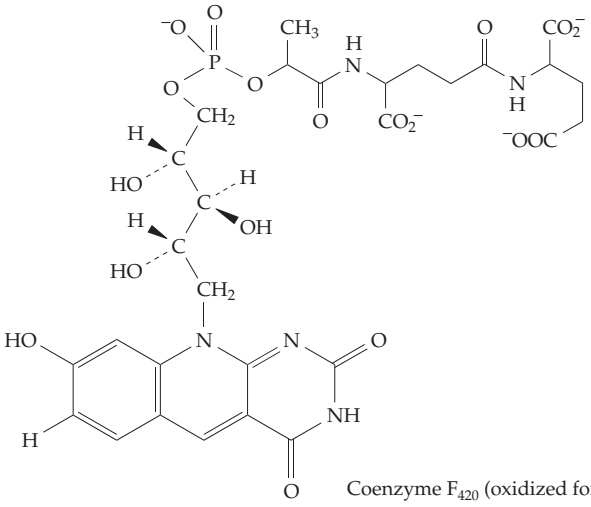
Flavoproteins function in virtually every area of metabolism and we have considered only a small fraction of the total number. Here are a few more. Flavin-dependent reductases use hydrogen atoms from NADH or NADPH to reduce many specific substances or classes of compounds. The FAD-containing ferredoxin: $NADP^+$ oxidoreductase catalyzes the reduction of free $NADP^+$ by reduced ferredoxin generated in the chloroplasts of green leaves.[200,201] Similar enzymes, some of which utilize reduced flavodoxins, are found in bacteria.[202,203] The FMN-containing subunit of NADH: ubiquinone oxidoreductase is an essential link in the mitochondrial electron transport chain for oxidation of NADH in plants and animals[183,204,205] and for related processes in bacteria. **Glutamate synthase**, a key enzyme in the nitrogen metabolism of plants and microorganisms, uses electrons from NADPH to reduce 2-oxoglutarate to glutamate in a complex glutamine-dependent process (see Fig. 24-5). The enzyme contains both FMN and FAD and three different iron–sulfur clusters.[205a] Flavin reductases use NADH or NADPH to reduce free riboflavin, FMN, or FAD needed for various purposes[206,206a] including emission of light by luminous bacteria.[207] They provide electrons to many enzymes that react with O_2 such as the cytochromes P450[208,209] and nitric oxide synthase (Chapter 18). An example is adrenodoxin reductase (see chapter banner, p. 764), which passes electrons from NADPH to cytochrome P450 via the small redox protein adrenodoxin. This system functions in steroid biosynthesis as is indicated in Fig. 22-7.[209a,b] Other flavin-dependent reductases have protective functions catalyzing the reduction of ascorbic acid radicals,[210,211] toxic quinones,[212–214] and peroxides.[215–218]



Covalently bound modified FAD of succinate dehydrogenase

has been isolated from a bacterial electron-transferring flavoprotein.[225] Commercial FAD may contain some riboflavin 5'-pyrophosphate which activates some flavoproteins and inhibits others.[226]

Methanogenic bacteria contain a series of unique coenzymes (Section F) among which is **coenzyme F_{420}**, a 5-deazaflavin substituted by H at position 7 and –OH at position 8 (8-hydroxy-7,8-didemethyl-5-deazariboflavin).[227,228]



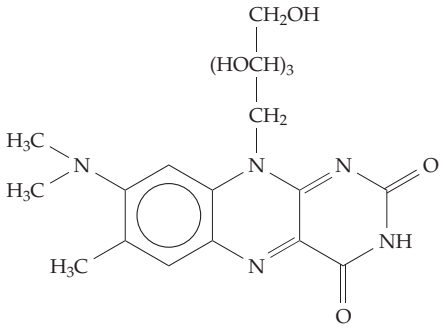
Coenzyme F_{420} (oxidized form)

4. Modified Flavin Coenzymes

Mitochondrial succinate dehydrogenase, which catalyzes the reaction of Eq. 15-21, contains a flavin prosthetic group that is covalently attached to a histidine side chain. This modified FAD was isolated and identified as 8α-($N^{\varepsilon 2}$-histidyl)-FAD.[219] The same prosthetic group has also been found in several other dehydrogenases.[220] It was the first identified member of a series of modified FAD or riboflavin 5'-phosphate derivatives that are attached by covalent bonds to the active sites of more than 20 different enzymes.[219]

These include 8α-($N^{\varepsilon 2}$-histidyl)-FMN,[221] 8α-($N^{\delta 1}$-histidyl)-FAD,[222] 8α-(*O*-tyrosyl-FAD),[223] and 6-(*S*-cysteinyl)-riboflavin 5'-phosphate, which is found in trimethylamine dehydrogenase (Fig. 15-9).[224] An 8-hydroxy analog of FAD (–OH in place of the 8-CH_3)

This unique redox catalyst links the oxidation of H_2 or of formate to the reduction of $NADP^+$[229] and also serves as the reductant in the final step of methane biosynthesis (see Section E).[228] It resembles NAD^+ in having a redox potential of about –0.345 volts and the tendency to be only a two-electron donor. More recently free 8-hydroxy-7,8-didemethyl-5-deazariboflavin has been identified as an essential light-absorbing chromophore in DNA photolyase of *Methanobacterium*, other bacteria, and eukaryotic algae.[230] **Roseoflavin** is not a coenzyme but an antibiotic from *Streptomyces davawensis*.[231] Many synthetic flavins have been used in studies of mechanisms and for NMR[232] and other forms of spectroscopy.

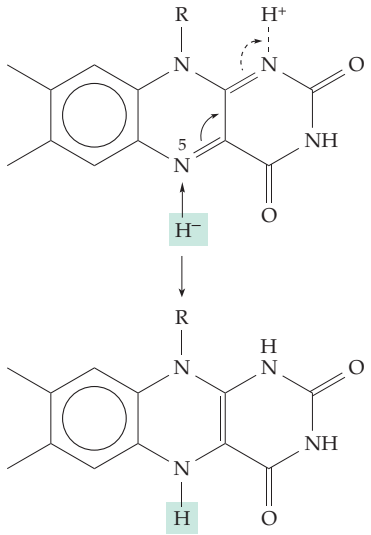


Roseoflavin

5. Mechanisms of Flavin Dehydrogenase Action

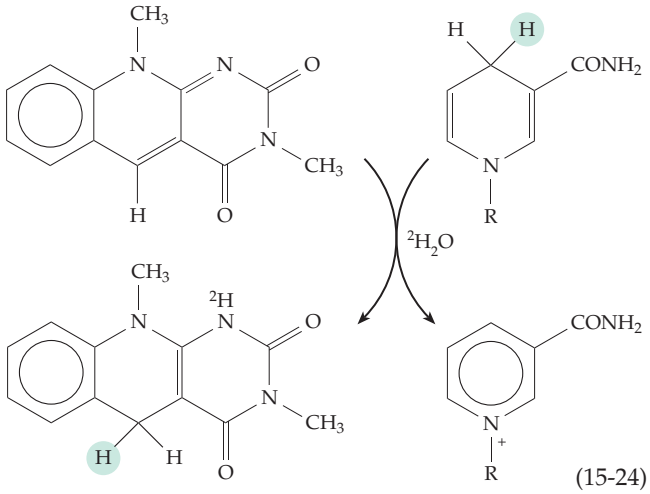
The chemistry of flavins is complex, a fact that is reflected in the uncertainity that has accompanied efforts to understand mechanisms. For flavoproteins at least four mechanistic possibilities must be considered.[153a,233] (a) A reasonable **hydride-transfer** mechanism can be written for flavoprotein dehydrogenases (Eq. 15-23). The hydride ion is donated at N-5 and a proton is accepted at N-1. The oxidation of alcohols, amines, ketones, and reduced pyridine nucleotides can all be visualized in this way. Support for such a mechanism came from study of the nonenzymatic oxidation of NADH by flavins, a reaction that occurs at moderate speed in water at room temperature. A variety of flavins and dihydropyridine derivatives have been studied, and the electronic effects observed for the reaction are compatible with the hydride ion mechanism.[234–236]

According to the mechanism of Eq. 15-23, a hydride ion is transferred directly from a carbon atom in a substrate to the flavin. However, a labeled hydrogen atom transferred to N-5 or N-1 would immediately exchange with the medium, rapid exchange being characteristic of hydrogens attached to nitrogen.



(15-23)

To avoid this problem, Brustlein and Bruice used a **5-deazaflavin** to oxidize NADH nonenzymatically.[237] When this reaction was carried out in ^2H_2O, no ^2H entered the product at C-5, indicating that a hydrogen atom (circled in Eq. 15-24) had been transferred directly from NADH to the C-5 position. Similar direct transfer of hydrogen to C-5 of 5-deazariboflavin 5'-phosphate is catalyzed by flavoproteins such as *N*-methylglutamate synthase[238] and acyl-CoA dehydrogenase.[237–239]



(15-24)

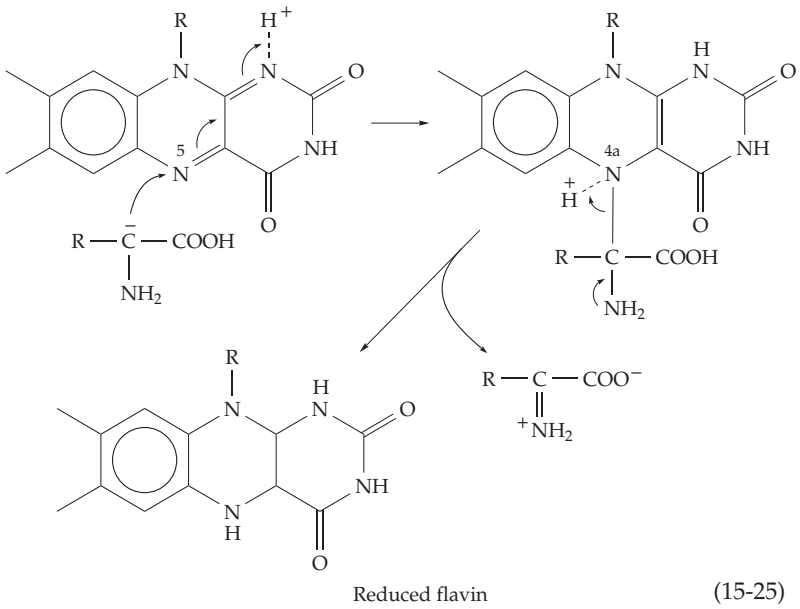
However, these experiments may not have established a mechanism for natural flavoprotein catalysis because the properties of 5-deazaflavins resemble those of NAD^+ more than of flavins.[239] Their oxidation–reduction potentials are low, they do not form stable free radicals, and their reduced forms don't react readily with O_2. Nevertheless, for an acyl-CoA dehydrogenase the rate of reaction of the deazaflavin is almost as fast as that of natural FAD.[238] For these enzymes a hydride ion transfer from the β CH (reaction type D of Table 15-1) is made easy by removal of the α-H of the acyl-CoA to form an enolate anion intermediate.

The three-dimensional structure of the medium chain acyl-CoA dehydrogenases with bound substrates and inhibitors is known.[174,175,240] A conserved glutamate side chain is positioned to pull the *pro-R* proton from the α carbon to create the initial enolate anion.[174,175,241] The *pro-R* β C–H lies by N-5 of the flavin ring seemingly ready to donate a hydride ion as in Eq. 15-23. NMR spectroscopy has been carried out with ^{13}C or ^{15}N in each of the atoms of the redox active part of the FAD. The results show directly the effects of strong hydrogen bonding to the protein at N-1, N-3, and N-5 and also suggest that the bound $FADH_2$ is really $FADH^-$ with the negative charge localized on N-1 by strong hydrogen bonding.[149] Many mutants have been made,[242] substrate analogs have been tested,[176,243] kinetic isotope effects have been measured,[242a] and potentiometric titrations have been done.[243] All of the results are compatible with the enolate anion hydride-transfer

mechanism. Questions about the acidity of the α-H and the mechanism of its removal to form the enolate anion[242a] are similar to those discussed in Chapter 13, Section B.

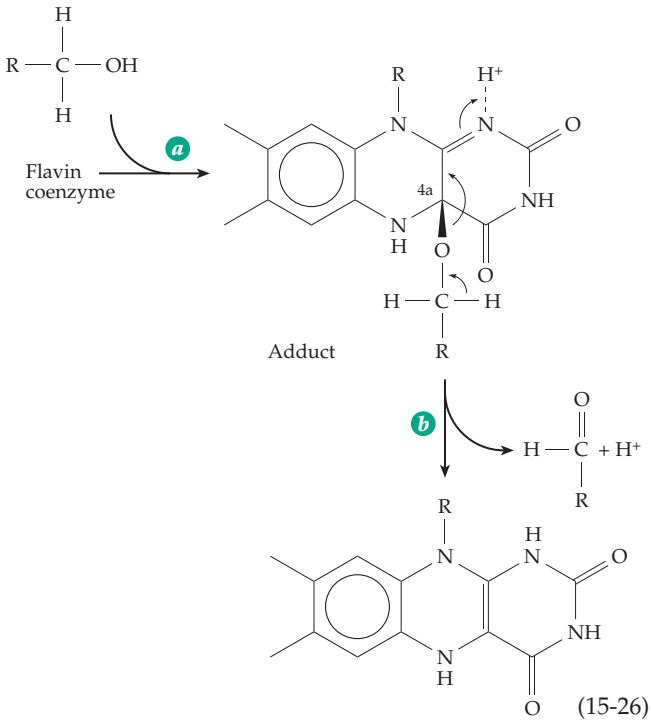
A peculiarity of several acyl-CoA dehydrogenases is a bright green color with an absorption maximum at 710 nm. This was found to result from tightly bound coenzyme A persulfide (CoA–S–S$^-$).[244,245]

(b) A second possible mechanism of flavin reduction is suggested by the occurrence of addition reactions involving the isoalloxazine ring of flavins. Sulfite adds to flavins by forming an N–S bond at the 5 position and nitroethane, which is readily dissociated to the carbanion $H_3C-CH^- - NO_2$, acts as a substrate for D-amino acid oxidase.[246,247] This fact suggested a **carbanion mechanism** according to which normal D-amino acid substrates form carbanions by dissociation of the αH (Eq. 15-25). Ionization would be facilitated by binding of the substrate carboxylate to an adjacent arginine side chain and the carbanion could react at N-5 of the flavin as in Eq. 15-25. Similar mechanisms have been suggested for other flavin enzymes.[248,249]



(15-25)

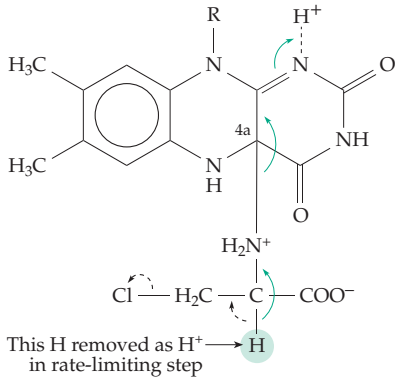
(c) The adducts with nitroethane and other compounds[250] pointed to reaction at N-5, but Hamilton[251] suggested that a better position for addition of nucleophiles is carbon 4a, which together with N-5 forms a cyclic Schiff base. He argued that other electrophilic centers in the flavin molecule, such as carbons 2, 4, and 10a, would be unreactive because of their involvement in amide or amidine-type resonance but an amine, alcohol, or other substrate could add to a flavin at position 4a (Eq. 15-26, step *a*). Cleavage of the newly formed C–O bond could then occur by movement of electrons from the alcohol part of the adduct into the flavin as indicated in step *b*. The products of this



(15-26)

4a adduct mechanism are the reduced flavin and an aldehyde, the same as would be obtained by the hydride ion mechanism. However, in Eq. 15-26, both hydrogens in the original substrate (that on oxygen and that on carbon) have dissociated as protons, the electrons having moved as a pair during the cleavage of the adduct. Hamilton argued that an isolated hydride ion has a large diameter while a proton is small and mobile; for this reason dehydrogenation may often take place by proton transfer mechanisms.

Experimental support for the mechanism of Eq. 15-26 has been obtained using D-chloroalanine as a substrate for D-amino acid oxidase.[252–254] Chloropyruvate is the expected product, but under anaerobic conditions pyruvate was formed. Kinetic data obtained with α-^{2}H and α-^{3}H substrates suggested a common intermediate for formation of both pyruvate and chloro-pyruvate. This intermediate could be an anion formed by loss of H$^+$ either from alanine or from a C-4a adduct. The anion could eliminate chloride ion as indicated by the dashed arrows in the following structure. This would lead to formation of pyruvate without reduction of the flavin. Alternatively, the electrons from the carbanion could flow into the flavin (green arrows), reducing it as in Eq. 15-26. A similar mechanism has been suggested for other flavoenzymes.[249,255] Objections to the carbanion mechanism are the expected



very high pK_a for loss of the α-H to form the carbanion[256] and the observed formation of only chloroalanine and no pyruvate in the reverse reaction of chloropyruvate, ammonia, and reduced flavoprotein.

A long-known characteristic of D-amino acid oxidase is its tendency to form charge-transfer complexes with amines, complexes in which a nonbonding electron has been transferred partially to the flavin. Complete electron transfer would yield a flavin radical and a substrate radical which could be intermediates in a **free radical mechanism**, as discussed in the next section.[256]

The three-dimensional structure of the complex of D-amino acid oxidase with the substrate analog benzoate has been determined. The carboxyl group of the inhibitor is bound by an arginine side chain (Fig. 15-11) that probably also holds the amino acid substrate. There is no basic group nearby in the enzyme that could serve to remove the α-H atom in Eq. 15-26 but the position is appropriate for a direct transfer of the hydrogen to the flavin as a hydride ion as in Eq. 15-23.[161,162,257] In spite of all arguments to the contrary the hydride ion mechanism could be correct! However, an adduct mechanism is still possible.

Experimental evidence supports a 4a adduct mechanism for glutathione reductase and related enzymes[191,258,258a] (Fig. 15-12). In this figure the reaction sequence is opposite to that in Eq. 15-26. The enzyme presumably functions as follows. NADPH binds next to the bound FAD and reduces it by transfer of the 4-*pro*-*S* hydrogen of the NADPH (Fig. 15-12, step *a*). The sulfur atom of Cys 63 is in van der Waals contact with the bound FAD at or near carbon atom 4a. In step *b* the nucleophilic center on atom C-4a of $FADH_2$ attacks a sulfur atom of the disulfide loop between cysteines 58 and 63 in the protein to create a C-4a adduct of a thiolate ion with oxidized FAD and to cleave the –S–S– linkage in the loop. In step *c* the thiol group of cysteine 63 is eliminated, after which the thiol of Cys 58 attacks the nearer sulfur atom of the oxidized glutathione in a nucleophilic displacement (step *d*) to give one reduced glutathione (GSH) and a mixed disulfide of glutathione and the enzyme (G-S-S-Cys 58). The thiolate anion of Cys 63, which is stabilized by interaction with the adjacent flavin ring, then attacks this disulfide (step *e*) to regenerate the internal disulfide and to free the second molecule of reduced glutathione. The imidazole group of the nearby His 467 of the second subunit presumably participates in catalysis as may some other side chains.[191] The disulfide exchange reactions are similar to those discussed in Chapter 12.

A variation is observed for *E. coli* thioredoxin reductase. The reducible disulfide and the NADPH binding site are both on the same side of the flavin rather than on opposite sides as in Fig. 15-12.[190,259] Mercuric reductase also uses NADPH as the reductant transferring the 4*S* hydrogen. The Hg^{2+} presumably binds to a sulfur atom of the reduced disulfide loop and there undergoes reduction. The observed geometry of the active site is correct for this mechanism.

6. Half-Reduced Flavins

A possible mechanism of flavin dehydrogenation consists of consecutive transfer of a hydrogen atom and of an electron with intermediate radicals being formed both on the flavin and on the substrate. Such

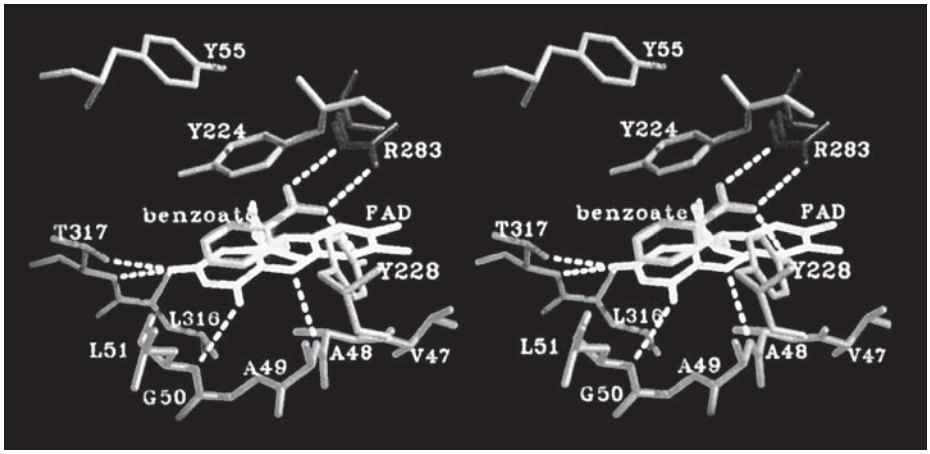


Figure 15-11 Stereoscopic view of the benzoate ion in its complex with D-amino acid oxidase. A pair of hydrogen bonds binds the carboxylate of the ligand to the guanidinium group of R283. Several hydrogen bonds to the flavin ring of the FAD are also indicated. Courtesy of Retsu Miura.[161]

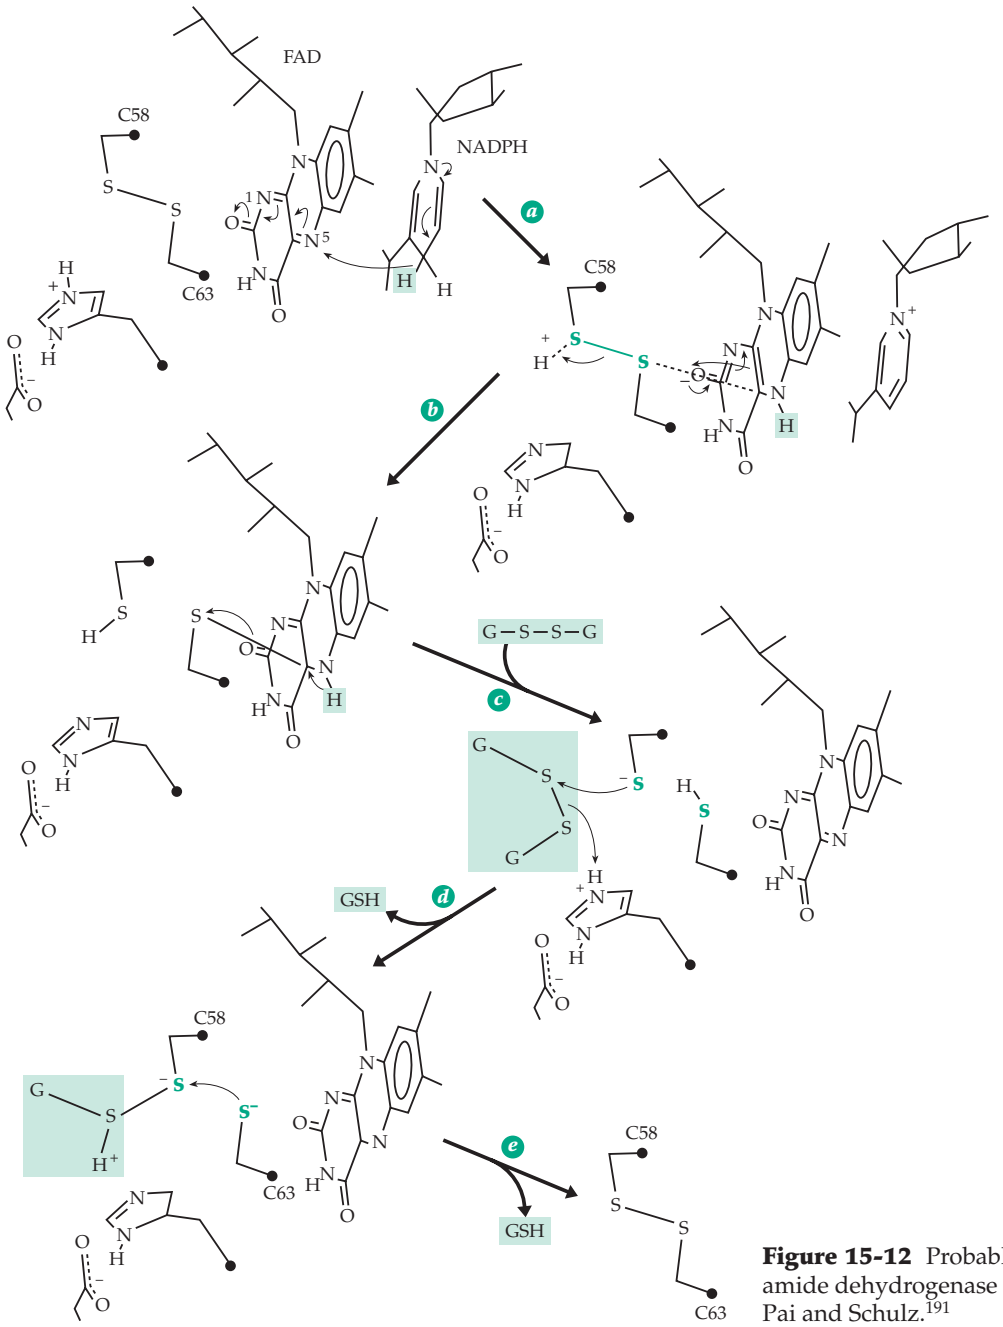

Figure 15-12 Probable reaction mechanism for lipoamide dehydrogenase and glutathione reductase. See Pai and Schulz.[191]

a mechanism takes full advantage of one of the most characteristic properties of flavins, their ability to accept single electrons to form **semiquinone** radicals. If the oxidized form Fl of a flavin is mixed with the reduced form FlH_2, a single hydrogen atom is transferred from FlH_2 to Fl to form two $^{\bullet}$F1H radicals (Eq. 15-27).

$$Fl + FlH_2 \underset{}{\overset{K_f}{\rightleftharpoons}} 2\ {}^{\bullet}FlH \qquad (15\text{-}27)$$

The equilibrium represented by this equation is independent of pH, but because all three forms of the flavin have different pK_a values (Fig. 15-13) the apparent equilibrium constants relating total concentrations of oxidized, reduced, and radical forms vary with pH.[143,260–262] The fraction of radicals present is greater at low pH and at high pH than at neutrality. For a 3-alkylated flavin the formation constant K_f has been estimated as 2.3×10^{-2} and for riboflavin[260] as 1.5×10^{-2}. From these values and the pK_a values in Fig. 15-13, it is possible to estimate the amount of radical present at any pH.

Neutral flavin radicals have a blue color (the wavelength of the absorption maximum, λ_{max}, is ~560 nm) but either protonation at N-1 or dissociation of a proton from N-5 leads to red cation or anion radicals with λ_{max} at ~477 nm. Both blue and red radicals are

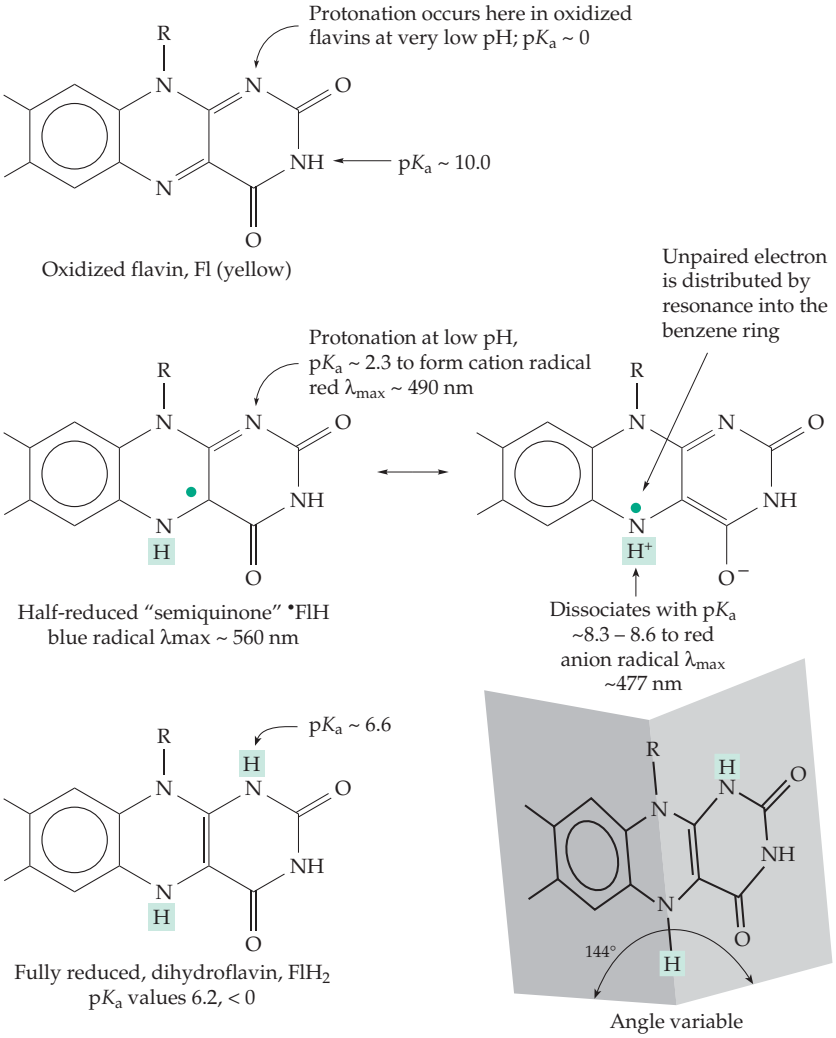

Figure 15-13 Properties of oxidized, half-reduced, and fully reduced flavins. See Müller *et al.*[263,264]

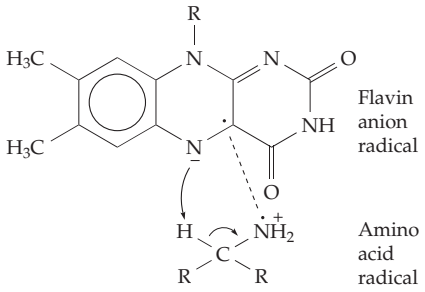


Another alternative to a radical pair is a hydrogen atom transfer followed by a second electron transfer.[265]

If an enzyme binds a flavin radical much more tightly than the fully oxidized or reduced forms, reduction of the flavoprotein will take place in two one-electron steps. In such proteins the values of $E°'$ for the two steps may be widely separated. The best known examples are the small, low-potential electron-carrying proteins known as **flavodoxins**.[266–269a] These proteins, which carry electrons between pairs of other redox proteins, have a variety of functions in anaerobic and photosynthetic bacteria, cyanobacteria, and green algae. Their functions are similar to those of the **ferredoxins**, iron–sulfur proteins that are considered in Chapter 16. In some bacteria ferredoxin and flavodoxin are interchangeable and the synthesis of flavodoxin is induced if the bacteria become deficient in iron. Flavodoxins all contain riboflavin monophosphate, which functions by cycling between the fully reduced anionic form and a blue semiquinone radical.[270] The two reduction steps, from oxidized flavin to semiquinone and from semiquinone to dihydroflavin, are well separated. For example, the values of $E°'$ (pH 7) for the flavodoxin from *Megasphaera elsdenii* are −0.115 and −0.373 V, while those of the *Azotobacter vinlandii* flavodoxin (azotoflavin) are + 0.050 and – 0.495 V. The latter is the lowest known for any flavoprotein.

Flavodoxins are small proteins with an α/β structure resembling that of the nucleotide binding domain of dehydrogenases. According to ^{31}P NMR data, the phosphate group of the coenzyme bound to flavodoxin is completely ionized,[271] even though it is deeply buried in the protein and is not bound to any positively charged side chain but to the N terminus of an α helix and to four –OH groups of serine and threonine side

observed in enzymes, with some enzymes favoring one and some the other. Hemmerich suggested that enzymes forming red radicals make a strong hydrogen bond to the proton in the 5 position of the flavin. This increases the basicity of N-1 leading to its protonation and formation of the red cation radicals.

It is possible that many flavoprotein oxygenases and dehydrogenases react via free radicals. For example, instead of the mechanism of Eq. 15-26, an electron could be transferred to the flavin, leaving a radical pair (at right). The crystallographic structure and modeling of the substrate complex support this possibility.[265,265a] In this pair the flavin radical would be more basic than in the fully oxidized form and the amino acid radical would be more acidic than in the uncharged form. A proton transfer as indicated together with coupling of the radical pair would yield the same product as the mechanism of Eq. 15-26.

chains. The flavin ring is partially buried near the surface of the 138-residue protein. An aromatic side chain, from tryptophan or tyrosine, lies against the flavin on the outside of the molecule. Flavodoxins can be crystallized in all three forms: oxidized, semiquinone, and fully reduced. In the crystals the flavin semiquinone, like the oxidized flavin, is nearly planar.

The **DNA photolyase** of *E. coli*, an enzyme that participates in the photochemical repair of damaged DNA (Chapter 23), contains a blue neutral FAD radical with a 580-nm absorption band and an appropriate ESR signal.[230,272] In contrast, the mitochondrial **electron-transferring flavoprotein** (ETF), a 57-kDa αβ dimer containing one molecule of FAD, functions as a single electron carrier cycling between oxidized FAD and the red anionic semiquinone.[273,274] The reduced forms of the acyl-CoA dehydrogenases transfer their electrons one at a time from their FAD to the FAD of two molecules of electron-transferring flavoprotein. Therefore, an intermediate enzyme-bound radical must be present in the FAD of acyl-CoA dehydrogenase at one stage of its catalytic cycle. A related ETF from a methylotrophic bacterium accepts single electrons from reduced trimethylamine dehydrogenase (Fig. 15-9).[275]

Another flavoprotein that makes use of both one- and two-electron transfer reactions is **ferredoxin-NADP⁺ oxidoreductase** (Eq. 15-28). Its bound FAD accepts electrons one at a time from each of the two

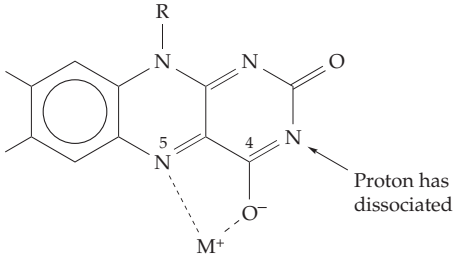
$$2Fd_{red} + NADP^+ + H^+ \rightarrow 2\,Fd_{ox}{}^+ + NADPH \qquad (15\text{-}28)$$

reduced ferredoxins (Fd_{red}) in chloroplasts and then presumably transfers a hydride ion to the $NADP^+$. The enzyme is organized into two structural domains,[201] one of which binds FAD and the other $NADP^+$. Similar single-electron transfers through flavoproteins also occur in many other enzymes. Chorismate mutase, an important enzyme in biosynthesis of aromatic rings (Chapter 25), contains bound FMN. Its function is unclear but involves formation of a neutral flavin radical.[276,277]

7. Metal Complexes of Flavins and Metalloflavoproteins

The presence of metal ions in many flavoproteins suggested a direct association of metal ions and flavins. Although oxidized flavins do not readily bind most metal ions, they form red complexes with Ag^+ and Cu^+ with a loss of a proton from N-3.[278] Flavin semiquinone radicals also form strong red complexes with many metals.[264] If the complexed metal ion can exist in more than one oxidation state, electron transfer between the flavin and a substrate could take place through the metal atom. However, *chelation by flavins in nature has not been observed*. Metalloflavoproteins probably function by having the metal centers close enough to the flavin for electron transfer to occur but not in direct contact. This is the case for a bacterial trimethylamine dehydrogenase in which the FeS cluster is bound about 0.4 nm from the alloxazine ring of riboflavin 5'-phosphate as shown in Fig. 15-9.

Some metalloflavoproteins contain heme groups. The previously mentioned **flavocytochrome b_2** of yeast is a 230-kDa tetramer, one domain of which carries riboflavin phosphate and another heme. A flavocytochrome from the photosynthetic sulfur bacterium *Chromatium* (cytochrome *c*-552)[279] is a complex of a 21-kDa cytochrome *c* and a 46-kDa flavoprotein containing 8α-(*S*-cysteinyl)-FAD. The 670-kDa **sulfite reductase** of *E. coli* has an $\alpha_8\beta_4$ subunit structure. The eight α chains bind four molecules of FAD and four of riboflavin phosphate, while the β chains bind three or four molecules of **siroheme** (Fig. 16-6) and also contain Fe_4S_4 clusters.[280,281] Many nitrate and some nitrite reductases are flavoproteins which also contain Mo or



Fe prosthetic groups.[282,283] A group of **aldehyde oxidases** and **xanthine dehydrogenases** also contain molybdenum as well as iron (Chapter 16). In every case the metal ions are bound independently of the flavin.[283a]

8. Reactions of Reduced Flavins with Oxygen

Free dihydroriboflavin reacts nonenzymatically in seconds and reduced flavin oxygenases react even faster with molecular oxygen to form hydrogen peroxide (Eq. 15-29).

$$FlH_2 + O_2 \rightarrow Fl + H_2O_2 \qquad (15\text{-}29)$$

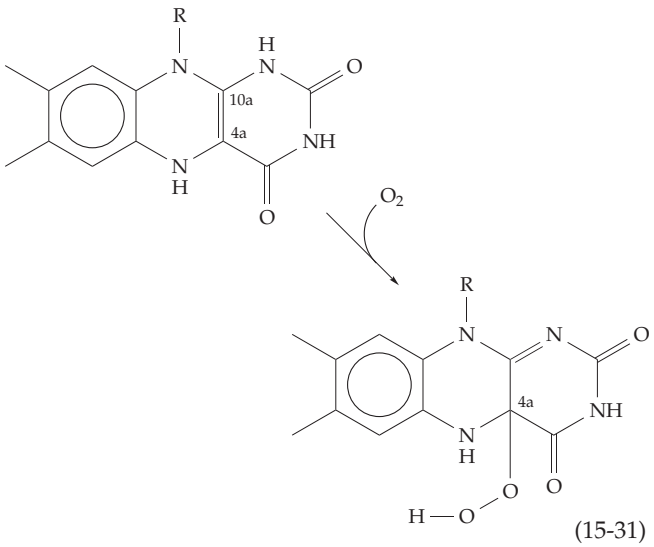
The reaction is more complex than it appears. As soon as a small amount of oxidized flavin is formed, it reacts with reduced flavin to generate flavin radicals $^\bullet$FlH (Eq. 15-27). The latter react rapidly with O_2 each donating an electron to form superoxide anion radicals $^\bullet O_2^-$ (Eq. 15-30a) which can then combine with flavin radicals (Eq. 15-30b).[284]

$$^\bullet FlH + O_2 \rightarrow {}^\bullet O_2^- + H^+ + Fl \qquad (15\text{-}30a)$$

$$^\bullet O_2^- + {}^\bullet FlH + H^+ \rightarrow Fl + H_2O_2 \qquad (15\text{-}30b)$$

During the corresponding reactions of reduced flavoproteins with O_2, intermediates have been detected. For example, spectrophotometric studies of the FAD-containing bacterial *p*-hydroxybenzoate hydroxylase (Chapter 18) revealed the consecutive appearance of three intermediate forms.[285–287] The first, whose absorption maximum is at 380–390 nm, is thought to be an adduct at position 4a (Eq. 15-31). That such a 4a peroxide really forms with the riboflavin phosphate of the light-emitting bacterial **luciferase** (Chapter 23) was demonstrated using coenzyme enriched with ^{13}C at position 4a.[147] A large shift to lower frequency (from 104 to 83 ppm) accompanied formation of the transient adduct. Comparison with reference compounds showed that this change agreed with that predicted.

Other structures for O_2 adducts have also been considered, as has the possibility of rearrangements among these structures.[288] Nevertheless, the products observed from many different flavoprotein reactions can be explained on the basis of a 4a peroxide.[289]



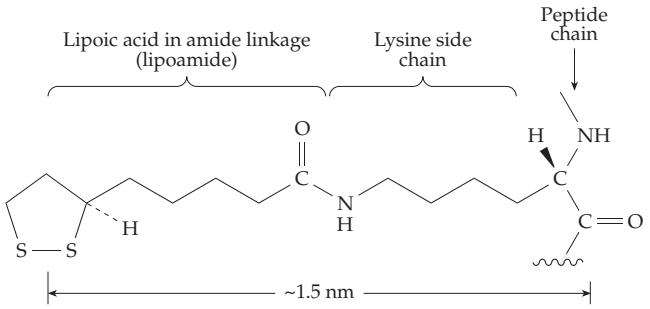
(15-31)

Formation of H_2O_2 by flavin oxidases can occur via elimination of a peroxide anion HOO^- from the adduct of Eq. 15-31 with regeneration of the oxidized flavin. In the active site of a hydroxylase, an OH group can be transferred from the peroxide to a suitable substrate (Eq. 18-42). Although radical mechanisms are likely to be involved, such hydroxylation reactions can also be viewed as transfer of OH^+ to the substrate together with protonation on the inner oxygen atom of the original peroxide to give a 4a –OH adduct. The latter is a covalent hydrate which can be converted to the oxidized flavin by elimination of H_2O. This hydrate is believed to be the third spectral intermediate identified during the action of *p*-hydroxybenzoate hydroxylase.[286,287,290]

C. Lipoic Acid and the Oxidative Decarboxylation of α-Oxoacids

The isolation of lipoic acid in 1951 followed an earlier discovery that the ciliate protozoan *Tetrahymena geleii* required an unknown factor for growth. In independent experiments acetic acid was observed to promote rapid growth of *Lactobacillus casei*, but it could be replaced by an unknown "acetate replacing factor." Another lactic acid bacterium *Streptococcus faecalis* was unable to oxidize pyruvate without addition of "pyruvate oxidation factor." By 1949, all three unknown substances were recognized as identical.[291,291a] After working up the equivalent of 10 tons of water-soluble residue from liver, Lester Reed and his collaborators isolated 30 mg of a fat-soluble acidic material which was named **lipoic acid** (or 6-thioctic acid).[292–294]

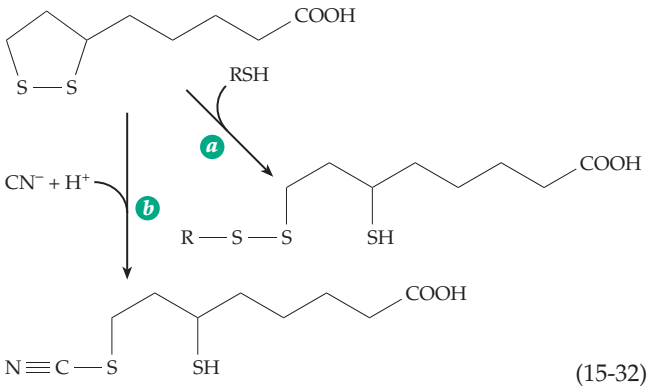
While *Tetrahymena* must have lipoic acid in its diet, we humans can make our own, and it is not considered a vitamin. Lipoic acid is present in tissues in extraordinarily small amounts. Its major function is to participate in the oxidative decarboxylation of α-oxoacids but it also plays an essential role in glycine catabolism in the human body as well as in plants.[295,296] The structure is simple, and the functional group is clearly the cyclic disulfide which swings on the end of a long arm. Like biotin, which is also present in tissues in very small amounts, lipoic acid is bound in covalent amide linkage to lysine side chains in active sites of enzymes:[296a]



1. Chemical Reactions of Lipoic Acid

The most striking chemical property of lipoic acid is the presence of ring strain of ~17–25 kJ mol^{-1} in the cyclic disulfide. Because of this, thiol groups and cyanide ions react readily with oxidized lipoic acid to give mixed disulfides (Eq. 15-32a) and isothiocyanates (Eq. 15-32b), respectively.

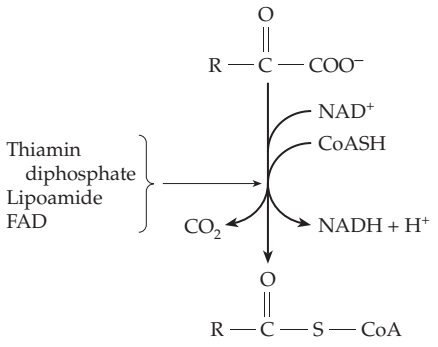
Another result of the ring strain is that the reduction potential $E^{\circ\prime}$ (pH 7, 25°C), is –0.30 V, almost the same as that of reduced NAD (–0.32V). Thus, reoxidation of reduced lipoic acid amide by NAD^+ is thermodynamically feasible. Yet another property attributed to the ring strain in lipoic acid is the presence of an absorption maximum at 333 nm.



(15-32)

2. Oxidative Decarboxylation of Alpha-Oxoacids

The oxidative cleavage of an α-oxoacid is a major step in the metabolism of carbohydrates and of amino acids and is also a step in the citric acid cycle. In many bacteria and in eukaryotes the process depends upon both thiamin diphosphate and lipoic acid. The oxoacid anion is cleaved to form CO_2 and the remaining acyl group is combined with coenzyme A (Eq. 15-33). NAD^+ serves as the oxidant. The reaction is catalyzed by a complex of enzymes whose molecular mass varies from ~4 to 10 x 10^6, depending on the species and exact substrate.[297] Separate oxoacid dehydrogenase systems are known for pyruvate,[298–300] 2-oxoglutarate,[301] and the 2-oxoacids with branched side chains derived metabolically from leucine, isoleucine, and



(15-33)

valine.[302,302a] In eukaryotes these enzymes are located in the mitochondria. The **pyruvate** and **2-oxoglutarate dehydrogenase** complexes of *E. coli* and *Azotobacter vinelandii* have been studied most. In both cases there are three major protein components. The first (E_1) is a **decarboxylase** (also referred to as a dehydrogenase) for which the thiamin diphosphate is the dissociable cofactor. The second (E_2) is a lipoic acid amide-containing "core" enzyme which is a **dihydrolipoyl transacylase.** The third (E_3) is the flavoprotein **dihydrolipoyl dehydrogenase**, a member of the glutathione reductase family with a three-dimensional structure and catalytic mechanism similar to those of glutathione reductase (Figs. 15-10, 15-12).[303 – 305]

Electron microscopy of the core dihydrolipoyl transacylase from *E. coli* reveals a striking octahedral symmetry which has been confirmed by X-ray diffraction.[306–307a] The core from pyruvate dehydrogenase has a mass of ~2390 kDa and contains 24 identical 99.5-kDa E_2 subunits. The 2-oxoglutarate dehydrogenase from *E. coli* has a similar but slightly less symmetric structure. Each core subunit is composed of three domains. A lipoyl group is bound in amide linkage to lysine 42 and protrudes from one end of the domain. A second domain is necessary for binding to subunits E_1 and E_3, while the third major 250-residue domain contains the catalytic acyltransferase center.[308,309] This center closely resembles that of chloramphenicol acetyltransferase (Chapter 12).[310,311] The lipoyl[301,309,312] and catalytic[307] domains of the dihydrolipoyl succinyltransferase from 2-oxoglutarate dehydrogenase resemble those of pyruvate dehydrogenase and also of the branched chain oxoacid dehydrogenase. The three domains of the proteins are joined by long 25- to 30-residue segments rich in alanine, proline, and ionized hydrophilic side chains.[309] This presumably provides flexibility for the lipoyl groups which must move from site to site. The presence of unexpectedly sharp lines in the proton NMR spectrum of the core protein may be a result of this flexibility.[309]

To obtain the X-ray structure of the core protein it was necessary to delete the lipoyl- and $E_1(E_2)$- binding domains. The resulting 24-subunit structure is shown in Fig 15-14A,B.[306] It has been assumed for many years that 12 of the dimeric decarboxylase units (E_1) are bound to the 12 edges of the transacetylase cube, while six (50.6 x 2 kDa) flavoprotein (E_3) dimers bind on the six faces of the cube. The active centers of all three types of subunits are thought to come close together in the regions where the subunits touch, permitting the sequence of catalytic reactions indicated in Fig. 15-15 to take place. Eukaryotic as well as some bacterial pyruvate decarboxylases have a core of 60 subunits in an icosahedral array with 532 symmetry. This can be seen in the image reconstructions of the enzyme from *Saccharomyces cerevisiae* shown in Fig. 15-14C and D. A surprising discovery is that in this yeast enzyme the E_3 units are not on the outside of the 5-fold symmetric faces but protrude into the inner cavity.[299] Each of the 12 E_3 subunits is assisted in binding correctly to the E_2 core by a molecule of the 47-kDa **E_3-binding protein** (BP), also known as protein X.[313,314] Absence of this protein is associated with congenital lactic acidosis.

The unique function of lipoic acid is in the oxidation of the thiamin-bound active aldehyde (Fig. 15-15) in such a way that when the complex with thiamin breaks up, the acyl group formed by the oxidative decarboxylation of the oxoacid is attached to the

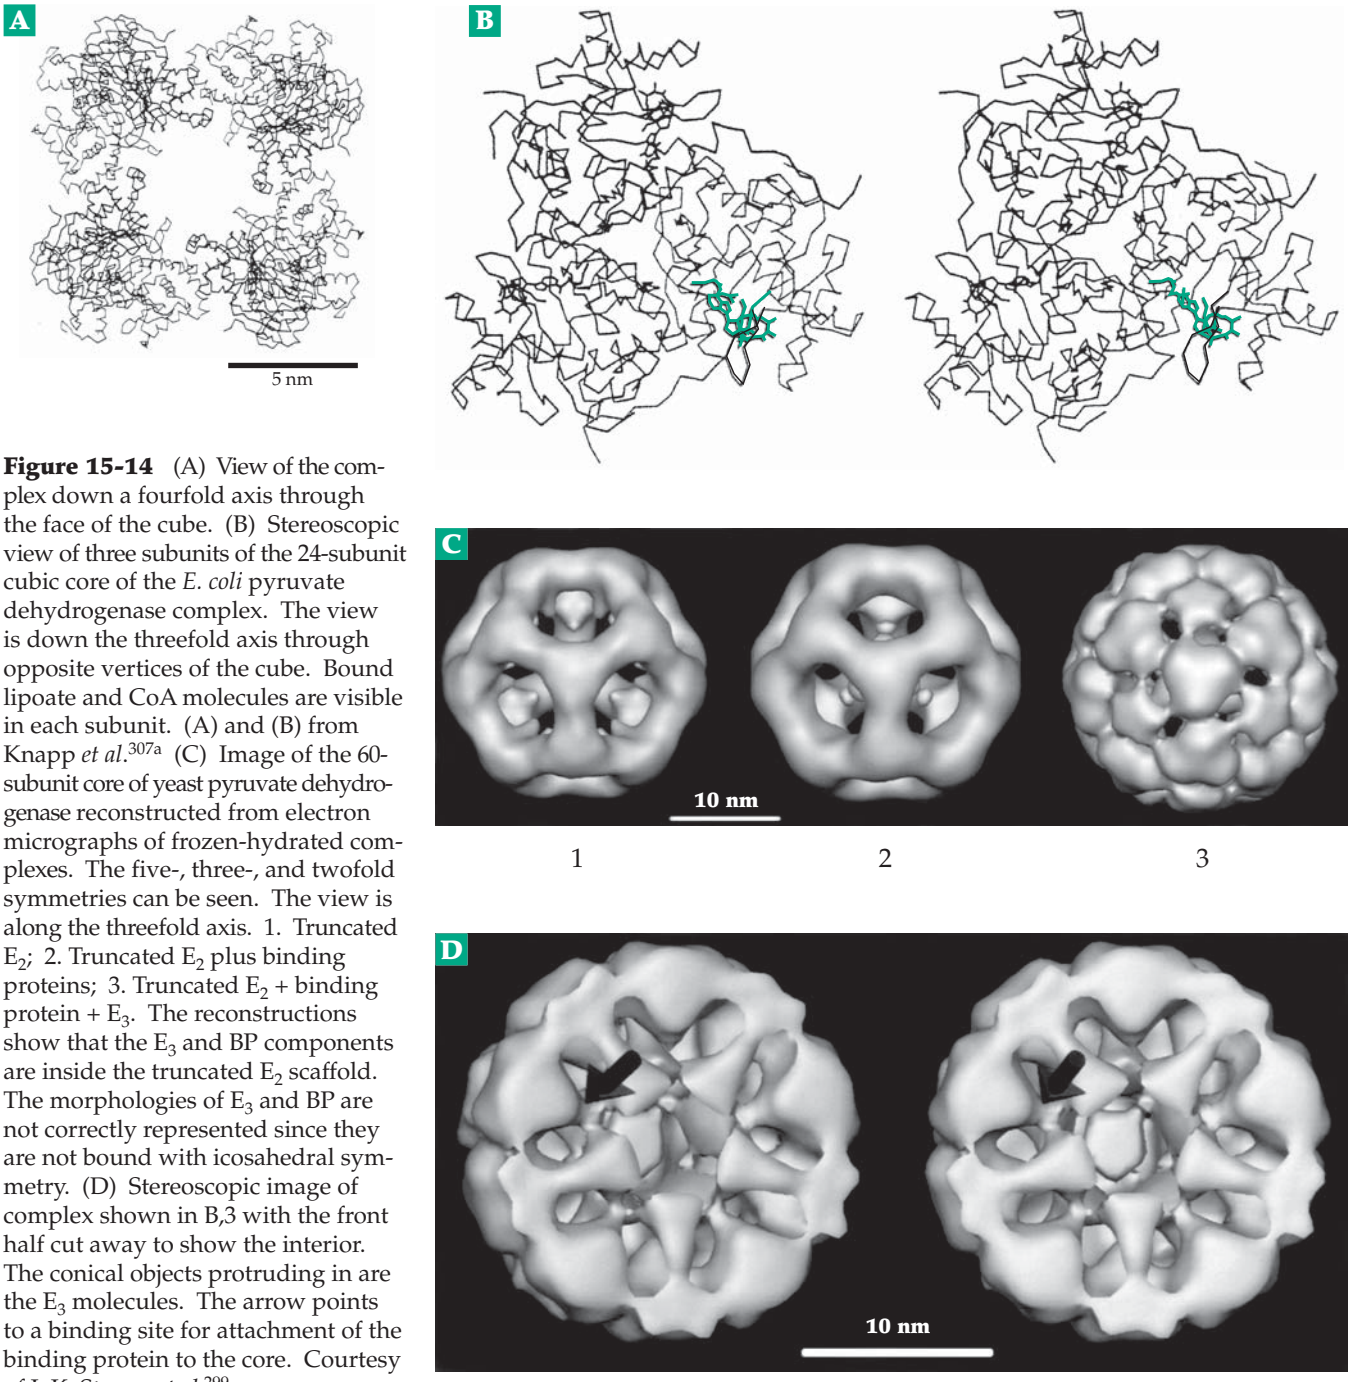


Figure 15-14 (A) View of the complex down a fourfold axis through the face of the cube. (B) Stereoscopic view of three subunits of the 24-subunit cubic core of the *E. coli* pyruvate dehydrogenase complex. The view is down the threefold axis through opposite vertices of the cube. Bound lipoate and CoA molecules are visible in each subunit. (A) and (B) from Knapp *et al*.[307a] (C) Image of the 60-subunit core of yeast pyruvate dehydrogenase reconstructed from electron micrographs of frozen-hydrated complexes. The five-, three-, and twofold symmetries can be seen. The view is along the threefold axis. 1. Truncated E_2; 2. Truncated E_2 plus binding proteins; 3. Truncated E_2 + binding protein + E_3. The reconstructions show that the E_3 and BP components are inside the truncated E_2 scaffold. The morphologies of E_3 and BP are not correctly represented since they are not bound with icosahedral symmetry. (D) Stereoscopic image of complex shown in B,3 with the front half cut away to show the interior. The conical objects protruding in are the E_3 molecules. The arrow points to a binding site for attachment of the binding protein to the core. Courtesy of J. K. Stoops *et al*.[299]

dihydrolipoyl group at the S-8 position.[315] The lipoic acid, which is attached to the flexible lipoyl domains of the core enzyme on a 1.5-nm-long arm, apparently first contacts the thiamin diphosphate site on one of the decarboxylase subunits. Bearing the acyl group, it now swings to the catalytic site on the core enzyme where CoA is bound. The acyl group is transferred to CoA producing a dihydrolipoyl group which then swings to the third subunit where the disulfide loop and a bound FAD of dihydrolipoamide dehydrogenase reoxidize the lipoyl group. The reduced flavin-disulfide enzyme is then oxidized by NAD^+ (Fig. 15-15) by the reverse of the mechanism depicted in Fig. 15-12.

Although the direct reaction of a lipoyl group with the thiamin-bound enamine (active aldehyde) is generally accepted, and is supported by recent studies,[315a] an alternative must be considered.[315] Hexacyanoferrate (III) can replace NAD^+ as an oxidant for pyruvate dehydrogenase and is also able to oxidize nonenzymatically thiamin-bound active acetaldehyde

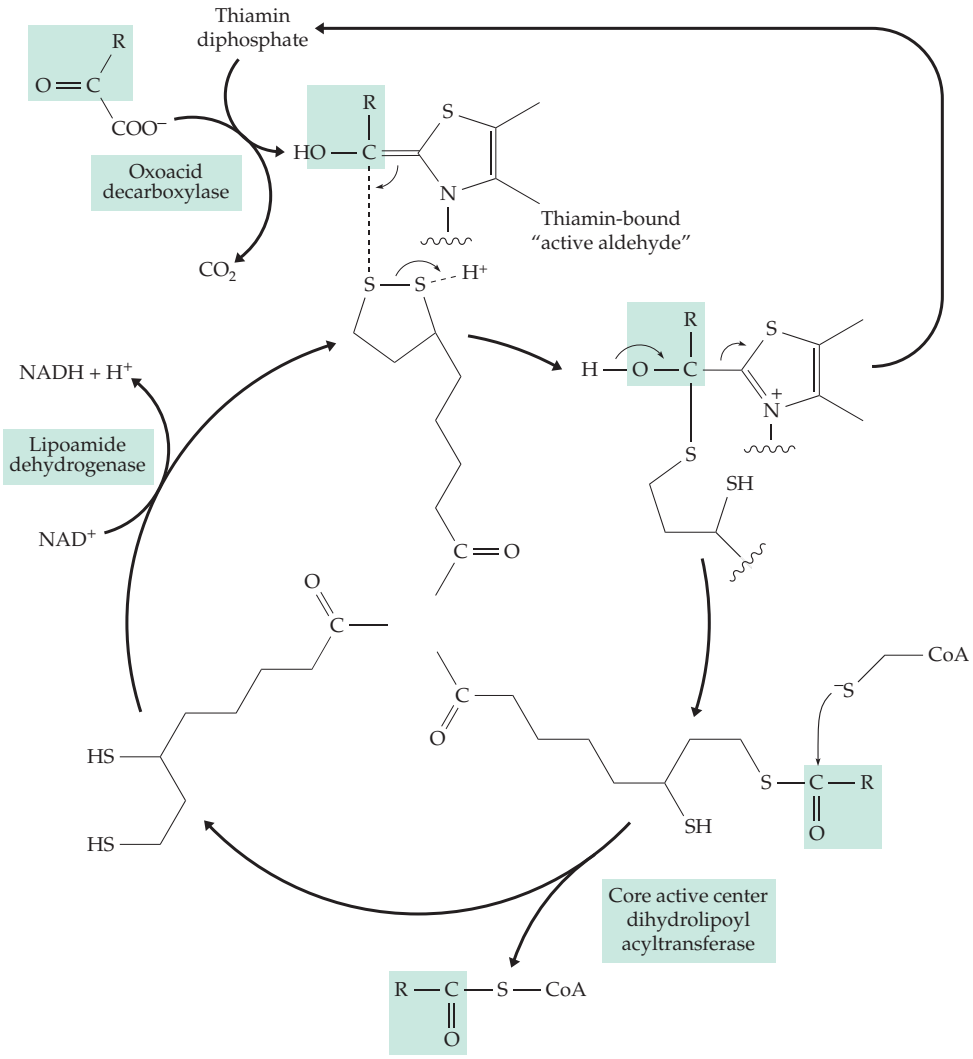

Figure 15-15 Sequence of reactions catalyzed by α-oxoacid dehydrogenases. The substrate and product are shown in boxes, and the path of the oxidized oxoacid is traced by the heavy arrows. The lipoic acid "head" is shown rotating about the point of attachment to a core subunit. However, a whole flexible domain of the core is also thought to move.

to 2-acetylthiamin, a compound in which the acetyl group has a high group transfer potential (Eq. 14-22). Thus, the lipoyl group could first oxidize the active aldehyde to a thiamin-bound acyl derivative, and then in the second step accept the acyl group by a nucleophilic displacement reaction. This mechanism fails to explain the unique role of lipoic acid in oxidative decarboxylation. However, as we will see in the next section, oxidative decarboxylation does not always require lipoic acid and acetylthiamin is probably an intermediate whenever lipoamide is not utilized.

Within many tissues the enzymatic activities of the pyruvate and branched chain oxoacid dehydrogenases complexes are controlled in part by a phosphorylation–dephosphorylation mechanism (see Eq. 17-9). Phosphorylation of the decarboxylase subunit by an ATP-dependent kinase produces an inactive phosphoenzyme. A phosphatase reactivates the dehydrogenase to complete the regulatory cycle (see Eq. 17-9 and associated discussion). The regulation is apparently accomplished, in part, by controlling the affinity of the protein for thiamin diphosphate.[315b] The lipoamide dehydrogenase component of all three dehydrogenase complexes appears to be the same.

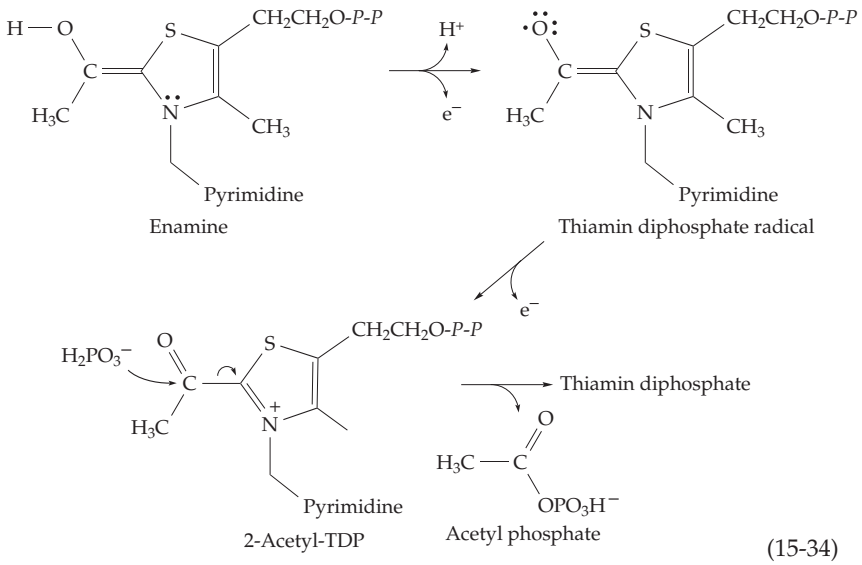
3. Other Functions of Lipoic Acid

In addition to its role in the oxidative decarboxylation of 2-oxoacids, lipoic acid functions in the human body as part of the essential mitochondrial glycine-cleavage system described in Section E. It may also participate in bacterial glycine reductase (Eq. 15-61) and other enzyme systems. Dihydrolipoamide dehydrogenase binds to G4-DNA structures of telomeres and may have a biological role in DNA-binding.[315c] Lipoic acid is being utilized as a nutritional supplement and appears to help in maintaining cellular levels of glutathione.[316]

4. Additional Mechanisms of Oxidative Decarboxylation

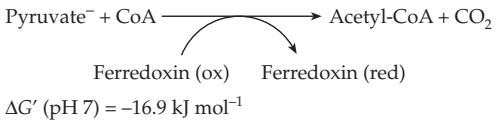
Pyruvate is a metabolite of central importance and a variety of mechanisms exist for its cleavage. The pyruvate dehydrogenase complex is adequate for strict aerobes and is very important in aerobic bacteria and in facultative anaerobes such as *E. coli*. Lactic acid bacteria, which lack cytochromes and other heme proteins, are able to carry out limited oxidation with flavoproteins such as **pyruvate oxidase**.[317] However, *strict* anaerobes have to avoid accumulation of reduced pyridine nucleotides and use a nonoxidative cleavage of pyruvate by **pyruvate formate-lyase**. The pyruvate dehydrogenase complex of *our* bodies generates NADH which can be oxidized in mitochondria to provide energy to our cells. However, NADH is a weak reductant. Some cells, such as those of nitrogen-fixing bacteria, require more powerful reductants such as reduced ferredoxin and utilize **pyruvate: ferredoxin oxidoreductase**. *Escherichia coli*, a facultative anaerobe, is adaptable and makes use of all of these types of pyruvate cleavage.[318]

Pyruvate oxidase. The soluble flavoprotein pyruvate oxidase, which was discussed briefly in Chapter 14 (Fig. 14-2, Eq. 14-22), acts together with a membrane-bound electron transport system to convert pyruvate to acetyl phosphate and CO_2.[319] Thiamin diphosphate is needed by this enzyme but lipoic acid is not. The flavin probably dehydrogenates the thiamin-bound intermediate to 2-acetylthiamin as shown in Eq. 15-34. The electron acceptor is the bound FAD and the reaction may occur in two steps as shown with a thiamin diphosphate radical intermediate.[319a] Reaction with inorganic phosphate generates the energy storage metabolite **acetyl phosphate**.



(15-34)

Pyruvate:ferredoxin oxidoreductase. Within clostridia and other strict anaerobes this enzyme catalyzes *reversible* decarboxylation of pyruvate (Eq. 15-35). The oxidant used by clostridia is the low-potential iron–sulfur ferredoxin.[320,320a] Clostridial ferredoxins contain two Fe–S clusters and are therefore two-electron oxidants. Ferredoxin substitutes for NAD^+ in Eq. 15-33 but the Gibbs energy decrease is much less (–16.9 vs – 34.9 kJ / mol. for oxidation by NAD^+).



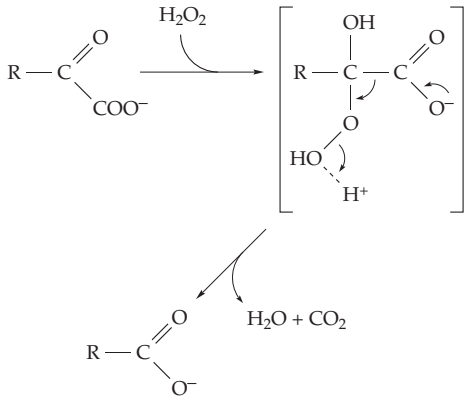
(15-35)

The enzyme does not require lipoic acid. It seems likely that a thiamin-bound enamine is oxidized by an iron–sulfide center in the oxidoreductase to 2-acetylthiamin which then reacts with CoA. A free radical intermediate has been detected[318,321] and the proposed sequence for oxidation of the enamine intermediate is that in Eq. 15-34 but with the Fe–S center as the electron acceptor. Like pyruvate oxidase, this enzyme transfers the acetyl group from acetylthiamin to coenzyme A. Cleavage of the resulting acetyl-CoA is used to generate ATP. An indolepyruvate: ferredoxin oxidoreductase has similar properties.[322]

In methanogenic bacteria[320] the low-potential 5-deazaflavin coenzyme F_{420} serves as the reductant in a reversal of Eq. 15-35. A similar enzyme, **2-oxoglutarate synthase**, apparently functions in synthesis of 2-oxoglutarate from succinyl-CoA and CO_2 by photosynthetic bacteria.[323] Either reduced ferredoxin or, in *Azotobacter*, reduced flavodoxin is generated in nitrogen-fixing bacteria (Chapter 24) by cleavage of pyruvate and is used in the N_2 fixation process.

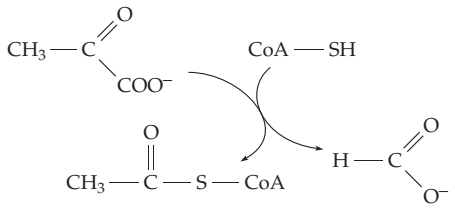
Oxidative decarboxylation by hydrogen peroxide. The nonenzymatic oxidative decarboxylation of α-oxoacids by H_2O_2 is well-known. The first step is the formation of an adduct, an organic peroxide, which breaks up as indicated in Eq. 15-36. An enzyme-catalyzed version of this reaction is promoted by **lactate monooxygenase**, a 360-kDa octameric flavoprotein obtained from *Mycobacterium smegmatis*[324] and a member of the glycolate oxidase family. Under anaerobic conditions, the enzyme produces pyruvate by a simple dehydrogenation. However, the pyruvate dissociates slowly and in the presence of

oxygen it forms acetic acid, with one of the oxygen atoms of the carboxyl group coming from O_2.[324,325] Hydrogen peroxide is the usual product formed from oxygen by flavoprotein oxidases, and it seems likely that with lactate monooxygenase the hydrogen peroxide formed immediately oxidizes the pyruvate according to Eq. 15-36. The α-oxoacids formed by amino acid oxidases *in vitro* are also oxidized by accumulating hydrogen peroxide. However, if catalase (Chapter 16) is present it destroys the H_2O_2 and allows the oxoacid to accumulate.



(15-36)

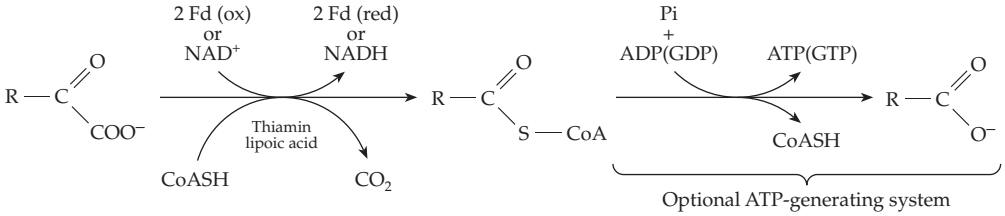
Pyruvate formate-lyase reaction. Anaerobic cleavage of pyruvate to acetyl-CoA and formate (Eq. 15-37) is essential to the energy economy of many cells, including those of *E. coli*. No external oxidant is needed, and the reaction does not require lipoic acid. The reaction has sometimes been called the "phosphoroclastic reaction" because the product acetyl-CoA usually reacts further with inorganic phosphate to form acetyl phosphate (see Fig. 15-16). The latter can then transfer its phospho group to ADP to form ATP.



$\Delta G'$ (pH 7) = –12.9 kJ mol^{-1} (15-37)

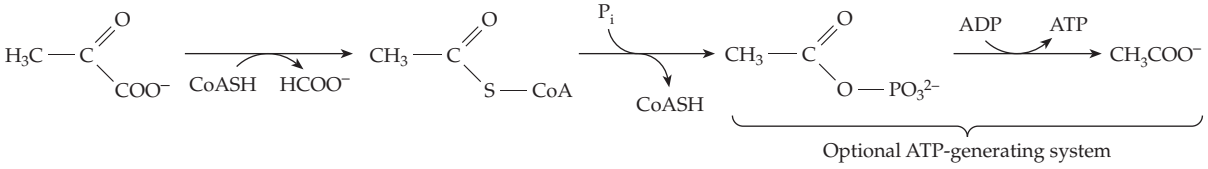
The mechanism of the cleavage of the pyruvate in Eq. 15-37 is not obvious. Thiamin diphosphate is not involved, and free CO_2 is not formed. The first identified intermediate is an acetyl-enzyme containing a thioester linkage to a cysteine side chain. This is cleaved by reaction with CoA-SH to give the final product. A clue came when it was found by Knappe and coworkers that the active enzyme, which is rapidly inactivated by oxygen, contains a long-lived free radical.[326] Under anaerobic conditions cells convert the inactive form E_i to the active form E_a by an enzymatic reaction with *S*-adenosylmethionine and reduced flavodoxin Fd(red) as shown in Eq. 15-38.[327–329] A deactivase reverses the process.[330]

A Oxidative decarboxylation of an α-oxoacid with thiamin diphosphate



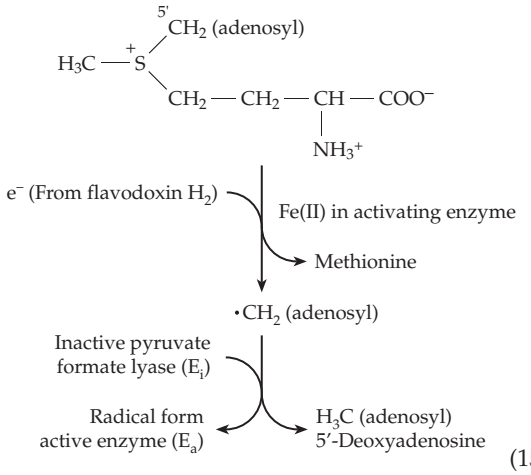
1. with lipoic acid and NAD^+ as oxidants — $\Delta G'$ (pH 7, for pyruvate) = –35.5 kJ/mol overall
2. with ferredoxin as oxidant — $\Delta G'$ (pH 7, for pyruvate) = –13.9 kJ/mol overall

B The pyruvate formate-lyase reaction



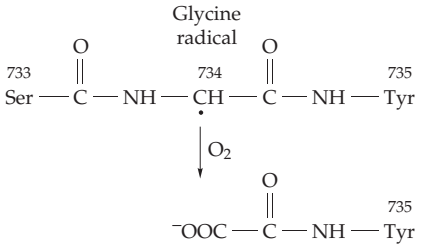
$\Delta G'$ (pH 7) = –13.5 kJ/mol overall

Figure 15-16 Two systems for oxidative decarboxylation of α-oxoacids and for "substrate-level" phosphorylation. The value of $\Delta G'$ = +34.5 kJ mol^{-1} (Table 6-6) was used for the synthesis of ATP^{4-} from ADP^{3-} and HPO_4^{2-} in computing the values of $\Delta G'$ given.



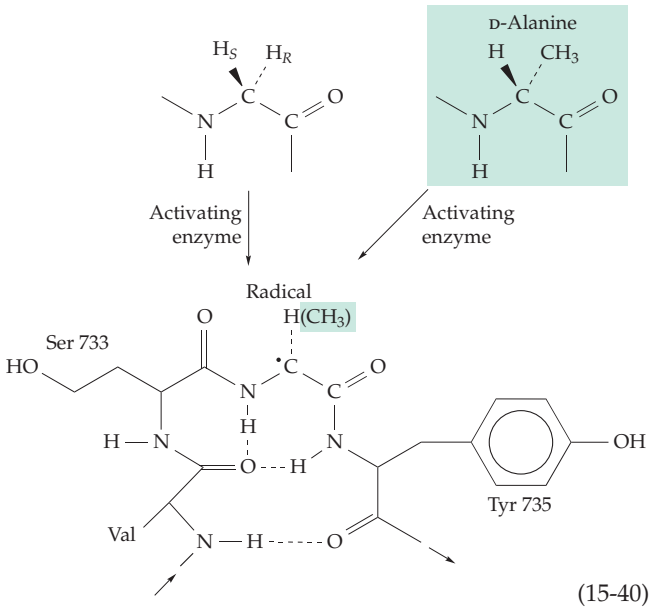
(15-38)

The activating enzyme, which is allosterically activated by pyruvate, is an iron–sulfur (Fe_4S_4) protein (Chapter 16).[331,331a] Formation of the observed radical may proceed via a 5'-deoxyadenosyl radical as has been proposed for lysine 2,3-aminomutase (Eq. 16-42).[332] The activation reaction also resembles the free radical-dependent reactions of vitamin B_{12} which are discussed in Chapter 16. When subjected to O_2 of air at 25°C pyruvate formate-lyase is destroyed with a half-life of ~10 s. The peptide chain is cleaved and sequence analysis and mass spectrometry of the resulting fragments show that the specific sequence Ser-Gly-Tyr at positions 733–755 is cut with formation of an oxalyl group on the N-terminal tyrosine of one fragment (Eq. 15-39). Various ^{13}C-containing amino acids were supplied to growing cells of *E. coli* and were incorporated into the proteins of the bacteria. Pyruvate formate-lyase containing ^{13}C in carbon-2 of glycine gave an EPR spectrum with hyperfine splitting arising from coupling of the unpaired electron of the radical with the adjacent ^{13}C nucleus.[333,333a] This experiment, together with the results described by Eq. 15-39, suggested that the radical is derived from Gly 734.



(15-39)

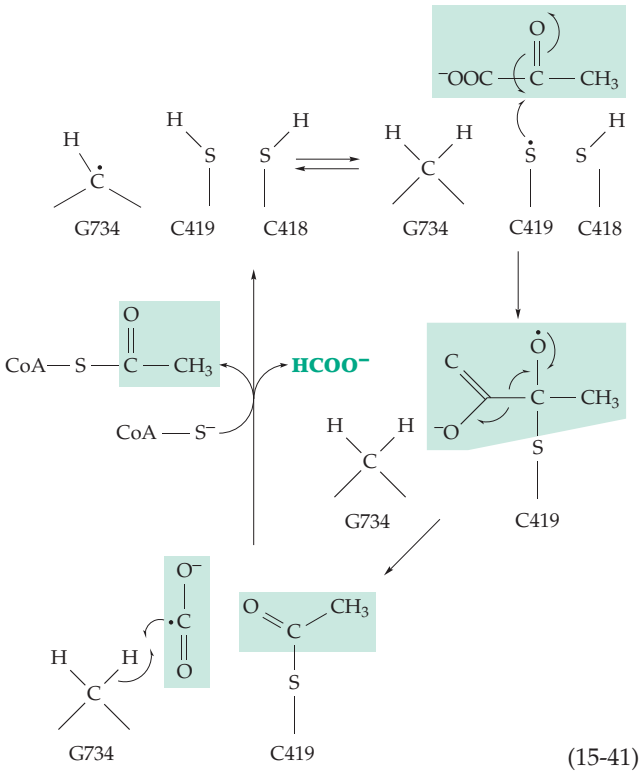
The activating enzyme will also generate radicals from short peptides such as Arg-Val-Ser-Gly-Tyr-Ala-Val, which corresponds to residues 731–737 of the pyruvate formate-lyase active site. If Gly 734 is replaced by L-alanine, no radical is formed, but radical *is* formed if D-alanine is in this position. This suggests that the *pro-S* proton of Gly 734 is removed by the activating



(15-40)

enzyme[329] as illustrated in Eq. 15-40. It has been suggested that the peptide exists in the β-bend conformation shown.

How does the enzyme work? The α-CH proton of the glycyl radical of the original *pro-R* proton undergoes an unexpected exchange with the deuterium of ^2H_2O. The exchange is catalyzed by the thiol group of Cys 419, suggesting that it is close to Gly 734 in the three-dimensional structure.[334] The mutants C419S and C418S are inactive but still allow formation of the Gly 734 radical.[334–335a] The mechanism has been proposed in Eq. 15-41.



(15-41)

5. Cleavage of α-Oxoacids and Substrate-Level Phosphorylation

The α-oxoacid dehydrogenases yield CoA derivatives which may enter biosynthetic reactions. Alternatively, the acyl-CoA compounds may be cleaved with generation of ATP. The pyruvate formate-lyase system also operates as part of an ATP-generating system for anaerobic organisms, for example, in the "mixed acid fermentation" of enterobacteria such as *E. coli* (Chapter 17). These two reactions, which are compared in Fig. 15-16, constitute an important pair of processes both of which accomplish substrate-level phosphorylation. They should be compared with the previously considered examples of substrate level phosphorylation depicted in Eq. 14-23 and Fig. 15-16.

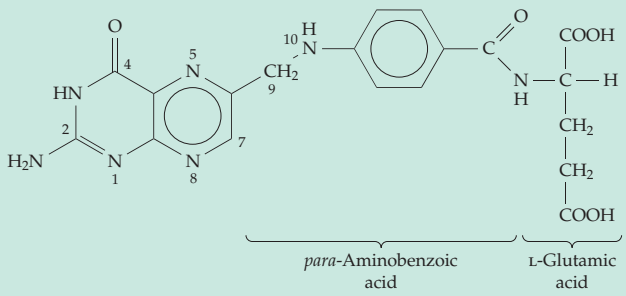
D. Tetrahydrofolic Acid and Other Pterin Coenzymes

In most organisms reduced forms of the vitamin **folic acid** serve as *carriers for one-carbon groups* at three different oxidation levels corresponding to **formic acid**, **formaldehyde**, and the **methyl group** and also facilitate their interconversion.[336,337] Moreover, folic acid is just one of the derivatives of the **pteridine** ring system that enjoy a widespread natural distribution.[338] One of these derivatives functions in the hydroxylation of aromatic amino acids and in nitric oxide synthase and yet another within several molybdenum-containing enzymes. Pteridines also provide coloring to insect wings and eyes and to the skins of amphibians and fish. They appear to act as protective filters in insect eyes and may function as light receptors. An example is a folic acid derivative found in some forms of the DNA photorepair enzyme **DNA photolyase** (Chapter 23).

1. Structure of Pterins

Because of the prevalence of its derivatives, 2-amino-4-hydroxypteridine has been given the trivial name **pterin**. Its structure resembles closely that of guanine, the 5-membered ring of the latter having been expanded to a 6-membered ring. In fact, pterins are derived

BOX 15-D FOLIC ACID (PTEROYLGLUTAMIC ACID)



In 1931, Lucy Wills, working in India, observed that patients with **tropical macrocytic anemia**, a disease in which the erythrocytes are enlarged but reduced in numbers, were cured by extracts of yeast or liver. The disease could be mimicked in monkeys fed the local diet, and a similar anemia could be induced in chicks. By 1938 it had also been shown that a factor present in yeast, alfalfa, and other materials was required for the growth of chicks. Isolation of the new vitamin came rapidly after it was recognized that it was also an essential nutrient for *Lactobacillus casei* and *Streptococcus faecalis* R.[a,b] Spinach was a rich source of the new compound, and it was named folic acid (from the same root as the word foliage).

The microbiological activity attributed to folic acid in extracts of natural materials was largely that of di- and triglutamyl derivatives, one of the facts that has led to the description of the history of folic acid as "the most complicated chapter in the story of the vitamin B complex."[a] Metabolic functions for folic acid were suggested by the observations that the requirement for *Streptococcus faecalis* could be replaced by thymine plus serine plus a purine base. Folic acid is required for the biosynthesis of all of these substances. A function in the interconversion of serine and glycine was suggested by the observation that certain mutants of *E. coli* required either serine or glycine for growth. Isotopic labeling experiments established that in the rat as well as in the yeast *Torulopsis* serine and glycine could be interconverted. It was also shown that the amount of interconversion decreased in the folate-deficient rat.

Deficiency of folic acid is a common nutritional problem of worldwide importance.[b] A recommended daily intake is 0.2 mg, but because of the association between low folic acid intake and neural tube defects in infants, women of child-bearing age should have 0.4 mg / day.[c–e]

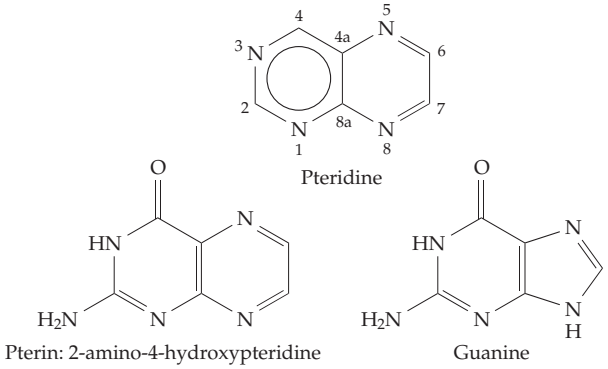
biosynthetically from guanine. The two-ring system of pterin is also related structurally and biosynthetically to that of riboflavin (Box 15-B).



Interest in pteridines began with Frederick G. Hopkins, who in 1891 started his investigation of the yellow and white pigments of butterflies. Almost 50 years and a million butterflies later, the structures of the two pigments, **xanthopterin** and **leucopterin** (Fig. 15-17), were established.[339] These pigments are produced in such quantities as to suggest that their synthesis may be a means of deposition of nitrogenous wastes in dry form.

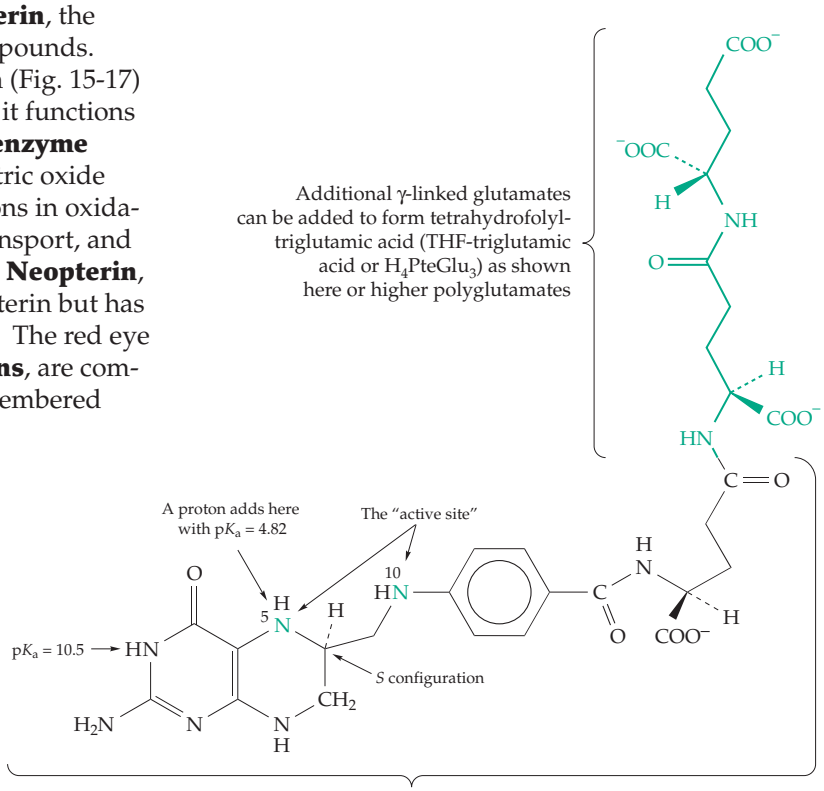
Among the simple pterins isolated from the eyes of *Drosophila*[340] is **sepiapterin** (Fig. 15-17), in which the pyrazine ring has been reduced in the 7,8 position and a short side chain is present at position 6. Reduction of the carbonyl group of sepiapterin with $NaBH_4$ followed by air oxidation produces **biopterin**, the most widely distributed of the pterin compounds. First isolated from human urine, biopterin (Fig. 15-17) is present in liver and other tissues where it functions in a reduced form as a **hydroxylation coenzyme** (see Chapter 18).[338] It is also present in nitric oxide synthase (Chapter 18).[341,342] Other functions in oxidative reactions, in regulation of electron transport, and in photosynthesis have been proposed.[343] **Neopterin**, found in honeybee larvae, resembles biopterin but has a D-*erythro* configuration in the side chain. The red eye pigments of *Drosophila*, called **drosopterins**, are complex dimeric pterins containing fused 7-membered rings (Fig. 15-17).[344,345]

In the pineal gland, as well as in the retina of the eye, light-sensitive pterins may be photochemically cleaved to generate such products as **6-formylpterin**, a compound that could serve as a metabolic regulator.[346] Another pterin acts as a chemical attractant for aggregation of the ameboid cells of *Dictyostelium lacteum*[347](Box 11-C). **Molybdopterin** (Fig. 15-17) is a component of several Mo-containing enzymes discussed in Chapter 16,[348,349] and **methanopterin** is utilized by methanogenic bacteria.[350–353]

2. Folate Coenzymes

The coenzymes responsible for carrying single-carbon units in most organisms are derivatives of **5,6,7,8-tetrahydrofolic acid** (abbreviated H_4PteGlu, H_4folate or THF). However, in methanogenic bacteria the tetrahydro derivative of the structurally unique methanopterin (Fig. 15-17) is the corresponding single-carbon carrier.[353] Naturally occurring tetrahydrofolates contain a chiral center of the *S* configuration.[354,355] They exhibit negative optical rotation at 589 nm. The folate coenzymes are present in extremely low concentrations and the reduced ring is readily oxidized by air.

In addition to the single L-glutamate unit present in tetrahydrofolic acid, the coenzymes occur to the greatest extent as conjugates called **folyl polyglutamates** in which one to eight or more additional molecules of L-glutamic acid have been combined via amide linkages.[356–357a] The first two of the extra glutamates are always joined through the γ (side chain) carboxyl groups but in *E. coli* the rest are joined through their α carboxyls.[358] The distribution of the polyglutamates varies from one organism to the next. Some bacteria contain exclusively the triglutamate derivatives, while in others almost exclusively the tetraglutamate or octaglutamate derivatives predominate.[359] The serum



Tetrahydrofolic acid (THF) or tetrahydropteroylglutamic acid (H_4PteGlu)

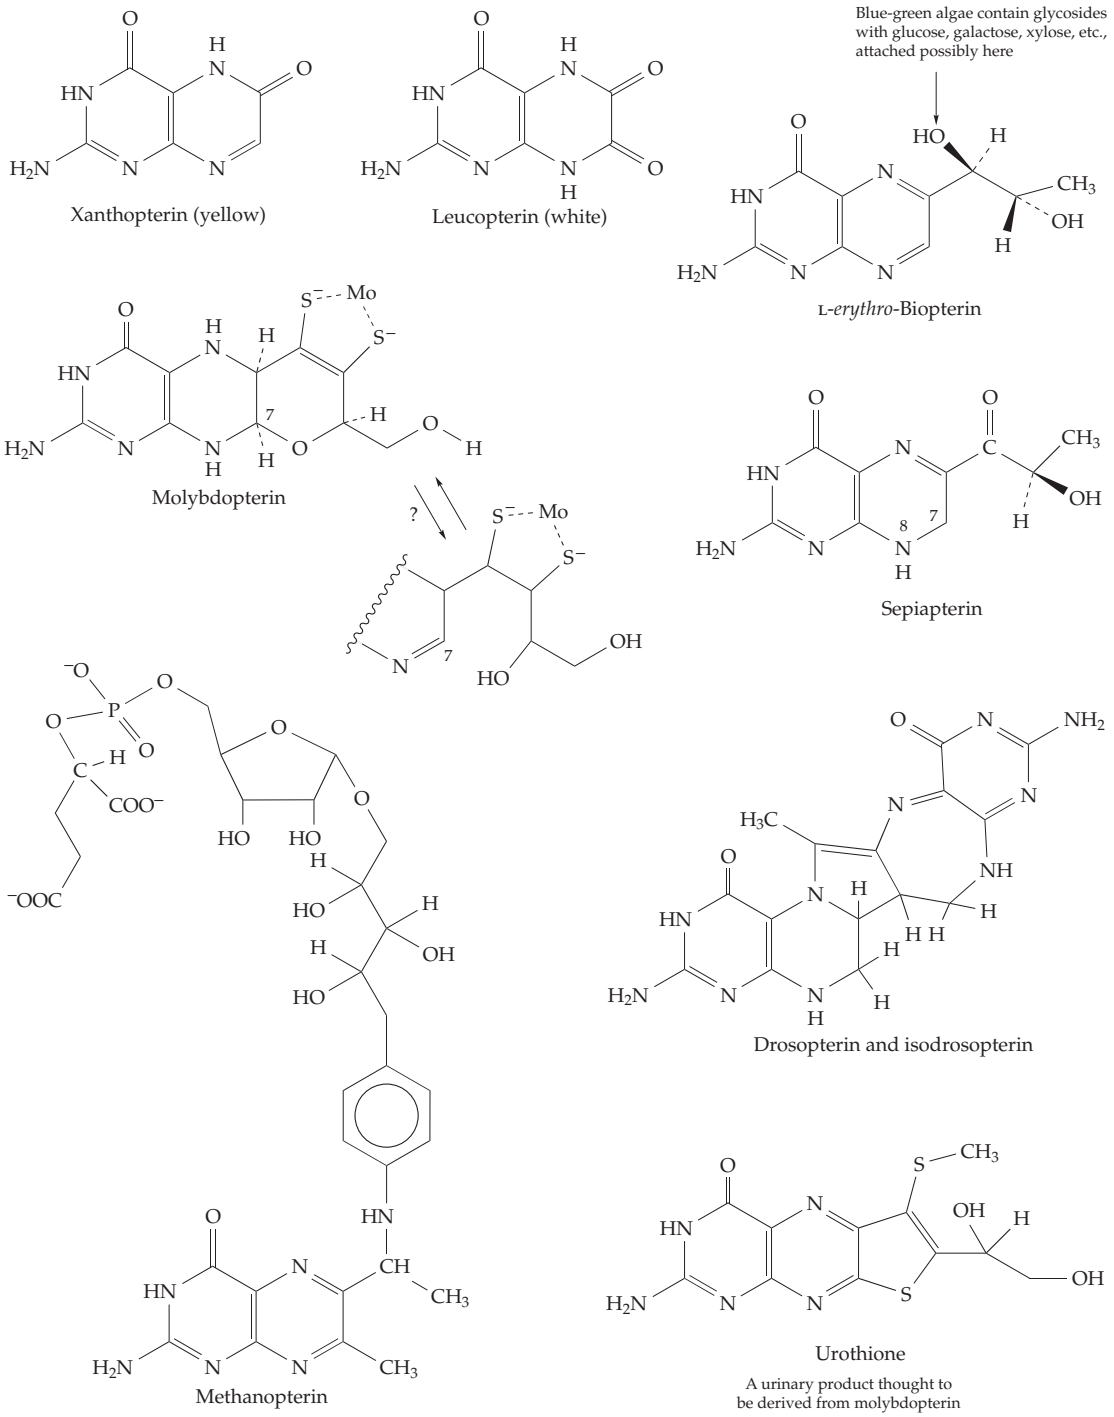


Figure 15-17 Structures of several biologically important pterins.

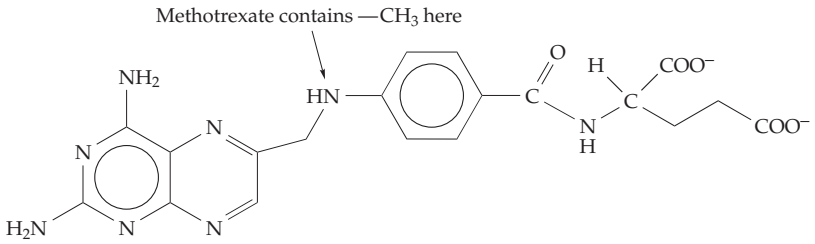
of many species contains only derivatives of folic acid itself but pteroylpentaglutamate is the major folate derivative present in rodent livers.[360,361] A large fraction of these pentaglutamates consists of the 5-methyl-THF derivative, while at the heptaglutamate level most consists of the free THF derivative. Folyl polyglutamate in its oxidized form is a component of some DNA photolyases (Chapter 23).[362]

3. Dihydrofolate Reductase

Folic acid and its polyglutamyl derivatives can be reduced to the THF coenzymes in two stages: the first step is a slow reduction with NADPH to 7,8-dihydrofolate (step *a*, Fig. 15-18). The same enzyme that catalyzes this reaction rapidly reduces the dihydrofolates

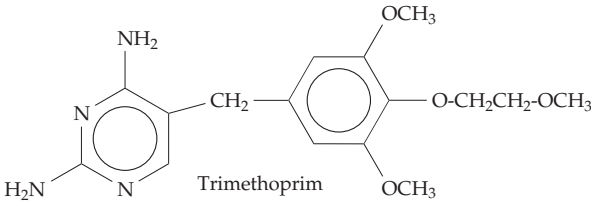
to tetrahydrofolates (step *b*, Fig. 15-18). Again, NADPH is the reducing agent and the enzyme has been given the name **dihydrofolate reductase**. An unusual fact is that bacteriophage T4 not only carries a gene for its own dihydrofolate reductase but also the enzyme is a structural unit in the phage baseplate.[363]

Inhibitors. Aside from its role in providing reduced folate coenzymes for cells, this enzyme has attracted a great deal of attention because it appears to be a site of action of the important anticancer drugs **methotrexate** (amethopterin) and aminopterin.[293,364,365] These compounds inhibit dihydrofolate reductase in concentrations as low as 10^{-8} to 10^{-9} M. Methotrexate is also widely used as an **immunosuppresant** drug and in the treatment of parasitic infections.

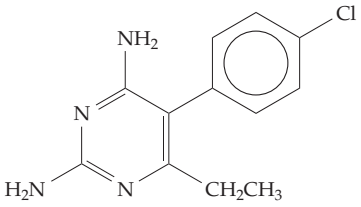


Aminopterin (4-amino-4-deoxyfolic acid)

Another dihydrofolate inhibitor **trimethoprim** is an important antibacterial drug, usually given together with a sulfonamide. Although it is not as close a structural analog of folic acid as is methotrexate, it is



Trimethoprim



Pyrimethamine

a potent inhibitor which binds far more tightly to the enzyme from bacteria than to that from humans.[366–368] The inhibitors **pyrimethamine** and **cycloguanil** are effective antimalarial drugs.[369,370]

An enormous number of synthetic compounds have been prepared in the hope of finding still more effective inhibitors. By 1984, over 1700 different inhibitors of dihydrofolate reductase had been studied.[367] However, methotrexate and trimethoprim remain outstanding. Methotrexate has been in clinical use for nearly 50 years and is very effective against leukemia and some other cancers.[371] Before 1960 persons with acute leukemia lived no more than 3–6 months. However, with antifolate treatment some have lived for 5 years or more and complete cures of the relatively rare choriocarcinoma have been achieved. New methods of chemotherapy use the antifolates in combination with other drugs.

Folate coenzymes are required in the biosynthesis of both purines and thymine. Consequently, rapidly growing cancer cells have a high requirement for activity of this enzyme. However, since all cells require the enzyme the antifolates are toxic and cannot be used for prolonged therapy. An even more serious problem is the development of resistance to the drug by cancer cells, often through "amplification" of the dihydrofolate reductase gene[365,372–374] as discussed in Chapter 27. Cells may also become resistant to methotrexate and other antifolates as a result of mutations that prevent efficient uptake of the drug,[375] cause increased action of effux pumps in the cell,[376] reduce the affinity of dihydrofolate reductase for the drug,[377] or interfere with conversion of the drug to polyglutamate derivatives which are better inhibitors than free methotrexate.[378,379] Cell surface **folate receptors**, present in large numbers in some tumor cells, can be utilized to bring suitably designed antifolate drugs or even unrelated cytotoxic compounds into tumor cells.[379a] Some tumor cells are more active than normal cells in generating folyl polyglutamates, contributing to the effectiveness of methotrexate.[379] Resistance of *E. coli* cells to trimethoprin may result from acquisition by the bacteria of a new form of dihydrofolate reductase carried by a plasmid.[380]

Structure and mechanism. Dihydrofolate reductase from *E. coli* is a small 159-residue protein with a central parallel stranded sheet,[381–383] while that from higher animals is 20% larger. The three-dimensional structures of the enzymes from *Lactobacillus*,[384] chicken, mouse, and human are closely similar. The NADP binds at the C-terminal ends of β strands as in other dehydrogenases. In Fig. 15-19 the reduced nicotinamide end of $NADP^+$ is seen next to a molecule of bound dihydrofolate.[381] The side chain carboxylate of Asp 27 makes a pair of hydrogen bonds to the pterin ring as shown on the right-hand side of Eq. 15-42. As can be seen from Fig. 15-19, the nicotinamide ring of $NADP^+$ is correctly positioned to have donated a hydride ion to C-6 to form THF with the 6*S* configuration. Notice that in Eq. 15-42 the NH hydrogen atom at the 3' position

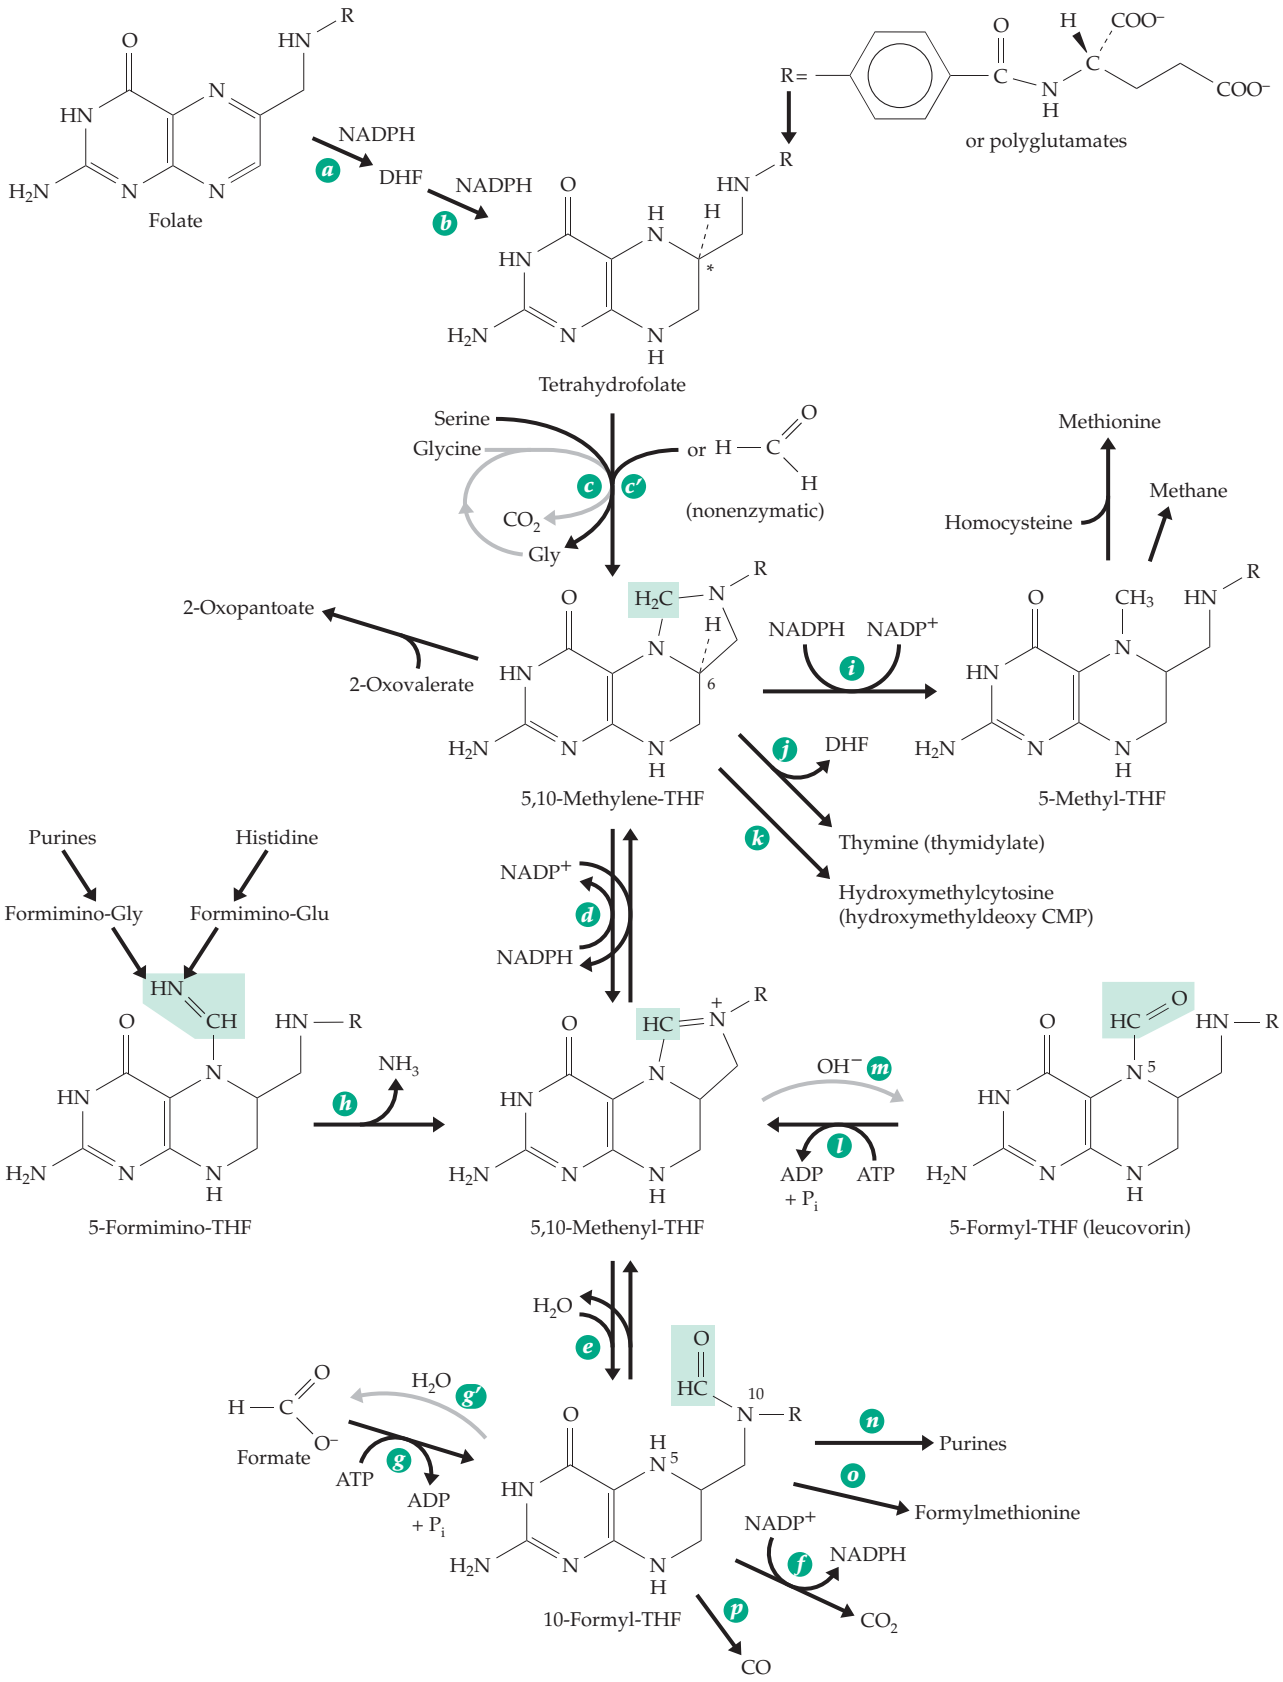


Figure 15-18 Tetrahydrofolic acid and its one-carbon derivatives.

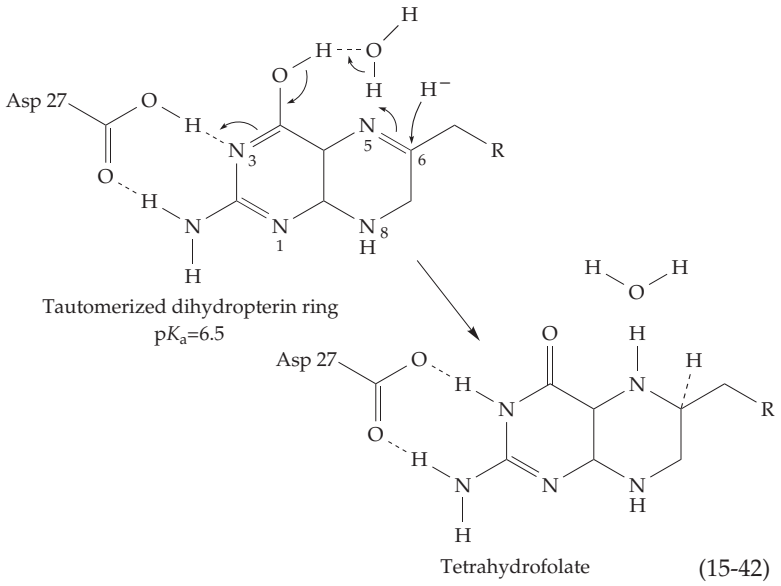

(15-42)

of the pterin makes a hydrogen bond to Asp 27. However, X-ray studies have shown that the pteridine ring of methotrexate is turned 180° so that its 4-NH_2 group forms hydrogen bonds to backbone carbonyls of Ala 97 and Leu 4 at the edge of the central pleated sheet while a protonated N-1 interacts with the side chain carboxylate of Asp 27.

Because of its significance in cancer therapy and its small size, dihydrofolate reductase is one of the most studied of all enzymes. Numerous NMR studies[385–387] and investigations of catalytic mechanism and of other properties[388] have been conducted. Many mutant forms have been created.[389–391] For example, substitution of Asp 27 (Asp 26 in *L. casei*) of the *E. coli*

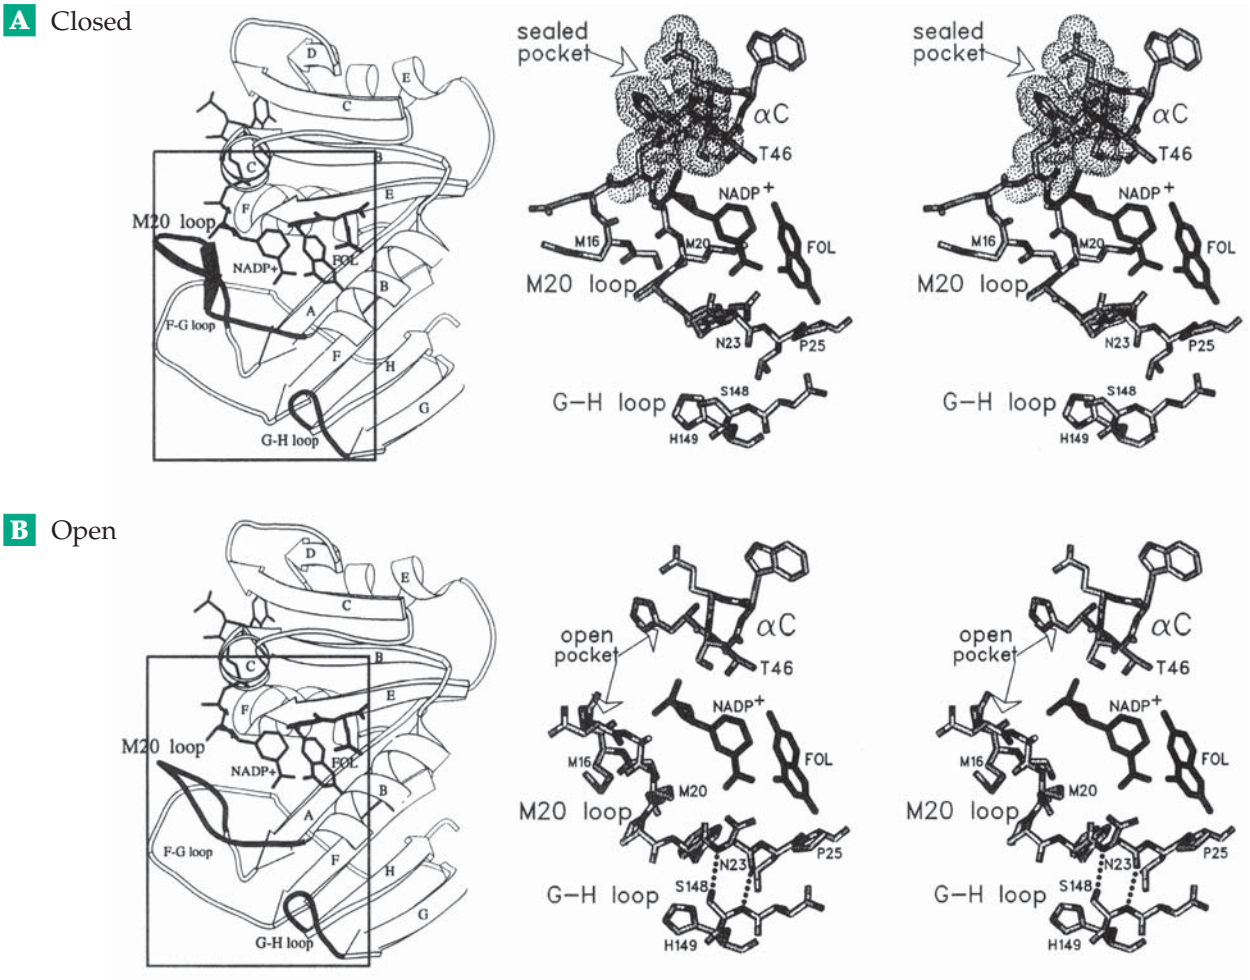

Figure 15-19 Drawings of the active site of *E. coli* dihydrofolate reductase showing the bound ligands $NADP^+$ and tetrahydrofolate. Several key amino acid side chains are shown in the stereoscopic views on the right. The complete ribbon structures are on the left. (A) Closed form. (B) Open form into which substrates can enter and products can escape. From Sawaya and Kraut.[381] Courtesy of Joseph Kraut. Molscript drawings (Kraulis, 1991).

enzyme by Asn reduced the specific catalytic activity to 1/300 that of native enzyme indicating that this residue is important for catalysis.[390] The value of k_{cat} for reduction of dihydrofolate is highest at low pH and varies around a pK_a of ~6.5.[392–394] One interpretation is that this pK_a belongs to the Asp 27 carboxyl group and another is that it belongs to an N-5 protonated species of the coenzyme. As we have seen (Chapter 6) it is often impossible to assign a pK_a to a single group because there may be a mixture of interacting tautomeric species. Despite the enormous amount of study, we still don't know quite how the proton gets to N-5 in this reaction. Only one possibility is illustrated in Eq. 15-42. Asp 27 is protonated, the pterin ring is enolized, and a buried water molecule serves to relay a proton to N-5. The X-ray crystallographic studies on the *E. coli* enzyme show that after the binding of substrates a conformational change closes a lid over the active site (Fig. 15-19). This excludes water from N-5 but it may permit intermittent access, allowing transfer of a proton from a water molecule bound to O-4 as shown in Eq. 15-42.[381] During the reduction of folate to dihydrofolate a different mechanism of proton donation must be followed to allow protonation at C-7.

4. Single-Carbon Compounds and Groups in Metabolism

Some single-carbon compounds and groups important in metabolism are shown in Table 15-3 in order (from left to right) of increasing oxidation state of the carbon atom. Groups at three different oxidation levels, corresponding to **formic acid**, **formaldehyde**, and the **methyl group**, are carried by tetrahydrofolic acid coenzymes. While the most completely reduced compound, methane, cannot exist in a combined form, its biosynthesis depends upon reduced methanopterin, as does that of carbon monoxide. Figure 15-18 summarizes the metabolic interrelationships of the compounds and groups in this table.

Serine as a C1 donor. For many organisms, from *E. coli* to higher animals, **serine** is a major precursor of C-1 units.[395–397] The β-carbon of serine is removed as formaldehyde through direct transfer to tetrahydrofolate with formation of methylene-THF and glycine (Eq. 14-30, Fig. 15-18, step *c*). This is a stereospecific transfer in which the *pro-S* hydrogen on C-3 of serine enters the *pro-S* position also in methylene-THF.[398] The glycine formed in this reaction can, in turn, yield another single-carbon unit by loss of CO_2 under the influence of the THF and the PLP-requiring glycine cleavage system which is discussed in the next paragraph. Free formaldehyde in a low concentration can also combine with THF to form methylene-THF (Fig. 15-18, step *c*′ and Eq. 15-43).[399]

(15-43)

The glycine decarboxylase–synthetase system. Glycine is cleaved reversibly within mitochondria of

plants and animals and also by bacteria to CO_2, NH_3, and a methylene group which is carried by tetrahydrofolic acid[296,400–403] (Fig. 15-20). Four proteins are required. The P-protein consists of two identical 100-kDa subunits, each containing a molecule of PLP. This protein is a **glycine decarboxylase** which, however, replaces the lost CO_2 by an electrophilic sulfur of lipoate rather than by a proton. Serine hydroxymethyltransferase can also catalyze this step of the sequence.[404] The lipoate is bound to a second protein, the H-protein. A third protein, the T-protein, carries bound tetrahydrofolate which displaces the aminomethyl group from the dihydrolipoate and converts it to N^5,N^{10}-methylene tetrahydrofolate with release of ammonia. The dihydrolipoate is then reoxidized by NAD^+ and dihydrolipamide dehydrogenase (Fig. 15-20). Glycine can be oxidized completely in liver mitochondria with the methylene group of methylene-THF being converted to CO_2 through reaction steps *d*, *e*, and *f* of Fig. 15-18. The glycine cleavage system is reversible and is used by some organisms to synthesize glycine.

Whether it arises from the hydroxymethyl group of serine or from glycine, the single-carbon unit of methylene-THF (which is at the formaldehyde level of oxidation) can either be oxidized further to 5,10-methenyl-THF and 10-formyl-THF (steps *d* and *e*, Fig. 15-18)

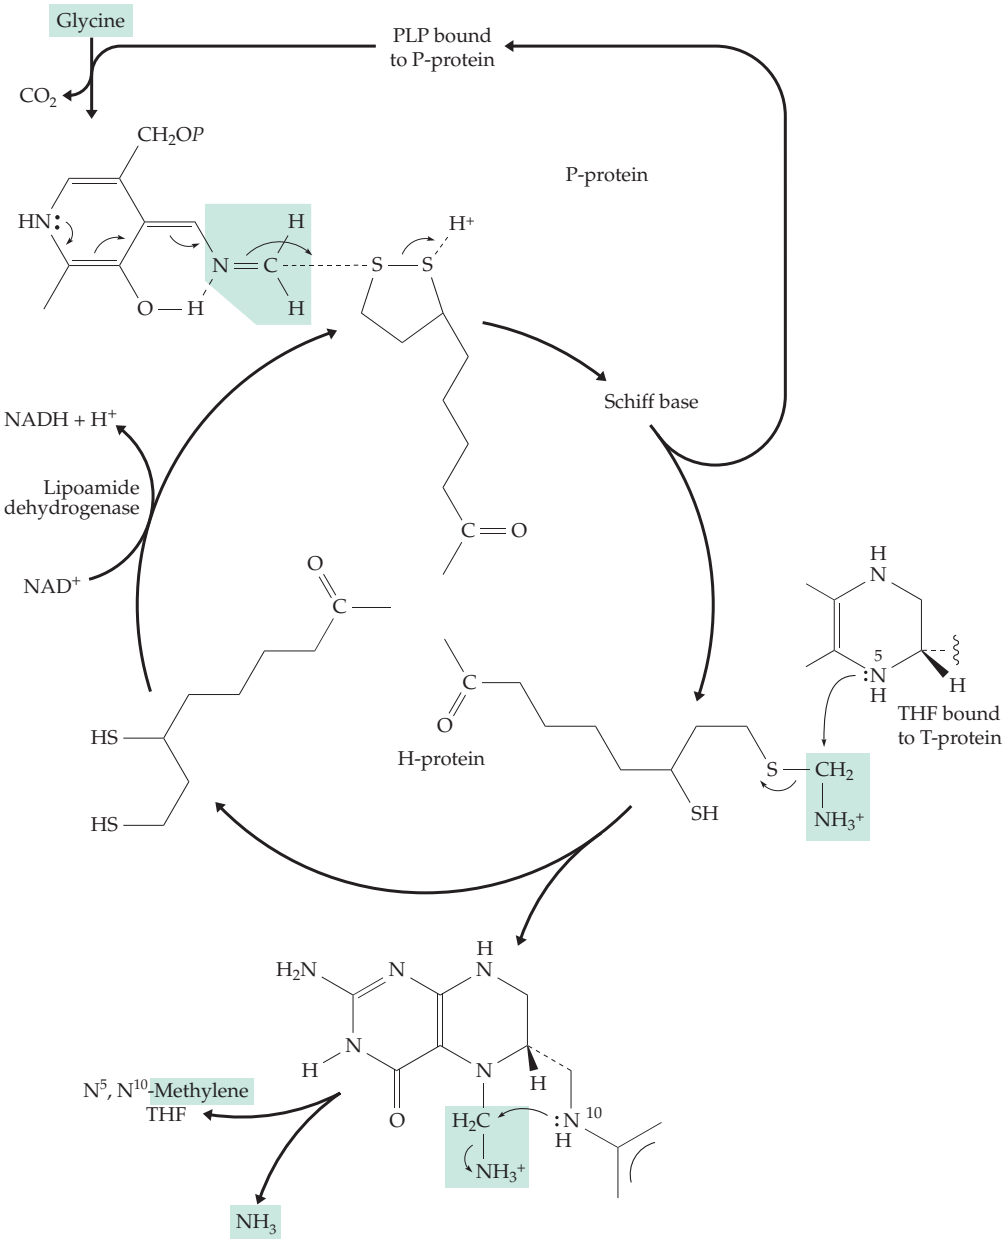

Figure 15-20 The reversible glycine cleavage system of mitochondria. Compare with Fig. 15-15.

or it can be reduced to methyl-THF (step *i*). The reactions of folate metabolism occurs in both cytoplasm and mitochondria at rates that are affected by the length of the polyglutamate chain. The many complexities of these pathways are not fully understood.[395,397]

Starting with formate or carbon dioxide. Most organisms can, to some extent, also utilize formate as a source of single-carbon units. Human beings have a very limited ability to metabolize formate and the accumulation of formic acid in the body following ingestion of methanol is often fatal. However, many bacteria are able to subsist on formate as a sole carbon source. Archaea may generate the formate by reduction of CO_2. Utilization of formate begins with formation of 10-formyl-THF (Fig. 15-18, step *g*, lower left corner). 10-Formyl-THF can be reduced to methylene-THF and the single-carbon unit can be transferred to glycine to form serine. In some bacteria three separate enzymes are required to convert formate to methylene-THF: 10-formyl-THF synthetase (Fig. 15-18, step *g*, presumably via formyl phosphate),[405] methenyl-THF cyclohydrolase (step *e*, reverse), and methylene-THF dehydrogenase (step *d*, reverse). NADH is used by the acetogens but in *E. coli* and in most higher organisms NADPH is the reductant. In some bacteria and in some tumor cells, two of the three enzymes are present as a bifunctional enzyme.[406–407a] In most eukaryotes all three of the enzymatic activities needed for converting formate to methylene-THF are present in a single large (200-kDa) dimeric trifunctional protein called **formyl-THF synthetase**.[407,408]

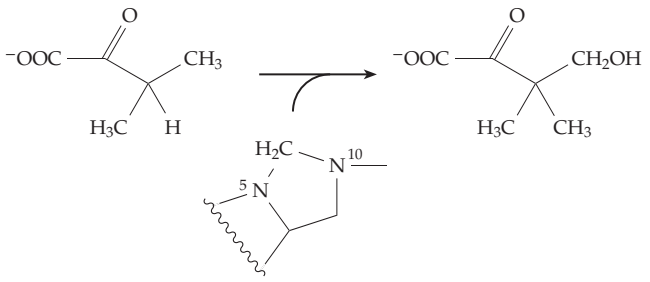
N^{10}-Formyl-THF serves as *a biological formylating agent* needed for two steps in the synthesis of purines[409–410b] (Chapter 25) and, in bacteria and in mitochondria and chloroplasts, for synthesis of formyl-methionyl-tRNA[411] which initiates synthesis of all polypeptide chains in bacteria and in these organelles (Chapter 29).

N^5-Formyl-THF (leucovorin). The N^5-formyl derivative of THF (5-formyl-THF) is a growth factor for *Leuconostoc citrovorum.* Following this discovery in 1949 it was called the "citrovorum factor" or **leucovorin**. Its significance in metabolism is not clear. Perhaps it serves as a storage form of folate in cells that have a dormant stage, e.g., of seeds or spores.[412] It may also have a regulatory function.[413] In some ants and in certain beetles, it is stored and hydrolyzed to formic acid. The carabid beetle *Galerita lecontei* ejects a defensive spray that contains 80% formic acid.[414]

5-Formyl-THF can arise by transfer of a formyl group from formylglutamate and there is an enzyme that converts 5-formyl-THF to 5,10-methenyl-THF with concurrent cleavage of ATP.[412] 5-Formyl-THF is sometimes used in a remarkable way to treat certain highly malignant cancers. Following surgical removal of the tumor the patient is periodically given what would normally be a lethal dose of methotrexate, then, about 36 h later, the patient is rescued by injection of 5-formyl-THF. The mechanism of rescue is thought to depend upon the compound's rapid conversion to 10-formyl-THF within cells. Tumor cells are not rescued, perhaps because they have a higher capacity than normal cells for synthesis of polyglutamates of methotrexate.[379] This observation also suggests that the major anti-cancer effect of methotrexate may not be on dihydrofolate reductase but on enzymes of formyl group transfer that are inhibited by polyglutamate derivatives of methotrexate.

Catabolism of histidine and purines. Another source of single-carbon units in metabolism is the degradation of histidine which occurs both in bacteria and in animals via **formiminoglutamate**. The latter transfers the –CH=NH group to THF forming 5-formimino-THF, which is in turn converted (step *h*, Fig. 15-18) to 5,10-methenyl-THF and ammonia. In bacteria that ferment purines, **formiminoglycine** is an intermediate. Again, the formimino group is transferred to THF and deaminated, the eventual product being 10-formyl-THF. In these organisms, the enzyme 10-formyl-THF synthase also has a very high activity.[415] It probably operates in reverse as a mechanism for synthesis of ATP in this type of fermentation. In other organisms excess 10-formyl-THF may be oxidized to CO_2 via an $NADP^+$-dependent dehydrogenase (step *f*, Fig. 15-16), providing a mechanism for detoxifying formic acid. In some organisms excess 10-formyl-THF may simply be hydrolyzed with release of formate (step *q*).[415a]

Thymidylate synthase. Methylene-THF serves as the direct precursor of the 5-methyl group of thymine as well as of the hydroxymethyl groups of **hydroxymethylcytosine**[416] and of **2-oxopantoate**, an intermediate in the formation of pantothenate and coenzyme A.[417] The latter is a simple hydroxymethyl transfer reaction (Eq. 15-44) that is related to an aldol condensation and which may proceed through an imine of the kind shown in Eq. 15-43.



$N^{5,10}$-Methylene-THF (15-44)

During thymine formation the coenzyme is oxidized to dihydrofolate, which must be reduced by dihydrofolate reductase to complete the catalytic cycle. A possible mechanistic sequence for **thymidylate synthase**, an enzyme of known three-dimensional structure,[354,418–421a] is given in Fig. 15-21. In the first step (*a*) a thiolate anion, from the side chain of Cys 198 of the 316-residue *Lactobacillus* enzyme, adds to the 5 position of the substrate 2'-deoxyuridine monophosphate (dUMP). As a consequence the 6 position becomes a nucleophilic center which can combine with methylene-THF as shown in step *b* of Fig. 15-21. After tautomerization (step *c*) this adduct eliminates THF (step *d*) to give a 5-methylene derivative of the dUMP. The latter immediately oxidizes the THF by a hydride ion transfer to form thymidylate and dihydrofolate.[422,422a]

In protozoa thymidylate synthase and dihydrofolate reductase exist as a single bifunctional protein.

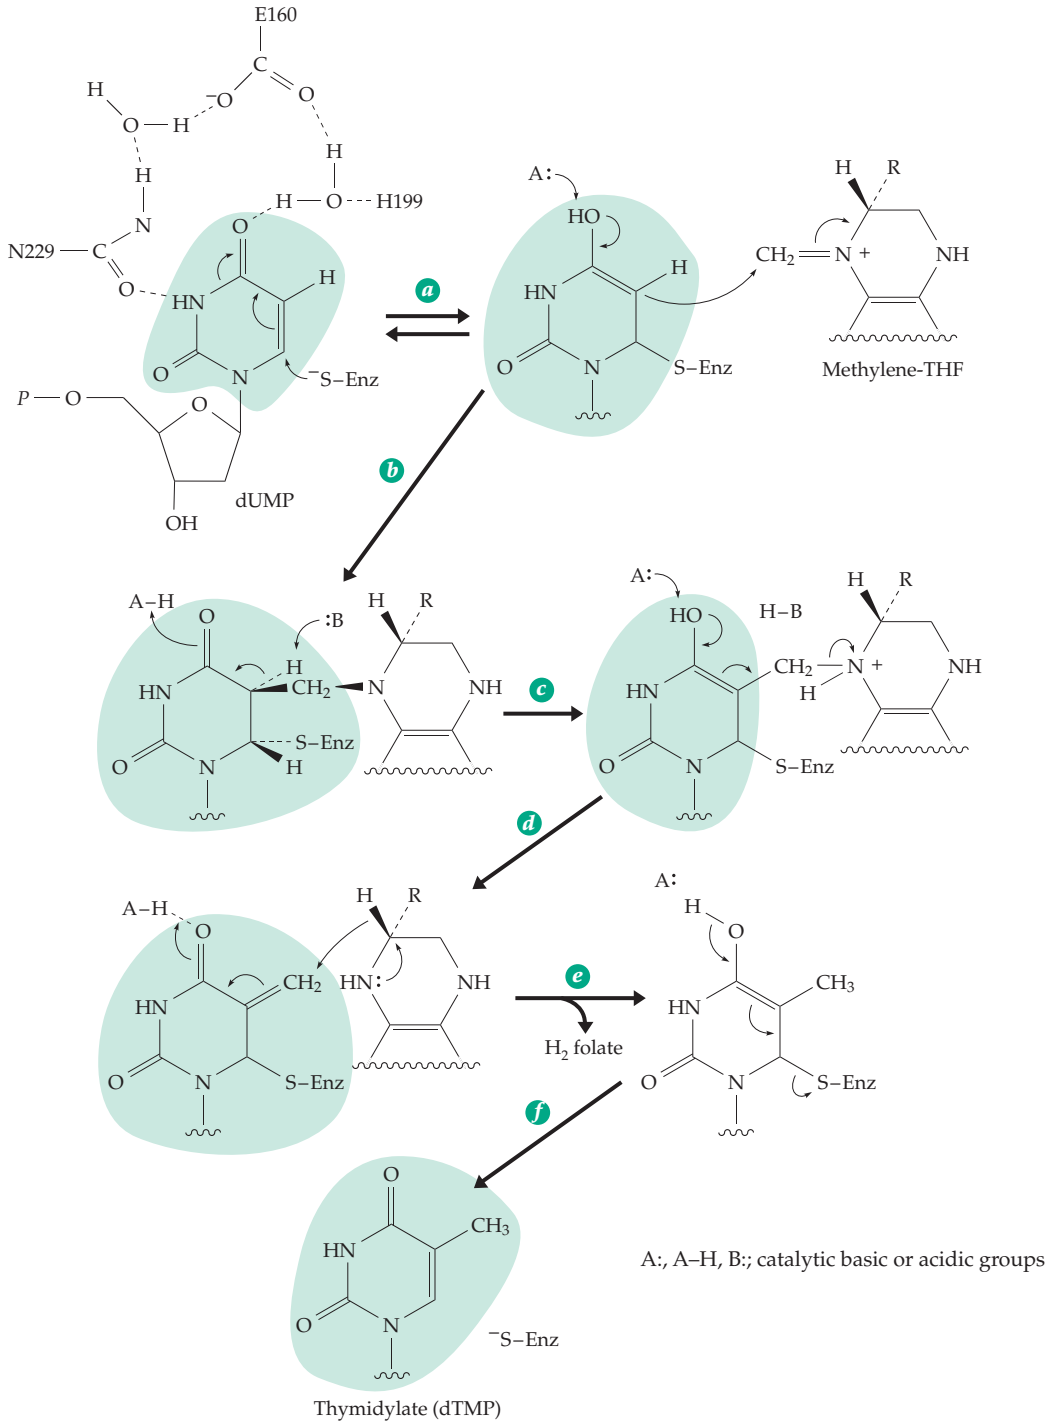


Figure 15-21 Probable mechanism of action of thymidylate synthase. After Huang and Santi[422] and Hyatt *et al.*[354]

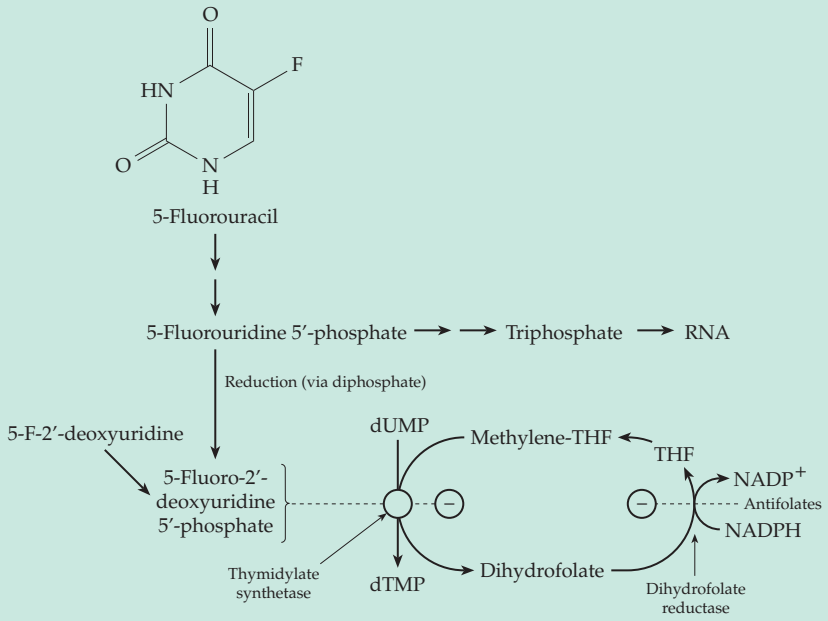
Consequently, in methotrexate-resistant strains of *Leishmania* (and also in cancer cells) both enzyme activities are increased equally by gene amplification.[423] This presents a serious problem in the treatment of protozoal parasitic diseases for which few suitable drugs are known.

Cells of *E. coli*, when infected with T-even bacteriophage, convert dCMP to 5-hydroxymethyl-dCMP[423a]

BOX 15-E THYMIDYLATE SYNTHASE, A TARGET ENZYME IN CANCER CHEMOTHERAPY[a]



If an animal or bacterial cells are deprived of thymine they can no longer make DNA. However, synthesis of proteins and of RNA continues for some time. This can be demonstrated experimentally with thymine-requiring mutants. However, sooner or later such cells lose their vitality and die. The cause of this **thymineless death**[b] is not entirely clear. Perhaps thymine is needed to repair damage to DNA and if it is not available transcription eventually becomes faulty. Chromosome breakage is also observed.[c] Whatever the cause of death, the phenomenon provides the basis for some of the most effective chemotherapeutic attacks on cancer. Rapidly metabolizing cancer cells are especially vulnerable to thymineless death. Consequently, thymidylate synthase is an important target enzyme for inhibition. One powerful inhibitor is the monophosphate of **5-fluoro-2'-deoxyuridine**. The inhibition was originally discovered when 5-fluorouracil was recognized as a useful cancer chemotherapeutic agent.

Fluorouracil has many effects in cells, including incorporation into RNA,[b] but the inhibition of thymidylate synthase by the reduction product may be the most useful effect in chemotherapy. In fact, 5-fluoro-2'-deoxyuridine is a much less toxic and more potent drug than 5-fluorouracil. It binds into the active site of thymidylate synthase and reacts in the initial steps of catalysis. However, the 5-H of 2'-deoxyuridine, the normal substrate, must be removed as H^+ (step *c* of Fig. 15-21) in order for the reaction to continue. The 5-F atom cannot be removed in this way and a stable adduct is formed.[d,e] A crystal structure containing both the bound 5-fluorodeoxyuridine and methylene-THF supports this conclusion.[e]

Thymidylate synthase requires methylene tetrahydrofolate as a reductant and the reduction of dihydrofolate is also an important part of the process. In protozoa dihydrofolate reductase and thymidylate synthase occur as a single-chain bifunctional enzyme.[f] As has been pointed out in the main text, such folic acid analogs as methotrexate are among the most useful anticancer drugs. By inhibiting dihydrofolate reductase they deprive thymidylate synthase of an essential substrate.

Because 5-fluorouracil acts on normal cells as well as cancer cells, its usefulness is limited. Knowledge of the chemistry and three-dimensional structure of thymidylate synthase complexes is being used in an attempt to discover more specific and effective drugs that attack this enzyme.[g,h]

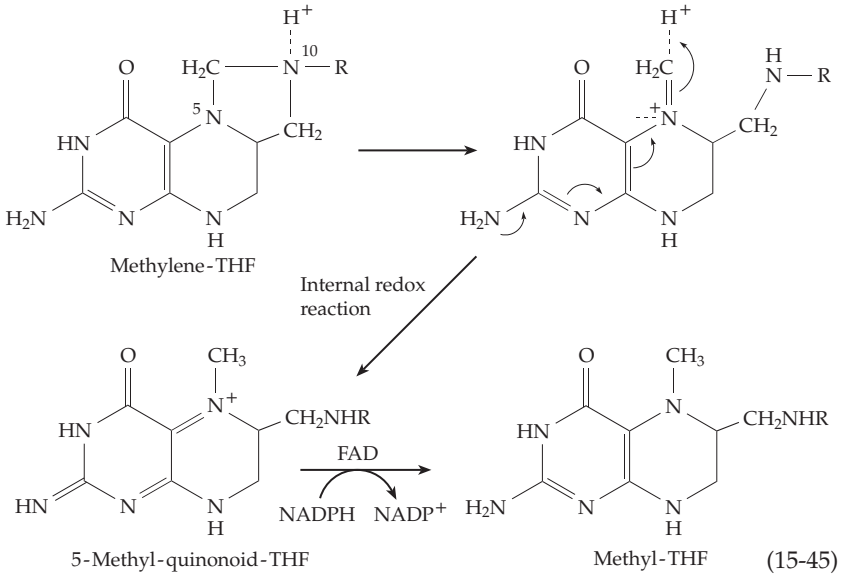
and suitably infected cells of *Bacillus subtilis* form 5-hydroxymethyl-dUMP.[424,425] These products can be formed by attack of OH^- on quinonoid intermediates of the type postulated for thymidylate synthetase (formed in step *d* of Fig. 15-21).[416] A related reaction is the posttransciptional conversion of a single uracil residue in tRNA molecules of some bacteria to a thymine ring (a **ribothymidylic acid** residue). In this case, $FADH_2$ is used as a reducing agent to convert the initial adduct of Fig. 15-21 to the ribothymidylic acid and THF.[426]



(15-45)

Synthesis of methyl groups. The reduction of methylene-THF to 5-methyl-THF within all living organisms from bacteria to higher plants and animals provides the methyl groups needed in biosynthesis.[426a] These are required for formation of methionine and, from it, *S*-adenosylmethionine. The latter is used to modify proteins, nucleic acids, and other biochemicals through methylation of specific groups. In the methanogens, reduction of a corresponding methylene derivative of methanopterin gives rise to methane (Section F).

Mammalian methylene-THF reductase is a FAD-containing flavoprotein that utilizes NADPH for the reduction to 5-methyl-THF.[427,428] Matthews[429] suggested that the mechanism of this reaction involves an internal oxidation–reduction reaction that generates a 5-methyl-quinonoid dihydro-THF (Eq. 15-45). Methylene-THF reductase of acetogenic bacteria is also a flavoprotein but it contains Fe–S centers as well. The 237-kDa $\alpha_4\beta_4$ oligomer contains two molecules of FAD and four to six of both Fe and S^{2-} ions.[430,431]

The methyl group of methyl-THF is incorporated into methionine by the vitamin B_{12}-dependent methionine synthase which is discussed in Chapter 16. Matthews suggested that methionine synthase may also make use of the 5-methyl-quinonoid-THF of Eq. 15-45. An initial reduction step would precede transfer of the methyl group. Methyl-THF is a precursor to acetate in the acetogenic bacteria.[432] This corrinoid coenzyme-dependent process is also considered in Chapter 16.

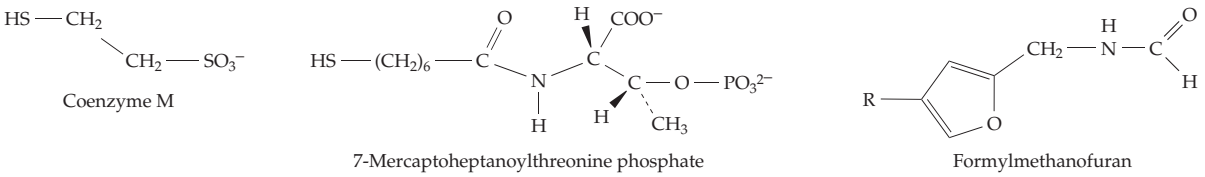
E. Specialized Coenzymes of Methanogenic Bacteria

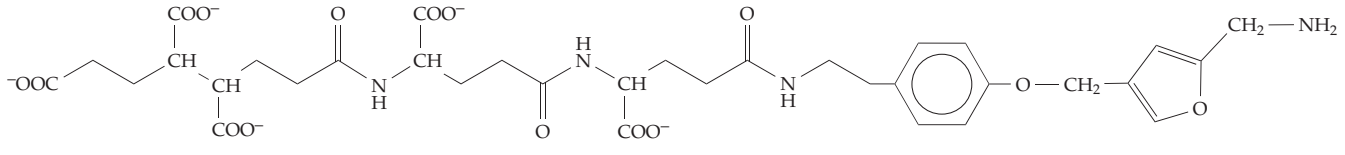
Methane-producing bacteria[433,434] obtain energy by reducing CO_2 with molecular hydrogen:

$$CO_2 + 4H_2 \rightarrow CH_4 + 2H_2O \qquad \Delta G^\circ = -131 \text{ kJ / mol} \qquad (15\text{-}46)$$

Some species are also able to utilize formate or formaldehyde as reducing agents.[435] These compounds are oxidized to CO_2, the reducing equivalents formed being used to reduce CO_2 to methane. Carbon monoxide can also be converted to CO_2.

$$CO + H_2O \rightarrow CO_2 + H_2 \qquad \Delta G^\circ = -20 \text{ kJ / mol} \qquad (15\text{-}47)$$





By using the combined reactions of Eqs. 15-46 and 15-47 the bacteria can subsist on CO alone (Eq. 15-48):

$$4CO + 2\,H_2O \rightarrow 3CO_2 + CH_4 \qquad \Delta G^\circ = -211 \text{ kJ / mol of methane formed} \qquad (15\text{-}48)$$

Some species reduce methanol to methane via Eqs. 15-49 or 15-50.

$$CH_3OH + H_2 \rightarrow CH_4 + H_2O \qquad \Delta G^\circ = -113 \text{ kJ / mol} \qquad (15\text{-}49)$$

$$4CH_3OH \rightarrow 3CH_4 + CO_2 + 2\,H_2O \qquad \Delta G^\circ = -107 \text{ kJ / mol of methane formed} \qquad (15\text{-}50)$$

To accomplish these reactions a surprising variety of specialized cofactors are needed.[351,352,434] The first of these, **coenzyme M**, 2-mercaptoethane sulfonate, was discovered in 1974.[436] It is the simplest known coenzyme. Later, the previously described **5-deazaflavin F_{420}** (Section B), a **nickel tetrapyrrole F_{430}** (Chapter 16), **methanopterin** (Fig. 15-17),[437] the "carbon dioxide reduction factor" called **methanofuran**,[352,438] and **7-mercaptoheptanoylthreonine phosphate**[439,440] were also identified.

A sketch of the metabolic pathways followed in methane formation is given in Fig. 15-22.[352,435] In the first step (*a*) the amino group of methanofuran is thought to add to CO_2 to form a carbamate which is reduced to formylmethanofuran by H_2 and an intermediate carrier H_2X in step *b*. The formyl group is then transferred to tetrahydromethanopterin (H_4MPT) (step *c*)[440a] and is cyclized and reduced in two stages in steps *d*, *e*, and *f*. The reductant is the deazaflavin F_{420} and the reactions parallel those for conversion of formyl-THF to methyl-THF (Fig. 15-18).[431,440b,441] The methyl group of methyl-H_4MPT is then transferred to the sulfur atom of the thiolate anion of coenzyme M, from which it is reduced off as CH_4. This is a complex process requiring the nickel-containing F_{430}, FAD, and 7-mercaptoheptanoylthreonine phosphate (HS-HTP).

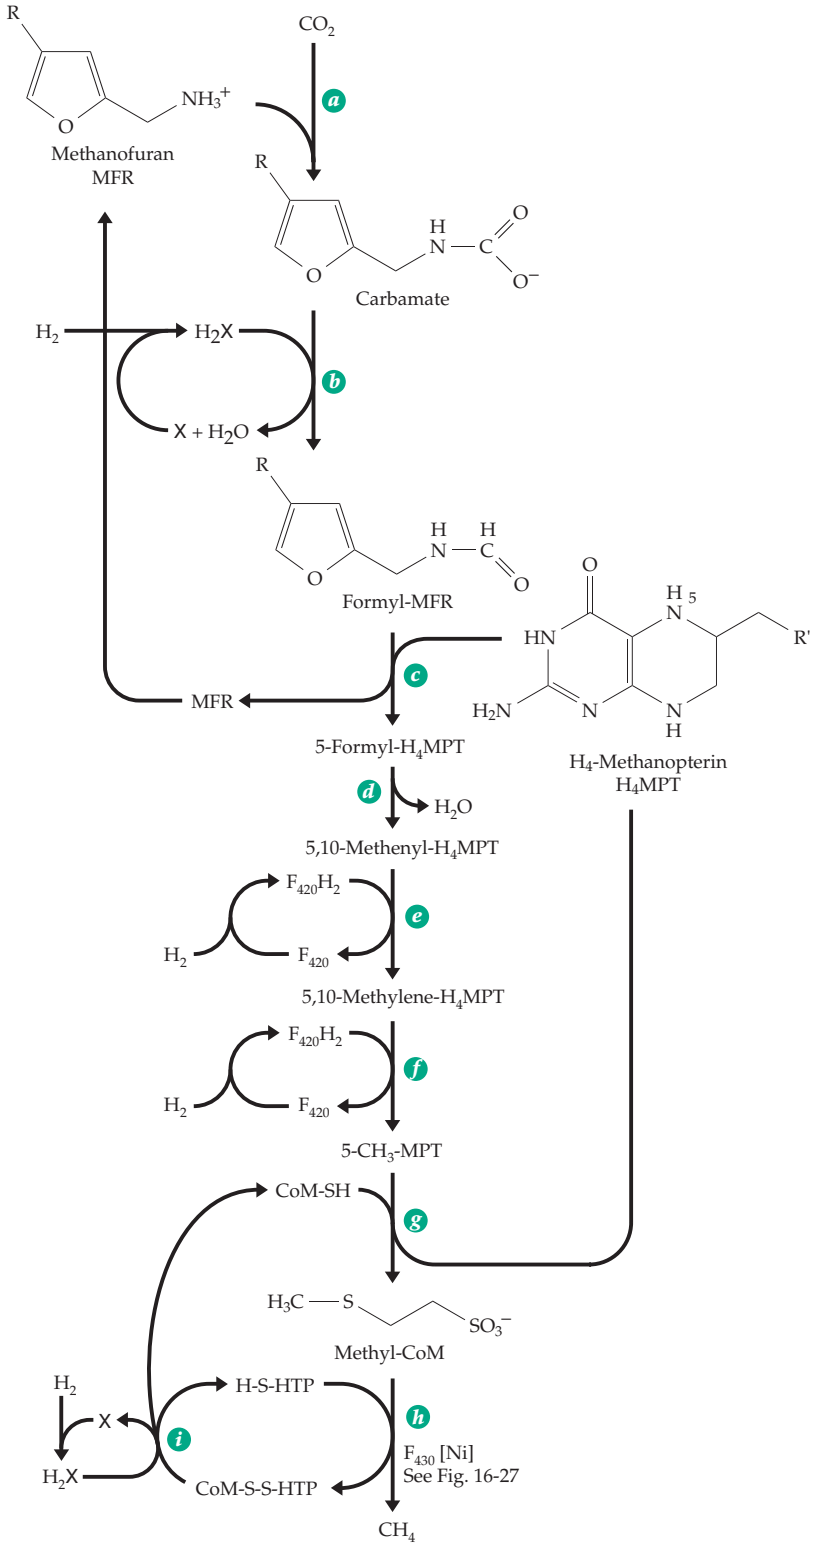


Figure 15-22 Tentative scheme for reduction of carbon dioxide to methane by methanogens. After Rouvière *et al.*[352] and Thauer *et al.*[435]

The HS-HTP may be the 2-electron donor for the reduction. The mixed-disulfide CoM-S-S-HTP appears to be an intermediate and also an allosteric effector for the first step, the reduction of CO_2 to formylmethanofuran. A complex of proteins that is unstable in oxygen is also needed. The principal component of the methyl reductase binds two molecules

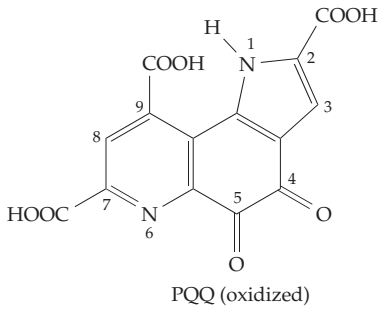
of the nickel-containing F_{430}. It also binds two moles of CoM-SH noncovalently. The binding process requires ATP as well as the presence of other proteins, notably those of the hydrogenase system.

Coenzyme M, previously found only in methanogenic archaeobacteria, has recently been discovered in both gram-negative and gram-positive alkene-oxidizing eubacteria. It seems to function in cleavage of epoxy rings and as a carrier of hydroxyalkyl groups.[441a] See also Chapter 17.

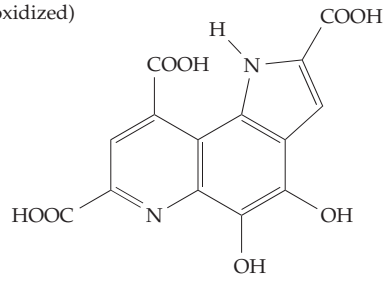
F. Quinones, Hydroquinones, and Tocopherols

1. Pyrroloquinoline Quinone (PQQ)

Bacteria that oxidize methane or methanol (**methylotrophs**) employ a periplasmic methanol dehydrogenase that contains as a bound coenzyme, the pyrroloquinoline quinone designated **PQQ** or methoxatin (Eq. 15-51).[442–444] This fluorescent *ortho*-quinone



PQQ (oxidized)

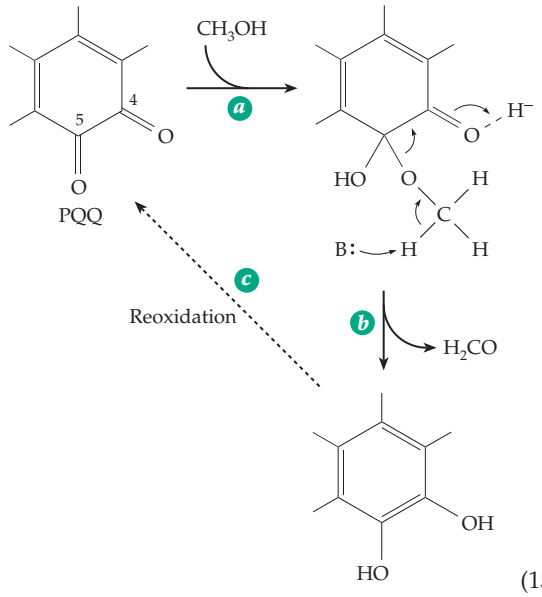


$PQQH_2$ (reduced)

is released when the protein is denatured. Some other bacterial alcohol dehydrogenases[445,445a] and glucose dehydrogenases[446-446d] contain the same cofactor.

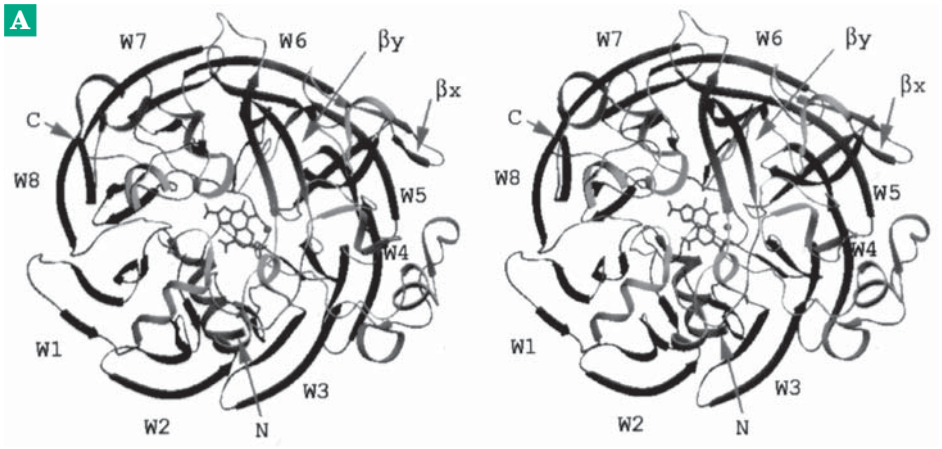
PQQ-containing methanol dehydrogenase from *Methylophilus* is a dimer of a 640-residue protein consisting of two disulfide-linked peptide chains with one noncovalently bound PQQ.[447] The large subunit contains a β propellor (Fig. 15-23), which is similar to that in the protein G_i shown in Fig. 11-7. The PQQ binding site lies above the propellor and is formed by a series of loops. The coenzyme interacts with several polar protein side chains and with a bound calcium ion.[448] Bacterial PQQ-dependent glucose dehydrogenases have also been studied intensively. The 450-residue soluble enzyme from *Acinetobacter calcoaceticus* is partially homologous to the methanol dehydrogenase.[446a,446b]

PQQ and the other quinone prosthetic groups described here all function in reactions that would be possible for pyridine nucleotide or flavin coenzymes. All of them, like the flavins, can exist in oxidized, half-reduced semiquinone and fully reduced dihydro forms. The questions to be asked are the same as we asked for flavins. How do the substrates react? How is the reduced cofactor reoxidized? In nonenzymatic reactions alcohols, amines, and enolate anions all add at C-5 of PQQ to give adducts such as that shown for methanol in Eq. 15-51, step *a*.[444,449,449a] Although many additional reactions are possible, this addition is a reasonable first step in the mechanism shown in Eq. 15-51. An enzymatic base could remove a proton as is indicated in step *b* to give $PQQH_2$. The pathway for reoxidation (step *c*) might involve a cytochrome *b*, cytochrome *c*, or bound ubiquinone.[445,446]



(15-51)

Although the soluble PQQ-dependent glucose dehydrogenase forms, with methylhydrazine, an adduct similar to that depicted in Eq. 15-51,[449b] the structure of a glucose complex of the $PPQH_2$- and Ca^{2+}-containing enzyme at a resolution of 0.2 nm suggests a direct hydride ion transfer. The only base close to glucose C1 is His 144. The C1-H proton lies directly above the $PQQH_2$ C5 atom. Oubrie *et al.*[446a] propose a deprotonation of the C1-OH by His 144 and H^- transfer to C5 of PQQ followed by tautomerization (Eq. 15-52). Theoretical calculations by Zheng and Bruice[449c] favor a simpler mechanism with hydride transfer to the oxygen atom of the C4 carbonyl (green arrows). In either case, the Ca^{2+} would assist by polarizing the C5 carbonyl group.



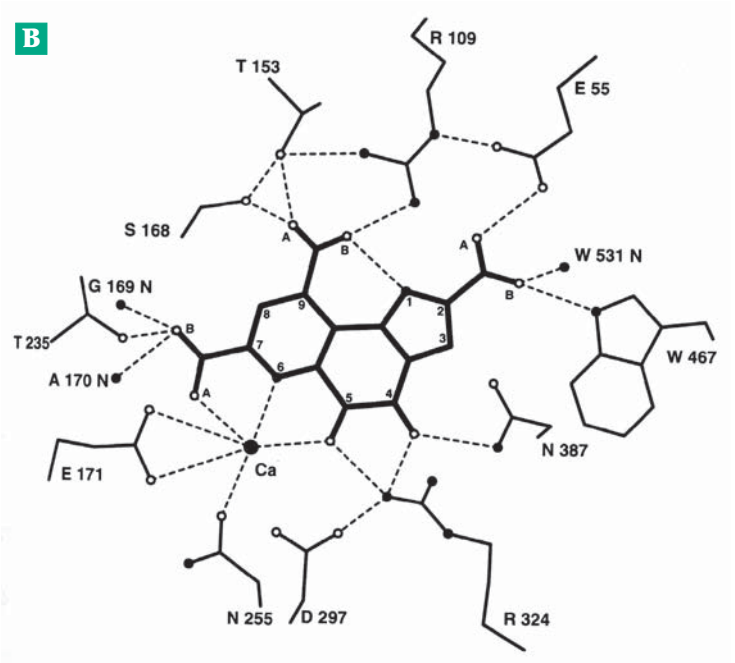


Figure 15-23 (A) Stereoscopic view of the H subunit of methanol dehydrogenase. Eight four-stranded antiparallel β sheets, labeled W1–W8, form the base of the subunit. Several helices and two additional β-sheet structures (labeled βx and βy) form a cap over the base. The PQQ is located in a funnel within the cap approximately on an eight-fold axis of pseudosymmetry. Courtesy of Xia *et al.*[447] (B) Schematic view of the active site. W467 is parallel to the plane of PQQ. All hydrogen-bond interactions between PQQ and its surrounding atoms, except for the three water molecules, are indicated. Courtesy of White *et al.*[448]

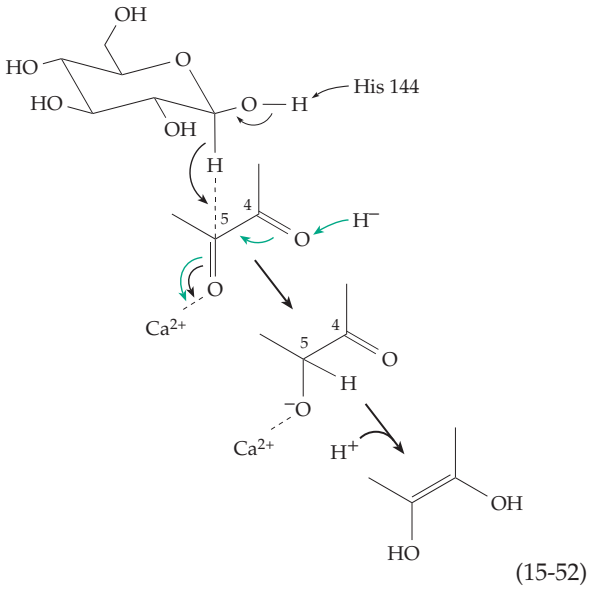


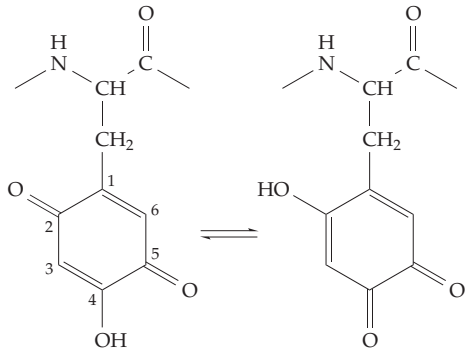
(15-52)

2. Copper Amine Oxidases

At first it appeared that PQQ had a broad distribution in enzymes, including eukaryotic amine oxidases. However, it was discovered, after considerable effort, that there are additional quinone cofactors that function in oxidation of amines. These are derivatives of tyrosyl groups of specific enzyme proteins. Together with enzymes containing bound PQQ they are often called **quinoproteins**.[450–454]

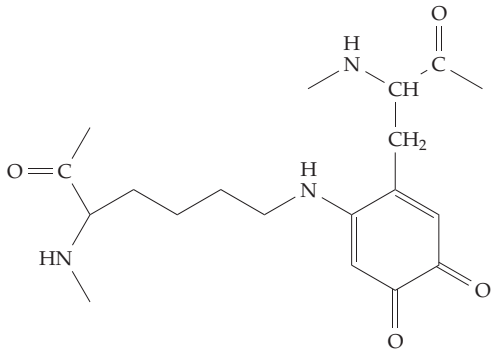
Topaquinone (TPQ). Both bacteria and eukaryotes contain amine oxidases that utilize bound copper ions and O_2 as electron acceptors and form an aldehyde, NH_3, and H_2O_2. The presence of an organic cofactor was suggested by the absorption spectra which was variously attributed to pyridoxal phosphate or PQQ. However, isolation from the active site of bovine serum

amine oxidase established the structure of the reduced form of the cofactor as a trihydroxyphenylalanyl group covalently linked in the peptide chain.[455,456] Its oxidized form is called topaquinone:



Topaquinone (TPQ)

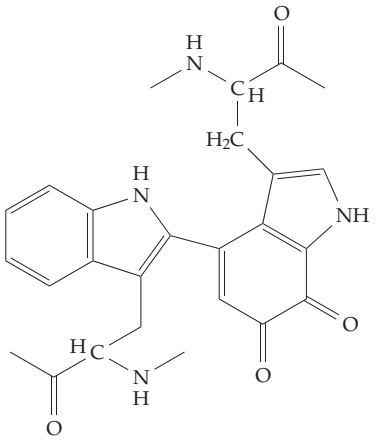
The same cofactor is present in an amine oxidase from *E. coli*[457–460] and in other bacterial[461–463] fungal,[463a] plant,[464] and mammalian[464a] amine oxidases.



Lysine tyrosylquinone (LTQ)

Lysine tyrosylquinone (LTQ). Another copper amine oxidase, **lysyl oxidase**, which oxidizes side chains of lysine in collagen and elastin (Eq. 8-8) contains a cofactor that has been identified as having a lysyl group of a different segment of the protein in place of the –OH in the 2 position of topaquinone.[465] Lysyl oxidase plays an essential role in the crosslinking of collagen and elastin.

Tryptophan tryptophanylquinone (TTQ). This recently discovered quinone cofactor is similar to the lysyl tyrosylquinone but is formed from two tryptophanyl side chains.[466] It has been found in **methylamine dehydrogenase** from methylotrophic gram-negative bacteria[467–469] and also in a bacterial aromatic amine dehydrogenase.[470]

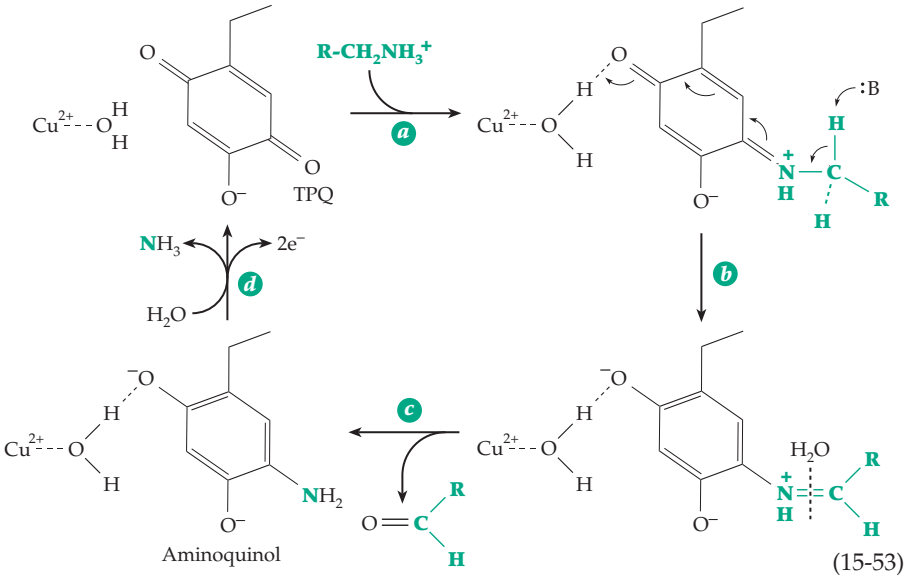


Tryptophan tryptophylquinone (TTQ)

Three-dimensional structures. The TPQ-containing amine oxidase from *E. coli* is a dimer of 727-residue subunits with one molecule of TPQ at position 402 in each subunit.[457,458] Methylamine dehydrogenase is also a large dimeric protein of two large 46.7-kDa subunits and two small 15.5-kDa subunits. Each large subunit contains a TTQ cofactor group.[468,471,471a] Reduced TTQ is reoxidized by the 12.5-kDa blue copper protein **amicyanin**. Crystal structures have been determined for complexes of methylamine dehydrogenase with amicyanin[471] and of these two proteins with a third protein, a small bacterial cytochrome *c*.[472,472a]

Mechanisms. Studies of model reactions[473–476] and of electronic, Raman,[466,477,478] ESR,[479,480] and NMR spectra and kinetics[481] have contributed to an understanding of these enzymes.[459,461,464,482,483] For these copper amine oxidases the experimental evidence suggests an aminotransferase mechanism.[450,453,474,474a-d] The structure of the *E.coli* oxidase shows that a single copper ion is bound by three histidine imidazoles and is located adjacent to the TPQ (Eq. 15-53). Asp 383 is a conserved residue that may be the catalytic base in Eq. 15-53.[474b] A similar mechanism can be invoked for LTQ and TTQ.

How is the reduced cofactor reoxidized? Presumably the copper ion adjacent to the TPQ functions in this process, passing electrons one at a time to the next carrier in a chain. There is no copper in the TTQ-containing subunits. Electrons apparently must jump about 1.6 nm to the copper ion of amicyanin, then another 2.5 nm to the iron ion of the cytochrome *c*.[472] Reoxidation of the aminoquinol formed in Eq. 15-53, step *d*, yields a Schiff base whose hydrolysis will release ammonia and regenerate the TTQ. Intermediate states with Cu^+ and a TTQ semiquinone radical have been observed.[483a]



3. Ubiquinones, Plastoquinones, Tocopherols, and Vitamin K

In 1955, R. A. Morton and associates in Liverpool announced the isolation of a quinone which they named ubiquinone for its ubiquitous occurrence.[484,485] It was characterized as a derivative of benzoquinone attached to an unsaturated polyprenyl (isoprenoid) side chain (Fig. 15-24). In fact, there is a family of ubiquinones: that from bacteria typically contains six prenyl units in its side chain, while most ubiquinones from mammalian mitochondria contain ten. Ubiquinone was also isolated by F. L. Crane and associates using isooctane extraction of mitochondria. These workers proposed that the new quinone, which they called **coenzyme Q**, might participate in electron transport. As is described in Chapter 18, this function has been fully established. Both the name ubiquinone and the abbreviation Q are in general use. A subscript indicates the number of prenyl units, e.g., Q_{10}. Ubiquinones can be reversibly reduced to the hydroquinone forms (Fig. 15-24), providing a basis for their function in electron transport within mitochondria and chloroplasts.[486–490]

While vitamin E (Box 15-G) and vitamin K (Box 15-F) are dietary essentials for humans, ubiquinone is apparently not. Animals are able to make ubiquinones in quantities adequate to meet the need for this essential component of mitochondria. However, an extra dietary supplement may sometimes be of value.[491] A reduced level of ubiquinone has been reported in gum tissues of patients with periodontal disease.[492] Ubiquinones are being tested as possible protectants against heart damage caused by lack of adequate oxygen or by drugs.[491]

A closely related series of **plastoquinones** occur in chloroplasts (Chapter 23). In these compounds the two methoxyl groups of ubiquinone are replaced by methyl groups (Fig. 15-24). The most abundant of these compounds, plastoquinone A, contains nine prenyl units.[493,494]

Addition of the hydroxyl group of the reduced ubiquinone or plastoquinone to the adjacent double bond leads to a chroman-6-ol structure. The compounds derived from ubiquinone in this way are called **ubichromanols** (Fig. 15-24). The corresponding ubichromenol (Fig. 15-24) has been isolated from human kidney. **Plastochromanols** are derived from plastoquinone. That from plastoquinone A, first isolated from tobacco, is also known as solanochromene.

A closely related and important family of chromanols are the **tocopherols** or vitamins E (Fig. 15-24, Box 15-G). Tocopherols are plant products found primarily in plant oils and are essential to proper nutrition of humans and other animals. α-Tocopherol is the most abundant form of the vitamin E family; smaller amounts of the β, δ, and γ forms occur, as do a series of **tocotrienols** which contain unsaturated isoprenoid units.[495] The configuration of α-tocopherol is 2*R*,4'*R*,8'*R* as indicated in Fig. 15-24. When α-tocopherol is oxidized, e.g., with ferric chloride, the ring can be opened by hydrolysis to give **tocopherolquinones** (Fig. 15-24), which can in turn be reduced to tocopherolhydroquinones. Large amounts of the tocopherolquinones have been found in chloroplasts.

Another important family of quinones, related in structure to those already discussed, are the **vitamins K** (Fig. 15-24, Box 15-F). These occur naturally as two families. The vitamins K_1 (**phylloquinones**) have only one double bond in the side chain and that is in the prenyl unit closest to the ring. This suggests again the possibility of chromanol formation. In the vitamin K_2 (**menaquinone**) series, a double bond is present in each of the prenyl units. A synthetic compound **menadione** completely lacks the polyprenyl side chain and bears a hydrogen in the corresponding position on the ring. Nevertheless, menadione serves as a synthetic vitamin K, apparently because it can be converted in the body to forms containing polyprenyl side chains.

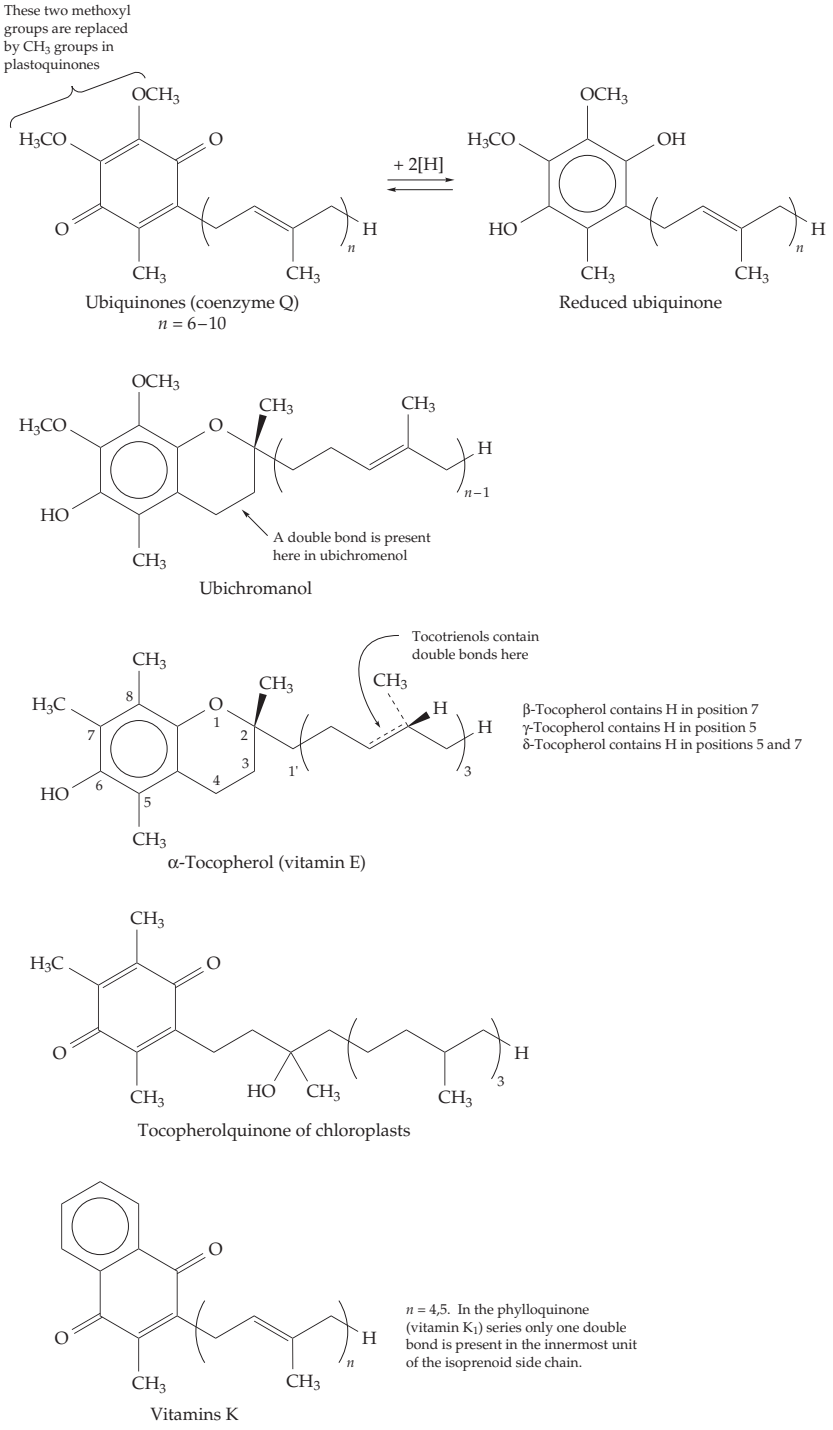


Figure 15-24 Structures of the isoprenoid quinones and vitamin E.

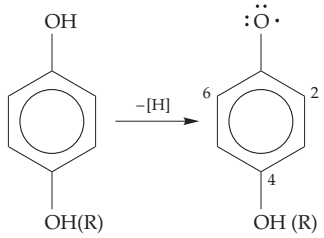
these membranes. Within some mycobacteria vitamin K apparently participates in electron transport chains in the same way (see Chapter 18). Some bacteria contain both menaquinones and ubiquinones.

The vitamin E derivative **α-tocopherolquinone** (Fig. 15-24) can also serve as an electron carrier, being reversibly reduced to the hydroquinone form α-tocopherolquinol. Such a function has been proposed for the anaerobic rumen bacterium *Butyrovibrio fibrisolvens*.[497]

When a single hydrogen atom is removed from a hydroquinone or from a chromanol such as a tocopherol, a free radical is formed (Eq. 15-54). Phenols substituted in the 2, 4, and 6 positions give especially stable radicals.



(15-54)

Both the presence of methyl substituents in the tocopherols and their chromanol structures increase the ability of these compounds to form relatively stable radicals.[498,499] This ability is doubtless probably important also in the function of ubiquinones and plastoquinones. Ubiquinone radicals (semiquinones) are probably intermediates in mitochondrial electron transport (Chapter 18) and radicals amounting to as much as 40% of the total ubiquinone in the NADH-ubiquinone reductase of heart mitochondria have been detected by EPR measurements.[500,501]

4. Quinones as Electron Carriers

Ubiquinones function as electron transport agents within the inner mitochondrial membranes[496] and also within the reaction centers of the photosynthetic membranes of bacteria (Eq. 23-32).[484,488,494] The plastoquinones also function in electron transport within

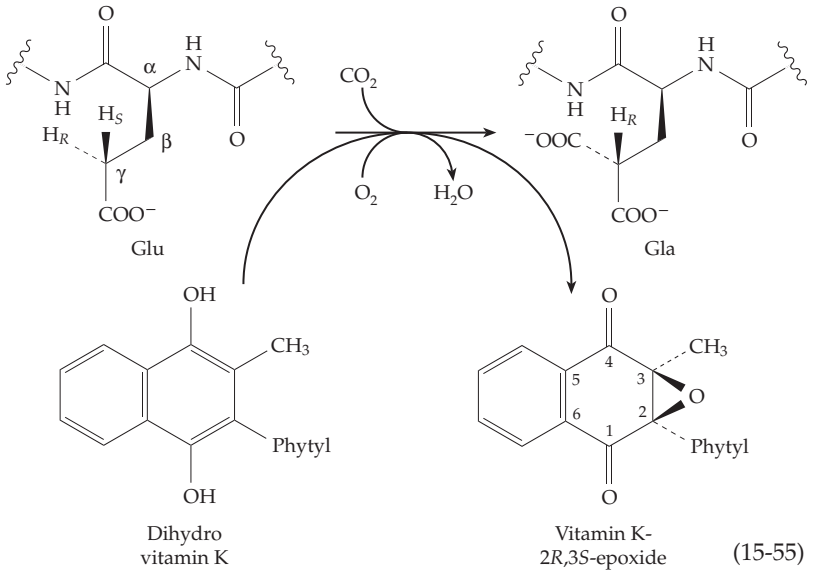
The equilibria governing semiquinone formation from quinones are similar to those for the flavin semiquinones which were discussed in Section B,6. Two consecutive one-electron redox steps can be defined. Their redox potentials will vary with pH because of a pK_a for the semiquinone in the pH 4.5–6.5 region. For ubiquinone this pK_a is about 4.9 in water and 6.45 in methanol. A pK_a of over 13 in the

hydroquinone form[502] will have little effect on redox potentials near pH 7. The potential for the one-electron reaction $Q + e^- \rightarrow Q^-$ is evaluated most readily. For this reaction $E°'$ (pH 7) is −0.074, −0.13, −0.17, and −0.23 for 2,3-dimethylbenzoquinone, plastoquinone, ubiquinone, and phylloquinone, respectively.

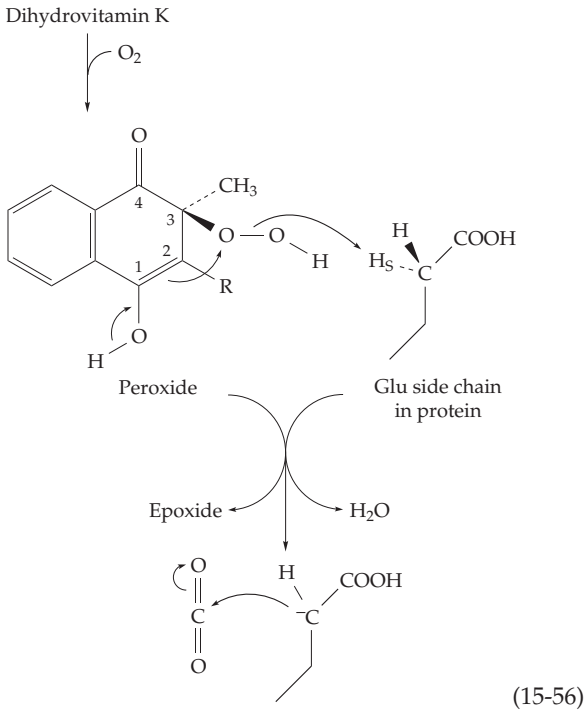
Why does this entire family of compounds have the long polyprenyl side chains? A simple answer is that they serve to anchor the compounds in the lipid portion of the cell membranes where they function. In the case of ubiquinones both the oxidized and the reduced forms may move freely through the lipid phase shuttling electrons between carriers.

5. Vitamin K and γ-Carboxyglutamate Formation

In higher animals the only known function of vitamin K is in the synthesis of γ-carboxyglutamate (Gla)-containing proteins, several of which are needed in blood clotting (Box 15-F, Chapter 12). Following the discovery of γ-carboxyglutamate, it was shown that liver microsomes were able to incorporate ^{14}C-containing bicarbonate or CO_2 into the Gla of prothrombin and could also generate Gla in certain simple peptides such as Phe-Leu-Glu-Val. Three enzymes are required. All are probably bound to the microsomal membranes.[503–507a] An NADPH-dependent reductase reduces vitamin K quinone to its hydroquinone form. Conversion of Glu residues to Gla residues requires this reduced vitamin K as well as O_2 and CO_2. During the carboxylation reaction the reduced vitamin K is converted into vitamin K 2,3-epoxide (Eq. 15-55).[508] The mechanism is uncertain but a peroxide intermediate such as that shown in Eq. 15-56 is probably involved. This could be used to generate a hydroxide ion adjacent to the *pro-S* -H of the glutamate side chain of the substrate. This hydrogen could be abstracted by the OH^- to form



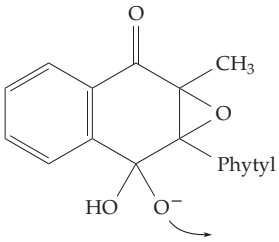
(15-55)



(15-56)

H_2O and a carbanion which would be stabilized by the adjacent carboxyl group[508–511] (Eq. 15-56).

Dowd and coworkers raised doubts that a hydroxide ion released in the active site in this manner is a strong enough base to generate the anion shown in Eq. 15-52.[512,513] They hypothesized a *"base strength amplification" mechanism* that begins with a peroxide formed at C-4 followed by ring closure to form a dioxetane and rearrangement to the following hypothetical strong base.[507,512,514]



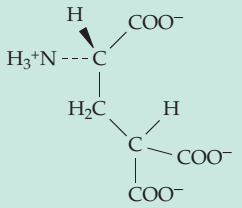
The proposal was supported by model experiments and also by observation of some incorporation of both atoms of $^{18}O_2$ into vitamin K epoxide. However, theoretical calculations support the simpler mechanism of Eq. 15-56.

The fact that L-*threo*-γ-fluoroglutamate residues, in which the fluorine atom is in the position corresponding to the *pro-S* hydrogen, are not carboxylated but that an *erythro*-γ-fluoroglutamate is carboxylated

BOX 15-F THE VITAMIN K FAMILY

The existence of an "antihemorrhagic factor" required in the diet of chicks to ensure rapid clotting of blood was reported in 1929 by Henrik Dam at the University of Copenhagen.[a,b] The fat-soluble material, later designated vitamin K, causes a prompt (2–6 h) decrease in the clotting time when administered to deficient animals and birds. The clotting time for a vitamin K-deficient chick may be greater than 240 s, but 6 h after injection of 2 μg of vitamin K_3 it falls to 50–100 s.[c] Pure vitamin K (Fig. 15-24), a 1,4-naphthoquinone, was isolated from alfalfa in 1939. Within a short time two series, the phylloquinones (vitamin K_1) and the menaquinones (vitamin K_2), were recognized. The most prominant phylloquinone contains the phytyl group, which is also present in the chlorophylls. For a human being a dietary intake of about 30 μg per day is recommended.[d] Additional vitamin K is normally supplied by intestinal bacteria.

The most obvious effect of a deficiency in vitamin K in animals is delayed blood clotting, which has been traced to a decrease in the activity of **prothrombin** and of clotting factors VII, IX, and X (Chapter 12, Fig. 12-17). Prothrombin formed by the liver in the absence of vitamin K lacks the ability to chelate calcium ions essential for the binding of prothrombin to phospholipids and to its activation to thrombin. The structural differences between this abnormal protein and the normal prothrombin have been pinpointed at the N terminus of the ~560 residue glycoprotein.[e,f] Tryptic peptides from the N termini differed in electrophoretic mobility. As detailed in Chapter 12, ten residues within the first 33, which were identified as glutamate residues by the sequence analysis on normal prothrombin, are actually **γ-carboxyglutamate** (Gla). The same amino acid is present near the N termini of clotting factors VII, IX, and X.

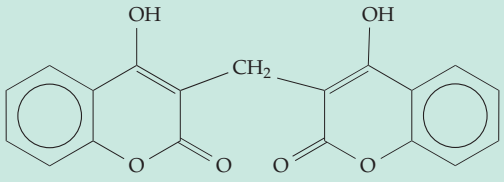


γ-Carboxyglutamate (Gla)

The fact that γ-carboxyglutamate had not been identified previously as a protein substituent is explained by its easy decarboxylation to glutamic acid during treatment with strong acid. The function of vitamin K is to assist in the incorporation of the additional carboxyl group into the glutamate residues of preformed prothrombin and other blood-clotting factors[g,h] with a resulting increase in calcium ion affinity.

Four other plasma proteins designated C, S, M, and Z contain γ-carboxyglutamate. The functions of proteins M and Z are unknown but protein C is a serine protease involved in regulation of blood coagulation and protein S is a cofactor that assists the action of protein C. Other proteins that require vitamin K for synthesis include the 49-residue **bone Gla protein** (or **osteocalcin**) and the 79-residue **matrix Gla protein** found in bone and cartilage.[i,j] These proteins contain three and five residues of Gla, respectively. Their possible functions in mineralization are considered in Chapter 8. At least two additional small human proline-rich Gla proteins of unknown function are synthesized in many tissues.[k] Gamma-carboxyglutamate also occurs in an invertebrate peptide from fish-hunting cone snails. This "sleeper peptide," which induces sleep in mice after intracerebral injection, has the sequence GEE*E*LQE*NQE*LIRE*KSN. Here E* designates the 5 residues of Gla.[l]

An interesting facet of vitamin K nutrition and metabolism was revealed by the observation that cattle fed on spoiled sweet clover develop a fatal hemorrhagic disease. The causative agent is **dicoumarol**, a compound arising from coumarin, a natural constituent of clover. Dicourmarol and the closely related synthetic **warfarin** are both potent vitamin K antagonists. Warfarin is used both as a rat poison and in the treatment of thromboembolic disease. As rodenticides hydroxycourmarin derivatives are usually safe because a single accidental ingestion by a child or pet does little harm, whereas regular ingestion by rodents is fatal.



Dicoumarol

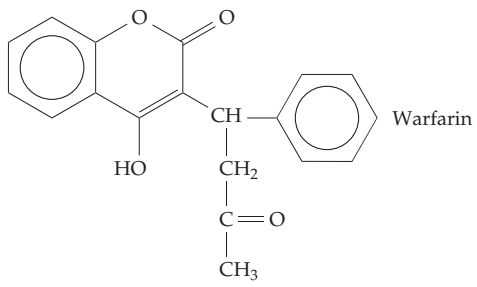
suggested the indicated stereospecificity.[515,516] This was confirmed by observation of a kinetic isotope effect when ^2H is present in the *pro-S* position.[517] Addition of the carbanion to CO_2 would generate the Gla residue. The two glutamates in the following sequence, in which X may be various amino acids, are carboxylated if the protein also carries a suitable N-terminal signal sequence: EXXXEXC. If a suitable glutamyl peptide is not available for carboxylation the postulated peroxide intermediate (Eq. 15-55) is still converted slowly to the 2,3-epoxide of vitamin K.

A third enzyme is required to reduce the epoxide to vitamin K (Eq. 15-57). The biological reductant is uncertain but dithiols such as dithiothreitol serve in the laboratory.[518] See also Eq. 18-47. Protonation of an intermediate enolate anion would give 3-hydroxy-2, 3-dihydrovitamin K, an observed side reaction product.

$$\text{Vitamin K epoxide} + 2[H] \rightarrow H_2O + \text{Vitamin K} \qquad (15\text{-}57)$$

This reaction is of interest because of its specific inhibition by such coumarin derivatives as Warfarin:



Warfarin

This synthetic compound, as well as natural coumarin anticoagulants (Box 15-F), inhibits both the vitamin K reductase and the epoxide reductase.[518,519] The matter is of considerable practical importance because of the spread of warfarin-resistant rats in Europe and the United States. One resistance mutation has altered the vitamin K epoxide reductase so that it is much less susceptible to inhibition by warfarin.[519,520]

While glutamate residues in peptides of appropriate sequence are carboxylated by the vitamin K-dependent system, aspartate peptides scarcely react.[503] Beta-carboxyaspartate is present in protein C of the blood anticoagulant system (Fig. 12-17)[521] and in various other proteins containing EGF homology domains (Table 7-3),[522] but the mechanism of its formation is unknown.

6. Tocopherols (Vitamin E) as Antioxidants

The major function of the tocopherols is thought to be the protection of phospholipids of cell membranes against oxidative attack by free radicals and organic peroxides. Peroxidation of lipids, which is described in Chapter 21, can lead to rapid development of rancidity in fats and oils. However, the presence of a small amount of tocopherol inhibits this decomposition, presumably by trapping the intermediate radicals in the form of the more stable tocopherol radicals (Eq. 15-54) which may dimerize or react with other radicals to terminate the chain. Even though only one molecule of tocopherol is present for a thousand molecules of phospholipid, it is enough to protect membranes.[523] That vitamin E does function in this way is supported by the observation that much of the tocopherol requirement of some species can be replaced by *N,N'*-diphenyl-*p*-phenylenediamine, a synthetic antioxidant (see Table 18-5 for the structure of a related substance). Three generations of rats have been raised on a tocopherol-free diet containing this synthetic antioxidant. However, not all of the deficiency symptoms are prevented.

The antioxidant role of α-tocopherol in membranes is generally accepted.[524–526] It is thought to be critical to defense against oxidative injury and to help the body combat the development of tumors and to slow aging. Gamma-tocopherol may be more reactive than α-tocopherol in removing radicals created by NO and other nitrogen oxides.[526] Its actions are strongly linked to those of ascorbic acid (Box 18-D) and selenium. Ascorbate may reduce tocopherol semiquinone radicals, while selenium acts to enhance breakdown of peroxides as described in the next section.

G. Selenium-Containing Enzymes

In 1957, Schwartz and associates showed that the toxic element selenium was also a nutritional factor essential for prevention of the death of liver cells in rats.[527] Liver necrosis would be prevented by as little as 0.1 ppm of selenium in the diet. Similar amounts of selenium were shown to prevent a muscular dystrophy called "white muscle disease" in cattle and sheep grazing on selenium-deficient soil. Sodium selenite and other inorganic selenium compounds were more effective than organic compounds in which Se had replaced sulfur. **Keshan disease**, an often fatal heart condition that is prevalent among childen in Se-deficient regions of China, can be prevented by supplementation of the diet with $NaSeO_3$.[528] Even the little crustacean "water flea" *Daphnia* needs 0.1 part per billion of Se in its water.[529]

Selenium has long been known to enhance the antioxidant activity of vitamin E. Recent work suggests that vitamin E acts as a radical scavenger, preventing

BOX 15-G VITAMIN E: THE TOCOPHEROLS

Vitamin E was recognized in 1926 as a factor preventing sterility in rats that had been fed rancid lipids.[a–e] The curative factor, present in high concentration in wheat germ and lettuce seed oils, is a family of vitamin E compounds, the tocopherols (Fig. 15-24). The first of these was isolated by Evans and associates in 1936. Vitamin E deficiency in the rabbit or rat is accompanied by muscular degeneration (**nutritional muscular dystrophy**; see also Box 15-A) and a variety of other symptoms that vary from one species to another. Animals deficient in vitamin E display obvious physical deterioration followed by sudden death. Muscles of deficient rats show abnormally high rates of oxygen uptake, and abnormalities appear in the membranes of the endoplasmic reticulum as viewed with the electron microscope. It is thought that deterioration of lysosomal membranes may be the immediate cause of death.

The tocopherol requirement of humans is not known with certainty, but about 5 mg (7.5 IU) / day plus an additional 0.6 mg for each gram of polyunsaturated fatty acid consumed may be adequate. It is estimated that the average daily intake is about 14 mg, but the increasing use of highly refined foods may lead to dangerously low consumption. Recent interest[d–f] has been aroused by studies that show that much larger amounts of vitamin E (e.g., 100–400 mg/day) substantially reduce the risk of coronary disease and stroke in both women[g] and men[h] and also decrease oxidative modification of brain proteins.[i] The decrease in heart attacks and stroke may be in part an indirect effect of the anticlotting action of vitamin E quinone.[f] Plant oils are usually the richest sources of tocopherols, while animal products contain lower quantities.

To some extent the vitamin E requirement may be lessened by the presence in the diet of synthetic antioxidants and by selenium. Much evidence supports a relationship between the nutritional need for selenium and that for vitamin E. Lack of either causes muscular dystrophy in many animals as well as severe edema (exudative diathesis) in chicks. Since vitamin E-deficient rats have a low selenide (Se^{2-}) content, it has been suggested that vitamin E protects reduced selenium from oxidation.[j] Vitamin C (ascorbic acid), in turn, protects vitamin E.

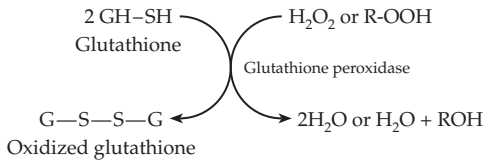
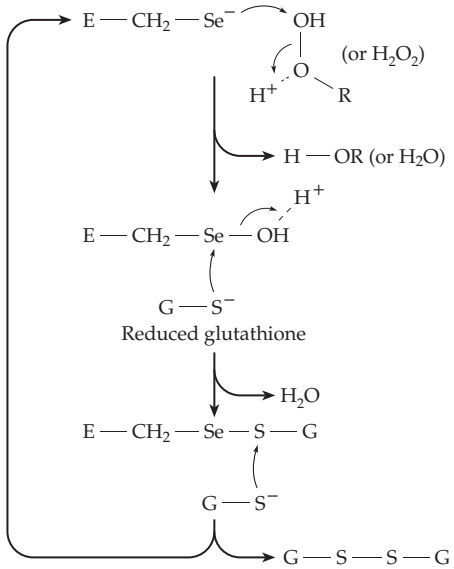
excessive peroxidation of membrane lipids, while selenium, in the enzyme **glutathione peroxidase**, acts to destroy the small amounts of peroxides that do form. This was the first established function of selenium in human beings, but there are others. If we include proteins from animals and bacteria, at least ten selenoproteins are known (Table 15-4).[530–534] Seven of these are enzymes and most catalyze redox processes. The active sites most often contain **selenocysteine**, whose selenol side chain is more acidic (pK_a ~5.2) than that of cysteine and exists as $-CH_2-Se^-$ at neutral pH.[530]

Glutathione peroxidases catalyze the reductive decomposition of H_2O_2 or of organic peroxides by glutathione (G–SH) according to Eq. 15-58. At least three isoenzyme forms have been identified in mammals: a cellular form,[531,535–537] a plasma form, and a



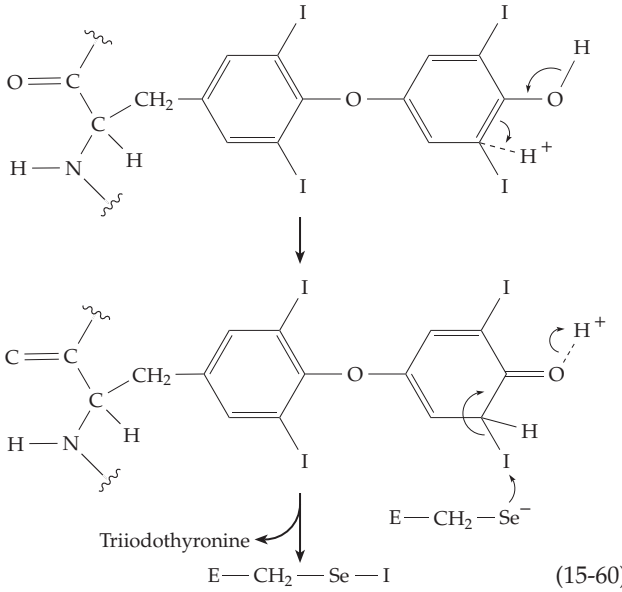
(15-58)

form with a preference for organic peroxides derived from phospholipids.[327,538–540] A related selenoprotein has been found in a human poxvirus.[540a] Selenocysteine is present at a position (residues 41–47) near the N terminus of an α helix, in the ~ 180-residue polypeptides. A possible reaction mechanism involves attack by the selenol on the peroxide to give a selenic acid intermediate which is reduced by glutathione in two nucleophilic displacement steps (Eq. 15-59).



(15-59)

Three types of **iodothyronine deiodinase** remove iodine atoms from thyroxine to form the active thyroid hormone triiodothyronine and also to inactivate the hormone by removing additional iodine[531,541–546] (see also Chapter 25). In this case the $-CH_2-Se^-$ may attach the iodine atom, removing it as I^+ to form $-CH_2-Se-I$. The process could be assisted by the phenolic –OH group if it were first tautomerized (Eq. 15-60).

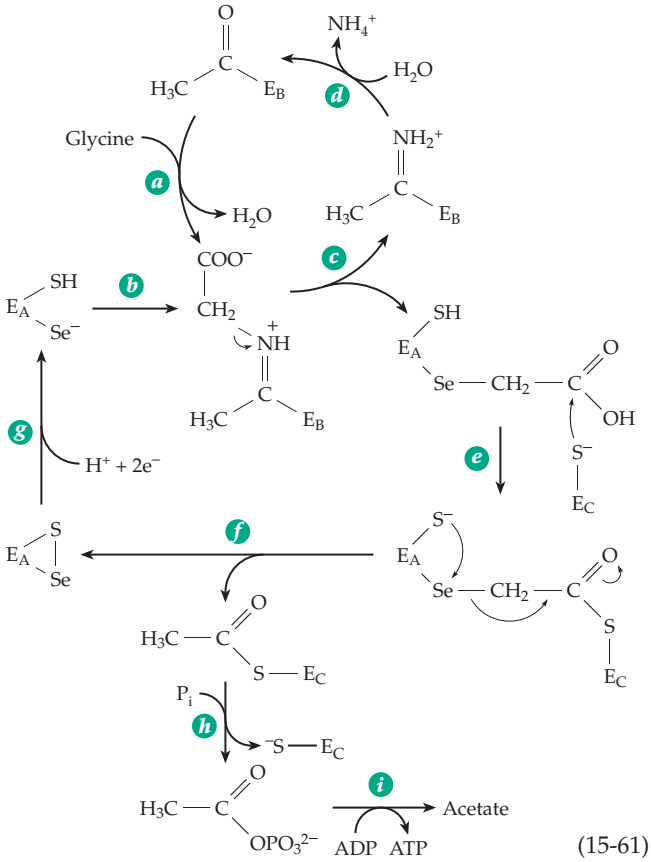


(15-60)

A recently discovered human selenoprotein is a **thioredoxin reductase** which is present in the T cells of the immune system as well as in placenta and other tissues.[189,547–549] The 55-kDa protein has one selenocysteine as the penultimate C-terminal residue. Another mammalian selenoprotein, of uncertain function, is the 57-kDa **selenoprotein P**. It contains over 60% of the selenium in rat plasma and is also present in the human body. Selenoprotein P contains ten selenocysteine residues.[550–552a] Some of these may be replaced by serine in a fraction of the molecules.[553] A smaller 9.6-kDa skeletal muscle protein, **selenoprotein W**, contains a single selenocysteine.[554–556] Another selenoprotein has been found in sperm cells, both in the tail and in a keratin-rich capsule that surrounds the mitochondria in the sperm midpiece.[557] Lack of this protein may be the cause of the abnormal immotile spermatozoa observed in Se-deficient rats and of reproductive difficulties among farm animals in Se-deficient regions.[558]

Several selenoproteins have been found in certain bacteria and archaea. A **hydrogenase** from *Methanococcus vannielii* contains selenocysteine.[559,560] This enzyme transfers electrons from H_2 to the C-5 *si* face of the 8-hydroxy-5-deazaflavin cofactor F_{420} (Section B,4). The same bacterium synthesizes two **formate dehydrogenases** (see Fig 15-23), one of which contains Se. Two Se-containing formate dehydrogenases are made by *E. coli*. One of them, which is coupled to a hydrogenase in the formate hydrogen-lyase system (see Eq. 15-37), is a 715-residue protein containing selenocysteine at position 140.[561–563] The second has selenocysteine at position 196 and functions with a nitrate reductase in anaerobic nitrate respiration.[561]

Glycine reductase is a complex enzyme[530,564–566] that catalyzes the reductive cleavage of glycine to acetyl phosphate and ammonia (Eq. 15-61) with the



(15-61)

subsequent synthesis of ATP (Eq. 14-43). Electrons for reduction of the disulfide that is formed are provided by NADH. A single selenocysteine residue is present in the small 12-kDa subunits. The enzyme contains a dehydroalanine residue (Chapter 14) in subunit B and a thiol group in subunit C.[566] An acetyl-enzyme derivative of subunit C, perhaps of its –SH group, has been identified.[546] The mechanism of action is uncertain but the steps in Eq. 15-61 have been suggested.[567] The subunits are designated E_A, E_B, and E_C. Step *e* is particularly hard to understand because formation of a thioester in this manner is not expected to occur spontaneously and must be linked in some way to other steps.

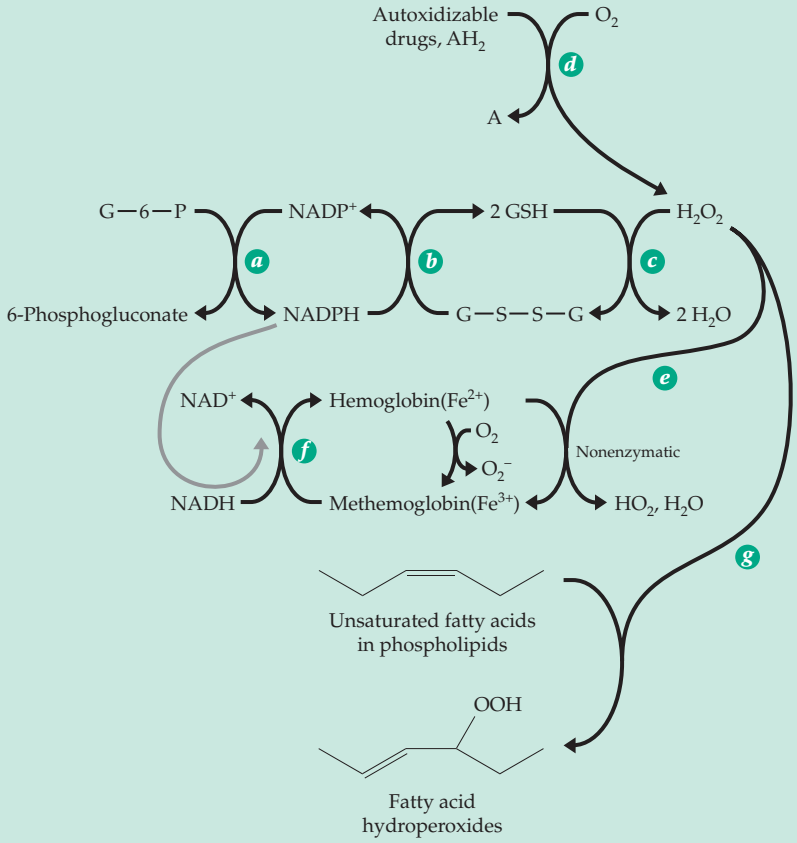
A selenium-containing **xanthine dehydrogenase** is present in purine-fermenting clostridia. Like other xanthine dehydrogenases (Chapter 16), it converts xanthine to uric acid and contains nonheme iron, molybdenum, FAD, and an Fe–S center. The selenium is probably present as Se^{2-} bound to Mo as is S^{2-} in xanthine oxidase (Fig. 16-32).[567a] A related reaction is catalyzed by the Fe–S protein **nicotinic acid hydroxylase** (Eq. 15-62) found in some clostridia.[568] Splitting of the Mo(V) EPR signal when ^{77}Se is present in the enzyme shows that the selenium is present as a ligand of molybdenum. Another member of the family is a purine hydroxylase that converts purine 2-hydroxypurine, or hypoxanthine to xanthine.[567a]

TABLE 15-4
Selenium-Containing Proteins

Enzyme	Source	Mass (kDa)	Subunit composition	Other cofactors
Glutathione peroxidases				None
Cellular	Mammals	21 x 4		
Plasma	Humans			
Phospholipid hydroperoxide	Pig, rat	18		
Iodothyronine deiodinases	Vertebrates			
Thioredoxin reductase	Humans	55 × 2		
Selenoprotein *P*	Mammals	57		None
Selenoprotein *W*	Rat	19.6		
Formate dehydrogenase	Bacteria - *E. coli*	600	$\alpha_2\beta_4\gamma_{2\text{-}4}$	Heme *b*
	Archaea			Mo; molybdopterin
Hydrogenase	Bacteria		$\alpha_2\beta_4\gamma_2$	FAD; NiFeSe
	Archaea			
Glycine reductase	Some clostridia		ABC	
Selenoprotein A		12		
Selenoprotein B		200		
Carbonyl protein C		250		Fe?
Nicotinic acid hydroxylase	Clostridia	300		FAD, FeS, Mo
Purine hydroxylase	Clostridia			FAD, FeS, Mo
Thiolase (contains selenomethionine)	*Clostridium kluyverii*	39 × 4		None
Carbon monoxide dehydrogenase	*Oligotropha carboxidovorans*	137 × 2	$\alpha_2\beta_2\gamma_2$	FAD; Mo; molybdopterin

BOX 15-H GLUTATHIONE PEROXIDASE AND ABNORMALITIES OF RED BLOOD CELLS

The processes by which hemoglobin is kept in the Fe(II) state and functioning normally within intact erythrocytes is vital to our health. Numerous hereditary defects leading to a tendency toward anemia have helped to unravel the biochemistry indicated in the accompanying scheme.[a]



About 90% of the glucose utilized by erythrocytes is converted by glycolysis to lactate, but about 10% is oxidized (via glucose 6-phosphate) to 6-phosphogluconate. The oxidation (reaction *a*) is catalyzed by glucose-6-phosphate dehydrogenase (Eq.15-10) using $NADP^+$. This is the principal reaction providing the red cell with NADPH for reduction of glutathione (Box 11-B) according to reaction *b*. Despite the important function of glucose-6-*P* dehydrogenase, ~400 million persons, principally in tropical and Mediterranean areas, have a hereditary deficiency of this enzyme. The genetic variations are numerous, with about 400 different ones having been identified. Although most individuals with this dificiency have no symptoms, the lack of the enzyme is truly detrimental and sometimes leads to excessive destruction of red cells and anemia during some sicknesses and in response to administration of various drugs.[b] The survival of the defective genes, like that for sickle cell hemoglobin (Box 7-B) is thought to result from increased resistance to malaria parasites.

Other erythrocyte defects that lead to drug sensitivity include a deficiency of glutathione (resulting from a decrease in its synthesis) and a deficiency of glutathione reductase (reaction *b*). The effects of drugs have been traced to the production of H_2O_2 (reaction *c*) in red blood cells; catalase, which converts H_2O_2 into H_2O and O_2, is thought to function in a similar way. Both enzymes are probably necessary for optimal health.

An excess of H_2O_2 can damage erythrocytes in two ways. It can cause excessive oxidation of functioning hemoglobin to the Fe(III)-containing methemoglobin. (Methemoglobin is also formed spontaneously during the course of the oxygen-carrying function of hemoglobin. It is estimated that normally as much as 3% of the hemoglobin may be oxidized to methemoglobin daily.) The methemoglobin formed is reduced back to hemoglobin through the action of **NADH-methemoglobin reductase** (reaction *f*). A smaller fraction of the methemoglobin is reduced by a similar enzyme requiring NADPH (as indicated by the colored arrow). A hereditary lack of the NADH-methemoglobin reductase is also known.

A second destructive function of H_2O_2 is attack on double bonds of unsaturated fatty acids of the phospholipids in cell membranes. The resulting fatty acid hydroperoxides can react further with C–C chain cleavage and disruption of the membrane. This is thought to be the principal cause of the hemolytic anemia induced by drugs in susceptible individuals. The selenium-containing glutathione peroxidase is thought to decompose these fatty acid hydroperoxides. Vitamin E (Box 15-G), acting as an antioxidant within membranes, is also needed for good health of erythrocytes.[c,d]

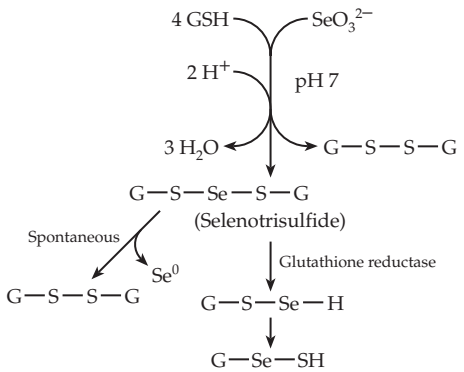
(15-62)

A **thiolase** (Eq. 13-35) from *Clostridium kluyveri* is one of only two known selenoproteins that contain selenomethionine.[569] However, the selenomethionine is incorporated randomly in place of methionine. This occurs in all proteins of all organisms to some extent and the toxicity of selenium may result in part from excessive incorporation of selenomethionine into various proteins.

Selenium is found to a minor extent wherever sulfur exists in nature. This includes the sulfur-containing modified bases of tRNA molecules. In addition to a small amount of nonspecific incorporation of Se into all S-containing bases there are, at least in bacteria, specific Se-containing tRNAs. In *E. coli* one of these is specific for lysine and one for glutamate. One of the modified bases has been identified as 5-methyl-aminomethyl-2-selenouridine.[570] It is present at the first position of the anticodon, the "wobble" position.[571]

Selenium has its own metabolism. Through the use of ^{75}Se as a tracer, normal rat liver has been shown to contain Se^{2-}, SeO_3^{2-}, and selenium in a higher oxidation state.[572] Glutathione may be involved in reduction of selenite to selenide.[573] The nonenzymatic reduction of selenite by glutathione yields a selenotrisulfide derivative (Eq. 15-63). The latter is spontaneously decomposed to oxidized glutathione and elemental selenium or by the action of glutathione reductase to glutathione and selenium. Selenocysteine can be converted to alanine + elemental selenium (Eq. 14-34). Some bacteria are able to oxidize elemental Se back to selenite.[574] Selenium undergoes biological methylation readily in bacteria, fungi, plants, and animals (Chapter 16).[575,576] This may in some way be related to the reported effect of selenium in protecting animals against the toxicity of mercury. Excess selenium may appear in the urine as trimethylselenonium ions.[577]



(15-63)

How is selenium incorporated into selenocysteine-containing proteins? This element does enter amino acids to a limited extent via the standard synthetic pathways for cysteine and methionine. However, the placement of selenocysteine into specific positions in selenoproteins occurs by the use of a minor serine-specific tRNA that acts as a suppressor of chain termination during protein synthesis.[532,533,578] (This topic is dealt with further in Chapter 29.) The genes for these and presumably for other selenocysteine-containing proteins have the "stop" codon TGA at the selenocysteine positions. However, when present in a suitable "context" the minor tRNA, carrying selenocysteine in place of serine, is utilized to place selenocysteine into the growing peptide chain. In bacteria, and presumably also in eukaryotes, the selenocysteinyl-tRNA is formed from the corresponding seryl-tRNA by a PLP-catalyzed β-replacement reaction. The selenium donor is not Se^{2-} but selenophosphate $Se-PO_3^{2-}$ in which the Se–P bond is quite weak.[579–581] After addition to the aminoacrylate intermediate in the PLP enzyme the Se–P bond may be hydrolytically cleaved to HPO_4^{2-} and selenocysteyl-tRNA.

Study Questions

1. *S*-adenosylmethionine is also a biological methyl group donor. The product of its methyl transferase reactions is *S*-adenosylhomocysteine. This product is further degraded by *S*-adenosylhomocysteine hydrolase, an enzyme that contains tightly bound NAD^+, to form homocysteine and adenosine.

   Write a step-by-step mechanism for the action of this hydrolase.

2. Compare the chemical mechanisms of enzyme-catalyzed decarboxylation of the following:
   a) a β-oxo-acid such as acetoacetate or oxaloacetate
   b) an α-oxo-acid such as pyruvate
   c) an amino acid such as L-glutamate

3. Describe the subunit structure of the enzyme pyruvate dehydrogenase. Discuss the functioning of each of the coenzymes that are associated with these subunits and write detailed mechanisms for each step in the pyruvate dehydrogenase reaction.

4. Free **formate** can be assimilated by cells via the intermediate **10-formyl-tetrahydrofolate** (10-formyl-THF).
   a) Describe the mechanism of synthesis of this compound from formate and tetrahydrofolate.
   b) Diagram a hypothetical transition state for the first step of this reaction sequence.
   c) Describe two or more uses that the human body makes of 10-formyl-THF.

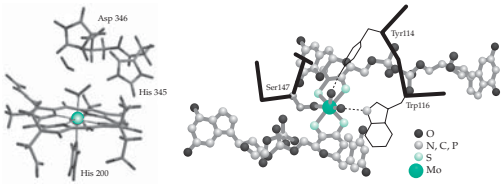
5. Using partial structural formulas, describe the reactions by which serine and methionine react to form *N*-formylmethionine needed for protein synthesis.

6. Write the equations for each of the reactions shown below. Using the $E^{0'}$ values below, calculate approximate Gibbs energies for each reaction, and show by the relative length of the arrows on which side of the reaction the equilibrium lies.
   a) The oxidation of malate by NAD^+
   b) The oxidation of succinate by NAD^+
   c) The oxidation of succinate by enzyme-bound FAD
   d) What can you say about the cofactor required for oxidation of succinate from your calculations?

   The values of $E^{0'}$ for several half reactions are given below. Everything has been rounded to one significant figure so that a calculator is unnecessary.

Reaction	$E^{0'}$ (volts)
$NAD^+ + H^+ + 2\ e^- \rightarrow NADH$	−0.3
enzyme bound FAD + $2\ H^+ + 2\ e^- \rightarrow$ enzyme bound $FADH_2$	0.0
fumarate + $2\ H^+ + 2\ e^- \rightarrow$ succinate	0.0
oxalacetate + $2\ H^+ + 2\ e^- \rightarrow$ malate	−0.2

7. Some acetogenic bacteria, which convert CO_2 to acetic acid, form pyruvate for synthesis of carbohydrates, etc., by formation of formaldehyde and conversion of the latter to glycine by reversal of the PLP and lipoic acid-dependent glycine decarboxylase, a 4-protein system. The glycine is then converted to serine, pyruvate, oxaloacetate, etc. Propose a detailed pathway for this sequence.



Transition metal ions function in many biological oxidation-reduction processes. (Left) A heme ring in **nitrite reductase** chelates an iron ion in its center, holding the Fe^{2+} or Fe^{3+} with bonds from four nitrogen atoms and a fifth bond from an imidazole ring below. Above the iron is a nitrite ion, NO_2^-, awaiting reduction to nitric oxide NO in a denitrifying bacterium. From Ranghino *et al.* (2000) *Biochemistry* **39**, 10958–10966. (Right) The active site of a bacterial **dimethylsulfoxide reductase** has an atom of molybdenum or tungsten at its center. The metal is held by four sulfur atoms from two molybdopterin molecules and an oxygen atom of a serine side chain. Two other oxygen atoms are bound as oxo groups and may participate in catalysis. From Stewart *et al.* (2000) *J. Mol. Biol.* **299**, 593–600.

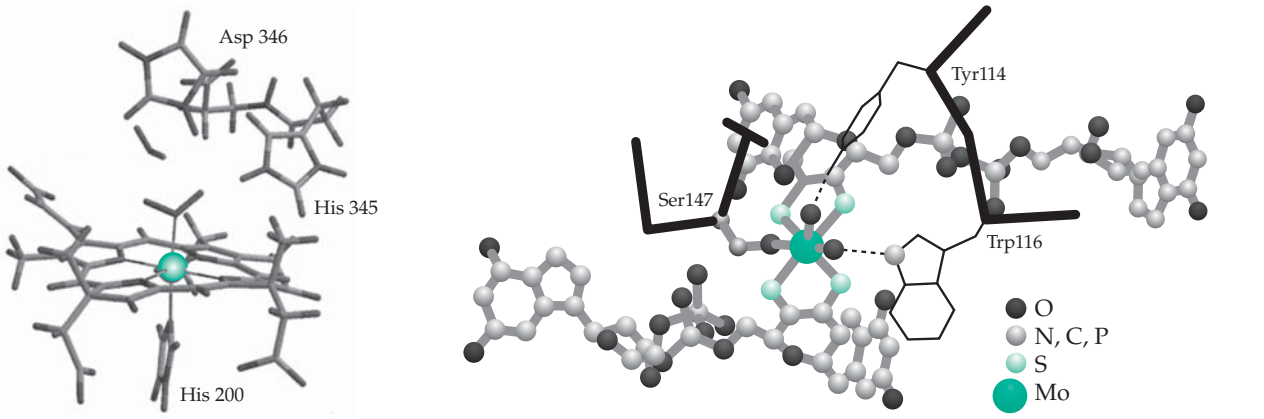
Transition Metals in Catalysis and Electron Transport 16



Although the amounts present within living cells are very small, the ions of the transition metals Fe, Co, Ni, Cu, and Mn are extremely active centers for catalysis, especially of reactions that take advantage of the ability of these metals to exist in more than one oxidation state.[1–4] Iron, copper, and nickel are also components of the electron carrier proteins that function as oxidants or reductants in many biochemical processes. These metals are all nutritionally essential, as are chromium and vanadium. Among the heavier transition elements molybdenum is a constituent of an important group of enzymes that includes the sulfite oxidase of human liver and nitrogenase of nitrogen-fixing bacteria. Tungsten occasionally substitutes for molybdenum.

A. Iron

Iron is one of the most abundant elements in the earth's crust, being present to the extent of ~4% in a typical soil. Its functions in living cells are numerous and diverse.[2,5–8] The average overall iron content of both bacteria and fungi is ~1 mmol / kg, but that of animal tissues is usually less. Seventy percent of the 3–5 g of iron present in the human body is located in the blood's erythrocytes, whose overall iron content is ~20 mM. In other tissues the total iron averages closer to 0.3 mM and consists principally of storage forms. The total concentration of iron in all of the iron-containing *enzymes* of tissues amounts to only about 0.01 mM. Although these concentrations are low, the iron is concentrated in oxidative enzymes of membranes and may attain much higher concentrations locally. Only a few parasitic or anaerobic bacteria, e.g. the lactic acid bacteria, possess no oxygen-requiring enzymes and are almost devoid of both iron and copper. All other organisms appear to require iron for life.

1. Uptake by Living Cells

A major problem for cells is posed by the relative insolubility of ferric hydroxide and other compounds from which iron must be extracted by the organism. A consequence is that iron is often taken up in a chelated form and is transferred from one organic ligand, often a protein, to another with little or no existence as free Fe^{3+} or Fe^{2+}. As can be calculated from the estimated solubility product of $Fe(OH)_3$ (Eq. 16-1),[7] the equilibrium concentration of Fe^{3+} at pH 7 is only 10^{-17} M.

$$K_{sp} = [Fe^{3+}][OH^-]^3 < 10^{-38}\ M^4 \qquad (16\text{-}1a)$$

$$\text{or } [Fe^{3+}] / [H^+]^3 < 10^4\ M^4 \text{ at } 25°\ C \qquad (16\text{-}1b)$$

For a 2 μm^3 bacterial cell this amounts to just one free Fe^{3+} ion in almost 100 million cells at any single moment. The importance of chelated forms of iron becomes obvious. It is also evident from Eq. 16-1 that, in addition to chelation, a low external pH can also facilitate uptake of Fe^{3+} by organisms.

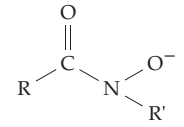
The values of the formation constants for chelates of Fe^{2+} typically lie between those of Mn^{2+} and Co^{2+} (Fig. 6-6, Table 6-9). For example, $K_1 = 10^{14.3}\ M^{-1}$ for formation of the Fe^{2+} chelate of EDTA. The smaller and more highly charged Fe^{3+} is bonded more strongly ($K_1 = 10^{25}\ M^{-1}$). These binding constants are independent of pH. However, the binding of any metal ion is affected by pH, as discussed in Chapter 6. A fact of

considerable biochemical significance is the stronger binding of Fe^{3+} to oxygen-containing ligands than to nitrogen atoms, while Fe^{2+} tends to bind preferentially to nitrogen. It is also significant that Fe^{3+} bound to oxygen ligands tends to exchange readily with other ferric ions in the medium, whereas Fe^{3+} bound to nitrogen-containing ligands such as heme exchanges slowly. This fact is important for both iron-transport compounds and enzymes.

Siderophores. If a suitably high content of iron (e.g., 50 μM or more for *E. coli*) is maintained in the external medium, bacteria and other microorganisms have little problem with uptake of iron. However, when the external iron concentration is low, special compounds called siderophores are utilized to render the iron more soluble.[7–11c] For example, at iron concentrations below 2 μM, *E. coli* and other enterobacteria secrete large amounts of **enterobactin** (Fig. 16-1). The stable Fe^{3+}–enterobactin complex is taken up by a transport system that involves receptors on the outer bacterial membrane.[9,12,13] Siderophores from many bacteria have in common with enterobactin the presence of **catechol** (*ortho*-dihydroxybenzene) groups that chelate the iron.

The three catechol groups of enterobactin are carried on a cyclic serine triester structure. A variety of both cyclic and linear structures are found among other catechol siderophores.[14–19] For example, **parabactin** and **agrobactin** (Fig. 16-1) contain a backbone of spermidine[20] (Chapter 24). After the Fe^{3+}–enterobactin complex enters a bacterial cell the ester linkages of a siderophore are cleaved by an esterase. Because of the extremely high formation constant of ~10^{52} M^{-1} for the complex[11] the only way for a cell to release the Fe^{3+} is through this irreversible destruction of the iron carrier.[11d] Reduction to Fe^{2+} may be involved in release of iron from some siderophores.[11e]

The first known siderophore, isolated in 1952 by Neilands,[22] is **ferrichrome** (Fig. 16-1), a cyclic hexapeptide containing **hydroxamate** groups at the iron-binding centers. Oxygen atoms form the bonds to iron



Hydroxamate group

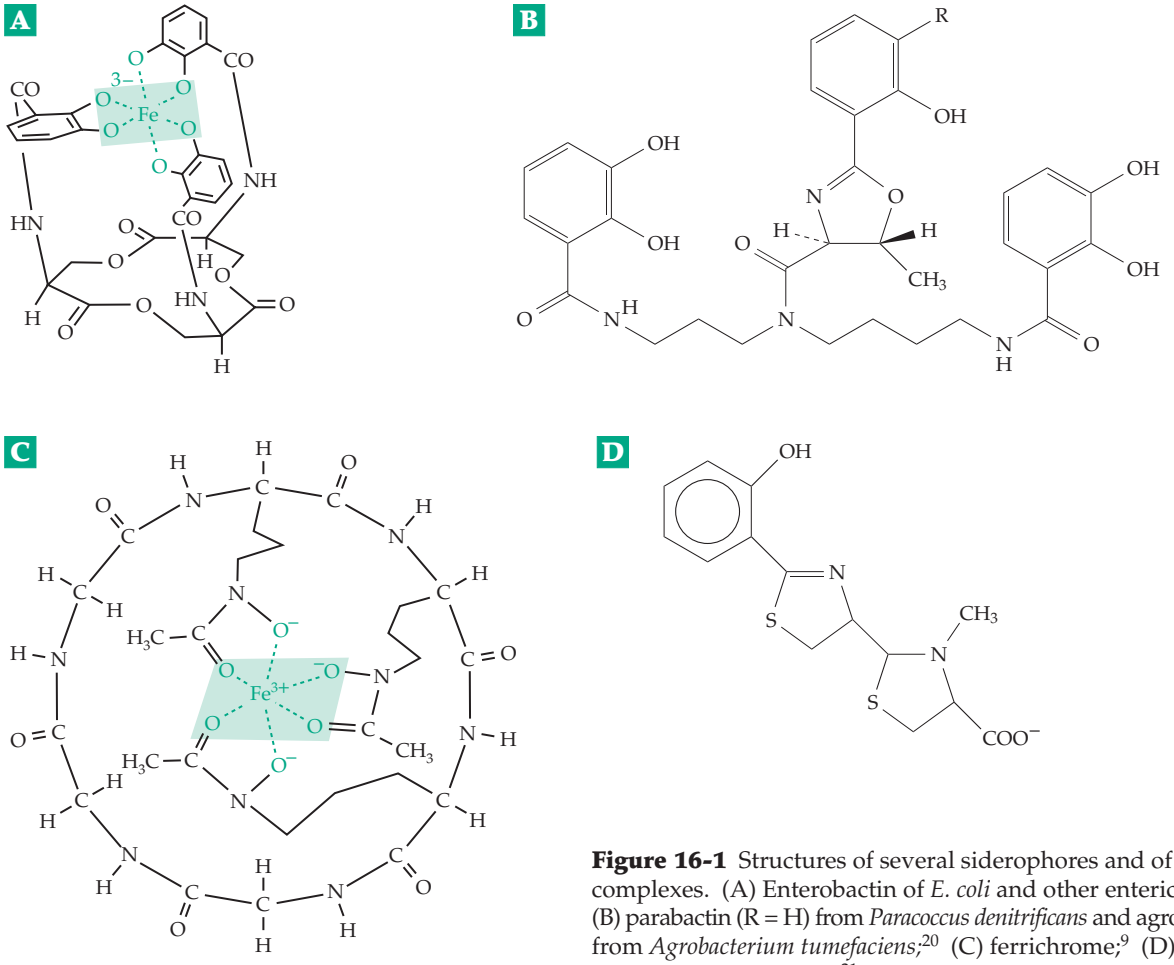


Figure 16-1 Structures of several siderophores and of their metal complexes. (A) Enterobactin of *E. coli* and other enteric bacteria;[12] (B) parabactin (R = H) from *Paracoccus denitrificans* and agrobactin (R = OH) from *Agrobacterium tumefaciens*;[20] (C) ferrichrome;[9] (D) pyochelin from *Pseudomonas aeruginosa*.[21]

in this compound also. Ferrichrome binds Fe^{3+} with a formation constant of ~10^{29} M^{-1}. The binding is not as tight as with enterobactin and the iron can be released by enzymatic reduction to Fe^{2+} which is much less tightly bound than is Fe^{3+}. The released ferrichrome can be secreted and used repeatedly to bring in more iron. Ferrichrome is produced by various fungi and bacilli and is only one of a series of known hydroxamate siderophores.[16] Since iron is essential to virtually all parasitic organisms the ability to obtain iron is often the limiting factor in establishing an infection.[23,24]

In *E. coli* there are seven different outer **membrane receptors** for siderophores.[25] One of these, the gated porin **FepA**, is specific for ferric enterochelin. With the assistance of another protein, **TonB**, it allows the ferric siderophore to penetrate the outer membrane.[26] A different receptor, **FhuA**, binds ferrichrome. Both FepA and FhaA are large 22-strand porins resembling the 16-strand porin shown in Fig. 8-20. However, they are nearly 7 nm long with internal diameters three times those of the 16-strand porins. In addition, loops of polypeptide chain on the outer edges can close while an N-terminal domain forms a "cork" that remains in place until the Fe^{3+}-siderophore complex enter the channel and binds. Like the hatches in an air lock on a spacecraft, the outer loops then close, after which the inner cork unwinds to allow the siderophore complex to enter the periplasmic space. The apparatus requires an energy supply, which apparently is provided by an additional complex consisting of proteins TonB, ExbA, and ExbD. They evidently couple the electrochemical gradient across the cell membrane (Chapter 8, B1 and C5 and Chapter 18) with the operation of the channel gates. Some bacteria use a different strategy for passage across the outer membrane.[11c] The channel of a receptor protein contains a molecule of an iron-free siderophore. When a molecule of Fe^{3+}-siderophore binds in the outside part of the channel the Fe^{3+} jumps to the inner siderophore, which then dissociates from the receptor, carrying the Fe^{3+}-siderophore complex into the periplasmic space. This mechanism also seems to be available in *E. coli*. The **ferric uptake regulation** (Fur) protein binds excess free Fe^{2+}, the resulting complex acting as a repressor of all of the iron uptake genes in *E. coli*.[11e]

Additional proteins are required for passage through the membrane.[11b,23,25,27] These are ABC transporters, which utilize hydrolysis of ATP as an energy source (Chapter 8, Section C,4). For uptake of the Fe^{3+}-ferrichrome complex protein **FhuD** is the periplasmic binding protein, **FhuC** is an integral membrane component, and the cytosolic **FhuC** contains the ATPase center.[11b] Another ABC transporter, found in many bacteria, carries unchelated Fe^{3+} across the inner membrane. The binding protein component for *Hemophilus influenzae*, designated Hit, resembles one lobe of mammalian transferrin (Fig. 16-2).[11b] The siderophore receptors of bacteria have been "parasitized" by various bacteriophages and toxic proteins. For example, FepA is also a receptor for the toxic colicins B and D (Box 8-D) and tonB is a receptor for bacteriophage T1.[9,13]

Some bacteria do not form siderophores but take up Fe^{2+}. Even *E. coli*, when grown anaerobically, synthesizes an uptake system for Fe^{2+}. It utilizes a 75-residue peptide encoded by gene *feoA* and a 773-residue protein encoded by *feoB*.[28,11b]

Uptake of iron by eukaryotic cells. The yeast *Saccharomyces cerevisiae* utilizes two systems for uptake of iron.[29,30] A low-affinity system transports Fe^{2+} with an apparent K_m of ~30 μM, while a high-affinity system has a K_m of ~0.15 μM. Study of these systems has been greatly assisted by the use of genetic methods developed for both bacteria and yeast (Chapter 26). The low-affinity iron uptake depends upon a protein transporter encoded by gene *FET*4 and on a reductase encoded by genes *FRE*1 and *FRE*2, proteins that are embedded in the cytoplasmic membrane.[29,31-33] It might seem reasonable that the *FET*3 copper oxidoreductase should keep Fe^{2+} *reduced* while it is transported. However, it appears to *oxidize* Fe^{2+} to Fe^{3+}. The high-affinity uptake system is more puzzling. It requires a permease encoded by *FTR I* and an additional protein encoded by *FET*3.[30,33–35] The Fet3 protein is a copper oxidoreductase related to **ceruloplasmin** (Section D). The protein **Fre1p** (encoded by *FRE*1) is a metalloreductase that reduces Cu^{2+} to Cu^{+}, as well as Fe^{3+} to Fe^{2+}. It is essential for copper uptake (Section D).[33] It has long been known that ceruloplasmin is required for mobilization of iron from mammalian tissues.[30] Hereditary ceruloplasmin deficiency causes accumulation of iron in tissues.[36] Yeast also contains both *mitochondrial* and *vacuolar* iron transporters.[37,37a,b]

The uptake of iron by animals is not as well understood[38–40] but it resembles that of yeast.[41] A general divalent cation transporter that is coupled to the membrane proton gradient is involved in intestinal iron uptake.[42,60] Ascorbic acid promotes the uptake of iron, presumably by reducing it to Fe(II), which is more readily absorbed than Fe(III), and also by promoting ferritin synthesis.[43] Uptake is also promoted by meat in the diet.[44] Within the body iron is probably transferred from one protein to another with only a transient existence as free Fe^{2+}. An average daily human diet contains ~15 mg of iron, of which ~1 mg is absorbed. This is usually enough to compensate for the small losses of the metal from the body, principally through the bile. Once it enters the body, iron is carefully conserved. The 9 billion red blood cells destroyed daily yield 20–25 mg of iron which is almost all reused or stored. The body apparently has no mechanism for excretion of large amounts of iron; a person's iron content is regulated almost entirely by the rate of

uptake. This rate is increased during pregnancy and, in young women, to compensate for iron lost in menstrual bleeding. Nevertheless, control of iron uptake is imperfect and perhaps 500 million people around the world suffer from iron deficiency.[44,45] For others, an excessive intake of iron or a genetic defect lead to accumulation of iron to toxic levels, a condition called **hemochromatosis**.[44,46a,b] This condition may also arise in any disease that leads to excessive destruction of hemoglobin or accumulation of damaged erythrocytes. Examples are β-thalassemia (Chapter 28) and cerebral malaria.[47] Treatment with chelating agents designed to remove iron is often employed.[47,48]

Transferrins. Within the body iron is moved from one location to another while bound as Fe^{3+} to transferrins, a family of related 680- to 700-residue 80-kDa proteins.[38,49–53] Each transferrin molecule contains two Fe^{+3} binding sites, one located in each of two similar domains of the folded peptide chain. A dianion, usually CO_3^{2-}, is bound together with each Fe^{3+}. Milk transferrin (**lactoferrin**[51a,b,c] also found in leukocytes), hen egg transferrin (**ovotransferrin**),[52,52a] and rabbit and human serum transferrin[54,54a] all have similar structures. Each Fe^{3+} is bonded to oxygen anions from two tyrosine side chains, an aspartate carboxylate, an imidazole group, and the bound carbonate ion (Fig. 16-2B). Transferrin of blood plasma is encoded by a separate gene but has a similar structure. Transferrin of chickens appears to be identical to conalbumin of egg whites. The iron-binding proteins of body fluids are sometimes given the group name **siderophilins**. Transferrins may function not only in transport of iron throughout the body but also as iron buffers that provide a relatively constant iron concentration within tissues.

The entrance of iron into the body through the intestinal mucosal cells may involve the transferrin present in those cells[44] and the influx of iron may also be regulated by blood plasma transferrin. There is also a nontransferrin pathway.[42,55] Transferrins bind Fe^{2+} weakly and it is likely that a transferrin– Fe^{2+}–HCO_3^- complex formed initially undergoes oxidation to the Fe^{3+}–CO_3^{2-} complex within cells and within the bloodstream. A conformational change closes the protein around the iron ions.[56] In yeast the previously mentioned copper oxidoreductase encoded by the *FET*3 gene appears to not only oxidize Fe^{2+} but also transfer the resulting Fe^{3+} to transferrin. Ceruloplasmin may play a similar role in mammals.[33]

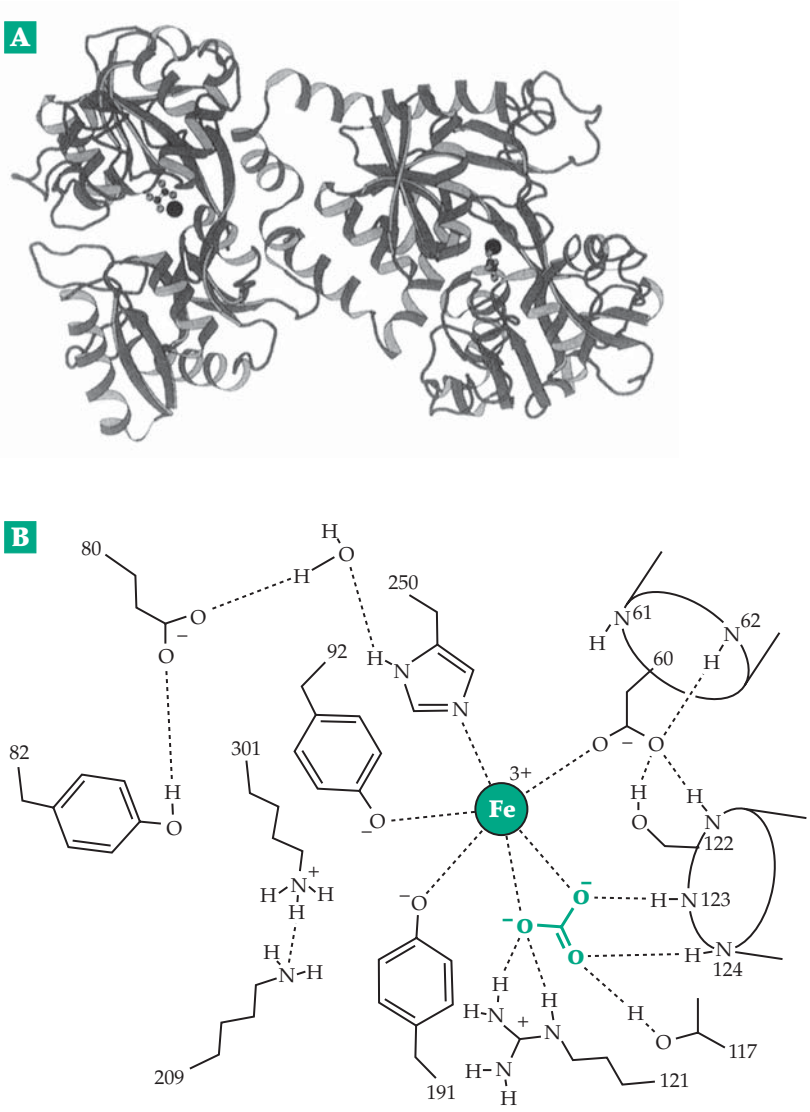

Figure 16-2 (A) Ribbon drawing of the polypeptide chain of a transferrin, human lactoferrin. The N lobe is to the left and the C lobe to the right. Each active site contains bound Fe^{3+} and a molecule of oxalate dianion which replaces the physiological CO_3^{2-}. From Baker *et al.*[51] Courtesy of Edward Baker. (B) Schematic diagram showing part of the hydrogen-bond network involved in binding the Fe^{3+} in the N lobe of hen ovotransferrin. Some side chain groups and water molecules have been omitted. The positions of hydrogen atoms and the charge state of acid–base groups are uncertain. Most of the hydrogen-bond distances (O - - O, O - - N, N - - N) indicated by dashed lines are between 0.27 and 0.3 nm. Release of the bound Fe^{3+} may be accomplished in part by protonation of the bound CO_3^{2-} to form HCO_3^-. See Kurokawa *et al.*[52]

Iron is transferred from the plasma transferrin into cells of the body following binding of the Fe^{3+}–transferrin complex to specific receptors. The surface of an immature red blood cell (reticulocyte) may contain 300,000 transferrin receptors, each capable of catalyzing the entry of ~36 iron ions per hour.[38] The receptor is a 180-kDa dimeric glycoprotein. When the Fe^{3+}–transferrin complex is bound, the receptors aggregate in coated pits and are internalized. The mechanism of release of the Fe^{3+} may occur by different mechanisms in the two lobes.[57] The pH of the endocytic vesicles containing the receptor complex is probably lowered to ~5.6 as in lysosomes. This may protonate the bound CO_3^{2-} in the complex[51c,54a,58] and assists in the release of the Fe^{3+}, possibly after reduction to Fe^{2+}. Both the apotransferrin and its receptor are returned to the cell surface for reuse, the apotransferrin being released into the blood. Chelating agents such as pyrophosphate, ATP, and citrate as well as simple anions[59] may also assist in removal of iron from transferrin. The same transmembrane transporter that is involved in intestinal iron uptake[42] is needed to remove iron from the endosome after release.[60]

2. Storage of Iron

Within tissues of animals, plants, and fungi much of the iron is packaged into the red-brown water-soluble protein **ferritin**, which stores Fe(III) in a soluble, nontoxic, and readily available form.[61–64] Although bacteria store very little iron,[65] some of them also contain a type of ferritin.[66–67a] On the other hand, the yeast *S. cerevisieae* stores iron in polyphosphate-rich granules, even though a ferritin is also present.[65] Ferritin contains 17–23% iron as a dense core of hydrated ferric oxide ~7 nm in diameter surrounded by a protein coat made up of twenty-four subunits of mo-

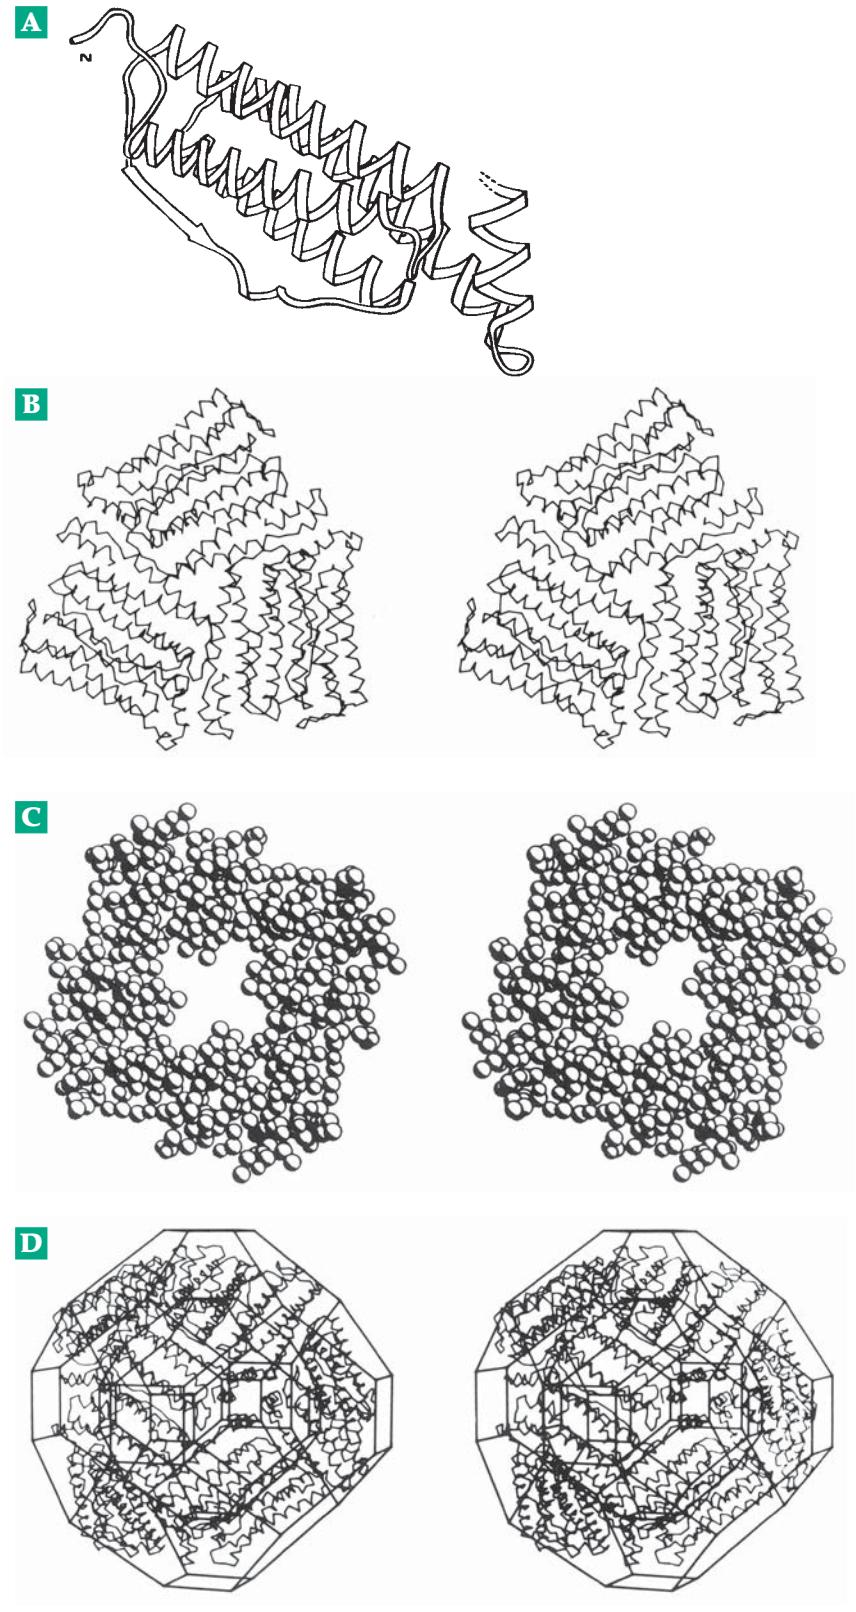

Figure 16-3 Structure of the protein shell of ferritin (apoferritin). (A) Ribbon drawing of the 163-residue monomer. From Crichton.[62] (B) Stereo drawing of a hexamer composed of three dimers. (C) A tetrad of four subunits drawn as a space-filling diagram and viewed down the four-fold axis from the exterior of the molecule. (D) A half molecule composed of 12 subunits inscribed within a truncated rhombic dodecahedron. B–D from Bourne *et al*.[74]

lecular mass 17- to 21-kDa. Each subunit is folded as a four-helix bundle (Fig. 16-3). Mammalian ferritins consist of combinations of subunits of two or more types. For example, human ferritins contain similarly folded 19-kDa L (light) and 21-kDa H (heavy) subunits.[68] The twenty-four subunits are arranged in a cubic array (Fig. 7-13, Fig. 16-3). The outer diameter of the 444-kDa apoferritin is ~12 nm. The completely filled ferritin molecule contains 23% Fe and over 2000 atoms of iron in a crystalline lattice. Larger ferritins may contain as many as 4500 atoms of iron with the approximate composition $[Fe(O)OH]_8FeOPO_3H_2$.[69] Phosphate ions are sometimes bound into surface layers of the ferritin cores.[69a] Ferritin cores are readily visible in the electron microscope, and ferritin is often used as a labeling reagent in microscopy. Another storage form of iron, **hemosiderin**, seems to consist of ferritin partially degraded by lysosomes and containing a higher iron content than does ferritin. Depositions of hemosiderin in the liver can rise to toxic levels if excessive amounts of iron are absorbed.

Iron can be deposited in ferritin by allowing apoferritin to stand with an Fe(II) salt and a suitable oxidant, which may be O_2. Physiological transfer of Fe(III) from transferrin to ferritin is thought to require prior reduction to Fe(II). The reoxidation by O_2 to Fe(III) for deposition in the ferritin core (Eq. 16-2) is catalyzed by **ferrooxidase sites** located in the centers of the helical bundles of the H-chains.[70–73]

$$2\,Fe^{2+} + O_2 + 4\,H_2O \rightarrow 2\,Fe(O)OH_{core} + H_2O_2 + 4\,H^+ \qquad (16\text{-}2)$$

BOX 16-A MAGNETIC IRON OXIDE IN ORGANISMS

An unusual form of stored iron is the magnetic iron oxide **magnetite** (Fe_3O_4). Honeybees,[a,b] monarch butterflies,[b–c] homing pigeons,[c–e] migrating birds, and even magnetotactic bacteria[f] contain deposits of Fe_3O_4 that are suspected of being used in nagivation.[c,g] Some bacteria have magnetic iron sulfide particles.[h-j] Human beings have magnetic bones in their sinuses[k] and in their brains[l] and may be able to sense direction magnetically. A set of possible magnetoreceptor cells, as well as associated nerve pathways, have been identified in trout.[j] In the magnetotactic bacteria found in the Northern Hemisphere the magnetic domains are oriented parallel with the axis of motility of the bacteria which tend to swim toward the geomagnetic North and downward into sediments. Similar bacteria from the Southern Hemisphere prefer to swim south and downward. The magnetic polarity of the bacterial magnetite crystals can be reversed by strong magnetic pulses, after which the bacteria swim in the direction opposite to their natural one.[m] Magnetic ferritin can be produced artificially in the laboratory.[n] The resulting particles may have practical uses, for example, in medical magnetic imaging. Magnetic materials in the human body are of interest not only in terms of a possible sensory function but also because of possible effects of electromagnetic fields on human health and behavior.[o]

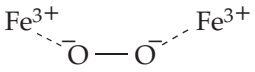
The ferrooxidase site is a dinuclear iron center (see Section 8) in which two iron ions (probably Fe^{2+}) are bound as in Fig. 16-4. They are then converted to Fe^{3+} ions by O_2, which may bind initially to the Fe^{2+}, forming a transient blue intermediate that is thought to have a peroxodiferric structure, perhaps of the following type.[71–73] Reaction of this intermediate with H_2O



may yield H_2O_2 plus a biomineral precursor $Fe^{2+} - O - Fe^{2+}$, which is incorporated into the core.[72a] Ferritin H subunits predominate in tissues with high oxygen levels, e.g., heart and blood cells, while the L subunits predominate in tissues with slower turnover of iron, e.g., liver.[72] The L subunits lack ferrooxidase activity but, in the centers of their helical bundles, contain polar side chains that may help to initiate growth of the mineral core.[64]

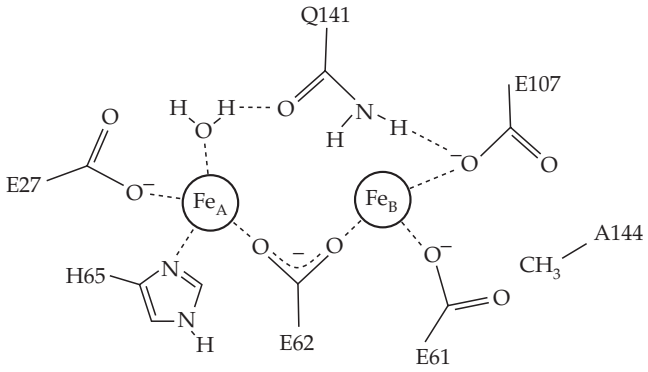


Figure 16-4 The dinuclear iron center or ferroxidase center of human ferritin based on the structure of a terbium(III) derivative.[73] Courtesy of Pauline Harrison.

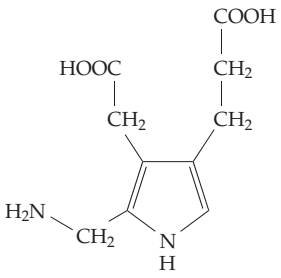
Removal of Fe(III) from storage in ferritin cores may require reduction to Fe(II) again, possibly by ascorbic acid[75] or glutathione. Some bacterial ferritins contain a bound cytochrome *b* which may assist in reduction.[67,67a] Released iron in the Fe^{2+} state can be incorporated into iron-containing proteins or into heme. The enzyme **ferrochelatase**[76–76b] catalyzes the transfer of free Fe^{2+} into protoporphyrin IX (Section 3) to form protoheme (Fig. 16-5). Iron in the Fe(II) state may also be oxidized to Fe^{3+} through action of the copper-containing ceruloplasmin (Section D) and be incorporated into heme by direct transfer from ferritin.[53]

3. Heme Proteins

In 1879, German physiological chemist Hoppe-Seyler showed that two of the most striking pigments of nature are related. The red iron-containing **heme** from blood and the green magnesium complex **chlorophyll a** of leaves have similar ring structures. Later, H. Fischer proved their structures and provided them with the names and numbering systems that are used today. This information is summarized in the following section.

Some names to remember. **Porphins** are planar molecules which contain large rings made by joining four pyrrole rings with methine bridges. In the **chlorins**, found in the chlorophylls, one of the rings (ring D in chlorophyll, Fig. 23-20) is reduced. The specific class of porphins known as **porphyrins** have eight substituents around the periphery of the large ring. Like the chlorins and the **corrins** of vitamin B_{12} (Section B), the porphyrins are all formed biosynthetically from **porphobilinogen**. This compound is polymerized in two ways (see Fig. 24-21) to give porphyrins of types I and III (Fig. 16-5). In type I porphyrins, polymerization of porphobilinogen has taken place in a regular way so that the sequences of the carboxymethyl and carboxyethyl side chains (often referred to as acetic acid and propionic acid side chains, respectively) are the same all the way around the outside of the molecule. However, most biologically important porphyrins belong to type III, in which the first three rings A, B, and C have the same sequence of carboxymethyl and carboxyethyl side chains, but in which ring D has been incorporated in a reverse fashion. Thus, the carboxyethyl side chains of rings C and D are adjacent to each other (Fig. 16-5). Porphyrins containing all four carboxymethyl and four carboxyethyl side chains intact are known as **uroporphyrins**.



Porphobilinogen

Uroporphyrins I and III are both excreted in small amounts in the urine. Another excretion product is **coproporphyrin** III, in which all of the carboxymethyl side chains have been decarboxylated to methyl groups. The feathers of the tropical touraco are colored with copper(II) complex of coproporphyrin III and this

porphyrin as well as others are commonly found in birds' eggs. The heme proteins are all derived from protoporphyrin IX, which is formed by decarboxylation and dehydrogenation of two of the carboxyethyl side chains of uroporphyrin III to vinyl groups (Fig. 16-5).

Hemes and heme proteins. Protoporphyrin IX contains a completely conjugated system of double bonds. In the center two hydrogen atoms are attached, one each to two of the nitrogens; they are free to move to other nitrogens in the center with rearrangement of the double bonds. Thus, there is tautomerism as well as resonance within the heme ring.[77–78a] The two central hydrogens can be replaced by many metal ions to form stable chelates. The complexes with Fe^{2+} are known as **hemes** and the Fe^{2+} complex with protoporphyrin IX as **protoheme**. Heme complexes of Fe^{2+} may be designated as **ferrohemes** and the Fe^{3+} compounds as **ferrihemes**. The Fe^{3+} protoporphyrin IX is also called **hemin**, and may be crystallized as a chloride salt.[78b] Iron tends to have a coordination number of six, and other ligands can attach to the iron from the two axial positions on opposite sides of the planar heme. If these are nitrogen ligands, such as pyridine or imidazole, the resulting compounds, called **hemochromes**, have characteristic absorption spectra. An example is cytochrome b_5, which contains two axial imidazole groups.

Several modifications of protoheme are indicated in Fig. 16-5. To determine which type of heme exists in a particular protein, it is customary to split off the heme by treatment with acetone and hydrochloric acid and to convert it by addition of pyridine to the pyridine hemochrome for spectral analysis. By this means, protoheme was shown to occur in hemoglobin, myoglobin, cytochromes of the *b* and P450 types, and catalases and many peroxidases. Cytochromes *a* and a_3 contain **heme *a***, while one of the terminal oxidase

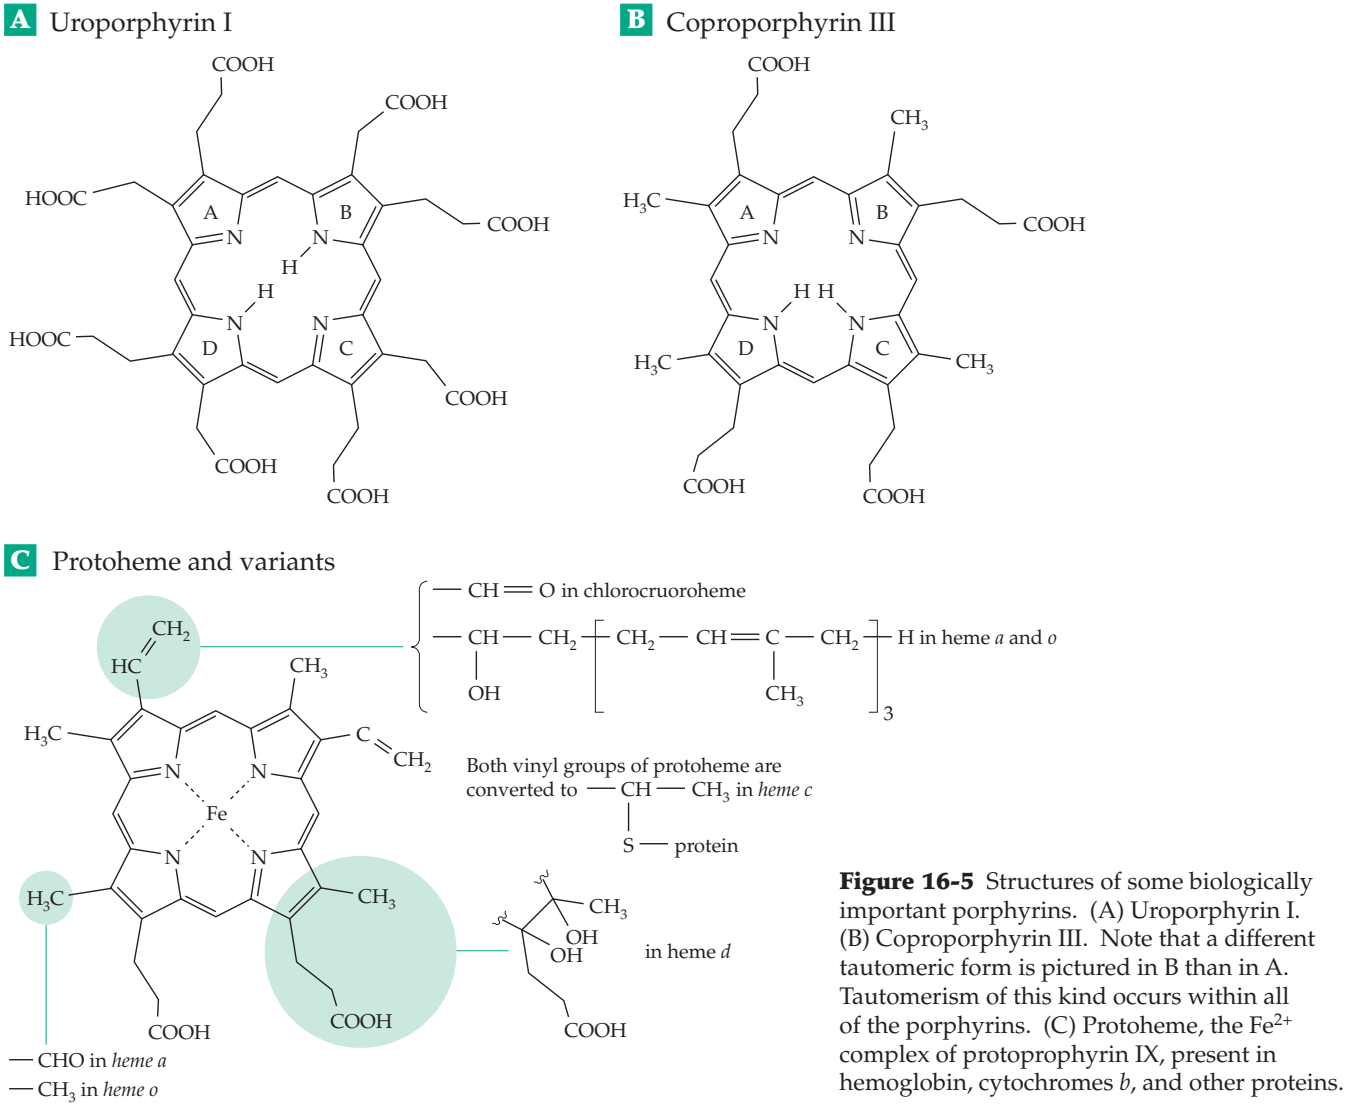


Figure 16-5 Structures of some biologically important porphyrins. (A) Uroporphyrin I. (B) Coproporphyrin III. Note that a different tautomeric form is pictured in B than in A. Tautomerism of this kind occurs within all of the porphyrins. (C) Protoheme, the Fe^{2+} complex of protoprophyrin IX, present in hemoglobin, cytochromes *b*, and other proteins.

systems of enteric bacteria contains the closely related heme *o* (Fig. 16-5).[79,80] A second terminal oxidase of those same bacteria contains **heme *d*** (formerly a_2). **Heme *c*** (present in cytochromes *c* and *f*) is a variation in which two SH groups of the protein have added to the vinyl groups of protoheme to form two thioether linkages (Fig. 16-5). A few cytochromes *c* have only one such linkage. In myeloperoxidase (Section 6) three covalent linkages, different than those in cytochrome *c*, join the heme to the protein.[81,82] There is a possibility that heme *a* may sometimes form a Schiff base with a lysyl amino group through its formyl group.[83,84]

Heme *d* is a chlorin,[85] as is **acrylochlorin heme** from certain bacterial nitrite reductases (Fig. 16-6).[86,87] **Siroheme** (Fig. 16-6), which is found in both nitrite and sulfite reductases of bacteria (Chapter 24),[88,89] is an isobacteriochlorin in which both the A and B rings are reduced. It apparently occurs as an amide **siroamide** (Fig. 16-6) in *Desulfovibrio*.[90] Heme d_1 of nitrite reductases of denitrifying bacteria is a dioxobacteriochlorin derivative (Fig. 16-6).[91,92]

As in myoglobin, hemoglobin (Fig. 7-23), and cytochrome *c* (see Fig 16-8), one axial coordination position on the iron of most heme proteins (customarily called the *proximal* position) is occupied by an imidazole group of a histidine side chain. However, in cytochrome P450 and chloroperoxidase a thiolate ($-S^-$) group from a cysteinyl side chain, and in catalase a phenolate anion from a tyrosyl side chain, occupies the proximal position. The sixth or *distal* coordination position is occupied by the sulfur atom of methionine in cytochrome *c* and most other cytochromes with low-spin iron but cytochromes b_5 and c_3 have histidine. The high-spin heme proteins, such as cytochromes *c*′, globins, peroxidase, and catalase, usually have no ligand other than weakly bound H_2O in the distal position.[93]

Hemes are found in all organisms except the anaerobic clostridia and lactic acid bacteria. Heme proteins of blood carry oxygen reversibly, whereas those of **terminal oxidase systems**, **hydroxylases**, and **oxygenases** "activate" oxygen, catalyzing reactions with hydrogen ions and electrons or with carbon compounds. The heme-containing **peroxidases** and **catalases** catalyze reactions not with O_2 but with H_2O_2. Another group of heme proteins includes most of the cytochromes, which are purely electron-transferring compounds.

4. The Cytochromes

The iron in the small proteins known as cytochromes acts as an electron carrier, undergoing alternate reduction to the +2 state and oxidation to the +3 state. The cytochromes, discovered in 1884 by McMunn,[94] were first studied systematically in the 1920s by Keilin (Chapter 18) and have been isolated from many sources.[95–97] The classification into groups *a*, *b*, and *c* according to the position of the longest wavelength light absorption band (the α band; Fig. 16-7) follows a practice introduced by Keilin. However, it is now customary to designate a new cytochrome by giving the heme type (*a*, *b*, *c* or *d*) together with the wavelength of the α band, e.g., cytochrome c_{552} or cyt $b_{557.5}$.

Cytochromes of the *b* type including bacterial cytochrome *o* contain protoheme. Because the sixth

position is ligated, most cytochromes *b* do not react with O_2. However, cytochromes *o* and *d* serve as terminal electron acceptors (cytochrome oxidases) and are oxidizable by O_2. Another protoheme-containing cytochrome, involved in hydroxylation (Chapter 18), is **cytochrome P450**. Here the 450 refers to the position of the intense "Soret band" (also called the γ band) of the spectrum (Fig. 16-7) in a difference spectrum run in the presence and absence of CO. Other properties are also used in arriving at designations for cytochromes. For example, cytochrome a_3 has a spectrum similar to that of cytochrome *a* but it reacts readily with both CO and O_2.

Another property that distinguishes various cytochromes is the redox potential $E°'$ (Table 6-8), which in this discussion is given for pH 7.0. Cytochromes carry electrons between other oxidoreductase proteins of widely varying values of $E^{0'}$. Because of the various heme environments cytochromes have greatly differing values of $E^{0'}$, allowing them to function in many different biochemical systems.[97a,97b] For mitochondrial cytochrome *c* the value of $E°'$ is ~ + 0.265 V but for the closely related cytochrome *f* of chloroplasts it is ~ +0.365 V and for cytochrome c_3 of *Desulfovibrio* about −0.330 V. There is more than an 0.6-volt difference between $E°'$ of cytochromes *f* and c_3. Cytochromes *b* tend to have lower $E°'$ values, close to zero, than most cytochromes *c*, while cytochrome a_3 has $E°' \sim +0.385$ V.

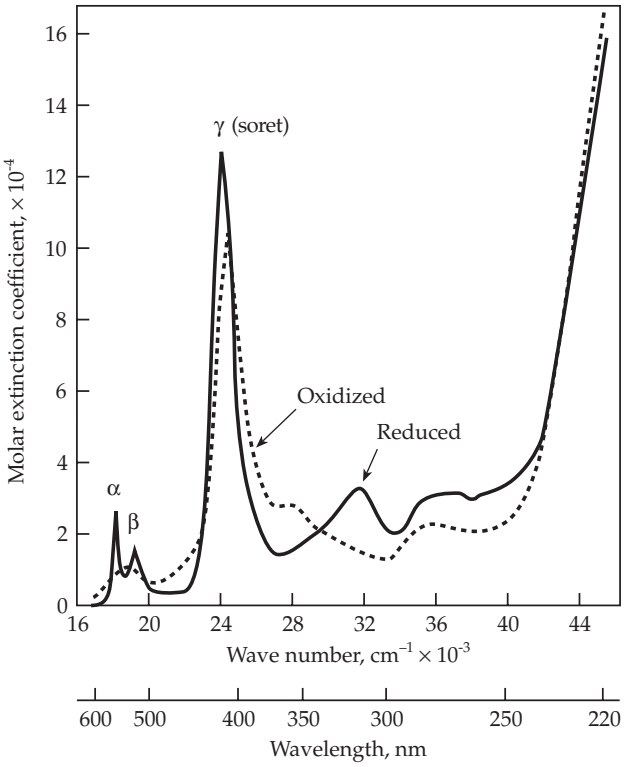

Figure 16-7 Absorption spectra of oxidized and reduced horse heart cytochrome *c* at pH 6.8. From data of Margoliash and Frohwirt.[98]

The c-type cytochromes. Mitochondrial cytochrome *c* is one of the few intracellular heme pigments that is soluble in water and that can be removed easily from membranes. A small 13-kDa protein typically containing about 104 amino acid residues, cytochrome *c* has been isolated from plants, animals, and eukaryotic microorganisms.[95–97,99,100] Complete amino acid sequences have been determined for over 100 species. Within the peptide chain 28 positions are invariant and a number of other positions contain only conservative substitutions. Cytochrome *c* was one of the first proteins to be used in attempting to trace evolutionary relationships between species by observing differences in sequence. Humans and chimpanzees have identical cytochrome *c*, but 12 differences in amino acid sequence occur between humans and the horses and 44 between human and *Neurospora*.[96] The related cytochrome c_2 of the photosynthetic bacterium *Rhodospillum rubrum* is thought to have diverged in evolution 2×10^9 years ago from the precursor of mammalian cytochrome *c*. Even so, 15 residues remain invariant.[101]

Structural studies[95–97,101–103] on cytochromes of the *c* and c_2 types show that the heme group provides a core around which the peptide chain is wound. The 104 residues of mitochondrial cytochrome *c* are enough to do little more than envelope the heme. In both the oxidized and reduced forms of the protein, methionine 80 (to the left in Fig. 16-8A) and histidine 18 (to the right) fill the axial coordination positions of the iron. The heme is nearly "buried" and inaccessible to the surrounding solvent.

The shorter chains of the 82- to 86-residue cytochromes c_{550} (from *Pseudomonas*[102]), c_{553},[102a] and c_{555} (from *Chlorobium*[105]) as well as the longer 112-residue polypeptide of cytochrome c_2 from *Rhodospirillum rubrum*[93] have nearly the same folding pattern as that in mitochondrial cytochrome *c*. However, the 128-residue chain of the dimeric cytochrome *c'* from *Rhodospirillum molischianum* forms an antiparallel four-helix bundle (Fig. 16-8).[106–109] This is the same folding pattern present in the ferritin monomer (Fig. 16-3), hemerythrin (Fig. 2-22), and many other proteins including cytochrome b_{562} of *E. coli*.[110] Cytochrome *f*, which functions in photosynthetic electron transport, is also a *c*-type cytochrome but with a unique protein fold.[111,112]

Most cytochromes have only one heme group per polypeptide chain,[112] but the 115-residue cytochrome c_3 from the sulfate-reducing bacterium *Desulfovibrio* binds four hemes (Fig. 16-8C).[104,113–115] Each one seems to have a different redox potential in the −0.20 to −0.38 V range.[114] Another *c*-type cytochrome, also from *Desulfovibrio*, contains six hemes in a much larger 66-kDa protein and functions as a nitrite reductase.[116]

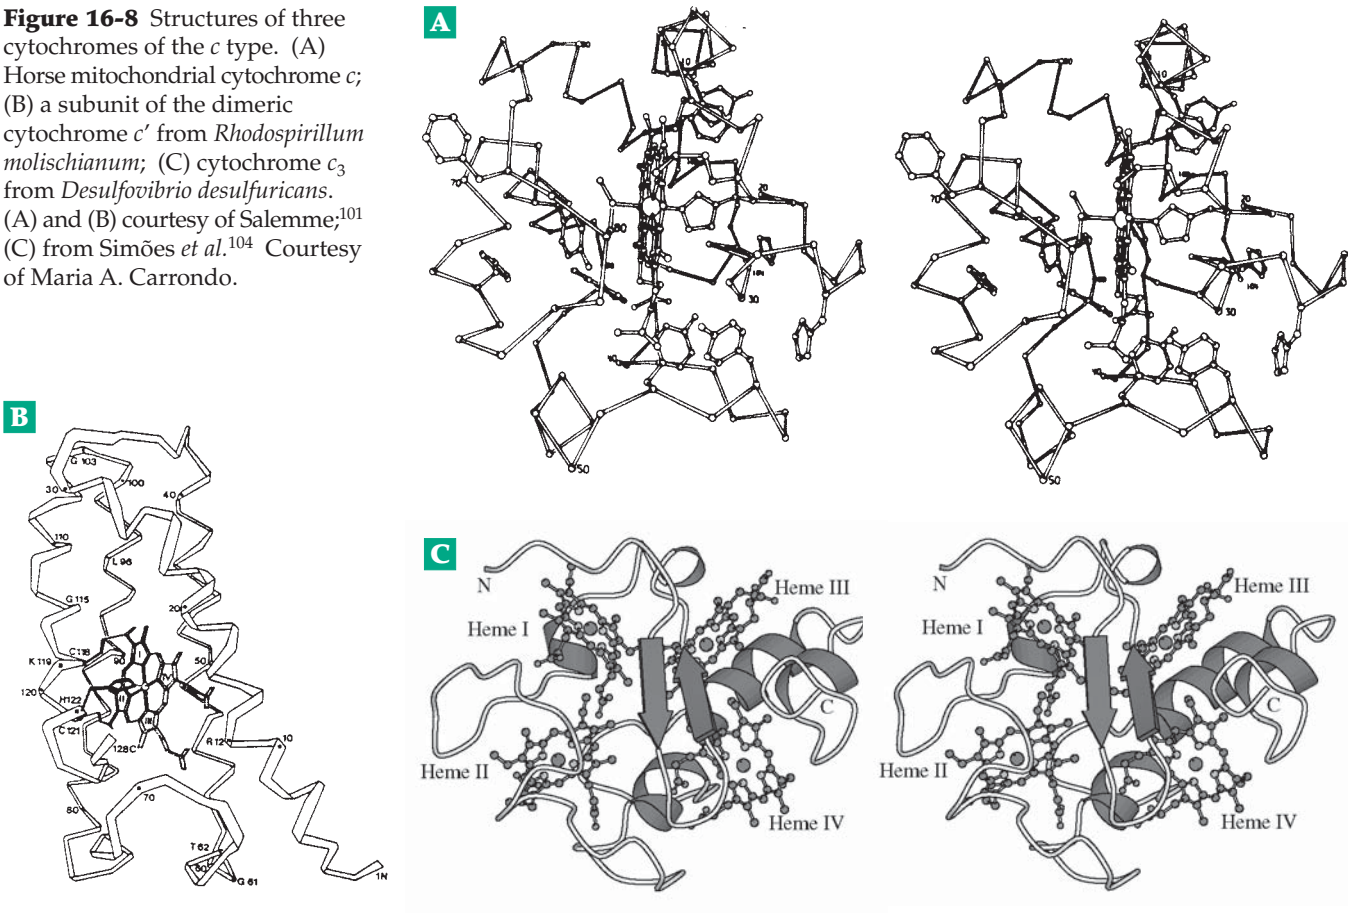

Figure 16-8 Structures of three cytochromes of the *c* type. (A) Horse mitochondrial cytochrome *c*; (B) a subunit of the dimeric cytochrome *c′* from *Rhodospirillum molischianum*; (C) cytochrome c_3 from *Desulfovibrio desulfuricans*. (A) and (B) courtesy of Salemme;[101] (C) from Simões *et al.*[104] Courtesy of Maria A. Carrondo.

Triheme and octaheme proteins are also known.[117]

Many cytochromes *c* are soluble but others are bound to membranes or to other proteins. A well-studied tetraheme protein binds to the reaction centers of many purple and green bacteria and transfers electrons to those photosynthetic centers.[118–120] Cytochrome c_2 plays a similar role in *Rhodobacter*, forming a complex of known three-dimensional structure.[121] Additional cytochromes participate in both cyclic and noncyclic electron transport in photosynthetic bacteria and algae (see Chapter 23).[120,122–124] Some bacterial membranes as well as those of mitochondria contain a **cytochrome bc_1 complex** whose structure is shown in Fig. 18-8.[125,126]

Cytochromes b, a, and o. Protoheme-containing cytochromes *b* are widely distributed.[127,128] There are at least five of them in *E. coli*. Whether in bacteria, mitochondria, or chloroplasts, the cytochromes *b* function within electron transport chains, often gathering electrons from dehydrogenases and passing them on to *c*-type cytochromes or to iron–sulfur proteins. Most cytochromes *b* are bound to or embedded within membranes of bacteria, mitochondria, chloroplasts, or endoplasmic reticulum (ER). For example, cytochrome b_5[129,129a] delivers electrons to a fatty acid desaturating system located in the ER of liver cells and to many other reductive biosynthetic enzymes.[130–132] The protein contains 132 amino acid residues plus another 85 largely hydrophobic N-terminal residues that provide a nonpolar tail which is thought to be buried in the ER membranes.[130] Solubilization of the protein causes loss of this N-terminal sequence. The heme in cytochrome b_5 is not covalently bonded to the protein but is held tightly between two histidine side chains. The polypeptide chain is folded differently than in either cytochrome *c* or myoglobin.

The folding pattern of cytochrome b_5 is also found in the complex heme protein **flavocytochrome b_2** from yeast (Chapter 15)[133] and probably also in liver **sulfite oxidase**[134,135] Both are 58-kDa peptides which can be cleaved by trypsin to 11-kDa fragments that have spectroscopic similarities and sequence homology with cytochrome b_5. Sulfite oxidase also has a molybdenum center (Section H). The 100-residue N-terminal portion of flavocytochrome b_2 has the cytochrome b_5 folding pattern but the next 386 residues form an eight-stranded $(\alpha/\beta)_8$ barrel that binds a molecule of FMN.[133,136] All of these proteins pass electrons to cytochrome *c*. In contrast, the folding of **cytochrome**

b_{562} of *E. coli* resembles that of cytochrome *c′* (Fig. 16-8).[110,137] However, it has methionine side chains as both the fifth and sixth iron ligands.

Cytochromes *b* of mitochondrial membranes are involved in passing electrons from succinate to ubiquinone in complex II[138] and also from reduced ubiquinone to cytochrome c_1 in the 248-kDa complex III (Fig. 18-8). A similar complex is present in photosynthetic purple bacteria.[123,139] Cytochrome b_{560} functions in the transport of electrons from succinate dehydrogenase to ubiquinone,[138] and cytochrome b_{561} of secretory vesicle membranes has a specific role in reducing ascorbic acid radicals.[140]

In bacteria some cytochromes *b* and d_1 serve as terminal electron carriers able to react with O_2, nitrite, or nitrate, while others act as carriers between redox systems.[141–143a] The aldehyde heme *a* is utilized by animals and by some bacteria in **cytochrome *c* oxidase**, a complex enzyme whose three-dimensional structure is known (see Fig. 18-10) and which is discussed further in Chapter 18.

5. Mechanisms of Biological Electron Transfer

The heme groups of the cytochromes as well as many other transition metal centers act as carriers of electrons. For example, cytochrome *c* may accept an electron from reduced cytochrome c_1 and pass it to cytochrome oxidase or cytochrome *c* peroxidase. The electron moves from one heme group to another over distances as great as 2 nm. Similar electron-transfer reactions between defined redox sites are met in photosynthetic reaction centers (Fig. 23-31), in metalloflavoproteins (Fig. 15-9), and in mitochondrial membranes.

What are the factors that determine the probability of an electron transfer reaction and the rate at which it may occur? They include: (1) The distance from the electron donor to the acceptor. (2) The thermodynamic driving force $\Delta G°$ for the reaction. This can be approximated using the difference in standard electrode potentials (as in Table 6-1) between donor and acceptor. $\Delta G° = -96.5\ \Delta E°$ kJ/mol at 25° C. (3) The chemical makeup of the material through which the electron transfer takes place. (4) Any changes in the geometry or charge state of the donor or acceptor that accompany the transfer. (5) The orientation of the acceptor and donor groups.[144–146] It is usually assumed that the Franck–Condon principle is obeyed, i.e., that the electron jump occurs so rapidly ($<10^{-12}$ s) that there is no change in the positions of atomic nuclei (see also Chapter 23). Subsequent rearrangement of nuclear positions may occur at rates that allow a rapid overall reaction.

The various factors that affect the rate of electron transfer were incorporated by Marcus into a quantitative theory. Electron transfer is often discussed in terms of this classic Marcus theory together with effects of quantum mechanical tunneling.[144,147–150] According to Marcus the electron transfer rate from a donor to an acceptor at a fixed separation depends upon $\Delta G°$, a nuclear reorganization parameter (λ), and the electronic coupling strength $|H_{AB}|$ between reactant and product in the transition state (Eq. 16-3):

$$k_{ET} = (4\pi^3 / h^2 \lambda k_B T)|H_{AB}|^2 \exp[-(\Delta G° + \lambda)^2 / 4\lambda k_B T] \quad (16\text{-}3)$$

Here $|H_{AB}|$ is a quantum mechanical matrix whose strength decreases exponentially with the distance of separation *R* as $e^{-\beta R}$ where β is a coefficient of the order of 9–14 nm^{-1}. At the closest contact (R = 0) the rate k_{ET}, by extrapolation from experimental data on small synthetic compounds, is close to the molecular vibration frequency of 10^{13} s^{-1}.[151,152] At distances greater than 2 nm the rate would be negligible were it not for other factors.

Using mutant proteins as well as a variety of redox pairs and electron-transfer distances the validity of the Marcus equation with respect to the thermodynamic driving force and distance dependence has been verified.[153] This is even true for cytochrome *c* mutants functioning in living yeast cells.[146]

A huge amount of experimental work with proteins has been done to test and refine the theories of electron transport. For example, electron donor groups with various reduction potentials have been attached to various sites on the surface of a protein containing a heme or other electron accepting group. Ruthenium complexes such as Ru(III) $(NH_3)_5^{3+}$ form tight covalent linkages to imidazole nitrogens[154,155] such as that of His 33 of horse heart cytochrome *c*. This metal can be reduced rapidly to Ru(II) by an external reagent, after which the transfer of an electron from the Ru(II) across a distance of 1.2 nm to the heme Fe(III) can be followed spectroscopically. The reduction potentials *E°* for the Ru(III) / Ru(II) and Fe(III) / Fe(II) couples at pH 7 in these compounds are 0.16 and 0.27 V, respectively. Thus, an electron will jump spontaneously from the Ru(II) to the Fe(III) with $\Delta G° = -15.4$ kJ/mol. A rate constant of ~5 s^{-1}, which was nearly independent of temperature, was observed. Since the structures of Fe(II) and Fe(III) forms of cytochrome *c* differ only slightly,[156] the electron transfer apparently occurs with only a small amount of geometric rearrangement. The distribution of charges and dipoles within the protein may be such that the Fe^{2+} and Fe^{3+} complexes have almost equal thermodynamic stability.

Electron-transfer pathways? In spite of the success of the Marcus theory, rates of electron-transfer from the iron of cytochrome *c* have been found to vary for different pathways.[150,153,155] For example, transfer of an electron from Fe(II) in reduced cytochrome *c* to an Ru(III) complex on His 33 was fast (~440 s^{-1})[157] but

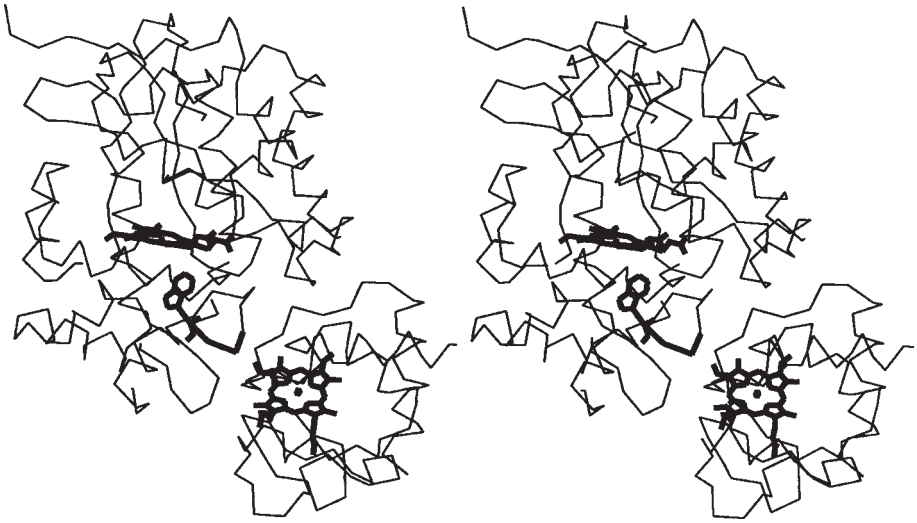

Figure 16-9 Stereoscopic α-carbon plot of yeast cytochrome *c* peroxidase (top) and yeast cytochrome *c* (below) as determined from a cocrystal by Pelletier and Kraut.[164] The heme rings of the two proteins appear in bold lines, as does the ring of tryptophan 191 and the backbone of residues 191–193 of the cytochrome *c* peroxidase. Drawing from Miller *et al.*[165]

the rate of transfer to an equidistant Fe(III) ion on Met 65 was at most 0.6 s^{-1}. These results suggested that distinct electron-transfer pathways exist. One suggestion was that the sulfur atom of Met 80 donates an electron to Fe^{3+} leaving an electron-deficient radical. The "hole" so created could be filled by an electron jumping in from the –OH group of the adjacent Tyr 67, which might then accept an electron from an external acceptor via Tyr 74 at the protein surface. Do electrons flow singly or as pairs from the surface through hydrogen-bonded paths? Use of both semisynthesis[155] and directed mutation[153] of cytochromes *c* is permitting a detailed study of these effects. A striking result is that substitution of the conserved residue phenylalanine 82 in a yeast cytochrome *c* with leucine or isoleucine retards electron transfer by a factor of ~10^4.

"Docking." It is now recognized that there are distinct "docking sites" on the surface of electron-transport proteins. For rapid electron transfer to occur the two electron carriers must be properly oriented and docked by formation of correct polar and nonpolar interactions. Early indications of the importance of docking came from study of modified cytochromes *c.* Each one of the 19 lysine side chains was individually altered by acylation or alkylation to remove the positive charge or to replace it with a negative charge. The rate of electron transfer into cytochrome *c* from hexacyanoferrate was decreased by a factor of 1.3–2.0 when any one lysine at positions 8, 13, 27, 72, or 79, which are clustered around the heme edge, was modified.[158] Modification of Lys 22, 55, 99, or 100, distant from this edge, had no effect. Electron transfer *into* cytochrome *c* from its natural electron donor ubiquinol:cytochrome *c* reductase was also strongly inhibited by modification of lysines that surround the heme edge.[159] Modification of these lysines also inhibited electron transfer *out of* cytochrome *c* into its natural acceptors, cytochrome *c* oxidase and cytochrome *c* peroxidase (Fig. 16-9).[160] A major factor in these effects is probably the large dipole moment in the cytochrome *c* that arises from the unequal distribution of surface charges. This charge distribution must assist in the proper docking of the cytochrome with its natural electron donors and acceptors. The positive surface charges presumably also facilitate the reaction with hexacyanoferrate (II) or ascorbate, both of which are negatively charged reductants that react rapidly with cytochrome *c*.

Measurements of many kinds have been made between natural donor–acceptor pairs such as cytochrome *c*–cytochrome b_5,[161,162] cytochrome *c*–cytochrome *c* peroxidase (Fig. 16-9),[153,163–166] trimethylamine dehydrogenase–FMN to Fe_4S_4 center (Fig. 15-9),[167] and methylamine dehydrogenase (TTQ radical)–amicyanin (Cu^{2+}).[168] Designed metalloproteins are being studied as well.[169] Femtosecond laser spectroscopy is providing a new approach.[169a]

Coupling and gating of electron transfer. Electrons are thought to be transferred into or out of cytochrome *c* through the exposed edge of the heme. The rate depends upon effective coupling, which in turn may depend upon orientation as well as the structure and dynamics of the protein.[170] Proteins with much β structure appear to provide stronger coupling than those that are largely composed of α helices.[144,171] The high nuclear reorganization energy λ of α helices may block electron transfer along some pathways.[153] A conformational change,[167,169] transfer of a proton, or binding of some other specific ion[172] before electron transfer occurs can be the "gating" process that determines the rate of electron transfer.[162,167,173] Electron transfer can also be "coupled" to an unfavorable, but fast, equilibrium.

Effects of ionic equilibria on electron transfer. The charge on an ion of Fe^{2+} in a heme is exactly balanced by two negative charges on the porphyrin ring. However, when the Fe^{2+} loses an electron to become Fe^{3+} an extra positive charge is suddenly present in the center of the protein. This change in charge will have a powerful electrostatic effect on charged groups in the immediate vicinity of the iron and even at the outer surface of the molecule. For example, an anion from the medium or from a neighboring protein molecule might become bound to the heme protein (Eq. 16-4).

$$X^- + [\,Fe(II)\ (heme)\,] \rightarrow [\,Fe(III)\ (heme)\,]^+\ X^- \ + \ e^- \qquad (16\text{-}4)$$

In this case the presence of a high concentration of X^- in the medium would favor the oxidation of Fe(II) to Fe(III). The reduced heme would be a better reducing agent and the oxidized form a weaker oxidant than in the absence of X^-. If –YH were a group in the protein the loss of an electron could cause –YH to dissociate so that Y^- and the Fe(III) would interact more tightly (Eq. 16-5).

$$\begin{aligned} HY &— [\ Fe\ (II)\ (heme)\ ] \rightarrow \\ Y^- &— [\ Fe\ (III)\ (heme)\ ]^+ + H^+ \ + e^- \end{aligned} \qquad (16\text{-}5)$$

We see that electron transfer can be accompanied by loss of a proton and that $E^{\circ\prime}$ may become pH dependent. (See also Eq. 16-18.) Even with cytochrome *c*, although there is little structural change upon electron transfer, there is an increased structural mobility in the oxidized form.[156] This may be important for coupling and could also facilitate associated proton-transfer reactions. For example, it is possible that in some cytochromes the imidazole ring in the fifth coordination position may become deprotonated upon oxidation. This possibility is of special interest because cytochromes are components of proton pumps in mitochondrial membranes (Chapter 18).

6. Reactions of Heme Proteins with Oxygen or Hydrogen Peroxide

As Ingraham remarked,[174] "Living in a bath of 20% oxygen, we tend to forget how reactive it is." From a thermodynamic viewpoint, all living matter is extremely unstable with respect to combustion by oxygen. Ordinarily, a high temperature is required and if we are careful with fire, we can expect to escape a catastrophe. However, one mole of properly chelated copper could catalyze consumption of all of the air in an average room within one second.[174] Biochemists are interested in both the fact that O_2 is kinetically stable and unreactive and also that oxidative enzymes such as cytochrome *c* oxidase are able to promote rapid reactions. Two oxygen atoms, each with six valence electrons, might reasonably be expected to form dioxygen, O_2, as a double-bonded structure with one σ and one π bond as follows (left):

Dioxygen

However, O_2 is paramagnetic and contains two unpaired electrons.[175] From this evidence O_2 might be assigned the structure on the right.[175] The oxygen molecule is very stable, and it is relatively difficult to add an electron to form the reactive **superoxide anion radical** O_2^-.

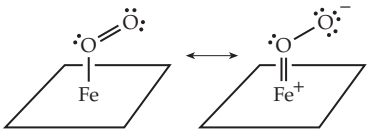
Superoxide anion radical

For this reason, oxidative attack by O_2 tends to be slow. However, once an electron has been acquired, it is easy for additional electrons to be added to the structure and further reduction occurs more easily. The biochemical question suggested is, "How can some heme proteins carry O_2 reversibly without any oxidation of the iron contained in them while others *activate* oxygen toward reaction with substrates?" Among this latter group, cytochrome *c* oxidase transfers electrons to both oxygen atoms so that only H_2O is a product, whereas the hydroxylases and oxygenases, which are discussed in Chapter 18, incorporate either one or two of the atoms of O_2, respectively, into an organic substrate. Before examining these reactions let us reconsider the heme oxygen carriers.

Oxygen-carrying proteins. In Chapter 7, we examined the behavior of hemoglobin in the cooperative binding of four molecules of O_2 and studied its structural relationship to the monomeric muscle protein myoglobin.[176] The iron in functional hemoglobin and myoglobin is always Fe(II) and is only very slowly converted by O_2 into the Fe(III) forms methemoglobin or metmyoglobin.[177,178] Erythrocytes contain an enzyme system for immediately reducing methemoglobin back to the Fe(II) state (see Box 15-H).

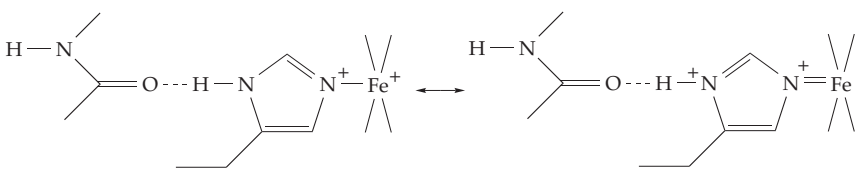
Binding of O_2 to the iron in the heme is usually considered not to cause a change in the oxidation state of the metal. However, oxygenated heme has some of the electronic characteristics of an Fe^{3+}–OO^- peroxide anion. Bonding of the heme iron to oxygen is thought to occur by donation of a pair of electrons by the oxygen to the metal. In deoxyhemoglobin the Fe(II) ion is in the "high-spin" state; four of the five 3*d* orbitals in the valence shell of the iron contain one unpaired electron and the fifth orbital contains two paired electrons. The binding of oxygen causes the iron to revert

to the "low-spin" state in which all of the electrons are paired and the paramagnetism of hemoglobin is lost. The stability of heme–oxygen complexes is thought to be enhanced by "back-bonding," i.e., the donation of an electron pair from one of the filled *d* orbitals of the iron atom to form a bond with the adjacent oxygen.[179] This can be indicated symbolically as follows:



These structures, which have been formulated by assuming that one of the unshared electron pairs on O_2 forms the initial bond to the metal, are expected to lead to an angular geometry which has been observed in X-ray structures of model compounds,[180] in oxymyoglobin (Fig. 16-10),[181,182] and in oxyhemoglobin.[183] Neutron diffraction studies have shown that the outermost oxygen atom of the bound O_2 is hydrogen bonded to the H atom on the N^{ε} atom of the distal imidazole ring of His E7 (Fig. 16-10). Carbon monoxide binds with the C≡O axis perpendicular to the heme plane and unable to form a corresponding hydrogen bond.[184] This decreases the affinity for CO and helps to protect us from carbon monoxide poisoning.

All oxygen-carrying heme proteins have another imidazole group that binds to iron on the side opposite the oxygen site. Without this proximal imidazole group, heme does not combine with oxygen. Coordination with heterocyclic nitrogen compounds favors formation of low-spin iron complexes and simple synthetic compounds that closely mimic the behavior of myoglobin have been prepared by attaching an imidazole group by a chain of appropriate length to the edge of a heme ring.[179,185] Similar compounds bearing a pyridine ring in the fifth coordination position have a low affinity for oxygen. Thus, the polarizable imidazole ring itself seems to play a role in promoting oxygen binding. The π electrons of the imidazole ring may also participate in bonding to the iron as is indicated in the following structures.[179] The π bonding to the iron would allow the iron to back-bond more strongly to an O_2 atom entering the sixth coordination position. These diagrams illustrate another feature found frequently in heme proteins: The N–H group of the imidazole is hydrogen bonded to a peptide backbone carbonyl group.



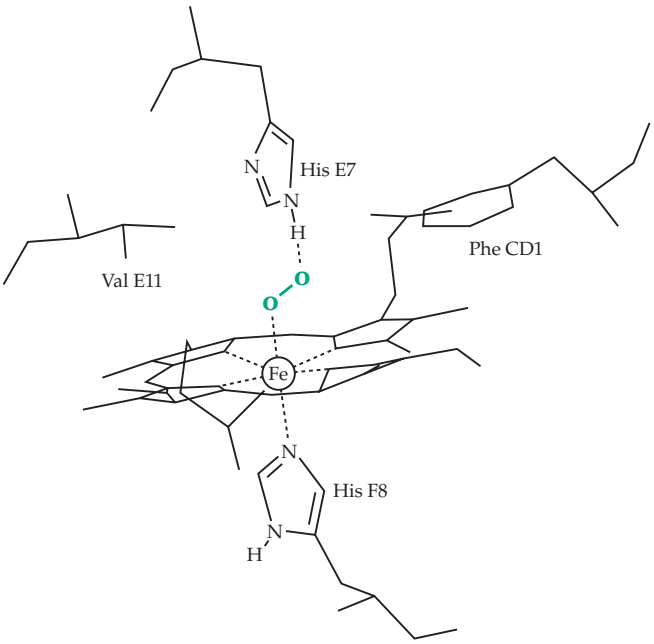


Figure 16-10 Geometry of bonding of O_2 to myoglobin and position of hydrogen bond to N^{ε} of the distal histidine E7 side chain. After Perutz.[182]

The coordination of the heme iron to histidine also appears to provide the basis for the cooperativity in binding of oxygen by hemoglobin.[186] The radius of high-spin iron, whether Fe(II) or Fe(III), is so large that the iron cannot fit into the center of the porphyrin ring but is displaced toward the coordinated imidazole group by a distance of ~0.04 nm for Fe(II).[187] Thus, in deoxyhemoglobin both iron and the imidazole group lie further from the center of the ring than they do in oxyhemoglobin. In the latter, the iron lies in the center of the porphyrin ring because the change to the low-spin state is accompanied by a decrease in ionic radius.[186,188] The change in protein conformation induced by this small shift in the position of the iron ion was described in Chapter 7. However, the exact nature of the linkage between the Fe position and the conformational changes is not clear.

The mechanical response to the movement of the iron and proximal histidine, described in Chapter 7, may explain this linkage. However, oxygenation may also induce a change in the charge distribution within the hydrogen-bond network of the protein. The carbonyl group shown in the foregoing structure is attached to the F helix (see Fig. 7-23) and is also hydrogen bonded to other amide groups. Electron withdrawal into the heme–oxygen complex would tend to strengthen the hydrogen bond as indicated by the resonance forms shown and also to weaken

competing hydrogen bonds.[189,190] This could affect the charge distribution in the upper end of the F helix and could conceivably induce a momentary conformational change that could facilitate the rearrangement of structure that was discussed in Chapter 7 (Fig. 7-25). The $\alpha_1\beta_2$ contact in which a change of hydrogen bonding takes place is located nearby behind the F and G helices. In any event, it is remarkable that nature has so effectively made use of the subtle differences in the properties of iron induced by changes in the electron distribution within the *d* orbitals of this transition metal.

A few groups of invertebrates, e.g., the sipunculid worms, use a nonheme iron-containing protein, **hemerythrin**, as an oxygen carrier.[191,192] Its 113-residue subunits are often associated as octamers of C_4 symmetry, each peptide chain having a four-helix bundle structure (Fig. 2-22). Instead of a heme group, each monomer contains two atoms of high-spin Fe(II) held by a cluster of histidine and carboxylate side chains (see Fig. 16-20).[193,194] Hemerythrin is a member of a group of such diiron oxoproteins which are considered further in Section 8. The copper oxygen carrier **hemocyanin** is discussed in Section D.

Catalases and peroxidases. Many iron and copper proteins do not bind O_2 reversibly but "activate" it for further reaction. We will look at such metalloprotein oxidases in Chapter 18. Here we will consider heme enzymes that react not with O_2 but with peroxides. The peroxidases,[194a] which occur in plants, animals, and fungi, catalyze the following reactions (Eq. 16-6, 16-7):

$$H_2O_2 + AH_2 \rightarrow 2\,H_2O + A \qquad (16\text{-}6)$$

$$ROOH + AH_2 \rightarrow R{-}OH + H_2O + A \qquad (16\text{-}7)$$

Here AH_2 is an oxidizable organic compound such as an alcohol or a pair of one-electron donor molecules. Catalases, which are found in almost all aerobic cells,[194b] may sometimes account for as much as 1% of the dry weight of bacteria. The enzyme catalyzes the breakdown of H_2O_2 to water and oxygen by a mechanism similar to that employed by peroxidases. If Eq. 16-7 is rewritten with H_2O_2 for AH_2 and O_2 for A, we have the following equation:

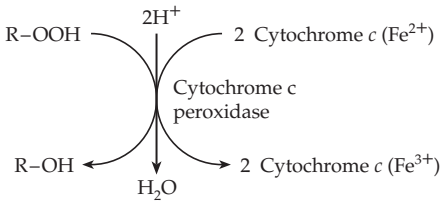
$$2\,H_2O_2 \xrightarrow{\text{Catalase}} 2\,H_2O + O_2 \qquad (16\text{-}8)$$

The action of catalase is very fast, almost 10^4 times faster than that of peroxidases. The molecular activity per catalytic center is about $2 \times 10^5\ s^{-1}$.

Catalase exerts a protective function by preventing the accumulation of H_2O_2 which might be harmful to cell constituents. The complete intolerance of obligate anaerobes to oxygen may result from their lack of this enzyme. Support for this protective function comes from the existence of the human hereditary condition **acatalasemia**.[195,196] Persons with extremely low catalase activity are found worldwide but are especially numerous in Korea. In Japan it is estimated that there are 1800 persons lacking catalase. Because about half of them have no symptoms, catalase might be judged unessential. However, many of the individuals affected develop ulcers around their teeth. Apparently, hydrogen peroxide produced by bacteria accumulates and oxidizes hemoglobin to methemoglobin (Box 15-H) depriving the tissues of oxygen.

Catalase from most eukaryotic species is tetrameric.[197] The protein from beef liver consists of 506-residue subunits.[198] Human catalase is similar.[198a] The proximal ligand to the heme Fe^{3+} is a tyrosinate anion (Tyr 358), while side chains of His 75 and Asn 148 lie close to the heme on the distal H_2O_2-binding side (Fig. 16-11). Larger ~650-residue fungal and bacterial catalases have a similar folding pattern but an extra C-terminal domain with a flavodoxin-like structure.[197,199] Catalase is gradually inactivated by its very reactive substrate. As isolated, beef liver catalase usually contains about two subunits in which the heme ring has been oxidatively cleaved to **biliverdin**[200] (Fig. 24-24) and various other alterations have been found.[197] Each subunit of mammalian catalases normally contains a bound molecule of NADPH which helps to protect against inactivation by H_2O_2.[201,202] Catalases from *Neurospora* and from *E. coli* contain heme *d* rather than protoporphyrin.[197,203] Some lactobacilli, lacking heme altogether, form a manganese-containing pseudocatalase.[204,205]

Of the plant peroxidases, which are found in abundance in the peroxisomes, the 40-kDa monomeric **horseradish peroxidase** has been studied the most.[206–208a] It occurs in over 30 isoforms and has an extracellular role in generating free radical intermediates for polymerization and crosslinking of plant cell wall components.[209] Secreted fungal peroxidases, e.g., such as those from *Coprinus*[210] and *Arthromyces*,[211] form a second class of peroxidases with related structues.[212] A third class is represented by **ascorbate peroxidase** from the cytosol of the pea[212–214] and by the small 34-kDa **cytochrome c peroxidase** from yeast mitochondria[215] (Fig. 16-11). The latter has a strong preference for reduced cytochrome *c* as a substrate (Eq. 16-9).[216,217]



(16-9)

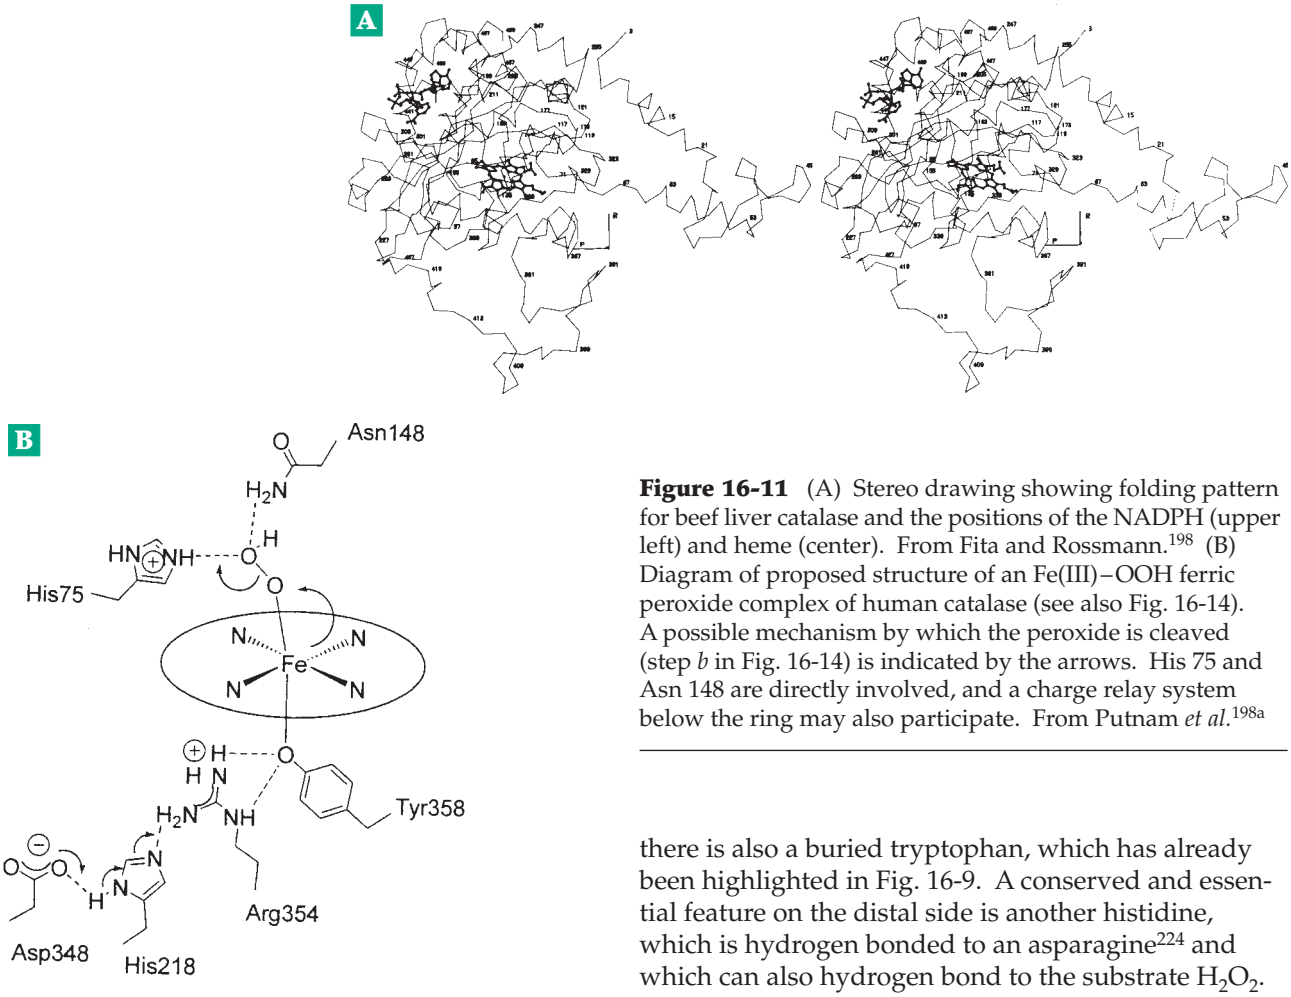


Figure 16-11 (A) Stereo drawing showing folding pattern for beef liver catalase and the positions of the NADPH (upper left) and heme (center). From Fita and Rossmann.[198] (B) Diagram of proposed structure of an Fe(III)–OOH ferric peroxide complex of human catalase (see also Fig. 16-14). A possible mechanism by which the peroxide is cleaved (step *b* in Fig. 16-14) is indicated by the arrows. His 75 and Asn 148 are directly involved, and a charge relay system below the ring may also participate. From Putnam *et al.*[198a]

Because the three-dimensional structures of the peroxidase, its reductant cytochrome *c*, and the complex of the two (Fig. 16-9) are known, cytochrome *c* peroxidase is the subject of much experimental study. Other fungal peroxidases, some of which contain manganese rather than iron, act to degrade lignin (Chapter 25).[218] A lignin peroxidase from the white wood-rot fungus *Phanerochaete chrysosporium* has a surface tryptophan with a specifically hydroxylated Cβ carbon atom which may have a functional role in catalysis.[218a,b]

The human body contains **lactoperoxidase**, a product of exocrine secretion into milk, saliva, tears, etc., and peroxidases with specialized functions in **saliva**, the **thyroid, eosinophils**,[219] and **neutrophils**.[220] The functions are largely protective but the enzymes also participate in biosynthesis. Mammalian peroxidases have heme covalently linked to the proteins, as indicated in Fig. 16-12.[220–222a]

The active site structure of peroxidases (Fig. 16-13) is quite highly conserved. As in myoglobin, an imidazole group is the proximal heme ligand, but it is usually hydrogen bonded to an aspartate carboxylate as a catalytic diad (Fig. 16-13).[223] In cytochrome *c* peroxidase there is also a buried tryptophan, which has already been highlighted in Fig. 16-9. A conserved and essential feature on the distal side is another histidine, which is hydrogen bonded to an asparagine[224] and which can also hydrogen bond to the substrate H_2O_2. Fungal peroxidases also have a conserved arginine on the distal side. However, even an octapeptide with a bound heme cut from cytochrome *c* acts as a "microperoxidase" with properties similar to those of natural peroxidases.[225]

Peroxidases and catalases contain high-spin Fe(III) and resemble metmyoglobin in properties. The enzymes are reducible to the Fe(II) state in which form they are able to combine (irreversibly) with O_2. We see that the same active center found in myoglobin and hemoglobin is present but its chemistry has been modified by the proteins. The affinity for O_2 has been altered drastically and a new group of catalytic activities for ferriheme-containing proteins has emerged.

Mechanisms of catalase and peroxidase catalysis. Attention has been focused on a series of strikingly colored intermediates formed in the presence of substrates. When a slight excess of H_2O_2 is added to a solution of horseradish peroxidase, the dark brown enzyme first turns olive green as **compound I** is formed, and then pale red as it turns into **compound II**. The latter reacts slowly with substrate AH_2 or with another H_2O_2 molecule to regenerate the original enzyme. This sequence of reactions is indicated by the colored arrows in Fig. 16-14, steps *a*–*d*.

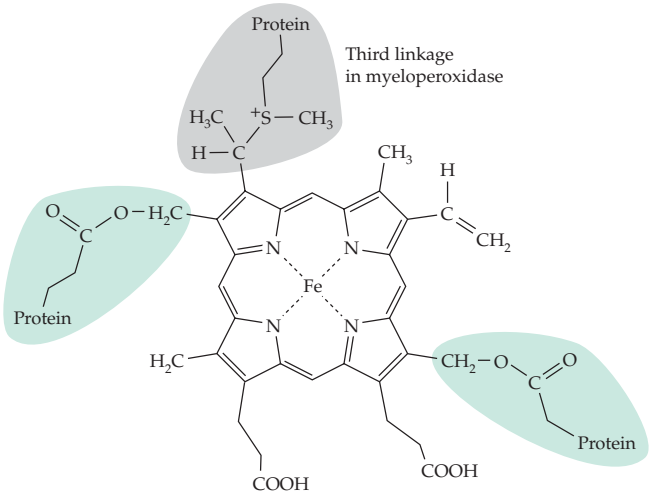

Figure 16-12 Linkage of heme to mammalian peroxidases. There are two ester linkages to carboxylate side chains from the protein.[220,221] Myeloperoxidase contains a third linkage.[222,222a]

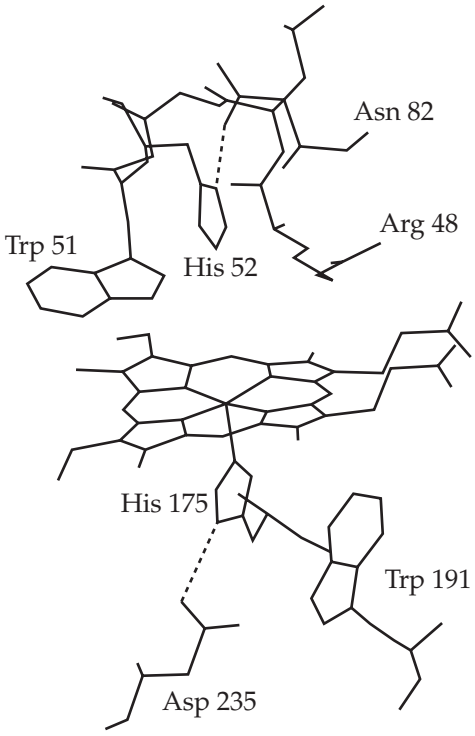

Figure 16-13 The active site of yeast cytochrome *c* peroxidase. Access for substrates is through a channel above the front edge of the heme ring as viewed by the reader. A pathway for entrance of electrons may be via Trp 191 and His 175. From Holzbaur *et al.*[206] Based on coordinates of Finzel *et al.*[215]

Titrations with such reducing agents as ferrocyanide or K_2IrBr_6 have established that compound I is converted into compound II by a one-electron reduction and compound II to free peroxidase by another one-electron reduction. Thus, the iron in compound I may formally be designated Fe(V) and that in II as Fe(IV). However, this does not tell us whether or not the oxygen atoms of H_2O_2 are present in compounds I and II. The enzyme in the Fe^{3+} form can be reduced to Fe^{2+} (Fig. 16-14, step *e*), as previously mentioned, and when the Fe^{2+} enzyme reacts with H_2O_2 it is apparently converted into compound II (Fig. 16-14, step *f*). This suggests that the latter is an Fe^{2+} complex of the peroxide anion. Here, P^{2-} represents the porphyrin ring:

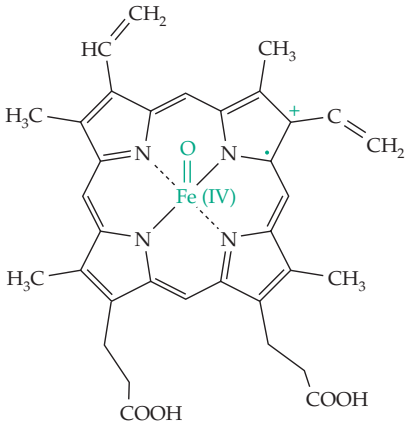
$$P^{2-}—Fe^{+}(II)—OOH$$

However, spectroscopic evidence suggests that compound II is a **ferryl iron** complex which could be derived from the preceding structure by addition of a proton and loss of water.[226,227]

$$P^{2-}—Fe^{2+}(IV)=O$$
Compound II

High concentrations of H_2O_2 convert II into compound III, which is thought to be the same as the **oxyperoxidase** that is formed upon addition of O_2 to the Fe(II) form of the free enzyme (Fig. 16-14, step *g*) and corresponds in structure to oxyhemoglobin.[228]

Compound I was at one time thought to be a complex of H_2O_2 or its anion with Fe(III), but its magnetic and spectral properties are inconsistent with this structure. Rather, it too appears to contain ferryl iron bound to an electron-deficient porphyrin π-cation radical.[229] The reaction with peroxide probably involves initial formation of a peroxide anion complex (Fig. 16-14, step *a*) which is cleaved with release of water (step *b*).[215,230] The resulting $Fe(V)^{+}=O$ compound is converted to compound I by transfer of a single elec-



Compound I. The unpaired electron and the positive charge are delocalized over the porphyrin ring and perhaps into the proximal histidine ring

tron from the porphyrin to the iron. In cytochrome *c* peroxidase compound I contains a free radical on the nearby Trp 191 ring instead of on the porphyrin radical.[216] Consistent with this is the fact that horseradish peroxidase contains phenylalanine in place of Trp 191.

If we consider the fate of substrate AH_2 during the action of a peroxidase, we see that donation of an electron to compound I to convert it into II (Fig. 16-14, step *c*) will generate a free radical •AH as well as a proton. The radical may then donate a second electron to II to form the free enzyme. Alternatively, a second molecule of AH_2 may react (Fig. 16-14, step *c*) to form a second radical •AH. The two •AH radicals may then disproportionate to form A and AH_2 or they may leave the enzyme and react with other molecules in their environment. Compound II of horse radish peroxidase is able to exchange the oxygen atom of its Fe(IV)=O center with water rapidly at pH 7, presumably by donation of a proton from the nearby histidine side chain (corresponding to His 52 of Fig. 16-13).[227,230a,b] This histidine presumably also functions in proton transfer during reactions with substrates (see Fig. 16-11B).[224]

The catalase compound I appears to be converted in a two-electron reduction by H_2O_2 directly to free ferricatalase without intervention of compound II (Fig. 16-14, step *c'*). The catalytic histidine probably donates a proton to help form water from one of the oxygen

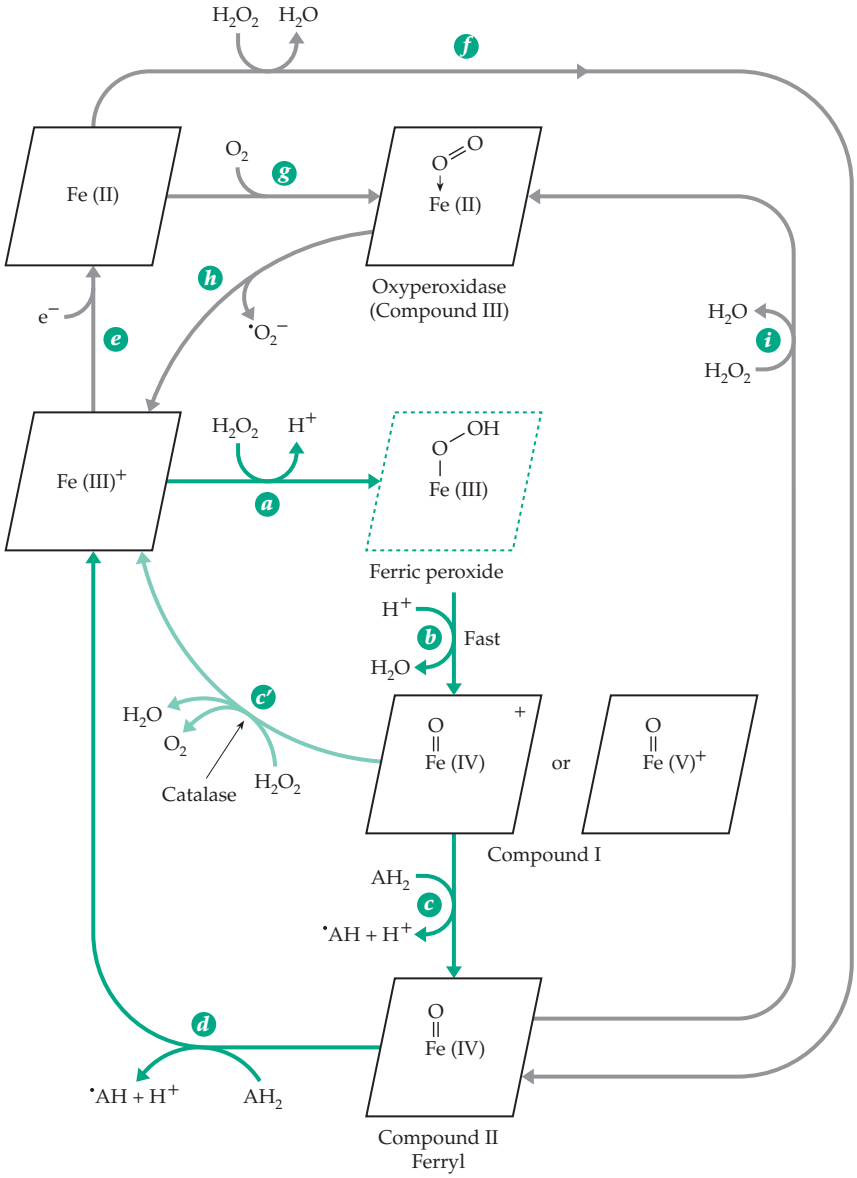


Figure 16-14 The catalytic cycles and other reactions of peroxidases and catalases. The principal cycle for peroxidases is given by the colored arrows. That of catalases is smaller, making use of step *a*, *b*, and *c'*, which is marked by a light green line.

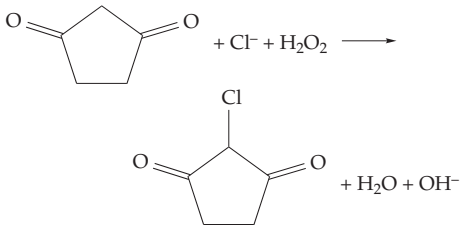
$$\underset{\text{Compound I}}{{}^{\bullet}P^{+}\text{—Fe(IV)=O}} + H_2O_2 \rightarrow H_2O + O_2 + \underset{}{P\text{—Fe(III)}^{+}} \qquad (16\text{-}10)$$

atoms of the H_2O_2. Nevertheless, compound II does form slowly, especially if a slow substrate such as ethanol is present. The previously mentioned bound NADPH apparently reduces compound II formed in this way, converting the inactivated enzyme back to active catalase.[201,231] This may involve unusual one-electron oxidation steps for the NADPH.[231] Under some circumstances compound II of peroxidases reacts with substrates in a two-electron process[232–235] with transfer of an oxygen atom to the substrate, a characteristic also of reactions catalyzed by cytochromes P450 (see Eq. 18-57).

Haloperoxidases. Many specialized peroxidases are active in halogenation reactions. **Chloroperoxidases** from fungi[236,237] catalyze chlorination reactions like that of Eq. 16-11 using H_2O_2 and Cl^- as well as the usual peroxidase reaction.

Chloroperoxidase is isolated in a low-spin Fe(III) state. The reduced Fe(II) enzyme is a high-spin form

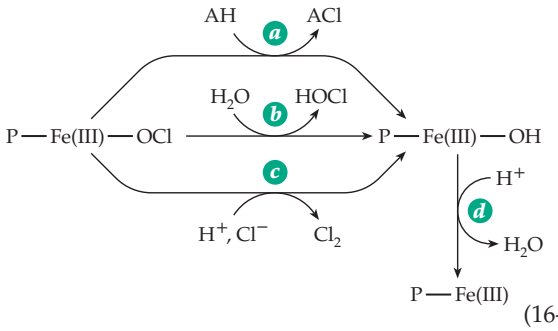


(16-11)

with spectroscopic properties similar to those of the oxygenases of the cytochrome P450 family, which are discussed in Chapter 18.[238,239] Like the cytochromes P450 chloroperoxidase contains a thiolate group of a cysteine side chain as the fifth iron ligand.[235,239,240] Chloroperoxidase forms compounds I and II, as do other peroxidases. A chloride ion may combine with compound I to form a complex of hypochlorite with the Fe(III) heme.

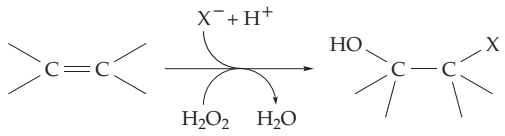
$$\bullet P^{+}\text{—Fe(IV)=O} + Cl^{-} \rightarrow P\text{—Fe(III)}^{+}\text{—OCl} \qquad (16\text{-}12)$$

This intermediate could then halogenate substrate AH (Eq. 16-13, step *a*), lose HOCl (Eq. 16-13, step *b*), or generate Cl_2 by reaction with Cl^- (Eq. 16-13, step *c*). These are all well-established reactions for the enzyme. In each case the chlorine in the peroxidase complex can be viewed as an electrophile which is transferred to an attacking nucleophile. A fourth reaction that can go

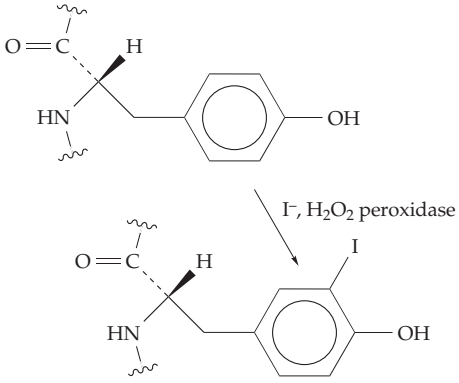


(16-13)

through the same intermediate is conversion of alkenes to α,β-halohydrins (Eq. 16-14).[241] **Lactoperoxidase** of milk, reacting with $I^- + H_2O_2$, promotes an analogous iodination of tyrosine and histidine residues of proteins. With radioactive $^{125}I^-$ or $^{131}I^-$ it provides a convenient and much used method for labeling of proteins in



(16-14)



(16-15)

exposed surfaces of membranes (Eq. 16-15).[242] Iodinated tyrosine derivatives are formed in the thyroid gland by a similar reaction catalyzed by **thyroid peroxidase**.[232] Even horseradish peroxidase can oxidize iodide ions but neither it nor lactoperoxidase will carry out chlorination or bromination reactions.

Myeloperoxidase, present in specialized lysosomes of polymorphonuclear leukocytes (neutrophils),[243] utilizes H_2O_2 and a halide ion to kill ingested bacteria.[244,245] Phagocytosis induces increased respiration by the leukocyte and generation of H_2O_2, partly by the membrane-bound NADPH oxidase described in Chapter 18. Some of the H_2O_2 is used by myeloperoxidase to attack the bacteria, apparently through generation of HOCl by peroxidation of Cl^-. Human myeloperoxidase is a tetramer of two 466-residue chains and two 108-residue chains, which carry the covalently linked heme.[222a,246] Another oxygen-dependent killing mechanism that may also be used by neutrophils is the generation of the reactive **singlet oxygen**.[247] This can occur by reaction of hypochlorite with H_2O_2 (Eq. 16-16) or from an enzyme-bound hypochlorite intermediate such as that shown in Eq. 16-13. Hereditary deficiency of myeloperoxidase is relatively common.[245]

$$OCl^- + H_2O_2 \rightarrow \underset{\text{singlet } O_2}{O_2(^1\Delta g)} + H_2O + Cl^- \qquad (16\text{-}16)$$

Lactoperoxidase[248] and chloroperoxidase[249] also generate singlet oxygen. The possible biological significance is discussed in Chapter 18. Eosinophil peroxidase appears to promote formation of **hydroxyl radicals**.[250] **Bromoperoxidases** are found in many red and green marine algae.[251] Many of them contain **vanadium** and function by a mechanism different than that used by heme peroxidases (see Section G).[252,253]

Another related nonheme enzyme is the selenoprotein glutathione peroxidase. It reacts by a mechanism very different (Eq. 15-59) from those discussed

here, as does **NADPH peroxidase**, a flavoprotein with a cysteine sulfinate side chain in the active site.[254–255a] A lignin-degrading peroxidase from the white wood rot fungus *Phanerochaete chrysosporium* is a simple heme protein,[256] while other peroxidases secreted by this organism contain Mn.[257,258]

7. The Iron–Sulfur Proteins

Not all of the iron within cells is chelated by porphyrin groups. Hemerythrin (see Fig. 16-20) has been known for many years, but the general significance of nonheme iron proteins was not appreciated until large-scale preparation of mitochondria was developed by Crane in about 1945. The iron content of mitochondria was found to far exceed that of the heme proteins present. In 1960, Beinert, who was studying the mitochondrial dehydrogenase systems for succinate and for NADH, observed that when the electron transport chain was partially reduced by these substrates and the solutions were frozen at low temperature and examined, a strong EPR signal was observed at $g = 1.94$. The signal was obtained only upon reduction by substrate, and fractionation pointed to the nonheme iron proteins. Six or more proteins of this type are involved in the mitochondrial electron transport chain (Eq. 18-1), and numerous others have become recognized as members of the same large family of **iron–sulfur proteins** (Fe–S proteins).[259,260]

Ferredoxins, high-potential iron proteins, and rubredoxins. The presence of nonheme iron proteins is most evident in the anaerobic clostridia, which contain no heme. It was from these bacteria that the first Fe–S protein was isolated and named **ferredoxin**. This protein has a very low reduction potential of $E°'$(pH 7) = –0.41 V. It participates in the pyruvate–ferredoxin oxidoreductase reaction (Eq. 15-35), in nitrogen fixation in some species, and in formation of H_2. A small green-brown protein, the ferredoxin of *Peptococcus aerogenes* contains only 54 amino acids but complexes eight atoms of iron. If the pH is lowered to ~1, eight molecules of H_2S are released. Thus, the protein contains eight "labile sulfur" atoms in an iron sulfide linkage. There are also eight iron atoms.

Another group of related electron carriers, the **high-potential iron proteins** (HIPIP) contain four labile sulfur and four iron atoms per peptide chain.[261–266] X-ray studies showed that the 86-residue polypeptide chain of the HIPIP of *Chromatium* is wrapped around a single **iron–sulfur cluster** which contains the side chains of four cysteine residues plus the four iron and four sulfur atoms (Fig. 16-15D).[261] This kind of cluster is referred to as [4Fe–4S], or as Fe_4S_4. Each cysteine sulfur is attached to one atom of Fe, with the four iron atoms forming an irregular tetrahedron with an Fe–Fe

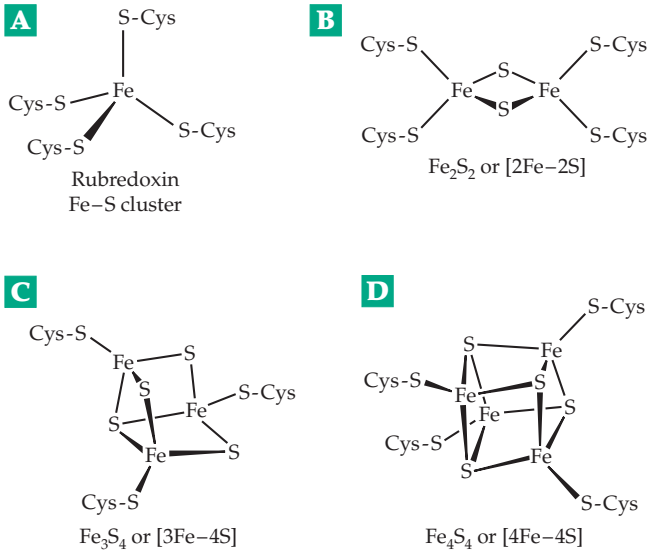


Figure 16-15 Four different iron–sulfur clusters of a type found in many proteins. From Beinert[259] with permission.

distance of ~0.28 nm. The four labile sulfur atoms (S^{2-}) form an interpenetrating tetrahedron 0.35 nm on a side with each of the sulfur atoms bonded to three iron atoms. The cluster is ordinarily able to accept only a single electron. The iron–sulfur cluster structure was a surprise, but after its discovery it was found that ions such as $[Fe_4S_4(S–CH_2CH_2COO^-)_4]^{6-}$ assemble spontaneously from their components and have a similar cluster structure.[259,266a] Thus, living things have simply improved upon a natural bonding arrangement.

The bacterial ferredoxins from *Peptococcus, Clostridium* (Fig. 16-16B),[267,268] *Desulfovibrio,* and other anaerobes each contain two Fe_4S_4 clusters with essentially the same structure as that of the *Chromatium* HIPIP.[267,269] Each cluster can accept one electron. Much of the amino acid sequence in the first half of the ferredoxin chain is repeated in the second half, suggesting that the chain may have originated as a result of gene duplication. Many invariant positions are present in the sequence, including those of the cysteine residues forming the Fe–S cluster. Ferredoxins with single Fe_4S_4 clusters are also known.[270]

The ferredoxins have reduction potentials $E°'$ (pH 7) from about – 0.4 V to as low as – 0.6 V. However, the corresponding values for HIPIP proteins range from +0.05 to +0.50 V at pH 7.[271] This wide range of potentials initially seemed strange because the structures of the active centers of both the clostridial ferredoxins and the *Chromatium* HIPIP appear virtually identical.[272] Part of the explanation lies in the fact that Fe_4S_4 clusters can exist in three oxidation states (Eq. 16-17) that differ, one from another, by a single electron.[273]

$$[Fe_4S_4]^{+} \xrightarrow[e^-]{} [Fe_4S_4]^{2+} \xrightarrow[e^-]{} [Fe_4S_4]^{3+}$$

Reduced Fd	Oxidized Fd; reduced high potential iron protein	Oxidized high potential iron protein; Super-oxidized Fd

(16-17)

Here the charges shown are those on the cluster. The cysteine ligands from the protein each add an additional negative charge. The *Chromatium* HIPIP and the clostridial ferredoxins have the middle oxidation state in common. The cluster is a little smaller in the more oxidized states; in the *Chromatium* HIPIP the Fe–Fe distance changes from 0.281 to 0.272 nm upon oxidation.

Rubredoxins. The simplest of the Fe–S proteins are the rubredoxins. These proteins contain iron but no labile sulfur. The rubredoxin of *Clostridium pasteurianum* is a 54-residue peptide containing four cysteines whose side chains form a distorted tetrahedron about a single iron atom (Fig. 16-16A).[274] Not shown for any

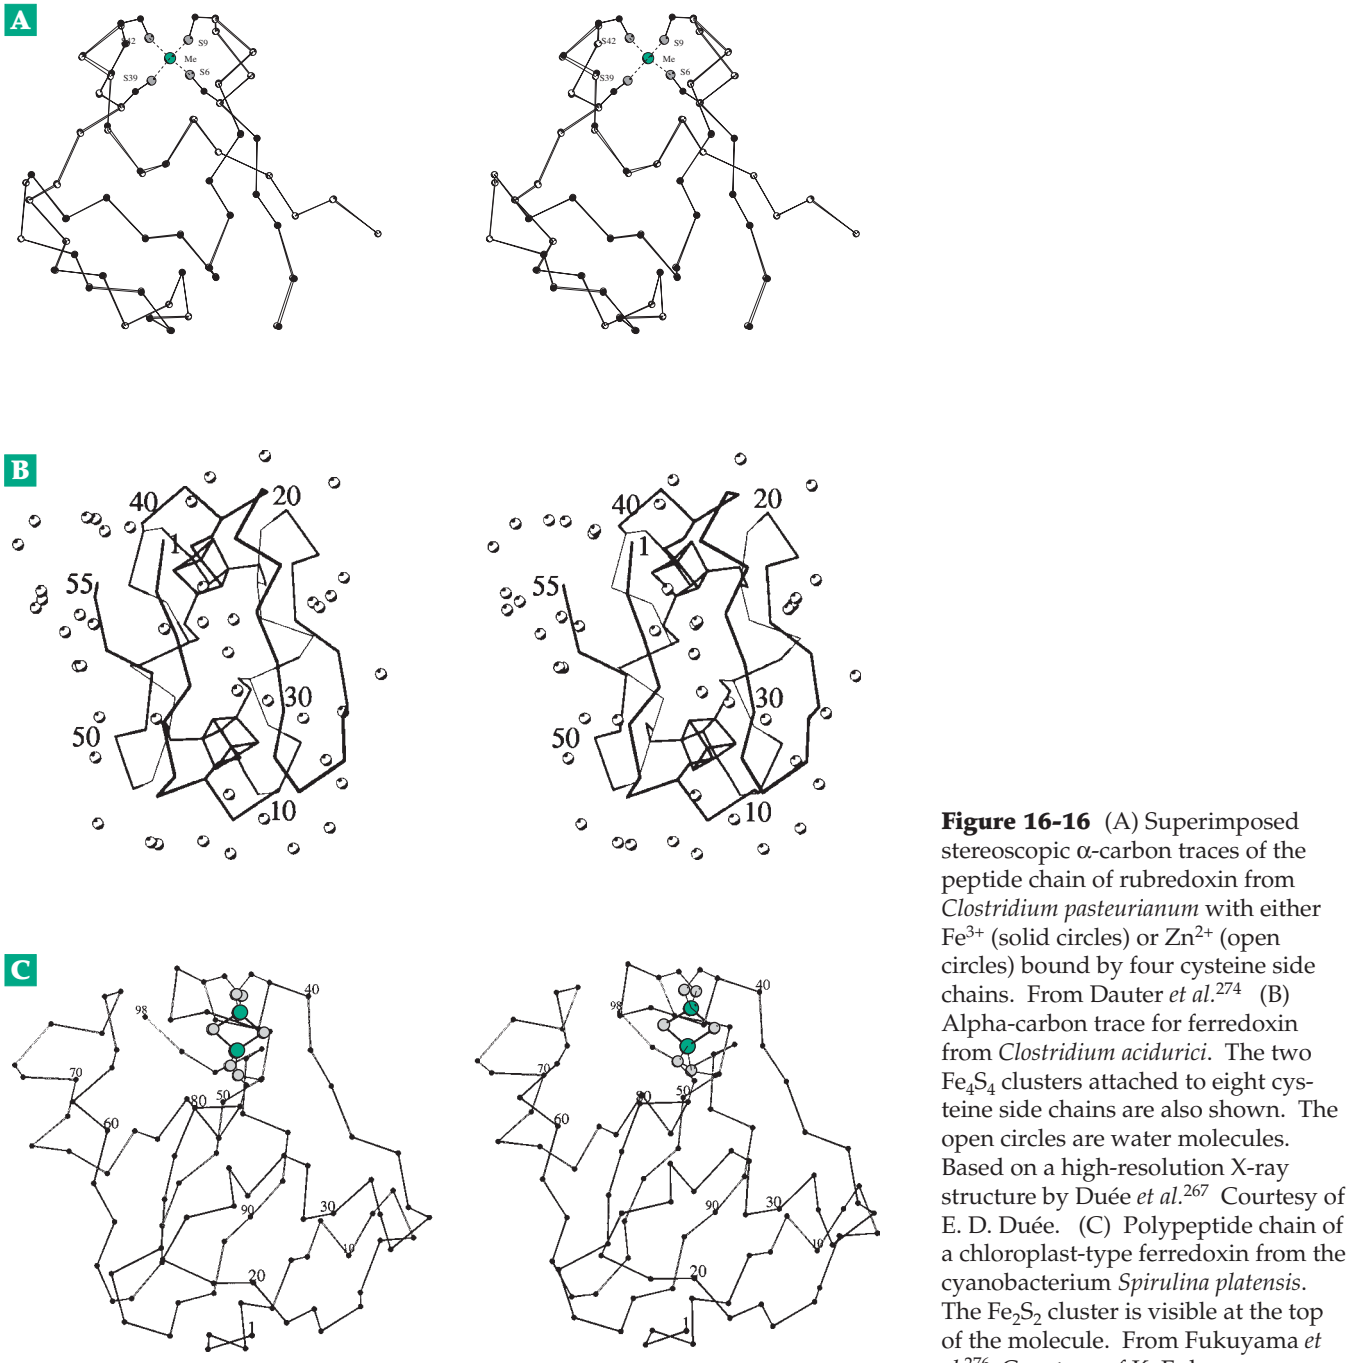

Figure 16-16 (A) Superimposed stereoscopic α-carbon traces of the peptide chain of rubredoxin from *Clostridium pasteurianum* with either Fe^{3+} (solid circles) or Zn^{2+} (open circles) bound by four cysteine side chains. From Dauter *et al.*[274] (B) Alpha-carbon trace for ferredoxin from *Clostridium acidurici*. The two Fe_4S_4 clusters attached to eight cysteine side chains are also shown. of the structures in Fig. 16-16 are NH—S hydrogen bonds that connect backbone NH groups of the peptide chain to the sulfur atoms of the cysteine groups, forming the clusters.[275] These bonds may have important effects on properties of the cluster. Rubredoxins also participate in electron transport and can substitute for ferredoxins in some reactions. Larger 14-kDa and 18-kDa rubredoxins able to bind two iron ions participate in electron transport in a hydroxylase system of *Pseudomonas* (Chapter 18).[277] A smaller 7.9-kDa 2-Fe **desulforedoxin** functions in sulfate-reducing bacteria.[278]

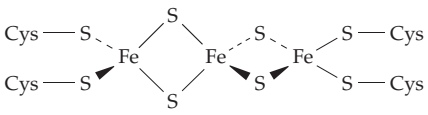
Chloroplast-type ferredoxins. Members of a large class of [2Fe–2S] or Fe_2S_2 ferredoxins each contain two iron atoms and two labile sulfur atoms with the linear structure of Fig. 16-15B.[279,279a] Best known are the chloroplast ferredoxins, which transfer electrons from photosynthetic centers of chloroplasts to the flavoprotein reductase that reduces $NADP^+$ to NADPH.[280,280a] The structure of a cyanobacterial protein of this type is shown in Fig. 16-16C.[276] A second group of Fe_2S_2 ferredoxins are found in bacteria including *E. coli*[281] and in human mitochondria.[282] For example, in steroid hormone-forming tissues the ferredoxin **adrenodoxin**[282a] carries electrons to cytochromes P450. Its Fe_2S_2 center receives electrons from adrenodoxin reductase (Chapter 15 banner).[282b] The nitrogen-fixing *Clostridium pasteurianum* also contains a ferredoxin of this class.[283] In *Pseudomonas putida* (Chapter 18) the related 106-residue **putidaredoxin** transfers electrons to cytochromes P450.[284]

The 3Fe–4S clusters. A 106-residue ferredoxin from *Azotobacter vinelandii* contains seven iron atoms in two Fe–S clusters that operate at very different redox potentials of –0.42 and +0.32 V.[285] Other similar seven-iron proteins are known.[286] From EPR measurements it appeared that both clusters function between the 2^+ and 3^+ (oxidized and superoxidized) states of Eq. 16-17, despite the widely differing potentials. A super-reduced all-Fe(II) form with $E^{\circ\prime}$ (pH 7) = –0.70 V can also be formed.[286] X-ray crystallographic studies have revealed that the protein contains one Fe_4S_4 cluster and one Fe_3S_4 cluster (Fig. 16-15C).[286–288] The structures and environments of the Fe_3S_4 clusters are similar to those of Fe_4S_4 clusters but they lack one iron and one cysteine side chain. An Fe_4S_4 cluster may sometimes lose S^{2-} to form an Fe_3S_4 cluster such as the one in the *A. vinelandii* ferredoxin. A less likely possibility is isomerization to a linear Fe_3S_4 structure.[289]



Aconitase (Eq. 13-17) isolated under aerobic conditions contains an Fe_3S_4 cluster and is catalytically inactive. Incubation with Fe^{2+} activates the enzyme and reconverts the Fe_3S_4 to an Fe_4S_4 cluster (Fig. 13-4).[260,289,290]

Properties of iron–sulfur clusters. These clusters were viewed for many years as unstable and unable to exist outside of a protein. However, if protected from oxygen and manipulated in the presence of soluble organic thiols they are stable and "cofactor-like."[260] Intact clusters can be "extruded" from proteins by treatment with thiols in nonaqueous media. Both Fe_4S_4 and Fe_2S_2 clusters as well as more complex forms have been synthesized[291] and nonenzymatic cluster interconversions have been demonstrated. Binding to proteins stabilizes the clusters further, but some (Fe–S) proteins are labile and difficult to study. This is evidently because of partial exposure of the cluster to the surrounding solvent. Not only can O_2 cause oxidation of exposed clusters[291a] but also superoxide,[292] nitric oxide, and peroxynitrite can react with the iron. Aconitase has only three cysteine side chains available for coordination with Fe and the protein is unstable. Apparently, a superoxidized $[Fe_4S_4]^{3+}$ cluster is formed in the presence of O_2 but loses Fe^{2+} to give an $[Fe_3S_4]^+$ cluster.[293]

Another interesting cluster conversion is the joining of two Fe_2S_2 clusters in a protein to form a single Fe_4S_4 cluster at the interface between a dimeric protein. Such a cluster is present in the nitrogenase iron protein (Fig. 24-2) and probably also in biotin synthase.[294] The clusters in such proteins can also be split to release the monomers.

Synthetic iron–sulfur clusters have weakly basic properties[273] and accept protons with a pK_a of from 3.9 to 7.4. Similarly, one clostridial ferredoxin, in the oxidized form, has a pK_a of 7.4; it is shifted to 8.9 in the reduced form.[295] If we designate the low-pH oxidized form of such a protein as HOx^+ and the reduced form as HRed, we can depict the reduction of each Fe_4S_4 cluster as follows.

$$HOx^+ + e^- \rightarrow HRed \qquad (16\text{-}18)$$

Comparing with Eq. 6-64 and using the Michaelis pH functions (first two terms of Eq. 7-13) for HOx^+ and HRed, it is easy to show that the value of $E^{\circ\prime}$ ($E_{1/2}$) at which equal amounts of oxidized protein (HOx^+ + Ox) and reduced protein (HRed + Red^-) are present is given by Eq. 16-19, in which K_{ox} and K_{red} are the K_a values for dissociation of the protonated oxidized and reduced forms, respectively.

$$E_{1/2} = E^0\ (\text{low pH}) + 0.0592 \log\left[\frac{(1 + K_{red}/[H^+])}{(1 + K_{ox}/[H^+])}\right] \text{V} \qquad (16\text{-}19)$$

At the high pH limit this becomes $E_{1/2} = E°$ (low pH) + 0.0592 ($pK_{ox} - pK_{red}$) and V = −0.371 + 0.0592 (7.4−8.9) V = −0.431 V. Thus, the value of $E_{1/2}$ changes from −0.371 to −0.460 V as the pH is increased. In the pH range between the pK_a values of 7.4 and 8.9 reduction of the protein will lead to binding of a proton from the medium and oxidation to loss of a proton. Human and other vertebrate ferredoxins also show pH-dependent redox potentials.[282] This suggests, as with the cytochromes, a possible role of Fe−S centers in the operation of proton pumps in membranes. Nevertheless, many ferredoxins, such as that of *C. pasteurianum*, show a constant value of $E°'$ from pH 6.3 to 10[296] and appear to be purely electron carriers.

Both the iron and labile sulfur can be removed from Fe−S proteins and the active proteins can often be reconstituted by adding sulfide and Fe^{2+} ions. Using this approach, the natural isotope ^{56}Fe (nuclear spin zero) has been exchanged with ^{57}Fe, which has a magnetic nucleus[297] and ^{32}S has been replaced by ^{77}Se. The resulting proteins appear to function naturally and give EPR spectra containing hyperfine lines that result from interaction of these nuclei with unpaired electrons in the Fe_4S_4 clusters (Fig. 16-17). These observations suggest that electrons accepted by Fe_4S_4 clusters are not localized on a single type of atom but interact with nuclei of both Fe and S. The native proteins as well as many mutant forms are being studied by NMR[299,300] and other spectroscopic techniques (Fig. 16-18),[260] by theoretical computations,[301–304] and by protein engineering and "rational design."[305,306]

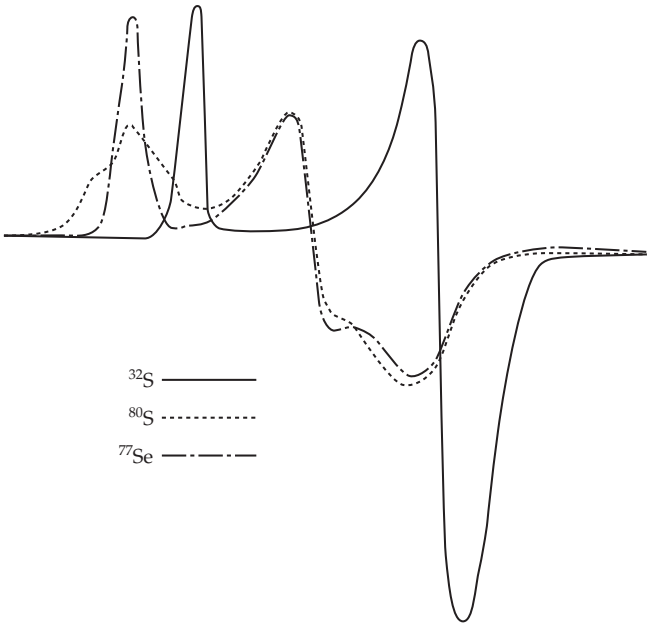


Figure 16-17 Electron paramagnetic resonance spectrum of the Fe−S protein putidaredoxin in the natural form (^{32}S) and with labile sulfur replaced by selenium isotopes. Well-developed shoulders are seen in the low-field end of the spectrum of the ^{77}Se (spin = 1/2)-containing protein. From Orme-Johnson *et al.*[298] Courtesy of W. H. Orme-Johnson.

Functions of iron–sulfur enzymes. Numerous iron−sulfur clusters are present within the membrane-bound electron transport chains discussed in Chapter 18. Of special interest is the Fe_2S_2 cluster present in a protein isolated from the cytochrome *bc* complex (complex III) of mitochondria. First purified by Rieske *et al.*,[307] this protein is often called the **Rieske iron–sulfur protein**.[308] Similar proteins are found in cytochrome *bc* complexes of chloroplasts.[125,300,309,310] In

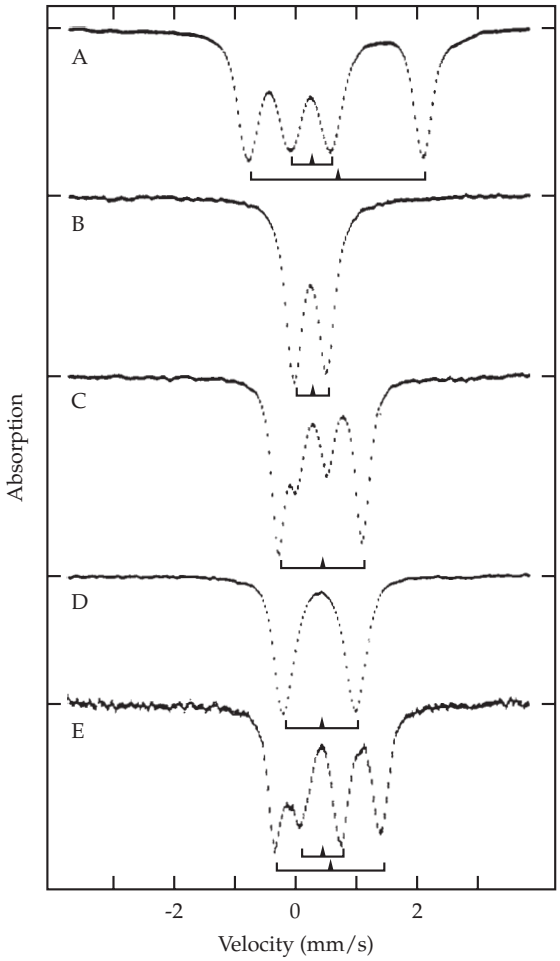

Figure 16-18 Mössbauer X-ray absorption spectra of iron−sulfur clusters. (See Chapter 23 for a brief description of the method.) Quadrupole doublets are indicated by brackets and isomer shifts are marked by triangles. (A) $[Fe_2S_2]^{1+}$ cluster of the Rieske protein from *Pseudomonas mendocina*, at temperature T = 200 K. (B) $[Fe_3S_4]^{1+}$ state of *D. gigas* ferredoxin II, T = 90 K. (C) $[Fe_3S_4]^{0}$ state of *D. gigas* ferredoxin II, T = 15 K. (D) $[Fe_4S_4]^{2+}$ cluster of *E. coli* FNR protein, T = 4.2 K. some bacteria Rieske-type proteins deliver electrons to oxygenases.[300] The 196-residue mitochondrial protein has an unusually high midpoint potential, E_m of ~ 0.30 V. The Fe_2S_2 cluster, which is visible in the atomic structure of complex III shown in Fig. 18-8, is coordinated by two cysteine thiolates and two histidine side chains. In a *Rhodobacter* protein they occur in the following conserved sequences:[311] C133-T-H-L-G-C138 and C153-P-C-H-G-S158. One iron is bound by C133 and C153 and the other by H135 and H156 as follows:

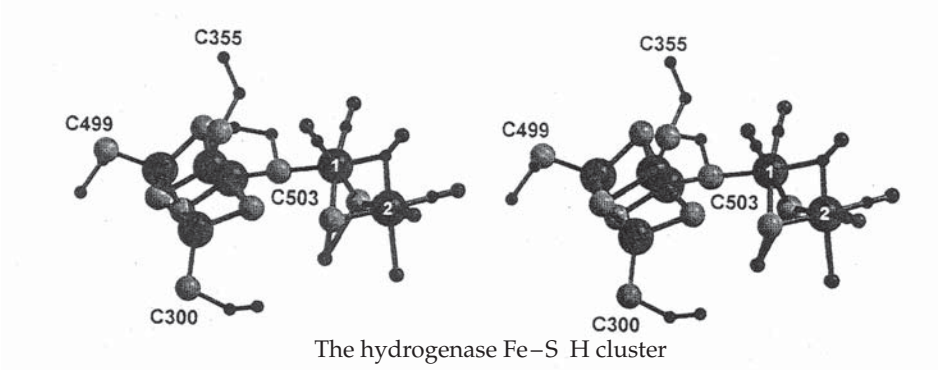
These proteins may also have an ionizable group with a pK_a of ~8.0, perhaps from one of the histidines that is linked to the oxidation–reduction reaction.

Iron–sulfur clusters are found in flavoproteins such as NADH dehydrogenase (Chapter 18) and trimethylamine dehydrogenase (Fig. 15-9) and in the siroheme-containing **sulfite reductases** and **nitrite reductases**.[312] These two reductases are found both in bacteria and in green plants. Spinach nitrite reductase,[313] which is considered further in Chapter 24, utilizes reduced ferredoxin to carry out a six-electron reduction of NO_2^- to NH_3 or of SO_3^{2-} to S^{2-}. The 61-kDa monomeric enzyme contains one siroheme and one Fe_4S_4 cluster. A sulfite reductase from *E. coli* utilizes NADPH as the reductant. It is a large $\beta_8\alpha_4$ oligomer.[312] The 66-kDa α chains contain bound flavin (4 FAD + 4 FMN),[312,314,315] while the 64-kDa β subunits contain both siroheme and a neighboring Fe_4S_4 cluster (Fig. 16-19).[89,304,312,316] The iron of the siroheme and the closest iron atom of the cluster are bridged by a single sulfur atom of a cysteine side chain.

A somewhat similar double cluster is present in **all-Fe hydrogenases** from *Clostridium pasteurianum*.[316a,b,c] These enzymes also contain two or three Fe_4S_4 clusters and, in one case, an Fe_2S_2 cluster.[316a] At the presumed active site a special **H cluster** consists of an Fe_3S_4 cluster with one cysteine sulfur atom shared by an adjoining Fe_2S_2 cluster: Because many hydrogenases contain nickel, their chemistry and functions are discussed in Section C,2.

The role of the iron–sulfur clusters in many of the proteins that we have just considered is primarily one of single-electron transfer. The Fe–S cluster is a place for an electron to rest while waiting for a chance to react. There may sometimes be an associated proton pumping action. In a second group of enzymes, exemplified by aconitase (Fig. 13-4), an iron atom of a cluster functions as a **Lewis acid** in facilitating removal of an –OH group in an α,β dehydration of a carboxylic acid (Chapter 13). A substantial number of other bacterial dehydratases as well as an important plant dihydroxyacid dehydratase also apparently use Fe–S clusters in a catalytic fashion.[317] Fumarases A and B from *E. coli*,[317] L-serine dehydratase of a *Peptostreptococcus* species,[317–319] and the dihydroxyacid



The hydrogenase Fe–S H cluster

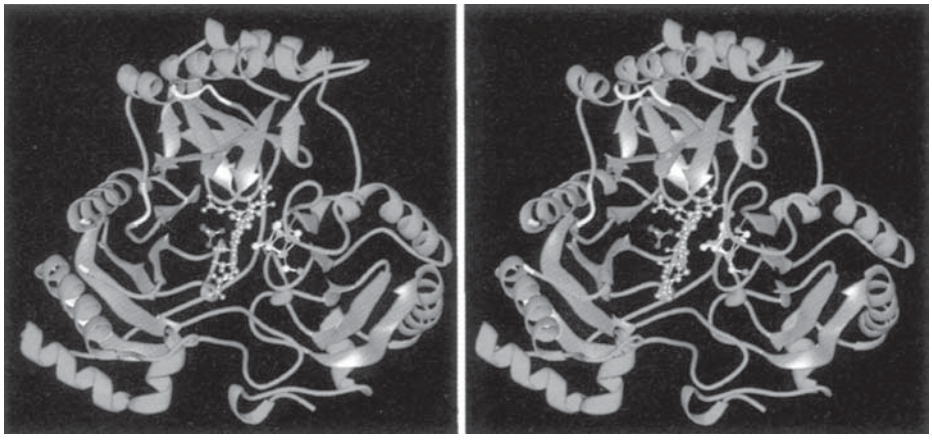


Figure 16-19 Stereoscopic view of *E. coli* assimilatory sulfite reductase. The siroheme (Fig. 16-6) is in the center with one edge toward the viewer and the Fe_4S_4 cluster is visible on its right side. A single S atom from a cysteine side chain bridges between the Fe of the siroheme and the Fe_4S_4 cluster. A phosphate ion is visible in the sulfite-binding pocket at the left center of the siroheme. From Crane *et al.*[312] Courtesy of E. D. Getzoff.

dehydratase[320,321] may all use their Fe_4S_4 clusters in a manner similar to that of aconitase (Eq. 13-17). However, the Fe–S enzymes that dehydrate *R*-lactyl-CoA to crotonyl-CoA,[322] 4-hydroxybutyryl-CoA to crotonyl-CoA,[323,324] and *R*-2-hydroxyglutaryl-CoA to *E*-glutaconyl-CoA[325] must act by quite different mechanisms, perhaps similar to those utilized in vitamin B_{12}-dependent reactions. In these enzymes, as in pyruvate formate lyase (Eq. 15-38), the Fe–S center may act as a radical generator.

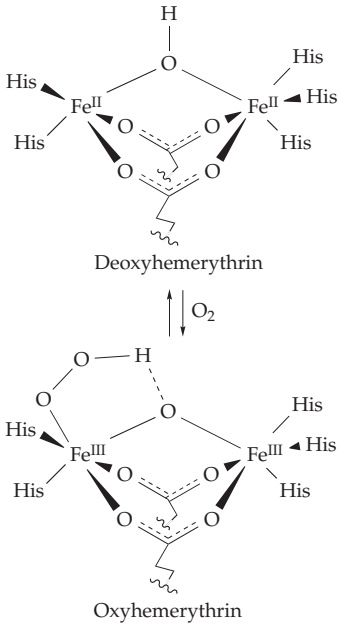
The molybdenum-containing enzymes considered in Section F also contain Fe–S clusters. Nitrogenases (Chapter 24) contain a more complex Fe–S–Mo cluster. Carbon monoxide dehydrogenase (Section C) contains 2 Ni, ~11 Fe, and 14 S^{2-} as well as Zn in a dimeric structure. In these enzymes the Fe–S clusters appear to participate in catalysis by undergoing alternate reduction and oxidation.

For a few enzymes such as aconitase and amido-transferases,[326] an Fe–S cluster plays a **regulatory role** in addition to or instead of a catalytic function.[327] Cytosolic aconitase is identical to **iron regulatory proteins 1** (IRP1), which binds to iron responsive elements in RNA to inhibit translation of genes asso-ciated with iron uptake. A high iron concentration promotes assembly of the Fe_4S_4 cluster (see Chapter 28, Section C,6). Another example is provided by the *E. coli* transcription factor SOXR. This protein, which controls a cellular defense system against oxygen-derived superoxide radicals, contains two Fe_2S_2 centers. Oxidation of these centers by superoxide radicals appears to induce the transcription of genes encoding superoxide dismutase and other proteins involved in protecting cells against oxidative injury (Chapter 18).[328–330]

8. The (μ-oxo) Diiron Proteins

Both the ferroxidase center of ferritin (Fig. 16-4) and the oxygen-carrying hemerythrin are members of a family of diiron proteins with similar active site structures.[331,332] The pair of iron atoms, with the bridging (μ) ligands such as O_2, HO^-, HOO^-, O_2^{2-}, is often held between four α helices, as can be seen in Fig. 2-22 and in Fig. 16-20C. In most cases each iron is ligated by at least one histidine, one glutamate side chain, and frequently a tyrosinate side chain. As many as three side chains may bind to each iron. In addition, one or two carboxylate groups from glutamate or aspartate side chains bridge to both irons, as does the μ-oxo group, which is typically H_2O or ^-OH. Examples of this structure are illustrated in Figs. 16-4 and 16-20. Although the active sites of all of the diiron proteins appear similar, the chemistry of the catalyzed reactions is varied.

Hemerythrin. When both iron atoms are in the Fe(II) state, hemerythrin, like hemoglobin, functions as a carrier of O_2. In the oxidized Fe(III) **methemerythrin** form the iron atoms are only 0.32 nm apart. Three bridging (μ) groups lie between them: two carboxylate groups and a single oxygen atom which may be either O^{2-} or OH^-. One coordination position on one of the hexacoordinate iron atoms is open and appears to be the site of binding of oxygen. The O_2 is thought to accept two electrons, oxidizing the two iron atoms to Fe(III) and itself becoming a peroxide dianion O_2^{2-}. The process is completely reversible. The conversion of the oxygen to a bound peroxide ion is supported by studies of resonance Raman spectra (see Chapter 23) which also suggest that the peroxide group is protonated. In the diferrous protein the μ-oxo bridge is thought to be an ^-OH group. Upon oxygenation the proton could be shared with or donated to the peroxo group (Eq. 16-20).[334] A similar binding of O_2 as a peroxide dianion appears to occur in the copper-containing hemocyanins (Section C,3).



(16-20)

Purple acid phosphatases. Diiron-tyrosinate proteins with acid phosphatase activity occur in mammals, plants, and bacteria. Most are basic glycoproteins with an intense 510- to 550-nm light absorption band. Well-studied members come from beef spleen, from the uterine fluid of pregnant sows (**uteroferrin**),[335] and from human macrophages and osteoclasts.[336–336b] One of the two iron atoms is usually in the Fe(III) oxidation state, but the second can be reduced to Fe(II) by mild reductants such as ascorbate. This half-reduced form is enzymatically active and has a pink color and a characteristic EPR signal. Treatment with oxidants such as H_2O_2 or hexacyannoferrate (III)

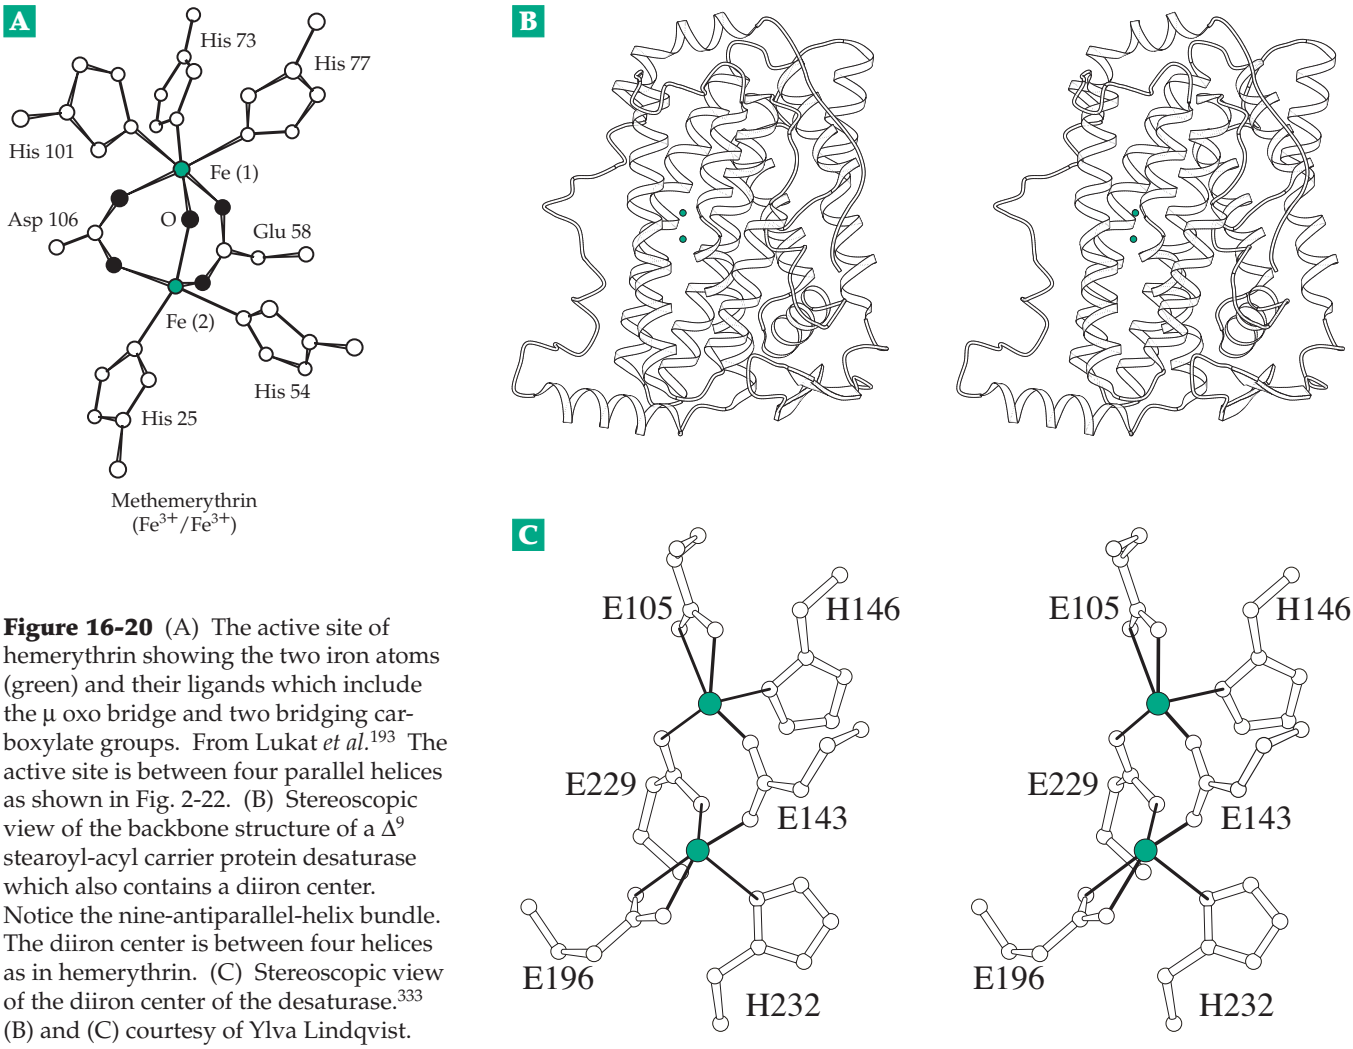


Figure 16-20 (A) The active site of hemerythrin showing the two iron atoms (green) and their ligands which include the μ oxo bridge and two bridging carboxylate groups. From Lukat *et al.*[193] The active site is between four parallel helices as shown in Fig. 2-22. (B) Stereoscopic view of the backbone structure of a Δ^9 stearoyl-acyl carrier protein desaturase which also contains a diiron center. Notice the nine-antiparallel-helix bundle. The diiron center is between four helices as in hemerythrin. (C) Stereoscopic view of the diiron center of the desaturase.[333] (B) and (C) courtesy of Ylva Lindqvist.

generates purple inactive forms which lack a detectable EPR signal.[337,338] The Fe^{3+} of the active enzyme can be replaced[339] with Ga^{3+} and the Fe^{2+} with Zn^{2+} with retention of activity; also, some plants contain phosphatases with Fe–Zn centers.[340,341] The catalytic mechanism resembles those of other metallophosphatases (Chapter 12) and the change of oxidation state of the Fe may play a regulatory role. On the other hand, a principal function of uteroferrin may be in transplacental transport of iron to the fetus.[342]

Diiron oxygenases and desaturases. In the (μ-oxo) diiron oxygenases O_2 is initially bound in a manner similar to that in hemerythrin but one atom of the bound O_2 is reduced to H_2O using electrons supplied by a cosubstrate such as NADPH. The other oxygen atom enters the substrate. This is illustrated by Eq. 16-21 for methane monooxygenase.[332,343–345] A toluene monooxygenase has similar properties.[346]

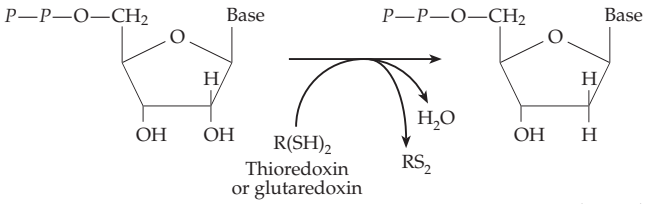
$$CH_4 + NADH + H^+ + O_2 \rightarrow CH_3OH + NAD^+ + H_2O \quad (16\text{-}21)$$

In green plants a soluble Δ^9 stearoyl-acyl carrier protein desaturase uses O_2 and NADH or NADPH to introduce a double bond into fatty acids. The structure of this protein (Fig. 16-20B,C) is related to those of methane oxygenase and ribonucleotide reductase.[333,347] The desaturase mechanism is discussed in Chapter 21.

9. Ribonucleotide Reductases

Ribonucleotides are reduced to the 2'-deoxyribonucleotides (Eq. 16-21) that are needed for DNA synthesis by enzymes that act on either the di- or triphosphates of the purine and pyrimidine nucleosides[348–351] (Chapter 25). These ribonucleotide reductases utilize either thioredoxin or glutaredoxin (Box 15-C) as the immediate hydrogen donors (Eq. 16-22). The pair of closely spaced –SH groups in the reduced thioredoxin or glutaredoxin are converted into a disulfide bridge at the same time that the 2'-OH of the ribonucleotide di- (or tri-) phosphate is converted to H_2O. While some organisms employ a vitamin B_{12}-

dependent enzyme for this purpose, most utilize iron–tyrosinate enzymes (Class I ribonucleotide reductases). These are two-protein complexes of composition $\alpha_2\beta_2$. The enzyme from *E. coli* contains 761-residue α chains and 375-residue β chains. That from *Salmonella typhimurium*[351a] is similar, as are corresponding mammalian enzymes and a virus-encoded ribonucleotide reductase formed in *E. coli* following infection by T4 bacteriophage.[352] In every case the larger α_2 dimer, which is usually called the **R1 protein**, contains the substrate binding sites, allosteric effector sites, and redox-active SH groups. Each α chain is folded into an unusual $(\alpha/\beta)_{10}$ barrel.[353,354] As in the more familiar $(\alpha/\beta)_8$ barrels, the active site is at the N termini of the β strands.

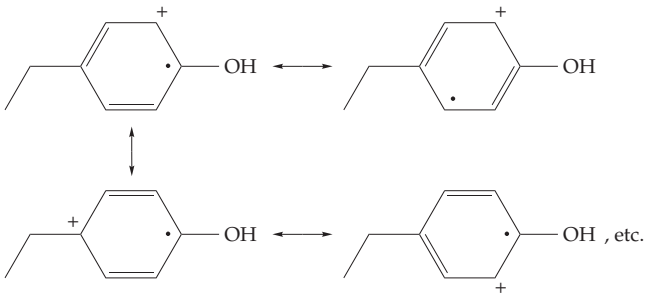


(16-22)

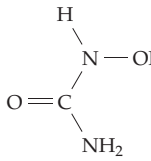
Each polypeptide chain of the β_2 dimer or **R2 protein** contains a diiron center which serves as a free radical generator.[354a,b,c] A few bacteria utilize a dimanganese center.[355] Oxygenation of this center is linked to the uptake of both a proton and an electron and to the removal of a hydrogen atom from the ring of tyrosine 166 to form H_2O and an organic radical (Eq. 16-23):[356–360]

$$2\ Fe(II)^{2+} + O_2 + H^+ + e^- + Y122\text{-}OH \rightarrow Fe(III)^{3+} - O^{2-} - Fe(III)^{3+} - Y122 - O\bullet + H_2O \quad (16\text{-}23)$$

The tyrosyl radical is used to initiate the ribonucleotide reduction at the active site in the R1 protein ~3.5 nm away. The tyrosyl radical is very stable and was discovered by a characteristic EPR spectrum of isolated enzyme. Alteration of this spectrum when bacteria were grown in deuterated tyrosine indicated that the radical is located on a tyrosyl side chain and that the spin density is delocalized over the tyrosyl ring.[361,362] Using protein engineering techniques the ring was located as Tyr 122 of the *E. coli* enzyme. A few of the resonance structures that can be used to depict the radical are the following:



A chain of hydrogen-bonded side chains apparently provides a pathway for transfer of an unpaired electron from the active site to the Tyr 122 radical and from there to the radical generating center.[363] The tyrosyl radical can be destroyed by removal of the iron by exposure to O_2 or by treatment of ribonucleotide reductases with hydroxyurea, which reduces the radical and also destroys catalytic activity:



Hydroxyurea

A second group of ribonucleotide reductases (Class II), found in many bacteria, depend upon the cobalt-containing **vitamin B_{12} coenzyme** which is discussed in Section B. These enzymes are monomeric or homodimeric proteins of about the size of the larger α subunits of the Class I enzymes. The radical generating center is the 5'-deoxyadenosyl coenzyme.[350,364,365]

Class III or **anaerobic nucleotide reductases** are used by various anaerobic bacteria including *E. coli* when grown anaerobically[350,366–369a] and also by some bacteriophages.[370] Like the Class I reductases, they have an $\alpha_2\beta_2$ structure but each β subunit contains an Fe_4S_4 cluster which serves as the free radical generator,[369] that forms a stable glycyl radical at G580.[369a] In this respect the enzyme resembles pyruvate formate-lyase (Eq. 15-40). As with other enzymes using Fe_4S_4 clusters as radical generators, *S*-adenosylmethionine is also required. All ribonucleotide reductases may operate by similar radical mechanisms.[350,351]

When a 2'-Cl or -F analog of UDP was used in place of the substrate an irreversible side reaction occurred by which Cl^- or F^-, inorganic pyrophosphate, and uracil were released.[349] When one of these enzyme-activated inhibitors containing ^3H in the 3' position was tested, the tritium was shifted to the 2' position with loss of Cl^- and formation of a reactive 3'-carbonyl compound (Eq. 16-24) that can undergo β elimination at each end to give an unsaturated ketone which inactivates the enzyme. This suggested that the Fe-tyrosyl radical abstracts an electron (through a

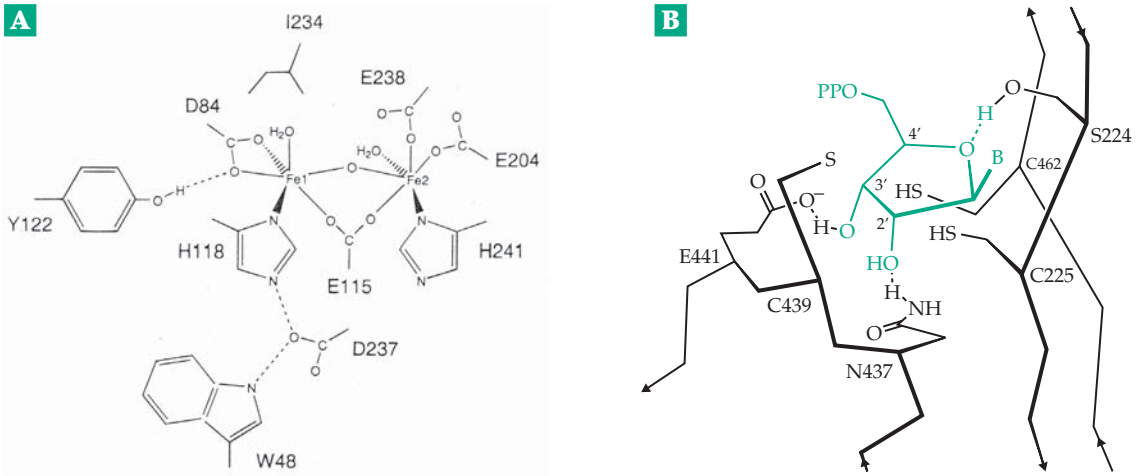


Figure 16-21 (A) Scheme showing the diiron center of the R2 subunit of *E. coli* ribonucleotide reductase. Included are the side chains of tyrosine 122, which loses an electron to form a radical, and of histidine 118, aspartate 237, and tryptophan 48. These side chains provide a pathway for radical transfer to the R1 subunit where the chain continues to tyrosines 738 and 737 and cysteine 429.[354a–c] From Andersson *et al.*[354c] (B) Schematic drawing of the active site region of the *E. coli* class III ribonucleotide reductase with a plausible position for a model-built substrate molecule. Redrawn from Lenz and Giese[373] with permission.

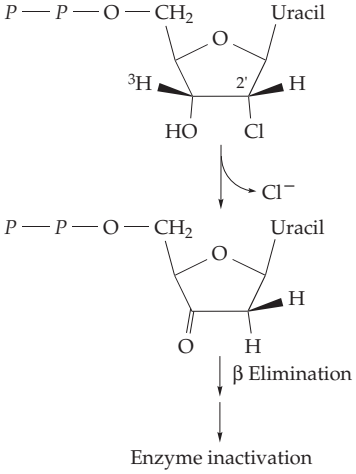
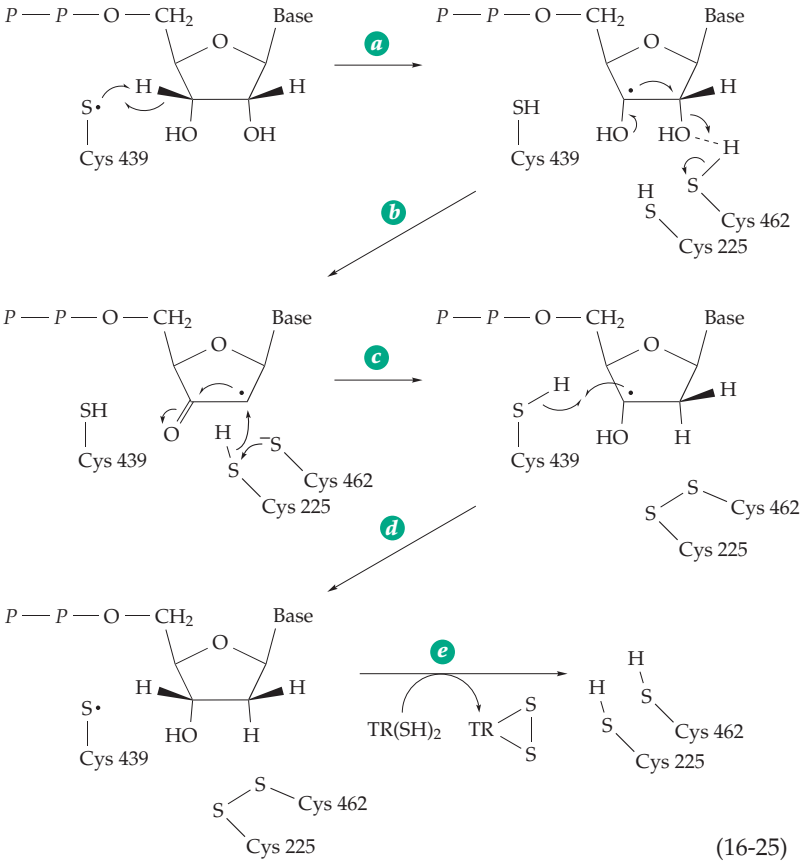
chain of intermediate groups) from an –SH group, now identified as C439 in the *E. coli* enzyme[371–372] (Fig. 16-21). The resulting thiyl radical is thought to abstract a hydrogen atom from C′-3 of a true substrate to form a substrate radical (Eq. 16-25, step *a*) which, with the help of the C462 –SH group, facilitates the loss of $^{-}$OH from C-2 in step *b*. The resulting C2 radical would be reduced by the nearby redox-active thiol pair C462 and C225 (Fig. 16-21 and Eq. 16-25, step *c*). In Eq. 16-25 the reaction is shown as a hydride transfer with an associated one-electron shift but the mechanism is uncertain. In step *d* of Eq. 16-25 the thiyl radical is regenerated and continues to function in subsequent rounds of catalysis. In the final step (step *e*) the redox active pair is reduced by reduced thioredoxin or glutaredoxin. The active site must open to release the product and to permit this reduction, which may involve participation of still other –SH groups in the protein.



(16-24)



(16-25)

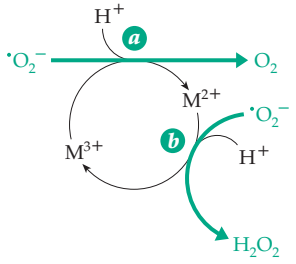
10. Superoxide Dismutases

Metalloenzymes of at least three different types catalyze the destruction of superoxide radicals that arise from reactions of oxygen with heme proteins, reduced flavoproteins, and other metalloenzymes. These superoxide dismutases (SODs) convert superoxide anion radicals $^{\bullet}O_2^-$ into H_2O_2 and O_2 (Eq. 16-26). The H_2O_2 can then be destroyed by catalase (Eq. 16-8).

$$2\ O_2^- + 2\ H^+ \longrightarrow H_2O_2 + O_2 \qquad (16\text{-}26)$$

The much studied Cu / Zn superoxide dismutase of eukaryotic cytoplasm is described in Section D. However, eukaryotic mitochondria contain manganese SOD and some eukaryotes also synthesize an iron-containing SOD. For example, the protozoan *Leishmania tropica*, which takes up residence in the phagolysosomes of a victim's macrophages, synthesizes an iron-containing SOD[374] to protect itself against superoxide generated by the macrophages. *Mycobacterium tuberculosis* secretes an iron SOD which assists its survival in living tissues and is also a target for the immune response of human hosts.[375]

Iron and manganese SODs have ~20-kDa subunits in each of which a single ion of Fe or Mn is bound by three imidazole groups and a carboxylate group.[376,377] The metal ion undergoes a cyclic change in oxidation state as illustrated by Eq. 16-27. Notice that two protons must be taken up for formation of H_2O_2. In Cu / Zn SOD the copper cycles between Cu^{2+} and Cu^+. The structure of the active site of an Fe SOD is shown in Fig. 16-22. That of Mn SOD is almost identical.[376] In addition to the histidine and carboxylate ligands, the metal binds a hydroxyl ion ^-OH or H_2O and has a site



(16-27)

open for binding of $^{\bullet}O_2^-$. As indicated in Eq. 16-27, uptake of one proton is associated with each reaction step. As illustrated in Fig 16-22 for step *a* of Eq. 16-27, the first proton may be taken up to convert the bound ^-OH to H_2O. The enzyme in the Fe^{2+} form has a pK_a of 8.5 that has been associated with tyrosine 34. Perhaps this residue is involved in the proton uptake process.[378] A similarly located Tyr 41 from *Sulfolobus* is covalently modified, perhaps by phosphorylation.[378a]

B. Cobalt and Vitamin B_{12}

The human body contains only about 1.5 mg of cobalt, almost all of it is in the form of **cobalamin**, vitamin B_{12}. Ruminant animals, such as cattle and sheep, have a relatively high nutritional need for cobalt and in regions with a low soil cobalt content, such as Australia, cobalt deficiency in these animals is a serious problem. This need for cobalt largely reflects the high requirement of the microorganisms of the rumen (paunch) for vitamin B_{12}. All bacteria require vitamin B_{12} but not all are able to synthesize it. For example, *E. coli* lacks one enzyme in the biosynthetic

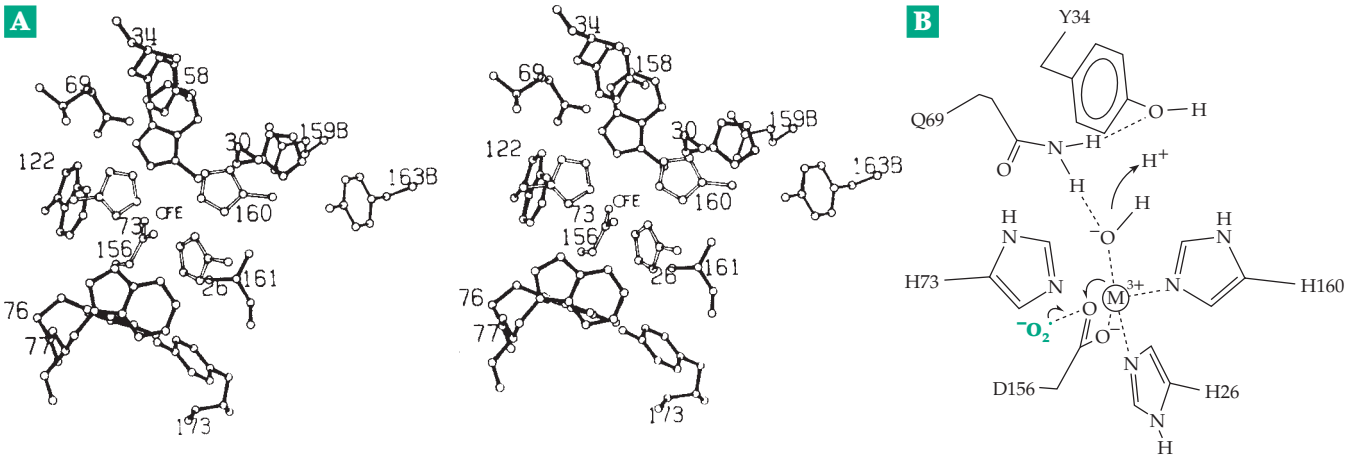


Figure 16-22 (A) Structure of the active site of iron superoxide dismutase from *E. coli*. From Carlioz *et al.*[379] Courtesy of M. Ludwig. (B) Interpretive drawing illustrating the single-electron transfer from a superoxide molecule to the Fe^{3+} of superoxide dismutase and associated proton uptake. Based on Lah *et al.*[376]

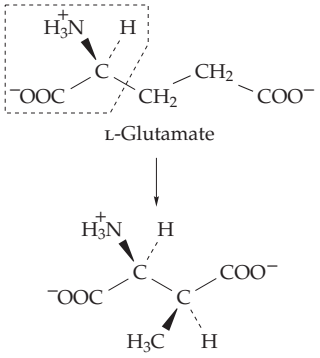
pathway and must depend upon other bacteria to complete the synthesis.

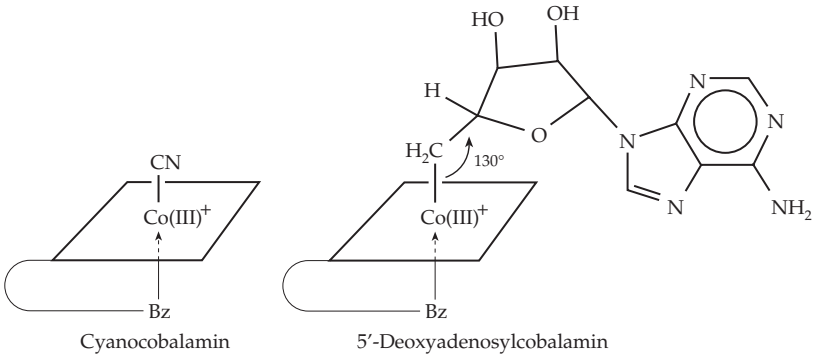
1. Coenzyme Forms

For several years after the discovery of cobalamin its biochemical function remained a mystery, a major reason being the extreme sensitivity of the coenzymes to decomposition by light. Progress came after Barker and associates discovered that the initial step in the anaerobic fermentation of glutamate by *Clostridium tetanomorphum* is rearrangement to β-methylaspartate[380,381] (Eq. 16-28).



(16-28)

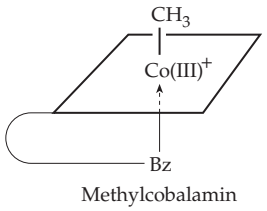
The latter compound can be catabolized by reactions that cannot be used on glutamate itself. Thus, the initial rearrangement is an indispensable step in the energy metabolism of the bacterium. A new coenzyme required for this reaction was isolated in 1958 after it was found that protection from light during the preparation was necessary. The coenzyme was characterized in 1961 by X-ray diffraction[382] as **5'-deoxyadenosylcobalamin**. It is related to cyanocobalamin (Box 16-B) by replacement of the CN group by a 5'-deoxyadenosyl group as indicated in the following abbreviated formulas.[383–385] Here the planes represent the corrin ring system and Bz the dimethylbenzimidazole that is coordinated with the cobalt from below the ring.



The most surprising structural feature is the Co–C single bond of length 0.205 nm. Thus, the coenzyme is an alkyl cobalt, the first such compound found in nature. In fact, alkyl cobalts were previously thought to be unstable. Vitamin B_{12} contains Co(III), and cyanocobalamin can be imagined as arising by replacement of the single hydrogen on the inside of the corrin ring by Co^{3+} plus CN^-. However, bear in mind that three other nitrogens of the corrin ring and a nitrogen of dimethylbenzimidazole also bind to the cobalt. Each nitrogen atom donates an electron pair to form coordinate covalent linkages. Because of resonance in the conjugated double-bond system of the corrin, all four of the Co–N bonds in the ring are nearly equivalent and the positive charge is distributed over the nitrogen atoms surrounding the cobalt.

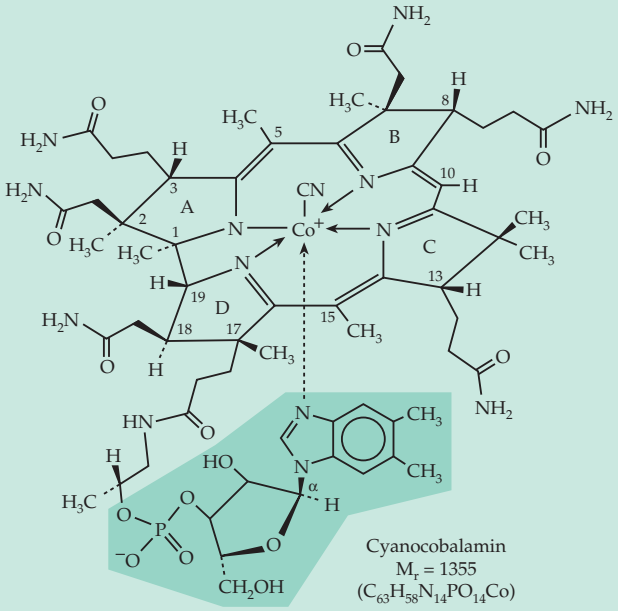
The strength of the axial Co–C bond is directly influenced by the strength of bonding of the dimethylimidazole whose conjugate base has a microscopic pK_a of 5.5.[386] Protonation of this base breaks its bond to cobalt and may thereby strengthen the Co–C bond.[387] Steric factors are also important in determining the strength of this bond. NMR techniques are now playing an important role in investigation of these factors.[386–388]

In both bacteria and liver, the 5'-deoxyadenosyl coenzyme is the most abundant form of vitamin B_{12}, while lesser amounts of **methylcobalamin** are present. Other naturally occurring analogs of the coenzymes include **pseudo vitamin B_{12}** which contains adenine in place of the dimethylbenzimidazole.



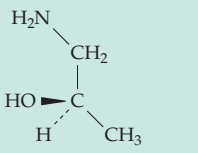
Like dimethylbenzimidazole, it is combined with ribose in the unusual α linkage. A compound called factor A is the vitamin B_{12} analog with 2-methyladenine. Related compounds have been isolated from such sources as sewage sludge which abounds in anaerobic bacteria. It has been suggested that plants may contain vitamin B_{12}-like materials which do not support growth of bacteria. Thus, we may not have discovered all of the alkyl cobalt coenzymes.

BOX 16-B COBALAMIN (VITAMIN B_{12})

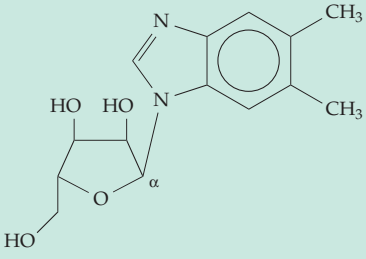


Cyanocobalamin
M_r = 1355
($C_{63}H_{58}N_{14}PO_{14}Co$)

The story of vitamin B_{12} began with pernicious anemia, a disease that usually affects only persons of age 60 or more but which occasionally strikes children.[a] Before 1926 the disease was incurable and usually fatal. Abnormally large, immature, and fragile red blood cells are produced but the total number of erythrocytes is much reduced from 4–6 x 10^6 mm^{-3} to 1–3 x 10^6 mm^{-3}. Within the bone marrow mitosis appears to be blocked and DNA synthesis is suppressed. The disease also affects other rapidly growing tissues such as the gastric mucous membranes (which stop secreting HCl) and nervous tissues. Demyelination of the central nervous system with loss of muscular coordination (ataxia) and psychotic symptoms is often observed.



R-1-Amino-2-propanol



α-Ribofuranoside of dimethylimidazole

In 1926, Minot and Murphy discovered that pernicious anemia could be controlled by eating one-half pound of raw or lightly cooked liver per day, a treatment which not all patients accepted with enthusiasm. Twenty-two years later vitamin B_{12} was isolated (as the crystalline derivative cyanocobalamin) and was shown to be the curative agent. It is present in liver to the extent of 1 mg kg^{-1} or ~10^{-6} M. Although much effort was expended in preparation of concentrated liver extracts for the treatment of pernicious anemia, the lack of an assay other than treatment of human patients made progress slow.

In the early 1940s nutritional studies of young animals raised on diets lacking animal proteins and maintained out of contact with their own excreta (which contained vitamin B_{12}) demonstrated the need for "animal protein factor" which was soon shown to be the same as vitamin B_{12}. The animal feeding experiments also demonstrated that waste liquors from streptomyces fermentations used in production of antibiotics were extremely rich in vitamin B_{12}. Later this vitamin was recognized as a growth factor for a strain of *Lactobacillus lactis* which responded with half-maximum growth to as little as 0.013 μg / l (10^{-11} M).

In 1948, red cobalt-containing crystals of vitamin B_{12} were obtained almost simultaneously by two pharmaceutical firms. Charcoal adsorption from liver extracts was followed by elution with alcohol and numerous other separation steps. Later fermentation broths provided a richer source. Chemical studies revealed that the new vitamin had an enormous molecular weight, that it contained one atom of phosphorus which could be released as P_i, a molecule of aminopropanol, and a ribofuranoside of dimethyl benzimidazole with the unusual α configuration.

Note the relationship of the dimethylbenzimidazole to the ring system of riboflavin (Box 15-B). Several molecules of ammonia could be released from amide linkages by hydrolysis, but all attempts to remove the cobalt reversibly from the ring system were unsuccessful. The structure was determined in 1956 by Dorothy C. Hodgkin and coworkers using X-ray diffraction.[b] At that time, it was the largest organic structure determined by X-ray diffraction. The complete laboratory synthesis was accomplished in 1972.[c]

The ring system of vitamin B_{12}, like that of porphyrins (Fig. 16-5), is made up of four pyrrole rings whose biosynthetic relationship to the corresponding rings in porphyrins is obvious from the structures. In addition, a number of "extra" methyl groups are present. A less extensive conjugated system of double bonds is present in the **corrin** ring of vitamin B_{12} than in porphyrins, and as a result, many chiral centers are found around the periphery

BOX 16-B (continued)

of the somewhat nonplanar rings.

Cyanocobalamin, the form of vitamin B_{12} isolated initially, contains cyanide attached to cobalt. It occurs only in minor amounts, if at all, in nature but is generated through the addition of cyanide during the isolation. **Hydroxocobalamin** (vitamin B_{12a}) containing OH^- in place of CN^- does occur in nature. However, the predominant forms of the vitamin are the coenzymes in which an alkyl group replaces the CN^- of cyanocobalamin.

Intramuscular injection of as little as 3–6 µg of crystalline vitamin B_{12} is sufficient to bring about a remission of pernicious anemia and 1 µg daily provides a suitable maintenance dose (often administered as hydroxocobalamin injected once every 2 weeks). For a normal person a dietary intake of 2–5 µg / day is adequate. There is rarely any difficulty in meeting this requirement from ordinary diets. Vitamin B_{12} has the distinction of being synthesized only by bacteria, and plants apparently contain none. Consequently, strict vegetarians sometimes have symptoms of vitamin B_{12} deficiency.

Pernicious anemia is usually caused by poor absorption of the vitamin. Absorption depends upon the **intrinsic factor**, a mucoprotein (or mucoproteins) synthesized by the stomach lining.[a,d–f] Pernicious anemia patients often have a genetic predilection toward decreased synthesis of the intrinsic factor. Gastrectomy, which decreases synthesis of the intrinsic factor, or infection with fish tapeworms, which compete for available vitamin B_{12} and interfere with absorption, can also induce the disease. Also essential are a plasma membrane receptor[g,h] and two blood transport proteins **transcobalamin**[d,i] and **cobalophilin**. The latter is a glycoprotein found in virtually every human biological fluid and which may protect the vitamin from photodegradation by light that penetrates tissues.[j] A variety of genetic defects involving uptake, transport, and conversion to vitamin B_{12} coenzyme forms are known.[f,k]

Normal blood levels of vitamin B_{12} are ~2×10^{-10} M or a little more, but in vegetarians the level may drop to less than one-half this value. A deficiency of folic acid can also cause megaloblastic anemia, and a large excess of folic acid can, to some extent, reverse the anemia of pernicious anemia and mask the disease.

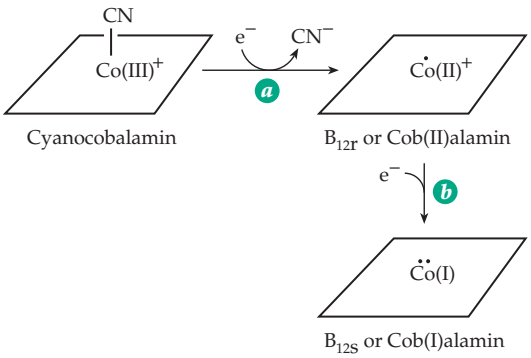
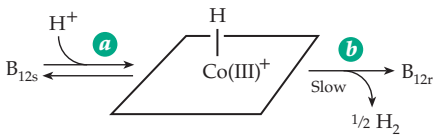
2. Reduction of Cyanocobalamin and Synthesis of Alkyl Cobalamins

Cyanocobalamin can be reduced in two one-electron steps (Eq. 16-29).[385,388] The cyanide ion is lost in the first step (Eq. 16-29, step *a*), which may be accomplished with chromous acetate at pH 5 or by catalytic hydrogenation. The product is the brown paramagnetic compound B_{12r}, a tetragonal low-spin cobalt(II) complex. In the second step (Eq. 16-29, step *b*), an additional electron is added, e.g., from sodium borohydride or from chromous acetate at pH 9.5, to give the gray-green exceedingly reactive B_{12s}. The latter is thought to be in equilibrium with cobalt(III) hydride, as shown in Eq. 16-30, step *a*. The hydride is unstable and breaks down slowly to H_2 and B_{12r} (Eq. 16-30, step *b*).[389]

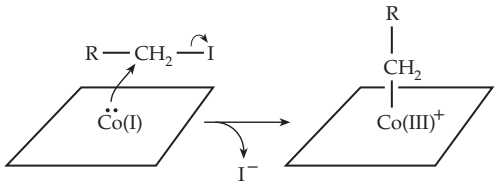


(16-29)



(16-30)

Vitamin B_{12s} reacts rapidly with alkyl iodides (e.g., methyl iodide or a 5'-chloro derivative of adenosine) via nucleophilic displacement to form the alkyl cobalt forms of vitamin B_{12} (Eq. 16-31). These reactions provide a convenient way of preparing isotopically labeled alkyl cobalamins, including those selectively

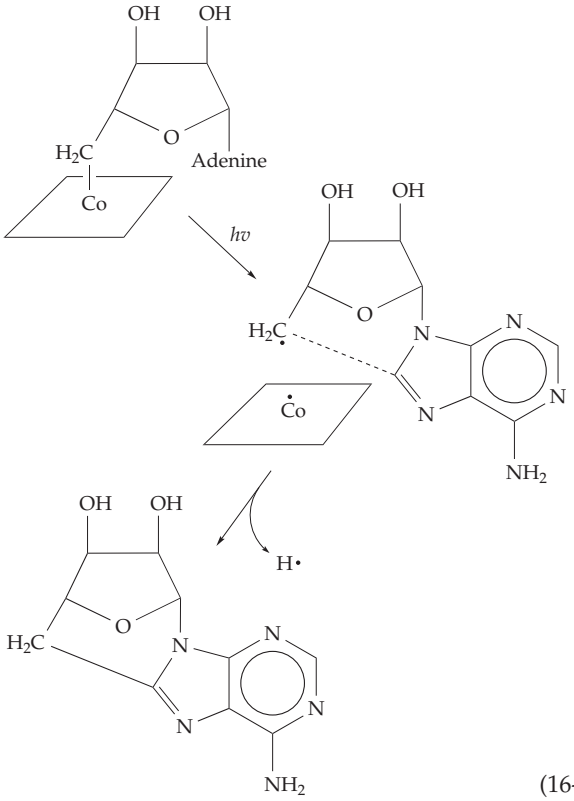


(16-31)

enriched in ^{13}C for use in NMR studies.[390] The biosynthesis of 5'-deoxyadenosylcobalamin utilizes the same type of reaction with ATP as a substrate.[391] A **B_{12s} adenosyltransferase** catalyzes nucleophilic displacement on the 5' carbon of ATP with formation of the coenzyme and displacement of inorganic tripolyphosphate PPP_i.

3. Three Nonenzymatic Cleavage Reactions of Vitamin B_{12} Coenzymes

The 5'-deoxyadenosyl coenzyme is easily decomposed by a variety of agents. Anaerobic irradiation with visible light yields principally vitamin B_{12r} and a cyclic 5',8-deoxyadenosine which is probably formed through an intermediate radical[391a] (Eq. 16-32):

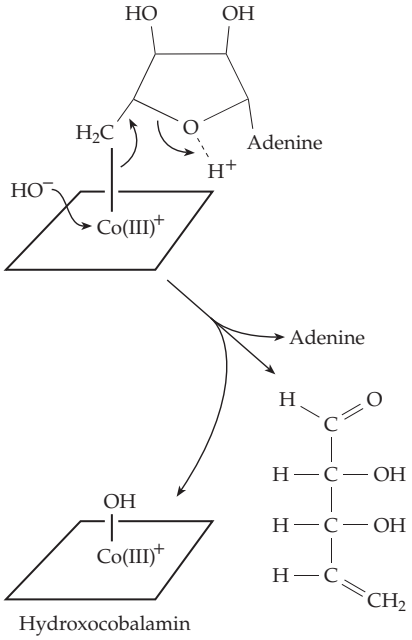


(16-32)

Irradiation in the presence of air gives a variety of products.

Hydrolysis of deoxyadenosylcobalamin by acid (1 M HCl, 100°, 90 min) yields hydroxycobalamin, adenine, and an unsaturated sugar (Eq. 16-33). The initial reaction step is thought to be protonation of the oxygen of the ribose ring.

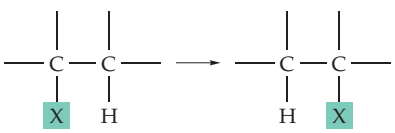
A related cleavage by alkaline cyanide can be viewed as a nucleophilic displacement of the deoxyadenosyl anion by cyanide. The end product is **dicyanocobalamin**, in which the loosely bound nucleotide containing dimethyl benzimidazole is replaced by a second cyanide ion. Methyl and other simple alkyl cobalamins are stable to alkaline cyanide. A number of other cleavage reactions of alkyl cobalamins are known.[392,393]



(16-33)

4. Enzymatic Functions of B_{12} Coenzymes

Three types of enzymatic reactions depend upon alkyl corrin coenzymes. The first is the reduction of ribonucleotide triphosphates by cobalamin-dependent ribonucleotide reductase, a process involving *intermolecular* hydrogen transfer (Eq. 16-21). The second type of reaction encompasses the series of isomerizations shown in Table 16-1. These can all be depicted as in Eq. 16-34. Some group X, which may be attached by a C–C, C–O, or C–N bond, is transferred to an adjacent carbon atom bearing a hydrogen. At the same time,



(16-34)

the hydrogen is transferred to the carbon to which X was originally attached. The third type of reaction is the transfer of methyl groups via methylcobalamin and some related bacterial metabolic reactions.

Cobalamin-dependent ribonucleotide reductase. Lactic acid bacteria such as *Lactobacillus leichmanni* and many other bacteria utilize a 5'-deoxyadenosylcobalamin-containing enzyme to reduce nucleoside triphosphates according to Eq. 16-21. Thioredoxin or dihydrolipoic acid can serve as the hydrogen donor. Early experiments showed that protons from water are reversibly incorporated at C-2' of the reduced nucleotide with retention of configuration. A more important finding was a large kinetic isotope effect of 1.8 when 3'-^{3}H-containing UTP was reduced by the enzyme.[394]

Reaction of the reductase with dihydrolipoic acid in the presence of deoxy-GTP, which apparently serves as an allosteric activator, leads to formation, within a few milliseconds, of a radical with a characteristic EPR spectrum that can be studied when the reaction mixture is rapidly cooled to 130°K. When GTP (a true substrate) is used instead of dGTP, the radical signal reaches a maximum in about 20 ms and then decays. Of the various oxidation states of cobalt (3+, 2+, and 1+)

TABLE 16-1
Isomerization Reactions Involving Hydrogen Transfer and Dependent upon a Vitamin B_{12} Coenzyme

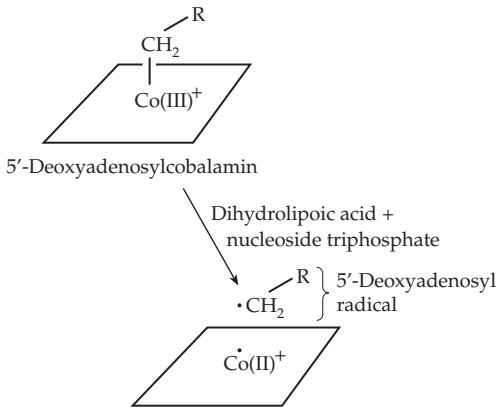
	Methylmalonyl-CoA mutase Isobutyryl-CoA mutase catalyzes the same type of reaction
	α-Methyleneglutarate mutase

only the 2+ state of vitamin B_{12r} is paramagnetic and gives rise to an EPR signal. The electronic absorption spectrum of the coenzyme of ribonucleotide reductase is also changed rapidly by substrate in a way that suggests formation of B_{12r}. Thus, it was proposed that a *homolytic* cleavage occurs to form B_{12r} and a stabilized 5'-deoxyadenosyl radical (Eq. 16-35).[395–396a] However, H^3 is not transferred from the 3' position of the substrate into the deoxyadenosyl part of the coenzyme.[394] The enzyme has many properties in common with the previously discussed iron–tyrosinate ribonucleotide reductases (Fig. 16-21) including limited peptide sequence homology.[350] Stubbe and coworkers suggested that the deoxyadenosyl radical is formed as a radical chain initiator[394,396b] and that the mechanism of ribonucleotide reduction is as shown in Eq. 16-25. Studies of enzyme-activated inhibitors support this mechanism.[364]



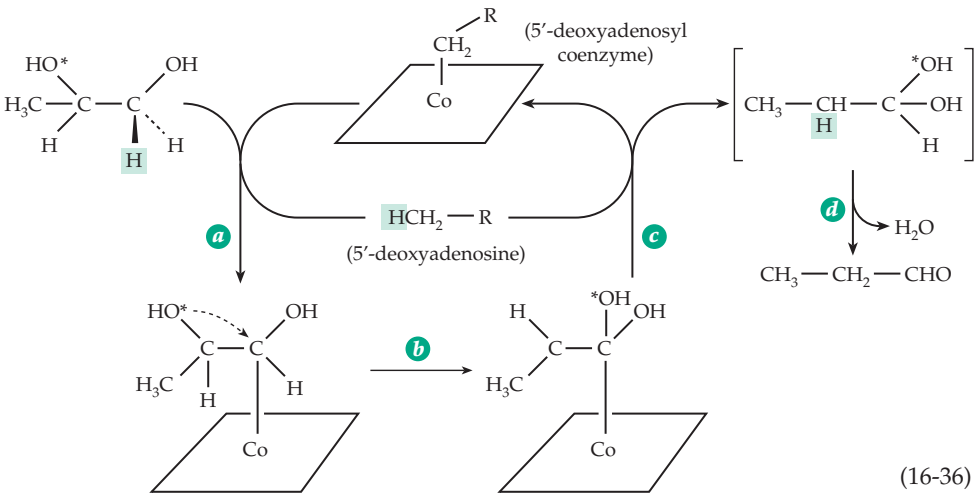
(16-35)

The isomerization reactions. At least 10 reactions of the type described by Eq. 16-34 are known[397] (Table 16-1). They can be subdivided into three groups. First, X = OH or NH_2 in Eq. 16-34; isomerization gives a *geminal*-diol or aminoalcohol that can eliminate H_2O or NH_3 to give an aldehyde. All of these enzymes, which are called **hydro-lyases** or **ammonia-lyases**, specifically require K^+ as well as the vitamin B_{12} coenzyme. Second, X = NH_2 in Eq. 16-34; For this group of **aminomutases** PLP is required as a second coenzyme. Third, X is attached via a carbon atom; the enzymes are called **mutases**. **Methylmalonyl-Co mutase** is required for catabolism of propionate in the human body, and is one of only two known vitamin B_{12}-dependent enzymes. The related isobutyryl-CoA mutase participates in the microbial synthesis of such polyether antibiotics as monensin A.[397a,b] Other mutases are involved in anaerobic bacterial fermentations.

In these reactions the hydrogen is always transferred via the B_{12} coenzyme. No exchange with the medium takes place. Since X may be an electronegative group such as OH, the reactions could all be treated formally as hydride ion transfers but it is more likely that they occur via homolytic cleavages. Such cleavage is indicated by the observation of EPR signals for several of the enzymes in the presence of their substrates.[398]

Abeles and associates showed that when **dioldehydratase** (Table 16-1) catalyzes the conversion of 1,2-[1-^{3}H]propanediol to propionaldehyde, tritium appears in the coenzyme as well as in the final product. When ^{3}H-containing coenzyme is incubated with unlabeled propanediol, the product also contains ^{3}H, which was shown by chemical degradation to be exclusively on C-5'. Synthetic 5'-deoxyadenosyl coenzyme containing ^{3}H in the 5' position transferred ^{3}H to product. Most important, using a mixture of propanediol and ethylene glycol, a small amount of *intermolecular* transfer was demonstrated; that is, ^{3}H was transferred into acetaldehyde, the product of dehydration of ethylene glycol. Similar results were also obtained with ethanolamine ammonia-lyase.[399]

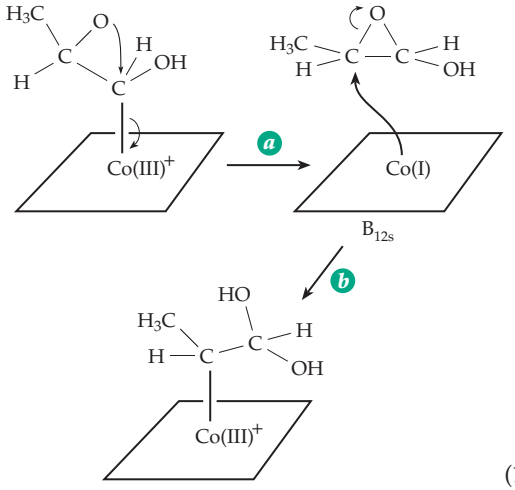
Another important experiment[398] showed that ^{18}O from [2-^{18}O]propanediol was transferred into the 1 position without exchange with solvent. Furthermore, ^{18}O from (*S*)-[1-^{18}O]propanediol was retained in the product while that from the (*R*) isomer was not. Thus, it appears that the enzyme stereospecifically dehydrates the final intermediate. From these and other experiments, it was concluded that initially a 5'-deoxyadenosyl radical is formed via Eq. 16-35. This radical then abstracts the hydrogen atom marked by a shaded box in Eq. 16-36 to form a substrate radical and 5'-deoxyadenosine. One proposal, illustrated in Eq. 16-36, is that the substrate radical immediately recombines with



(16-36)

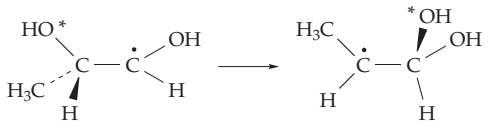
the Co(II) of the coenzyme to form an organo-cobalt substrate compound (step *a* of Eq. 16-36). The 5'-deoxyadenosine now contains hydrogen from the substrate; because of rotation of the methyl group this hydrogen becomes equivalent to the two already present in the coenzyme. The substrate–cobalamin compound formed in this step then undergoes isomerization, which, in the case of dioldehydratase, leads to intramolecular transfer of the OH group (step *b*). In step *c* the hydrogen atom is transferred back from the 5'-deoxyadenosine to its new location in the product and in step *d* the resulting *gem*-diol is dehydrated to form the aldehyde product.[401a]

Carbocation, carboanion, and free radical intermediates have all been proposed for the isomerization step in the reaction. A carbocation would presumably be cyclized to an epoxide which could react with the B_{12s} (Eq. 16-37, step *b*) to complete the isomerization.



(16-37)

At present most evidence favors, for the isomerization reactions, an enzyme-catalyzed rearrangement of the substrate radical produced initially during formation of the 5'-deoxyadenosine (Eq. 16-38).[400–401c]

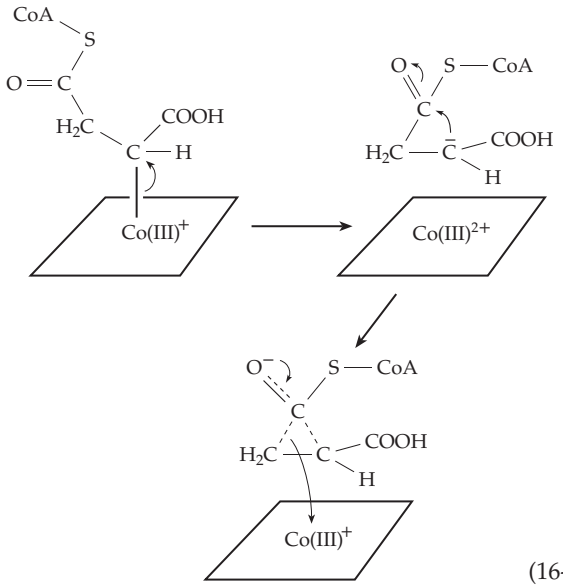


(16-38)

According to this mechanism the Co(II) of the B_{12r} formed in Eq. 16-35 has no active role in the isomerization and does not form an organocobalt intermediate as in Eq. 16-36. Its only role is to be available to recombine with the 5'-deoxyadenosyl radical at the end of the reaction sequence. Support for this interpretation has been obtained from study of model reactions and of organic radicals generated in other ways.[400]

Recently, EPR spectroscopy with ^{2}H- and ^{13}C-labeled glutamates as substrates for glutamate mutase permitted identification of a 4-glutamyl radical as a probable intermediate for that enzyme.[402,402a,b]

On the other hand, for methylmalonyl-CoA mutase Ingraham suggested cleavage of the Co–C bond of an organocobalt intermediate to form a carbanion, the substrate–cobalamin compound serving as a sort of "biological Grignard reagent." The carbanion would be stabilized by the carbonyl group of the thioester forming a "homoenolate anion" (Eq. 16-39). The latter could break up in either of two ways reforming a C–Co bond and causing the isomerization.[403] Some experimental results also favor an ionic or organocobalt pathway.[404]



(16-39)

The three-dimensional structure of methylmalonyl-CoA mutase from *Propionibacterium shermanii* shows that the vitamin B_{12} is bound in a base-off conformation with the dimethylbenzimidazole group bound to the protein far from the corrin ring (Fig. 16-23; see also Fig. 16-24).[405,405a] A histidine of the protein coordinates the cobalt, as also in methionine synthase. The entrance to the deeply buried active site is blocked by the coenzyme part of the substrate. The buried active site may be favorable for free radical rearrangement reactions. The structure of substrate complexes shows that the coenzyme is in the cob(II)alamin (B_{12r}) form with the 5'-deoxyadenosyl group detached from the cobalt, rotated, shifted, and weakly bound to the protein.[405a] Side chains from neighboring Y89, R207, and H244 all hydrogen bond to the substrate. The R207 guanidinium group makes an ion pair with the substrate carboxylate, and the phenolic and imidazole groups may have catalytic functions.[405b,c,d,406] Studies are also in progress on crystalline glutamate mutase.[406,406a]

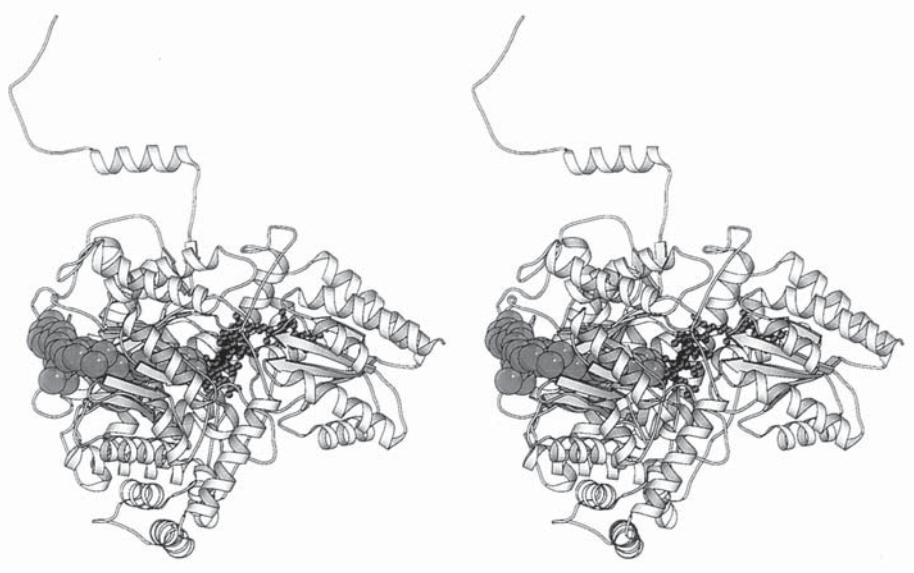


Figure 16-23 Three-dimensional structure of methylmalonyl-CoA mutase from *Propionobacterium shermanii*. The B_{12} coenzyme is deeply buried, as is the active site. A molecule of bound desulfocoenzyme A, a substrate analog, blocks the active site entrance on the left side. From Mancia *et al.*[405] Courtesy of Philip R. Evans.

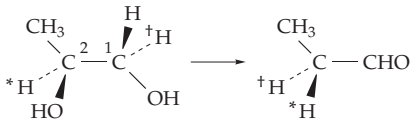
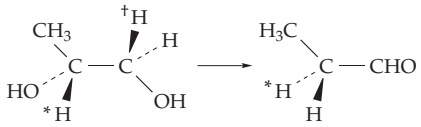
According to all of these mechanisms, 5'-deoxyadenosine is freed from its bond to cobalt during the action of the enzymes. Why then does the deoxyadenosine not escape from the coenzyme entirely, leading to its inactivation? Substrate-induced inactivation is not ordinarily observed with coenzyme B_{12}-dependent reactions, but some quasi-substrates do inactivate their enzymes. Thus, glycolaldehyde converts the coenzyme of dioldehydratase to 5'-deoxyadenosine and ethylene glycol does the same with ethanolamine deaminase. When 5'-deoxyinosine replaces the 5'-deoxyadenosine of the normal coenzyme in dioldehydratase, 5'-deoxyinosine is released quantitatively by the substrate. This suggests that the dehydratase may normally hold the adenine group of 5'-deoxyadenosine through hydrogen bonding to the amino group. Because the OH group of inosine tautomerizes to C=O, inosine may not be held as tightly. The deeply buried active site (Fig. 16-23) may also prevent escape of the deoxyadenosine.

Despite the evidence in its favor, there was initially some reluctance to accept 5'-deoxyadenosine as an intermediate in vitamin B_{12}-dependent isomerization reactions. It was hard to believe that a methyl group could exchange hydrogen atoms so rapidly. It was suggested that protonation of the oxygen of the ribose ring as in Eq. 16-33 might facilitate release of a hydrogen atom. However, substitution of the ring oxygen by CH_2 in a synthetic analog did not destroy the coenzymatic activity.[407] Another possibility is that the methyl group has an unusual reactivity if the cobalt is reduced to Co(II).

Stereochemistry of the isomerization reactions. Dioldehydratase acts on either the (*R*) or (*S*) isomers of 1,2-propanediol (Eqs. 16-40 and 16-41; asterisks and daggers mark positions of labeled atoms in specific experiments).



(*S*)-1,2-Propanediol (16-40)



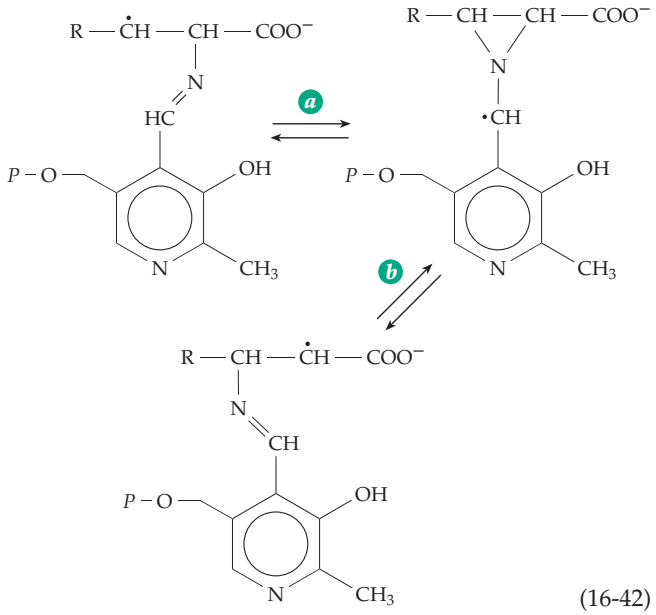
(*R*)-1,2-Propanediol (16-41)

In both cases the reaction proceeds with retention of configuration at C-2 and with stereochemical specificity[408] for one of the two hydrogens at C-1. The reaction catalyzed by methylmalonyl-CoA mutase likewise proceeds with retention of configuration at C-2 (Table 16-1)[409] but the glutamate mutase reaction is accompanied by inversion (Eq. 16-28).

Aminomutases. The enzymes **L-β-lysine mutase** (which is also **D-α-lysine mutase**) and **D-ornithine mutase** catalyze the transfer of an ω-amino group to an adjacent carbon atom[410] (Table 16-1). Two proteins are needed for the reaction; pyridoxal phosphate is required and is apparently directly involved in the amino group migration. In the β-lysine mutase the 6-amino group of L-β-lysine replaces the pro-*S* hydrogen at C-5 but with inversion at C-5 to yield (3*S*, 5*S*)-3,5-diaminohexanoic acid.[411] A bacterial D-lysine 5,6-aminomutase interconverts D-lysine with 2,5-diaminohexanoic acid.[411a] Another related enzyme

is **L-leucine 2,3-aminomutase**, which catalyzes the reversible interconversion of L-leucine and β-leucine.[410,412] It was reported to be present in plants and also in the human body, but the latter could not be confirmed.[413]

The interconversion of L-α-lysine and L-β-lysine is catalyzed by a lysine 2,3-aminomutase found in certain clostridia.[414-415a] This enzyme also requires pyridoxal phosphate and catalyzes a reaction with the same stereochemistry as that of β-lysine mutase. However, it does not contain vitamin B_{12} but depends upon *S*-adenosylmethionine (AdoMet) and an iron–sulfur cluster. The adenosyl group of AdoMet may function in the same manner as does the deoxyadenosyl group of the adenosylcobalamin coenzyme. In these mutases a 5'-deoxyadenosyl radical may abstract a hydrogen atom from the β position of a Schiff base of PLP with the amino acid substrate. The radical isomerizes (Eq. 16-42) and then accepts a hydrogen atom back from the 5'-deoxyadenosine to complete the reaction. Its properties suggest that lysine 2,3-aminomutase is related to the pyruvate formate-lyase of *E. coli* (Eq. 15-37),[410] class I ribonucleotide reductases, and other enzymes that act by homolytic mechanisms.



(16-42)

Transfer reactions of methyl groups. The generation and utilization of methyl groups is a quantitatively important aspect of the metabolism of all cells. As we have seen (Fig. 15-18), methyl groups can be created by the reduction of one-carbon compounds attached to tetrahydrofolic acid. Methyl groups of methyltetrahydrofolic acid (N^5-CH_3THF) can then be transferred to the sulfur atom of homocysteine to form methionine (Eq. 16-43). The latter is converted to *S*-adenosylmethionine, the nearly universal methyl group donor for transmethylation reactions (Eq. 12-3). In some bacteria, fungi, and higher plants, the methyl-THF-homocysteine transmethylase does not depend upon vitamin B_{12} but is a metalloenzyme with zinc at the active center.[416] However, human beings share with certain strains of *E. coli* and other bacteria the need for methylcobalamin.

The structure of the *E. coli* enzyme (Fig. 16-24) shows methylcobalamin bound in a base-off conformation, with histidine 759 of the protein replacing dimethylbenzimidazole in the distal coordination position on the cobalt. This histidine is part of a sequence Asp-X-His-X-X-Gly that is found not only in methionine synthase but also in methylmalonyl-CoA mutase, glutamate mutase, and 2-methyleneglutarate mutase. However, diol dehydratase lacks this sequence and binds adenosylcobalamin with the dimethylbenzimidazole–cobalt bond intact.[417]

The coenzyme evidently functions in a cyclic process. The cobalt alternates between the +1 and +3 oxidation states as shown in Eq. 16-43. The first indication of such a cyclic process was the report by Weissbach that ^{14}C-labeled methylcobalamin could be isolated following treatment of the enzyme with such methyl donors as AdoMet and methyl iodide

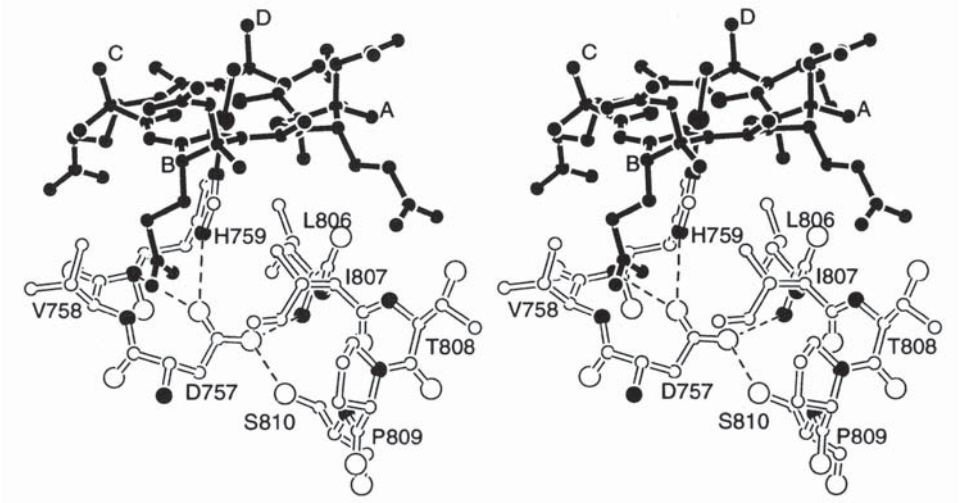


Figure 16-24 Stereoscopic views of the active site of methionine synthase from *E. coli*. Methylcobalamin (black) is in the active site with His 759 of the protein in the distal position of the coenzyme in a base-off conformation. The dimethylbenzimidole nucleotide has been omitted for clarity. Notice the hydrogen-bonded His 759 – D757 – S810 triad. From Jarret *et al.*[418a] Courtesy of R. G. Matthews.

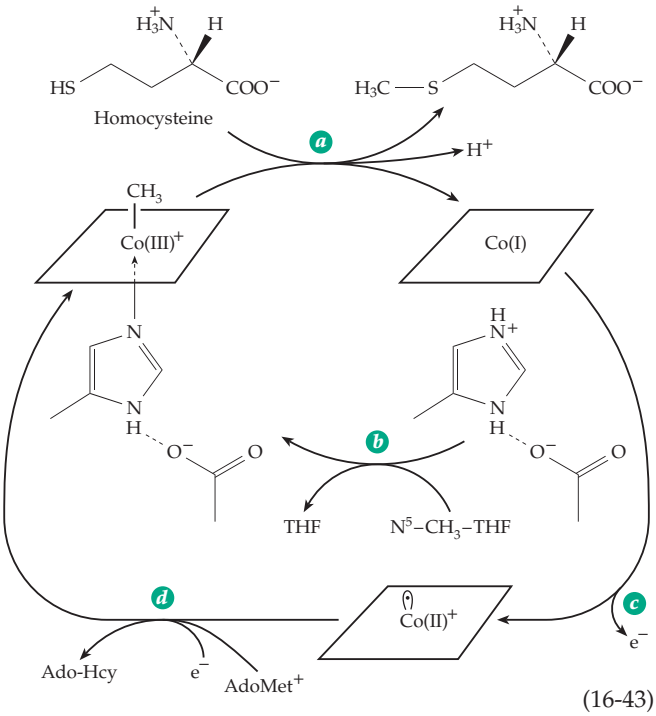
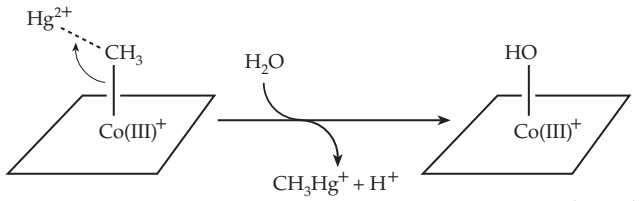


(16-43)

after reduction (e.g., with reduced riboflavin phosphate). The sequence parallels that of Eq. 16-31 for the laboratory synthesis of methylcobalamin. Nevertheless, the transmethylase demonstrates some complexities. Initially, it must be "activated" by AdoMet or methyl iodide, after which it cycles according to Eq. 16-43, steps *a* and *b*, but is gradually inactivated. This apparently happens by oxidation to a Co(II) form of the enzyme (Eq. 16-43, step *c*) that must be reductively methylated with AdoMet and reduced flavodoxin (step *d*) to regenerate the active form.[418] It is also possible that the methyl group is not transferred as a formal CH_3^+ as pictured in Eq. 16-43 but as a $^{\bullet}CH_3$ radical generated by homolytic cleavage of methylcobalamin to cob(II)alamin. Whatever the mechanism, a chiral methyl group is transferred from 5-methyl-THF to homocysteine with overall retention of configuration.[419]

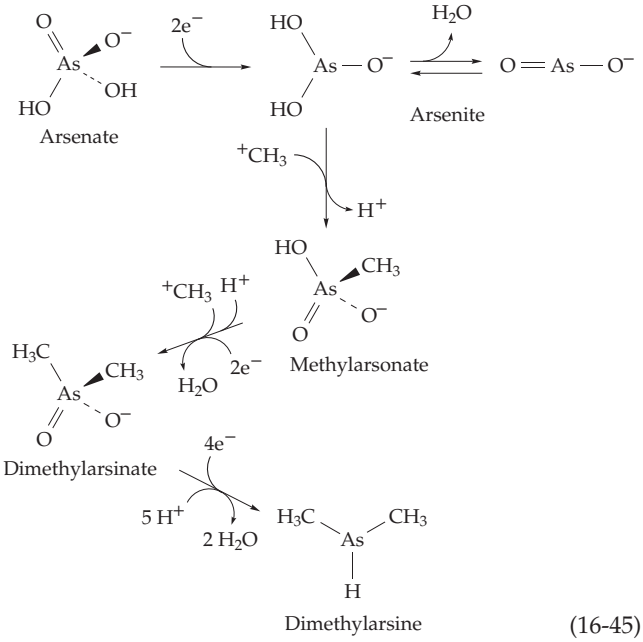
Another important group of methyl transfer reactions are those from methyl corrinoids to mercury, tin, arsenic, selenium, and tellurium. For example, Eq. 16-44 describes the methylation of Hg^{2+}. These reactions are of special interest because of the generation of toxic methyl and dimethyl mercury and dimethylarsine.

Notice that whereas in Eq. 16-43 the methyl group is transferred as CH_3^+ by nucleophilic displacement on a carbon atom, the transfer to Hg^{2+} in Eq. 16-44 is that of a carbanion, CH_3^-, with no valence change occurring in the cobalt. However, it is also possible that transfer occurs as a methyl radical.[420] Methyl corrinoids are able to undergo this type of reaction nonenzymatically, and the ability to transfer a methyl anion is a property of methyl corrinoids not shared by other transmethylating agents such as AdoMet. At the conclusion of the reaction in Eq. 16-44 the cobalt is in the +3 state. To be remethylated, it must presumably be reduced to Co(II). A second methyl group can be transferred by the same type of reaction to form $(CH_3)_2Hg$.



(16-44)

Methylation of arsenic is an important pollution problem because of the widespread use of arsenic compounds in insecticides and because of the presence of arsenate in the phosphate used in household detergents.[421,422] After reduction to arsenite, methylation occurs in two steps (Eq. 16-45). Additional reduction steps result in the formation of **dimethylarsine**, one of the principal products of action of methanogenic bacteria on arsenate. The methyl transfer is shown as occurring through CH_3^+, with an accompanying loss of a proton from the substrate. However, a CH_3 radical may be transferred with formation of a cobalt(II) corrinoid.[423]



(16-45)

Corrinoid-dependent synthesis of acetyl-CoA.

The anaerobic bacterium *Clostridium thermoaceticum* obtains its energy for growth by reduction of CO_2 with hydrogen (Eq. 16-46). One of the CO_2 molecules is reduced to formate which is converted via 5-methyl-THF to the methyl corrinoid 5-methoxybenzimidazolyl-

cobamide. The methyl group of the latter

$$4\,H_2 + 2\,CO_2 \longrightarrow CH_3COO^- + H^+ + 2\,H_2O$$
$$\Delta G'\ (\text{pH } 7) = -94.9\ \text{kJ mol}^{-1} \qquad (16\text{-}46)$$

combines with another CO_2 to form acetyl-CoA. The process, which requires the nickel-containing carbon monoxide dehydrogenase, is discussed in Section C.

C. Nickel

It was not until the 1970s that nickel was first recognized as a dietary essential for animals.[424–426] Nickel-deficient chicks grew poorly, had thickened legs, and developed dermatitis. Tissues of deficient animals contained swollen mitochondria and swollen perinuclear space suggesting a function for Ni in membranes. However, doubts have been raised about the conclusions based on these experiments.[427] Within tissues the nickel content ranges from 1 to 5 μg / l. Some of the metal in serum is present as complexes of low molecular mass and some is bound to serum albumin[428] and to a specific nickel-containing protein of the macroglobulin class, known as **nickeloplasmin**.[429] Nickel is also present in plants; in some, e.g., *Allysum*, it accumulates to high concentrations.[430] It is essential for legumes and possibly for all plants.[431] Nickel uptake proteins have been identified in bacteria and fungi.[432,432a] Because of its ubiquitous occurrence it is difficult to prepare a totally Ni-free diet. The acute toxicity of orally ingested Ni(II) is low, and homeostatic mechanisms exist in the animal body for regulating its concentration. However, the volatile nickel carbonyl $Ni(CO)_4$ is very toxic[426] and Ni from jewelry is a common cause of dermatitis.[428,433]

In its compounds nickel usually has the +2 oxidation state but the +3 and +4 states occur rarely in complexes. The Ni^{2+} ion contains eight 3d electrons, a configuration that favors square-planar coordination of four ligands. However, the ion is also able to form a complex with six ligands and an octahedral geometry. It has been suggested that this "ambivalence" may be of biochemical significance.

Nickel is found in at least four enzymes: **urease**, certain **hydrogenases, methyl-CoM reductase** (in its **cofactor F_{430}**) of methanogenic bacteria, and **carbon monoxide dehydrogenase** of acetogenic and methanogenic bacteria.[434]

1. Urease

Urease, which was first isolated from the jack bean has a special place in biochemical history as the first enzyme to be crystallized. This was accomplished by J. B. Sumner in 1926, and although Sumner eventually obtained the Nobel Prize, his first reports were greeted with skepticism and outright disbelief. The presence of two atoms of nickel in each molecule of urease[435] was not discovered until 1975. The metal ions had been overlooked previously, despite the fact that the absorption spectrum of the purified enzyme contains an absorption "tail" extending into the visible region with a shoulder at 425 nm and weak maxima at 725 and 1060 nm. Urease catalyzes the hydrolytic cleavage of urea to two molecules of ammonia and one of bicarbonate and is useful in the analytical determination of urea.

Jack bean urease is a trimer or hexamer of identical 91-kDa subunits while that of the bacterium *Klebsiella* has an $(\alpha\beta_2\gamma_2)_2$ stoichiometry. Nevertheless, the enzymes are homologous and both contain the same binickel catalytic center (Fig. 16-25).[435–437a] The three-dimensional structure of the *Klebsiella* enzyme revealed that the two nickel ions are bridged by a carbamyl group of a carbamylated lysine. Like ribulose bisphosphate carboxylase (Fig. 13-10), urease also requires CO_2 for formation of the active enzyme.[438] Formation of the metallocenter also requires four additional proteins, including a chaperonin and a nickel-binding protein.[438,439]

The mechanism of urease action is probably related to those of metalloproteases such as carboxypeptidase A (Fig. 12-16) and of the zinc-dependent carbonic

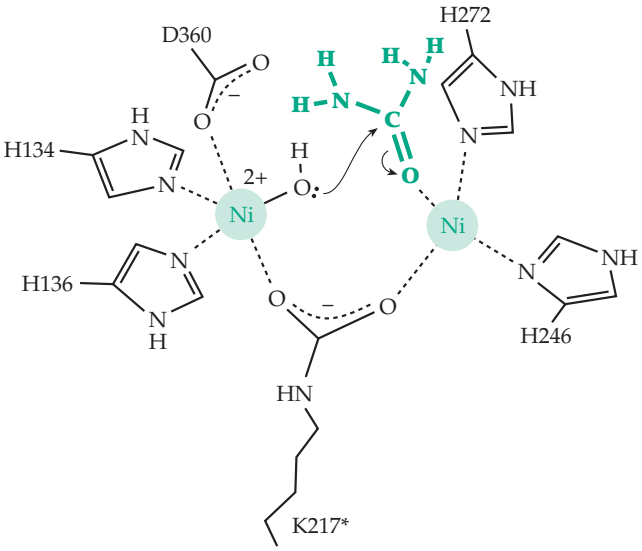


Figure 16-25 The active site of urease showing the two Ni^+ ions held by histidine side chains and bridged by a carbamylated lysine (K217*). A bound urea molecule is shown in green. It has been placed in an open coordination position on one nickel and is shown being attacked for hydrolytic cleavage by a hydroxyl group bound to the other nickel. Based on a structure by Jabri *et al*.[436] and drawing by Lippard.[437]

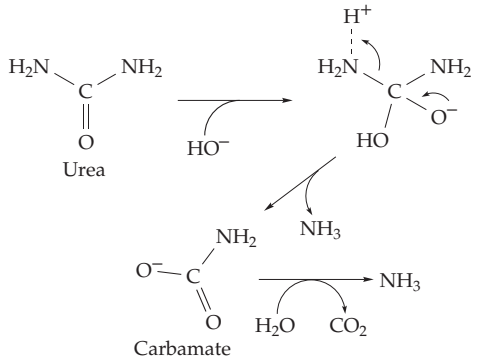


(16-47)

anhydrase (Fig. 13-1). In Fig. 16-25 one nickel ion is shown polarizing the carbonyl group, while the second provides a bound hydroxyl ion that serves as the attacking nucleophile. A probable intermediate product is a carbamate ion (Eq. 16-47).

Urease is an essential enzyme for bacteria and other organisms that use urea as a primary source of nitrogen. The peptic ulcer bacterium *Helicobacter pylori* uses urease to hydrolyze urea in order to defend against the high acidity of the stomach.[439a] The enzyme is also present in plant leaves and may play a necessary role in nitrogen metabolism.[431] In nitrogen-fixing legumes urea derivatives, the **ureides**, have an important function (Chapter 25) but urease may not be involved in the catabolism of these compounds.[440]

2. Hydrogenases

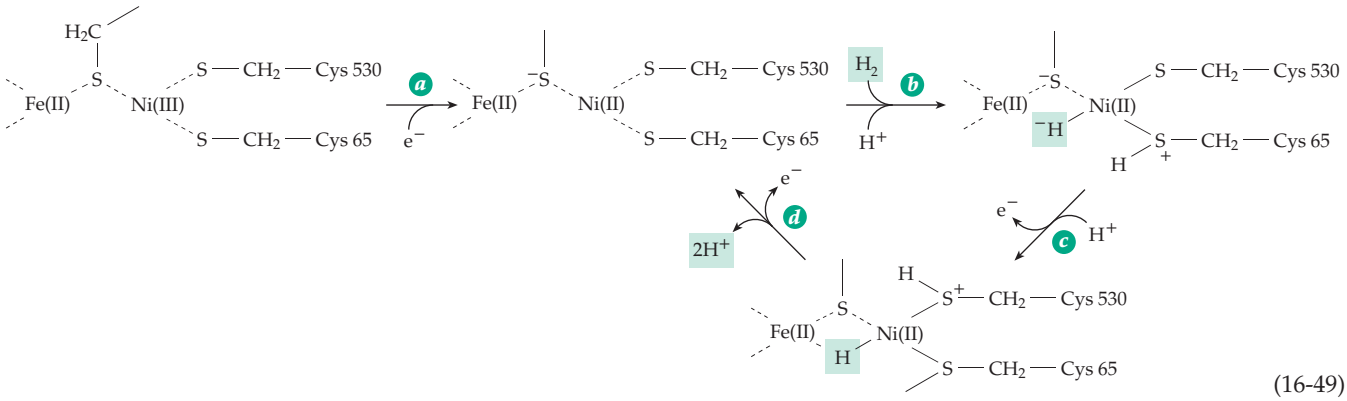
Many plants, animals, and microorganisms are able to evolve H_2 by reduction of hydrogen ions (Eq. 16-48) or to oxidize H_2 by the reverse of this reaction.[441,442]

$$2H^+ + 2e^- \rightarrow H_2 \qquad (16\text{-}48)$$

Hydrogenases have been classified into two main types: **Fe-hydrogenases**, which contain iron as the only metal,[443] and **Ni-hydrogenases**, which contain both iron and nickel.[444] In a few Ni-hydrogenases a selenocysteine residue replaces a conserved cysteine side chain.[445,446] Fe-hydrogenases are often extremely active and are utilized to rid organisms of an excess of electrons by evolution of H_2. Since they may also be used to acquire electrons by oxidation of H_2, they are often described as *bidirectional*. Ni-hydrogenases, as well as some Fe-hydrogenases, are involved primarily in *uptake* of H_2.[447] All hydrogenases contain one or more Fe–S centers in addition to the H_2-forming catalytic center.[441] Some hydrogenases are membrane bound and are often coupled through unidentified carriers to formate dehydrogenase (Chapter 17). In the strict anaerobes such as clostridia, hydrogenases are linked to ferredoxins. Hydrogenases are inactivated readily by O_2, which oxidizes the catalytic centers but can sometimes be reactivated by treatment with reducing agents.[448]

The 60-kDa all-iron monomeric hydrogenase I of *Clostridium pasteurianum* (mentioned on p. 861) contains ferredoxin-like Fe_4S_4 clusters plus additional Fe and sulfur atoms organized as a special H cluster. The EPR spectrum of the catalytic center, recognized because the spectrum is altered by the binding of carbon monoxide, is unusual. Its g values of 2.00, 2.04, and 2.10 are similar to those of oxidized high-potential iron proteins.[449] The *C. pasteurianum* hydrogenase II is a 53-kDa monomer containing eight Fe and eight S^{2-} ions. These are organized into one ferredoxin-like Fe_4S_4 cluster plus a three-Fe cluster and one iron ion in a unique environment.[449]

In contrast to these iron-only hydrogenases, the large periplasmic hydrogenase of *Desulfovibrio gigas* consists of one 28-kDa subunit and one 60-kDa subunit and contains two Fe_4S_4 clusters, one Fe_3S_4 cluster, and another dimetal center containing a single atom of Ni.[450,451] These are seen clearly in the three-dimensional structure depicted in Fig. 16-26. The three Fe–S clusters, at 5- to 6-nm intervals, form a chain from the external surface to the deeply buried nickel–iron center.[450–453a] A plausible pathway for transport of protons to the active center can also be seen.[450,451] The nickel center also contains an atom of Fe. Four cysteine side chains participate in forming the Ni–Fe cluster, two of them provide sulfur atoms that bridge between the metals while two others are ligands to Ni (Fig. 16-26).



(16-49)

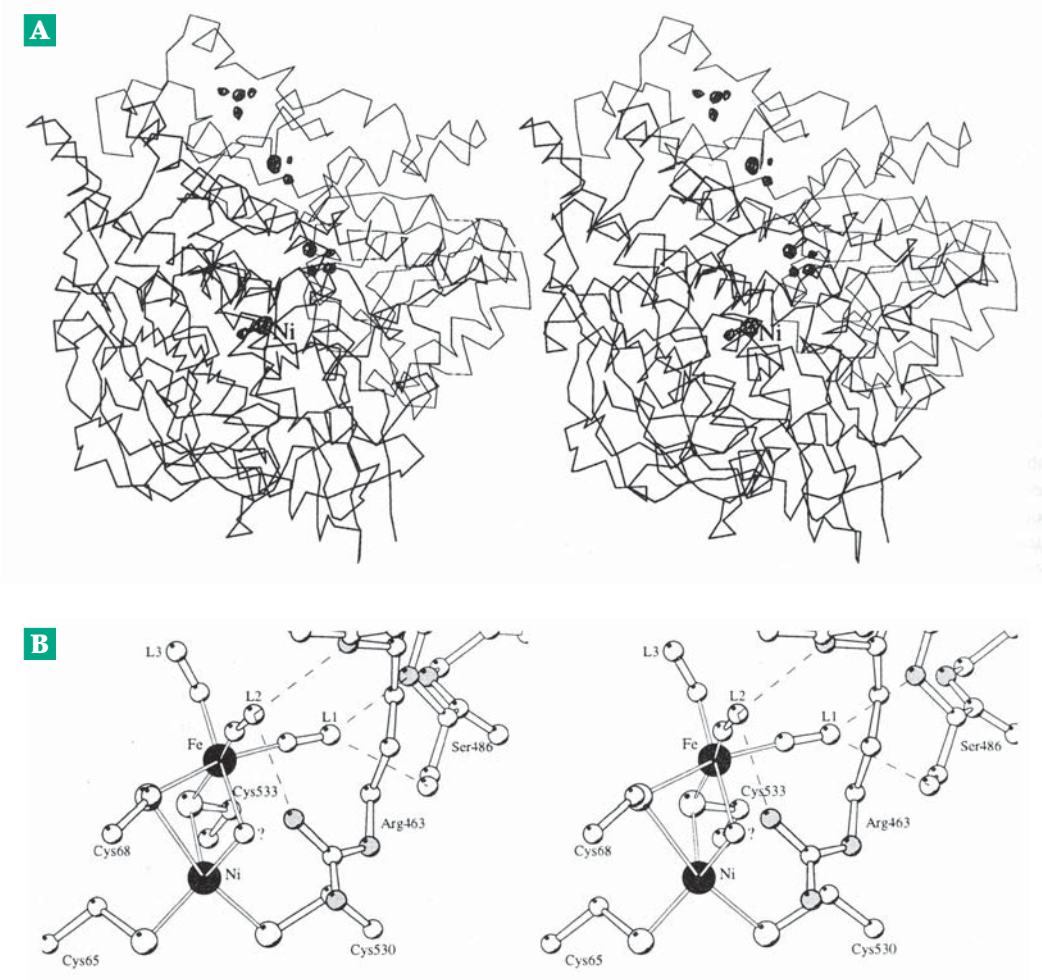


Figure 16-26 (A) Stereoscopic view of the structure of the *Desulfovibrio gigas* hydrogenase as an α-carbon plot. The electron density map at the high level of 8σ is superimposed and consists of dark spheres representing the Fe and Ni atoms. The iron atoms of the two Fe_4S_4 and one Fe_3S_4 clusters are seen clearly forming a chain from the surface of the protein to the Ni–Fe center. (B) The structure of the active site Ni–Fe pair. The two metals are bridged by two cysteine sulfur atoms and an unidentified atom, perhaps O, and the nickel is also coordinated by two additional cysteine sulfurs. Unidentified small molecules L1, L2, and L3 are also present. From Volbeda *et al.*[453] Courtesy of M. Frey.

A hydrogenase from *chromatium vinosum* has a similar structure.[453b] There are still uncertainties about other nonprotein ligands such as H_2O.[452–453a]

All of the Ni-hydrogenases display an EPR signal that can be assigned to Ni(III).[452] However, the active enzyme from *D. gigas* contains Ni(II). A proposed mechanism[452] is indicated in Eq. 16-49. Step *a* of this equation is a reductive activation. In step *b* a molecule of H_2 is bound as a hydride ion on Ni and a proton on a nearby sulfur. Protonation of a second sulfur ligand to Ni is needed to promote the cleavage of H_2 prior to the two-step oxidation of the bound H^-. One of two Ni-containing hydrogenases of *Methanobacterium thermoautotrophicum* contains FAD as well as Fe–S clusters.[454] It specifically reduces the 5-deazaflavin cofactor F_{420} (Chapter 15). A major function of this deazaflavin is reduction of the nickel-containing cofactor F_{430}.

3. Cofactor F_{430} and Methyl-Coenzyme M Reductase

Cofactor F_{430} is a nickel tetrapyrrole with a structure (Fig. 16-27)[455,456] similar to those of vitamin B_{12} and of siroheme. The tetrapyrrole ring is the most highly reduced in cofactor F_{430}, which functions in reduction of methyl-CoM to methane in methanogens (Fig. 16-28). The methyl CoM reductase of *Methanobacterium thermoautotrophicum* is a large 300-kDa protein with subunit composition $\alpha_2\beta_2\gamma_2$ and containing two molecules of bound F_{430}. The nickel in F_{430} is first thought to be reduced, in an activation step, to Ni(I),[456a] which may attack the methyl group of methyl-CoM homolytically to yield a methyl nickel complex and a sulfur radical.[457,458] Alkyl nickel compounds react with protons, and in this case they would yield methane and would regenerate the Ni(II) form of the cofactor. The CoM radical could be reduced back to free CoM.

High-resolution crystal structures of the enzyme in two inactive Ni(II) forms[458] show the two F_{430} molecules. Each is bound in an identical channel about 3 nm in length and extending from the surface deep into the interior of the protein. The F_{430} lies at the bottom of this channel with its nickel atom coordinated with the oxygen atom of a glutamine side chain. In one form CoM lies directly above the nickel, with its

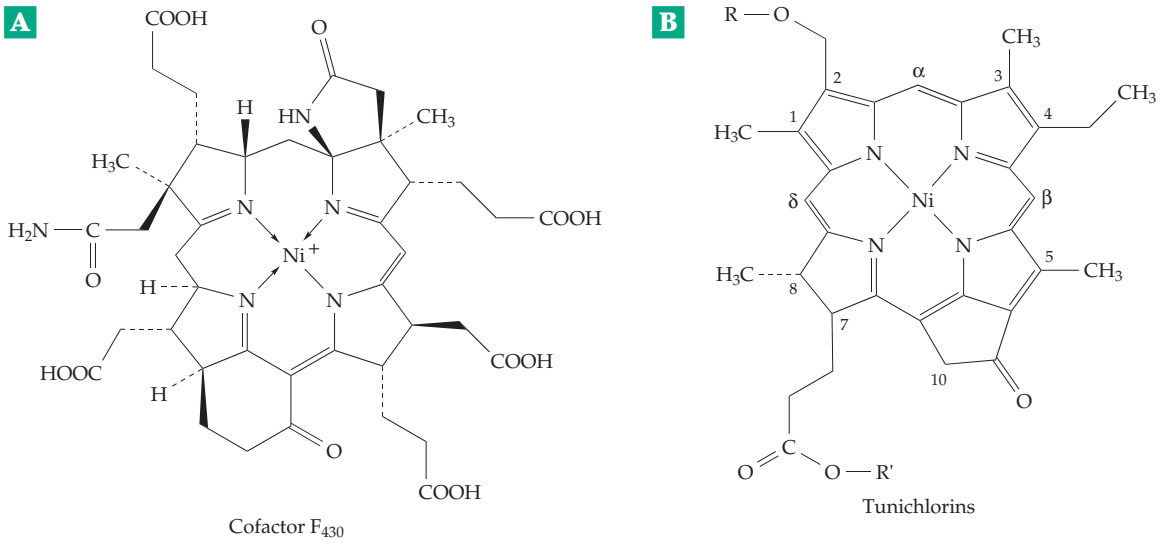

Figure 16-27 (A) Structure of the nickel-containing prosthetic group F_{430} as isolated in the esterified (methylated) form. From Pfaltz *et al.*[459] The "front" face, which reacts with methyl-coenzyme M, is toward the reader.[458] (B) Structure of a representative member of a family of tunichlorins isolated from marine tunicates.[460] For tunichlorin R = R′ = H. Related compounds have R′ = CH_3 and/or R = an alkyl group with 13–21 carbon atoms and up to six double bonds.

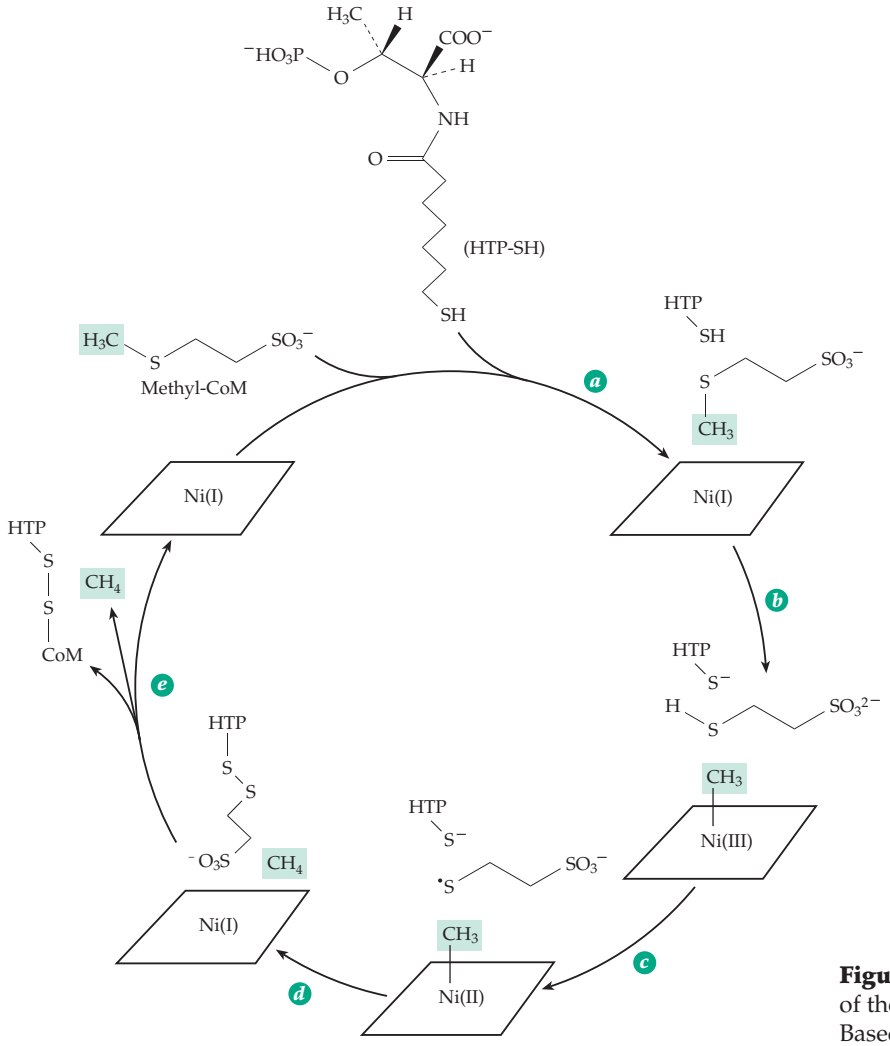

Figure 16-28 Proposed mechanism of action of the methane-forming coenzyme M reductase. Based on the crystal structure.

thiolate sulfur providing the sixth ligand for the nickel. The long –SH-containing side chain of **heptanoyl threonine phosphate** (HTP; also called coenzyme B; Chapter 15, Section E) also lies within the channel with its amino acid head group blocking the entrance. In a second crystal form the mixed disulfide HTP–S–S–CoM, an expected product of the reaction (Fig. 16-28), is present in the channel.[458] Because of the distance from the –SH group of HTP and the nickel atom it is clear that there must be some motion of the methyl-CoM and that the methane formed may stay trapped in the active site until the HTP–S–S–CoA product leaves.

A proposed mechanism for the catalytic cycle based on the X-ray results as well as previous chemical studies and EPR spectroscopy is shown in Fig. 16-28. The substrates enter in step *a*. The position of the HTP, with its extended side chain, is probably the same as that seen in the X-ray structures of the Ni(II) complexes but the conformation of the methyl-CoM is different. The methyl transfer in step *b* is reminiscent of that of methionine synthase (Eq. 16-43). Although the distance from the CoM sulfur and the HTP–SH is too great for direct proton transfer between the two, as indicated for step *b*, there are two tyrosine hydroxyls that could provide a pathway for proton transfer. The region around the surface of the nickel coenzyme is largely hydrophobic and could facilitate formation of the thiyl radical in step *c*. In the structure with the bound HTP–S–S–CoM heterodisulfide an oxygen atom of the sulfonate group of CoM is bonded tightly to the Ni(II). However, in the active Ni(I) form the nickel is nucleophilic and would probably repel the sulfonate, perhaps assisting the product release.[458]

The enzyme contains five posttranslationally modified amino acids near the active site: *N*-methylhistidine, 5-methylarginine, 2-methylglutamine, 2-methylcysteine, and thioglycine in a thiopeptide bond. The latter may be the site of radical formation.[458a,b]

4. Tunichlorins

Nickel is found in various marine invertebrates. In the tunicates (sea squirts and their relatives) it occurs in a fixed ratio with cobalt, suggesting a metabolic role.[460] A new class of nickel chelates called tunichlorins have been isolated. An example is shown in Fig. 16-27B. The function of tunichlorins is unknown but their existence suggests the possibility of unidentified biochemical roles for nickel.

5. Carbon Monoxide Dehydrogenases and Carbon Monoxide Dehydrogenase/Acetyl-CoA Synthase

There are several bacterial carbon monoxide dehydrogenases that catalyze the reversible oxidation of CO to CO_2:

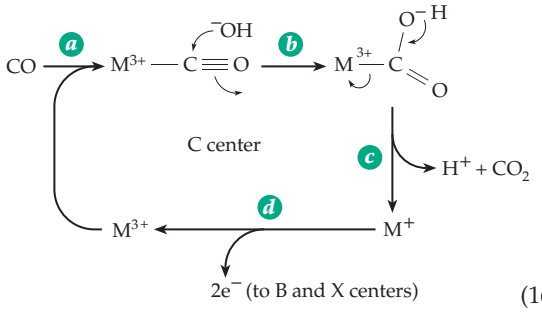
$$CO + H_2O \rightarrow CO_2 + H^+ + 2\ e^- \qquad (16\text{-}50a)$$

$$CO + H_2O \rightarrow CO_2 + H_2 \qquad \Delta G^\circ = -38.1\ \text{kJ / mol} \qquad (16\text{-}50b)$$

Some bacteria use CO as both a source of energy and for synthesis of carbon compounds. The purple photosynthetic bacterium *Rhodospirillum rubrum* employs a relatively simple monomeric Ni-containing CO dehydrogenase containing one atom of Ni and seven or eight iron atoms, apparently arranged in Fe_4S_4 clusters. These bacteria can grow anaerobically with CO as the sole source of both energy and carbon.[461] Some aerobic bacteria oxidize CO using a molybdenum-containing enzyme (Section H). However, the most studied CO dehydrogenase is a complex enzyme that also synthesizes, reversibly, acetyl-CoA from CO and a methyl corrin. Employed by methanogens, acetogens, and sulfate-reducing bacteria, it is at the heart of the **Wood–Ljundahl pathway** of autotrophic metabolism, which is discussed further in Chapter 17.

Both oxidation of CO to CO_2 and reduction of CO_2 to CO are important activities of CO dehydrogenase / acetyl-CoA synthase. During growth on CO, some CO must be oxidized to CO_2 and then reduced by the pathways of Fig. 15-22 to form a methyl-tetrahydropterin which can be used to form the methyl group of acetyl-CoA. During growth on any other carbon compound CO_2 must be reduced to CO to form the carbonyl group of acetyl-CoA which can serve as a precursor to all other carbon compounds. Native CO dehydrogenase/acetyl CoA synthase was isolated from cells of *Clostridium thermoaceticum* grown in the presence of radioactive ^{63}Ni. The protein is a 310-kDa $\alpha_2\beta_2$ oligomer. Each αβ dimer contains 2 atoms of Ni, 1 of Zn, ~12 of Fe and ~12 sulfide ions,[462–464] which are organized into three metal clusters referred to as A, B, and C. Each cluster contains 4 Fe atoms and clusters A and C also contain 1 Ni each. Oxidation of CO occurs in the β subunits, each of which contains both cluster B, an Fe_4S_4 ferredoxin-type cluster, and cluster C, where the oxidation of CO is thought to occur. Cluster C contains 1 nickel ion as well as an Fe_4S_4 cluster that resembles that of aconitase (Fig. 13-4). Cluster A, which is in the α subunit, also contains 1 atom of Ni and 4 Fe ions and is probably the site of synthesis of acetyl-CoA.

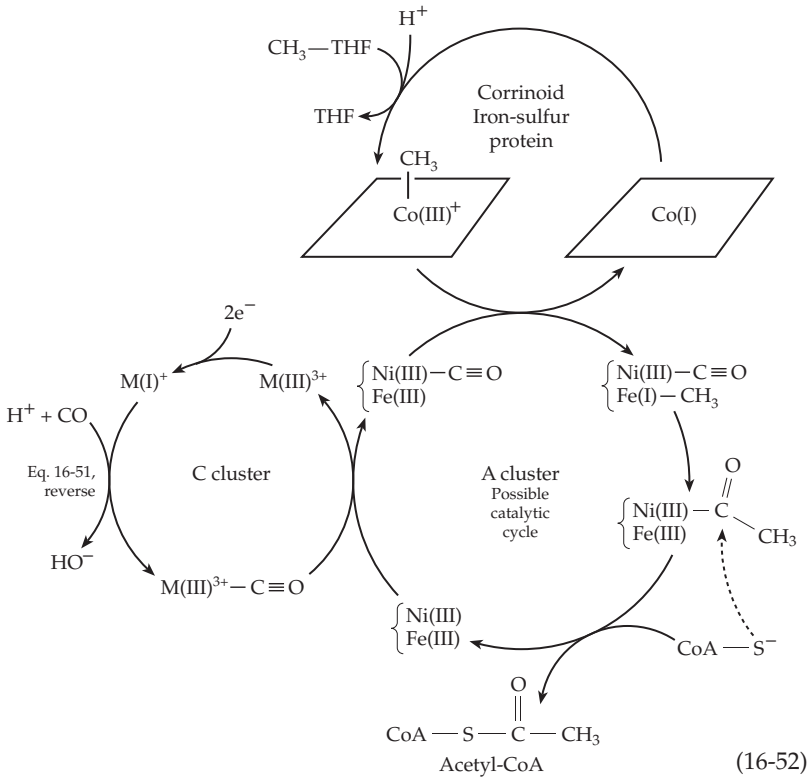
Oxidation of CO may require cooperation of the nickel ion and the Fe_4S_4 group within the C cluster.



(16-51)

CO probably binds to one of these metals and is attacked by a hydroxyl ion (Eq. 16-51, step *b*) which may be donated by the other metal of the pair.[465,465a] CO_2 and a proton are released rapidly (step *c*), after which the reduced metal center is reoxidized (step *d*). One electron is thought to be transferred directly to the Fe_4S_4 cluster B and the second by an alternative route.[465] A multienzyme complex isolated from the methanogen *Methanosarcina* has an $(\alpha\beta\gamma\delta\varepsilon)_6$ structure, with the subunits having masses of 89, 60, 50, 48, and 20 kDa, respectively.[466] In this complex the CO dehydrogenase/acetyl-CoA synthase activity appears to reside in the $\alpha_2\varepsilon_2$ complex, the $\gamma\delta$ complex has a tetrahydropteridine: cob(I)amide–protein transferase, and the β subunit has an acetyltransferase that binds acetyl-CoA and transfers the acetyl group to a group on the β subunit.[466]

Although the *Clostridium* and *Methanosarcina* systems are not identical, similar mechanisms are presumably involved.[467,467a] To generate acetyl-CoA a methyl group is first transferred from a tetrahydropterin such as tetrahydrofolate or, in methanogens, tetrahydromethanopterin or tetrahydrosarcinapterin (Fig. 15-17) to form a methylcorrinoid. At the A center of the CO dehydrogenase a molecule of CO, which may be bound to the Ni, equilibrates with the methyl group, and with acetyl-CoA. As depicted in Eq. 16-52, acetyl-Ni may be an intermediate. Other details shown here are hypothetical. It is possible that the methyl group is transferred to the Ni atom in the M cluster before reaction with the CO, which might be bound to either Ni of cluster C or to Fe. This reaction of two transition-metal-bound ligands parallels a proposed industrial process for synthesis of acetic acid from methanol and CO and involving catalysis by rhodium metal and methyl iodide. It is thought that rhodium-bound CO is inserted into bound Rh–CH_3 to form an intermediate Rh–$\overset{\overset{O}{\|}}{C}$–$CH_3$. The acetyl group is released as acetyl iodide which is hydrolyzed to acetic acid. An acetyl-nickel intermediate may be involved in the corresponding biological reaction of Eq. 16-52. The stereochemistry of the sequence has been investigated using methyl-THF containing a chiral methyl group. Overall retention of the configuration of the methyl group in acetyl-CoA was observed.[468,469]



(16-52)

D. Copper

Copper was recognized as nutritionally essential by 1924 and has since been found to function in many cellular proteins.[470–474] Copper is so broadly distributed in foods that a deficiency has only rarely been observed in humans.[474a] However, animals may sometimes receive inadequate amounts because absorption of Cu^{2+} is antagonized by Zn^{2+} and because copper may be tied up by molybdate as an inert complex. There are copper-deficient desert areas of Australia where neither plants nor animals survive. Copper-deficient animals have bone defects, hair color is lacking, and hemoglobin synthesis is impaired. Cytochrome oxidase activity is low. The protein elastin of arterial walls is poorly crosslinked and the arteries are weak. Genetic defects in copper metabolism can have similar effects.

An adult human ingests ~2–5 mg of copper per day, about 30% of which is absorbed. The total body content of copper is ~100 mg (~2 x 10^{-4} mol / kg), and both uptake and excretion (via the bile) are regulated. Since an excess of copper is toxic, regulation is important.

Because Cu^{2+} is the most tightly bound metal ion in most chelating centers (Table 6-9), almost all of the copper present in living cells is complexed with proteins. Copper is transported in the blood by a 132-kDa, 1046-residue sky-blue glycoprotein called **ceruloplasmin**.[471,475–477] This one protein contains 3% of the total body copper.

Regulation of copper uptake has been studied in most detail in the yeast *Saccharomyces cerevisiae*. Uptake of Cu^{2+} is similar to that of Fe^{3+}. The same plasma membrane reductase system, consisting of proteins Fre1p and Fre2p (encoded by genes *FRE*1 and *FRE*2), acts to reduce both Fe^{3+} and Cu^{2+}.[478–481] These two genes are controlled in part by a transcriptional activator that responds to the internal copper concentration.[410,482,483] Similar regulation is thought to occur in both plants[484] and animals.
