$$A_{v,min} = 0.06 \sqrt{f'_c} \frac{b_w s}{f_{yk}} \text{ mm}^2 \quad (\text{MPa and mm}) \quad (15.18)$$

Figure 15.26 presents a comparison of the minimum amounts of shear reinforcement. The ACI 318-02 and CSA A23.3-94 expressions give similar amounts of shear reinforcement, while the EC2-02

FIGURE 15.26 Minimum shear reinforcement requirements of the different codes as a function of f'_c .

expression gives a larger amount of minimum shear reinforcement for all concrete strengths. Both ACI 318-02 and CSA A23.3-94 require that a minimum amount of shear reinforcement be provided in all reinforced concrete flexural members where the factored shear force exceeds one-half the factored shear resistance of the concrete, except for slabs, footings, joists, and shallow beams meeting geometrical restrictions. In contrast, EC2-02 requires that all beams that contribute significantly to the overall resistance and stability of the structure must contain at least a minimum amount of shear reinforcement.

15.6.9 Development Length for Reinforcing Bars

The ACI 318-02 Code gives the following expression for the tension development length l_d for deformed bars for situations where the clear spacing of the bars being developed and clear cover are not less than d_b , and stirrups or ties throughout l_d are not less than the code minimum.

$$l_d = \frac{1}{20} \alpha \beta \gamma \lambda \frac{f_y}{\sqrt{f'_c}} d_b \quad (\text{psi and in.})$$

$$l_d = \frac{3}{5} \alpha \beta \gamma \lambda \frac{f_y}{\sqrt{f'_c}} d_b \quad (\text{MPa and mm})$$
(15.19)

where α is the reinforcement location factor, β is the coating factor, γ is the reinforcement size factor (0.8 for No. 6 or 19 mm and smaller bars and 1.0 for larger bars), and λ is the lightweight aggregate concrete factor.

The development length requirements in CSA A23.3-94 are based on the ACI Code provisions, but have been modified to account for the larger required minimum spacing between bars of $1.4d_b$, but not less than 30 mm. This results in shorter development lengths with the factor $\frac{3}{5}$ in the metric expression of Equation 15.19 being replaced by 0.45.

EC2-02 requires a minimum clear spacing between bars of d_b , but not less than 25 mm (assuming 20 mm maximum aggregate size). The tension development length of reinforcing bars is given by

$$l_d = \alpha_1 \alpha_2 \alpha_3 \alpha_4 \alpha_5 \frac{1}{0.7 \alpha_{ct} f_{ctm} / \gamma_c} \frac{d_b}{4} \quad (\text{MPa and mm}) \quad (15.20)$$

where α_1 is a factor accounting for presence of bends (1.0 for straight bar anchorage). The factor α_2 accounts for concrete cover and bar spacing and is taken as $1 - 0.15(c_d - d_b)/d_b$, but not less than 0.7, and not greater than 1.0. The distance c_d is the smaller of the clear cover to the bars being developed and one half of the clear spacing between the bars. The factor α_3 is the transverse reinforcement confinement factor; α_4 is the factor accounting for welded transverse bars; and α_5 is the factor accounting for pressure, p , transverse to the plane of splitting, taken as $1 - 0.04p$, but not less than 0.7, and not greater than 1.0.

The factor η_1 accounts for the quality of the bond (depends on position of the bar, member size, and other factors such as the use of slip forming); η_2 is the bar size factor, taken as $(132 - d_b)/100$ for d_b greater than 32 mm, and taken as 1.0 for d_b less than or equal to 32 mm.

The factors γ_c and γ_s are partial safety factors for concrete and steel (Table 15.12); f_{yk} is the characteristic yield strength of the reinforcement; f_{ctm} is the mean value of the axial tensile strength of concrete (see Equation 15.9); and σ_{ct} is a factor accounting for long-term and other unfavorable effects, usually taken as 1.0.

Figure 15.27 compares the tension development lengths required by ACI 318-02, EC2-02, and CSA A23.3-94 for beams containing the minimum shear reinforcement required by the respective codes. This comparison is made for two bar sizes, having diameters of 16 mm (0.6 in.) and 35.7 mm (1.4 in.). In making this comparison it has been assumed that the factors in the ACI and CSA code expressions

FIGURE 15.27 Comparison of the tension development lengths required by ACI 318-02, EC2-02, and CSA A23.3-94 for beams containing the minimum shear reinforcement, as a function of f'_c .

for reinforcement location, bar coating, and concrete density are all 1.0. It was also assumed that all of the α factors, η_1 , and α_{ct} in Equation 15.20 are 1.0. In addition, it was assumed that the minimum concrete cover to the bars being developed was 40 mm (1.5 in.) and that spacing between the bars was between $1.4d_b$ and $2d_b$. Both the EC2-02 and CSA A23.3-94 expressions give shorter development lengths than the ACI 318-02 expression. This is due to the different requirements in the three codes regarding minimum shear reinforcement and minimum bar spacing. On the one hand, EC2-02 requires larger amounts of minimum shear reinforcement (Figure 15.25), but has the same minimum clear bar spacing as ACI 318-02. On the other hand, CSA A23.3-94 requires similar amounts of shear reinforcement as ACI 318-02 (Figure 15.25), but requires a larger minimum clear spacing between bars.

ACI 318-02 and CSA A23.3-94 limit the value of $\sqrt{f'_c}$ to 100 psi (25/3 MPa) and 8 MPa, respectively, in applying the expressions for determining the development length. EC2-02 cautions designers that due to the increasing brittleness of higher-strength concrete, the tensile strength of concrete required in calculating the bond strength should be limited to that corresponding to concrete with a compressive strength of 60 MPa, unless it can be verified that the average bond strength increases above this limit. It is noted that tests [82] indicate that bond failures in high-strength concrete members are more brittle than those in normal-strength concrete members unless adequate transverse reinforcement is provided. More research is needed to determine the relationship between the amount of confinement reinforcement and the required development length for higher-strength concrete.

15.6.10 Column Confinement for Seismic Design

ACI 318-02 requires that the total cross-sectional area of rectangular hoop reinforcement in ductile columns be not less than that given by the following expressions:

$$A_{sh} = 0.3sh_c \frac{f'_c}{f_{yh}} \left(\frac{A_g}{A_{ch}} - 1 \right) \text{ in.}^2 \quad (15.21)$$

$$A_{sh} = 0.09sh_c \frac{f'_c}{f_{yh}} \left(\frac{A_g}{A_{ch}} - 1 \right) \text{ mm}^2 \quad (15.22)$$

where A_{sh} is the total cross-sectional area of transverse reinforcement within spacing s , s is the hoop spacing, h_c is the cross-sectional dimension of the column core measured center-to-center of confining reinforcement, A_g is the gross cross-sectional area, A_{ch} is the cross-sectional area of the column measured out-to-out of transverse reinforcement, and f_{yh} is the specified yield strength of the transverse reinforcement.

NZS 3101-95 includes the influence of axial load level in determining the required A_{sh} as follows:

$$A_{sh} = \frac{(1.3 - \rho_g m)sh''}{3.3} \frac{A_g}{A_{ch}} \frac{f'_c}{f_{yh}} \frac{N^*}{\phi A_g f'_c} - 0.006sh'' \quad (15.23)$$

where ρ_g is the ratio of total longitudinal reinforcement area to cross-sectional area of column; $m = f_y / (0.85f'_c)$; h'' is the dimension of the concrete core measured perpendicular to the direction of the hoop bars to outside of peripheral hoop; and N^* is the design axial load at ultimate limit state.

Figure 15.28 compares the confinement requirements of ACI 318-02 and NZS 3101-95 as a function of concrete compressive strength. Unlike the ACI 318-02 requirements, the NZS 3101-95 requirements are strongly affected by the axial load. For low axial loads and low concrete compressive strengths, the

FIGURE 15.28 Transverse confinement reinforcement requirements of ACI 318-02 and NZS 3101-95 for rectangular columns as a function of f'_c .

New Zealand confinement equation results in considerably less confinement reinforcement than the ACI Code. For high axial loads and high-strength concrete, the NZS 3101-95 requirements are more stringent than those in ACI 318-02.

16.1 Analysis and Design of FRP Pultruded Structures

16.1.1 Introduction

Truss structures and braced framed structures have been designed and constructed using thin-walled composite material fiber-reinforced polymer (FRP, commonly referred to as fiber-reinforced plastic) pultruded members for over 30 years. Pultruded structural members (referred to as pultrusions or pultruded shapes or pultruded profiles) have been used in a significant number of structures to-date, such as pedestrian bridges, vehicular bridges, building frames, stair towers, cooling towers, and walkways and platforms (Bakis et al. 2002). Pultruded members are often the materials of choice where significant corrosion and chemical resistance is required (food processing, cooling towers, offshore platforms), where electromagnetic transparency is required (electronics manufacturing, radomes), or where accessibility is limited and lightweight skeletal structures are assembled on-site (pedestrian bridges in parklands).

Pultrusion is a continuous, and highly cost-effective, manufacturing technology for producing constant cross-sectional FRP structural shapes (profiles) (Meyer 1985). Pultruded materials consist of fiber reinforcements (typically, glass fiber or carbon fiber) and thermosetting resins (typically, polyester, vinylester, and epoxy polymers). The fiber architecture within a thin “panel” or “plate” in a pultruded shape (such as a web or a flange) typically consists of longitudinal continuous fiber bundles (called

rovings or tows) and continuous filament fiber mats (CFM). In specialized custom pultrusions bidirectional stitched fabrics are also used to improve mechanical or physical properties. The volume fraction of the fiber reinforcement in a pultruded shape is typically between 30 and 50%. In addition to the base polymer resin, pultruded materials typically contain inorganic fillers, chemical catalysts and promoters, release agents, ultraviolet retardants, fire retardants, pigments, and surfacing veils. Commercially produced pultruded materials made with glass fibers are sold in the \$2 to \$3 per pound range. Specialized pultruded products utilizing higher-performance carbon fibers, sophisticated fabrics, and higher-performance resin systems may be considerably more costly.

Currently, no building codes or specifications provide consensus guidelines for the design of composite material framed structures using either “standard” or “custom” pultruded structural shapes. Two design manuals that are currently available provide much of the fundamental information that is needed for the analysis and the design of pultruded structures. These are the *Structural Plastics Design Manual* (SPDM 1984) and the *Eurocomp Design Code and Handbook* (EDCH 1996).

While there are no text books currently available that specifically cover the design of FRP pultruded structures for structural engineering (as there are for steel, concrete, and wood structures), there are many excellent classic texts on the mechanics (and, to a lesser extent, design) of composite materials for aerospace and mechanical engineering structures, such as Tsai and Hahn (1980), Vinson and Sierakowski (1986), Agarwal and Broutman (1990), and Jones (1999). Books by Hollaway (1993), Barbero (1998), and Hollaway and Head (2001) bridge the gap between the mechanics of composite materials and composite structures and lay more emphasis on applications to civil engineering.

Pultruded structural shapes are produced by a number of commercial companies throughout the world (e.g., Strongwell [United States], Creative Pultrusions [United States], Bedford Reinforced Plastics [United States], Fiberline [Denmark], TopGlass [Italy], Pacific Composites [Australia, Asia, United Kingdom]). There is a commonality (similarity) in the types of shapes and the properties of these shapes, and although there is no official standard for these shapes and their properties, they are referred to commonly as standard pultruded structural shapes. Company-specific literature provides details of the geometries and properties of their common shapes (e.g., Fiberline 1995; Creative Pultrusions 2000; Strongwell 2002). Commonly produced standard pultruded shapes that are usually available from stock inventories include I section, wide-flange (WF), square tube, rectangular tube, channels, and angles, and plate materials. Standard sections range from 2 in. in height and width to approximately 12 in. in height and width and have pultruded material thicknesses of $\frac{1}{4}$ to $\frac{1}{2}$ in. Company design guides also provide a design basis and analytical methods used for designing with their products. Design equations in company design guides are often empirical and are based on fits to test data.

Pultrusion companies also produce custom pultruded shapes. Companies generally do not make geometry and property data available for their custom shapes. A number of industry groups represent and loosely coordinate the activities of pultrusion manufacturers. Leading groups are the Pultrusion Industry Council of the American Composites Manufacturers Association (ACMA) and the European Pultrusion Technology Association (EPTA).

Thin-walled shapes can be produced by many other processes, such as filament winding, resin-transfer-molding, and centrifugal casting. No commonality exists in these products (except perhaps for composite poles and pipes). They are generally not intended for use in framed structures and are not discussed in what follows.

Experimental testing has been conducted in earnest since the mid-1980s to characterize the behavior and performance of pultruded structures and structural members. Much effort has been devoted to investigating whether the design equations presented in design manuals are in fact suitable for standard pultruded shapes and whether or not design approaches used for conventional thin-walled metallic members are applicable to pultruded structures. Less work has been done on the applicability of the equations to custom shapes. Based on these studies, there is sufficient evidence that many of the design equations presented in the design manuals are in fact suitable for use when designing framed structures with standard pultruded shapes.

Although the suitability of using specific analytical equations to predict the behavior of pultruded members and structures has been confirmed, there is significantly less consensus on the established safety factors (for allowable-stress design [ASD]) and the material resistance factors (for load and resistance factor design) than exists for other materials, such as steel and reinforced concrete.

16.1.2 Properties of Pultruded Shapes

Standard FRP pultruded shapes are constructed of “specially” orthotropic thin plate elements. The internal architecture of the plate elements (the “lamination”), which may consist of roving bundles, fabrics, and mats, is such that the laminate is both balanced and symmetric to prevent extensional–shear coupling and extensional–flexural coupling (Tsai and Hahn 1980) in the plate and in the section. Specially orthotropic means that the orthotropic axes of the plate elements coincide with the structural axes of the pultruded section.

The in-plane (or extensional) stiffness properties of an orthotropic plate of pultruded material can be defined by five independent in-plane “effective” engineering constants:

E_L = longitudinal elastic modulus

E_T = transverse elastic modulus

G_{LT} = in-plane shear modulus

ν_L = in-plane longitudinal (major) Poisson ratio

ν_T = in-plane transverse (minor) Poisson ratio = $\nu_L E_T / E_L$

It is typically assumed that the stiffness properties are the same in tension and in compression; however, manufacturers generally report tensile and compressive moduli separately. In this case the subscript t is used for tension and the subscript c is used for compression. The longitudinal and the transverse directions are also commonly referred to as lengthwise and the crosswise directions, respectively.

The in-plane extensional strength properties of an orthotropic plate of pultruded material can be defined by five independent constants:

$\sigma_{L,t}$ = longitudinal tensile strength

$\sigma_{L,c}$ = longitudinal compressive strength

$\sigma_{T,t}$ = transverse tensile strength

$\sigma_{T,c}$ = transverse compressive strength

τ_{LT} = in-plane shear strength

The out-of-plane (through-the-thickness [TT]) properties of an orthotropic plate of pultruded material are generally not measured and are not used in design. The exception to this is the interlamina shear strength (ILSS), also known as the short beam shear (SBS) strength, which is routinely measured. It is a measure of the transverse shear strength of the laminate and is denoted by

τ_{TT} = interlamina shear strength

In addition, for design purposes a “quasi-structural” bearing strength, either in the longitudinal or in the transverse direction, is also measured and reported as

$\sigma_{L,br}$ = longitudinal bearing strength

$\sigma_{T,br}$ = transverse bearing strength

Since a plate of pultruded material is not homogenous through its thickness (i.e., it consists of layers or laminae [or plies] of fiber-reinforced materials having different in-plane properties), the in-plane flexural properties of pultruded materials are not the same as the in-plane extensional properties of the material due to the dependence on the location of the layers through the thickness of the material (Tsai and Hahn 1980). Consequently, there exists a set of effective flexural properties for pultruded material

that is analogous to the set of effective extensional properties described earlier in this section. These properties are often represented by the superscript b to distinguish them from the extensional properties (often represented by the superscript 0). For example, E_L^b and E_L^0 are the in-plane longitudinal flexural modulus and the in-plane longitudinal extensional modulus, respectively.

The in-plane extensional and flexural engineering properties may be obtained theoretically from classical lamination theory (CLT) in which the laminated plate is characterized by in-plane extensional stiffness coefficients (A_{ij} with $i, j = 1, 2, 6$) and in-plane flexural stiffness coefficients (D_{ij} with $i, j = 1, 2, 6$) (Tsai and Hahn 1980). For global (member) stress calculations the in-plane extensional properties (the A matrix coefficients) are used to determine the engineering extensional properties. For local (plate) stress calculations the flexural properties (the D matrix coefficients) are used to determine the flexural engineering properties. In this approach the laminate is assumed to be inhomogeneous on the ply level but nevertheless able to be represented by laminate properties for the purposes of stress-resultant calculations.

Alternatively, the in-plane engineering stiffness properties may be obtained from standard tests on coupons extracted from the pultruded section. In this approach the laminate is assumed to be homogeneous. Standard ASTM tests (ASTM 2003) that are recommended for determining the properties of pultruded materials can be found in Bank et al. (2003) and in manufacturers' design guides (Creative Pultrusions 2000; Strongwell 2002) and are shown in Table 16.1.

If the orthotropic plates are assumed to be homogeneous, then the plate flexural properties can be calculated from the in-plane extensional engineering properties (either obtained from test data or from

the in-plane extensional matrix). This assumption is frequently made in the analysis of pultruded structures. The orthotropic plate flexural stiffnesses are then given as

$$D_L = \frac{E_L t_p^3}{12(1 - \nu_L \nu_T)} \quad (16.1)$$

$$D_T = \frac{E_T t_p^3}{12(1 - \nu_L \nu_T)} \quad (16.2)$$

$$D_{LT} = \frac{\nu_T E_L t_p^3}{12(1 - \nu_L \nu_T)} = \frac{\nu_L E_T t_p^3}{12(1 - \nu_L \nu_T)} \quad (16.3)$$

$$D_{SS} = \frac{G_{LT} t_p^3}{12} \quad (16.4)$$

Alternatively, the plate flexural properties (the D s above) may be obtained from the in-plane flexural properties, however, this is seldom done in practice for commercially produced pultruded materials consisting of layers of unidirectional roving and continuous filament mats. In this case, for example, the longitudinal flexural stiffness, D_L , is written as (Barbero 1998)

$$D_L = \frac{E_L^b t_p^3}{12(1 - \nu_L^b \nu_T^b)} \quad (16.5)$$

The in-plane strength properties may be obtained from theoretical calculations or from testing of coupons taken from the laminate. Where theoretical predictions are used, the first-ply-failure (FPF) is assumed to represent the strength of the laminate. Coupon testing is highly recommended for obtaining the strength properties.

Property data provided in pultrusion company manuals and design guides are obtained from tests on coupons of pultruded materials taken from sections. Data reported are typically applicable to a broad range of section sizes and types. The specific fiber architectures (volume fractions of roving, mats, and fabrics) in the different section sizes and types varies. Fiber architecture may also vary within the section (e.g., web reinforcement architecture may be different from flange reinforcement architecture). The properties given by manufacturers can be assumed to be lower bounds for the sections indicated in the manuals. No data are provided to determine the statistics of these properties for use in probabilistic-based design. In addition, the property data are not related to the capacity of members subjected to specific loading conditions (e.g., axial load, flexure) and are based on coupon testing. Representative mechanical property data for pultruded materials used in commercially available pultruded shapes, flat sheets, and rods are shown in Table 16.2. Properties of pultruded carbon-reinforced epoxy strips for structural strengthening of concrete are shown for comparison purposes. Selected physical and electrical property data reported by manufacturers are shown in Table 16.3.

It is assumed that the pultruded material behaves in a linear elastic manner in tension, compression, and shear in both the longitudinal and the transverse directions and that failure is brittle. This assumption is reasonable in the service range ($\sim 20\%$ ultimate) but is not reasonable, especially in the shear and transverse directions, at higher loads where the stress-strain behavior is highly nonlinear.

All orthotropic plates of pultruded material in pultruded shapes are assumed to be thin (i.e., the out-of-plane thickness is an order of magnitude less than the in-plane length and breadth of the plate).

Standard pultruded structural shapes are often assumed to be homogenous on the section level (i.e., the shape consists of plates all having the same properties). However, it should be noted that some manufacturers (e.g., Creative Pultrusions) have optimized their shapes and provide properties separately for the webs and the flanges of many of their shapes.

It is assumed that the properties of the junctions between the plates (e.g., the web-flange junctions in an I beam) are the same as those of the plates themselves.

The ratio of the longitudinal modulus to the shear modulus, E_L/G_{LT} , for pultruded orthotropic material plates can be much larger than that for isotropic material plates. As a result of this, shear deformation

plays a significant role in the analysis of thin-walled pultruded shapes. The effects of shear deformation should be accounted for in deflection calculations as well as in stability calculations wherever possible.

The properties of pultruded shapes are affected by the environment in which they are used and the conditions under which they are used. These “environmental-use” effects can include time, temperature, radiation, solvents, fire, impact, abrasion, and fatigue. The way in which these effects are accounted for in design is not yet clear. In some cases (e.g., temperature, creep) some guidance is available. The safety factors recommended by pultrusion companies for use in design are intended to account for some of these effects.

In the case of elevated temperature service, pultrusion companies specifically recommend reductions in strength and stiffness properties as a function of temperature for different resin systems (usually isophthalic polyester or vinylester). At 65°C (150°F) the strength of isophthalic polyester resin pultrusions is 50% of the room temperature strength and the modulus is 85% of the room temperature modulus. For vinylester resin pultrusions at 65°C (150°F) the strength and modulus are 80 and 90% of their room temperature values, respectively. At temperatures higher than 65°C (150°F) the use of isophthalic polyester resin pultrusions is not recommended and vinylester resin pultrusions are recommended to a maximum use temperature of 93°C (200°F) with further strength and stiffness reductions (strength = 50%, moduli = 85%).

Stiffness and strength properties used in design are typically obtained from short-term testing. Long-term changes in stiffness and strength can be accounted for using different models. For creep deflections the models proposed by the SPDM (1984) developed by Findley can be used to determine effective *viscoelastic* moduli for use in predicting long-term deflections of pultruded structures.

Long-term degradation due to corrosive environments is typically determined by use of *corrosion resistance guides* that provide recommendations on the use of different pultruded materials in a variety of different chemical environments and temperatures. These guides are based on coupon test data. Fundamental studies to develop models to predict the long-term degradation of FRP composites in different service environments are ongoing but cannot yet be used for reliable lifetime prediction.

16.1.3 Design Basis for Pultruded Structures

A basis for design of FRP pultruded structures is needed. In the absence of an approved design code for FRP pultruded structures a *design basis* must be agreed upon by all parties (owner, designer, contractor, and local authorities). Four types of design basis approaches are typically used for FRP pultruded structures:

1. Allowable-stress design (ASD).
2. Limit states design (LSD).
3. Load and resistance factor design (LRFD).
4. Performance-based design (PBD).

16.1.3.1 Allowable-Stress Design

ASD requires that the calculated design stresses (the required demand, σ_{reqd}) obtained from nominal service loads be less than the ultimate strengths (the capacity, σ_{ult}) divided by an appropriate factor of safety (SF). The ultimate strength divided by the safety factor is termed the *allowable* stress (σ_{allow}). Safety factors have traditionally been determined from industry practice and are not based on probabilistic methods. They do not provide a measurable reliability index

$$\sigma_{\text{reqd}} \leq \frac{\sigma_{\text{ult}}}{\text{SF}} \quad (16.6)$$

ASD is recommended by most pultrusion companies (e.g., Creative Pultrusions 2000; Strongwell 2002) in their design manuals. For ASD the safety factors typically recommended by pultrusion companies for their common structural shapes are

Flexural members (beams)	= 2.5
Compression members (columns)	= 3.0
Shear	= 3.0
Connections	= 4.0

These factors are applied to strength and stability. For deformation calculations the safety factors recommended are

$$\begin{aligned} \text{Longitudinal and transverse moduli} &= 1.0 \\ \text{Shear moduli} &= 1.0 \end{aligned}$$

These factors are applied to the material properties and design equations provided in the company literature. These design equations are often empirically derived from test data. Material properties are provided in the company literature for different grades of pultruded material. Designs are based on unfactored nominal service loads.

ASD is also recommended by AASHTO (2001) in the *Standard Specifications for Structural Supports for Highway Signs, Luminaires and Traffic Signals*. The design equations provided in this specification are based on theoretical equations for orthotropic plates, beams, and columns of linear elastic materials made of glass reinforced polyester. Structural members may be manufactured by pultrusion, centrifugal casting, or filament winding. The following minimum safety factors are recommended:

$$\begin{aligned} \text{Bending strength} &= 2.5 \\ \text{Tensile strength} &= 2.0 \\ \text{Compressive strength} &= 3.0 \\ \text{Shear strength} &= 3.0 \\ \text{Moduli} &= 1.0 \end{aligned}$$

Material properties to be used in the design equations are obtained from American Standard for Testing and Materials (ASTM) standard test methods. Designs are based on loads provided in the American Association for State Highway and Transportation Officials (AASHTO) specification. Full-scale testing according to ASTM 4923 is provided as a PBD method as an alternative to the analytical design. Where the analytical ASD method is used “design calculations provided shall be verified by documented test results on similar structures.” (AASHTO 2001, p. 8-5).

ASD is also commonly used by structural designers in conjunction with design equations based on theoretical equations for orthotropic plates, beams, and columns. Equations provided in the SPDM (1984) are typically used in calculations. Material properties are often obtained from standard ASTM tests. Minimum properties are usually specified in a *design basis document* (often referred to as a “Special Provision to the Specifications”). Safety factors recommended by the pultrusion companies are usually used in this approach. Designs are based on unfactored nominal service loads.

16.1.3.2 Limit States Design

LSD requires that the design requirement (or actions) of the loads be less than the design resistance (or capacity) of the structure or structural members. The design loads and capacity are both multiplied by appropriate factors. The two primary limit states considered are the ultimate limit state (ULS) and the serviceability limit state (SLS). The ULS is associated with collapse, instability, and failure of the structure or structural members. The SLS is associated with states in which excessive deflection, vibration, and degradation make the structure or structural members unserviceable (EDCH 1996).

LSD is recommended by the *Structural Plastics Design Manual*. The service loads are factored to account for variations in applied loads, eccentricities, and differences between analytical and real behavior. Specific recommendations for load factors are not provided; however, example values are suggested for some cases. Capacity reduction factors are recommended for design of different structural members to account for long-term load effects and manufacturing variations. Example values are suggested. Design equations are based on the analysis of orthotropic plates, beams, and columns. In many cases equations for isotropic metallic structures are suggested where design equations are not available for FRP members. Material properties are obtained from manufacturers or from ASTM standard tests.

For the design of a pultruded column the following load and capacity reduction factors are given as an example (SPDM 1984, p. 717):

Load factors	
All service loads	= 2.5
Capacity reduction factors	
Ultimate compressive strength	= 0.5
Elastic moduli	= 0.7

For the design of a pultruded beam the following load and capacity reduction factors are given as an example (SPDM 1984, p. 741):

Load factors	
All service loads	= 2.0
Capacity reduction factors	
Ultimate compressive strength	= 0.5
Ultimate tensile strength	= 0.4
Ultimate shear strength	= 0.3
Elastic moduli	= 0.7

The load and capacity reduction factors suggested are based on standard industry practice and were not determined by probabilistic methods. They do not provide a measurable reliability index.

LSD is also recommended by *Eurocomp Design Code and Handbook* (EDCH). In the Eurocomp approach load factors are provided by the pertinent European Codes. Material partial safety factors, γ_m , are used to obtain appropriate capacity reduction factors. Material properties are divided by partial safety factors. According to the Eurocode the partial safety factors of FRP composites for structural applications account for (1) the method in which the material property data were obtained ($\gamma_{m,1}$), (2) the material manufacturing process ($\gamma_{m,2}$), and (3) the effects of environment and the duration of loading ($\gamma_{m,3}$). The material partial safety factor is given as the product of the three coefficients, $\gamma_m = \gamma_{m,1} \times \gamma_{m,2} \times \gamma_{m,3}$, and may not be less than 1.5 for ULSs and not less than 1.3 for SLSs. The following are examples of recommended values of the coefficients:

Material property data derived from theory	$\gamma_{m,1} = 1.5$
Material property data derived from testing	$\gamma_{m,1} = 1.15$
Fully cured pultruded material	$\gamma_{m,2} = 1.1$
Nonfully cured pultruded material	$\gamma_{m,2} = 1.7$
Hand-layup fully cured material	$\gamma_{m,2} = 1.4$
Hand-layup non-fully cured material	$\gamma_{m,2} = 2.0$
Long-term loading for $0 < T < 25^\circ\text{C}$ and $T_g > 55^\circ\text{C}$	$\gamma_{m,3} = 2.5$
Short-term loading for $25 < T < 50^\circ\text{C}$ and $55 < T_g < 80^\circ\text{C}$	$\gamma_{m,3} = 1.2$
Short-term loading for $25 < T < 50^\circ\text{C}$ and $T_g > 90^\circ\text{C}$	$\gamma_{m,3} = 1.0$

where T_g is the glass transition temperature (or the heat distortion temperature) of the FRP composite material. The material manufacturer is required to provide proof that the material is fully cured before the designer can use the fully cured partial safety coefficients.

Additionally, the design resistance is multiplied by an *analytical uncertainty factor* that ranges from 0.5 to 1.0 depending on the sophistication of the analytical method used in the design procedure. The material partial safety factors and the analytical uncertainty factors provided are based on standard industry practice and were not determined by probabilistic methods. They do not provide a measurable reliability index.

16.1.3.3 Load and Resistance Factor Design

A probability-based LRFD guide for FRP composite structures does not exist at present. Conceptually, the use of the LRFD approach for the design of FRP pultruded structures is quite possible and

a prestandard outline has been prepared by ASCE (Chambers 1997). Fundamental issues associated with developing an LRFD procedure for pultruded FRP structural sections, with measurable reliability indices, have been discussed by Ellingwood (2003).

The difficulties associated with an LRFD reliability approach are primarily associated with the determination of the statistical material design properties for common pultruded sections. Since a standard material specification does not exist at this time, the statistical properties of pultruded materials are not well defined. A material specification for FRP composite materials for civil engineering applications has been proposed (Bank et al. 2002).

An LRFD procedure for the design of doubly symmetric and singly symmetric pultruded columns that accounts for global flexural buckling, global torsional buckling, flexural–torsional buckling, and material compression has been presented by Zureick and Scott (1997) and Zureick and Steffen (2000). According to these studies, load factors provided by ASCE 7-02 (2002) are used in conjunction with resistance factors that have been determined based on detailed tests of pultruded materials and pultruded column buckling experiments. Equations are presented for determining the capacity of the column with appropriate resistance factors as follows:

Doubly symmetric sections

Flexural buckling $\phi = 0.85$

Axial shortening $\phi = 0.80$

Singly symmetric angles

Flexural buckling $\phi = 0.65$

Flexural–torsional buckling $\phi = 0.85$

Compressive failure $\phi = 0.50$

For the singly symmetric angles Zureick and Steffen (2000) have targeted reliability indices, β , of 3, 3, and 4 for the flexural buckling, flexural–torsional buckling, and material compressive failure limit states. Design values for the material properties were based on the 95% lower confidence limit on the fifth percentile of the population, obtained from tests conducted on the materials. For doubly symmetric sections (Zureick and Scott 1997) a rigorous statistical analysis was not performed and the resistance factors were obtained from lower bounds of comparisons between experimental data and theoretical predictions. Reliability indices were therefore not provided for these resistance factors.

Based on a recent analysis, Ellingwood (2003) has concluded that as more data become available from experiments on FRP composites for structural applications, LRFD design procedures for FRP pultruded structural members “might be expected to fall in the following ranges” (Ellingwood 2003):

Compression $\phi = 0.7–0.8$

Flexure $\phi = 0.8–0.9$

Shear $\phi = 0.7–0.8$

Tension $\phi = 0.7–0.8$

Fasteners $\phi = 0.6–0.7$

Adhesives $\phi = 0.6–0.7$

16.1.3.4 Performance-Based Design

A design can be based on a performance specification. In this approach the entire structure or a portion of the structure is required to meet certain performance requirements. The performance requirements are typically applied to both local and global deformations and capacities. Full-scale testing of the structure or a portion of the structure is usually required to meet the performance specification. Both proof testing of the actual structure and failure testing of a full-size mock-up of the structure (or parts thereof) are used.

In many cases for FRP composite structures a prescriptive set of material specifications is provided along with the structural performance requirements. The material specification can stipulate the

manufacturing method, the limiting mechanical and physical properties of the materials produced, and the requirements for quality assurance testing.

The factor of safety for a PBD is defined in the design basis documents. ASTM and other standard test methods are usually used to conduct the performance testing. Special performance testing is defined in the design basis documents that are incorporated into the construction specifications.

16.1.4 Design of Pultruded Structural Members

Fundamentals needed for the design of transversely loaded members (beams), axially loaded compression members (columns), and axially loaded tension members (ties, truss members) are presented in the following. Connections for beams and columns are treated in the [Section 16.1.5](#). The limit states discussed here for the members assume that the connections are appropriately designed to transfer all loads into the members. For each type of member various limit states are identified and discussed.

Analytically derived equations are presented for analyzing strength, stability, and deformation limit states. While the equations may be appropriately used with any of the four design basis approaches discussed previously, they are only valid if appropriate factors can be determined for the conditions for which they are used. The equations are primarily those presented in the SPDM (which are in most cases identical to those in the EDCH) and can therefore reasonably be assumed to be suitable for use in an LSD approach or in an ASD approach. Many of the equations presented may also be found in pultrusion manufacturer design guides, which are a combination of analytical and empirical equations. It can be assumed that the safety factors recommended by pultrusion manufacturers can be used with confidence with the analytical equations presented in this section. In addition, material properties provided by pultrusion manufactures can similarly be used in an ASD approach with the equations provided herein.

16.1.4.1 Transversely Loaded Members

Members considered are symmetric with respect to the flexural plane and consist of horizontal plates (flanges) and vertical plates (webs). Where singly symmetric sections are used it is assumed that they are loaded in the plane of symmetry through the shear center. Typical common pultruded shapes that fall in this definition, and that are routinely used as beams, include I, WF, and tubular “box” sections. Channel sections and angles are often used in pairs to form built-up doubly symmetric or singly symmetric sections.

The member is designed to resist stress-resultants that are due to the applied transverse forces (loads). These stress-resultants are the bending moment (M) and the transverse shear force (V). Due to the stress-resultant M the member is assumed to develop an axial (flexural) stress,

$$\sigma_z = \frac{M_x y}{I_x} \quad (16.7)$$

Due to the stress-resultant V the member is assumed to develop a transverse shear stress,

$$\tau = \frac{V_y Q_x}{I_x t} \quad (16.8)$$

Due to local concentrated loads P and reactions R at supports in the plane of the web at the point of load application or at the support, the member is assumed to develop a transverse compressive stress given by

$$\sigma_y = \frac{P}{A_{\text{eff}}} \quad \text{or} \quad \sigma_y = \frac{R}{A_{\text{eff}}} \quad (16.9)$$

where A_{eff} is the effective area over which the concentrated load or reaction is applied and can be taken as

$$A_{\text{eff}} = n(t_w + 2t_f + 2t_{\text{bp}})L_{\text{eff}} \quad (16.10)$$

where n is the number of webs, and L_{eff} is the effective bearing length along the beam and is taken as the width of the support or the length over which the concentrated load is applied. t_w , t_f , and t_{bp} , are the web

thickness, the flange thickness, and the thickness of the bearing plate under the flange (if applicable), respectively.

Due to the stress-resultants M and V it is assumed that the member will deflect in its plane of loading. The elastic curve that describes the deflected shape is a function of the flexural rigidity of the member (EI) and the transverse shear rigidity of the member (KAG). It can be obtained from the Timoshenko (shear deformation) beam theory as

$$\delta(z) = \frac{f_1(z)}{EI} + \frac{f_2(z)}{KAG} \quad (16.11)$$

where the functions $f_1(z)$ and $f_2(z)$ depend on the loading and boundary conditions and can be found in standard engineering texts.

For flexural members SLSs (deflection) and ULSs (strength and stability) are considered. Procedures are presented to determine the short-term and long-term member deflections as a function of the material properties and member geometric properties. The calculated design stresses (or design force resultants) must be less than the critical strengths and critical buckling stresses (the critical resistances or capacities) according to the design basis selected. The calculated deflections (serviceability design deflections) must be less than the building code stipulated deflections. The EDCH (1996) recommends limiting total deflections to the range of $L/400$ to $L/250$ for FRP frame structures.

Since pultruded members have low stiffness to strength ratios relative to conventional structural materials, the stiffness controlled limit states are checked first (i.e., deflection and stability). Thereafter, the ultimate strength limit states are checked. The order of the limit states presented follows this order. It may be noted that this is typically not the order in which limit states are considered for design with conventional materials.

16.1.4.1.1 Transverse Deflection

Shear deformation beam theory is used to determine the deflection of the beam. This is the procedure recommended by the SPDM (1984) and the EDCH (1996). The use of shear deformation beam theory is especially important in FRP pultruded beams due to the relatively low longitudinal modulus (leading to beams with short spans) and the relatively high E/G ratios (and low shear moduli) (see Bank 1989a,b; Mottram 1992). To calculate the design deflection, appropriate choices of the flexural rigidity, EI , and the transverse shear rigidity, KAG , are required. For homogenous (i.e., having the same properties in the flanges and webs of the section) pultruded beams the following are recommended:

$$EI = E_L I_x \quad (16.12)$$

and

$$KAG = k_{tim} A G_{LT} \quad (16.13)$$

where k_{tim} is the (Timoshenko) shear coefficient. It can be found for both homogenous and non-homogenous thin-walled composite beam sections as described by Bank (1987). The flexural rigidity is primarily a function of the longitudinal moduli of the flanges and the webs. For nonhomogenous sections having different longitudinal moduli in the flanges and the webs the conventional mechanics of *composite* sections or the “transformed-section” method can be used to find the effective flexural rigidity of the section. The section transverse shear rigidity is a function of the *shear flow* in the flanges and the webs of the section (Bank 1987). However, for common pultruded I, WF, and box sections it has been shown that this term can be reasonably replaced by either the full-section shear rigidity defined as AG_b or the area of the web multiplied by the in-plane shear modulus of the web, $A_w G_{LT}$ (Bank 1989a,b). The full-section shear modulus is found by tests on full-section pultruded beams (Bank 1989a,b; Roberts 2002).

The short-term longitudinal and shear moduli presented in the deflection equation will both decrease as a function of time due to the viscoelastic nature of the FRP composite. To predict the long-term deflection, time-dependent *viscoelastic* moduli are substituted for the short-term moduli that are

typically measured by coupon tests. Both the longitudinal modulus and the in-plane shear modulus will be time dependent; however, their time dependency will be different. In general, the shear modulus will be more time dependent than the longitudinal modulus since it is primarily a resin matrix-dependent property. The viscoelastic longitudinal modulus, $E_L = E_v$, and the viscoelastic in-plane shear modulus, $G_{LT} = G_v$, are given as (Bank and Mosallam 1992).

$$E_v(t) = \frac{E_0 E_t}{E_t + E_0 t^{n_e}} \quad (16.14)$$

and

$$G_v(t) = \frac{G_0 G_t}{G_t + G_0 t^{n_g}} \quad (16.15)$$

where t is the time in hours, E_0 and G_0 are the short-term time-independent moduli and E_t and G_t are the (constant) time-dependent moduli determined from the sustained loading (or from long-term creep tests), and n_e and n_g are the empirical constants obtained from curve fitting (from creep tests) according to the linearized version of Findley's theory (SPDM 1984; Bank and Mosallam 1992). For common commercially produced pultruded FRP materials the constants obtained by Mosallam and Bank (1991) based on 2,000 and 10,000-h creep tests are $n_e = n_g = 0.30$, $E_t = 180 \times 10^6$ psi and $G_t = 30 \times 10^6$ psi. Coefficients for a variety of plastics and other nonpultruded composites are reported in the SPDM (1984). In typical pultruded structures the long-term sustained stress is between 10 and 20% of the ultimate strength of the material.

16.1.4.1.2 Global Lateral-Torsional Buckling

Lateral-torsional buckling of symmetric pultruded beams has been studied by a number of researchers. It appears that the well-known equation that is used for isotropic beam sections can be used for standard pultruded I and WF sections provided the appropriate values of E and G are used in the equations (Mottram 1992). Other analytical approaches have been suggested (Barbero and Raftoyiannis 1994; Davalos and Qiao 1997); however, simple design equations are not presented in these works. Inclusion of the effects of shear deformation is discussed by Roberts (2002). The equation to determine the critical lateral-torsional buckling stress for an I or WF section loaded through its centroid (not including the effects of shear deformation) is

$$\sigma_{cr} = \frac{C_1}{S_x} \sqrt{\frac{\pi^2 E_L I_y G_{LT} J}{(k_f L)^2} + \frac{\pi^4 E_t^2 I_y I_\omega}{(k_f L)^2 (k_\omega L)^2}} \quad (16.16)$$

where C_1 is a coefficient that accounts for moment variation along the beam, $S_x = I_x/c$ is the section modulus about the strong (bending) axis, J is the torsional constant, I_y is the second moment about the weak (vertical) axis, I_ω is the warping constant, k_f is an end restraint coefficient for flexural buckling, k_ω is an end restraint coefficient for torsional buckling, and L is the unbraced length of the member. For WF sections $I_\omega = I_y(d^2/4)$, where d is the section depth.

For closed cross-sections such as rectangular tubes the warping torsional resistance is large and lateral buckling is not a critical condition. For singly symmetric sections such as channels and angles little experimental data is available for pultruded members. Use of appropriate equations for isotropic metallic members is recommended at this time with substitution of the isotropic material properties with those of the orthotropic material properties.

16.1.4.1.3 Local Compressive Flange Buckling

Transversely loaded thin-walled sections can fail due to local buckling of the compressive flange (Barbero et al. 1991; Bank et al. 1994b, 1995). The critical buckling load (or stress) in the flange is a function of the boundary conditions on the longitudinal edges of the flange. In I and WF sections one edge is free, while the other edge is elastically restrained. There is no exact closed-form solution for this case. For the characteristic equations and computations see Bank and Yin (1996). For I and WF beams both the SPDM (1984) and the EDCH (1996) recommend that the elastically restrained edge be assumed to

be simply supported. This is a conservative assumption. Test results show clearly that the local buckling stress is higher than that predicted by this assumption; however, it is lower than that predicted by assuming that the edge is fixed (see Bank et al. 1995). The Equations presented below are taken from the SPDM (1984) and are attributed to Haaijer (1957). They are shown in terms of the effective engineering properties of the section in terms of the flexural stiffness coefficients (D_{ij}) in the SPDM.

Assuming the restrained edge to be simply supported, the local buckling stress for flanges in compression is calculated as follows:

$$\sigma_{cr} = \frac{\pi^2}{t_f(b_f/2)^2} \left[\frac{E_L t_f^3}{12(1 - \nu_L \nu_T)} \left(\frac{b_f/2}{a} \right)^2 + \frac{G_{LT} t_f^3}{\pi^2} \right] \quad (16.17)$$

where t_f is the flange thickness, b_f is the (entire) flange width, and a is the unbraced length of the flange. For long unbraced flanges the first term in the square brackets is negligible and the critical stress can be found from

$$\sigma_{cr} = 4G_{LT} \left(\frac{t_f}{b_f} \right)^2 \quad (16.18)$$

If the restrained edge is assumed to be fixed (i.e., built-in or clamped), then the local buckling stress is calculated as follows:

$$\sigma_{cr} = \frac{\pi^2}{t_f(b_f/2)^2} \left[0.935 \left(\frac{t_f^3 \sqrt{E_L E_T}}{12(1 - \nu_L \nu_T)} \right) - 0.656 \left(\frac{t_f^3 \nu_T E_L}{12(1 - \nu_L \nu_T)} \right) + 2.082 \left(\frac{t_f^3 G_{LT}}{12} \right) \right] \quad (16.19)$$

and the length of the half-buckle wavelength is given by

$$a = 1.46 \left(\frac{b_f}{2} \right) \sqrt[4]{\frac{E_L}{E_T}} \quad (16.20)$$

A reasonable approximation based on test data obtained by Bank et al. (1994b, 1995) for common pultruded WF beams is to assume that the critical local buckling stress for the compression flange is equal to the average of the simply supported and the fixed conditions given in Equations 16.17 and 16.19.

For compression flanges where both longitudinal edges are restrained, such as in box beams or hat sections, the flange is assumed to be simply supported on both of its longitudinal edges and the critical buckling stress is given as

$$\sigma_{cr} = \frac{2\pi^2 t_f^2}{b_f^2} \left(\frac{\sqrt{E_L E_T}}{12(1 - \nu_L \nu_T)} + \frac{\nu_T E_L}{12(1 - \nu_L \nu_T)} + \frac{G_{LT}}{6} \right) \quad (16.21)$$

and the length of the half-buckle wavelength is given by

$$a = b_f \sqrt[4]{\frac{E_L}{E_T}} \quad (16.22)$$

The equation for the case of flange fixed (built-in) at both longitudinal edges is given as

$$\sigma_{cr} = \frac{4.52\pi^2 t_f^2}{b_f^2} \left(\frac{\sqrt{E_L E_T}}{12(1 - \nu_L \nu_T)} + 0.543 \frac{\nu_T E_L}{12(1 - \nu_L \nu_T)} + 0.543 \frac{G_{LT}}{6} \right) \quad (16.23)$$

and the length of the half-buckle wavelength is given by

$$a = 0.67 b_f \sqrt[4]{\frac{E_L}{E_T}} \quad (16.24)$$

16.1.4.1.4 Web Flexural Buckling

Deep webs may be susceptible to flexural buckling in the plane of the web due to the linearly distributed axial (flexural) stress along the beam web. Experimental evidence of this buckling mode in common

pultruded beams has not been reported in the literature. The critical buckling stress for this case is given as

$$\sigma_{cr} = \frac{k_{LL}\pi^2 E_L t_w^2}{12(1 - \nu_L \nu_T) d_w^2} \tag{16.25}$$

where k_{LL} is a coefficient that depends on the degree of web restraint and the orthotropy ratio of the web. It is given in charts (SPDM 1984, p. 680). In typical pultruded beams where the orthotropy ratio of the web $E_T/E_L < 0.5$, $k_{LL} = 20$ is recommended.

16.1.4.1.5 Web Shear Buckling

The vertical web of a WF or box beam can buckle in shear at locations of high shear forces (typically near supports). The equation for the buckling of an orthotropic plate in pure shear is a function of the restraint provided by the flanges, the aspect ratio, and the orthotropy ratio (E_L/E_T). Experimental evidence of this buckling mode in common pultruded beams has not been reported in the literature. The critical shear stress for an orthotropic web simply supported on its edges is given as

$$\tau_{cr} = \frac{4k_{LT}}{t_w d_w^2} \sqrt[4]{\frac{E_L t_w^3}{12(1 - \nu_L \nu_T)}} \sqrt[4]{\left(\frac{E_T t_w^3}{12(1 - \nu_L \nu_T)}\right)^3} \tag{16.26}$$

where d_w is the depth of the web and k_{LT} is a coefficient given in charts (SPDM 1984, p. 682). A minimum value of $k_{LT} = 8$ is recommended unless the charts are used to obtain a more exact value.

16.1.4.1.6 Transverse Web Crushing and Buckling

Webs of pultruded beams are particularly susceptible to local failure at the location of concentrated loads at applied load points and at seated supports, due to the relatively low transverse compressive strength and stiffness of the web. This is often referred to as “web resistance to transverse forces.” Concentrated loads and seated supports for single-web members such as I or WF beams should always be placed directly over (or under) the web of the section and not on outstanding cantilevered flanges. Due to processing, pultruded sections tend to have slightly concave flanges (i.e., “curled” inward) such that the load is transferred directly to the web or webs in a concentrated fashion (Mottram 1992). The critical crushing strength is assumed to be equal to the transverse compressive strength of the material in the web

$$\sigma_{y,crit} = \sigma_{T,c} \tag{16.27}$$

In addition to the web being susceptible to crushing at locations of local concentrated forces, it may also buckle in the vertical plane. In this case it is assumed that the web acts as a plate simply supported on all four sides loaded in the transverse direction with the load applied over an effective width, b_{eff} . The equation is identical to that of the compression flange simply supported on its two longitudinal edges presented previously. In terms of the effective width (along the beam length) it is written as

$$\sigma_{cr} = \frac{2\pi^2 t_w^2}{b_{eff}^2} \left(\frac{\sqrt{E_L E_T}}{12(1 - \nu_L \nu_T)} + \frac{\nu_T E_L}{12(1 - \nu_L \nu_T)} + \frac{G_{LT}}{6} \right) \tag{16.28}$$

and

$$a = b_{eff} \sqrt[4]{\frac{E_T}{E_L}} \tag{16.29}$$

where b_{eff} is assumed to be equal to the web depth (d_w) or the distance between vertical web stiffeners, whichever is smaller. Note that in this case multiple half-wavelengths occur in the vertical direction and the single half-wavelength occurs in the longitudinal direction of the web.

16.1.4.1.7 Longitudinal Flange and Web Crushing or Tensile Rupture

For members where the b/t ratio of the flange or the d/t ratio of the web is small or local buckling is prevented by multiple longitudinal and transverse stiffeners the flexural member may fail due to

compressive crushing or tensile rupture of the pultruded material. In this case the critical compressive strength is equal to the longitudinal compressive strength of the pultruded material in the web or the flange and the critical tensile strength is equal to the longitudinal tensile strength of the material,

$$\sigma_{z,\text{crit}} = \sigma_{L,t} \quad \text{or} \quad \sigma_{L,c} \quad (16.30)$$

16.1.4.1.8 Shear Failure in the Flange and Web

The critical shear strength in the flanges and webs of a pultruded thin-walled section is typically taken as the in-plane shear strength of the pultruded material in the web:

$$\tau_{\text{crit}} = \tau_{LT} \quad (16.31)$$

The interlamina shear strength may also be a critical shear strength in flanges. In this case it is prudent to calculate the out-of-plane shear stress and compare this to the interlamina shear strength. For this case the critical shear stress is

$$\tau_{\text{crit}} = \tau_{TT} \quad (16.32)$$

16.1.4.2 Axially Loaded Compression Members

Members considered are symmetric with respect to both axes and consist of horizontal plates (flanges) and vertical plates (webs). They are loaded by an axial load that is applied at the centroid of the cross-section. Typical standard pultruded shapes that fall into this definition, and that are routinely used as columns, include I, WF, and tubular box sections. The member is designed to resist a single stress-resultant that is due to the applied axial forces (loads). This stress-resultant is the axial force P . Since the force is applied at the centroid of the section, no eccentricity is considered (i.e., beam-columns are not considered). Due to the stress-resultant P_z the member is assumed to develop a uniform axial stress:

$$\sigma = \frac{P_z}{A_z} \quad (16.33)$$

where A_z is the cross-sectional area of the member.

Due to the stress-resultant P it is assumed that the member will undergo axial deformation (shortening):

$$\delta = \frac{P_z L}{A_z E} \quad (16.34)$$

where $A_z E$ is the axial stiffness of the member in compression.

For compression members serviceability (deflection) and ultimate (strength and stability) design states are considered. The calculated design stresses must be less than the critical strengths and critical buckling stresses according to the design basis selected.

16.1.4.2.1 Axial Shortening

For calculation of axial deformation the axial stiffness is taken as

$$A_z E = A_z E_L \quad (16.35)$$

where E_L is the longitudinal modulus of the material. Note that it is often assumed that the tensile and compressive moduli of the FRP material are the same. If experimental tests indicate that the compressive modulus is not the same as the tensile modulus, then it should be used to determine axial shortening of columns. In the case of a nonhomogenous section the effective (composite) axial stiffness is used. To determine long-term axial shortening, the viscoelastic longitudinal modulus should be used.

16.1.4.2.2 Global Flexural Buckling

Global flexural (Euler) buckling of common pultruded columns has been studied in some detail (Barbero and Tomblin 1993; Zureick and Scott 1997; Zureick and Steffen 2000). It has been shown that the well-known Euler equation can be used. The classical equation, modified to account for shear

deformation effects, is recommended (Zureick and Scott 1997; Zureick and Steffen 2000). The critical buckling stress including the effects of shear deformation is given as

$$\sigma_{cr} = \frac{\pi^2 E_L}{(kL/r)_{MAX}^2} \left[\frac{1}{1 + (1/k_{tim} A_z G_{LT}) (\pi^2 E_L / (kL/r)_{MAX}^2)} \right] \quad (16.36)$$

where $(kL/r)_{MAX}$ is the maximum slenderness ratio for bending about the critical axis, k is the end restraint coefficient for the axis under consideration, L is the unbraced length of the column, and r is the radius of gyration for the axis under consideration. k_{tim} is the Timoshenko shear coefficient and A is the cross-sectional area of the section. To neglect the effects of shear deformation, the term in the square brackets is set to unity. The Timoshenko shear coefficient used in this equation is the same as that used in the shear deformation beam theory.

16.1.4.2.3 Local Compressive Flange Buckling

The local buckling of unsupported flanges in columns is identical to the local buckling of compression flanges in beams and has been discussed in Section 16.1.4.1.3.

16.1.4.2.4 Local Compressive Web Buckling

Local buckling of column webs that are supported on both longitudinal edges is identical to that of the flanges supported on two longitudinal edges discussed previously. It is conservatively assumed that the web is simply supported at the longitudinal edges. The equation for determining this buckling stress is

$$\sigma_{cr} = \frac{2\pi^2 t_w^2}{d_w^2} \left(\frac{\sqrt{E_L E_T}}{12(1 - \nu_L \nu_T)} + \frac{\nu_T E_L}{12(1 - \nu_L \nu_T)} + \frac{G_{LT}}{6} \right) \quad (16.37)$$

and the length of the half-buckle wavelength is given by

$$a = d_w \sqrt[4]{\frac{E_L}{E_T}} \quad (16.38)$$

The equation for the case of the web fixed (built-in) at both edges is (for comparison purposes)

$$\sigma_{cr} = \frac{4.52\pi^2 t_w^2}{d_w^2} \left(\frac{\sqrt{E_L E_T}}{12(1 - \nu_L \nu_T)} + 0.543 \frac{\nu_T E_L}{12(1 - \nu_L \nu_T)} + 0.543 \frac{G_{LT}}{6} \right) \quad (16.39)$$

and the length of the half-buckle wavelength is given by

$$a = 0.67 d_w \sqrt[4]{\frac{E_L}{E_T}} \quad (16.40)$$

16.1.4.2.5 Global Torsional Buckling

Open-section axially loaded compression members can buckle in a pure torsional mode. For doubly symmetric sections such as I and WF sections the critical torsional buckling stress (not including effects of shear deformation) is given as (Roberts 2002)

$$\sigma_{cr} = \frac{A_z}{I_x} \left[\frac{\pi^2 E_L I_{\omega}}{(k_{\omega} L)^2} + G_{LT} J \right] \quad (16.41)$$

where A_z is the cross-sectional area, I_x is the second moment of area about the strong axis, J is the torsional constant, I_{ω} is the warping constant, k_{ω} is an end restraint coefficient for torsional buckling, and L is the unbraced length of the member. For a wide-flange section $I_{\omega} = I_y (d^2/4)$, where d is the section depth.

In the case of singly symmetric sections such as angle sections, members may also buckle axially in a flexural-torsional mode consisting of Euler buckling about the strong axis of the cross-section and torsional buckling about the longitudinal axis of the member. Equations for this special case are presented by Zureick and Steffen (2000). It is interesting to note that for the special case of single angles the pure torsional buckling stress is identical to the local flange buckling stress.

16.1.4.2.6 Longitudinal Flange and Web Crushing

For members where the b/t ratio of the flange or the d/t ratio of the web is small or local and global buckling is prevented the axial member may fail due to compressive crushing of the pultruded material. In this case the critical compressive strength is equal to the longitudinal compressive strength of the pultruded material in the web or the flange:

$$\sigma_{z,\text{crit}} = \sigma_{L,c} \quad (16.42)$$

16.1.4.3 Axially Loaded Tension Members

Members considered are symmetric with respect to both axes and consist of horizontal plates (flanges) and vertical plates (webs). They are loaded by an axial load that is applied at the centroid of the cross-section and in the longitudinal direction of the material. Typical standard shapes that fall into this definition, and that are routinely used as tension members in trusses or as bracing members in frames, include I, WF, and tubular box sections. The member is designed to resist a single stress-resultant that is due to the applied axial forces (loads). This stress-resultant is the axial force P . Since the force is applied at the centroid of the section, no eccentricity is considered. Due to the stress-resultant P_z the member is assumed to develop a uniform axial tensile stress:

$$\sigma = \frac{P_z}{A_z} \quad (16.43)$$

where A_z is the cross-sectional area of the member.

Due to the stress-resultant P it is assumed that the member will undergo axial deformation (stretching):

$$\delta = \frac{P_z L}{A_z E} \quad (16.44)$$

where $A_z E$ is the axial stiffness of the member in tension.

For tension members serviceability (deflection) and ultimate (gross and net section strength) design states are considered. The calculated design stresses must be less than the critical strengths according to the design basis selected.

16.1.4.3.1 Axial Extension

For calculation of axial deformation the axial stiffness is taken as

$$A_z E = A_z E_L \quad (16.45)$$

where E_L is the longitudinal modulus of the material. In the case of a nonhomogenous section the effective (composite) axial stiffness is used.

16.1.4.3.2 Longitudinal Rupture of the Gross Section

The critical tensile strength on the gross section of the member in tension is equal to the longitudinal tensile strength of the pultruded material:

$$\sigma_{z,\text{gross}} = \sigma_{L,t} \quad (16.46)$$

and the design stress is calculated over the gross section, A_g .

16.1.4.3.3 Longitudinal Rupture of the Net Section

Where the cross-section of a tensile member is reduced due to the presence of holes (typically for bolted connections), the tensile strength is reduced due to the effect of stress concentrations due to the holes. The critical tensile strength for the net section can be taken as (ECDH 1996)

$$\sigma_{z,\text{net}} = 0.9\sigma_{L,t} \quad (16.47)$$

and the design stress is calculated over the net section, A_{net} .

16.1.4.4 Combined Axial and Flexural Members

Members subjected to combined bending (flexure) and compression (beam–columns) or combined flexure and tension may be designed by assuming a linear interaction between the flexural and axial load effects according to the SPDM (1984), EDCH (1996), and AASHTO (2001). For the ASD basis the interaction formula is given as

$$\frac{\sigma_A}{\sigma_{A,\text{allow}}} + \frac{\sigma_F}{\alpha \sigma_{F,\text{allow}}} \leq 1 \quad (16.48)$$

where the subscript A stands for axial and the subscript F stands for flexural. The allowable axial and flexural stresses in the equation are the critical axial and flexural stresses divided by their appropriate safety factors, respectively. The parameter α represents the effect of moment magnification, due to second-order P – δ effects, for members subjected to combined flexure and compression. It is given as

$$\alpha = \left(1 - \frac{\sigma_A}{\sigma_{\text{cr}}^{\text{Euler}}} \right) \quad (16.49)$$

where $\sigma_{\text{cr}}^{\text{Euler}}$ is the critical Euler buckling load (see Section 16.1.4.2.2) for the axis about which the beam–column is subjected to flexure. Members subjected to combined flexure and compression should also be checked for the case of $\alpha = 1$ at locations where lateral displacement is restrained in the member. For members subjected to combined flexure and tension, $\alpha = 1$.

For LSD or LRFD design bases the equations take an analogous form having a linear interaction between the limiting states. Few experimental data have been presented for pultruded members subjected to combined loads and further research is needed in this area to validate the interaction equation presented previously (16.48).

16.1.5 Design of Pultruded Structural Connections

Pultruded FRP sections can be used in trusses and braced frame structures. As with the design of FRP structural sections there is no design guide or code for connections for pultruded structures. Connections are currently designed based on the first principles of mechanics and tests of full-sized connections.

For common FRP pultruded sections mechanical fasteners (bolts, rivets, screws) and adhesive bonding (epoxy, polyester) are most commonly used. Both steel and FRP bolts are available; however, most structures utilize metallic fasteners (usually galvanized or stainless steel fasteners).

For future routine design of FRP pultruded structures standard connection analysis and design procedures are needed. Connections include both simple single- and double-shear lap joints as well as frame connections consisting of multiple parts (members themselves and gusset plates, inserts, clip angles, and stiffeners) that are typically used to connect beams, columns, and bracing members in structural braced frames and trusses made of I, WF, and tubular FRP pultruded members.

Unique specialty connections can be designed for custom pultruded structures. These include slotted, clipping, and expansion connections and can be designed for custom pultrusions to reduce the number of parts needed in the connection and also to facilitate rapid prefabricated construction.

This discussion will focus on connections for existing standard pultruded sections for use in braced frame and truss structures. Pultruded frames should be designed as simple frames (Type 2). Due to the low stiffness of the materials used in the members themselves and the parts of the connection it is not possible to develop significant moment resistance in the connections (Bank et al. 1990, 1994a, 1996; Bass and Mottram 1994; Mottram and Zheng 1996, 1999a,b; Lopez-Anido et al. 1999; Smith et al. 1999).

Pultruded frames may be designed as semirigid frames (Type 3) provided sufficient information on the moment–rotation characteristics of the frame connection can be obtained. At the present time semirigid analysis and design for pultruded frames is not recommended (Turvey 2001) unless accompanied by a rigorous experimental investigation to determine connection failure modes and moment–rotation characteristics. A state-of-the-art report on semirigid frame connections for FRP structures (primarily, pultruded materials) was published in 1998 (Mottram and Turvey 1998).

In recent years test data have been reported for single and double lap single- and multibolted joints in commercially produced pultruded materials (Abd-el-Naby and Holloway 1993a,b; Cooper and Turvey 1995; Erki 1995; Rosner and Rizkalla 1995; Hassan et al. 1997; Turvey 1998; Wang 2002). It is important to note that most of the data reported have been from tests on commercially produced pultruded plate materials, which may be different from the pultruded material used in structural sections (profile shapes). Test data have also been reported for simple shear and semirigid frame connections (Bank et al. 1990, 1994b, 1996; Bass and Mottram 1994; Mottram and Zheng 1996, 1999a,b; Lopez-Anido et al. 1999; Smith et al. 1999). There is nevertheless very little design guidance that has been developed from these test data for routine design of connections in pultruded structures, and full-scale testing of typical pultruded frame or truss connections is recommended at this time (Turvey 2001).

16.1.5.1 Connections in Existing Pultruded Structures

Typically “standard” braced frame connections are detailed using equal leg or unequal leg angles and pultruded gusset plates together with steel fasteners or FRP threaded rods and nuts. Connections of this type mimic steel Type 2 simple framing connections and have been used in numerous pultruded frame structures to-date. Connection parts are usually bonded with an epoxy adhesive as well as fastened with bolts. Details for standard clip angle shear connections are provided in manufacturers design guides (Creative Pultrusions 2000; Strongwell 2002). Base plate clip angle details are also provided.

Typical standard truss connections are detailed using tubular members with tubular “telescoping” inserts (either hollow or solid) of different sizes with steel bolts. Standard pultruded square tubular members in the 2 by 2 to 4 by 4 sizes are used in this manner to construct lattice-like truss structures usually used for footbridges spanning up to approximately 80 ft (Johansen et al. 1999) and “stick-built” cooling towers. Larger gusset plates may also be used for truss connections with tubular members.

Often, custom framed connections are designed for custom pultruded sections for use in prefabricated FRP structures such as cooling towers, walkways, and platforms. Pultruded and molded grating or plank-type flooring systems are often integrated into these building systems to develop lateral stability.

16.1.5.2 Bolted Connections

Advantages of bolted connections for FRP pultruded structures include amenability to field or shop assembly, simplicity of fabrication, ease of inspection, unsophisticated tooling, familiarity to steel workers, relatively low cost, and speed of assembly (as opposed to bonded connections). Disadvantages of bolted connections for FRP pultruded structures include the lack of high-strength FRP fasteners, stress concentrations in the base pultruded materials, and their structural inefficiency.

16.1.5.2.1 Design Considerations for Bolted FRP Pultruded Connections

The following material properties of pultruded materials should be considered when designing a bolted connection for a pultruded structure: anisotropy, inhomogeneity, viscoelasticity, environmental degradation, and potentially brittle failure. The following geometric parameters should be considered: bolt diameter, d_b , hole diameter, d , edge (side) distance, s , end distance, e , pitch, p (distance between “rows” of fasteners parallel to the load direction), and gage, g (distance between “columns” of fasteners perpendicular to the load direction). The following fabrication parameters should be considered: FRP or steel fasteners, bolt torque, clearance, washer size, and the fact that there are limited sizes of members and connection parts.

16.1.5.2.2 Failure Modes of Bolted Connections

FRP pultruded connections can fail due to failure of the fasteners in the following modes: bolt shear, bolt tension, bolt thread shear, and nut thread shear. The base pultruded material can fail in the plane of loading in the following modes: net tension, bearing, shear-out, cleavage, splitting, or combinations of the above. The base pultruded material can fail out of the plane of the loading due to punching or crushing.

16.1.5.3 Design Recommendations for Bolted Connections

Models are available for predicting failure modes for base pultruded materials used in connections. Hassan et al. (1997) have presented models for single- and multihole double-lap tension connections. Models are based on the Hart-Smith (1978) semiempirical approach and require testing of specific materials to obtain material constants. Models predict failure modes (net tension, bearing and cleavage) and have been calibrated for a typical pultruded plate material. Simplified “strength-of-materials” models based typically on bearing, shear-out, or net-tension failure modes have been discussed by many authors (Mottram 2001).

A review of design recommendations for spacing and edge distances for lap joints in pultruded materials loaded in tension has revealed that there is reasonable agreement between research data and manufacturers’ recommendations (Mottram 2001). Based on the data presented by Mottram (2001) the following design geometric parameters are suggested for in-plane tensile loads on connection elements:

1. Edge distance to bolt diameter, $e/d_b \geq 4$.
2. Element (member) width to bolt diameter, $w/d_b = 5$.
3. Side distance to bolt diameter, $s/d_b \geq 2$.
4. Pitch to bolt diameter, $p/d_b \geq 4$.
5. Gage to bolt diameter, $g/d_b \geq 4$.
6. Bolt diameter to plate thickness, $d_b/t_{pl} \geq 1$.
7. Washer diameter to bolt diameter, $d_w/d_b \geq 2$.

It is important to note that the geometric design recommendations presented above are for single- and double-lap joints loaded in tension and are intended to cause bearing failure in the material at the locations of the fasteners and to avoid net tension, shear-out, and combined failure modes (e.g., block shear) that are regarded as more brittle than bearing failures. It is also important to note that the recommendations provided are based on the tensile load being applied in the longitudinal material direction. Little guidance is available for shear loaded (in-plane) joints used in typical simple beam framing connections. These recommendations are often also used for joints loaded in shear.

For constructibility bolt holes should be oversized by $\frac{1}{16}$ in. However, if possible, holes should not be oversized. It is possible to not oversize holes and still fit the connection together (provided holes are accurately drilled) since the pultruded material is relatively soft and bolts (especially when steel bolts are used) can be inserted with light tapping with a rubber mallet.

It is assumed that FRP nuts are tightened to the manufacturer’s recommended torque to achieve a measure of clamping pressure on the connection. It has been shown that clamping pressure can increase the bearing strength of the base material (Cooper and Turvey 1995). In addition, clamping pressure is needed where bonded and bolted connections are used in order to achieve a good bond line. Clamping torque depends on the nominal diameter of the FRP bolt and ranges from 15 to 110 ft lb for FRP bolts $\frac{1}{2}$ to 1 in. in diameter, respectively. If steel bolts are used, care must be taken not to overtighten the nuts so as to cause out-of-plane crushing of the base material. Finger tight plus one-half-turn of the nut is recommended. Even though some tightening of the nut is used in bolted connections for pultruded structures, all connections are designed to be bearing-type connections. Friction (“slip-critical”) connections can not be achieved in pultruded structures due to the low through-the-thickness stiffness of the pultruded material.

The safety factor is taken as 4.0 for all connection parts when the design is based on the ASD. Partial safety factors for LSD are provided in the EDCH. Tentative resistance factors for LRFD are provided by Prabhakaran et al. (1996).

Pultruded connections are currently designed only for the ultimate strength limit state. Bearing strengths for pultruded materials used are the ultimate bearing strengths (i.e., the load required to cause local failure at the hole) and not the serviceability bearing strength (often defined as the load causing an axial deformation equal to 4% of the hole diameter per ASTM 953). All joints are assumed to be pinned for braced frame analysis or truss analysis for the purposes of serviceability analysis of the structure (and the members). No specific requirements are available for the local deformation of the pultruded connections.

16.1.5.3.1 Design Stress States

For a joint in tension the average bearing design stress at the hole in the base pultruded material is given as

$$\sigma_{br} = \frac{P}{d_b t_{pl}} \quad (16.50)$$

where P is the far field tensile force, d_b is the bolt diameter, and t_{pl} is the thickness of the base pultruded material.

For a joint in tension the net-tension design stress at the location of the hole in the pultruded material is given as

$$\sigma_{net} = \frac{P}{A_{net}} \quad (16.51)$$

where

$$A_{net} = t_{pl}(W - nd) \quad (16.52)$$

for a row of n fasteners where holes are not staggered. W is the plate width perpendicular to the load direction. This assumes that the critical section will be through the row of holes and perpendicular to the longitudinal direction of the material. Due to the orthotropy of the pultruded material, however, the critical section may be “staggered” though multiple rows (Prabhakaran et al. 1996). At this time the empirical formula used for staggered rows for joints in steel members is recommended as a first approximation for orthotropic pultruded materials:

$$A_{net} = t_{pl} \left(W - nd + \sum \frac{p^2}{4g} \right) \quad (16.53)$$

where the summation is over all diagonal distances in an assumed failure “path.” This equation assumes that the strength of the material is the same along all paths, which is not the case for orthotropic materials. Where elements of profile sections are connected in tension (such as flanges of angles and I-sections), it is recommended that only the area of the outstanding element be considered as being effective (and not the area of the entire section). For bolts in rows perpendicular to the load direction the load may not be distributed evenly among the bolt rows. The “forward” row carries a proportionally greater share that depends on fiber orientation. Recommendations are given in the ECDH for load distribution to rows of bolts. For preliminary calculations it can be assumed that load is distributed evenly among all bolts.

For a joint in tension the shear-out design stress at the bolt location at the material edge in the direction of the tensile load is given as

$$\tau_{shear-out} = \frac{P}{2t_{pl}e} \quad (16.54)$$

The design shear stress on a fastener is given as

$$\tau_f = \frac{V_f}{A_f} \quad (16.55)$$

where V_f is the shear force on the fastener (accounting for single- of double-shear configurations) and A_f is the cross-sectional area of the fastener shank.

The shear stress in the parts of the connection (angles) is calculated as

$$\tau_{pl} = \frac{V}{A_{pl}} \quad (16.56)$$

where V is the design shear force on the element and A_{pl} is the effective shear area of the element. Where clip angles are used to transfer shear at the beam web in beam-to-column connections, the shear stress is

typically calculated at the “heel” of the angle and is taken as the length of the angle multiplied by the angle thickness.

Combinations of shear and tensile stresses in parts of the connection or the connected members must be checked to prevent “block-shear” failure of the pultruded material through the fastener holes. Where flanges of beams are coped to detail the connection, this is often a governing failure mode.

Even in shear-type connections, tensile loads (due to prying action) may develop in the members and the parts of a connection due to eccentricities in the connection. Such eccentricities are neglected in the design of steel shear connections. However, in pultruded structures these eccentricities should be considered. The local tensile stress on the member or the element should be determined since such loads typically are applied transverse to the longitudinal direction of the pultruded material. The appropriate tensile load and the effective area are difficult to determine precisely due to complex stress states in the connecting elements, and simple approximations based on the geometry of the connection are usually made for design calculations.

16.1.5.3.2 Critical Connection Limit States

Bearing failure in the base pultruded material is the recommended failure mode for pultruded connections. This failure mode is generally ductile and leads to a progressive shear-out failure of the material when loads are in the longitudinal direction of the pultruded material and sufficient transverse reinforcement is provided (in the form of mats and fabrics). (In the transverse direction bearing failure may not be ductile and may lead to brittle net-tension transverse failure of the base material.) The bearing strength provided by pultrusion manufacturers can be used in calculations. If bearing strength is not available from test data, it can be conservatively approximated as the material compressive strength (for bearing in the longitudinal direction) and the transverse tensile strength (for bearing in the transverse direction). Either the longitudinal bearing strength or the transverse bearing strength is used depending on the direction of the member or element relative to the load.

$$\sigma_{cr} = \sigma_{L,br} \quad \text{OR} \quad \sigma_{T,br} \quad (16.57)$$

Tensile failure in the elements of the connection is a function of the tensile strength of the pultruded material either in the longitudinal or in the transverse direction. For tensile stress on the gross area

$$\sigma_{cr} = \sigma_{L,t} \quad \text{OR} \quad \sigma_{T,t} \quad (16.58)$$

For tensile stress on the net area a reduced ultimate strength is recommended to account for stress concentrations (as with members in tension):

$$\sigma_{cr} = 0.9\sigma_{L,t} \quad \text{OR} \quad 0.9\sigma_{T,t} \quad (16.59)$$

Shear failure (and shear-out failure) of the elements of the connection is a function of the in-plane shear strength for the pultruded material:

$$\tau_{cr} = \tau_{LT} \quad (16.60)$$

Shear failure of the fasteners is a function of the shear strength of the fasteners. For steel fasteners this is typically not a likely ULS. For FRP fasteners shear in the fasteners can govern the design of the connection:

$$\tau_{cr} = \tau_{ult} \quad (16.61)$$

where τ_{ult} is the ultimate shear strength of the fastener.

Where FRP threaded rods or bolts are used in connections, the threads of the bolt can shear off longitudinally. This limit state is a function of the longitudinal shear strength of the rods or bolts used. It should be checked when FRP bolts and nuts are used. Ultimate thread shear strength is given in manufacturers' design guides.

In semirigid connections in which top and bottom seats made of pultruded angles are used, extreme caution must be used to ensure that the angles do not fail locally in through-the-thickness radial tension or compression in either an “opening” or a “closing mode” (Bass and Mottram 1994; Smith et al. 1999).

In addition, the flange–web junction behind the flange in the column section to which the top and bottom angles are connected must be checked for transverse tensile local failure (Bank et al. 1994a). As noted previously, semirigid connection design should only be used where test data are available for a full-sized connection as detailed in the structure.

16.2 Analysis and Design of FRP Reinforcements for Concrete

16.2.1 Introduction

FRP reinforcing bars and grids have been produced for reinforcing concrete structures for over 20 years (Nanni 1993; ACI 440R-96 1996). FRP reinforcing bars have been developed for prestressed and non-prestressed (conventional) concrete reinforcement. This section will consider only non-prestressed reinforcement for concrete structures. A review of design recommendations for FRP reinforcement for prestressed concrete structures can be found in Gilstrap et al. (1997) and ACI 440.4R-04 (2004).

Current FRP reinforcing bars and grids (henceforth referred to as FRP rebars) are commercially produced using thermosetting polymer resins (commonly vinylester and epoxy) and glass, carbon or aramid reinforcing fibers. The bars are primarily longitudinally reinforced with volume fractions of fibers in the 50 to 65% range. FRP rebars with thermoplastic polymer resins, which may allow them to be bent in the field, are in the developmental stages. FRP reinforcing bars are usually produced by a process similar to pultrusion and have a surface deformation or texture to develop bond to concrete (see ACI 440R-96 1996 for photographs of typical FRP rebars).

A number of design guides and national standards are currently published to provide recommendations for the analysis, design, and construction of concrete structures reinforced with FRP rebars (JSCE 1997; Sonobe et al. 1997; Bakht et al. 2000; CSA 2002; ACI 440.1R-03 2003). This section will provide a brief review of the ACI 440.1R-03 guidelines. A number of industry groups coordinate the activities of FRP rebar producers in the United States, such as, the ACMA. Activities of these organizations are closely coordinated with the American Concrete Institute (ACI) Technical Committee 440 — FRP Reinforcements.

Research in the use of FRP reinforcements in concrete structures has been the focus of intense international research activity since the late 1980s. A biannual series of symposia entitled “Fiber Reinforced Plastics in Reinforced Concrete Structures” or “FRPRCS” has been the leading venue for reporting and disseminating research results. The most recent symposium, the sixth in the series dating back to 1993, was held in Singapore in July 2003 (Tan 2003).

16.2.2 Properties of FRP Reinforcing Bars

Glass fiber reinforced vinylester bars are the most commonly commercially produced FRP rebars. They are available from a number of manufacturers. Bars are typically produced in sizes ranging from $\frac{3}{8}$ in. to 1 in. in diameter (i.e., #3 to #8 bars). Bars have a sand coated external layer, a molded deformation layer, or a spiral wind layer to create a nonsmooth surface.

The properties of FRP rebars are reported by manufacturers in accordance with ACI 440.1R-03 recommendations for guaranteed tensile strength and longitudinal modulus. It is important to note that the reported strength of FRP rebars decreases with the diameter of the bar. This is attributed to the relatively low in-plane shear strength of the FRP rebars. Designers need to consult manufacturers’ recommended properties to be used for design. Typical properties are shown in Table 16.4 for glass fiber FRP rebars and carbon fiber FRP bars. It should be noted that the carbon fiber bars are typically used as prestressing tendons or “near-surface-mounted” (NSM) strengthening and not as conventional reinforcing bars due to cost considerations.

FRP rebars are considered to be transversely isotropic from a mechanics perspective (Bank 1993). Theoretical equations are available to predict the mechanical and physical properties of the FRP rebars from the properties of the fiber and resin constituents. Theoretical methods are not available to predict the bond properties and the long-term durability characteristics of FRP rebars. A specification has been

TABLE 16.4 Properties of Typical Commercially Produced FRP Reinforcing Bars

proposed for determining long-term properties for FRP rebars based on the Arrhenius accelerated aging procedure (Bank et al. 2003). Test methods for determining the properties of FRP rebars can be found in JSCE (1997) and in ACI 440.3R-04 (2004).

FRP rebars should only be used at service temperatures below the glass transition temperature of the polymer resin system used in the bar. For typical vinylester polymers this is around 200°F. The bond properties have been shown to be highly dependent on the glass transition temperature of the polymer (Katz et al. 1999). In addition, it is important to note that the coefficients of thermal expansion of FRP rebars are not the same in the transverse (radial) direction as in the longitudinal direction. The coefficient of thermal expansion may be close to an order of magnitude higher in the transverse direction of the bar due to its anisotropic properties (see typical properties in Table 16.4). This may cause longitudinal splitting in the concrete at elevated temperatures if insufficient cover is not provided.

FRP rebars containing glass fibers can fail catastrophically under sustained load at stresses significantly lower than their tensile strengths, a phenomenon known as creep rupture or static fatigue. The amount of sustained load on FRP rebars is therefore limited by design guides.

FRP reinforcing bars made of thermosetting polymers (e.g., vinylester, epoxy) cannot be bent in the field and must be produced by the FRP rebar manufacturer with “bends” for anchorages or stirrups. The strength of the FRP rebar at the bend is substantially reduced and must be considered in the design.

FRP rebars should not be used for carrying compressive stress in concrete members (i.e., compression reinforcement) where they are used in the compression zone they should be suitably confined to prevent local instability.

16.2.3 Design Basis for FRP Reinforced Concrete

A design basis for FRP reinforced concrete has been recommended by a number of standards and professional organizations. The LRFD basis is recommended by the ACI 440.1R-03; however, at this time resistance factors are not probabilistically based. Load factors are those recommended for all concrete structures by ACI 318-95 (1995).

For the design of flexural members reinforced with FRP rebars the ACI 440.1R-03 recommends the following resistance factors:

Flexural capacity (tensile reinforcement only):

$$\phi = 0.5 \text{ for an underreinforced beam section } (\rho_f < \rho_{fb})$$

$$\phi = 0.7 \text{ for a substantially overreinforced beam section } (\rho_f > 1.4\rho_{fb})$$

$$\phi = 0.5\rho_f/\rho_{fb} \text{ for a lightly overreinforced beam section } (\rho_{fb} < \rho < 1.4\rho_{fb})$$

Shear capacity (stirrups):

$$\phi = 0.85 \text{ per ACI 318-95.}$$

where ρ_f is the FRP reinforcement ratio and ρ_{fb} is the balanced FRP reinforcement ratio.

Characteristic strength (also called the guaranteed strength) and strain to failure of FRP rebars are defined as the mean minus three standard deviations of a minimum of 25 test samples. The design strength, f_{fu} , and design failure strain, ϵ_{fu} , are obtained from the characteristic strength and failure strain by multiplying them by an environmental reduction factor, C_E , which depends on the fiber type in the bar and the type of intended service of the structure. For example, for weather exposed concrete with glass FRP rebars, C_E is 0.7 (ACI 440.1R-03 2003).

Since FRP rebars typically have a lower modulus than steel rebars, the serviceability limit state (deflections and crack widths) can often control the design of FRP reinforced concrete sections. The ACI 440.1R-03 provides procedures for calculating deflections and crack widths in FRP reinforced members.

16.2.4 Design of Flexural Members with FRP Reinforcing Bars

16.2.4.1 Moment Capacity

Design of flexural members follows the *strength design method* of the ACI limit states version of an LRFD design basis. In this approach the nominal factored moment resistance (ϕM_n) of the member must be greater than the factored ultimate moment required (M_u).

The nominal moment capacity of FRP reinforced concrete members is determined in a similar fashion to that of a steel reinforced section; however, since FRP rebars do not yield (i.e., are linear elastic to failure), the ultimate strength of the bar replaces the yield strength of the steel rebar in the traditional concrete beam design formula based on strain compatibility (assuming plane sections remain plane and bars are perfectly bonded to the concrete) and equilibrium of forces (ACI 440.1R-03 2003). Both underreinforced section design and overreinforced section design are permitted; however, due to serviceability limits (deflections and crack widths) most glass FRP reinforced flexural members will be substantially overreinforced.

The flexural reinforcement ratio for an FRP reinforced rectangular beam section (where the subscript f is used to indicate FRP reinforcement to distinguish it from conventional reinforcement) is given as

$$\rho_f = \frac{A_f}{bd} \quad (16.62)$$

and the balanced FRP reinforcement ratio is given as

$$\rho_{fb} = 0.85\beta_1 \frac{f'_c}{f_{fu}} \frac{E_f \epsilon_{cu}}{E_f \epsilon_{cu} + f_{fu}} \quad (16.63)$$

where A_f is the area of FRP reinforcement, b is the beam width, d is the effective depth, β_1 is a factor that depends on concrete strength (0.85 for 4000 psi concrete), f'_c is the cylinder compressive strength of the concrete, E_f is the longitudinal modulus of the FRP rebar, ϵ_{cu} is the ultimate nominal compressive strain in the concrete (taken as 0.003), and f_{fu} is the longitudinal design strength of the FRP rebar.

When $\rho_f > \rho_{fb}$ the section will fail due to concrete crushing and the nominal moment capacity is given in a similar fashion to that for a section reinforced with steel rebar (where the rebar has not reached its

yield stress). The stress in the rebar needs to be calculated to determine the capacity. Design is usually done by trial and error. The nominal moment capacity is given as

$$M_n = A_f f_f \left(d - \frac{a}{2} \right) \quad (16.64)$$

where

$$a = \frac{A_f f_f}{0.85 f'_c b} \quad (16.65)$$

$$f_f = \left(\sqrt{\frac{(E_f \varepsilon_{cu})^2}{4} + \frac{0.85 \beta_1 f'_c}{\rho_f} E_f \varepsilon_{cu}} - 0.5 E_f \varepsilon_{cu} \right) \quad (16.66)$$

where f_f is the stress in the FRP rebar at concrete compressive failure and a is the depth of the equivalent rectangular (Whitney) stress block in the concrete.

When $\rho_f < \rho_b$, the section will fail due to rupture of the FRP rebars in tension and nominal moment capacity is given in a similar fashion to that for a section reinforced with steel rebar if the rebar does not reach its yield stress before tensile failure (which will not happen for a conventional steel bar but will always happen for a FRP rebar). Since the reinforcement has not yielded in this case failure cannot be assumed to occur due to concrete compression failure following yielding of the rebar and the stress in the concrete at the time of rebar failure needs to be calculated. This calculation requires knowledge of the nonlinear stress-strain characteristics of the concrete and requires an incremental solution procedure, which is not suited to design calculations. To overcome this situation the ACI 440.1R-03 guide recommends computing the approximate (and conservative) nominal flexural capacity as follows:

$$M_n = 0.8 A_f f_{fu} \left(d - \frac{\beta_1 c_b}{2} \right) \quad (16.67)$$

where the depth of the neutral axis, c_b , is given as

$$c_b = \left(\frac{\varepsilon_{cu}}{\varepsilon_{cu} + \varepsilon_{fu}} \right) d \quad (16.68)$$

16.2.4.2 Shear Capacity

The nominal shear capacity of an FRP reinforced concrete member in flexure is determined in a similar fashion to that of a steel rebar reinforced section; however, due to the lower modulus of FRP rebars, which leads to a shallower compression zone and larger deflections at flexural failure of FRP reinforced beams, the shear capacity of the concrete is reduced from its conventional value. In addition, the strain in the FRP stirrups is limited to prevent large shear cracks from developing in the FRP reinforced member. The strength of the FRP stirrup is also limited by its strength at its bent portion. The nominal shear capacity, V_n , is given as

$$V_n = V_{c,f} + V_f \quad (16.69)$$

where $V_{c,f}$ is the nominal shear capacity of the concrete with FRP rebars used as main tension reinforcement, and can be taken as

$$V_{c,f} = \frac{\rho_f E_f}{90 \beta_1 f'_c} V_c \quad (16.70)$$

and V_f (in Equation 16.69) is the nominal shear capacity of the FRP stirrups. For vertical shear stirrups

$$V_f = \frac{A_{fv} f_{fv} d}{s} \quad (16.71)$$

where the strength of the FRP stirrup, f_{fv} , is limited by the smaller of

$$f_{fv} = 0.004E_f \quad (16.72)$$

and the strength of the FRP rebar at its bend,

$$f_{fb} = \left(0.05 \frac{r_b}{d_b} + 0.3 \right) f_{fu} \quad (16.73)$$

where r_b is the inside radius of the bend and d_b is the diameter of the FRP rebar. Standard bend radii are reported by manufacturers and range from 4.25 to 6 in. for typical FRP rebars.

For the SLS both crack width and deflections must be checked according to the procedures detailed in ACI 440.1R-03. The designer is required to check stresses under sustained service loads against creep rupture stress limits and fatigue stress limits. These limits depend on the type of fiber in the FRP rebar and are the most restrictive for glass FRP rebars where the limiting stress is only 20% of the design strength (i.e., $0.2f_{fu}$). Limits on minimum FRP reinforcement ratios for flexural and shear reinforcement are also provided. For further details see ACI 440.1R-03 (2003).

16.2.5 Detailing of FRP Reinforcements

The development length of an FRP rebar is different from the development length of a conventional steel rebar. The properties of hooks in FRP rebars are also different from those in steel rebars due to the decrease in strength at the bends in FRP rebars. The ACI 440.1R-03 guide provides recommendations for detailing FRP rebar anchorages and splices so that the FRP rebar can develop its tensile strength at member ends, at hooks, and at locations where bars are overlapped or terminated. It should be noted that current recommendations are based on limited, and sometimes conflicting, data.

Failure due to insufficient development length is called a bond failure and may be due to splitting of the concrete surrounding the bar or due to pull-out of the bar itself. Two equations are provided by ACI 440.1R-03, one for splitting controlled failure and one for pull-out controlled failure. For splitting failure

$$l_{bf} = K_2 \frac{d_b^2 f_{fu}}{\sqrt{f'_c}} \quad (16.74)$$

and for pull-out failure

$$l_{bf} = \frac{d_b f_{fu}}{2700} \quad (16.75)$$

where l_{bf} is the development length and K_2 ranges from $\frac{1}{21.3}$ to $\frac{1}{5.6}$ depending on FRP rebar type and the source of the test data (ACI 440.1R-03 2003). Manufacturers of FRP rebars also provide data on development lengths for the bars they produce.

For hooked bars the development length is given as a function of the FRP rebar design strength. For FRP rebars with design strengths in the range of 75 to 150 ksi (typical of glass FRP rebars) the length of a hooked bar, l_{bth} , is given as

$$l_{bth} = \frac{f_{fu}}{37.5} \frac{d_b}{\sqrt{f'_c}} \quad (16.76)$$

The tail length should not be less than $12d_b$ or 9 in.

Tension lap splices for FRP rebars are based on recommendations for steel rebars and limited test data. For Class A and Class B lap splices the recommended development lengths are $1.3l_{df}$ and $1.6l_{df}$, respectively.

FRP stirrups can be spaced at a maximum of $d/2$ (or 24 in.) and should have a minimum r_b/d_b ratio of 3. The tail length of 90° hooks in the stirrups must be at least $12d_b$.

Minimum concrete cover for FRP rebars is d_b .

16.3 Analysis and Design of FRP Strengthening for Concrete

16.3.1 Introduction

FRP reinforcing systems for strengthening structurally deficient concrete structural members and for repairing damaged or deteriorated concrete structures have been used since the mid-1980s. The first applications involved beams strengthened to increase their flexural capacity using high-strength, lightweight fiber reinforced epoxy laminates that were bonded to the soffits of the beams (e.g., Meier and Kaiser 1991; Saadatmanesh and Ehsani 1991; Meier 1995). The method is a modification of the one where epoxy bonded steel plates are used to strengthen concrete beams, which has been in use since the mid-1960s. The FRP systems were shown to provide significant benefits in constructibility and durability over the steel plates. Thereafter, significant work was conducted on strengthening of concrete columns to enhance their axial capacity, shear capacity, and ductility, primarily for seismic loadings (e.g., Seible et al. 1997). This method is a modification of the one using steel jackets to strengthen concrete columns. This was followed closely by work on shear strengthening of beams (e.g., Triantafillou 1998). A review of the state-of-the-art on the subject can be found in Teng et al. (2001) and Bakis et al. (2002). The method has also been used to strengthen masonry and timber structures; however, applications of this type are not discussed in this section.

Current FRP strengthening systems for concrete fall into two popular types. One type consists of factory manufactured (typically unidirectional pultruded) laminates (also known as strips or plates) of carbon- or glass-reinforced thermosetting polymers (epoxy or vinylester) that are bonded to the surface of the concrete using an epoxy adhesive. The manufactured laminates typically have a volume fraction of fibers in the range of 55 to 65% and are cured at high temperatures (typically $>300^{\circ}\text{F}$), but are bonded in the field at ambient temperatures. The other type consists of layers (or plies) of unidirectional sheets or woven or stitched fabrics of dry fibers (glass, carbon, or aramid) that are saturated in the field with a thermosetting polymer (epoxy or vinylester) that simultaneously bonds the FRP laminate (thus formed) to the concrete. These “formed-in-place” or “laid-up” FRP systems typically have a fiber volume fraction of between 20 and 30% and are cured at ambient temperatures in the field.

A number of design guides and national standards are currently published that provide recommendations for the analysis, design, and construction of concrete structures strengthened with FRP materials (ACI 25 1997; TR55 2000; FIB 2001; JSCE 2001; ACI 440.2R-02 2002). This section will provide a brief review of the ACI guidelines.

Manufacturers of FRP strengthening systems for concrete typically provide their own design and installation guides for their proprietary systems. Since the performance of the FRP strengthening system is highly dependent on the adhesive or saturating polymer used, the preparation of the concrete surface prior to application of the FRP strengthening system, and the field installation and construction procedures, manufacturers typically certify “approved contractors” to ensure that their systems are designed and installed correctly. In addition, code guidance is provided to ensure that FRP strengthening systems are appropriately installed (ACI 187 2001; ACI 440.2R-02 2002; TR57 2003).

Research in the use of FRP strengthening systems for concrete structures has been the focus of intense international research activity since the early 1990s. A biannual series of symposia entitled *Fiber Reinforced Plastics in Reinforced Concrete Structures* or “FRPRCS” has been the leading venue for reporting and disseminating research results. The most recent symposium, the sixth in the series dating back to 1993, was held in Singapore in July 2003 (Tan 2003).

16.3.2 Properties of FRP Strengthening Systems

Carbon fiber-reinforced epoxy laminates (or strips) are the most commonly used in the adhesively bonded type of products. Depending on the type of carbon fiber used in the strip, different longitudinal strengths and stiffnesses are produced. Strips are typically thin (less than 0.100 in.) and are available in a variety of widths (typically 2 to 4 in.). Since the strips are reinforced with unidirectional fibers they are highly

orthotropic with very low properties in the transverse and through the thickness directions. Manufacturer's typically only report properties in the longitudinal directions and report very little data on physical properties. The strips are bonded to the concrete with a compatible adhesive that is supplied by the strip manufacturer. Typical properties of strips are shown in Table 16.5. It is important to note that the properties shown for the strips are properties of the FRP composite and not the properties of the fibers alone.

In the type of products for FRP strengthening that consist of dry fibers in sheet or fabric form with compatible polymer saturating resins there is a greater array of available products that depend on fiber type and sheet or fabric architecture. In this group of products a unidirectional, highly orthotropic carbon fiber tow-sheet is produced by a number of manufacturers and is often used in strengthening applications. The individual carbon tows in the sheet are held together by a very light polymeric binder (or a light stitching) and it is supplied on a wax paper backing. Sheets are typically 10 to 40 in. wide and are often applied in multiple layers with different orientations. Other common fabric materials in this group are woven glass fiber materials typically consisting of 12 to 32 Oz/yd² materials with a variety of weaves, which can give the fabric properties from highly orthotropic to square symmetric. Carbon fiber tow fabrics and hybrid fabrics (with more than one fiber type) are also available. Fabrics are typically much thicker than tow-sheets and are also used in multiple layers. Because of the wide variety of products available and their different thicknesses it is not easy to compare their properties directly. In addition, the fibers must be used with a compatible resin system applied with a controlled volume fraction to achieve an FRP composite with measurable properties. In the case of sheet and fabric materials, manufacturers typically report the mechanical properties of the dry fibers and the thickness (or area) of the fibers. It is important to note that when reported in this fashion the properties are not the properties of the FRP composite. Properties of some commonly available fiber sheet materials are listed in Table 16.6.

The performance of the FRP strengthening system is highly influenced by the properties of the adhesive layer in the case of the bonded strip and by the properties of the saturating polymeric resin in the case of the sheets and fabrics. The interface between the FRP composite and the concrete substrate transfers the loads from the concrete to the FRP composite. In the case of flexural, shear, or axial tensile strengthening this load transfer is primarily in shear and the properties and the quality of the interface bond between the FRP composite and the concrete effects load transfer into the FRP strengthening

TABLE 16.5 Properties of Typical Commercially Produced FRP Strengthening Strips

system. Such applications are termed “bond-critical” applications. In the case of axial compressive strengthening where the role of the strengthening system is to confine the lateral expansion of the cracked concrete the interface bond is not as critical as long as the FRP strengthening system is in intimate contact with the concrete and is wrapped around the concrete continuously so as to provide a confining pressure with appropriate hoop stiffness and strength. Such applications are termed “contact-critical.” It is important to note, however, that in either type of system the polymer resin still plays a critical role in the FRP composite in transferring load to the fibers and protecting the fibers. A poorly applied sheet or fabric having a low fiber volume fraction (<20%) and a relatively thick (uneven thickness) polymer layer with large void content (>3%) will not provide a durable FRP strengthening system even though the amount of fiber placed in the wrap may be according to design requirements.

Since most FRP strengthening systems depend on the curing of polymer adhesives or resins at ambient temperature in the field, the glass transition temperatures of these components may be quite low (120 to 180°F). Since the effectiveness of the strengthening system depends to a great degree on the stiffness of the adhesive or resin used to bond the FRP composite, to the concrete, an FRP strengthening system can be severely degraded at even moderately high temperatures ($\sim 120^\circ\text{F}$). In certain cases where the fibers are sufficiently anchored away from the region subjected to the high temperature the FRP strengthening system may still be effective (Meier 1995). Designers should always be aware of the transition temperature of the FRP composite or adhesive they are using in a design. In the event of fire the integrity of an FRP strengthening system may be severely compromised in a short time. Test methods for FRP strips and sheets are provided in JSCE (2001) and ACI 440.3R-04 (2004).

16.3.3 Design Basis for FRP Strengthening Systems

A design basis for FRP strengthening systems for concrete structures has been recommended by a number of standards and professional organizations. The LRFD basis is recommended by the ACI 440.2R-02 (2002); however, at this time resistance factors are not probabilistically based. Load factors are those recommended for all concrete structures by ACI 318-99.

For the design of concrete members with FRP strengthening systems the ACI recommends the following resistance factors:

Flexural capacity (tensile strengthening)

$$\phi = 0.9 \text{ for ductile failure of the member following steel yielding } (\epsilon_s > 0.005)$$

$$\phi = 0.7 \text{ for a brittle failure when the member fails prior to steel yielding } (\epsilon_s < \epsilon_{sy})$$

$$\phi = 0.7\text{--}0.9 \text{ for an intermediate region } (\epsilon_{sy} < \epsilon_s < 0.005)$$

$$\psi_f = 0.85 \text{ for FRP bond-critical strengths (in addition to } \phi \text{ factors)}$$

Shear capacity (shear strengthening)

$$\phi = 0.85 \text{ per ACI 318-99}$$

$\psi_f = 0.85$ for FRP bond-critical strengths (in addition to ϕ factor)

$\psi_f = 0.95$ for FRP contact-critical strengths (in addition to ϕ factor)

Axial compressive capacity (confinement)

$$\phi = 0.75 \text{ per ACI 318-99 for steel spiral reinforcement}$$

$$\phi = 0.70 \text{ per ACI 318-99 for steel tied reinforcement}$$

$\psi_f = 0.95$ for FRP contact-critical strengths (in addition to ϕ factors)

Characteristic strength (also called the guaranteed strength) and strain to failure of FRP composite materials for strengthening are defined as the mean minus three standard deviations of a minimum of 20 test samples. The design strength, f_{fu} , and design failure strain, ϵ_{fu} , are obtained from the characteristic strength and failure strain by multiplying them by an environmental reduction factor, C_E , which depends on the fiber type in the FRP strengthening system and the type of intended service of the structure. For example, for weather exposed concrete with a glass-reinforced epoxy FRP strengthening system, C_E is 0.65 (ACI 440.2R-02 2002).

While flexural strengthening over 100% of the original strength is achievable, the ACI limits the amount of strengthening to prevent catastrophic failure of the concrete member in the event of loss of, or damage to, the strengthening system (due to vandalism or environmental degradation). The ACI recommends that the strengthened member have sufficient original factored capacity (i.e., discounting the additional strengthening system) to resist a substantial portion of the factored load on the strengthened member, given as

$$1.2D + 0.85L$$

To account for fire, additional restrictions are placed on the factored capacity of the FRP strengthened structured (ACI 440.2R-02 2002).

When a concrete member is strengthened to increase its capacity in a selected mode (e.g., flexure) the member must be checked to ensure that the capacities in other failure modes (e.g., shear) are not exceeded. If this is the case the strengthening should be decreased or the secondary capacity needs to be enhanced with its own strengthening system.

At this time the ACI 440.2R-02 guide does not provide recommendations for the determination of serviceability criteria (such as deflections or crack widths) for FRP strengthened members. The ACI 440.2R-02 guide does, however, limit the stress in the steel at service loads to 80% of the steel yield stress and limits the “sustained plus cyclic” stress in the FRP strengthening system to account for creep rupture and fatigue depending on the fiber system. For carbon FRP strengthening systems this limit is 55% of the ultimate strength. For deflections in flexural members where stresses are in the service range the contribution of the FRP strengthening system is typically small. Flexural deflections in the service range can be estimated by the use of an effective “composite-section” second moment-of-area (I_e) analysis where the tensile contribution of the FRP is added to the contribution of the steel reinforcing. In the inelastic range (after the primary reinforcing steel has yielded) the contribution of the FRP strengthening to the postyield stiffness can be quite considerable and should be accounted for, in inelastic analysis.

It is extremely important to note that the method of determining the tensile force resultant in an FRP strengthening system depends on the type of system used. In the bonded strip (or plate) system the ultimate force is obtained from the strength of the FRP composite (see Table 16.5) and the gross cross-sectional area of the strip. In the dry fiber systems the ultimate force is obtained from the strength of the fibers and the thickness of the net area of the fibers (see Table 16.6). The designer must know if the reported strength (and stiffness) for an FRP strengthening system is for the FRP composite (gross cross-section) or for the fibers alone (net fiber cross-section). Both methods of calculation are permitted by the ACI 440.2R-02 guide at this time.

16.3.4 Design of FRP Flexural Strengthening Systems

Flexural strengthening is achieved by attaching an FRP strengthening system (bonded strip or saturated dry fabric) to the underside (or soffit) of a flexural member to increase the effective tensile force resultant in the member and thereby increase the moment capacity of the member. This is analogous to adding steel strengthening strips (or plates) to the soffit of a member. However, two fundamental differences exist. First, the FRP strengthening system behaves in a linear elastic fashion and does not yield, and second, the FRP strengthening system is more susceptible to detachment (debonding or delamination) failures than steel plate systems. Epoxy bonded steel plates are typically anchored with steel bolts at their ends in addition to the epoxy bonding. Since the steel plates themselves will yield at a similar strain to the internal steel reinforcing, the stress level in the steel strengthening system is limited. In the case of FRP strengthening with FRP systems having ultimate tensile strengths exceeding 300 ksi (see Table 16.5 and Table 16.6) the stress level in the FRP can be significantly higher than that in steel strengthening systems. In the event that the internal steel reinforcing yields before the FRP strengthening system fails (the desired failure mode) the concrete member will undergo large deflections and cracking. All these factors lead to the greater likelihood that the FRP strengthening system will detach from the concrete long before it achieves its ultimate tensile capacity.

Strengthening of members in flexure can only be achieved if there is sufficient additional compressive capacity in the concrete to allow for the increase in internal moment. Therefore, flexural strengthening is most suitable for concrete members that are lightly to moderately reinforced, having steel reinforcement in the range of 20 to 40% of the balanced ratio. This is not uncommon in reinforced concrete members, especially in older structures.

The existing tensile strain in the concrete at the location of the applied FRP strengthening system due to sustained loads when the FRP strengthening system is applied should be accounted for in design calculations if a shoring system is not used.

The key to flexural strengthening with FRP strengthening systems is to understand the failure modes of the system. These include rupture of the FRP strengthening system, detachment of the FRP strengthening system (due to a variety of delamination or debonding modes), or compressive failure of the concrete. All of these modes can occur either before or after the internal steel has yielded. The desired mode of failure is concrete compressive failure after the internal steel has yielded with the FRP strengthening system still attached. This is often difficult to achieve and the mode of FRP detachment (or less frequently rupture) at large deflections after the internal steel has yielded is often achieved.

The FRP strengthening system can detach in a number of modes. The FRP system can delaminate from the concrete substrate (due to failure in the concrete, the adhesive layer, or the FRP laminate itself) either at the ends (due to high peeling and shear stresses) or in the interior of the beam due to flexural and shear cracks in the beam at large deflections. For a detailed discussion on detachment failure modes see Teng et al. (2001). Analytical methods to predict the various detachment failure modes are still not fully developed and the ACI 440.2R-02 guide limits the tensile strain level in the FRP strengthening system to prevent delamination failure by the use of an empirically obtained bond-dependent coefficient, κ_m , which is a function of the unit stiffness of the FRP system and is defined as

$$\kappa_m = \begin{cases} \frac{1}{60\varepsilon_{fu}} \left(1 - \frac{nE_f t_f}{2,000,000} \right) \leq 0.90 & \text{for } nE_f t_f \leq 1,000,000 \text{ lb/in.} \\ \frac{1}{60\varepsilon_{fu}} \left(\frac{500,000}{nE_f t_f} \right) \leq 0.90 & \text{for } nE_f t_f > 1,000,000 \text{ lb/in.} \end{cases} \quad (16.77)$$

where ε_{fu} is the ultimate strain in the FRP, n is the number of layers (or plies) of FRP strips or sheets or fabrics, E_f is the longitudinal tensile modulus of the FRP composite in the case of strips or the longitudinal modulus of the fibers in the strengthening direction in the case of sheets or fabrics, and t_f is the thickness of an individual strip in the case of FRP strips or the net thickness of the fibers in a single sheet or fabric in the case of sheets or fabrics.

The strain level in the FRP strengthening system is limited by the strain in the concrete or the ultimate strain in the FRP system and is given as

$$\varepsilon_{fe} = \varepsilon_{cu} \left(\frac{h - c}{c} \right) - \varepsilon_{bi} \leq \kappa_m \varepsilon_{fu} \quad (16.78)$$

where ε_{fe} is the effective ultimate strain in the FRP at failure, ε_{cu} is the ultimate compressive strain in the concrete (0.003), c is the depth of the neutral axis, h is the depth of the section, and ε_{bi} is the existing tensile strain in the concrete substrate at the location of the FRP strengthening system. The effective stress, f_{fe} , in the FRP is the ultimate strength of the FRP that can be achieved at failure and is linearly related to the ultimate strain as

$$f_{fe} = E_f \varepsilon_{fe} \quad (16.79)$$

The nominal moment capacity, M_n , of the strengthened section (with an existing layer of tensile steel reinforcement only) is given as

$$M_n = A_s f_s \left(d - \frac{\beta_1 c}{2} \right) + \psi_f A_f f_{fe} \left(h - \frac{\beta_1 c}{2} \right) \quad (16.80)$$

with

$$c = \frac{A_s f_s + A_f f_{fe}}{\gamma f'_c \beta_1 b} \quad (16.81)$$

and

$$f_s = E_s \varepsilon_s = E_s (\varepsilon_{fe} + \varepsilon_{bi}) \left(\frac{d - c}{h - c} \right) \leq f_y \quad (16.82)$$

where A_s is the area of the tensile steel, f_s is the stress in the steel at failure, d is the depth of the steel reinforcing, β_1 is the depth ratio of the equivalent Whitney stress block, A_f is the area of the FRP strip or the fibers in a dry fiber system, γ is the concrete stress resultant factor (0.85 when concrete compressive failure governs), b is the width of the section, and f_y is the yield stress in the reinforcing steel. The solution to the above equations is typically found by a trial and error method by assuming a number of plies (or layers) of strengthening and calculating the resulting nominal moment. The desirable failure mode is achieved when the internal steel has yielded. Therefore, the current stress state in the steel can be assumed to be at yield and then checked. If the steel has not yielded before FRP rupture or detachment occurs, a new design should be attempted with a different strengthening system or a different number of plies.

The stresses in the steel and the FRP strengthening system at service loads should be determined using an elastic cracked section and checked against appropriate stress limits for sustained loads on FRP strengthened structures (ACI 440.2R-02 2002).

Mechanical anchorages or FRP wraps can be used to enhance the attachment of the FRP strengthening system to the concrete beam, especially at the ends of the FRP strengthening system. Design guidance is not provided by the ACI 440.2R-02 for this at the present time.

16.3.5 Design of FRP Shear Strengthening Systems

FRP strengthening systems can be used to increase the shear capacity of concrete beams and columns. FRP strengthening systems are applied to the webs of beams (or columns) and function in an analogous fashion to internal steel shear reinforcement. Because FRP shear strengthening systems are applied to concrete members that are often monolithic with other continuous members (such as floors and walls), it is not always possible “wrap” the FRP strengthening system completely around the member (which is the desirable condition). The FRP strengthening system must therefore be terminated at the top of the web (a three-sided “U-wrap”) or both at the top and at the bottom of the web (a two-sided system).

The non-fully wrapped systems are susceptible to detachment failures (similar to flexural strengthening) and their strains are limited by a shear bond-reduction coefficient, κ_v .

The nominal shear capacity of an FRP strengthened concrete member with existing steel shear reinforcing is determined by adding the contribution of the FRP strengthening system to the existing shear capacity, given as

$$V_n = V_c + V_s + \psi_f V_f \quad (16.83)$$

where

$$V_f = \frac{A_{fv} f_{fe} (\sin \alpha + \cos \alpha) d_f}{s_f} \quad (16.84)$$

and

$$A_{fv} = 2n_t f_w w_f \quad (16.85)$$

where V_c is the existing shear capacity of the concrete, V_s is the shear capacity of the existing steel shear reinforcement, V_f is the shear capacity of the FRP strengthening system, $f_{fe} = E_f \epsilon_{fu}$ is the effective tensile stress in the FRP at ultimate, α is the inclination of the fiber in the FRP strengthening system to transverse axis (the horizontal axis in a beam or the vertical axis in a column), d_f is the effective depth of the FRP strengthening system, s_f is the center-to-center spacing of the FRP shear strengthening strips, and w_f is the width of the FRP shear strengthening strip. (For a continuous FRP shear strengthening sheet or fabric $s_f = w_f$.) The FRP capacity reduction factor, ψ_f , is taken as 0.95 for completely wrapped sections (contact-critical) and as 0.85 for two- or three-sided wrapped sections (bond-critical).

The effective strain in the FRP shear strengthening system is limited to prevent detachment failures and also to maintain the integrity of the concrete aggregate interlock in the concrete member. For completely wrapped FRP shear strengthening systems the maximum effective strain in the FRP strengthening system at failure is limited to

$$\epsilon_{fe} = 0.004 \leq 0.75 \epsilon_{fu} \quad (16.86)$$

For three-sided or two-sided shear strengthening the effective shear strain in the FRP strengthening system at failure is limited to

$$\epsilon_{fe} = \kappa_v \epsilon_{fu} \leq 0.004 \quad (16.87)$$

where the shear bond-reduction coefficient is a function of the concrete strength, the wrapping type used, and the stiffness of the FRP strengthening system. Empirical equations for determining this coefficient are given in the ACI 440.2R-02 guide.

Mechanical anchorages can be used to anchor two- or three-sided wraps in the compression zone of the web; however, design guidance is not provided by the ACI 440.2R-02 for this at the present time.

Limits on spacing of discrete FRP shear strengthening strips and the maximum shear strength enhancement that can be obtained using FRP strengthening are provided in the ACI 440.2R-02 guide.

16.3.6 Design of FRP Axial Strengthening Systems

Concrete compression members can be strengthened to increase their axial load carrying capacity, their shear capacity, their steel rebar lap splice capacity, and their lateral load carrying deformation capacity (ductility). FRP strengthening of columns is most effective when applied to circular columns and always consists of complete wrapping to obtain confinement of the concrete. FRP strengthening systems for confinement of columns are classified as contact-critical applications. It is also important to note that FRP axial strengthening systems are regarded as “passive” systems. That is, they are not effective (or active) until the concrete reaches its transverse cracking strain in compression and begins to dilate, thus placing hoop stress on the FRP wrap. This is in contrast to the FRP flexural and shear strengthening systems, which must be active at all load levels.

For a nonslender, nonprestressed, normal-weight concrete column reinforced with spiral reinforcement and steel ties the nominal axial capacity is given as

$$P_n = 0.85(0.85\psi_f f'_{cc}(A_g - A_{st}) + f_y A_{st}) \quad (16.88)$$

and

$$P_n = 0.80(0.85\psi_f f'_{cc}(A_g - A_{st}) + f_y A_{st}) \quad (16.89)$$

respectively, with the confined compressive strength, f'_{cc} , given as

$$f'_{cc} = f'_c \left(2.25 \sqrt{1 + 7.9 \frac{f_l}{f'_c}} - 2 \frac{f_l}{f'_c} - 1.25 \right) \quad (16.90)$$

in terms of the confining pressure provide by the FRP wrap (or jacket), f_l , given as

$$f_l = \frac{\kappa_a \rho_f E_f \epsilon_{fe}}{2} \quad (16.91)$$

where A_g is the gross area of the concrete, A_{st} is the area of the longitudinal steel, κ_a is an efficiency factor that depends on the shape of the column, and ρ_f is the reinforcement ratio of the FRP strengthening system. For circular columns, κ_a is 1.0 and the reinforcement ratio is given as

$$\rho_f = \frac{A_f}{A_g} = \frac{4n t_f}{h} \quad (16.92)$$

where h is the diameter of the circular column. It is important to note that the fiber layers must all be oriented in the hoop direction around the column. If layers are also oriented in the longitudinal direction, these layers should not be considered to contribute to axial strengthening. For noncircular columns FRP strengthening for increasing axial capacity is much less effective due to stress concentrations at the corners (even when rounded) and the nonuniform confining pressure developed by the wrap.

Limits are placed on axial strengthening to ensure that the concrete does not approach its transverse cracking strain, or the steel its yield strain, in the service range (ACI 440.2R-02 2002).

The lateral displacement capacity (or ductility) of a concrete column can also be increased by confining it with FRP strengthening wraps. The maximum concrete compressive strain for an FRP wrapped circular column is given as

$$\epsilon'_{cc} = \frac{1.71(5f'_{cc} - 4f'_c)}{E_c} \quad (16.93)$$

where E_c is the elastic modulus of the concrete and f'_{cc} is as defined previously (Equation 16.90).

17.1 Introduction

This chapter provides a basic understanding of earthquakes, by first discussing the causes of earthquakes, then defining commonly used terms, explaining how earthquakes are measured, discussing the distribution of seismicity, and, finally, explaining how seismicity can be characterized.

Earthquakes are broad-banded vibratory ground motions, resulting from a number of causes including tectonic ground motions, volcanism, landslides, rockbursts, and man-made explosions. Of these, naturally occurring tectonic-related earthquakes are the largest and most important. These are caused by the fracture and sliding of rock along *faults* within the Earth's crust. A fault is a zone of the earth's crust within which the two sides have moved — faults may be hundreds of miles long, from one to over one hundred miles deep, and are sometimes not readily apparent on the ground surface. Earthquakes initiate a number of phenomena or agents, termed *seismic hazards*, which can cause significant damage to the built environment — these include fault rupture, vibratory ground motion (i.e., shaking), inundation (e.g., tsunami, seiche, dam failure), various kinds of permanent ground failure (e.g., liquefaction), fire, or hazardous materials release. In a particular earthquake event, any particular hazard can dominate, and historically each has caused major damage and great loss of life in particular earthquakes.

For most earthquakes, shaking is the dominant and most widespread agent of damage. Shaking near the actual earthquake rupture lasts only during the time when the fault ruptures, a process that takes

seconds or at most a few minutes. The seismic waves generated by the rupture propagate long after the movement on the fault has stopped, however, spanning the globe in about 20 min. Typically, earthquake ground motions are powerful enough to cause damage only in the near field (i.e., within a few tens of kilometers from the causative fault) — in a few instances, long period motions have caused significant damage at great distances, to selected lightly damped structures. A prime example of this was the 1985 Mexico City Earthquake, where numerous collapses of mid- and high-rise buildings were due to a magnitude 8.1 Earthquake occurring at a distance of approximately 400 km from Mexico City.

17.2 Causes of Earthquakes and Faulting

In a global sense, tectonic earthquakes result from motion between a number of large plates comprising the earth's crust or lithosphere (about 15 large plates, in total), [Figure 17.1](#).

These plates are driven by the convective motion of the material in the earth's mantle, which in turn is driven by the heat generated at the earth's core. Relative plate motion at the fault interface is constrained by friction and/or *asperities* (areas of interlocking due to protrusions in the fault surfaces). However, strain energy accumulates in the plates, eventually overcomes any resistance, and causes slip between the two sides of the fault. This sudden slip, termed *elastic rebound* by Reid (1910) based on his studies of regional deformation following the 1906 San Francisco Earthquake, releases large amounts of energy, which constitutes or *is* the earthquake. The location of initial radiation of seismic waves (i.e., the first location of dynamic rupture) is termed the *hypocenter*, while the projection on the surface of the earth directly above the hypocenter is termed the *epicenter*. Other terminology includes *near-field*¹ (within one source dimension of the epicenter, where source dimension refers to the width or length of faulting, whichever is shorter), *far-field* (beyond near-field), and *meizoseismal* (the area of strong shaking and damage). Energy is radiated over a broad spectrum of frequencies through the earth, in *body waves* and *surface waves* (Bolt 1993). Body waves are of two types: P waves (transmitting energy via push-pull motion) and slower S waves (transmitting energy via shear action at right angles to the direction of motion). Surface waves are also of two types: horizontally oscillating *Love waves* (analogous to S body waves) and vertically oscillating *Rayleigh waves*.

While the accumulation of strain energy within the plate can cause motion (and consequent release of energy) at faults at any location, earthquakes occur with greatest frequency at the boundaries of the tectonic plates. The boundary of the Pacific plate is the source of nearly half of the world's great earthquakes. Stretching 40,000 km (24,000 miles) around the circumference of the Pacific Ocean, it includes Japan, the west coast of North America, and other highly populated areas, and is aptly termed the *Ring of Fire*. The interiors of plates, such as ocean basins and continental shields, are areas of low seismicity but are not inactive — the largest earthquakes known to have occurred in North America, for example, occurred in 1811–1812 in the New Madrid area, far from a plate boundary. Tectonic plates move relatively slowly (5 cm per year is relatively fast) and irregularly, with relatively frequent small and only occasional large earthquakes. Forces may build up for decades or centuries at plate interfaces until a large movement occurs all at once. These sudden, violent motions produce the shaking that is felt as an earthquake. The shaking can cause direct damage to buildings, roads, bridges, and other man-made structures as well as triggering landslides, fires, tidal waves (tsunamis), and other damaging phenomena.

Faults are the physical expression of the boundaries between adjacent tectonic plates and thus may be hundreds of miles long. In addition, there may be thousands of shorter faults parallel to or branching out from a main fault zone. Generally, the longer a fault the larger the earthquake it can generate. Beyond the main tectonic plates, there are many smaller subplates, “platelets,” and simple blocks of crust that occasionally move and shift due to the “jostling” of their neighbors and the major plates. The existence of these many subplates means that smaller but still damaging earthquakes are possible almost anywhere, although often with less likelihood.

¹Not to be confused with *near-source* as used in the 1997 Uniform Building Code, which can be as much as 15 km, depending on type of faulting.

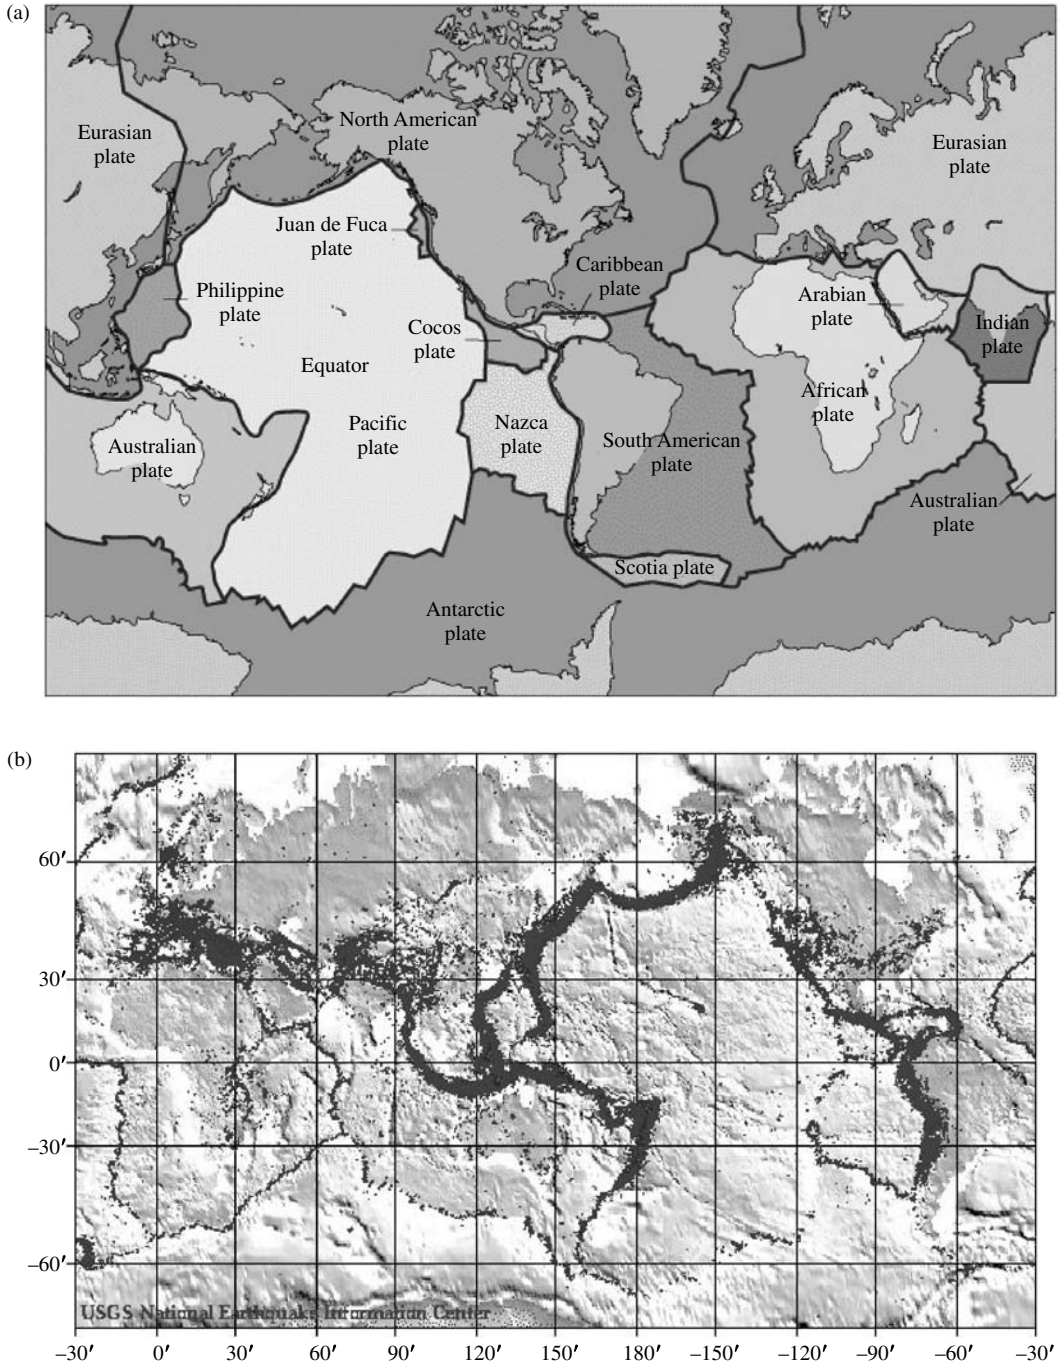

FIGURE 17.1 (a) Global tectonic plate boundaries. (b) Global seismicity 1975–1995 (from: U.S. Geological Survey [USGS]).

Faults are typically classified according to their sense of motion, Figure 17.2. Basic terms include *transform* or *strike slip* (relative fault motion occurs in the horizontal plane, parallel to the *strike* of the fault), *dip-slip* (motion at right angles to the strike, up- or down-slip), *normal* (dip-slip motion, two sides in tension, move away from each other), *reverse* (dip-slip, two sides in compression, move toward each other), and *thrust* (low-angle reverse faulting).

Generally, earthquakes will be concentrated in the vicinity of faults, faults that are moving more rapidly than others will tend to have higher rates of seismicity, and larger faults are more likely than others to produce a large event. Many faults are identified on regional geological maps, and useful information on fault location and displacement history is available from local and national geological surveys in areas of high seismicity. Considering this information, areas of an expected large earthquake in the near future (usually measured in years or decades) can, and have, been identified. However, earthquakes continue to occur on “unknown” or “inactive” faults. An important development has been the growing recognition of *blind thrust faults*, which emerged as a result of the several earthquakes in the 1980s, none of which were accompanied by surface faulting (Stein and Yeats 1989). Blind thrust faults are faults at depth occurring under anticlinal folds — since they have only subtle surface expression, their seismogenic potential can only be evaluated by indirect means (Greenwood 1995). Blind thrust faults are particularly worrisome because they are hidden, are associated with folded topography in general, including areas of lower and infrequent seismicity, and, therefore, result in a situation where the potential for an earthquake exists in any area of anticlinal geology, even if there are few or no earthquakes in the historic record. Recent major earthquakes of this type have included the 1980 M_w 7.3 El Asnam (Algeria), 1988 M_w 6.8 Spitak (Armenia), and 1994 M_w 6.7 Northridge (California) events.

Focal mechanism refers to the direction of slip in an earthquake and the orientation of the fault on which it occurs. Focal mechanisms are determined from seismograms and typically displayed on maps as a black and white “beach ball” symbol. This symbol is the projection on a horizontal plane of the lower half of an imaginary, spherical shell (focal sphere) surrounding the earthquake source (USGS, n.d.). A line is scribed where the fault plane intersects the shell. The beach ball depicts the stress-field orientation at the time of rupture such that the black quadrants contain the tension axis (T), which reflects the minimum compressive stress direction, and the white quadrants contain the pressure axis (P), which reflects the maximum compressive stress direction. For mechanisms calculated from first-motion directions (as well as some other methods), more than one focal mechanism solution may fit the data equally well, so that there is an ambiguity in identifying the fault plane on which the slip

FIGURE 17.2 (a) Types of faulting and (b) focal mechanisms (after U.S. Geological Survey).

FIGURE 17.3 Schematic diagram of subduction zone, typical of west coast of South America, Pacific Northwest of United States or Japan.

occurred, from the orthogonal, mathematically equivalent, auxiliary plane. The ambiguity may sometimes be resolved by comparing the two fault-plane orientations to the alignment of small earthquakes and aftershocks. The first three examples describe fault motion that is purely horizontal (strike slip) or vertical (normal or reverse). The oblique-reverse mechanism illustrates that slip may also have components of horizontal and vertical motion.

Subduction refers to the plunging of one plate (e.g., the Pacific) beneath another, into the mantle, due to convergent motion, as shown in Figure 17.3. Subduction zones are typically characterized by volcanism, as a portion of the plate (melting in the lower mantle) re-emerges as volcanic lava. Four types of earthquakes are associated with subduction zones: (1) shallow crustal events, in the accretionary wedge; (2) intraplate events, due to plate bending; (3) large interplate events, associated with slippage of one plate past the other; and (4) deep Benioff zone events. Subduction occurs along the west coast of South America at the boundary of the Nazca and South American plate, in Central America (boundary of the Cocos and Caribbean plates), in Taiwan and Japan (boundary of the Philippine and Eurasian plates), and in the North American Pacific Northwest (boundary of the Juan de Fuca and North American plates), among other places.

Probabilistic methods can be usefully employed to quantify the likelihood of an earthquake's occurrence. However, the earthquake generating process is not understood well enough to reliably predict the times, sizes, and locations of earthquakes with precision. In general, therefore, communities must be prepared for an earthquake to occur at any time.

17.3 Measurement of Earthquakes

Earthquakes are complex multidimensional phenomena, the scientific analysis of which requires measurement. Prior to the invention of modern scientific instruments, earthquakes were qualitatively measured by their effect or *intensity*, which differed from point to point. With the deployment of seismometers, an instrumental quantification of the entire earthquake event — the unique *magnitude* of the event — became possible. These are still the two most widely used measures of an earthquake, and a number of different scales for each have been developed, which are sometimes confused.²

²Earthquake magnitude and intensity are analogous to a lightbulb and the light it emits. A particular lightbulb has only one energy level, or wattage (e.g., 100 W, analogous to an earthquake's magnitude). Near the lightbulb, the light intensity is very bright (perhaps 100 ft-candles, analogous to MMI IX), while farther away the intensity decreases (e.g., 10 ft-candles, MMI V). A particular earthquake has only one magnitude value, whereas it has many intensity values.

Engineering design, however, requires measurement of earthquake phenomena in units such as force or displacement. This section defines and discusses each of these measures.

17.3.1 Magnitude

An individual earthquake is a unique release of strain energy — quantification of this energy has formed the basis for measuring the earthquake event. Richter (1935) was the first to define earthquake magnitude, as

$$M_L = \log A - \log A_0 \quad (17.1)$$

where M_L is the *local magnitude* (which Richter only defined for Southern California), A is the maximum trace amplitude in micrometers recorded on a standard Wood–Anderson short-period torsion seismometer,³ at a site 100 km from the epicenter, and $\log A_0$ is a standard value as a function of distance for instruments located at distances other than 100 km and less than 600 km. Subsequently, a number of other magnitudes have been defined, the most important of which are surface wave magnitude M_S , body wave magnitude m_b , and moment magnitude M_W . Due to the fact that M_L was only locally defined for California (i.e., for events within about 600 km of the observing stations), surface wave magnitude M_S was defined analogously to M_L , using teleseismic observations of surface waves of 20 s period (Richter 1935). Magnitude, which is defined on the basis of the amplitude of ground displacements, can be related to the total energy in the expanding wave front generated by an earthquake, and thus to the total energy release — an empirical relation by Richter is

$$\log_{10} E_S = 11.8 + 1.5M_S \quad (17.2)$$

where E_S is the total energy in ergs.⁴ Note that $10^{1.5} = 31.6$, so that an increase of one magnitude unit is equivalent to 31.6 times more energy release, two magnitude units increase equivalent to $998.6 \cong 1000$ times more energy, etc. Subsequently, due to the observation that deep-focus earthquakes commonly do not register measurable surface waves with periods near 20 s, a body wave magnitude m_b was defined (Gutenberg and Richter 1954), which can be related to M_S (Darragh et al. 1994):

$$m_b = 2.5 + 0.63M_S \quad (17.3)$$

Body wave magnitudes are more commonly used in eastern North America, due to the deeper earthquakes there. A number of other magnitude scales have been developed, most of which tend to *saturate* — that is, asymptote to an upper bound due to larger earthquakes radiating significant amounts of energy at periods longer than used for determining the magnitude (e.g., for M_S , defined by measuring 20 s surface waves, saturation occurs at about $M_S > 7.5$). More recently, *seismic moment* has been employed to define a *moment magnitude* M_W (Hanks and Kanamori 1979; also denoted as boldface **M**), which is finding increased and widespread use

$$\log M_0 = 1.5M_W + 16.0 \quad (17.4)$$

where seismic moment M_0 (dyne cm) is defined as (Lomnitz 1974)

$$M_0 = \mu A \bar{u} \quad (17.5)$$

where μ is the material shear modulus, A is the area of fault plane rupture, and \bar{u} is the mean relative displacement between the two sides of the fault (the averaged fault slip). Comparatively, M_W and M_S are

³The instrument has a natural period of 0.8 s, critical damping ratio 0.8, magnification 2800.

⁴Richter (1958) gives 11.4 for the constant term, rather than 11.8, which is based on subsequent work — the uncertainty in the data makes this difference inconsequential.

FIGURE 17.4 Relationship between moment magnitude and various magnitude scales (Campbell, K.W. 1985).

numerically almost identical up to magnitude 7.5. Figure 17.4 indicates the relationship between moment magnitude and various magnitude scales.

For lay communications, it is sometimes customary to speak of great earthquakes, large earthquakes, etc. There is no standard definition for these, but the following is an approximate categorization:

Earthquake Magnitude ^a	Micro Not felt	Small <5	Moderate 5–6.5	Large 6.5–8	Great >8
-----------------------------------	-------------------	-------------	-------------------	----------------	-------------

^a Not specifically defined.

From the foregoing discussion, it can be seen that magnitude and energy are related to fault rupture length and slip. Slemmons (1977) and Bonilla et al. (1984) have determined statistical relations between these parameters for worldwide and regional data sets, aggregated and segregated by type of faulting (normal, reverse, strike-slip). Bonilla et al.’s worldwide results for all types of faults are

$$M_s = 6.04 + 0.708 \log_{10} L, \quad s = 0.306 \tag{17.6}$$

$$\log_{10} L = -2.77 + 0.619 M_s, \quad s = 0.286 \tag{17.7}$$

$$M_s = 6.95 - 0.723 \log_{10} d, \quad s = 0.323 \tag{17.8}$$

$$\log_{10} d = -3.58 + 0.550 M_s, \quad s = 0.282 \tag{17.9}$$

which indicates, for example, that, for $M_s = 7$, the average fault rupture length is about 36 km (and the average displacement is about 1.86 m), and s indicates standard deviation. Conversely, a fault of 100 km length is capable of about an $M_s = 7.5$ event⁵. More recently, Wells and Coppersmith (1994) have performed an extensive analysis of a dataset of 421 earthquakes — their results are presented in [Table 17.1](#).

⁵Note that $L = g(M_s)$ should not be inverted to solve for $M_s = f(L)$, as a regression for $y = f(x)$ is different than a regression for $x = g(y)$.

17.3.2 Intensity

In general, seismic intensity is a metric of the effect, or the strength, of an earthquake hazard at a specific location. While the term can be generically applied to engineering measures such as peak ground acceleration (PGA), it is usually reserved for qualitative measures of location-specific earthquake effects, based on observed human behavior and structural damage. Numerous intensity scales developed in preinstrumental times — the most common in use today are the modified Mercalli (MMI) (Wood and Neumann 1931), Rossi–Forel (R–F), Medvedev–Sponheur–Karnik (MSK-64 1981; Grunthal 1998) and its successor the European Macroseismic Scale (EMS-98 1998), and Japan Meteorological Agency (JMA) (Kanai 1983) scales.

Modified Mercalli Intensity (MMI) is a subjective scale defining the level of shaking at specific sites on a scale of I to XII. (MMI is expressed in Roman numerals, to connote its approximate nature.) For example, moderate shaking that causes few instances of fallen plaster or cracks in chimneys constitutes MMI VI. It is difficult to find a reliable relationship between magnitude, which is a description of the earthquake's total energy level, and intensity, which is a subjective description of the level of shaking of the earthquake at specific sites, because shaking severity can vary with building type, design and construction practices, soil type, and distance from the event (Table 17.2).

Note that MMI X is the maximum considered physically possible due to “mere” shaking, and that MMI XI and XII are considered due more to permanent ground deformations and other geologic effects than to shaking.

TABLE 17.2 Modified Mercalli Intensity Scale of 1931 (after Wood and Neumann 1931)

I	Not felt except by a very few under especially favorable circumstances
II	Felt only by a few persons at rest, especially on upper floors of buildings. Delicately suspended objects may swing
III	Felt quite noticeably indoors, especially on upper floors of buildings, but many people do not recognize it as an earthquake. Standing motor cars may rock slightly. Vibration like passing track. Duration estimated
IV	During the day felt indoors by many, outdoors by few. At night some awakened. Dishes, windows, and doors disturbed; walls make creaking sound. Sensation like heavy truck striking building. Standing motorcars rock noticeably
V	Felt by nearly everyone; many awakened. Some dishes, windows, etc., broken; a few instances of cracked plaster; unstable objects overturned. Disturbance of trees, poles, and other tall objects sometimes noticed. Pendulum clocks may stop
VI	Felt by all; many frightened and run outdoors. Some heavy furniture moved; a few instances of fallen plaster or damaged chimneys. Damage slight
VII	Everybody runs outdoors. Damage negligible in buildings of good design and construction slight to moderate in well-built ordinary structures; considerable in poorly built or badly designed structures. Some chimneys broken. Noticed by persons driving motor cars
VIII	Damage slight in specially designed structures; considerable in ordinary substantial buildings, with partial collapse; great in poorly built structures. Panel walls thrown out of frame structures. Fall of chimneys, factory stacks, columns, monuments, walls. Heavy furniture overturned. Sand and mud ejected in small amounts. Changes in well water. Persons driving motor cars disturbed
IX	Damage considerable in specially designed structures; well designed frame structures thrown out of plumb; great in substantial buildings, with partial collapse. Buildings shifted off foundations. Ground cracked conspicuously. Underground pipes broken
X	Some well-built wooden structures destroyed; most masonry and frame structures destroyed with foundations; ground badly cracked. Rails bent. Landslides considerable from river banks and steep slopes. Shifted sand and mud. Water splashed over banks
XI	Few, if any (masonry), structures remain standing. Bridges destroyed. Broad fissures in ground. Underground pipelines completely out of service. Earth slumps and land slips in soft ground. Rails bent greatly
XII	Damage total. Waves seen on ground surfaces. Lines of sight and level distorted. Objects thrown upward into the air

TABLE 17.3 Comparison of Modified Mercalli (MMI) and Other Intensity Scales

(3162)*	XII	—	XII	

* *a* values provided for reference only. MMI > X are due more to geologic effects.

Other intensity scales are defined analogously, Table 17.3, which also contains an approximate conversion from MMI to acceleration *a* (PGA, in cm/s² or gals). The conversion is due to Richter (1935) (other conversions are also available: Trifunac and Brady 1975; Murphy and O'Brien 1977)

$$\log a = \text{MMI}/3 - 1/2 \tag{17.10}$$

Intensity maps are produced as a result of detailed investigation of the type of effects tabulated in Table 17.2, as shown in Figure 17.5 for the 1994 *M_W* 6.7 Northridge Earthquake. Correlations have been developed between the area of various MMI intensities and earthquake magnitude, which are of value for seismological and planning purposes).

Figure 17.6, for example, correlates *A_{felt}* versus *M_W*. For preinstrumental historical earthquakes, *A_{felt}* can be estimated from newspapers and other reports, which then can be used to estimate the event magnitude, thus supplementing the seismicity catalog. This technique has been especially useful in regions with a long historical record (Ambrayses and Melville 1982; Woo and Muirwood 1984).

17.3.3 Time History

Sensitive strong motion seismometers have been available since the 1930s, and record actual ground motions specific to their location, Figure 17.7. Typically, the ground motion records, termed *seismographs* or *time histories*, have recorded acceleration (these records are termed *accelerograms*) for many years in analog form on photographic film and, more recently, digitally. Analog records required considerable effort for correction due to instrumental drift, before they could be used.

Time histories theoretically contain complete information about the motion at the instrumental location, recording three *traces* or orthogonal records (two horizontal and one vertical). Time histories (i.e., the earthquake motion at the site) can differ dramatically in duration, frequency content, and amplitude. The maximum amplitude of recorded acceleration is termed the peak ground acceleration, PGA (also termed the ZPA, or zero period acceleration) — peak ground velocity (PGV) and peak

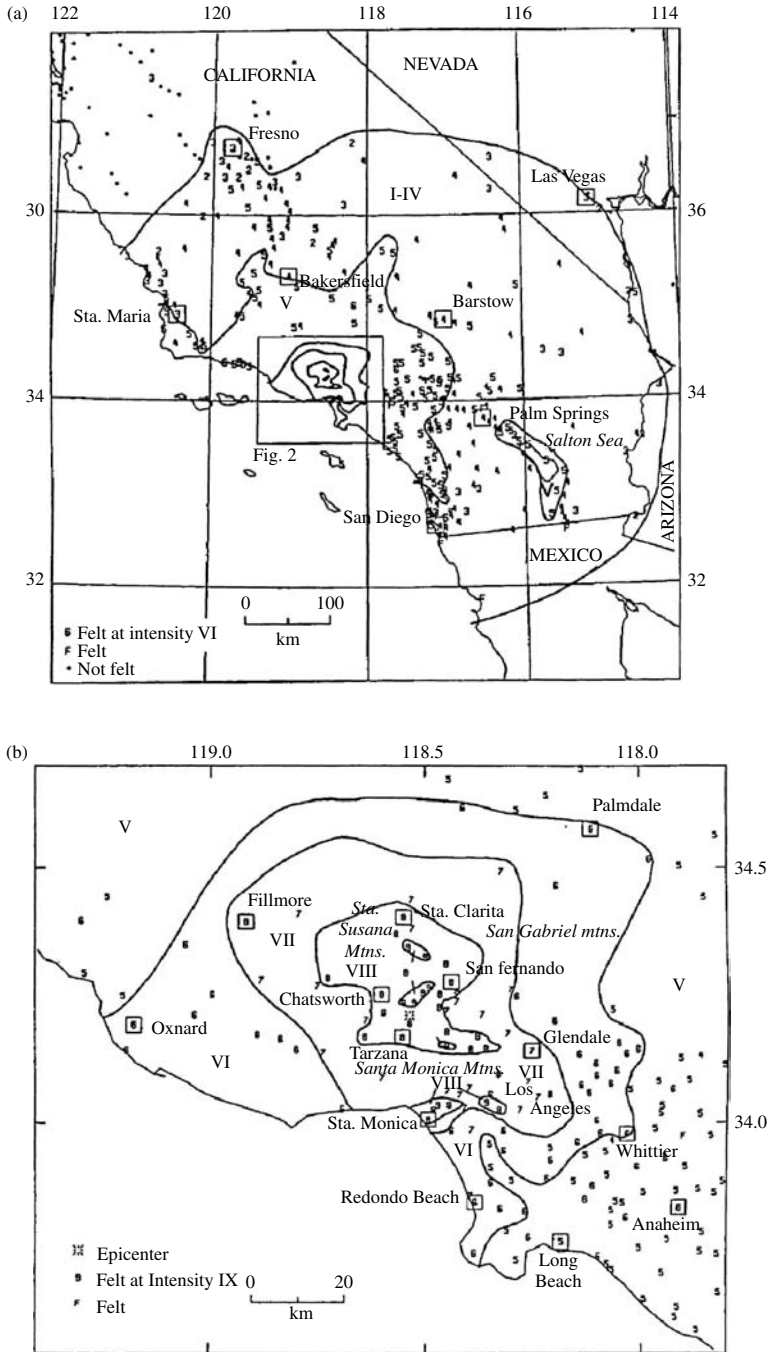

FIGURE 17.5 MMI maps, 1994 M_W 6.7 Northridge Earthquake (courtesy Dewey et al. 1995).

ground displacement (PGD) are the maximum respective amplitudes of velocity and displacement. Acceleration is normally recorded, with velocity and displacement being determined by integration; however, actual velocity and displacement meters are also deployed, to a lesser extent. Acceleration can be expressed in units of cm/s^2 (termed gals), but is often also expressed in terms of the fraction or

FIGURE 17.6 $\log A_{felt}$ (km^2) versus M_w (courtesy Hanks, T.C. and Kanamori, H. 1992).

FIGURE 17.7 Typical earthquake accelerograms (courtesy Darragh, R.B., Huang, M.J., and Shakal, A.F. 1994).

percentage of the acceleration of gravity (980.66 gals, termed 1g). Velocity is expressed in cm/s (termed kine). Recent earthquakes (1994 Northridge, M_w 6.7 and 1995 Hanshin [Kobe] M_w 6.9) have recorded PGAs of about 0.8g and PGVs of about 100 kine — almost 2g was recorded in the 1992 Cape Mendocino Earthquake.⁶

⁶ While almost 2g was recorded in the Cape Mendocino event, the portion of the record was a very narrow spike and while considered genuine, is not considered to be a significant acceleration for structures.

17.3.4 Elastic Response Spectra

If a single degree-of-freedom (SDOF) mass is subjected to a time history of ground (i.e., base) motion similar to that shown in Figure 17.7, the mass or elastic structural response can be readily calculated as a function of time, generating a structural response time history, as shown in Figure 17.8 for several oscillators with differing natural periods. The response time history can be calculated by direct integration of Equation 17.1 in the time domain, or by solution of the Duhamel integral (Clough and Penzien 1975). However, this is time consuming, and the elastic response is more typically calculated

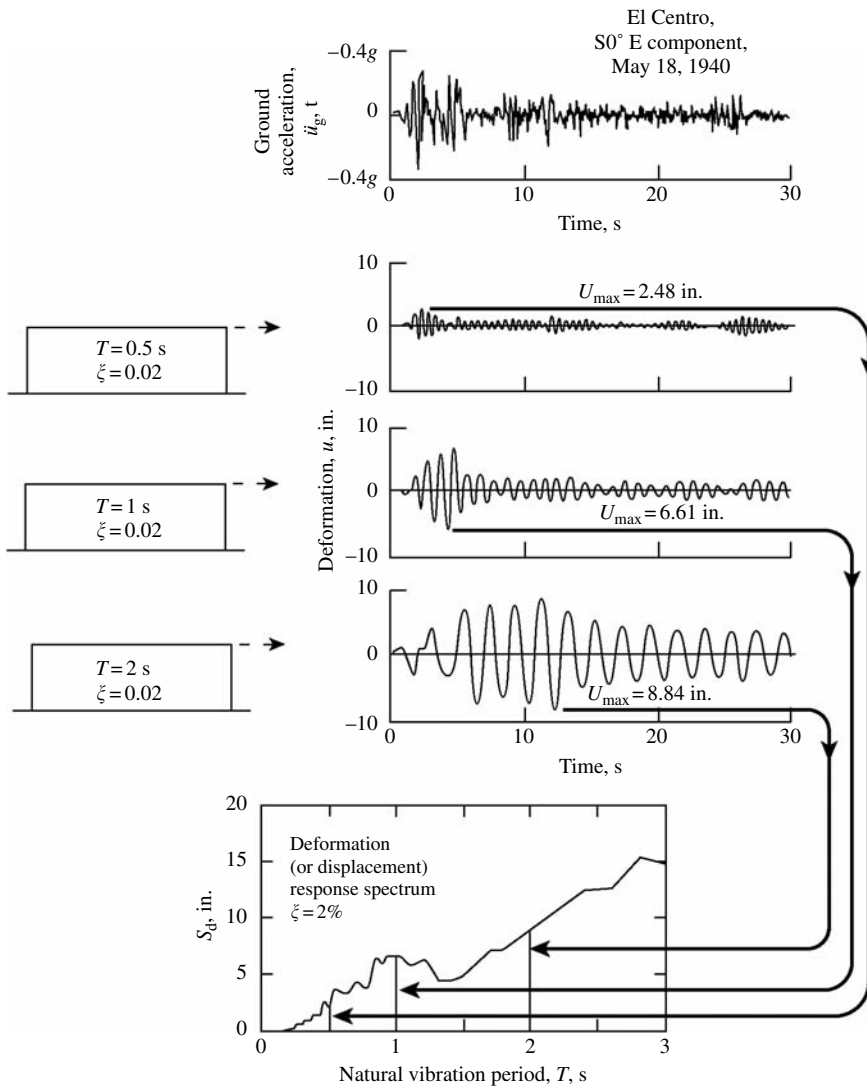

FIGURE 17.8 Computation of deformation (or displacement) response spectrum (Chopra, A.K. 1981).

in the frequency domain

$$\nu(t) = \frac{1}{2\pi} \int_{\varpi=-\infty}^{\infty} H(\varpi)c(\varpi) \exp(i\varpi t) d\varpi \quad (17.11)$$

where $\nu(t)$ is the elastic structural displacement response time history, ϖ is the frequency,

$$H(\varpi) = \frac{1}{-\varpi^2 m + ic + k}$$

is the complex frequency response function, and

$$c(\varpi) = \int_{\varpi=-\infty}^{\infty} p(t) \exp(-i\varpi t) dt$$

is the Fourier transform of the input motion (i.e., the Fourier transform of the ground motion time history), which takes advantage of computational efficiency using the fast Fourier transform (Clough and Penzien 1975).

For design purposes, it is often sufficient to know only the maximum amplitude of the response time history. If the natural period of the SDOF is varied across a spectrum of engineering interest (typically, for natural periods from 0.03 to 3 or more seconds, or frequencies of 0.3 to 30+ Hz), then the plot of these maximum amplitudes is termed a response spectrum. Figure 17.8 illustrates this process, resulting in S_d , the *displacement response spectrum*, while Figure 17.9 shows (a) the S_d , displacement response spectrum, (b) S_v , the *velocity response spectrum* (also denoted PSV, the pseudospectral velocity, pseudo to emphasize that this spectrum is not exactly the same as the relative velocity response spectrum; Hudson, 1979), and (c) S_a , the *acceleration response spectrum*. Note that

$$S_v = \frac{2\pi}{T} S_d = \varpi S_d \quad (17.12)$$

and

$$S_a = \frac{2\pi}{T} S_v = \varpi S_v = \left(\frac{2\pi}{T}\right)^2 S_d = \varpi^2 S_d \quad (17.13)$$

Response spectra form the basis for much modern earthquake engineering structural analysis and design. They are readily calculated if the ground motion is known. For design purposes, however, response spectra must be estimated — this process is discussed in another chapter. Response spectra may be plotted in any of several ways, as shown in Figure 17.9 with arithmetic axes, and in Figure 17.10, where the velocity response spectrum is plotted on tripartite logarithmic axes, which equally enables reading of displacement and acceleration response. Response spectra are most normally presented for 5% of critical damping.

While actual response spectra are irregular in shape, they generally have a concave-down arch or trapezoidal shape, when plotted on tripartite log paper. Newmark observed that response spectra tend to be characterized by three regions: (1) a region of constant acceleration, in the high frequency portion of the spectra; (2) constant displacement, at low frequencies; and (3) constant velocity, at intermediate frequencies, as shown in Figure 17.11. If a *spectrum amplification factor* is defined as the ratio of the spectral parameter to the ground motion parameter (where parameter indicates acceleration, velocity, or displacement), then response spectra can be estimated from the data in Table 17.4, provided estimates of the ground motion parameters are available. An example spectrum using these data is given in Figure 17.11.

A standardized response spectrum is provided in the Uniform Building Code (UBC 1997). The spectrum is a smoothed average of a normalized 5% damped spectrum obtained from actual ground motion records grouped by subsurface soil conditions at the location of the recording instrument, and are applicable for earthquakes characteristic of those that occur in California (SEAOC 1988). This normalized shape may be employed to determine a response spectra, appropriate for the soil conditions. Note that the maximum amplification factor is 2.5, over a period range approximately 0.15 s to 0.4–0.9 s, depending on the soil conditions.

FIGURE 17.9 Response spectra (Chopra, A.K. 1981).

17.3.5 Inelastic Response Spectra

While the foregoing discussion has been for elastic response spectra, most structures are not expected, or even designed, to remain elastic under strong ground motions. Rather, structures are expected to enter the *inelastic* region — the extent to which they behave inelastically can be defined by the ductility factor, μ :

$$\mu = \frac{u_m}{u_y} \tag{17.14}$$

where u_m is the actual displacement of the mass under actual ground motions and u_y is the displacement at yield (i.e., that displacement which defines the extreme of elastic behavior). Inelastic response spectra can be calculated in the time domain by direct integration, analogous to elastic response spectra but with the structural stiffness as a nonlinear function of displacement, $k = k(u)$. If elastoplastic

behavior is assumed, then elastic response spectra can be readily modified to reflect inelastic behavior (Newmark and Hall 1982), on the basis that (1) at low frequencies (<0.3 Hz) displacements are the same, (2) at high frequencies (>33 Hz), accelerations are equal, and (3) at intermediate frequencies, the absorbed energy is preserved. Actual construction of inelastic response spectra on this basis is shown in Figure 17.13, where $DVA A_0$ is the elastic spectrum, which is reduced to D' and V' by the ratio of $1/\mu$ for frequencies less than 2 Hz, and by the ratio of $1/(2\mu - 1)^{1/2}$ between 2 and 8 Hz. Above 33 Hz there is no reduction. The result is the inelastic acceleration spectrum ($D'V'A'A_0$), while $A''A'_0$ is the inelastic

displacement spectrum. A specific example, for ZPA = 0.16g, damping = 5% of critical, and $\mu = 3$ is shown in Figure 17.14.

17.4 Distribution of Seismicity

This section discusses and characterizes the nature and distribution of seismicity.

It is evident from Figure 17.1 that some parts of the globe experience more and larger earthquakes than others. The two major regions of seismicity are the circum-Pacific *Ring of Fire* and the *Trans-Alpide belt*, extending from the western Mediterranean through the Middle East and the northern Indian subcontinent to Indonesia. The Pacific plate is created at its South Pacific extensional boundary — its motion is generally northwestward, resulting in relative strike-slip motion in California and New Zealand (with however a compressive component), and major compression and subduction in Alaska, the Aleutians, Kuriles, and northern Japan. Subduction also occurs along the west coast of South America at the boundary of the Nazca and South American plate, in Central America (boundary of the Cocos and Caribbean plates), in Taiwan and Japan (boundary of the Philippine and Eurasian plates), and in the North American Pacific Northwest (boundary of the Juan de Fuca and North American plates). Seismicity in the Trans-Alpide seismic belt is basically due to the relative motions of the African and Australia plates colliding and subducting with the Eurasian plate. The reader is referred to Chen and Scawthorn (2002) for a more extended discussion of global seismicity.

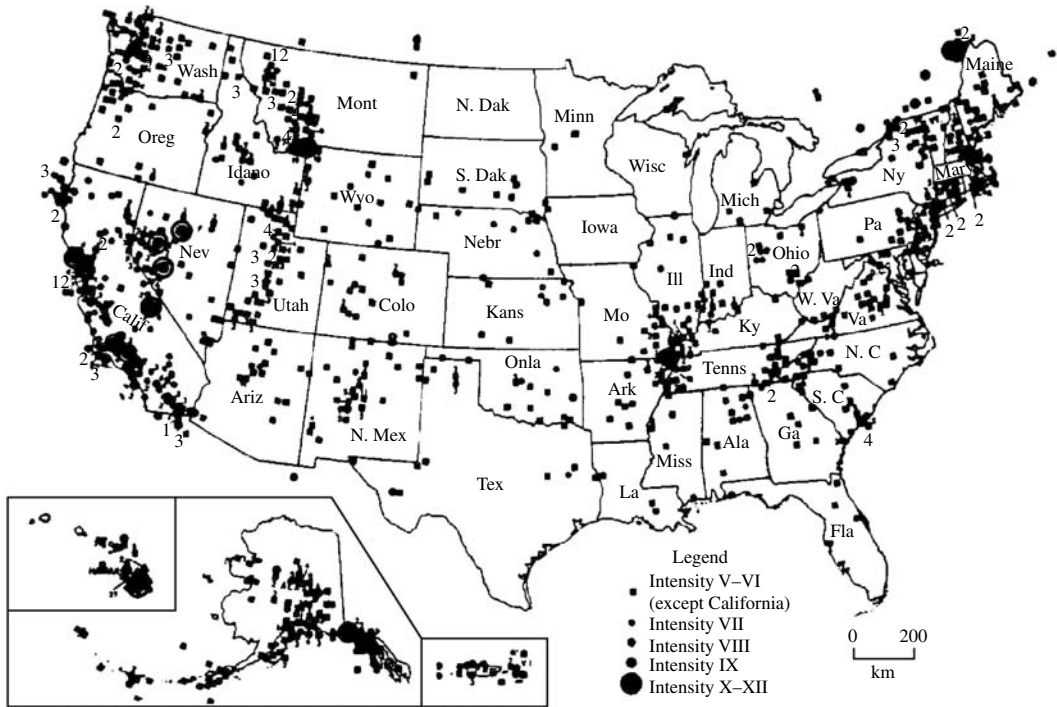

FIGURE 17.15 U.S. seismicity (Algermissen, S.T. 1983; after Coffman et al. 1980).

Regarding U.S. seismicity, the San Andreas fault system in California and the Aleutian Trench off the coast of Alaska are part of the boundary between the North American and Pacific tectonic plates, and are associated with the majority of U.S. seismicity, Figure 17.15. There are many other smaller fault zones throughout the western United States that are also helping to release the stress that is built up as the tectonic plates move past one another, Figure 17.16.

While California has had numerous destructive earthquakes, there is also clear evidence that the potential exists for great earthquakes in the Pacific Northwest (Atwater et al. 1995). On February 28, 2001, the M_W 6.8 Nisqually struck the Puget Sound area, a very similar earthquake to the M_W 6.5 1965 event. Fortunately, the Nisqually event was relatively deep (~ 50 km), and caused relatively few casualties, although still about \$1 billion in damage.

On the east coast of the United States, the cause of earthquakes is less well understood. There is no plate boundary and very few locations of active faults are known so that it is more difficult to assess where earthquakes are most likely to occur. Several significant historical earthquakes have occurred, such as in Charleston, South Carolina, in 1886, and New Madrid, Missouri, in 1811 and 1812, indicating that there is potential for very large and destructive earthquakes (Wheeler et al. 1994; Harlan and Lindbergh 1988). However, most earthquakes in the eastern United States are smaller magnitude events. Because of regional geologic differences, eastern and central U.S. earthquakes are felt at much greater distances than those in the western United States, sometimes up to a thousand miles away (Hopper 1985).

17.5 Strong Motion Attenuation and Duration

The rate at which earthquake ground motion decreases with distance, termed *attenuation*, is a function of the regional geology and inherent characteristics of the earthquake and its source. Three

FIGURE 17.16 Seismicity for California and Nevada, 1980–86 $M > 1.5$ (courtesy Jennings, C.W. 1994).

major factors affect the severity of ground shaking at a site: (1) *source* — the size and type of the earthquake; (2) *path* — the distance from the source of the earthquake to the site, and the geologic characteristics of the media earthquake waves pass through; and (3) *site-specific effects* — type of soil at the site. In the simplest of models, if the seismogenic source is regarded as a point then, from considering the relation of energy and earthquake magnitude, and the fact that the volume of a hemisphere is proportion to R^3 (where R represents radius), it can be seen that energy per unit volume is proportional to $C10^{aM} R^{-3}$, where C is a constant or constants dependent on the earth's crustal properties. The constant C will vary regionally — for example, it has long been observed that attenuation in eastern North America (ENA) varies significantly from that in western North America (WNA) — earthquakes in ENA are felt at far greater distances. Therefore, attenuation relations are regionally dependent. Another regional aspect of attenuation is the definition of terms, especially magnitude, where various relations are developed using magnitudes defined by local observatories.

A very important aspect of attenuation is the definition of the distance parameter — since attenuation is the change of ground motion with location, this is clearly important. Many investigators use differing definitions — as study has progressed, several definitions have emerged: (1) hypocentral distance (i.e., straight line distance from point of interest to hypocenter, where hypocentral distance may be arbitrary, or based on regression rather than observation; (2) epicentral distance; (3) closest distance to the causative fault; and (4) closest horizontal distance from the station to the point on the earth's surface that lies directly above the seismogenic source. In using attenuation relations, it is critical that the correct definition of distance is consistently employed.

An extensive discussion of attenuation is beyond the scope of this chapter, and the reader is referred to Chen and Scawthorn for an extended discussion. However, for completeness, we present one attenuation relation, that of Campbell and Bozorgnia (2003 from which the following is excerpted), which can be represented by the expression:

$$\ln Y = c_1 + f_1(M_W) + c_4 \ln \sqrt{f_2(M_W, r_{\text{seis}}, S)} + f_3(F) + f_4(S) + f_5(\text{HW}, M_W, r_{\text{seis}}) + \varepsilon \quad (17.15)$$

where the magnitude scaling characteristics are given by

$$f_1(M_W) = c_2 M_W + c_3 (8.5 - M_W)^2 \quad (17.16)$$

The distance scaling characteristics are given by

$$f_2(M_W, r_{\text{seis}}, S) = r_{\text{seis}}^2 + g(S)^2 (\exp[c_8 M_W + c_9 (8.5 - M_W)^2])^2 \quad (17.17)$$

in which the near-source effect of local site conditions is given by

$$g(S) = c_5 + c_6 (S_{\text{VFS}} + S_{\text{SR}}) c_7 S_{\text{FR}} \quad (17.18)$$

The effect of faulting mechanism is given by

$$f_3(F) = (c_{10} F_{\text{RV}} + c_{11} F_{\text{TH}}) \quad (17.19)$$

The far-source effect of local site conditions is given by

$$f_4(S) = c_{12} S_{\text{VFS}} + c_{13} S_{\text{SR}} + c_{14} S_{\text{FR}} \quad (17.20)$$

and the effect of the hanging wall (HW) is given by

$$f_5(\text{HW}, F, M_W, r_{\text{seis}}) = \text{HW} f_3(F) f_{\text{HW}}(M_W) f_{\text{HW}}(r_{\text{seis}}) \quad (17.21)$$

where

$$\text{HW} = \begin{cases} 0 & \text{for } r_{\text{jb}} \geq 5 \text{ km} \quad \text{or} \quad \delta > 70^\circ \\ (S_{\text{VFS}} + S_{\text{SR}} + S_{\text{FR}})(5 - r_{\text{jb}})/5 & \text{for } r_{\text{jb}} < 5 \text{ km} \quad \text{and} \quad \delta \leq 70^\circ \end{cases} \quad (17.22)$$

$$f_{\text{HW}}(M_W) = \begin{cases} 0 & \text{for } M_W < 5.5 \\ M_W - 5.5 & \text{for } 5.5 \leq M_W \leq 6.5 \\ 1 & \text{for } M_W > 6.5 \end{cases} \quad (17.23)$$

and

$$f_{\text{HW}}(r_{\text{seis}}) = \begin{cases} c_{15}(r_{\text{seis}}/8) & \text{for } r_{\text{seis}} < 8 \text{ km} \\ c_{15} & \text{for } r_{\text{seis}} \geq 8 \text{ km} \end{cases} \quad (17.24)$$

The parameter HW quantifies the effect of the hanging wall and will always evaluate to zero for firm soil and for a horizontal distance of 5 km or greater from the rupture plane. The standard deviation of $\ln Y$ is defined as a function of magnitude according to the expression:

$$\sigma_{\ln Y} = \begin{cases} c_{16} - 0.07 M_W & \text{for } M_W < 7.4 \\ c_{16} - 0.518 & \text{for } M_W \geq 7.4 \end{cases} \quad (17.25)$$

or as a function of PGA according to the expression:

$$\sigma_{\ln Y} = \begin{cases} c_{17} + 0.351 & \text{for } \text{PGA} \leq 0.07g \\ c_{17} - 0.132 \ln(\text{PGA}) & \text{for } 0.07g < \text{PGA} < 0.25g \\ c_{17} + 0.183 & \text{for } \text{PGA} \geq 0.25g \end{cases} \quad (17.26)$$

Note: Uncorrected PGA is to be used only when an estimate of PGA is required. Corrected PGA is to be used when an estimate of PGA compatible with PSA is required.

Source: Adapted from Campbell, K.W. and Bozorgnia, Y. (2003) Updated Near-Source Ground Motion (Attenuation) Relations for the Horizontal and Vertical Components of Peak Ground Acceleration and Acceleration Response Spectra, *Bull. Seismol. Soc. Am.*

where PGA is either uncorrected PGA or corrected PGA, depending on the application (see footnote to Table 17.5). The regression coefficients are listed in Table 17.5 and Table 17.6. The relation is considered valid for $MW \geq 4.7$ and $r_{\text{seis}} \leq 60$ km.

The relation predicts ground motion for firm soil, equivalent to the condition $SFS = 1$, unless one of the site parameters in $g(S)$ and $f_4(S)$ is set to one, in which case it predicts ground motion for either very firm soil, soft rock, or firm rock. The relationship between the faulting mechanism parameters FRV (reverse faulting with dip greater than 45°) and FTH (thrust faulting with dip less than or equal to 45°) and the rake angle λ is⁷ (a) strike slip: $F=0$, rake angle $\lambda = 0-22.5, 177.5-202.5, 337.5-360$; (b) normal: $F=0$, rake angle $\lambda = 202.5-337.5$; (c) reverse (FRV = 1) $F=1.0$, rake angle $\lambda = 22.5-157.5$ ($\delta > 45$); and (d) thrust (FTH = 1) $F=1.0$, rake angle $\lambda = 22.5-157.5$ ($\delta \leq 45$).

Sediment depth D was evaluated and found to be important, but it was not included as a parameter, since it is rarely used in engineering practice. If desired, sediment depth can be included in an estimate of ground motion by using the attenuation relation developed by Campbell (1997, 2000, 2001).

17.6 Characterization of Seismicity

The previous section described the global distribution of seismicity, in qualitative terms. This section describes how that seismicity may be mathematically characterized, in terms of magnitude–frequency and other relations.

The term magnitude–frequency relation was first characterized by Gutenberg and Richter (1954) as

$$\log N(m) = a_N - b_N m \quad (17.27)$$

where $N(m)$ is the number of earthquake events equal to or greater than magnitude m occurring on a seismic source per unit time, and a_N and b_N are regional constants ($10a_N$ is equal to the total number of earthquakes with magnitude >0 , and b_N is the rate of seismicity; b_N is typically 1 ± 0.3). Gutenberg and Richter's examination of the seismicity record for many portions of the earth indicated this relation was valid for selected magnitude ranges. The Gutenberg–Richter relation can be normalized to

$$F(m) = 1 - \exp[-B_M(m - M_0)] \quad (17.28)$$

where $F(m)$ is the cumulative distribution function (CDF) of magnitude, B_M is a regional constant, and M_0 is a small enough magnitude such that lesser events can be ignored. Combining this with a Poisson distribution to model large earthquake occurrence (Esteva 1976) leads to the CDF of earthquake magnitude per unit time:

$$F(m) = \exp[-\exp\{-a_M(m - \mu_M)\}] \quad (17.29)$$

which has the form of a Gumbel (1958) extreme value type I (largest values) distribution (denoted $EX_{I,L}$), which is an unbounded distribution (i.e., the variate can assume any value). The parameters a_M and μ_M can be evaluated by a least squares regression on historical seismicity data, although the probability of very large earthquakes tends to be overestimated. Several attempts have been made to account for this (e.g., Cornell and Merz 1973). Yegulalp and Kuo (1974) have used Gumbel's Type III (largest value, denoted $EX_{III,L}$) to successfully account for this deficiency. This distribution

$$F(m) = \exp\left[-\left(\frac{w - m}{w - u}\right)^k\right] \quad (17.30)$$

has the advantage that w is the largest possible value of the variate (i.e., earthquake magnitude), thus permitting (when w , u , and k are estimated by regression on historical data) an estimate of the source's largest possible magnitude. It can be shown (Yegulalp and Kuo 1974) that estimators of w , u , and k can

⁷Rake is a continuous variable representing the angle between the direction of slip on the fault plane and the **strike** or the orientation of the fault on the Earth's surface.

be obtained by satisfying Kuhn–Tucker conditions although, if the data are too incomplete, the $EX_{III,L}$ parameters approach those of the $EX_{I,L}$:

$$u \longrightarrow \mu_M, \quad k/(w - u) \longrightarrow a_M$$

Determination of these parameters requires careful analysis of historical seismicity data (which is highly complex and something of an art; Donovan and Bornstein 1978), and the merging of the resulting statistics with estimates of maximum magnitude and seismicity made on the basis of geological evidence (i.e., as discussed above, maximum magnitude can be estimated from fault length, fault displacement data, time since last event and other evidence, and seismicity can be estimated from fault slippage rates combined with time since last event, see Schwartz, 1988, for an excellent discussion of these aspects). In a full probabilistic seismic hazard analysis, many of these aspects are treated fully or partially probabilistically, including the attenuation, magnitude–frequency relation, upper and lower bound magnitudes for each source zone, geographical bounds of source zones, fault rupture length, and many other aspects. The full treatment requires complex specialized computer codes, which incorporate uncertainty via use of multiple alternative source zonations, attenuation relations, and other parameters (EPRI 1986; Bernreuter et al. 1989) often using a logic tree format. A number of codes have been developed using the public domain FRISK (Fault Risk) code first developed by McGuire (1978).

Several topics are worth noting briefly:

- While analysis of the seismicity of a number of regions indicates that the Gutenberg–Richter relation $\log N(M) = a - bM$ is a good overall model for the magnitude–frequency or probability of occurrence relation, studies of late Quaternary faults during the 1980s indicated that the exponential model is not appropriate for expressing earthquake recurrence on individual faults or fault segments (Schwartz 1988). Rather, it was found that many individual faults tend to generate essentially the same size or *characteristic earthquake* (Schwartz and Coppersmith 1984), having a relatively narrow range of magnitudes at or near the maximum that can be produced by the geometry, mechanical properties, and state of stress of the fault. This implies that, relative to the Gutenberg–Richter magnitude–frequency relation, faults exhibiting characteristic earthquake behavior will have relatively less seismicity (i.e., higher b value) at low and moderate magnitudes, and more near the characteristic earthquake magnitude (i.e., lower b value).
- Most probabilistic seismic hazard analysis models assume the Gutenberg–Richter exponential distribution of earthquake magnitude, and that earthquakes follow a Poisson process, occurring on a seismic source zone randomly in time and space. This implies that the time between earthquake occurrences is exponentially distributed and that the time of occurrence of the next earthquake is independent of the elapsed time since the prior earthquake.⁸ The CDF for the exponential distribution is

$$F(t) = 1 - \exp(-\lambda t) \quad (17.31)$$

Note that this forms the basis for many modern building codes, in that the probabilistic seismic hazard analysis results are selected such that the seismic hazard parameter (e.g., PGA) has a “10% probability of exceedance in 50 years” (UBC 1994) — if $t = 50$ years and $F(t) = 0.1$ (i.e., only 10% probability that the event has occurred in t years), then $\lambda = 0.0021$ per year, or 1 per 475 years. A number of more sophisticated models of earthquake occurrence have been investigated, including time-predictable models (Anagnos and Kiremidjian 1984), renewal models (Kameda and Takagi 1981; Nishenko and Buland 1987), and time-dependent models (Ellsworth et al. 1999). The latter have formed the basis for state-of-the-art estimation of seismic hazard for the San Francisco Bay Area by the U.S. Geological Survey, but can only be used when sufficient data are available.

⁸For this aspect, the Poisson model is often termed a *memoryless* model.

- Construction of response spectra is usually performed in one of two ways:
 - A. Using probabilistic seismic hazard analysis to obtain an estimate of the PGA, and using this to scale a normalized response spectral shape. Alternatively, estimating PGA and PSV (also perhaps PSD) and using these to fit a normalized response spectral shape, for each portion of the spectrum. Since probabilistic response spectra are a composite of the contributions of varying earthquake magnitudes at varying distances, the ground motions of which attenuate differently at different periods, this method has the drawback that the resulting spectra have varying (and unknown) probabilities of exceedance at different periods. Because of this drawback, this method is less favored at present, but still offers the advantage of economy of effort.
 - B. An alternative method results in the development of *uniform hazard spectra* (Anderson and Trifunac 1977), and consists of performing the probabilistic seismic hazard analysis for a number of different periods, with attenuation equations appropriate for each period (e.g., those of Boore, Joyner, and Fumal). This method is currently preferred, as the additional effort is not prohibitive, and the resulting response spectra has the attribute that the probability of exceedance is independent of frequency.

The reader is referred to Chen and Scawthorn (2002) for a more extensive discussion of this topic.

Glossary

Attenuation — The rate at which earthquake ground motion decreases with distance.

Benioff zone — A narrow zone, defined by earthquake foci, that is tens of kilometers thick dipping from the surface under the earth's crust to depths of 700 km (also termed Wadati–Benioff zone).

Body waves — Vibrational waves transmitted through the body of the earth, and are of two types: (1) P waves (transmitting energy via dilatational or push-pull motion) and (2) slower S waves (transmitting energy via shear action at right angles to the direction of motion).

Characteristic, earthquake — A relatively narrow range of magnitudes at or near the maximum that can be produced by the geometry, mechanical properties, and state of stress of a fault (Schwartz and Coppersmith 1984).

Completeness — Homogeneity of the seismicity record.

Corner frequency, f_0 — The frequency above which earthquake radiation spectra vary with ω^{-3} below f_0 , the spectra are proportional to seismic moment.

Cripple wall — A carpenter's term indicating a wood frame wall of less than full height T , usually built without bracing.

Critical damping — The value of damping such that free vibration of a structure will cease after one cycle ($c_{\text{crit}} = 2m\omega$). Damping represents the force or energy lost in the process of material deformation (damping coefficient c = force per velocity).

Dip — The angle between a plane, such as a fault, and the earth's surface.

Dip slip — Motion at right angles to the strike, up- or down-slip.

Ductile detailing — Special requirements such as, for reinforced concrete and masonry, close spacing of lateral reinforcement to attain confinement of a concrete core, appropriate relative dimensioning of beams and columns, 135° hooks on lateral reinforcement, hooks on main beam reinforcement within the column, etc.

Ductile frames — Frames required to furnish satisfactory load-carrying performance under large deflections (i.e., ductility). In reinforced concrete and masonry this is achieved by ductile detailing.

Ductility factor — The ratio of the total displacement (elastic plus inelastic) to the elastic (i.e., yield) displacement.

Epicenter — The projection on the surface of the earth directly above the hypocenter.

Far-field — Beyond near-field, also termed teleseismic.

Fault — A zone of the earth's crust within which the two sides have moved — faults may be hundreds of miles long, from one to over one hundred miles deep, and not readily apparent on the ground surface.

- Focal mechanism** — Refers to the direction of slip in an earthquake, and the orientation of the fault on which it occurs.
- Fragility** — The probability of having a specific level of damage given a specified level of hazard.
- Hypocenter** — The location of initial radiation of seismic waves (i.e., the first location of dynamic rupture).
- Intensity** — A metric of the effect, or the strength, of an earthquake hazard at a specific location, commonly measured on qualitative scales such as MMI, MSK, and JMA.
- Lateral force resisting system** — A structural system for resisting horizontal forces, due, for example, to earthquake or wind (as opposed to the vertical force resisting system, which provides support against gravity).
- Liquefaction** — A process resulting in a soil's loss of shear strength, due to a transient excess of pore water pressure.
- Magnitude** — A unique measure of an individual earthquake's release of strain energy, measured on a variety of scales, of which the moment magnitude M_W (derived from seismic moment) is preferred.
- Magnitude–frequency relation** — The probability of occurrence of a selected magnitude — the commonest is $\log_{10} n(m) = a - bm$ (Gutenberg and Richter 1954).
- Meiroseismal** — The area of strong shaking and damage.
- Near-field** — Within one source dimension of the epicenter, where source dimension refers to the length or width of faulting, whichever is less.
- Nonductile frames** — Frames lacking ductility or energy absorption capacity due to lack of ductile detailing — ultimate load is sustained over a smaller deflection (relative to ductile frames), and for fewer cycles.
- Normal fault** — A fault that exhibits dip-slip motion, where the two sides are in tension and move away from each other.
- Peak ground acceleration (PGA)** — The maximum amplitude of recorded acceleration (also termed the ZPA, or zero period acceleration).
- Pounding** — The collision of adjacent buildings during an earthquake due to insufficient lateral clearance.
- Response spectrum** — A plot of maximum amplitudes (acceleration, velocity, or displacement) of a single-degree-of-freedom (SDOF) oscillator as the natural period of the SDOF is varied across a spectrum of engineering interest (typically, for natural periods from 0.03 to 3 or more seconds or frequencies of 0.3 to 30+ Hz).
- Reverse fault** — A fault that exhibits dip-slip motion, where the two sides are in compression and move away toward each other.
- Ring of fire** — A zone of major global seismicity due to the interaction (collision and subduction) of the Pacific plate with several other plates.
- Sand boils or mud volcanoes** — Ejecta of solids (i.e., sand, silt) carried to the surface by water, due to liquefaction.
- Seismic gap** — A portion of a fault or seismogenic zone that can be deduced to be likely to rupture in the near term, based on patterns of seismicity and geological evidence.
- Seismic hazards** — The phenomena and/or expectation of an earthquake-related agent of damage, such as fault rupture, vibratory ground motion (i.e., shaking), inundation (e.g., tsunami, seiche, dam failure), various kinds of permanent ground failure (e.g., liquefaction), fire, or hazardous materials release.
- Seismic moment** — The moment generated by the forces generated on an earthquake fault during slip.
- Seismic risk** — The product of the hazard and the vulnerability (i.e., the expected damage or loss, or the full probability distribution).
- Seismotectonic model** — A mathematical model representing the seismicity, attenuation, and related environment.

- Soft story** — A story of a building significantly less stiff than adjacent stories (i.e., the lateral stiffness is 70% or less than that in the story above, or less than 80% of the average stiffness of the three stories above (BSSC 1194).
- Spectrum amplification factor** — The ratio of a response spectral parameter to the ground motion parameter (where parameter indicates acceleration, velocity, or displacement).
- Strike** — The intersection of a fault and the surface of the earth, usually measured from north (e.g., the fault strike is N60° W).
- Subduction** — Refers to the plunging of a tectonic plate (e.g., the Pacific) beneath another (e.g., the North American) down into the mantle, due to convergent motion.
- Surface waves** — Vibrational waves transmitted within the surficial layer of the earth, and are of two types: horizontally oscillating Love waves (analogous to S body waves) and vertically oscillating Rayleigh waves.
- Tectonic** — Relating to, causing, or resulting from structural deformation of the earth's crust, (from Greek *tektonikos*, from *tektō*, builder).
- Thrust fault** — Low-angle reverse faulting (blind thrust faults are faults at depth occurring under anticlinal folds — they have only subtle surface expression).
- Trans-alpide belt** — A zone of major global seismicity, extending from the Mediterranean through the Middle East, Himalayas, and Indonesian archipelago, resulting from the collision of several major tectonic plates.
- Transform or strike-slip fault** — A fault where relative fault motion occurs in the horizontal plane, parallel to the strike of the fault.
- Uniform hazard spectra** — Response spectra with the attribute that the probability of exceedance is independent of frequency.
- Vulnerability** — The expected damage given a specified value of a hazard parameter.

18.1 Introduction

18.1.1 Earthquakes

Most earthquakes occur due to the movement of faults. Faults slowly build up stresses that are suddenly released during an earthquake. We measure the size of earthquakes using moment magnitude as defined in Equation 18.1:

$$M = \left(\frac{2}{3}\right) [\log(M_0) - 16.05] \quad (18.1)$$

where M_0 is the seismic moment as defined in Equation 18.2:

$$M_0 = GAD \quad (\text{in dyne cm}) \quad (18.2)$$

where G is the shear modulus of the rock (dyne/cm²), A is the area of the fault (cm²), and D is the amount of slip or movement of the fault (cm).

The largest-magnitude earthquake that can occur on a particular fault is the product of the fault length times its depth (A), the average slip rate times the recurrence interval of the earthquake (D), and the hardness of the rock (G).

For instance the northern half of the Hayward Fault (in the San Francisco Bay Area) has an annual slip rate of 9 mm/year (Figure 18.1). It has an earthquake recurrence interval of 200 years. It is 50 km long and 14 km deep. G is taken as 3×10^{11} dyne/cm².

$$M_0 = (0.9 \times 200)(5 \times 10^6)(1.4 \times 10^6)(3 \times 10^{11}) = 3.78 \times 10^{26}$$

$$M = (2/3)[\log 3.78 \times 10^{26} - 16.05] = 7.01$$

Therefore, about a magnitude 7.0 earthquake is the maximum event that can occur on the northern section of the Hayward Fault. Since G is a constant, the average slip is usually a few meters, and

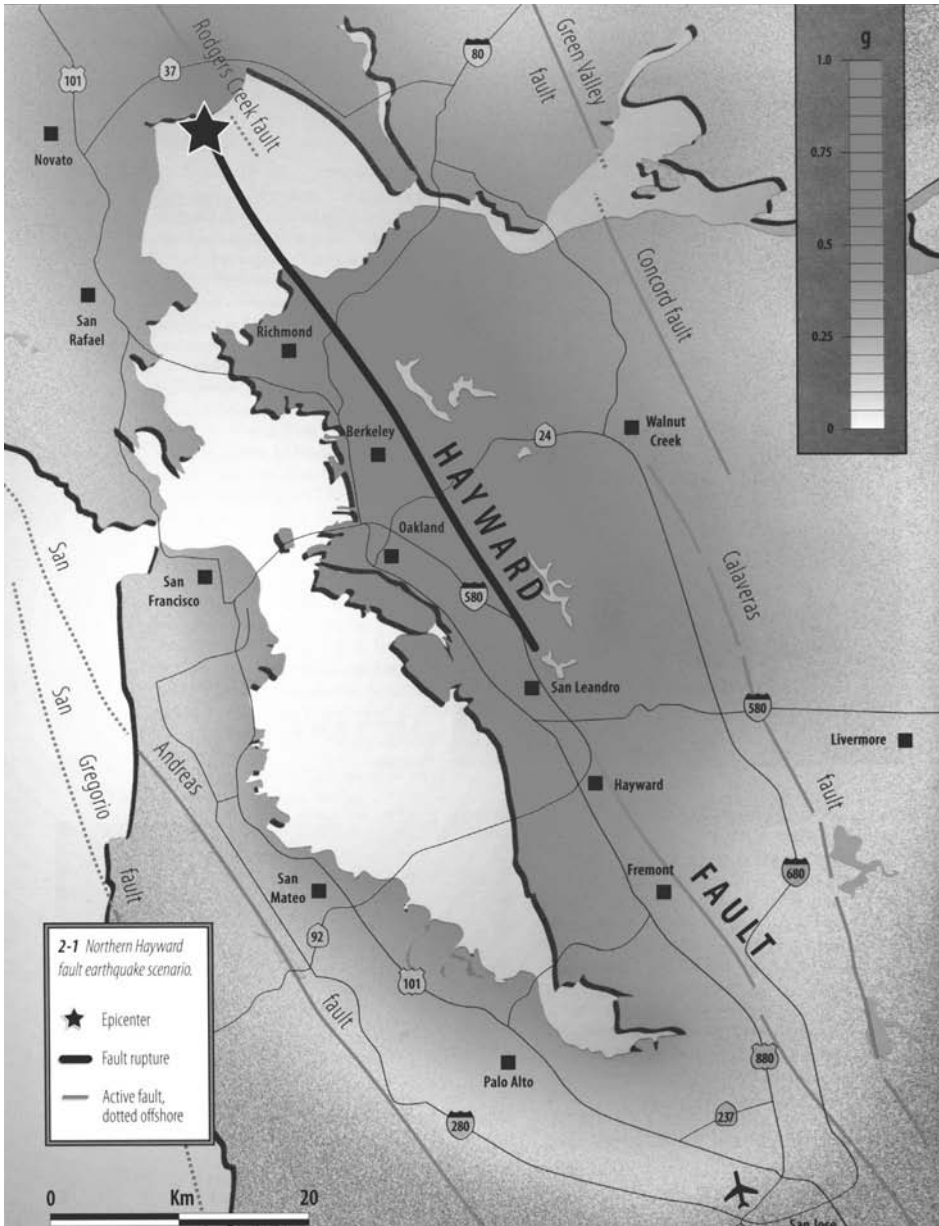

FIGURE 18.1 Map of Hayward Fault (courtesy of EERI, Earthquake Engineering Research Institute, HF-96, The Institute, Oakland, CA, 1996).

FIGURE 18.2 Attenuation curve developed by Mualchin and Jones [2].

the depth of the crust is fairly constant, the size of the earthquake is usually controlled by the length of the fault.

Magnitude is not particularly revealing to the structural engineer. Engineers design structures for the peak accelerations and displacements at the site. After every earthquake, seismologists assemble the recordings of acceleration versus distance to create attenuation curves that relate the peak ground acceleration (PGA) to the magnitude of earthquakes with distance from the fault rupture (Figure 18.2).

All of the data available on active faults is assembled to create a seismic hazard map. The map has contour lines that provide the peak acceleration based on attenuation curves that provide the reduction in acceleration due to the distance from a fault. The map is based on deterministic derived earthquakes or on earthquakes with the same return period.

18.1.2 Structural Damage

Every day, regions of high seismicity experience many small earthquakes. However, structural damage does not usually occur until the magnitude approaches 5.0. Most structural damage during earthquakes is caused by the failure of the surrounding soil or from strong shaking. Damage also results from surface ruptures, the failure of nearby lifelines, or the collapse of more vulnerable structures. We consider these effects secondary because they are not always present during an earthquake. However, when there is a long surface rupture such as that which accompanied the 1999 Ji Ji, Taiwan, earthquake, secondary effects can dominate.

Since damage can mean anything from minor cracks to total collapse, categories of damage have been developed as shown in Table 18.1. These levels of damage give engineers a choice for the performance of their structure during earthquakes. Most engineered structures are designed only to prevent collapse. This is not only to save money, but also because as a structure becomes stronger it attracts larger forces. Thus, most structures are designed to have sufficient ductility to survive an earthquake. This means that elements will yield and deform but they will be strong in shear and continue to support their load during and after the earthquake.

As shown in Table 18.1, the time that is required to repair damaged structures is an important parameter that weighs heavily on the decision making process. When a structure must be quickly repaired or must remain in service, a different damage state should be chosen.

During large earthquakes the ground is jerked back and forth, causing damage to the element whose capacity is furthest below the earthquake demand. Figure 18.3 shows that the cause may be the supporting soil, the foundation, weak flexural or shear elements, or secondary hazards such as surface

TABLE 18.1 Categories of Structural Damage

Damage state	Functionality	Repairs required	Expected outage
None (preyield) (1)	No loss	None	None
Minor/slight (2)	Slight loss	Inspect, adjust, patch	<3 days
Moderate (3)	Some loss	Repair components	<3 weeks
Major/extensive (4)	Considerable loss	Rebuild components	<3 months
Complete/collapse (5)	Total loss	Rebuild structure	>3 months

**FIGURE 18.3** Common types of damage during large earthquakes.

faulting or failure of a nearby structure. Damage also frequently occurs due to the failure of connections, from large torsional moments, from tension and compression, buckling, pounding, etc.

In this chapter structural damage as a result of soil problems, structural shaking, and secondary causes will be discussed. These types of damage illustrate the most common structural hazards that have been seen during recent earthquakes.

18.2 Damage as a Result of Problem Soils

18.2.1 Liquefaction

One of the most common causes of damage to structures is the result of liquefaction to the surrounding soil. When loose saturated sands, silts, or gravel are shaken, the material consolidates, reducing the porosity and increasing pore water pressure. The ground settles, often unevenly, tilting and toppling structures that were formerly supported by the soil. During the 1955 Niigata, Japan, earthquake, several four-story apartment buildings toppled over due to liquefaction (Figure 18.4).

These buildings fell as the liquefied soil lost its ability to support them. As can be seen clearly in Figure 18.5, there was little damage to these buildings and it was reported that their collapse took place over several hours.

Partial liquefaction of the soil in Adapazari during the 1999 Kocaeli, Turkey, earthquake caused several buildings to settle or fall over. Figure 18.6 shows a building that settled as pore water was pushed to the surface, reducing the bearing capacity of the soil. Note that the weight of the building squeezed the weakened soil under the adjacent roadway. Another problem during liquefaction is that the increased pore pressure pushes quay walls, riverbanks, and the piers of bridges toward adjacent bodies of water, often dropping the end spans in the process.

The Shukugawa Bridge is a three-span, continuous, steel box girder superstructure with a concrete deck. The end spans are 87.5 m and the center span is 135 m. The superstructure is supported by steel, multicolumn bents with dropped-bent caps. It is part of a long elevated viaduct, and has expansion joints at Pier 131 and Pier 134. The columns are supported by steel piles embedded in reclaimed land along Osaka Bay.

During the 1995 Kobe, Japan, earthquake, increased pore pressure pushed the quay wall near the west end of the bridge toward the river, allowing the soil and westernmost pier (Pier 134) to move 1 m

FIGURE 18.4 Liquefaction caused building failure in Niigata, Japan. (Photo by Joseph Penzien; photo courtesy of Steinbrugge Collection, Earthquake Engineering Research Center, University of California, Berkeley.)

FIGURE 18.5 Liquefaction caused building failure in Niigata, Japan. (Photo by Joseph Penzien; photo courtesy of Steinbrugge Collection, Earthquake Engineering Research Center, University of California, Berkeley.)

eastward (Figure 18.7). This resulted in the girders falling off their bearings, damaging the expansion joint devices and making the bridge inaccessible. The easternmost pier (Pier 131) moved half a meter toward the river. It appears that the restrainers were the only thing that kept the superstructure at the expansion joint above Pier 134 together, preventing the collapse of the west span. The expansion joint had a 0.6-m vertical offset, and excavation showed that the piles at Pier 134 were also damaged due to the longitudinal movement.

Structures supported on liquefied soil topple, structures that retain liquefied soil are pushed forward, and structures buried in liquefied soil (like culverts and tunnels) float to the surface in the newly buoyant medium.

FIGURE 18.6 Settlement of building due to loss of bearing during the 1999 Kocaeli Earthquake.

FIGURE 18.7 Liquefaction caused bridge damage during the Kobe Earthquake.

The Webster and Posey Street Tube Crossings are 4500-ft-long tubes carrying two lanes of traffic under the Oakland, California, Estuary. The Posey Street Tube was built in the 1920s (Figure 18.8) while the Webster Street Tube was built in the 1960s (Figure 18.9). They are reinforced concrete (RC) tubes with a bituminous coating for waterproofing. The ground was excavated and each tube section was joined to the previously laid section. The tube descends to 70 ft below sea level.

During the 1989 Loma Prieta, California, earthquake, the soil surrounding the Webster and Posey Tubes (that carry traffic through the Oakland Estuary) liquefied. The tunnels began to float to the surface, breaking the joints between sections and slowly filling with water (Figure 18.10 and Figure 18.11).

18.2.2 Landslides

When a steeply inclined mass of soil is suddenly shaken, a slip-plane can form and the material slides downhill. During a landslide, structures sitting on the slide move downward and structures below the slide are hit by falling debris (Figure 18.12).

Landslides frequently occur in canyons, along cliffs, on mountains, and anywhere else where unstable soil exists. Landslides can occur without earthquakes (they often occur during heavy rains that increase the weight and reduce the friction of the soil) but the number of landslides is greatly increased wherever large earthquakes occur. Landslides can move a few inches or hundreds of feet. They can be the result of liquefaction, weak clays, erosion, subsidence, ground shaking, etc.

During the 1999 Ji Ji, Taiwan, earthquake, many of the mountain slopes were denuded by slides, which continued to be a hazard for people traveling on mountain roads in the weeks following the earthquake. The many RC gravity retaining walls that supported the road embankments in the mountainous terrain were all damaged: either from being pushed downhill by the slide (Figure 18.13) or in some cases broken when the retaining wall was restrained from moving downhill (Figure 18.14).

One of the more interesting retaining wall failures during the Ji Ji Earthquake was in a geogrid fabric and mechanically stabilized earth (MSE) wall at the entrance to the Southern International University (Figure 18.15). This wall was quite long and tall and its failure was a surprise since MSE walls have a good performance record during earthquakes. It was speculated that the geogrid retaining system had insufficient embedment into the soil and also it was unclear why an MSE wall would be used in a cut roadway section.

One of the best-known and largest landslides occurred at Turnagain Heights in Anchorage during the 1964 Great Alaska Earthquake. The area of the slide was about 8500 ft wide by 1200 ft long. The average drop was about 35 ft. This slide was complex, but the main cause was the failure of the weak clay layer and the unhindered movement of the ground down the wet mud flats to the sea. Figure 18.16 and Figure 18.17 provide a section and plan view of the slide.

The soil failed due to the intense shaking, and the whole neighborhood of houses, schools, and other buildings slid hundreds of yards downhill, many remaining intact during the fall (Figure 18.18).

Bridges are also severely damaged by landslides. During the 1999 Ji Ji, Taiwan, earthquake, landslides caused the collapse of two bridges. The Tsu Wei Bridges were two parallel three-span structures that crossed a tributary of the Dajia River near the city of Juolan. The superstructure was simply supported "T" girders on hammerhead single-column bents with "drum"-type footings and seat-type abutments. The girders sat on elastomeric pads between transverse shear keys. The spans were about 80 ft long by 46 ft wide, and had a 30° skew. The head scarp was clearly visible on the hillside above the bridge. During the earthquake, the south abutment was pushed forward by the landslide, the first spans fell off the bent caps on the (far) north side, and the second span of the left bridge also fell off of the far bent cap (Figure 18.19).

Also, the tops of the columns at Bent 2 had rotated away from the (south) Abutment 1. Therefore, it appears that both the top of Abutment 1 and the top of Bent 2 had moved away from the slide, while the remaining spans, restrained by Bent 3 and Abutment 4, had remained in place. Perhaps the landslide originally had pushed against Bent 2, rotating the columns forward, and the debris had

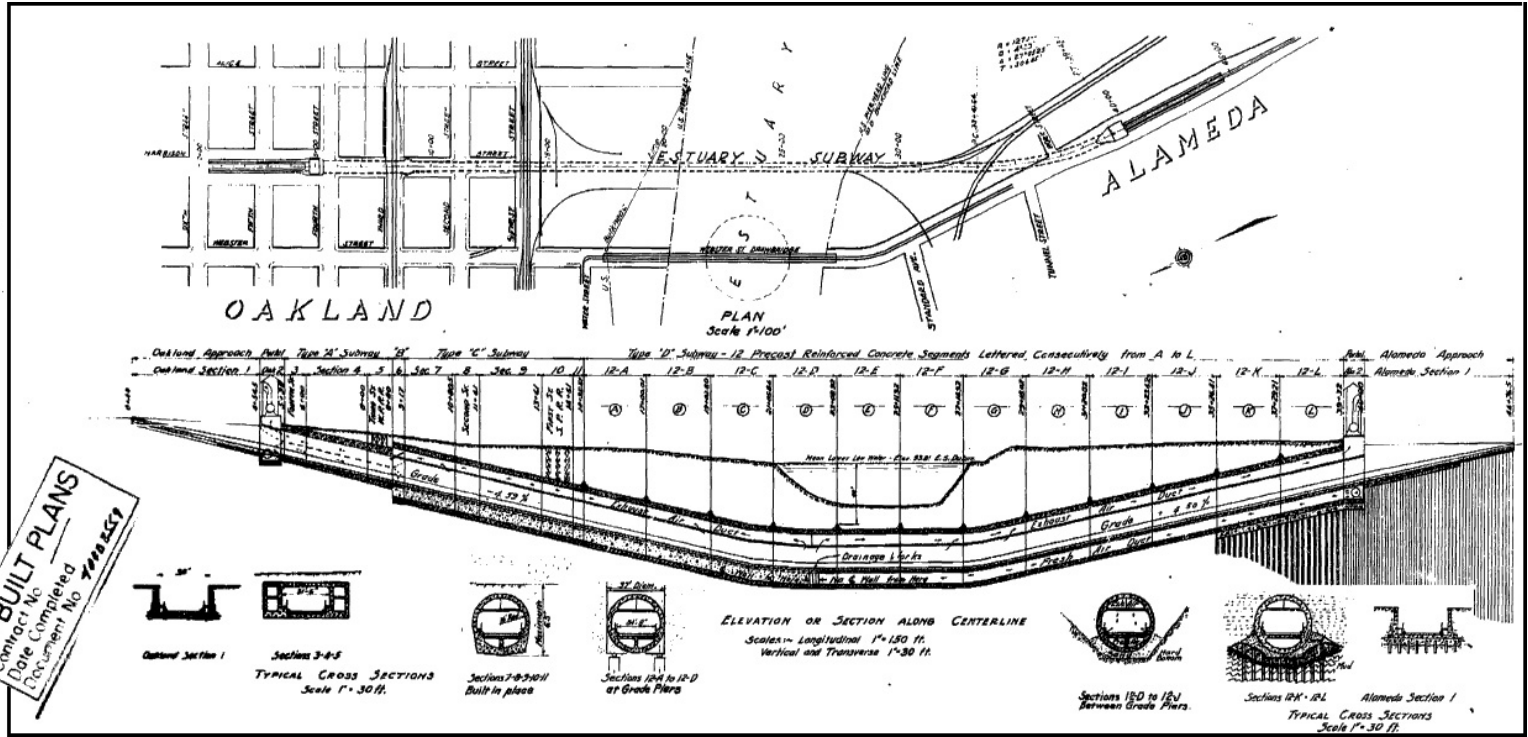

FIGURE 18.8 Elevation view of the Posey Street Tube.

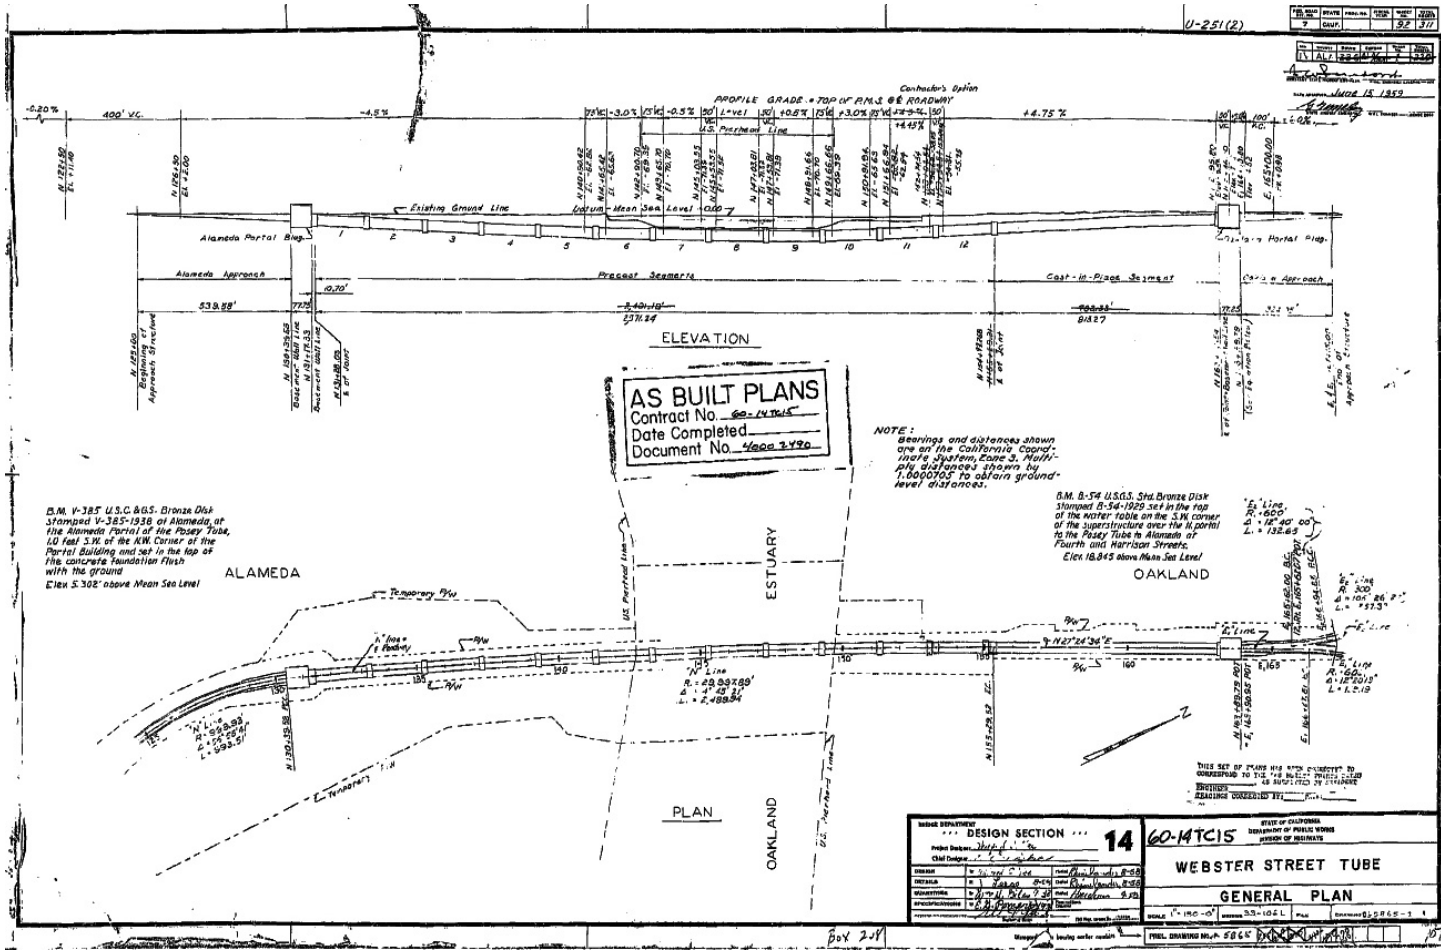

FIGURE 18.9 Elevation view of the Webster Street Tube.

FIGURE 18.10 Liquefaction induced damage to the Webster Street Tube tunnel.

FIGURE 18.11 Liquefaction induced damage to the Webster Street Tube tunnel.

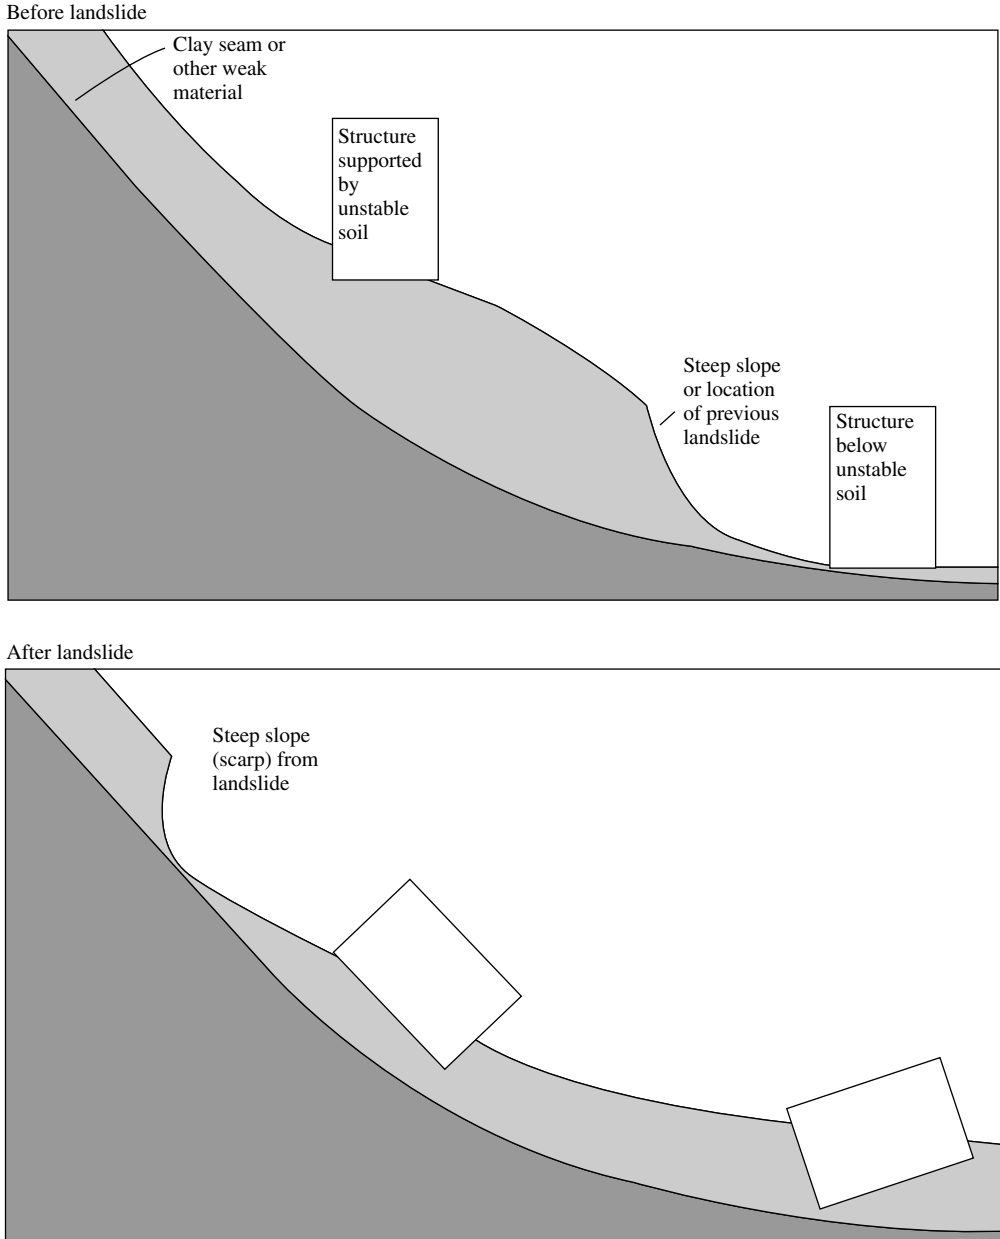

FIGURE 18.12 Diagram showing typical features of landslides.

since been removed by the current or by a construction crew. Perhaps the skew had rotated the spans to the right as they fell, pushing them against the shear keys at Bent 2, which rotated the top of the columns forward and eventually pushed the spans off the tops of Bent 2 and Bent 3. Or perhaps there was an element of strong shaking that combined with the landslide to create the column rotation and fallen spans.

Dams are particularly vulnerable to landslides since they are frequently built to hold back the water in canyons and mountain streams. Moreover, inspection of the dam after an earthquake is often difficult when slides block the roads leading to the dam. When the Pacoima concrete arch dam was built in the

FIGURE 18.13 Gravity retaining wall pushed outward by landslide.

1920s, a covered tunnel was constructed to allow access to the dam. However this tunnel, along with roads and a tramway to the dam, were damaged by massive landslides during and for several days after the 1971 San Fernando Earthquake (Figure 18.20).

The Lower San Fernando Dam for the Van Norman Reservoir was also severely damaged during the 1971 San Fernando Earthquake. It was fortunate that water levels were low as the concrete crest on this earthen dam collapsed due to a large landslide along both the upstream (Figure 18.21) and the downstream (Figure 18.22) faces. Considering the vulnerability of thousands of residences in the San Fernando Valley below (Figure 18.23), a dam failure can be extremely costly in terms of human lives and property damage.

18.2.3 Weak Clay

The problems encountered at soft clay sites include the amplification of the ground motion as well as vigorous soil movement that can damage foundations. Several bridges suffered collapse during the 1989 Loma Prieta Earthquake due to the poor performance of weak clay.

Two parallel bridges were built in 1965 to carry Highway 1 over Struve Slough near Watsonville, CA. Each bridge was 800 ft long with spans ranging from 80 to 120 ft. The superstructures were continuous for several spans with transverse hinges located in spans 6, 11, and 17 on the right bridge and in spans 6, 11, and 16 on the left bridge (they are both 21-span structures). Each bent was composed of four 14-in.-diameter concrete piles extending above the ground into a cap beam acting as an end diaphragm for the superstructure. The surrounding soil was a very soft clay (Figure 18.24). The bridges were retrofit in 1984 by adding cable restrainers to tie the structure together at the transverse hinges.

During the earthquake the soft saturated soil in Struve Slough was violently shaken. The soil pushed against the piles, breaking their connection to the superstructure (Figure 18.25), and pushing them away from the cap beam so that they punctured the bridge deck (Figure 18.26). Investigators arriving at the bridge found shear damage at the top of the piles, indicating that the soil limited the point of fixity of the piles to near the surface. They also found long, oblong holes in the soil, indicating that the piles were dragged from their initial position during the earthquake. It was believed that the damage at Struve

FIGURE 18.14 Gravity retaining wall with shear damage from landslide.

Slough was the result of vertical acceleration, but the structure's vertical period of 0.20 s was too short to be excited by the ground motion at this site.

Similarly, The Cypress Street Viaduct collapsed only at those locations that were underlain by weak Bay mud. This was a very long, two-level structure with a cast-in-place, RC, box girder superstructure with spans of 68 to 90 ft. The substructure was multicolumn bents with many different configurations including some prestressed top bent caps. Most of the bents had pins (shear keys) at the top or bottom of the top columns and all the bents were pinned above the pile caps as well. There was a superstructure hinge at every third span on both superstructures. Design began on the Cypress Viaduct in 1949, and

FIGURE 18.15 Fabric retaining wall damaged during the 1999 Ji Ji, Taiwan, earthquake.

FIGURE 18.16 Section through eastern part of Turnagain Heights Slide. (Drawing courtesy of the National Academy of Sciences. National Research Council (U.S.) no. 1603, National Academy of Sciences, Washington, DC, 1968–1973, 8 v. in 10.)

construction was completed in 1957. The pins and hinges were used to simplify the analysis for this long, complicated structure. The northern two thirds of the Cypress Viaduct was on Bay Mud with 50-ft-long piles while the southern one third was on Merritt sand with 20-ft piles (Figure 18.27).

During the 1989 Loma Prieta Earthquake, the upper deck of the Cypress Viaduct collapsed from Bent 63 in the south all the way to Bent 112 in the north. Only Bents 96 and 97 remained standing. This collapse was the result of the weak pin connections at the base of the columns of the upper frame (Figure 18.28). There was inadequate confinement around the four #10 bars to restrain them during the earthquake. However, the soft Bay mud also played a role in the collapse. The southern portion of the bridge with the same vulnerable details but supported on sand remained standing (Figure 18.29). The northern portion was supported by soft Bay mud that was sensitive to the long-period motion and caused large movements that overstressed the pinned connections.

Buildings on weak clay also are susceptible to earthquake damage. Mexico City was located 350 km from the epicenter of the magnitude 8.1, 1985 Mexico Earthquake, but the city is underlain by an

FIGURE 18.17 Aerial view of Turnagain Slide. (Photograph courtesy of Steinbrugge Collection, Earthquake Engineering Research Center, University of California, Berkeley.)

FIGURE 18.18 About 75 homes were damaged as a result of the Turnagain Heights Slide. (Photograph courtesy of Steinbrugge Collection, Earthquake Engineering Research Center, University of California, Berkeley.)

old lakebed composed of soft silts and clays (Figure 18.30). This material was extremely sensitive to the long-period (about 2 s) ground motion coming from the distant but high-magnitude (8.1) source, as were the many medium-height (10 to 14 story) buildings that were damaged or had collapsed during the earthquake (Figure 18.31). Many much taller and shorter buildings were undamaged due to the difference in their fundamental period of vibration.

FIGURE 18.19 Collapse of Tsu Wei Bridge due to landslide during the Ji Ji, Taiwan, earthquake.

18.3 Damage as a Result of Structural Problems

18.3.1 Foundation Failure

Usually, it is the connection to the foundation or an adjacent member rather than the foundation itself that is damaged during a large earthquake. However, materials that cannot resist lateral forces, such as hollow masonry blocks, make a poor foundation and their use should be avoided (Figure 18.32).

Engineers will occasionally design foundations to rock during earthquakes as a way of dissipating energy and of reducing the demand on the structure. However, when the foundation is too small, it can become unstable and rock over. During the magnitude 7.6, 1999 Ji Ji, Taiwan, earthquake, a local

FIGURE 18.21 Damage to the Lower San Fernando Dam. (Photograph courtesy of Steinbrugge Collection, Earthquake Engineering Research Center, University of California, Berkeley.)

FIGURE 18.22 Closer view of damage to the Lower San Fernando Dam. (Photograph courtesy of Steinbrugge Collection, Earthquake Engineering Research Center, University of California, Berkeley.)

three-span bridge rocked over transversely due to small, drum-shaped footings that provided little lateral stability (Figure 18.33).

We have already seen pile damage as a result of weak clay on the Struve Slough bridges during the 1989 Loma Prieta Earthquake. Similar damage occurred during the 1964 Great Alaska Earthquake. After the 1971 San Fernando and 1995 Kobe Earthquakes, an inspection was made of bridge foundations, but only a little damage to the tops of piles was found. As long as the foundation is embedded in good material, it usually has ample strength and ductility to survive large earthquakes. Usually, it is the more vulnerable

FIGURE 18.23 Aerial view of Lower San Fernando Dam and San Fernando Valley. (Photograph courtesy of Steinbrugge Collection, Earthquake Engineering Research Center, University of California, Berkeley.)

FIGURE 18.24 Soil profile for Struve Slough bridges.

FIGURE 18.27 Geology of Cypress Freeway Viaduct site. (Housner et al., Report to the Governor George Deukmejian, State of California Office of General Services May 1990.)

elements above the foundation that can fail or become damaged during earthquakes. Still, as structures are designed to resist larger and larger earthquakes, we may begin to see more foundation damage.

18.3.2 Foundation Connections

The major cause of damage to electrical transformers, storage bins, and a variety of other structures and lifeline facilities during earthquakes is the lack of a secure connection to the foundation. Houses need to be anchored to the foundation with hold-downs connected to the stud walls and anchor bolts connected to the sill plates. Otherwise, the house will fall off its foundation as shown in Figure 18.34.

The connections to bridge foundations also need to be carefully designed. Route 210/5 Separation and Overhead was a seven-span RC box girder bridge with a hinge at Span 3 and seat-type abutments. The superstructure was 770 ft long on a 800-ft-radius curve. The piers were 4 ft by 6 ft single-column bents. Piers 2 and 3 were on piles, while Piers 4 to 7 were supported by 6-ft-diameter drilled shafts. This interchange was built on consolidated sand.

FIGURE 18.28 Damage to Cypress Street Viaduct.

FIGURE 18.29 Aerial view of Cypress Viaduct showing collapse where the structure crossed over Bay mud.

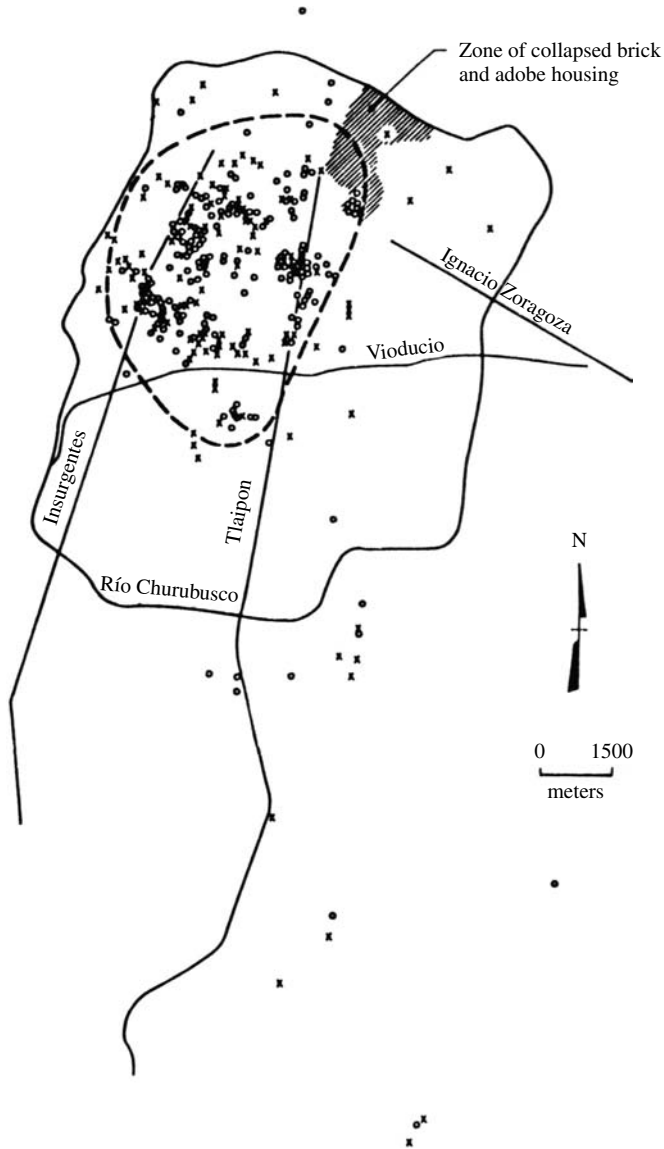

FIGURE 18.30 Locations of building damage at old lake bed in Mexico City (courtesy of EERI; EERI, *Earthquake Spectra*, 4, 3, 569–589, 1988).

During the 1971 San Fernando Earthquake, this structure collapsed onto its west (outer) side, breaking into several pieces and causing considerable damage to two lower-level bridges. A close examination of the fallen structure revealed that the collapse was due to pull-out of the column reinforcement from the foundations.

There was no top mat of reinforcement (and no ties) in the pile caps at Piers 2 and 3. The column longitudinal reinforcement (22 #18 bars) was placed in the footing with 12" 90° bends at the bottom of the reinforcement. Transverse reinforcement was #4 bars at 12 in. around the longitudinal reinforcement. During the earthquake, the longitudinal reinforcement did not have sufficient development length to transfer the force to the footings. Insufficient confinement reinforcement in the footings and

FIGURE 18.31 Damaged 10-story building between the Plaza de la Constitución and Zona Rosa in Mexico City. (Photo by Karl Steinbrugge, from the EERC NISEE Photo Library.)

FIGURE 18.32 Failed hollow concrete block foundation during the magnitude 6.0, 1987 Whittier, California, earthquake. (Photo by Karl Steinbrugge. Photo courtesy of Steinbrugge Collection, Earthquake Engineering Research Center, University of California, Berkeley.)

columns, and the lack of a top mat of reinforcement resulted in the rebar (and columns) pulling out of the footing (Figure 18.35). Piers 5 to 7 had straight #18 bars embedded 6 ft into pile shafts, and they also pulled cleanly out during the earthquake (Figure 18.36).

After the San Fernando Earthquake, the development length of large-diameter bars was increased, splices to longitudinal rebars were no longer allowed in the plastic hinge area, and more confinement steel was provided in footings and columns.

FIGURE 18.33 Three-span bridge rocked over during the 1999 Ji Ji, Taiwan, earthquake.

FIGURE 18.34 House that fell from its foundation during the 1971 San Fernando Earthquake. (Photograph courtesy of Steinbrugge Collection, Earthquake Engineering Research Center, University of California, Berkeley.)

18.3.3 Soft Story

During the 1989 Loma Prieta Earthquake, many houses and apartment buildings in the San Francisco area had severe damage on the ground floor. These structures had less lateral support on the ground floor to allow room for cars to park under the structure. The remaining supports could not support the movement of the upper stories and dropped the top stories onto the ground (Figure 18.37).

However, a soft story does not always occur on the bottom floor. During the 1995 Kobe, Japan, earthquake, many tall buildings had damage at the midstory, often due to designing the upper floors for a reduced seismic load.

FIGURE 18.35 Failure of column to pile shaft connection.

FIGURE 18.36 Failure of column to footing connection.

Most buildings in Japan are either built of RC or of steel and reinforced concrete (SRC). These SRC buildings, when correctly designed, provide a great deal of ductility and more fire protection during large earthquakes. However, the design practice in Japan was to discontinue either the RC or the SRC above a certain floor. [Figure 18.38](#) shows typical details used in SRC buildings.

[Figure 18.39](#) shows a ten-story SRC building where the third story collapsed during the 1995 Kobe Earthquake.

18.3.4 Torsional Moments

Curved, skewed, and eccentrically supported structures often experience a torsional moment during earthquakes.

FIGURE 18.37 Soft story collapse in San Francisco during the 1989 Loma Prieta Earthquake. (Photo courtesy of the USGS; The Loma Prieta, USGS, 1998.)

A nine-story building in Kobe, Japan, consisted of shear walls along three sides and a moment-resisting frame on the fourth (east) side (Figure 18.40). Shaking during the 1995 Kobe Earthquake caused a torsional moment in the building. The first-story columns on the east side failed in shear, the building leaned to the east (Figure 18.41), and it eventually collapsed (Figure 18.42).

Since rivers, railroad tracks, and other obstacles do not usually cross perpendicularly under bridge alignments, columns and abutments must be built on a skew to accommodate them. These skewed bridges are vulnerable to torsion.

The Gavin Canyon Undercrossing consisted of two bridges over 70 ft tall, with a 67° skew, and was composed of three frames. An integral abutment and a two-column bent supported each end-frame. The center frame was supported by two 2-column bents while supporting the cantilevered end-frames. The superstructure was RC box girders at the end-frames and posttensioned concrete box girders at the center-frame. Each column was a 6 ft by 10 ft rectangular section, fixed at the top and bottom, with a flare at the top. The bridges were retrofitted in 1974 with cable restrainer units at transverse in-span hinges with an 8-in. seat width that connected the frames.

During the 1994 Northridge Earthquake, the superstructures were unseated due to the following factors. The tall, center frame had a large, long-period motion that was out of phase with the stiff end-frames. The end-frame center of stiffness was near the abutment, while its mass was near the bent, causing the end-frame to twist about the abutment. The sharp skew allowed the acute corners to slide off the narrow seats. The cable restrainers, being among the first in the country, were grouted in the ducts, making them too brittle and prone to failure. Both bridges failed as shown in Figure 18.43.

Another interesting example of torsional damage occurred at the Ji Lu Bridge during the 1999 Ji Ji, Taiwan, earthquake. This is a cable-stayed bridge with a single tower and cast-in-place, 102-m-long, box girder spans sitting on two-column end bents that connect the structure to precast "I" girder approach spans (Figure 18.44). The tower is 58 m from the top of the deck to the top of the tower, and 20 m from the top of the footing to the soffit. All the foundations are supported on driven piles. Construction was almost completed on this bridge at the time of the earthquake. All of the cables had been tensioned and all but one had been permanently socketed into the tower. The false work had been pretty much removed except for a few final pours for the portion of the superstructure where it connects to the tower.

FIGURE 18.38 Examples of SRC construction. (Drawing courtesy of NIST; NIST, The January 17, 1995 Hyogoken (Kobe) Earthquake, U.S. NIST, Gaithersburg, MD, 1969.)

The dominant mode of shaking for this structure was twisting of the tower as the two cantilever spans moved back and forth. Looking at [Figure 18.45](#) we can see that the key at the end of the spans walked up and down the bent seat almost to the end of the support. T.Y. Lin engineers explained that this was because the final pour around the tower had not been completed, making this structure extremely flexible in this direction.

Similar damage occurred to the center piers of curved ramps to the Minatogawa Interchange during the Kobe Earthquake. In this case, the superstructure swung off its end supports and the center column suffered severe torsional damage ([Figure 18.46](#)).

As one member of a bridge goes into flexure it can create large torsional moments in adjacent members. For instance, flexure in the columns of outrigger bents causes large torsional moments in the bent cap ([Figure 18.47](#)). All of these examples reinforce the idea that most structures require consideration of all three translations and rotations.

18.3.5 Shear

Most building structures use shear walls or moment-resisting frames to resist lateral forces during earthquakes. Damage to these systems varies from minor cracks to complete collapse. [Figure 18.48](#) is a photo of the Mt. McKinley Apartments after the 1964 Great Alaska Earthquake. It was a 14-story RC building composed of narrow exterior shear walls and spandrel beams ([Figure 18.48](#)), as well as interior and exterior columns and a central tower. During the 1964 earthquake, this structure suffered major structural damage to most of the load bearing members.

The most serious damage was to a shear wall on the north side of the building ([Figure 18.49](#)). A very wide shear crack split the wall in two directly under a horizontal beam. This crack was because there was not enough transverse reinforcement to hold the wall together as it moved transversely and also due to a cold joint in the concrete at that location. The spandrel beams between the walls had large “X” cracks

FIGURE 18.46 Column damage to the Minatogawa interchange during the Kobe Earthquake.

FIGURE 18.47 Column flexure causing torsion in the bent cap.

associated with shear damage as the building moved back and forth. These cracks decreased in size on the upper floors.

There was also shear damage to many of the columns. [Figure 18.50](#) is one of the exterior columns on the south side of the building with a diagonal shear crack. Again, the problem was insufficient transverse reinforcement to resist the large shear forces that occurred during the earthquake. The central tower was also damaged. However, the Mt. McKinley Apartment can be viewed as a success since there was no collapse and no lives lost during this extremely large earthquake.

Bridges are equally susceptible to shear damage. For instance, there was considerable shear damage to piers on elevated Route 3 during the Kobe Earthquake. The superstructure is mostly steel girders and the substructure is RC single-column bents. Between Piers 148 and 150, the superstructure is a three-span, continuous, double-steel box with span lengths of 45 m, 75 m (between Piers 149 and 150), and 45 m. Pier 149 is a 10-m-tall by 3.5-m square RC single-column bent supported on a 12-m square pile cap.

FIGURE 18.49 Damage to north side of Mt. McKinley Apartments. (Photograph by Karl Steinbrugge, Earthquake Engineering Research Center, University of California, Berkeley.)

Pier 150 is a 9.1-m-tall by 3.5-m square RC single-column bent supported on a 14.5-m by 12-m rectangular pile cap.

Figure 18.51 shows the shear failure at Pier 150. This damage was the result of insufficient transverse reinforcement and poor details. During the large initial jolt (amplified by near-field directivity effects) the transverse reinforcement came apart and resulted in the column failing in shear. Pier 149 was also severely damaged, but because it was taller (and more flexible), most of the force went to stiff Pier 150. The three-span continuous superstructure survived the collapse of Pier 150 with minor damage.

FIGURE 18.50 Damage to the south side of Mt. McKinley Apartments. (Photograph by Karl Steinbrugge, Earthquake Engineering Research Center, University of California, Berkeley.)

FIGURE 18.51 Shear failure of Pier 150 on Kobe Route 3.

18.3.6 Flexural Failure

Flexural members are often designed to form plastic hinges during large earthquakes. A plastic hinge allows a member to yield and deform while continuing to support its load. However, when there is insufficient confinement for RC members (and insufficient b/t ratios for SRC members), a flexural failure will occur instead. Often, flexural damage is accompanied by compression or shear damage as the capacity of the damaged area has been lowered.

The Dakkai subway station in Japan is a two-story underground RC structure. It was constructed by removing the ground, building the structure, and then covering it (the-cut-and-cover method). During the 1995 Kobe Earthquake, the center columns on both levels suffered a combination of flexural and compression damage that caused both roofs to collapse along with a roadway that ran above the station (Figure 18.52). Figure 18.53 shows the rather slender center columns at the lower level after the earthquake. The columns had insufficient transverse reinforcement at the location of maximum moment. The transverse reinforcement broke as the columns were displaced, allowing the longitudinal reinforcement to buckle and the concrete to fall out of the column.

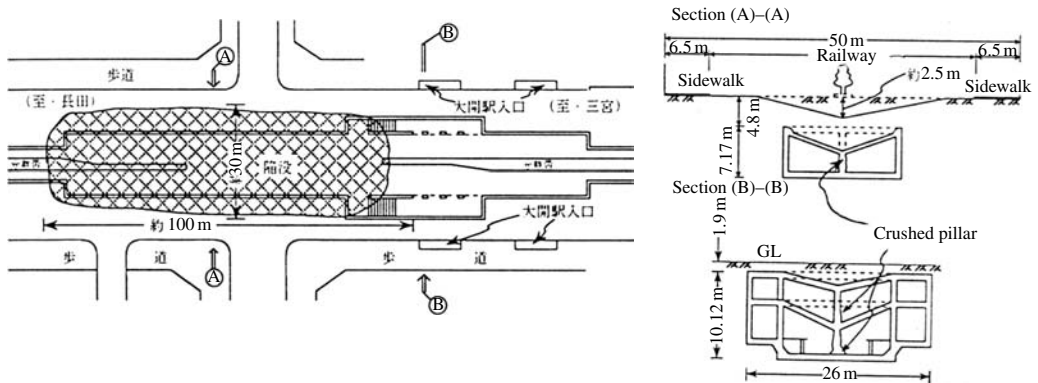

FIGURE 18.52 Plan and section drawings of the Dakkai subway station after the Kobe Earthquake. (Drawing courtesy of JSCE, JSCE, Preliminary report on the Great Hanshin Earthquake, January 17, 1995, JSCE, 1995.)

FIGURE 18.53 Flexural damage to columns at lower level of Dakkai subway during the 1995 Kobe Earthquake. (Photo courtesy of JSCE, JSCE, Preliminary report on the Great Hanshin earthquake, January 17, 1995, JSCE, 1995.)

Steel columns experience similar damage when the flexural demand exceeds the capacity. In downtown Kobe, in the Nagata District, Route 3 splits into two parallel structures with the superstructure composed of 50-m-long simple spans with steel girders and a three-span, continuous, steel box girder section between Piers 585 and 588. The substructure consists of 2.2-m-diameter, 14-m-tall steel hammerhead single columns. The steel columns are bolted onto 4-m-diameter hollow, concrete 20-m-long shafts. The column bottoms are filled with concrete to protect against vehicular impact. During the Kobe Earthquake, these steel columns had damage varying from local buckles to a complete section buckle, and at a few locations, the steel shell had torn, splitting the column. Most of the buckling occurred in a thinner section of the column. In some cases (Figure 18.54), the column underwent an excursion in only one direction and consequently had a buckle on one side of the column.

In some cases the buckled face tore in the tension cycle (Figure 18.55). The tears occurred in low-ductility welds. After the earthquake, the columns were tilting dangerously to the side. Buckling occurred before a plastic hinge was formed. A few columns remained undamaged as a result of failed bearings. Although local buckling cannot be completely eliminated, its spread can be prevented by maintaining smaller b/t ratios. This is accomplished with thicker sections, more frequent stiffeners, and diaphragms, or by filling the steel shells with lightweight concrete.

18.3.7 Connection Problems

The most catastrophic type of structural damage is the failure of connections. When a bridge superstructure moves off its expansion joint or when the connection between building columns and beams fail, the result is too often the collapse of the structure.

Between Piers 39 and 43 on Kobe Route 3, the superstructure was a series of 52-m-long simple-span steel boxes supporting a concrete deck. Steel web plate restrainers with oversized holes at one end connected the girders together over each pier support. Fixed pin bearings and movable roller bearings supported each span. The substructure was hammerhead piers with 3.5-m-diameter circular or 3.5-m square concrete columns over 10 m in height. Each column was supported on a rectangular footing supported by 18- to 1.0-m-diameter by 16.5-m-long piles.

During the earthquake, the piers moved back and forth longitudinally, sustaining cracks or shear damage at the column bases. At the same time, the girder spans were moving west (toward Pier 43) as a result of the impact with the five-span, continuous, steel girder bridge east of Pier 38. The relative displacement between the piers and the simple spans exceeded the 0.8-m seat width at Piers 40 and 41 and the expansion end of Spans 40 and 41 fell off the piers (Figure 18.56). Most of the web plate restrainers failed in tension (Figure 18.57) and almost all of the fixed and expansion bearings were damaged, mostly due to the top shoe pulling out of the bearing (Figure 18.58).

RC structures must be carefully designed to allow the shear transfer at joints. A common kind of residence in Turkey was four- to eight-story buildings composed of concrete columns supporting concrete slabs and infill walls of unreinforced masonry blocks. During the 1999 Kocaeli Earthquake, these buildings collapsed at very low levels of acceleration, killing thousands of people. The large inertia force from these heavy structures had to be carried by the slender columns and by the inadequately reinforced connections (Figure 18.59). Sufficient concrete and reinforcement must be provided to resist the large tension and compression forces in moment-resisting joints during earthquakes. Joints of moment-resisting RC frames should be stronger than the elements that join them.

The connections of steel moment-resisting frames, with detailing recommended by design codes prior to 1994, suffered considerable damage during the Northridge (and Kobe) Earthquakes. During the Northridge Earthquake, over 100 steel moment-resisting frame buildings had some damage to the

FIGURE 18.56 Superstructure collapse at Spans 40 and 41 on Kobe Route 3.

FIGURE 18.57 Broken restrainer at Pier 39. (Photo courtesy of Hanshin Expressway Public Corporation.)

column to beam connections. As previously mentioned, flexural elements are supposed to form plastic hinges during large earthquakes. However, during the Northridge Earthquake the connection fractured instead. In this connection the beam flanges are welded to the column with a column flange stiffener placed along the column web to provide continuity to the joint. The beam web is bolted to the column with a shear connection plate. As shown in Figure 18.60, a large crack fractured the flange and web of some columns. Although this damage was unexpected and looked serious, no building during the Northridge Earthquake was reported to have collapsed as a result of the failure of this connection. Still, a few more cycles of motion (from a much larger earthquake than the magnitude 6.7 event) could easily

FIGURE 18.58 Broken bearings at Pier 40. (Photo courtesy of Hanshin Expressway Public Corporation.)

FIGURE 18.59 Collapsed reinforced concrete building during the 1999 Kocaeli Earthquake.

tear apart this fractured column. Consequently, new connection details have been developed as well as retrofit details for the many buildings with this connection.

18.3.8 Problem Structures

Some types of structures have performed particularly poorly during previous earthquakes. Usually, this is the result of vulnerabilities such as weak connections, improper detailing, and eccentric loads that predispose these structures to severe damage and collapse during earthquakes.

Unreinforced masonry should never be used to resist lateral forces since it is very weak in tension and very heavy, resulting in walls that immediately fall over, seriously injuring anyone nearby (Figure 18.61). However, reinforced masonry walls have performed very well when thoughtfully designed.

FIGURE 18.60 Steel moment-resisting frame connection after the 1994 Northridge Earthquake. (Photo courtesy of EQE International; EQE, *EQE Int. Rev.*, Fall, 1–6, 1994.)

FIGURE 18.61 Rear view of damaged unreinforced masonry (URM) building facing Pacific Garden Mall, Santa Cruz Area, California. (Photo by James R. Blacklock, Loma Prieta Collection, Earthquake Engineering Research Center, University of California, Berkeley.)

Tilt-up buildings have also performed poorly during past earthquakes because the walls pull away from the roof diaphragm, because of the discontinuity at the vertical joints between panels, because of poor connections to the roof joists, etc. Similarly, precast prestressed bridges tend to fall apart due to inadequate connections between members.

Tanks, bins, silos, grain elevators, concrete mix plants, etc. are the most commonly damaged structures during earthquakes. They are tall, heavy, and too often designed with weak supports and inadequate anchors (Figure 18.62).

Construction sites are particularly dangerous places to be on during an earthquake. Too often, little thought is given to providing lateral strength to partially constructed structures. This can result in millions of dollars in damage as well as fatalities. For instance a new expressway was being built during the 1999 Ji Ji, Taiwan, earthquake. This included two simple-span, precast, and prestressed “I” girder bridges on two-column bents near the epicenter. The girders were 84 in. tall by 24 in. wide and sat on

FIGURE 18.62 California Water Service 150,000-gal tank on six legs; the typical failure of tanks is upside down, with riser on top (Bakersfield, California, photo by Karl V. Steinbrugge, Steinbrugge Collection, slide/image No. S64, photo date July 25, 1952, Kern County, California, earthquake, July 21, 1952, magnitude 7.69; courtesy of Steinbrugge Collection, Earthquake Engineering Research Center, University of California, Berkeley).

FIGURE 18.63 Collapsed precast, prestressed “I” girders during construction of new expressway in Taiwan due to the 1999 Ji Ji, Taiwan, earthquake.

24 in. by 16 in. by 5 in.-tall elastomeric pads. The bents were at least 30 ft tall from the ground to the top of the bent caps. The bridge had 13 approximately 150-ft-long spans. At the time of the earthquake, the girders had been placed on the bents and the seat-type abutments, and the intermediate and end-diaphragms were just beginning to be cast between the girders. Wherever the intermediate diaphragms had not been placed, the girders had been shaken off of their supports and had fallen to the ground, breaking into pieces (Figure 18.63). This resulted in the loss of about 100 girders. The use of temporary supports before the casting of diaphragms could have saved about a million dollars.

All of these structures can be designed to perform adequately when they are provided with sufficient strength and ductility and a good understanding of their structural behavior during earthquakes.

18.4 Secondary Causes of Structural Damage

18.4.1 Surface Faulting

Few structures are designed to accommodate an offset of several meters laterally or vertically at any location. Yet, that is what is required near active faults. When the fault reaches the surface, the ground can be pushed together, pulled apart, raised, or dropped 5, 6, and even 10 m. Some of the most spectacular structural damage from faulting occurred during the 1999 Ji Ji, Taiwan, earthquake. The Shih Kang Dam was one of several structures across the ill-fated Dajia River north of Route 3 (Figure 18.64). During the earthquake, the north end of the dam dropped 9 m (Figure 18.65).

The Dajia River Bridge was a 14-span, RC bridge with a “T” girder superstructure, single-column bents with hammerhead bent caps, and drum-shaped footings. The girders sat on elastomeric pads and between transverse shear keys. It was one of several bridges a little north of Route 3 across the Dajia River near the town of Shargang (Figure 18.64).

This bridge had spans 30 m long by 10 m wide and columns about 10 m in height at the center of the bridge. During the earthquake, the first three southerly spans collapsed along with Pier 3 (Figure 18.66). The south abutment and first two piers moved 6.5 m vertically and 3 m to the west. The column

FIGURE 18.64 Location map of damaged structures along the Dajia river after the 1999 Ji Ji, Taiwan, earthquake.

FIGURE 18.65 North end of Shih Kang Dam after the Ji Ji, Taiwan, earthquake.

FIGURE 18.66 Elevation drawing of Dajia Bridge collapse.

FIGURE 18.67 The Dajia River bridge and 6-m fault scarp.

foundation rotated out of ground. The bridge collapse was due to a 6-m fault scarp that created a waterfall alongside the bridge (Figure 18.67).

18.4.2 Damage Caused by Nearby Structures and Lifelines

Weak or poorly designed facilities will often cause damage to nearby structures during earthquakes. The intelligent planning of adjacent lifelines (called colocation) is a good way to minimize disruptions to lifelines during earthquakes and other disasters.

When buildings, bridges, and other structures are built too closely together, one problem is pounding. This is particularly a problem for connectors on highway interchanges that are sometimes in such close proximity that the column of a higher structure will go through the lower bridge deck. Buildings are often built too closely together causing pounding and moderate structural damage during earthquakes. Pounding can cause serious damage since impact loads of very short duration can carry a very large force. However, pounding may also be beneficial when it prevents resonance.

More serious damage occurs when a poorly designed structure collapses onto an otherwise seismically resistant structure. There are no benefits from this interaction.

Piers 352 and 353 on the Route 3 Expressway in Kobe, Japan, supported the superstructure on steel hammerhead piers. The columns were 2 m by 1.5 m by 8.8 m in height, supported on pile foundations, and built using the 1964 specifications. The piers were 8.8 m tall and on pile foundations. The superstructure consisted of 30-m-long, steel simply supported plate girders, one end fixed and the other end on elastomeric expansion bearings. During the 1995 Kobe Earthquake, the bridge was damaged when a collapsing building fell against the expressway. The building (shown in Figure 18.68) applied a lateral load to the superstructure. This resulted in buckling of the vertical stiffeners on the girder webs, bearing damage, and also some damage to the bottom of Pier 353. The main damage was separation of a metal plate that was installed to protect the steel column from traffic collisions. However, because there was a collapsed building leaning against the bridge, it was felt to be expedient to provide shoring to the piers after the earthquake. The ability of the superstructure to move laterally over the piers helped to prevent more serious damage from occurring to the substructure.

FIGURE 18.68 Collapsed building leaning against the Kobe Route 3 Expressway. (Photo courtesy of Hanshin Expressway Public Corporation.)

FIGURE 18.69 Washed-out abutment fill caused by water pipe break.

A lifeline can often cause problems to other nearby lifelines during earthquakes. The Balboa Boulevard Overcrossing is a three-span (actually two spans with a 22-ft-long bin-type abutment between Abutment 1 and Bent 2) cast-in-place prestressed concrete bridge (except for a concrete slab for the bin-type abutment) on Highway 118 near Northridge, CA. The superstructure is 283 ft long and 117 ft wide. Bent 3 is a three-column bent on a spread footing. The columns are 5-ft octagonal sections with a large flare. The abutments and wingwalls are on piles. During the 1994 Northridge Earthquake the Balboa Boulevard Overcrossing experienced minor spalling of the concrete cover at the top of the columns during the earthquake. The shaking broke a small-diameter water line under Abutment 1 that washed out the backfill behind the abutment. Figure 18.69 shows the collapsed slab for the bin-type abutment and the cast-in-drilled-hole (CIDH) pile supporting Abutment 1. The grade beam that supports the wingwall is on the left.

These are just a few of the many secondary causes of damage during large earthquakes. What typifies this kind of damage is that its prevention may not rely on structural issues. In fact, the best solution is to find a better site during the planning of the structure. There is little the engineer can do once the structure straddles an active fault or is within a few feet of a vulnerable structure.

18.5 Recent Improvements in Earthquake Performance

Much of the damage that has occurred during recent earthquakes was the result of the failure of the surrounding soil or structural elements. Not surprisingly, most of the recent improvements to the earthquake resistance of structures have focused on methods of improving poor soil, on soil–structure interaction, and on structural elements and systems that increase strength, stability, ductility, etc.

There has also been some work to prevent secondary earthquake damage. For instance, California has begun to retrofit bridges that cross over active faults. On the Colton Interchange, a bridge was provided with additional supports to catch the superstructure if it is pulled off its piers. Another California bridge was provided with large galleries at the abutments to accommodate large movements. A couple of bridges have even been provided with gates that close the bridge when the ground begins to shake.

Some effort has also been made to improve lifeline performance, most notably in Wellington, New Zealand, where facilities are carefully planned and located to prevent disruptions in service during large earthquakes.

18.5.1 Soil Remediation Procedures

Because much of Japan is covered with either weak clay or saturated, loosely consolidated material, the development of soil remediation procedures has flourished in that country. After the 1994 Kobe Earthquake researchers did a careful study of soil-remediation sites and found that these locations performed much better than the surrounding area [10].

The following are a few examples of soil improvement methods commonly used in Japan.

18.5.1.1 Gravel Drains: Ariake Quay-Wall Improvement Project

Ariake is a man-made island in Tokyo Bay. The weak material of the island is supported by a quay-wall made of timber piles and steel sheet piles. The goal of this project was to protect the quay-wall from damage during an earthquake (Figure 18.70). The wharf is composed of loose sand that could liquefy during an earthquake. Increased pore water pressure would then push over the quay-wall. Gravel drains were installed to reduce pore water pressure during an earthquake. The advantage of this method is that it is quick, inexpensive, and free of vibration. The disadvantage is that it does not prevent settlement of

FIGURE 18.70 Gravel drain construction. (Drawing courtesy of Japan's Public Works Research Institute.)

the soil during an earthquake. Since the goal is protection of the quay-wall, this is not considered a problem. The procedure is to drill a hole in the ground using a casing auger. Gravel is carried to the auger by a front-end loader. It is dropped into a hopper, lifted to the top of the auger, and poured into the casing. The casing is then removed from the ground leaving a sand drain. The gravel is fairly uniform. The casing has replaceable steel teeth to help it cut through soil and push away rocks. The gravel drains are placed close enough together to form a grid that will effectively drain out all the water. This project consisted of 3997 gravel drain piles in an area of 2770 m² for 1.4 piles/m² (the drains are 0.8 m apart). The drains are 0.5 m in diameter and 17 m long and cost about 50,000 Yen (\$500) per pile or about 200 million Yen for the project. It takes less than an hour to make a gravel drain and there were four augers at the job site.

18.5.1.2 Deep Mixing Method: Kawaguchi City

The area along the Arakawa River has poorly consolidated soil. This project used deep soil mixing to improve the unconfined compressive strength of the ground (Figure 18.71). Without the DMM the soil would be expected to settle 1.5 m after the embankment is placed. With the DMM the settlement should be less than 0.03 m.

On this project, a modified pile-driving machine rotates a pair of rods with stirring wings for mixing the soil. The distance between piles can be changed by moving the rods closer together or further apart. The pile diameter is 1 m on this project. First, the machine pushes the stirring wings down 30 m,

FIGURE 18.71 Soil deep mixing construction. (Drawing courtesy of Japan’s Public Works Research Institute.)

breaking up the soil and making it soft and permeable. The wings rotate 20 cycles per minute as they descend into the soil. Then, the stirring wings are pulled up while injecting cement milk into the soil. The milk is composed of an equal weight of cement and water. About 100 to 150 kg of cement milk is injected per cubic yard of soil. The wings rotate at 40 cycles per minute as they ascend. Loose soil comes up during this procedure and is removed with an excavator. The stirring wings descend and ascend at 1 m/min. There is a cement plant for each machine and a separate pump for each rod. The cement milk flows through flexible hoses from the cement plant to the top of the rods where it is injected into the soil. When the piles are completed the machine crawls to the next location on a plywood mat and drills another pile. Display panels in the machine cab give information about depth, rotation, and the amount of cement milk being pumped.

The deep mixing method is also very effective in preventing soil liquefaction. In fact, this method was used to prevent liquefaction for some flood prevention works next to this site. In this case the piles are placed in a lattice pattern to contain the liquefiable soil.

The deep mixing method was found to be the most effective method for creating strong, highly ductile ground that does not liquefy or settle. It is also the most expensive method, but the lack of noise and vibration makes it ideal for city environments.

18.5.1.3 Sand Compaction Pile Method: Ohgishima Island, Tokyo

Sand compaction piles are a popular way of preventing liquefaction of loose alluvium. However, the noise and vibration make it unacceptable at some locations.

This project was on a man-made island in Tokyo Bay (Figure 18.72). It is the location of an LNG tank farm. Soil remediation was required at the toe of an embankment that covers these tanks.

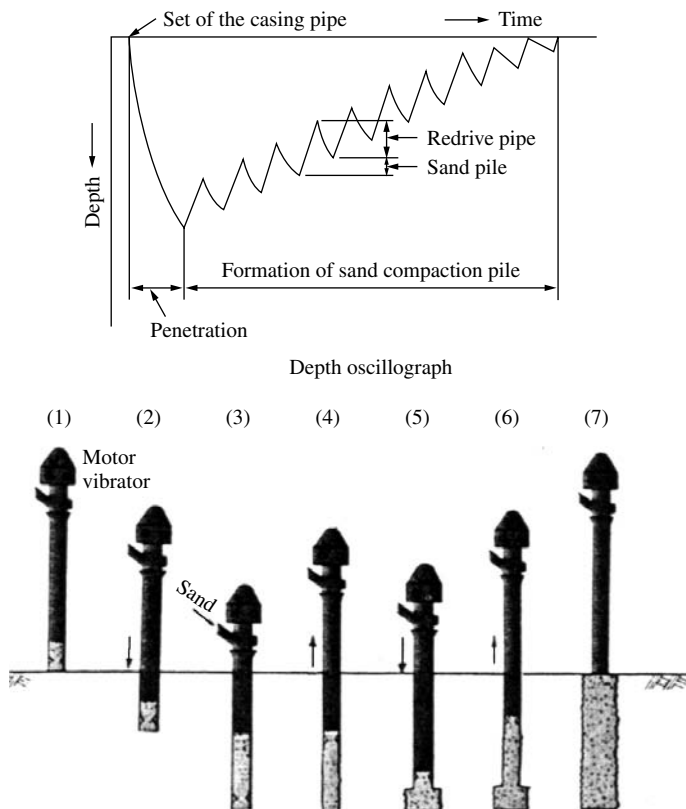

FIGURE 18.72 Sand compaction pile method. (Drawing courtesy of Japan's Public Works Research Institute.)

Because it was a remote site, the loud noise and vibrations were not a problem. The sand compaction pile method uses a modified pile-driving machine to vibrate a steel pipe into the ground. When the penetration reaches the proper depth, sand is carried to the top by a hopper and forced to the bottom of the pipe with compressed air. Then, the pipe is raised and lowered in the hole as sand is repeatedly shot to the bottom of the hole. The result is a pile of compacted sand and an area between the piles of compacted soil. The equipment is similar to the gravel drain method. The pile driver has a steel casing with a lid that can be opened and closed at the bottom. Sand is brought in by dump truck to the site. A front-end loader pours the sand into the hopper. The hopper carries the sand to the top of the pipe where it is poured into the air compression chamber. The steel casing with the lid closed is vibrated to the required depth. In this project the depth was 17 m and the pile diameter was 0.7 m. When the pile is completed, the panels the truck sits on are moved back and the pile driver is moved back to drive a new pile. The pile is driven at about 2 min/m and a pile is completed in about 30 min. Before this project began, the soil had an average N value of 10 to 12. The areas that have been completed now have an N value of 15 to 20.

18.5.2 Improving Slope Stability and Preventing Landslides

The failure of many retaining walls during the 1999 Ji Ji, Taiwan, earthquake was surprising. Well-designed cantilever and MSE walls have performed well during recent earthquakes. For instance, there was an MSE wall that continued supporting the embankment adjacent to the Arifiye Bridge that collapsed during the 1999 Kocaeli, Turkey, earthquake (Figure 18.73). A cribwall in the Santa Cruz Mountains was severely distressed during the 1989 Loma Prieta Earthquake but continued to support the steeply sloping ground (Figure 18.74). There is no record of a cantilever retaining wall failure during a California Earthquake. Therefore, well-designed retaining walls continue to be a good method for supporting most soils.

Other methods of preventing soil movement include planting trees and other vegetation, the use of geotextiles, installing piles, etc. The foundations of structures may also be strengthened to prevent their movement. Many of the methods used for preventing liquefaction can also be used to stabilize soils. However, when an area has a long history of landslides, it may be more prudent to build elsewhere.

FIGURE 18.73 Mechanically stabilized earth wall continues to support the embankment behind the collapsed Arifiye Overcrossing after the 1999 Kocaeli, Turkey, earthquake.

18.5.3 Soil–Structure Interaction to Improve Earthquake Response

Soil–structure interaction modifies the ground-input motion at the foundation. By taking advantage of soil–structure interaction, structures can be protected during earthquakes. Frank Lloyd Wright’s 1915 Imperial Tokyo Hotel survived the 1923 Great Kanto Earthquake because he built his foundation in 70 ft of weak clay. During the earthquake, the ground underneath moved violently while his hotel (effectively isolated by this plastic material) remained relatively immobile.

Similarly, a common retrofit technique for bridges is to allow the foundation to rock during large earthquakes. As the foundation rocks, the period is lengthened and damping is increased, all of which lowers the demand on the structure. To insure stability, the foundation may be connected to flexible anchors or an outer perimeter of piles may be placed under (but not connected to) a widened foundation. The piles will provide support for the foundation as it rocks back and forth.

Special foundations are sometimes used to improve seismic response. For instance, a popular bridge foundation in California is the large-diameter drilled pile shaft. These foundations are very flexible, replacing potentially damaging seismic forces with large displacements. Moreover, when the pile shaft is allowed to yield, a large plastic hinge forms, which provides more ductility for the structure.

In contrast to California’s efforts to provide more flexibility and ductility in its foundations, Japan has been developing stiffer and more massive foundations for bridges and other structures. Besides the advantage of handling very large forces elastically, many of these new foundations use advanced automation techniques to simplify their construction. *The open caisson construction method* pushes a precast hollow cylindrical caisson into the ground while excavating the ground beneath with a grab bucket. Additional sections are attached to the top until it bears on good material. The caisson segments can be constructed up to 4 m in diameter and are match-cast for a tight fit. After they are completely assembled,

FIGURE 18.75 Precast caissons were used for the Chiba City, Japan, monorail. (Drawing Courtesy of Japan's Public Works Research Institute.)

they are filled with soil, and a steel assembly is attached to mount the substructure. This method was used for the Chiba City Monorail System. The open caisson construction method allowed them to build large caissons often within a few feet of an existing building (Figure 18.75).

Another innovative foundation in Japan is the *continuous diaphragm wall*. This method involves excavating wall-type ditches and casting wall elements in them (Figure 18.76). These walls are connected together with joint elements. Then, an upper slab connects the top of the walls to the pier. The walls typically vary in thickness from 1 to 2.8 m. Continuous diaphragm walls come in a variety of shapes. Circles, rectangles, and grids are all very common. These are used for deep, stiff foundations as well as enormous shafts and storage tanks.

18.5.4 Structural Elements that Prevent Damage and Improve Dynamic Response

Improved structural performance during large earthquakes depends on a balanced structural system. Elements that share the same displacement during large earthquakes must be designed to have about the same stiffness. Otherwise, the stiffer elements will be forced to resist most of the earthquake force. Elements that share the same force are often provided with a fuse to limit the force and protect adjacent members.

Providing great strength to resist earthquakes is usually self-defeating. As the elements are made stronger, they attract larger earthquake forces. If an element along the load path cannot resist these forces, it will break, sometimes with disastrous consequences. Elements like shear walls are often used to limit displacements in buildings, but they are nonductile and will often shatter when unexpectedly large earthquakes occur.

FIGURE 18.76 Construction sequence for diaphragm foundations. (Drawing courtesy of Japan’s Public Works Research Institute.)

FIGURE 18.77 Construction of the new San Francisco Airport International Terminal. (Photo courtesy of Earthquake Protection Systems Inc.)

The use of isolation and damping devices has gained popularity because they can protect a structure during several large earthquakes without suffering damage or requiring replacement. Moreover, these devices have proven to be effective for new construction as well as for retrofitting vulnerable existing structures.

The new San Francisco Airport International Terminal is a large steel frame building with a truss roof (Figure 18.77). It is the largest base-isolated building in the world. To ensure that it would remain in service after a very large (magnitude 8) earthquake, 267 friction pendulum seismic isolation bearings were placed between the steel columns and the foundations (Figure 18.78 and Figure 18.79). Each bearing can move 20 in. while supporting 6000 kip. The bearings increased the building’s fundamental period to 3 s and reduced the earthquake force by 70%.

These interesting devices are surprisingly simple in principle. For service level loads, static friction restrains the system. During an earthquake, the system operates like a pendulum (Figure 18.80) with the amount of damping controlled by dynamic friction and with the period

FIGURE 18.78 Layout of foundations and friction pendulum devices for the new San Francisco Airport International Terminal. (Photo courtesy of Earthquake Protection Systems Inc.)

FIGURE 18.79 One of the 267 friction pendulum devices for the new San Francisco Airport International Terminal. (Photo courtesy of Earthquake Protection Systems Inc.)

and stiffness as shown below (where R is the radius, W is the weight, and g is the acceleration due to gravity).

$$T = 2\pi\sqrt{\frac{R}{g}} \tag{18.3}$$

$$K = \frac{W}{R} \tag{18.4}$$

The period of the structure is increased by flattening the bearing’s concave surface and the force–displacement relationship is modified by changing the friction or the dead load. Similarly, the design of the pyramid-shaped “Money Store” in West Sacramento ([Figure 18.81](#)) included fluid viscous dampers (FVD) to absorb energy and allow the steel moment-resisting frame to remain elastic during large

FIGURE 18.80 The structure's period is controlled by the radius of the curved bearing. (Drawing courtesy of Earthquake Protection Systems Inc. Zayas et al., The FPS earthquake resisting system, University of California, Berkeley, CA, 1987.)

FIGURE 18.81 The uniquely shaped "Money Store" was designed with fluid viscous dampers to improve its seismic behavior. (Photo courtesy of Marr-Shaffer & Miyamoto, Structural Engineers.)

earthquakes. The FVDs are cylinders filled with liquid silicon. When a load is applied, a piston pushes through the viscous fluid in the cylinder, absorbing energy (Figure 18.82). Concentrically braced frames were built with FVDs between the diagonal braces and the columns to increase the damping ratio of the building to 15% and reduce the story drift ratio to 0.005 (Figure 18.83).

FIGURE 18.82 Schematic drawing of a fluid viscous damper. (Drawing courtesy of Taylor Devices Inc.)

FIGURE 18.83 The steel frames included fluid viscous dampers to reduce the story drift. (Photo courtesy of Marr-Shaffer & Miyamoto, Structural Engineers.)

Isolation and damping devices are equally adept at providing protection for seismically vulnerable existing buildings. The Long Beach VA Hospital is a concrete shear-wall structure that was found to be vulnerable to large earthquakes (Figure 18.84). Many retrofit strategies were studied before isolation was finally accepted as the best way to keep the hospital functioning after a large earthquake on the nearby Pales Verdes and San Andreas Faults. Because the hospital also had to remain in service during construction, the sequence of the construction was crucial and the contractor had to be responsive to any problems that developed that could impact the daily operations of the hospital. Most challenging was completely isolating the structure. A moat had to be dug around the building and flexible connections had to be designed for all the utility lines as they entered the building.

Lead-rubber bearings were installed a few feet above the base of all 150 concrete columns that supported the building (Figure 18.85). Each bearing was 22 in. tall and 24 in. in diameter. First, friction gripping devices were used to transfer the load from the column onto hydraulic jacks. Then, a 20-ft section of the column was replaced with a lead-rubber isolation bearing. These bearings have a lead core that provides an initial high stiffness for service loads. During large earthquakes the lead core yields, providing damping for the structure. The bearings used on the Long Beach VA Hospital will allow the ground to move 16 in. without impacting the building.

Isolation and damping devices can also be used on other structures. The All American Canal Bridge in California is one of the many bridges that uses lead-rubber bearings to isolate the superstructure from earthquake ground motions (Figure 18.86).

The Vincent Thomas Suspension Bridge (a mile from the Long Beach VA Hospital) was retrofit with 80 FVDs to absorb energy and prevent the bridge deck from pounding against the towers and cable bents (Figure 18.87). The connection between the towers and the truss was modified to allow very large relative movements. The truss section on each side of the towers was replaced with a new unit that includes a deck section with 26-ft-long finger joints and large viscous dampers to absorb energy and prevent the truss from pounding against the towers (Figure 18.88).

In general, isolation and damping devices have performed very well during large earthquakes. However, isolated structures have usually been too far away to experience really large accelerations. The one occurrence where isolation and damping devices were very close to a fault rupture was on the Bolu

FIGURE 18.84 The existing Long Beach VA Hospital was seismically retrofit with lead-rubber bearings. (Photo courtesy of Dynamic Isolation Systems, Inc.)

FIGURE 18.85 The concrete columns were cut at midheight and lead-rubber isolation devices were installed. (Photo courtesy of Dynamic Isolation Systems Inc.)

Viaduct during the 1999 Duzce Earthquake. However, in this installation the bearings were eccentric to the dampers, resulting in out-of-plane motions that locked up the dampers and caused significant damage to the bridge. It will probably take several earthquakes to work out all the bugs and come up with installations that work most effectively. Because of the increased use of isolation and damping devices on structures in highly seismic areas, there should be many more opportunities to study their behavior.

When isolation and damping devices are not used, a sacrificial element will often limit the force and increase the damping in a structure. New RC beams and columns are provided with welded hoops and spirals that allow these members to form plastic hinges during large earthquakes. Existing concrete members are sometimes wrapped in steel casings, fiberglass, carbon fiber, and many other materials to increase their shear capacity and allow for the formation of a plastic hinge (Figure 18.89).

Steel structures have undergone similar improvements. Beginning in the late 1970s *eccentrically braced frames* (EBFs) were developed that provide greater stiffness and ductility during earthquakes. The EBF has a ductile link between the connections that is specially designed to act as an energy dissipater. This concept has been expanded to include a variety of different configurations (Figure 18.90).

The poor performance at the connections of moment-resisting frames during the Northridge and Kobe Earthquakes has resulted in a great deal of research and testing. There are now a variety of welded beam–column joints that ensure ductile behavior in the members rather than brittle fracture of the joint. One popular new connection is the “dog bone” (Figure 18.91). Testing has shown that plastic hinging will occur at the reduced section, protecting the connection.

There are a number of other devices and structural elements that improve structural response during large earthquakes. Restrainers, shear keys, catchers, and seat extenders are used to prevent bridge superstructures from falling from their supports. A variety of materials are wrapped around weak columns to increase their ductility. However, isolation and damping devices show the greatest potential

FIGURE 18.89 Steel shell being wrapped around a concrete bridge column to increase its ductility and shear strength.

FIGURE 18.90 Two of the many configurations that have been developed for eccentrically braced connections.

to control the amount of damage on a structure, particularly when the goal is to keep the structure in service after a very large earthquake.

By ensuring that the supporting soil remains undamaged, by avoiding sites near active faults or other secondary hazards, and by the effective use of isolation and damping devices, most serious earthquake damage can be avoided. However, every structure should also be provided with abundant ductility and

FIGURE 18.91 Examples of beams in moment-resisting frames that use a reduced flange section to prevent fracturing of the connection.

large seats in case an expectedly large earthquake were to occur. Moreover, all structures must be carefully designed to be relatively uniform and without eccentric loads.

19.1 Introduction

Seismic design involves two distinct steps — determining (or estimating) the forces that will act on a structure and designing the structure so as to both resist these forces and keep deflections within prescribed limits. This chapter provides a basic explanation of the seismic design of buildings, by first discussing how earthquake forces are caused in buildings and the systems that have been developed to deal with these forces, then reviewing the most common types of buildings and their typical seismic performance, then discussing selected key aspects of seismic design, and, finally, discussing the force-determination aspect currently used in building codes.

19.2 Earthquakes — Their Cause and Effect

As discussed in [Chapter 17](#), displacement of a fault results in the propagation of time-varying displacements throughout the earth — this vibratory ground motion is what is termed an *earthquake*. From a structural viewpoint, the essence of earthquakes is the dynamic displacement of the ground supporting a building, resulting in lateral and vertical forces on the building. In this chapter, emphasis will be on the lateral forces on a building due to shaking — vertical forces due to shaking are usually of somewhat less significance, but not always, and building codes and good practice require that vertical forces also be considered in the seismic design of buildings. While earthquakes also result in other effects on buildings,

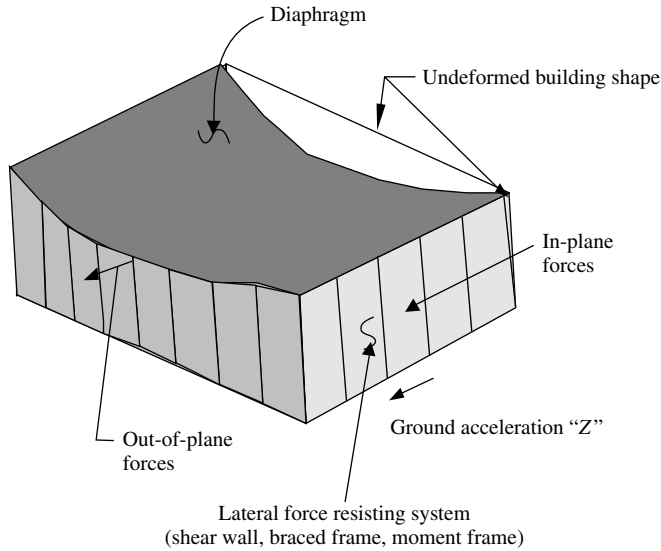

FIGURE 19.1 Effect of ground displacements on a building.

such as partial or complete ground failure, fire, and tsunami, design for these effects is more specialized and will not be covered here.

For a structure connected to the earth (and very few buildings are not connected to the earth through their base or foundation), as the base moves or displaces, the inertia and flexibility of the structure result in a time lag before the rest of the structure can displace in response to its base's displacement. The interaction of these displacements and the response of the structure result in time-varying displacements and strains within the structure, which the structure must be designed to sustain. For a structure responding to a moving base there is an equivalent system, in which the base is fixed and the structure is acted upon by forces (called inertia forces) that cause the same displacements as are occurring in the moving base system. In seismic design it is customary to visualize the structure as a fixed base system acted upon by inertia forces. Figure 19.1 shows such a system, in which the base has moved (due to the ground accelerations) and the roof is deflected. The roof's deflection is relative to its base, and is due to it and its supporting walls not moving or displacing as quickly as the base has displaced underneath it. This is exactly equivalent as if a force had been applied to the roof, which deflected the roof and its supporting walls the same amount, relative to its base.

19.3 Lateral Force Resisting Systems

The parts of the structure that connect the structure's mass to the ground and resist or otherwise accommodate these displacements or equivalent forces are termed the *lateral force resisting system* (LFRS). An LFRS is usually capable of resisting only forces that result from ground motions parallel to them. However, the combined action of LFRS along the width and length of a building can typically resist earthquake motion from any direction. LFRS differ from building to building because the type of system is controlled to some extent by the basic layout and structural elements of the building. Figure 19.2 illustrates the basic elements that may be used in LFRS, which consist of axial (tension and/or compression bracing) elements, shear (wall) elements, and/or bending resistant (frame) elements. Horizontal load distributing elements are termed diaphragms and are most often floor or roof slabs, but can be horizontally braced (i.e., truss) elements. Few buildings would use all of these LFRS elements, but most buildings would use one or more.

The earthquake resisting systems in modern steel buildings take many forms, Figure 19.3. Many types of bracing configurations have been used (diagonal, "X," "V," "K," etc.). Moment resisting steel frames

FIGURE 19.2 Types of elements comprising an LFRS.

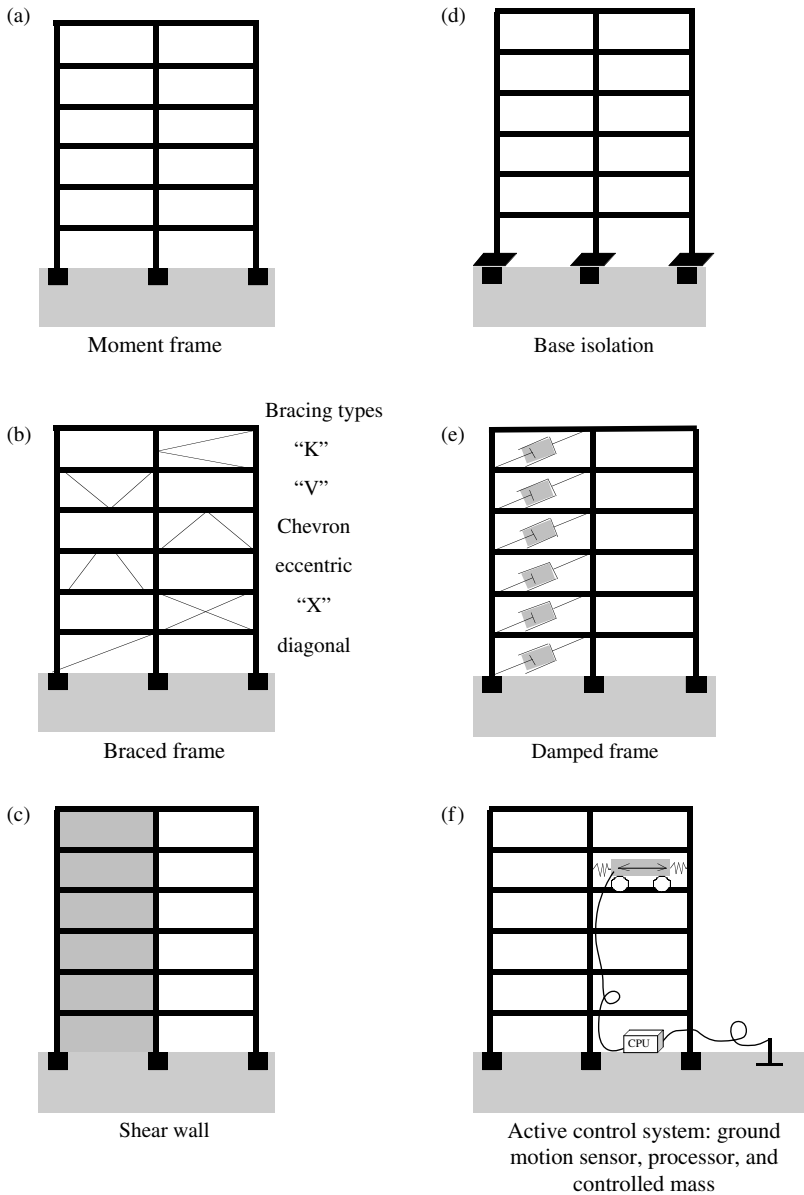

FIGURE 19.3 (a)–(c) Traditional earthquake force resisting systems. (d)–(f) Emerging technologies for earthquake force reducing systems.

are also capable of resisting lateral loads. In this type of construction, the connections between the beams and the columns are designed to resist the rotation of the column relative to the beam. Thus, the beam and the column work together and resist lateral movement by bending. This is contrary to the braced frame, where loads are resisted through tension and compression forces in the braces. Steel buildings are sometimes constructed with moment resistant frames in one direction and braced frames in the other, or with integral concrete or masonry shear walls.

In concrete and masonry structures, moment-resisting frames (MRFs) or *shear walls*¹ are used to provide lateral resistance. Ideally, these shear walls are continuous walls extending from the foundation to the roof of the building and can be exterior or interior walls. They are interconnected with the rest of the concrete frame and thus resist the motion of one floor relative to another. Shear walls can be constructed of cast-in-place reinforced concrete, precast concrete, reinforced brick, or reinforced hollow concrete block. Steel shear walls have been employed, but are not common.

19.3.1 Innovative Techniques

In about the last two decades, a number of innovative techniques have been developed and introduced to enable buildings and structures to better withstand earthquake ground motions. The general aim of these techniques, which are also shown in [Figure 19.3](#), has been the *avoidance* of earthquake-induced forces, rather than their resistance. Innovative techniques can be divided into two broad categories, *passive control* (base isolation, energy dissipation) and *active control*, which are being increasingly applied to the design of new structures or to the retrofit of existing structures against wind, earthquakes, and other external loads (Soong and Constantinou 1994; Iemura and Pradono 2002; Yang et al. 2002).

19.3.1.1 Passive Control

The distinction between passive and active controls is that passive systems require no active intervention or energy source, while active systems typically monitor the structure and incoming ground motion and seek to actively control masses or forces in the structure (via moving weights, variable tension tendons, etc.) so as to develop a structural response (ideally) equal and opposite to the structural response due to the incoming ground motion. Recently developed semiactive control systems appear to combine the best features of both approaches, offering the reliability of passive devices and yet maintaining the versatility and adaptability of fully active systems. Magnetorheological (MR) dampers, for example, are new semiactive control devices that use MR fluids to create a controllable damper.

Passive control includes several categories: *base isolation* consists of softening of the shear capacity of a structure's connection with the ground, while maintaining vertical load-carrying capacity, so as to reduce the earthquake ground motion input to the structure. This has mostly been accomplished to date via the use of various types of rubber, lead-rubber, rubber-steel composite, or other types of bearings beneath columns. Key aspects of most of the base isolation systems developed to date are (a) economically limited to selected classes of structures (not too tall or short); (b) require additional foundation expense, including special treatment of incoming utility lines; and (c) require a certain amount of "rattlespace" around the structure to accommodate the additional displacements that the bearings will undergo. For new structures, these requirements are not especially onerous and a number of new structures in Japan and a few in other countries have been designed for base isolation. Most applications of this technology in the United States, however, have been for the retrofit of existing (usually historic) structures, where the technology permitted increased seismic capacity without major modification to the architectural features. The technique has been applied to a number of highway bridges and some industrial structures in the United States.

¹Termed shear walls because the depth to width ratio is so large that deformation is primarily due to shear rather than bending.

19.3.1.1.1 Supplemental Damping

If damping can be significantly increased, then structural responses (and therefore forces and displacements) are greatly reduced (Hanson et al. 1993). Supplemental damping systems include *friction* systems (e.g., Sumitomo, pall, and friction-slip) based on Coulomb friction, *self-centering* friction resistance that is proportional to displacement (e.g., Fluor–Daniel energy dissipating restraint), or various *energy dissipation* mechanisms: ADAS (added damping and stiffness) elements, which utilize the yielding of mild-steel X-plates; viscoelastic shear dampers using a 3M acrylic copolymer as the dissipative element; or nickel–titanium alloy shape-memory devices that take advantage of reversible, stress-induced phase changes in the alloy to dissipate energy (Aiken et al. 1993). These systems are generally still in the developmental stage although there are no special obstacles for the implementation of the ADAS system, which has seen one application to date in the United States (Perry et al. 1993) and more in other countries.

19.3.1.2 Active Control

Active control depends on actively modifying a structure's mass, stiffness, or geometric properties during its dynamic response in such a manner so as to counteract and reduce excessive displacements (Iemura and Pradono 2002). Tuned mass dampers, reliance on liquid sloshing (Lou et al. 1994), and active tensioning of tendons are methods currently under investigation. Most methods of active control are real time, relying on measurement of structural response, rapid structural computation, and fast-acting energy sources. A number of issues of reliability remain to be resolved (Spencer et al. 1994).

19.4 Types of Buildings and Typical Earthquake Performance

There are many different types of buildings, with varying kinds of earthquake performance and seismic design needs. This section discusses general earthquake performance of buildings, with the emphasis more toward those buildings typically built in the western United States. Specific aspects of structural analysis and design of buildings, other structures, steel, concrete, wood, masonry, and other topics are discussed in other chapters.

In buildings, earthquake performance can be divided into two categories: structural and non-structural, both of which when unsatisfactory can be hazardous to building occupants — when *damage* occurs. Structural damage means degradation of the building's structural support systems (i.e., vertical and lateral force resisting systems), such as the building frames and walls. Nonstructural damage refers to any damage that does not affect the integrity of the structural support system. Examples of nonstructural damage are a chimney collapsing, windows breaking, ceilings falling, piping damage, and disruption of pumps, control panels, telecommunications equipment, etc. Nonstructural damage can still be life threatening and costly. The type of damage to be expected is a complex issue that depends on the structural type and age of the building, its configuration, construction materials, the site conditions, the proximity of the building to neighboring buildings, and the type of nonstructural elements.

The typical earthquake performances of different types of common building structural systems are described in this section to provide insights into seismic design for buildings.

19.4.1 Wood Frame

Wood-frame structures tend to be mostly low rise (one to three stories, occasionally four stories). Vertical framing may be of several types, for example, stud wall, braced post and beam, or timber pole:

- Stud walls are typically constructed of 2 in. by 4 in. wood members vertically set about 16 in. apart — multiple story buildings may have 2 × 6 or larger studs. These walls are braced by plywood sheathing or by diagonals made of wood or steel. Most detached single and low-rise multiple family residences in the United States are of stud wall wood frame construction, [Figure 19.4](#).

10. Diagonal blocking
11. Let-in brace (only in vintage)

FIGURE 19.4 Schematic of wood light-frame construction. (From Federal Emergency Management Agency, 1988. *Rapid Visual Screening of Buildings for Potential Seismic Hazards: A Handbook*, FEMA 154, FEMA, Washington, DC.)

- Post and beam construction is not very common in the United States, although it is the basis of the traditional housing in other countries (e.g., Europe, Japan); in the United States, it is found mostly in older housing and larger buildings (i.e., warehouses, mills, churches, and theaters). This type of construction consists of larger rectangular (6 in. by 6 in. and larger) or sometimes round wood columns framed together with large wood beams or trusses.
- Timber pole buildings are a less common form of construction found mostly in suburban/rural areas. Generally adequate seismically when first built, they are more often subject to wood deterioration due to the exposure of the columns, particularly near the ground surface. Together with an often-found “soft story” in this building type, this deterioration may contribute to unsatisfactory seismic performance.

In wood frame stud-wall buildings, the resistance to lateral loads is typically provided by (a) for older buildings, especially houses, wood diagonal “let-in” bracing and (b) for newer (primarily

post-World War II) buildings, plywood siding “shear walls.” Without the extra strength provided by the bracing or plywood, walls would distort excessively or “rack,” resulting in broken windows, stuck doors, cracked plaster, and, in extreme cases, collapse.

Stud-wall buildings have performed very well in past U.S. earthquakes for ground motions of about 0.5g or less, due to inherent qualities of the structural system and because they are lightweight and low rise. Cracking in plaster and stucco may occur and these act to degrade the strength of the building to some extent (i.e., the plaster and stucco may in fact form part of the LFRS, sometimes by design) — this is usually classified as nonstructural damage but, in fact, dissipates a lot of the earthquake-induced energy. However, the most common type of structural damage in older wood-frame buildings results from a lack of connection between the superstructure and the foundation — the so-called “cripple wall” construction. This kind of construction is common in the milder climes of the west, where full basements are not required, and consists of an air space (typically 2–3 ft) left under the house — the short stud walls under the first floor (termed by carpenters a cripple wall because of their less than full height) were usually built without bracing so that there is no adequate LFRS for this short height. Plywood sheathing nailed to the cripple studs may have been used to strengthen the cripple walls. Additionally, the mud sill in these older (typically pre-World War II) housing may not be bolted to the foundation. As a result, houses can slide off their foundations when not properly bolted to the foundation, resulting in major damage to the building as well as to plumbing and electrical connections. Overturning of the entire structure is usually not a problem because of the low-rise geometry. In many municipalities, modern codes require wood structures to be bolted to their foundations. However, the year that this practice was adopted will differ from community to community and should be checked.

Garages often have a very large door opening in one wall with little or no bracing. This wall has almost no resistance to lateral forces, which is a problem if a heavy load such as a second story sits on top of the garage (the so-called house over garage, or HOGs). Homes built over garages have sustained significant amounts of damage in past earthquakes, with many collapses. Therefore, the HOG configuration, which is found commonly in low-rise apartment complexes and some newer suburban detached dwellings, should be examined more carefully and perhaps strengthened.

Unreinforced masonry (URM) chimneys also present a life-safety problem. They are often inadequately tied to the building and therefore fall when strongly shaken. On the other hand, chimneys of reinforced masonry generally perform well.

Some wood-frame structures, especially older buildings in the eastern United States, have masonry veneers that may represent another hazard. The veneer usually consists of one wythe of brick (a wythe is a term denoting the width of one brick) attached to the stud wall. In older buildings, the veneer is either insufficiently attached or has poor quality mortar, which often results in peeling off of the veneer during moderate and large earthquakes.

Post and beam buildings tend to perform well in earthquakes if adequately braced. However, walls often do not have sufficient bracing to resist horizontal motion and thus they may deform excessively.

The 1994 M_w 6.7 Northridge earthquake was the largest earthquake to occur directly within an urbanized area since the 1971 San Fernando earthquake — ground motions were as high as 0.9g and substantial numbers of modern wood-frame dwellings sustained significant damage, including major cracking of veneers, gypsum board walls, and splitting of wood wall studs. It may be inferred from this, as well as the performance observed in the more sparsely populated epicentral regions of the 1989 M_w 7.1 Loma Prieta Earthquake, that U.S. single family dwelling design begins to sustain substantial non-structural and structural damage for peak ground acceleration in excess of about 0.5g.

19.4.2 Steel-Frame Buildings

Steel-frame buildings generally may be classified as MRFs, braced frames, or mixed construction (e.g., steel frame for vertical forces and reinforced concrete shear wall for the LFRS) based on their LFRSs. In concentric braced frames the lateral forces or loads are resisted by the tensile and compressive

strength of the bracing, which can assume a number of different configurations including diagonal, “V,” inverted “V” also termed chevron, “K,” etc. A recent development in seismic bracing is the eccentric brace frame. Here, the bracing is slightly offset from the main beam to column connection, and the short section of the beam is expected to deform significantly under major seismic forces and thereby dissipate a considerable portion of the energy. MRFs resist lateral loads and deformations by the bending stiffness of the beams and columns (there is no bracing), [Figure 19.5](#).

Steel-frame buildings have tended to perform satisfactory in earthquakes with ground motions less than about 0.5g because of their strength, flexibility, and lightness. Collapse in earthquakes has been very rare, although steel-frame buildings did collapse, for example, in the 1985 Mexico City Earthquake. More recently, following the 1994 M_W 6.7 Northridge Earthquake, a number of MRFs were found to have sustained serious cracking in the beam column connection; see [Figure 19.6](#), which shows one of a number of different types of cracking that were found following the Northridge Earthquake. The cracking typically initiated at the lower beam flange location and propagated upward into the shear panel. Similar cracking was also observed following the 1995 M_W 6.9 Hanshin (Kobe) Earthquake, which experienced similar levels of ground motion as Northridge. More worrisome is that, as of this writing, some steel buildings in the San Francisco Bay Area have been found to have similar cracking, presumably as a result of the 1989 M_W 7.1 Loma Prieta Earthquake. As a result, there is an ongoing effort by a consortium of research organizations, termed SAC (funded by the Federal Emergency Management Agency) to better understand and develop solutions for this problem.

Light-gage steel buildings are used for agricultural structures, industrial factories, and warehouses. They are typically one story in height, sometimes without interior columns, and often enclose a large floor area, [Figure 19.7](#). Construction is typically of steel frames spanning the short dimension of the building and resisting lateral forces as moment frames. Forces in the long direction are usually resisted by diagonal steel rod bracing. These buildings are usually clad with lightweight metal or asbestos reinforced concrete siding, often corrugated. Because these buildings are low rise, lightweight, and constructed of steel members, they usually perform relatively well in earthquakes. Collapses do not usually occur. Some typical problems are (a) insufficient capacity of tension braces can lead to their elongation and, in turn, building damage and (b) inadequate connection to the foundation can allow the building columns to slide.

19.4.3 Concrete Buildings

Several construction subtypes fall under this category: (a) MRFs (nonductile or ductile); (b) shear wall structures; and (c) precast, including tilt-up structures. The most prevalent of these is nonductile reinforced concrete frame structures with or without infill walls built in the United States between about 1920 and (in the western United States) 1972. In many other portions of the United States this type of construction continues to the present. This group includes large multistory commercial, institutional, and residential buildings constructed using flat slab frames, waffle slab frames, and the standard girder-column-type frames. These structures generally are more massive than steel frame buildings, are underreinforced (i.e., have insufficient reinforcing steel embedded in the concrete), and display low ductility. Some typical problems are (a) large tie spacings in columns can lead to a lack of concrete confinement and/or shear failure; (b) placement of inadequate rebar splices at the same location can lead to column failure; (c) insufficient shear strength in columns can lead to shear failure prior to the development of moment hinge capacity; (d) insufficient shear tie anchorage can prevent the column from developing its full shear capacity; (e) lack of continuous beam reinforcement can result in hinge formation during load reversal; (f) inadequate reinforcing of beam-column joints or location of beam bar splices at columns can lead to failures; and (g) the relatively low stiffness of the frame can lead to substantial nonstructural damage.

Ductile reinforced concrete frames where special reinforcing details are required in order to furnish satisfactory load-carrying performance under large deflections (termed ductility) have usually only been required in the highly seismic portions of the United States since the mid-1970s. ACI-318 (1995)

FIGURE 19.5 Steel moment resisting frame construction. (From Federal Emergency Management Agency. 1988. *Rapid Visual Screening of Buildings for Potential Seismic Hazards: A Handbook*, FEMA 154, FEMA, Washington, DC.)

FIGURE 19.6 Example steel moment-frame connection cracking.

FIGURE 19.7 Light steel construction.

provides comprehensive treatment for the *ductile detailing*, which involves a number of special requirements including close spacing of lateral reinforcement in order to attain *confinement* of a concrete core, appropriate relative dimensioning of beams and columns, 135° hooks on lateral reinforcement, hooks on main beam reinforcement within the column, etc.

Concrete shear wall buildings consist of a concrete box or frame structural system with walls constituting the main LFRS, Figure 19.8. The entire structure, along with the usual concrete diaphragm, is typically cast in place. Shear walls in buildings can be located along the perimeter, as interior walls, or around the service or elevator core. This building type generally tends to perform better than concrete frame buildings. They are heavier than steel-frame buildings but they are also rigid due to the shear walls. Some types of damage commonly observed in taller buildings are caused by vertical discontinuities, pounding, and/or irregular configuration. Other damages specific to this building type are (a) shear cracking and distress can occur around openings in concrete shear walls during large seismic events; (b) shear failure can occur at wall construction joints usually at a load level below the expected capacity; and (c) bending failures can result from insufficient chord steel lap lengths.

Tilt-up buildings are a common type of construction in the western United States and consist of concrete wall panels cast on the ground and then tilted upward into their final positions. More recently, wall panels are fabricated off-site and trucked in. The wall panels are welded together at embedments or held in place by cast-in-place columns or steel columns, depending on the region. The floor and roof beams are often glue-laminated wood or steel open webbed joists that are attached to the tilt-up wall panels; these panels may be load bearing or nonload bearing, depending on the region. These buildings tend to be low-rise industrial or office buildings. Before 1973 in the western United States, many tilt-up buildings did not have sufficiently strong connections or anchors between the walls and the roof and floor diaphragms. During an earthquake, weak anchors pull out of the walls, causing the floors or roofs

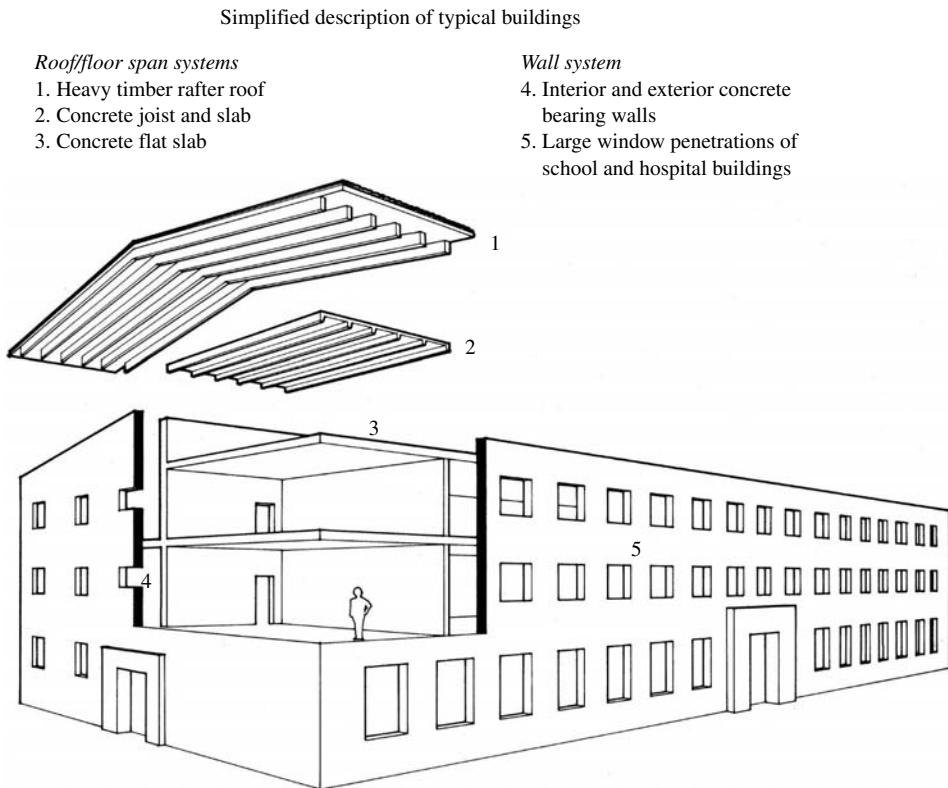

FIGURE 19.8 Reinforced concrete shear wall construction.

to collapse. The connections between concrete panels are also vulnerable to failure. Without these, the building loses much of its lateral force resisting capacity. For these reasons, many tilt-up buildings were damaged in the 1971 San Fernando Earthquake. Since 1973, tilt-up construction practices have changed in California and other high-seismicity regions, requiring positive wall–diaphragm connection and prohibiting cross-grain bending in wall ledgers. (Such requirements may not have yet been made in other regions of the country.) However, a large number of these older, pre-1970s vintage tilt-up buildings still exist and have not been retrofitted to correct this wall-anchor defect. These buildings are a prime source of seismic hazards. In areas of low or moderate seismicity, inadequate wall anchor details continue to be employed. Damage to tilt-up buildings was observed again in the 1994 M_w 6.7 Northridge earthquake, where the primary problems were poor wall anchorage into the concrete and excessive forces due to flexible roof diaphragms amplifying ground motion to a greater extent than anticipated in the code.

Precast concrete frame construction, first developed in the 1930s, was not widely used until the 1960s. The precast frame is essentially a post and beam system in concrete where columns, beams, and slabs are prefabricated and assembled on site, Figure 19.9. Various types of members are used: vertical load-carrying elements may be Ts, cross-shapes, or arches and are often more than one story in height. Beams are often Ts and double Ts or rectangular sections. Prestressing of the members, including pretensioning and posttensioning, is often employed. The LFRS is often concrete cast-in-place shear walls. The earthquake performance of this structural type varies greatly and is sometimes poor. This type of building can perform well if the details used to connect the structural elements have sufficient strength and ductility (toughness). Because structures of this type often employ cast-in-place concrete shear walls for lateral load resistance, they experience the same types of damage as other shear wall building types. Some of the problem areas specific to precast frames are (a) poorly designed connections between

FIGURE 19.9 Precast concrete construction.

prefabricated elements can fail; (b) accumulated stresses can result due to shrinkage and creep and due to stresses incurred in transportation; (c) loss of vertical support can occur due to inadequate bearing area and/or insufficient connection between floor elements and columns; and (d) corrosion of metal connectors between prefabricated elements can occur. A number of precast parking garages failed in the 1994 M_W 6.7 Northridge Earthquake, including a large structure at the Cal State Northridge campus that sustained a progressive failure. This structure had a perimeter precast MRF and interior nonductile columns — the MRF sustained large but tolerable deflections; however, interior nonductile columns failed under these deflections, resulting in an interior collapse, which then pulled the exterior MRFs over.

19.4.4 Masonry Buildings

Reinforced masonry buildings are mostly low-rise perimeter bearing wall structures, often with wood diaphragms although precast concrete is sometimes used. Floor and roof assemblies usually consist of timber joists and beams, glue-laminated beams, or light steel joists. The bearing walls consist of grouted and reinforced hollow or solid masonry units. Interior supports, if any, are often wood or steel columns, wood stud frames, or masonry walls. Generally, they are less than five stories in height although many mid-rise masonry buildings exist. Reinforced masonry buildings can perform well in moderate earthquakes if they are adequately reinforced and grouted and if sufficient diaphragm anchorage exists.

Most URM bearing wall structures in the western United States were built before 1934, although this construction type was permitted in some jurisdictions having moderate or high seismicity until the late 1940s or early 1950s (in low-seismicity jurisdictions URM may still be a common type of construction, even today). These buildings usually range from one to six stories in height and typically construction varies according to the type of use, although wood floor and roof diaphragms are common. Smaller commercial and residential buildings usually have light wood floor/roof joists supported on the typical perimeter URM wall and interior wood load-bearing partitions. Larger buildings, such as industrial warehouses, have heavier floors and interior columns, usually of wood. The bearing walls of these industrial buildings tend to be thick, often as much as 24 in. or more at the base. Wall thicknesses of residential buildings range from 9 in. at upper floors to 18 in. at lower floors. URM structures are recognized as perhaps the most hazardous structural type. They have been observed to fail in many modes during past earthquakes. Typical problems are

1. *Insufficient anchorage.* Because the walls, parapets, and cornices are not positively anchored to the floors, they tend to fall out. The collapse of bearing walls can lead to major building collapses. Some of these buildings have anchors as a part of the original construction or as a retrofit. These older anchors exhibit questionable performance.
2. *Excessive diaphragm deflection.* Because most of the floor diaphragms are constructed of wood sheathing, they are very flexible and permit large out-of-plane deflection at the wall transverse to the direction of the force. The large drift, occurring at the roof line, can cause the masonry wall to collapse under its own weight.
3. *Low shear resistance.* The mortar used in these older buildings is often made of lime and sand, with little or no cement, and has very little shear strength. The bearing walls will be heavily damaged and collapse under large loads.
4. *Wall slenderness.* Some of these buildings have tall story heights and thin walls. This condition, especially in nonload-bearing walls, will result in buckling out-of-plane under severe lateral load. Failure of a nonload-bearing wall represents a falling hazard, whereas the collapse of a load-bearing wall will lead to partial or total collapse of the structure.

19.4.5 Configuration, Irregularities, and Pounding

Certain problems in earthquake performance are common to many building types and include issues of configuration, irregularities, and pounding.

19.4.5.1 Configuration and Irregularities

Configuration, or the general vertical and/or horizontal shape of buildings, is an important factor in earthquake performance and damage. Buildings that have simple, regular, symmetric configurations generally display the best performance in earthquakes. The reasons for this are (a) nonsymmetric buildings tend to have twist (i.e., have significant torsional modes) in addition to shaking laterally and (b) the various “wings” of a building tend to act independently, resulting in differential movements, cracking, and other damage. Rotational motion introduces additional damage, especially at re-entrant or “internal” corners of the building. The term “configuration” also refers to the geometry of lateral load resisting systems as well as the geometry of the building. Asymmetry can exist in the placement of bracing systems, shear walls, or MRFs that are used to provide earthquake resistance in a building. This type of asymmetry, of the LFRS, can result in twisting or differential motion, with the same consequences as asymmetry in the building plan. An important aspect of configuration is *soft story*, which is a story of a building significantly less stiff than adjacent stories (i.e., a story in which the lateral stiffness is 70% or less than that in the story above or less than 80% of the average stiffness of the three stories above; BSSC 2001). Soft stories often (but not always) occur on the ground floor, where commercial or other reasons require a greater story height, and large windows or openings for ingress or commercial display (e.g., the building might have masonry curtain walls for the full height, except at the ground floor, where these are replaced with large windows for a store’s display). Due to inadequate stiffness, a disproportionate amount of the entire building’s drift is concentrated at the soft story, resulting in nonstructural and potential structural damage. Many older buildings with soft stories but built prior to recognition of this aspect collapse due to excessive ductility demands at the soft story.

The National Earthquake Hazard Reduction Program (NEHRP) provisions for the design of new buildings (BSSC 2001) have defined when a building’s configuration is “irregular,” and provided required strength increase factors or other approaches to deal with these irregularities. The NEHRP definitions for plan and vertical irregularities are illustrated in [Table 19.1](#) and [Table 19.2](#).

19.4.5.2 Pounding

Pounding is the collision of adjacent buildings during an earthquake due to insufficient lateral clearance. Such collision can induce very high and unforeseen accelerations and story shears in the overall structure. Additionally, if adjacent buildings have varying story heights, a relatively rigid floor or roof diaphragm may impact adjacent buildings at or near mid-column height, causing bending or shear failure in the columns and subsequent story collapse. Under earthquake lateral loading, buildings deflect significantly — these deflections or drift are limited by code — and adjacent buildings must be separated by a seismic gap equal to the sum of their actual calculated drifts (i.e., ideally, each building set back from its property line by the drift). Pounding has been the cause of a number of mid-rise building collapses, most notably in the 1985 Mexico City Earthquake.

19.5 2000 NEHRP Recommended Provisions

19.5.1 Overview

The *2000 NEHRP Recommended Provisions for Seismic Regulation for Buildings and Other Structures* (NEHRP Provisions) represents the current state of the art in prescriptive, as opposed to performance-based, provisions for seismic-resistant design. Its provisions form the basis for earthquake design specifications contained in the 2001 edition of *ASCE-7, Minimum Design Loads for Buildings and other Structures*, either through reference or direct incorporation, the seismic regulations in the 2003 edition of the *International Building Code*, and also the 2002 edition of the *NFPA 5000 Building Code* (NFPA, n.d.). As such, it will form the basis for most earthquake-resistant design in the United States, as well as other nations that base their codes on U.S. practices, throughout much of the first decade of the twenty-first century.

TABLE 19.1 NEHRP 2000 Plan Structural Irregularities

1: Torsional irregularity — when diaphragms are not flexible

Torsional irregularity exists (1a) when the maximum story drift, computed including accidental torsion, at one end of the structure transverse to an axis is more than 1.2 times the average of the story drift at the two ends of the structure. (1b) Extreme torsional irregularity exists when ratio >1.4

2: Re-entrant corners

Plan configurations of a structure and its lateral-force-resisting system contain re-entrant corners where both projections of the structure beyond a re-entrant corner are greater than 15% of the plan dimension of the structure in the given direction

3: Diaphragm discontinuity

Diaphragms with abrupt discontinuities or variations in stiffness including those having cutout or open areas greater than 50% of the gross enclosed diaphragm area or changes in effective diaphragm stiffness of more than 50% from one story to the next

4: Out-of-plane offsets

Discontinuities in a lateral-force-resistance path such as out-of-plane offsets of the vertical elements

5: Nonparallel systems

The vertical lateral-force-resisting elements are not parallel to or symmetric about the major orthogonal axes of the lateral-force-resisting system

The *NEHRP Provisions* assume significant amounts of nonlinear behavior will occur under design level events. The extent of nonlinear behavior that may occur is dependent on the structural systems employed in resisting earthquake forces, the configuration of these systems, and the extent that the structural systems are detailed for ductile behavior under large cyclic inelastic deformation. The *NEHRP Provisions* may therefore be thought to consist of two component parts:

- One part relates to specification of the required design strength and stiffness of the structural system.
- The second part relates to issues of structural detailing.

TABLE 19.2 NEHRP 2000 Vertical Structural Irregularities

1: Stiffness irregularity — soft story

(1a) A soft *story* is one in which the lateral stiffness is less than 70% of that in the *story* above or less than 80% of the average stiffness of the three stories above. (1b) An extreme soft *story* is for ratios of less than 60% or less than 70%, respectively

2: Weight (mass) irregularity

Mass irregularity exists where the effective mass of any *story* is more than 150% of the effective mass of an adjacent *story*. A roof that is lighter than the floor below need not be considered

3: Vertical geometric irregularity

Vertical geometric irregularity exists where the horizontal dimension of the lateral-force-resisting system in any *story* is more than 130% of that in an adjacent *story*

4: In-plane discontinuity in vertical lateral-force-resisting elements

An in-plane offset of the lateral-force-resisting elements greater than the length of those elements or a reduction in stiffness of the resisting elements in the *story* below

5: Discontinuity in capacity — weak story

A weak *story* is one in which the *story* lateral strength is less than 80% of that in the *story* above. The *story* strength is the total strength of all seismic-resisting elements sharing the *story* shear for the direction under consideration

For this second part, the *NEHRP Provisions* adopt, with modification, design standards and specifications developed by industry groups such as the American Concrete Institute or the American Institute of Steel Construction. This second part of the *NEHRP Provisions* is not discussed in this chapter, but is covered in detail in each of the following chapters, which treat the individual structural materials.

Instead, this article focuses primarily on the manner in which the *NEHRP Provisions* regulate the required strength and stiffness of structures.

19.5.2 Performance Intent and Objectives

The *NEHRP Provisions* are intended to provide a tiered series of performance capabilities for structures, depending on their intended occupancy and use. Under the *NEHRP Provisions*, each structure must be assigned to a seismic use group (SUG). Three SUGs are defined and are respectively labeled I, II, and III:

- SUG-I encompasses most ordinary occupancy buildings including typical commercial, residential, and industrial structures. For these facilities the basic intent of the *NEHRP Provisions*, just as with earlier codes, is to provide a low probability of earthquake-induced life safety endangerment.
- SUG-II includes facilities that house large numbers of persons, persons who are mobility impaired, or large quantities of materials that if released could pose substantial hazards to the surrounding community. Examples of such facilities include large assembly facilities, housing several thousand persons, daycare centers, and manufacturing facilities containing large quantities of toxic or explosive materials. The performance intent for these facilities is to provide a lower probability of life endangerment, relative to SUG-I structures, and a low probability of damage that would result in release of stored materials.
- SUG-III includes those facilities such as hospitals and emergency operations and communications centers deemed essential to disaster response and recovery operations. The basic performance intent of the *NEHRP Provisions* with regard to these structures is to provide a low probability of earthquake-induced loss of functionality and operability.

In reality, the probability of damage resulting in life endangerment, release of hazardous materials, or loss of function should be calculated using structural reliability methods as the total probability of such damage over a period of time (Ravindra 1994). Mathematically, this is equal to the integral, over all possible levels of ground motion intensity, of the conditional probability of excessive damage given that a ground motion intensity is experienced and the probability that such ground motion intensity will be experienced in the desired period of time. Although such an approach would be mathematically and conceptually correct, it is currently regarded as too complex for practical application in the design office.

Instead, the *NEHRP Provisions* design for desired limiting levels of nonlinear behavior for a single design earthquake intensity level, termed *maximum considered earthquake* (MCE) ground shaking. In most regions of the United States, the MCE is defined as that intensity of ground shaking having a 2% probability of exceedance in 50 years. In certain regions, proximate to major active faults, this probabilistic definition of MCE motion is limited by a conservative deterministic estimate of the ground motion intensity anticipated to result from an earthquake of characteristic magnitude on these faults. The MCE is thought to represent the most severe level of shaking ever likely to be experienced by a structure, though it is recognized that there is some limited possibility of more severe motion occurring.

Structures categorized as SUG-I are designed with the expectation that MCE shaking would result in severe damage to both structural and nonstructural elements, with damage perhaps being so severe that following the earthquake the structure would be on the verge of collapse. This damage state has come to be termed *collapse prevention*, because the structure is thought to be at a state of incipient but not actual collapse. Theoretically, SUG-I structures behaving in this manner would be total or near total financial losses, in the event that MCE shaking was experienced. To the extent that shaking experienced by the structure exceeds the MCE level, the structure could actually experience partial or total collapse.

SUG-III structures are designed with the intent that when subjected to MCE shaking they would experience both structural and nonstructural damages; however, the structures would retain significant residual structural resistance or margin against collapse. It is anticipated that when experiencing MCE shaking such structures may be damaged to an extent that they would no longer

be suitable for occupancy, until repair work had been instituted, but that repair would be technically and economically feasible. This superior performance relative to SUG-I structures is accomplished through specification that SUG-III structures be designed with 50% greater strength and more stiffness than their SUG-I counterparts. SUG-II structures are designed for performance intermediate to that for SUG-I and SUG-III with strengths and stiffness that are 25% greater than those required for SUG-I structures.

19.5.3 Seismic Hazard Maps and Ground Motion Parameters

The *NEHRP Provisions* incorporate a series of national seismic hazard maps for the United States and territories, developed by the United States Geologic Survey (USGS), specifically for this purpose (available at <http://geohazards.cr.usgs.gov/eq/index.html>). Two sets of maps are presented. One set presents contours of MCE, 5% damped, elastic spectral response acceleration at a period of 0.2 s, termed S_s . The second set presents contours of MCE, 5% damped, elastic spectral response acceleration at a period of 1.0 s, termed S_1 . In both cases, the spectral response acceleration values are representative of sites with subsurface conditions bordering between firm soil or soft rock. Contours are presented in increments of 0.02g in areas of low seismicity and 0.05g in areas of high seismicity. By locating a site on the maps and interpolating between the values presented for contours adjacent to the site, it is possible to rapidly estimate the MCE level shaking parameters for the site, given that it has a soft rock or firm soil profile Figure 19.10 shows, for a portion of the western United States, contours of the 0.2 s spectral acceleration with a 90% probability of not being exceeded in 50 years. As indicated in the figure, in zones of high seismicity these contours are quite closely spaced, making use of the maps difficult. Therefore, the USGS has furnished software, available both over the internet (at the URL indicated above) and on a CD-ROM, which permits determination of the MCE spectral response acceleration parameters based on longitude and latitude.

Since many sites are located neither on soft rock nor on firm soil sites, it is necessary to correct the mapped values of spectral response acceleration to account for site amplification and de-amplification effects. To facilitate this process, a site is categorized into one of six site class groups, labeled A through F. Table 19.3 summarizes the various site class categories.

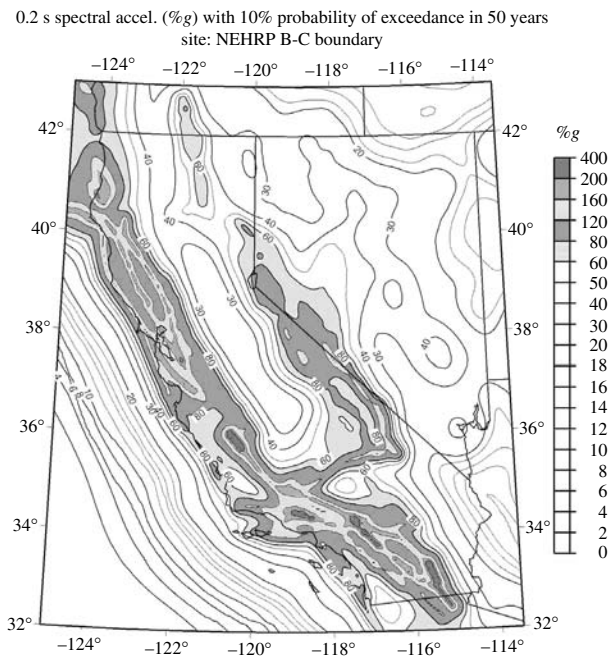

FIGURE 19.10 MCE Seismic Hazard Map (0.2 s spectral response acceleration) for western United States.

TABLE 19.3 Site Categories

Site class	Description	Shear wave velocity, \bar{v}_s	Penetration resistance, \bar{N}	Unconfined shear strength, $\bar{\tau}_u$
A	Hard rock	>5000 ft/s		
B	Rock	2500 ft/s $< \bar{v}_s \leq 5000$ ft/s		
C	Very firm soil or soft rock	1200 ft/s $< \bar{v}_s \leq 2500$ ft/s	>50	>2000 psf
D	Stiff soil	600 ft/s $< \bar{v}_s \leq 1200$ ft/s	15–50	1000–2000 psf
E	Soil	$\bar{v}_s < 600$ ft/s	<15	<1000 psf
F	Special soils	Soils requiring site-specific evaluations: <ol style="list-style-type: none"> 1. Soils vulnerable to potential failure or collapse under seismic loading such as liquefiable soils, quick and highly sensitive clays, collapsible weakly cemented soils 2. Peats and/or highly organic clays ($H > 10$ ft of peat and/or highly organic clay where H = thickness of soil) 3. Very high plasticity clays ($H > 25$ ft [8 m] with $PI > 75$) 4. Very thick soft/medium stiff clays ($H > 120$ ft [36 m]) 		

Note: \bar{v}_s , \bar{N} , $\bar{\tau}_u$ represent the average value of the parameter over the top 30 m (100 ft) of soil.

TABLE 19.4 Coefficient F_a as a Function of Site Class and Mapped Spectral Response Acceleration

Site class	Mapped maximum considered earthquake spectral response acceleration at short periods				
	$S_s = 0.25$	$S_s = 0.50$	$S_s = 0.75$	$S_s = 1.00$	$S_s = 1.25$
A	0.8	0.8	0.8	0.8	0.8
B	1.0	1.0	1.0	1.0	1.0
C	1.2	1.2	1.1	1.0	1.0
D	1.6	1.4	1.2	1.1	1.0
E	2.5	1.7	1.2	0.9	a
F	a	a	a	a	a

Note: “a” indicates site-specific evaluation required.

Once a site has been categorized within a site class, a series of coefficients are provided that are used to adjust the mapped values of spectral response acceleration for site response effects. These coefficients were developed based on observed site response characteristics in ground motion recordings from past earthquakes. Two coefficients are provided:

- The F_a coefficient is used to account for site response effects on short period ground shaking intensity.
- The F_v coefficient is used to account for site response effects of longer period motions.

Table 19.4 and Table 19.5 indicate the values of these coefficients as a function of site class and mapped MCE ground shaking acceleration values. Site-adjusted values of the MCE spectral response acceleration parameters at 0.2 and 1 s, respectively, are found from the following equations:

$$S_{MS} = F_a S_s \tag{19.1}$$

$$S_{M1} = F_v S_1 \tag{19.2}$$

The two site-adjusted spectral response acceleration parameters, S_{MS} and S_{M1} , permit a 5% damped, maximum considered earthquake ground shaking response spectrum to be constructed for the building site. This spectrum is constructed as indicated in Figure 19.11 and consists of a constant response acceleration range, between periods of T_0 and T_s , a constant response velocity range for periods in excess of T_s , and a short period range that ramps between an estimated zero period acceleration given by $S_{MS}/2.5$ and S_{MS} . Site-specific spectra can also be used. Regardless of whether site-specific spectra or

E	3.5	3.2	2.8	2.4	a
F	a	a	a	a	a

Note: "a" indicates site-specific evaluation required.

FIGURE 19.11 Maximum considered earthquake response spectrum.

spectra based on mapped values are used, the actual design values are taken as two thirds of the MCE values. The resulting design parameters are, respectively, labeled S_{DS} and S_{D1} and the design spectrum is identical to the MCE spectrum, except that the ordinates are taken as two thirds of the MCE values. The reason for using design values that are two thirds of the maximum considered values is that the design procedures, described in later sections, are believed to provide a minimum margin against collapse of 150%. Therefore, if design is conducted for two thirds of the MCE ground shaking, it is anticipated that buildings experiencing MCE ground shaking would be at incipient collapse, the desired performance objective for SUG-I structures.

19.5.4 Seismic Design Categories

The seismicity of the United States, and indeed the world, varies widely. It encompasses zones of very high seismicity in which highly destructive levels of ground shaking are anticipated to occur every 50 to 100 years and zones of much lower seismicity in which only moderate levels of ground shaking are ever anticipated. The *NEHRP Provisions* recognize that it is neither technically necessary nor economically appropriate to require the same levels of seismic protection for all buildings across these various regions of seismicity. Instead, the *NEHRP Provisions* assign each structure to a seismic design category (SDC) based on the level of seismicity at the building site, as represented by mapped shaking parameters, and the SUG.

Six SDCs, labeled A through F, are defined. SDC A represents the least severe seismic design condition and includes structures of ordinary occupancy located on sites anticipated to experience only very limited levels of ground shaking. SDC F represents the most severe design condition and includes

TABLE 19.6 Categorization of Structures into Seismic Design Category, Based on Design Short Period Spectral Response Acceleration, S_{DS} and Seismic Use Group

Value of S_{DS}	Seismic Use Group		
	I	II	III
$S_{DS} < 0.167g$	A	A	A
$0.167g \leq S_{DS} < 0.33g$	B	B	C
$0.33g \leq S_{DS} < 0.50g$	C	C	D
$0.50g \leq S_{DS}$	D ^a	D ^a	D ^a

^a Seismic Use Group I and II structures located on sites with mapped maximum considered earthquake spectral response acceleration at 1 s period, S_1 , equal to or greater than 0.75g shall be assigned to Seismic Design Category E and Seismic Use Group III structures located on such sites shall be assigned to Seismic Design Category F.

TABLE 19.7 Categorization of Structures into Seismic Design Category, Based on Design One-Second Period Spectral Response Acceleration, S_{D1} and Seismic Use Group

Value of S_{D1}	Seismic Use Group

structures assigned to SUG-III and located within a few kilometers of major, active faults, anticipated to produce very intense ground shaking. A designer determines to which SDC a structure should be assigned by reference to a pair of tables, reproduced as Table 19.6 and Table 19.7. A structure is assigned to the most severe category indicated by either table.

Nearly all aspects of the seismic design process are affected by the SDC that a structure is assigned to. This includes designation of the permissible structural systems, specification of required detailing, limitation on permissible heights and configuration, the types of analyses that may be used to determine the required lateral strength and stiffness, and the requirements for bracing and anchorage of non-structural components.

19.5.5 Permissible Structural Systems

The *NEHRP Provisions* define more than 70 individual seismic-force-resisting system types. These systems may be broadly categorized into five basic groups that include: bearing wall systems, building frame systems, moment-resisting frame systems, dual systems, and special systems:

- Bearing wall systems include those structures in which the vertical elements of the LFRS comprise either shear walls or braced frames in which the shear-resisting elements (walls or braces) are required to provide support for gravity (dead and live) loads in addition to providing lateral resistance. This is similar to the “box system” contained in earlier codes.
- Building frame systems include those structures in which the vertical elements of the LFRS comprise shear walls or braces, but in which the shear-resisting elements are not also required to provide support for gravity loads.
- Moment-resisting frame systems are those structures in which the lateral-force resistance is provided by the flexural rigidity and strength of beams and columns, which are interconnected in such a manner that stress is induced in the frame by lateral displacements.

- Dual systems rely on a combination of MRFs and either braced frames or shear walls. In dual systems, the braced frames or shear walls provide the primary lateral resistance and the MRF is provided as a back-up or redundant system, to provide supplemental lateral resistance in the event that earthquake response damages the primary lateral-force-resisting elements to an extent that they lose effectiveness.
- Special systems include unique structures, such as those that rely on the rigidity of cantilevered columns for their lateral resistance.

Within these broad categories, structural systems are further classified in accordance with the quality of detailing provided and the resulting ability of the structure to withstand earthquake-induced inelastic, cyclic demands. Structures that are provided with detailing believed capable of withstanding large cyclic inelastic demands are typically termed “special” systems. Structures that are provided with relatively little detailing and therefore, incapable of withstanding significant inelastic demands are termed “ordinary.” Structures with limited levels of detailing and inelastic response capabilities are termed “intermediate.” Thus, within a type of structure, for example, moment-resisting steel frames or reinforced concrete bearing walls, it is possible to have “special” MRFs or bearing walls, “intermediate” MRFs or shear walls, and “ordinary” MRFs or shear walls. The various combinations of such systems and construction materials results in a wide selection of structural systems to choose from. The use of “ordinary” and “intermediate” systems, regarded as having limited capacity to withstand cyclic inelastic demands, is generally limited to SDC A, B, and C and to certain low-rise structures in SDC D.

19.5.6 Design Coefficients

Under the *NEHRP Provisions*, required seismic design forces and, therefore, required lateral strength is typically determined by elastic methods of analysis, based on the elastic dynamic response of structures to design ground shaking. However, since most structures are anticipated to exhibit inelastic behavior when responding to the design ground motions, it is recognized that linear response analysis does not provide an accurate portrayal of the actual earthquake demands. Therefore, when linear analysis methods are employed, a series of design coefficients are used to adjust the computed elastic response values to suitable design values that consider probable inelastic response modification. Specifically, these coefficients are the response modification factor, R , the overstrength factor, Ω_0 , and the deflection amplification coefficient, C_d . Tabulated values of these factors are assigned to a structure based on the selected structural system and the level of detailing employed in that structural system:

- The response modification coefficient, R , is used to reduce the required lateral strength of a structure, from that which would be required to resist the design ground motion in a linear manner to that required to limit inelastic behavior to acceptable levels, considering the characteristics of the selected structural system. Structural systems deemed capable of withstanding extensive inelastic behavior are assigned relatively high R values, as large as eight, permitting minimum design strengths that are only $\frac{1}{8}$ that required for elastic response to the design motion. Systems deemed to be incapable of providing reliable inelastic behavior are assigned low R values, approaching unity, requiring sufficient strength to resist design motion in a nearly elastic manner.
- The deflection amplification coefficient, C_d , is used to estimate the total elastic and inelastic lateral deformations of the structure when subjected to design earthquake ground motion. Specifically, lateral deflections calculated for elastic response of the structure to the design ground motion, reduced by the response modification coefficient R , are amplified by the factor C_d to obtain this estimate. The C_d coefficient accounts for the effects of viscous and hysteretic damping on structural response, as well as the effects of inelastic period lengthening. Structural systems that are deemed capable of developing significant amounts of viscous and hysteretic damping are assigned C_d values somewhat less than the value of the R coefficient. This results in an estimate of total lateral deformation that is somewhat lower than would be anticipated for a pure elastic response.

For structural systems with relatively poor capability to develop viscous and/or hysteretic damping, the C_d value may exceed R , resulting in estimates of lateral drift that exceed that calculated for elastic response.

- The overstrength coefficient, Ω_0 , is used to provide an estimate of the maximum force likely to be delivered to an element in the structure, considering that due to effects of system and material overstrength this may be larger than the force calculated by elastic analysis of the structure's response to design ground motion, reduced by the response modification coefficient R . This overstrength factor is used to compute the required strength to resist behavioral modes that have limited capacity for inelastic response, such as column buckling or connection failure in braced frames.

Figure 19.12 illustrates the basic concepts behind these design coefficients. The figure contains an elastic design response spectrum, an elastic response line, and an inelastic response curve for an arbitrary structure, all plotted in lateral inertial force (base shear) versus lateral roof displacement coordinates. Response spectra are more familiarly plotted in coordinates of spectral response acceleration (S_a) versus structural period (T). It is possible to convert a spectrum plotted in that form to the spectrum shown in the figure through a two-step process. The first step consists of converting the response spectrum for S_a versus T coordinates to S_a versus spectral response displacement (S_d) coordinates. This is performed using the following relationship between S_a , S_d , and T :

$$S_d = \frac{T^2}{4\pi^2} S_a \tag{19.3}$$

Then the response spectrum is converted to the form shown in the figure by recognizing that for a structure responding in a given mode of excitation the base shear is equal to the product of the mass participation factor for that mode, the structure's mass, and the spectral response acceleration, S_a , at that period. Similarly, the lateral roof displacement for a structure responding in that mode is equal to the spectral response displacement times the modal participation factor. For a single degree of freedom structure, the mass participation factor and modal participation factor are both unity and the lateral base shear, V , is equal to the product of the spectral response acceleration at the mode of response and the mass of the structure, while the lateral roof displacement is equal to the spectral response displacement.

The dashed diagonal line in the figure represents the elastic response of the arbitrary structure. It is a straight line because a structure responding in an elastic manner will have constant stiffness and, therefore, a constant proportional relationship between the applied lateral force and resulting

Figure 19.12 Schematic illustration of design coefficients.

displacement. The intersection of this diagonal line with the design response spectrum indicates the maximum total lateral base shear, V_E , and roof displacement, D_E , of the structure would develop if it responded to the design ground motion in an elastic manner. The third plot in the figure represents the inelastic response characteristics of this arbitrary structure, sometimes called a pushover curve. The pushover curve has an initial elastic region having the same stiffness as the elastic response line. The point V_y, D_y on the pushover curve represents the end of this region of elastic behavior. Beyond V_y, D_y , the curve is represented by a series of segments, with sequentially reduced stiffness, representing the effects of inelastic softening of the structure. The lateral base shear force, V_M , at the peak of the pushover curve, represents the maximum lateral force that the structure is capable of developing at full yield.

The response modification coefficient, R , is used in the provisions to set the minimum acceptable strength at which the structure will develop its first significant yielding, V_y . This is given by the simple relationship

$$V_y = \frac{V_E}{R} \quad (19.4)$$

The coefficient Ω_0 is used to approximate the full yield strength of the structure through the relationship

$$V_M = \Omega_0 V_y \quad (19.5)$$

The maximum total drift of the structure, D_I , is obtained from the relationship

$$D_I = C_d D_y \quad (19.6)$$

19.5.7 Analysis Procedures

The *NEHRP Provisions* permit the use of five different analytical procedures to determine the required lateral strength of a structure and to confirm that the structure has adequate stiffness to control lateral drift. The procedures permitted for a specific structure are dependent on the structure's SDC and its regularity.

19.5.7.1 Index Force Procedure

The index force procedure is permitted only for structures in SDC A. In this procedure, the structure must be designed to have sufficient strength to resist a static lateral force equal to 1% of the weight of the structure, applied simultaneously to each level. The forces must be applied independently in two orthogonal directions. Structures in SDC A are not anticipated ever to experience ground shaking of sufficient intensity to cause structural damage, provided that the structures are adequately tied together and have a complete LFRS. The nominal, 1%, lateral force function used in this procedure is intended as a means of ensuring that the structure has a complete LFRS of nominal, though somewhat arbitrary, strength. In addition to providing protection for the low levels of ground motion, anticipated for SDC A structures, this procedure is also considered to be a structural integrity provision, intended to provide nominal resistance against blast and other possible loading events.

19.5.7.2 Equivalent Lateral Force Analysis

The estimation of forces an earthquake may impose on a building can be accomplished by use of an equivalent lateral force (ELF) procedure. The ELF is commonly employed for simpler buildings and is provided in most building codes. The reader is referred to Hamburger (2002) for a review of building code and ELF development, but it will be noted that for many years the uniform building code (UBC) and other building codes determined the ELF according to variants on the equation $V = ZICKSW$, where V was the ELF or total design lateral force applied to the structure (or shear at the structure's base), determined from Z , a seismic zone factor varying between 0.075 (Zone 1, low-seismicity areas) and 0.40 (Zone 4, high-seismicity areas); I , an importance factor varying between 1.0 and 1.5; C , a function of the

structure's fundamental period T , which effectively defined a response spectral shape; K , a factor varying by type of structure that accounted for the ductility of the structure and its material; S , a factor to account for site soil conditions; and W , the total seismic dead load.

In the 2000 *NEHRP Provisions*, ELF analysis may be used for any structure in SDC B and C, for any structure of light-frame construction, and for all regular structures, with a calculated structural period, T , not greater than $3.5T_s$, where T_s is as previously defined in Figure 19.11. ELF analysis consists of a simple approximation to modal response spectrum analysis. It only considers the first mode of a structure's lateral response and presumes that the mode shape for this first mode of response is represented by that of a simple shear beam. For structures having sufficiently low periods of first mode response ($T < 3.5T_s$) and regular vertical and horizontal distribution of stiffness and mass, this procedure approximates modal response spectrum analysis well. However, for longer period structures, higher mode response becomes significant and neglecting these higher modes results in significant errors in the estimation of structural response. Also, as the distribution of mass and stiffness in a structure becomes irregular, for example, the presence of torsional conditions or soft story conditions, the assumptions inherent in the procedure with regard to mode shape also become quite approximate, leading to errors. In SDCs D, E, and F, this method is permitted only for those structures where these inaccuracies are unlikely to be significant. The procedure is permitted for more general use in other SDCs because it is felt that the severity of design ground motion is low enough that inaccuracies in analysis of lateral response is unlikely to result in unacceptable structural performance and also because it is felt that designers in these regions of low seismicity may not be able to implement the more sophisticated and accurate methods properly.

As with the index force analysis procedure, the ELF consists of the simultaneous application of a series of static lateral forces to each level of the structure in each of the two independent orthogonal directions. In each direction, the total lateral force, known as the base shear, is given by the formula

$$V = \frac{S_{DS}}{R/I} W \quad (19.7)$$

This formula gives the maximum lateral inertial force that acts on an elastic, single degree of freedom structure with a period that falls within the constant response acceleration (periods shorter than T_s) portion of the design spectrum, reduced by the term R/I . In this formula, S_{DS} is the design spectral response acceleration at short periods, W is the dead weight of the structure and a portion of the supported live load, R is the response modification coefficient, and I is an occupancy importance factor, assigned based on the structure's SUG. For SUG-1 structures, I is assigned a value of unity. For SUG II and III structures, I is assigned values of 1.25 and 1.5, respectively. The effect of I is to reduce the permissible response modification factor, R , for structures in higher SUGs, requiring that the structures have greater strength, thereby limiting the permissible inelasticity and damage in these structures.

The base shear force given by Equation 19.7 need never exceed the following:

$$V = \frac{S_{D1}}{(R/I)T} W \quad (19.8)$$

Equation 19.8 represents the maximum lateral inertial force that acts on an elastic, single degree of freedom structure with period T that falls within the constant response velocity portion of the design spectrum (periods longer than T_s), reduced by the response modification coefficient, R and the occupancy importance factor, I . In this equation, all terms are as previously defined except that S_{D1} is the design spectral response acceleration at 1 s. For short period structures, Equation 19.7 will control. For structures with periods in excess of T_s , Equation 19.8 will control.

The shape of the design response spectrum shown in Figure 19.11 is not representative of the dynamic characteristics of ground motion found close to the fault rupture zone. Such motions are often dominated by a large velocity pulse and very large spectral displacement demands. Therefore, for structures in SDCs E and F, the seismic design categories for structures located close to major active faults, the base

shear may not be taken less than the value given by Equation 19.9. Equation 19.9 approximates the effects of the additional long period displacements that have been recorded in some near field ground motion records

$$V = \frac{0.5S_1}{R/I} \quad (19.9)$$

The total, lateral base shear force given by Equations 19.7–19.9 must be distributed vertically for application to the various mass or diaphragm levels of the structure. For a structure with n levels, the force at diaphragm level x is given by the equation

$$F_x = C_{vx} V \quad (19.10)$$

where

$$C_{vx} = \frac{w_x h_x}{\sum_{i=1}^n w_i h_i} \quad (19.11)$$

h_x and h_i , respectively, are the heights of levels x and i above the structure's base. These formula are based on the assumption that the structure is responding in its first mode, in pure sinusoidal motion, and that the mode shape is linear. That is, it is assumed that at any instant of time, the displacement at level x of the structure is

$$\delta_x = \frac{h_x}{h_n} \delta_n \quad (19.12)$$

where δ_x and δ_n are the lateral displacements at level x and the roof of the structure, respectively, and h_n is the total height of the structure. For a structure responding in pure sinusoidal motion, the displacement δ_x , velocity v_x , and acceleration a_x , of level x at any instant of time, t , is given by the following equations:

$$\delta_x = \delta_{x \max} \sin\left(\frac{2\pi}{T} t\right) \quad (19.13)$$

$$v_x = \delta_{x \max} \frac{2\pi}{T} \cos\left(\frac{2\pi}{T} t\right) \quad (19.14)$$

$$a_x = -\delta_{x \max} \frac{4\pi}{T^2} \sin\left(\frac{2\pi}{T} t\right) \quad (19.15)$$

Since acceleration at level x is directly proportional to the displacement at level x , the acceleration at level x in a structure responding in pure sinusoidal motion is given by the equation

$$a_x = \frac{h_n}{h_x} a_n \quad (19.16)$$

where a_n is the acceleration at the roof level. Since the inertial force at level x is equal to the product of mass at level x and the acceleration at level x , Equation 19.11 can be seen to be an accurate distribution of lateral inertial forces in a structure responding in a linear mode shape.

The lateral forces given by Equation 19.10 are applied to a structural model of the building and the resulting member forces and building interstory drifts are determined. The analysis must consider the relative rigidity of both the horizontal and vertical elements of the LFRS, and when torsional effects are significant, must consider three-dimensional distributions of stiffness, centers of mass, and rigidity. The structure must then satisfy two basic criteria. First, the elements of the LFRS must have sufficient strength to resist the calculated member forces in combination with other loads, and second, the structure must have sufficient strength to maintain computed interstory drifts within acceptable levels. The specific load combinations that must be used to evaluate member strength and the permissible interstory drifts are described in succeeding sections.

In recognition of the fact that higher mode participation can result in significantly larger forces at individual diaphragm levels, than is predicted by Equation 19.11, forces on diaphragms are computed using an alternative equation, as follows:

$$F_{px} = \frac{\sum_{i=x}^n F_i}{\sum_{i=x}^n w_i} w_{px} \quad (19.17)$$

where F_{px} is the design force applied to diaphragm level x , F_i is the force computed from Equation 19.11 at level i , w_{px} is the effective seismic weight, at level x , and w_i is the effective weight at level i .

19.5.7.3 Response Spectrum Analysis

Response spectrum analysis is permitted to be used for the design of any structure. The procedure contained in the *NEHRP Provisions* uses standard methods of elastic modal dynamic analysis, which are not described here, but are well documented in the literature, for example, by Chopra (1981). The analysis must include sufficient modes of vibration to capture participation of at least 90% of the structure's mass in each of the two orthogonal directions. The response spectrum used to characterize the loading on the structure may be either the generalized design spectrum for the site, shown in [Figure 19.11](#), or a site-specific spectrum developed considering the regional seismic sources and site characteristics.

Regardless of the spectrum used, the ground motion is scaled by the factor (I/R), just as in the ELF technique. The *NEHRP Provisions* require that the member forces determined by response spectrum analysis be scaled so that the total applied lateral force in any direction be not less than 80% of the base shear calculated using the ELF method for regular structures nor 100% for irregular structures. This scaling requirement was introduced to ensure that assumptions used in building the analytical model does not result in excessively flexible representation of the structure and, consequently, an underestimate of the required strength.

19.5.7.4 Response History Analysis

Response history analysis is also permitted to be used for the design of any structure but, due to the added complexity, is seldom employed in practice except for special structures incorporating special base isolation or energy dissipation technologies. Either linear or nonlinear response history analysis is permitted to be used. When response history analysis is performed, input ground motion must consist of a suite of at least three pairs of orthogonal horizontal ground motion components, obtained from records of similar magnitude, source, distance, and site characteristics as the event controlling the hazard for the building's site. Each pair of orthogonal records must be scaled such that with a period range approximating the fundamental period of response of the structure, the square root of the sum of the squares of the orthogonal component ordinates envelopes 140% of the design response spectrum. Simple amplitude, rather than frequency domain scaling, is recommended. Actual records are preferred, though simulations may be used if a sufficient number of actual records representative of the design earthquake motion are not available. If a suite of less than seven records is used as input ground motion, the maximum of the response parameters (element forces and deformations) obtained from any of the records is used for design. If seven or more records are used, the mean values of the response parameters obtained from the suite of records may be used as design values. This requirement was introduced with the understanding that the individual characteristics of a ground motion record can produce significantly different results for some response quantities. It was hoped that this provision would encourage engineers to use larger suites of records and obtain an understanding of the variability associated with possible structural response.

When linear response history analyses are performed, the ground motion records, scaled as previously described, are further scaled by the quantity (I/R). The resulting member forces are combined with other loads, just as they would be if the ELF or response spectrum methods of analysis were performed.

When nonlinear response history analyses are performed, they must be used without further scaling. Rather than evaluating the strength of members using the standard load combinations considered with other analysis techniques, the engineer is required to demonstrate acceptable performance capability of the structure, given the predicted strength and deformation demands. The intention is that laboratory and other relevant data be used to demonstrate adequate behavior. This is a rudimentary introduction of performance-based design concepts, which will likely have significantly greater influence in future building codes.

19.5.8 Load Combinations and Strength Requirements

Structures must be proportioned with adequate strength to resist the forces predicted by the lateral seismic analysis together with forces produced by response to vertical components of ground shaking as well as dead and live loads. Unless nonlinear response history analysis is performed using ground motion records that include a vertical component of motion, the effects of vertical earthquake shaking are accounted for by the equation

$$E = Q_E \pm 0.2S_{DS}D \quad (19.18)$$

where Q_E are the element forces predicted by the lateral seismic analysis, S_{DS} is the design spectral response acceleration at a 0.2 s response period, and D are the forces produced in the element by the structure's dead weight. The term $0.2S_{DS}D$ represents the effect of vertical ground shaking response. For structures in zones of high seismicity, the term S_{DS} has a value approximating 1.0g and, therefore, the vertical earthquake effects are taken as approximately 20% increase or decrease in the dead load stress demands on each element. In fact, there are very few cases on record where structural collapse has been ascribed to the vertical response of a structure. This is probably because design criteria for vertical load resistance incorporate substantial factors of safety and also because most structures carry only a small fraction of their rated design live loads when they are subjected to earthquake effects. Therefore, most structures inherently have substantial reserve capacity to resist additional loading induced by vertical ground motion components. In recognition of this, most earlier codes neglected vertical earthquake effects. However, during the formulation of *ATC3.06*, it was felt to be important to acknowledge that ground shaking includes three orthogonal components. The resulting expression, which was somewhat arbitrary, ties vertical seismic forces to the short period design spectral response acceleration, as most structures are stiff vertically and have very short periods of structural response for vertical modes.

The earthquake forces on structural elements derived from Equation 19.18 are combined with dead and live loads in accordance with the standard strength level load combinations of *ASCE-7*. The pertinent load combinations are

$$Q = 1.4D \pm E \quad (19.19)$$

$$Q = 1.4D + 0.75(L + E) \quad (19.20)$$

where D , L , and E are the dead, live, and earthquake forces, respectively. Elements must then be designed to have adequate strength to resist these combined forces. The reduction factor of 0.75 on the combination of earthquake and live loads accounts for the low likelihood that a structure will be supporting full live load at the same time that it experiences full design earthquake shaking. An alternative set of load combinations is also available for use with design specifications that utilize allowable stress design formulations. These are essentially the same as Equations 19.19 and 19.20, except that the earthquake loads are further reduced by a factor of 1.4.

The *NEHRP Provisions* recognize that it is undesirable to allow some elements to experience inelastic behavior as they may be subject to brittle failure and in doing so compromise the ability of the structure to develop its intended inelastic response. The connections of braces to braced frames are an example of such elements. The *Provisions* also recognize that inelastic behavior in some elements, such as columns

supporting discontinuous shear walls, could trigger progressive collapse of the structure. For these elements, the earthquake force E that must be used in the load combination (Equations 19.19 and 19.20) is given by the formula:

$$E = \Omega_0 Q_E \pm 0.2 S_{DS} D \tag{19.21}$$

where the term $0.2 S_{DS} D$ continues to represent the effects of vertical ground shaking response and the term $\Omega_0 Q_E$ represents an estimate of the maximum force likely to be developed in the element as a result of lateral earthquake response, considering the inelastic response characteristics of the entire structural system. In Equation 19.20, the term $\Omega_0 Q_E$ need never be taken larger than the predicted force on the element derived from a nonlinear analysis or plastic mechanism analysis.

19.5.9 Drift Limitations

It is important to control lateral drift in structures because excessive drift can result in extensive damage to cladding and other nonstructural building components. In addition, excessive lateral drift can result in the development of $P-\Delta$ instability and collapse.

Lateral drift is evaluated on a story by story basis. Story drift, δ , is computed as the difference in lateral deflection at the top of a story and that at the bottom of the story, as predicted by the lateral analysis. If the lateral analysis was other than a nonlinear response history analysis, design story drift, Δ , is obtained from the computed story drift, δ , by the equation:

$$\Delta = C_d \delta \tag{19.22}$$

where C_d is the design coefficient previously discussed. The design interstory drift computed from Equation 19.22 must be less than a permissible amount, dependent on the SUG and structural system as given in Table 19.8.

The provisions require evaluation of potential $P-\Delta$ instability through consideration of the quantity θ given by the equation:

$$\theta = \frac{P_x \Delta}{V_x h_x C_d} \tag{19.23}$$

In this equation, P_x is the dead weight of the structure above story x , Δ is the design story drift, computed from Equation 19.22, V_x is the design story shear obtained from the lateral force analysis, h_x is the story height, and C_d is the coefficient previously discussed. If the quantity θ computed by this equation is found to be less than 0.1, $P-\Delta$ effects may be neglected. If the quantity θ is greater than 0.1, $P-\Delta$ effects must be directly considered in performing the LFA. If the quantity θ exceeds 0.3, the structure should be considered potentially unstable and must be redesigned.

This approach to $P-\Delta$ evaluation has remained essentially unchanged since its initial introduction in ATC3.06. It was introduced in that document as a placeholder, pending the development of a more

TABLE 19.8 Permissible Drift Limits^a

Structure	Seismic use group		
	I	II	III
Structures other than masonry shear wall or masonry wall-frame structures, four stories or less in height with interior walls, partitions, ceilings, and exterior wall systems that have been designed to accommodate the story drifts	0.025 h_{sx} ^b	0.020 h_{sx}	0.015 h_{sx}
Masonry cantilever shear wall structures ^c	0.010 h_{sx}	0.010 h_{sx}	0.010 h_{sx}
Other masonry shear wall structures	0.007 h_{sx}	0.007 h_{sx}	0.007 h_{sx}
Masonry wall-frame structures	0.013 h_{sx}	0.013 h_{sx}	0.010 h_{sx}
All other structures	0.020 h_{sx}	0.015 h_{sx}	0.010 h_{sx}

^a There shall be no drift limit for single-story structures with interior walls, partitions, ceilings, and exterior wall systems that have been designed to accommodate the story drifts.

^b h_{sx} is the story height below Level x .

^c Structures in which the basic structural system consists of masonry shear walls designed as vertical elements cantilevered from their base or foundation support which are so constructed that moment transfer between shear walls (coupling) is negligible.

accurate method for evaluating drift-induced instability. Obvious deficiencies in this current approach include the fact that it evaluates drift effects at the somewhat artificial design-base shear levels. A more realistic evaluation would consider the actual expected lateral deformations of the structure as well as the yield level shear capacity of the structure at each story. As contained in the current provisions, evaluation of $P-\Delta$ effects seldom controls a structure's design.

19.5.10 Structural Detailing

Structural detailing is a critical feature of seismic-resistant design but is not generally specified by the *NEHRP Provisions*. Rather, the Provisions adopt detailing requirements contained in standard design specifications developed by the various materials industry associations including the American Institute of Steel Construction, the American Concrete Institute, the American Forest Products Association, and the Masonry Society. Other chapters in this handbook present the requirements of these various design standards.

Glossary

- Attenuation** — The rate at which earthquake ground motion decreases with distance.
- Base shear** — The total lateral force for which a structure is designed using equivalent lateral force techniques.
- Characteristic earthquake** — A relatively narrow range of magnitudes at or near the maximum that can be produced by the geometry, mechanical properties, and state of stress of a fault (Schwartz and Coppersmith 1987).
- Completeness** — Homogeneity of the seismicity record.
- Cripple wall** — A carpenter's term indicating a wood frame wall of less than full height T , usually built without bracing.
- Critical damping** — The value of damping such that free vibration of a structure will cease after one cycle ($\zeta_{crit} = 2 m\omega$).
- Damage** — Permanent, cracking, yielding, or buckling of a structural element or structural assemblage.
- Damping** — Energy dissipation that occurs in a dynamically deforming structure, either as a result of frictional forces or structural yielding. Increased damping tends to reduce the amount that a structure responds to ground shaking.
- Degradation** — A behavioral mode in which structural stiffness or strength is reduced as a result of inelastic behavior.
- Design (basis) earthquake** — The earthquake (as defined by various parameters, such as PGA, response spectra, etc.) for which the structure will be, or was, designed.
- Ductile detailing** — Special requirements, such as for reinforced concrete and masonry, close spacing of lateral reinforcement to attain confinement of a concrete core, appropriate relative dimensioning of beams and columns, 135° hooks on lateral reinforcement, hooks on main beam reinforcement within the column, etc.
- Ductile frames** — Frames required to furnish satisfactory load-carrying performance under large deflections (i.e., ductility). In reinforced concrete and masonry this is achieved by ductile detailing.
- Ductility factor** — The ratio of the total displacement (elastic plus inelastic) to the elastic (i.e., yield) displacement.
- Elastic** — A mode of structural behavior in which a structure displaced by a force will return to its original state upon release of the force.
- Fault** — A zone of the earth's crust within which the two sides have moved — faults may be hundreds of miles long — from one to over one hundred miles deep, and not readily apparent on the ground surface.

- Ground shaking** — A random, rapid cyclic motion of the ground produced by an earthquake.
- Hysteresis** — A form of energy dissipation that is related to inelastic deformation of a structure.
- Inelastic** — A mode of structural behavior in which a structure, displaced by a force, exhibits permanent unrecoverable deformation.
- Lateral force resisting system (LFRS)** — A structural system for resisting horizontal forces due, for example, to earthquake or wind (as opposed to the vertical force resisting system, which provides support against gravity).
- Liquefaction** — A process resulting in a soil's loss of shear strength due to a transient excess of pore water pressure.
- Magnitude** — A unique measure of an individual earthquake's release of strain energy, measured on a variety of scales, of which the moment magnitude M_w (derived from seismic moment) is preferred.
- Mass participation** — That portion of total mass of a multidegree of freedom structure that is effective in a given mode of response.
- MCE** — Maximum considered earthquake — the earthquake intensity forming the basis for design in the *NEHRP Provisions*.
- Mode shape** — A deformed shape in which a structure can oscillate freely when displaced.
- Natural mode** — A characteristic dynamic property of a structure in which it will oscillate freely.
- Nonductile frames** — Frames lacking ductility or energy absorption capacity due to lack of ductile detailing — ultimate load is sustained over a smaller deflection (relative to ductile frames) and for fewer cycles.
- Participation factor** — A mathematical relationship between the maximum displacement of a multi-degree of freedom structure and a single degree of freedom structure.
- Peak ground acceleration (PGA)** — The maximum amplitude of recorded acceleration (also termed the ZPA, or zero period acceleration).
- Period** — The amount of time it takes a structure that has been displaced in a particular natural mode and then released to undergo one complete cycle of motion.
- Pounding** — The collision of adjacent buildings during an earthquake due to insufficient lateral clearance.
- Response spectrum** — A plot of maximum amplitudes (acceleration, velocity, or displacement) of a single degree of freedom oscillator (sdof), as the natural period of the sdof is varied across a spectrum of engineering interest (typically, for natural periods from 0.03 to 3 or more seconds, or frequencies of 0.3 to 30+ Hz).
- Reverse fault** — A fault that exhibits dip-slip motion, where the two sides are in compression and move away toward each other.
- Seismic risk** — The product of the hazard and the vulnerability (i.e., the expected damage or loss, or the full probability distribution).
- Soft story** — A story of a building significantly less stiff than adjacent stories (i.e., the lateral stiffness is 70% or less than that in the story above, or less than 80% of the average stiffness of the three stories above; BSSC 1994).
- Spectral acceleration** — The maximum response acceleration that a structure of given period will experience when subjected to a specific ground motion.
- Spectral displacement** — The maximum response displacement that a structure of given period will experience when subjected to a specific ground motion.
- Spectral velocity** — The maximum response velocity that a structure of given period will experience when subjected to a specific ground motion.
- Spectrum amplification factor** — The ratio of a response spectral parameter to the ground motion parameter (where parameter indicates acceleration, velocity, or displacement).
- Viscous** — A form of energy dissipation that is proportional to velocity.
- Yielding** — A behavioral mode in which a structural displacement increases under application of constant load.

20.1 Introduction

Bridges are very important elements in the modern transportation system. Recent earthquakes, particularly the 1989 Loma Prieta and the 1994 Northridge Earthquakes in California, the 1995 Hyogo-Ken Nanbu Earthquake in Japan, the 1999 Jiji Earthquake in Taiwan, and the 1999 Kocaeli Earthquake in Turkey, have caused collapse of, or severe damage to, a considerable number of major bridges [1,2]. Since the 1989 Loma Prieta Earthquake in California [3], extensive research [4–18] has been conducted on seismic design and retrofit of bridges in Japan and the United States, especially in California.

*Much of the material of this chapter was taken from Duan, L. and Chen, W.F., Chapter 19: Bridges, in Earthquake Engineering Handbook, Chen, W.F. and Scawthorn, C., Ed., CRC Press, Boca Raton, FL, 2002.

This chapter first addresses the seismic bridge design philosophies and conceptual design in general, then discusses mainly the U.S. seismic design practice to illustrate the process, and finally presents briefly seismic design practice in Japan.

20.2 Earthquake Damages to Bridges

Past earthquakes have shown that the damage induced in bridges can take many forms depending on the ground motion, site conditions, structural configuration, and specific details of the bridge [1]. Damage within the superstructure has rarely been the primary cause of collapse. Most of the severe damage to bridges has taken one of the following forms [1]:

- *Unseating of the superstructure at in-span hinges or simple supports due to inadequate seat lengths or restraint.* A skewed, curved, or complex superstructure framing configuration further increases the vulnerability. [Figure 20.1](#) shows the collapsed upper and lower decks of the eastern portion of the San Francisco–Oakland Bay Bridge (SFOBB) in the 1989 Loma Prieta Earthquake, which can be attributed to anchor bolt failures allowing the span to move. [Figure 20.2](#) shows collapsed I-5 Gavin Canyon Undercrossing, California, in the 1994 Northridge Earthquake, which can be attributed to geometric complexities arising from 66° skew angle abutments, in-span expansion joints, as well as the inadequate 300 mm seat width. For simply supported bridges, these failures are most likely when ground failure induces relative motion between the spans and their supports.
- *Column brittle failure due to deficiencies in shear capacity and inadequate ductility.* In reinforced concrete columns, the shear capacity and ductility concerns usually stem from inadequate lateral and confinement reinforcement. [Figure 20.3](#) shows the collapsed 600 m of Hanshin Expressway in the 1995 Hyogo-Ken Nanbu Earthquake in Japan where failure was attributed to deficiencies in shear design and poor ductility. In steel columns, the inadequate ductility usually stems from progressive local buckling, fracture, and global buckling leading to collapse.
- *Unique failures in complex structures.* [Figure 20.4](#) shows the collapsed Cypress Street Viaduct, California, in the 1989 Loma Prieta Earthquake where the unique vulnerability was the inadequately reinforced pedestal above the first level. In outrigger column bents, the vulnerability may be in the cross-beam or the beam–column joint.

20.3 Seismic Design Philosophies

20.3.1 Design Evolution

Seismic bridge design has been improving and advancing, based on research findings and lessons learned from past earthquakes. In the United States, prior to the 1971 San Fernando Earthquake, the seismic design of highway bridges was partially based on lateral force requirements for buildings.

FIGURE 20.4 Collapse of Cypress Viaduct, California, in the 1989 Loma Prieta Earthquake.

Lateral loads were considered as levels of 2 to 6% of dead loads. In 1973, California Department of Transportation (Caltrans) developed new seismic design criteria (SDC) related to site, seismic response of the soils at the site, and dynamic characteristics of bridges. The American Association of State Highway and Transportation Officials (AASHTO) modified the Caltrans 1973 Provisions slightly and adopted Interim Specifications. Applied Technology Council (ATC) developed guidelines ATC-6 [19] for seismic design of bridges in 1981. AASHTO adopted ATC-6 as the Guide Specifications in 1983 and in 1991 incorporated it into the Standard Specifications for Highway Bridges [20].

Prior to the 1989 Loma Prieta Earthquake, bridges in California were typically designed using a single-level force-based design approach based on a “no-collapse” design philosophy. Seismic loads were determined based on a set of soil conditions and a suite of four site-based standard acceleration response spectra (ARS). Structures were analyzed using the three-dimensional elastic dynamic multimodal response spectrum analysis method. Structural components were designed to resist forces from the response spectrum analysis that were modified with a “Z-factor.” The “Z-factor” was based on the individual structural element ductility and degree of risk. Minimum transverse reinforcement levels were required to meet confinement criteria [21].

Since 1989, the design criteria specified in Caltrans design manuals [21–27] have been updated continuously to reflect recent research findings and development in the field of seismic bridge design. Caltrans has been shifting toward a displacement-based design approach emphasizing element and system capacity design. For important bridges in California the performance-based project-specific design criteria [28–30] have been developed since 1989.

FHWA updated its *Seismic Design and Retrofit Manual for Highway Bridges* in 1995 [31,32]. ATC published the improved SDC recommendations for California bridges [33] in 1996 and for U.S. bridges and highway structures [34] in 1997. Caltrans published the performance and displacement-based Seismic Design Criteria Version 1.3 [35] in 2004, which focuses mainly on concrete bridges, and the Guide Specifications for Seismic Design of Steel Bridge (*Guide*) [36] in 2001. Most recently, the NCHRP 12-49 team developed a new set of LFRD Guidelines (*Guidelines*) for the seismic design of highway bridges [37], compatible with the AASHTO-LFRD Bridge Design Specifications [38]. Significant advances in earthquake engineering were made during the last decade of the twentieth century.

20.3.2 No-Collapse-Based Design

The basic design philosophy is to prevent bridges from collapsing during severe earthquakes [24–27,35–37] that have only a small probability of occurring during the useful life of the bridge. To prevent collapse, two alternative approaches are commonly used in design. The first is a conventional force-based approach where the adjustment factor Z for ductility and risk assessment [21], or the response modification factor R [20,37], is applied to elastic member forces obtained from a response spectra analysis or an equivalent static analysis. The second approach is a more recent displacement-based approach [24,35] where displacements are a major consideration in design. For more detailed information, references can be made to comprehensive discussions in *Seismic Design and Retrofit of Bridges* by Prietley et al. [16], *Bridge Engineering Handbook* by Chen and Duan [39], and Refs [40,41].

20.3.3 Performance-Based Design

Following the 1989 Loma Prieta Earthquake, bridge engineers [3] have faced three essential challenges:

- Ensure that earthquake risks posed by new construction are acceptable.
- Identify and correct unacceptable seismic safety conditions in existing structures.
- Develop and implement the rapid, effective, and economic response mechanism for the recovering structural integrity after damaging earthquakes.

Performance-based project-specific criteria [28–30] and design memoranda [24] have been developed and implemented for the design and retrofitting of important bridges by California bridge engineers. These performance-based criteria included guidelines for development of site-specific ground motion estimates, ductile design details to preclude brittle failure modes, rational procedures for concrete joint shear design, and the definition of limit states for various performance objectives [15]. The performance-based criteria usually require a two-level design approach. The first level of design is to ensure the performance (service) of a bridge in small-magnitude earthquake events that may occur several times during the life of the bridge. The second level of design is to achieve the performance (no collapse) of a bridge under severe earthquakes that have only a small probability of occurring during the useful life of the bridge. [Figure 20.5](#) shows a flowchart for development of performance-based SDC.

20.4 Seismic Conceptual Design

Bridge design is a complex engineering process involving consideration of numerous important factors, such as bridge structural systems, materials, dimensions, foundations, esthetics, and local landscape and surrounding environment [16,42]. Selecting an appropriate earthquake-resisting system (ERS) to resolve the potential conflicts between the configuration and seismic performance should be completed as early as possible in the design effort. For a desirable seismic resistant design, the following guidelines may be useful:

- Bridge type, component and member dimensions, and esthetics shall be investigated to reduce the seismic demands to the greatest extent possible. Esthetics should not be the primary reason for producing undesirable frame and component geometry.
- Bridges should ideally be as straight as possible. Curved bridges complicate and potentially magnify seismic responses.
- Superstructures should be continuous with as few joints as possible. Necessary restrainers and sufficient seat width shall be provided between adjacent frames at all expansion joints, and at the seat-type abutments to eliminate the possibility of unseating during a seismic event.
- Support skew angles should be as small as possible, that is, abutments and piers should be oriented as close to perpendicular to the bridge longitudinal axis as practical (within 20 to 25°) even at the expense of slightly increasing the bridge length. Highly skewed abutments and piers are vulnerable to damage from undesired rotational response and increased seismic displacement demands.

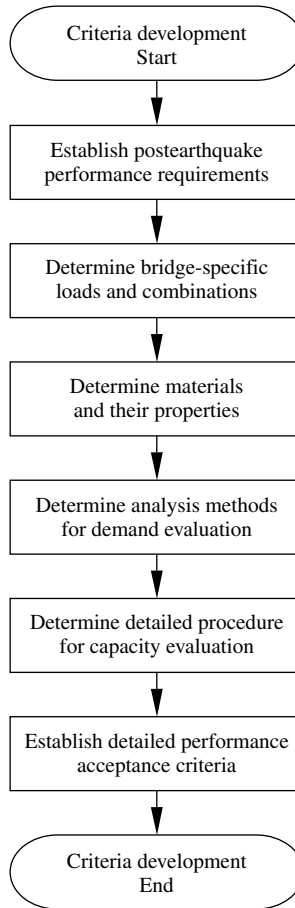

FIGURE 20.5 Development of performance-based seismic design criteria.

- Adjacent frames or piers should be proportioned to minimize the differences in the fundamental periods and skew angles, and to avoid drastic changes in stiffness and strength in both the longitudinal and transverse directions. Dramatic changes in stiffness can result in damage to the stiffer frames or piers. It is strongly recommended [35] that the effective stiffness between any two bents within a frame, or between any two columns within a bent, not vary by a factor of more than two. Similarly, it is highly recommended that the ratio of the shorter fundamental period to the longer fundamental period for adjacent frame in the longitudinal and transverse directions be larger than 0.7.
- Structural configurations that cannot accommodate the recommendations must be capable of accommodating the associated large relative displacement without compromising structural integrity. Each frame shall provide a well-defined load path with predetermined plastic hinge locations and utilize redundancy whenever possible. Balanced mass and stiffness distribution (Figure 20.6) in a frame results in a structure response that is more predictable and is more likely to respond in its fundamental mode of vibration. Simple analysis tools can then be used to predict the structures response with relative accuracy, whereas irregularities in geometry increase the likelihood of complex nonlinear response that is difficult to accurately predict by elastic modeling or plane frame inelastic static analysis. The following various techniques may be used to achieve balanced geometry to create a uniform and more predictable structure response [43]:
 - a. Adjust foundation rotational and translation stiffness (e.g., use oversized pile shafts).
 - b. Adjust effective column lengths (e.g., lower footings, provide isolation casings).

FIGURE 20.6 Frame stiffness [35].

- c. Modify end fixities.
- d. Reduce/redistribute superstructure mass.
- e. Vary the column cross-section and longitudinal reinforcement ratios.
- f. Add or relocate columns/piers.
- g. Modify the hinge/expansion joint layout.

In the event of other constraints preventing the designer from achieving balance between frames of a bridge, the following recommendations may be considered [35]:

- a. Isolate adjacent frames longitudinally by providing a large expansion gap to reduce the likelihood of pounding.
- b. Provide adequate seat width to prevent unseating at hinges. Seat extenders may be used; however, they should be isolated transversely to avoid transmitting large lateral shear forces between frames.
- c. Limit the transverse shear capacity between frames to prevent large lateral forces from being transferred to the stiffer frame.

- d. Avoid placing hinge seats between unbalanced frames by placing expansion joints between frames with short cantilever spans that butt up to one another.
- Seismic protective devices, that is, energy dissipation and isolation devices may be provided at appropriate locations, thereby reducing the seismic force effects. The energy dissipation devices are to increase the effective damping of the structure thereby reducing forces, deflections, and impact loads. Isolation devices are to lengthen the fundamental mode of vibration and to isolate potentially large superstructure inertial loads from the substructure so that structure is subject to lower earthquake forces.
 - For concrete bridges, structural components shall be proportioned to direct inelastic damage into the columns, pier walls, and abutments. The superstructure shall have sufficient overstrength to remain essentially elastic if the columns/piers reach their most probable plastic moment capacity. The superstructure-to-substructure connection for nonintegral caps may be designed to fuse prior to generating inelastic response in the superstructure. Concrete columns shall be well proportioned, moderately reinforced, and easily constructed. The girders, bent caps, and columns shall be proportioned to minimize joint stresses. Moment-resisting connections shall have sufficient joint shear capacity to transfer the maximum plastic moments and shears without joint distress.
 - Initial sizing of columns should be based on slenderness ratios, bent cap depth, compressive dead-to-live load ratio, and service loads. Columns shall demonstrate dependable postyield displacement capacity without an appreciable loss of strength. Thrust–moment–curvature ($P-M-\Phi$) relationships should be used to verify a column's satisfactory performance under service and seismic loads. Abrupt changes in the cross-section and the bending capacity of columns should be avoided. Columns must have sufficient rotation capacity to achieve the target displacement ductility requirements.
 - For steel bridges, structural components shall be generally designed to ensure that inelastic deformation only occur in the specially detailed ductile substructure elements. Inelastic behavior in the form of controlled damage may be permitted in some of the superstructure components such as end cross-frames or diaphragms, shear keys, and bearings. The inertial forces generated by the deck must be transferred to the substructure through girders, trusses, cross-frames, lateral bracings, end diaphragms, shear keys, and bearings. As an alternative, specially designed ductile end-diaphragms may be used as structural fuses to reduce potential damage in other parts of the structure.
 - Steel multicolumn bents or towers shall be designed as ductile moment-resisting frames (MRFs) or ductile braced frames such as concentrically braced frames (CBFs) and eccentrically braced frames (EBFs). For components expected to behave inelastically, elastic buckling (local compression and shear, global flexural, and lateral torsion) and fracture failure modes shall be avoided. All connections and joints should preferably be designed to remain essentially elastic. For MRFs, the primary inelastic deformation shall preferably be columns. For CBFs, diagonal members shall be designed to yield when members are in tension and to buckle inelastically when they are in compression. For EBFs, a short beam segment designated as a “link” shall be well designed and detailed to provide ductile structural behavior.
 - The ATC/MCEER recommended LRFD *Guidelines* [37] classify the ERS into permissible and not recommended categories (Figure 20.7 to Figure 20.11) based on consideration of the most desirable seismic performance ensuring wherever possible postearthquake serviceability. Figure 20.12 shows design approaches for the permissible ERS.

20.5 Seismic Performance Criteria

20.5.1 ATC/MCEER Guidelines

Table 20.1 gives the seismic performance criteria for highway bridges specified in the proposed ATC/MCEER *Guidelines* [37]. As a minimum, a bridge shall be designed for the life safety level of

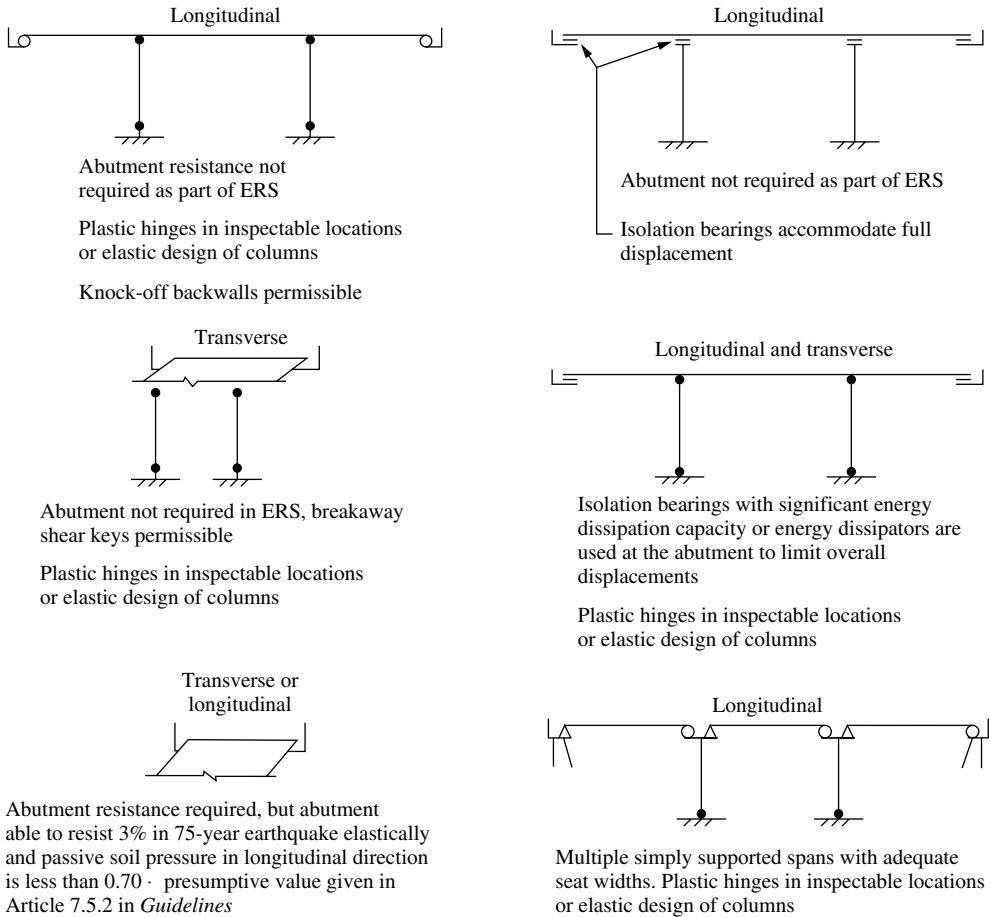

FIGURE 20.7 Permissible earthquake resisting systems [37].

performance. Higher level of performance may be required depending upon the bridge’s importance and owner’s requirements.

The seismic performance criteria shown in Table 20.1 shall be achieved by the following design objectives:

- *Columns as primary energy dissipation mechanism.* The main objective is to force the inelastic deformations to occur primarily in the columns in order that the earthquake damage can be easily inspected and readily repaired after an earthquake. The amount of longitudinal steel in the reinforced columns should be minimized to reduce foundation and connection costs.
- *Abutments as an additional energy dissipation mechanism.* The objective is to expect the inelastic deformations to occur in the columns as well as the abutments in order to either minimize column size and reduce ductility demand on the column.
- *Isolation bearings as main energy dissipation mechanism.* The objective is to lengthen the period of a relatively stiff bridge and which results in a lower design seismic force. Energy dissipation will occur in the isolation bearings and columns are usually then expected to perform elastically.
- *Structural components between deck and columns/abutments as energy dissipation mechanism.* The objective is to design ductile components that do not result in reduced design force but will reduce the ductility demands on the columns in order to minimize the energy that is dissipated in the plastic hinge zone of columns.

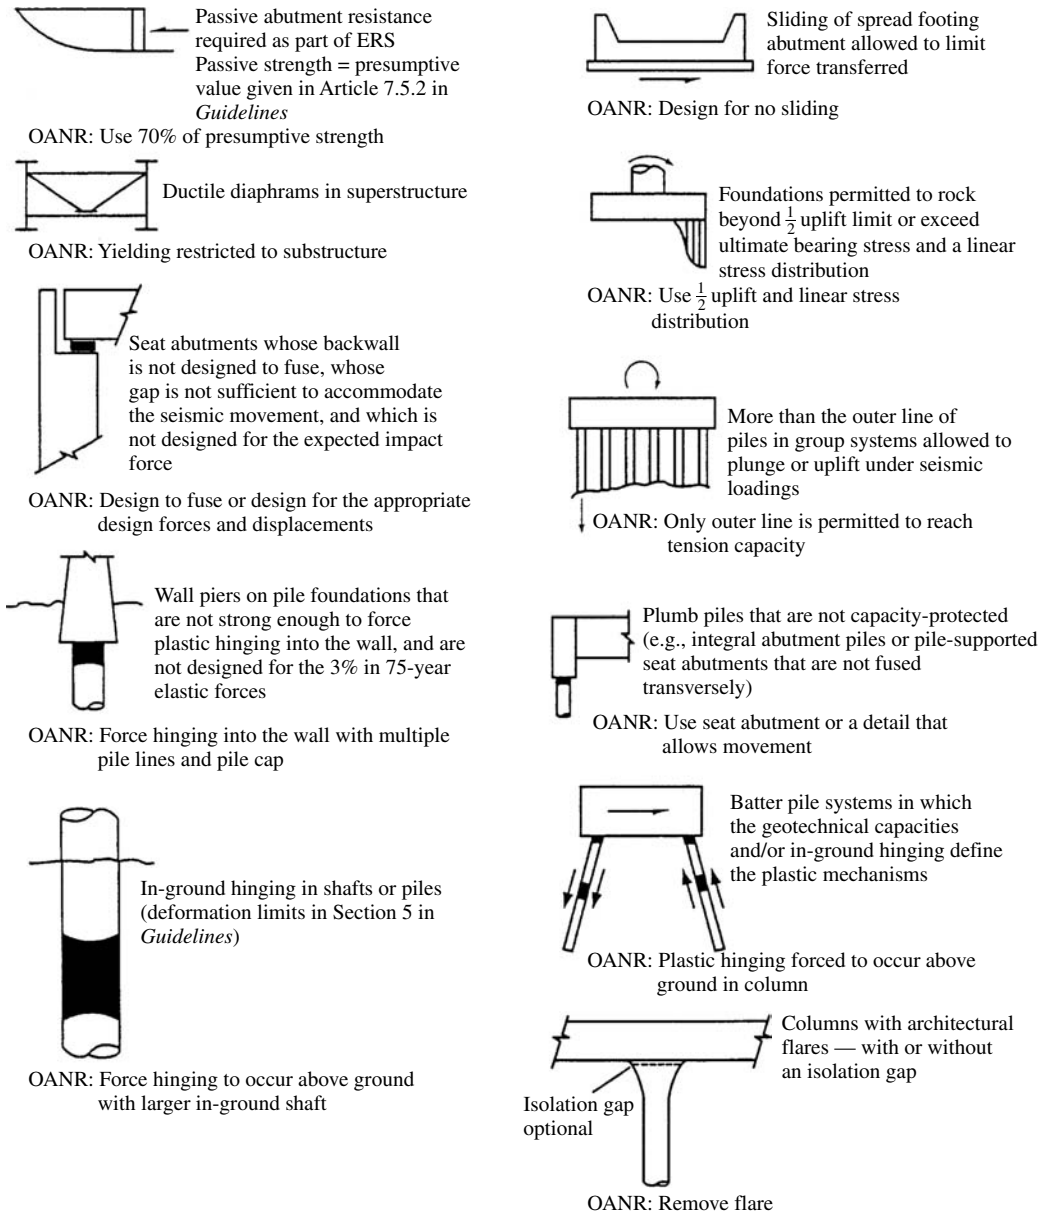

FIGURE 20.8 Permissible earthquake resisting elements [37].

- *Replaceable/renewable sacrificial plastic hinge elements as energy dissipation mechanism.* The objective is to control damage and permit significant inelastic deformation to occur at a specially designed replaceable/renewable sacrificial plastic hinge elements in the plastic hinge zone of a column. The concept is similar to the conventional ductile design concept that permits significant inelastic deformation in the plastic hinge zone of a column. The difference compared with the conventional ductile design is that construction details in the plastic hinge zone of concrete columns provide a replaceable/renewable sacrificial plastic hinge elements. The concept has been extensively tested [44] but has not been used in practice.

20.5.2 Caltrans

Table 20.2 outlines Caltrans seismic performance criteria [24] including the bridge classification, the service, and damage levels established in 1994 [15]. A bridge is categorized as “Important” or “Ordinary.”

For Standard “Ordinary” bridges, the displacement-based one-level safety-evaluation design (“no-collapse” design) is only required in the Caltrans SDC [35]. Nonstandard “Ordinary” bridges feature irregular geometry and framing (multilevel, variable width, bifurcating, or highly horizontally

Note: OANR means a design alternate where owners approval is not required and a higher level of analysis (pushover in SDAP E) can be avoided.

FIGURE 20.9 Permissible earthquake resisting elements that require owner’s approval [37].

curved superstructures, varying structure types, outriggers, unbalanced mass and stiffness, high skew) and unusual geologic conditions (soft soil, moderate to high liquefaction potential and proximity to an earthquake fault). In this case, project-specific criteria need to be developed to address their nonstandard features.

For important bridges such as the San Francisco-Oakland Bay Bridge and the Benicia-Martinez Bridge or structures in a designated lifeline route, performance-based project-specific two-level seismic design criteria [28–30] are required.

FIGURE 20.10 Earthquake resisting elements that are not recommended for new bridges (ATC/MCEER Joint Venture, 2001).

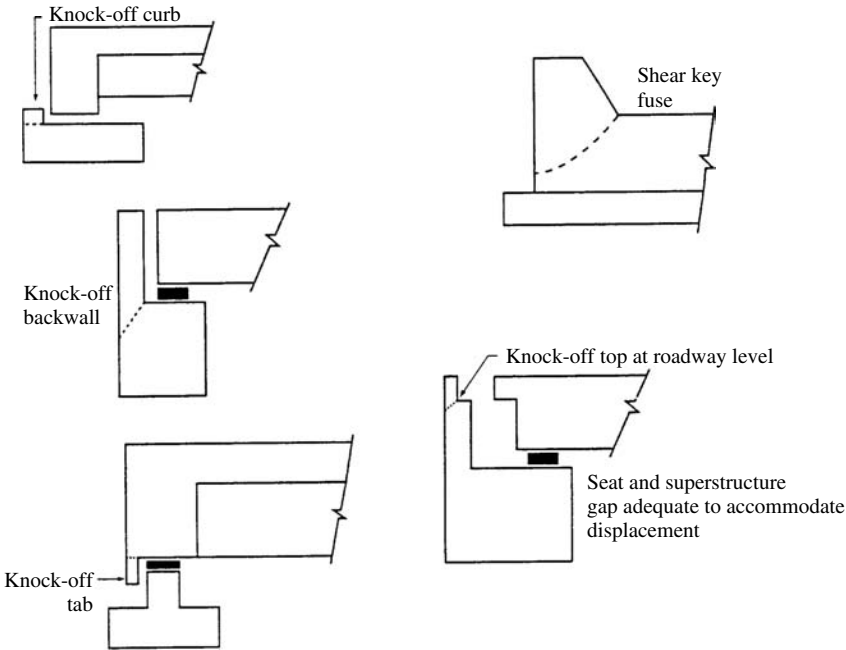

FIGURE 20.11 Methods of minimizing damage to abutment foundation [37].

The SDC shown in Table 20.2 shall be achieved by the following design objectives:

- All bridges shall be designed to withstand deformation imposed by the design earthquake.
- All structure components have sufficient strength and ductility to ensure collapse will not take place during the maximum credible earthquake (MCE). Ductile behavior can be provided by inelastic actions either through selected structural members and through protective systems — seismic isolations and energy dissipation devices.
- Inelastic behavior shall be limited to the preidentified locations, that is, ductile components explicitly designed for ductile performance, within the bridge that are easily inspected and

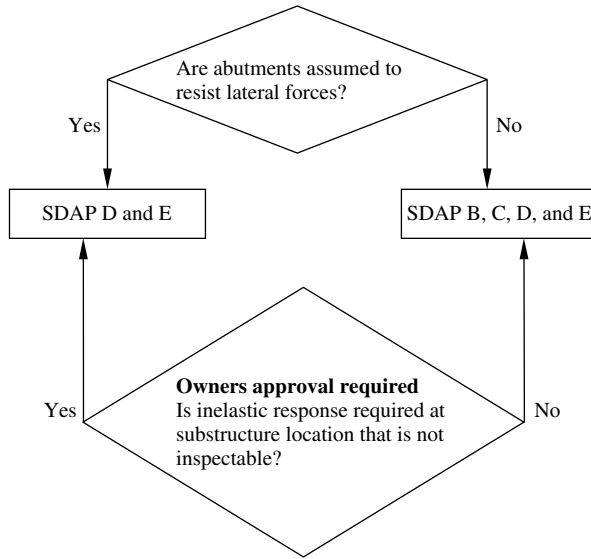

FIGURE 20.12 Design approaches for permissible earthquake resisting systems [37].

repaired following an earthquake. Because inelastic response of a concrete superstructure is difficult to inspect and repair and superstructure damage may cause a bridge to be unserviceable after an earthquake, inelastic behavior on most concrete bridges should be preferably be located in columns, pier walls, backwalls, and wingwalls.

- Structural components not explicitly designed for ductile performance, that is, capacity-protected components shall be designed to remain essentially elastic. That is, (1) response in concrete components shall be limited to minor cracking or limited to force demands not exceeding the nominal strength capacity determined by current Caltrans SDC [35] and (2) response in steel components shall be limited to force demands not exceeding the nominal strength capacity determined by the current Caltrans *Guide* [36]. To assure the yielding mechanism occurs in the desired location, the capacity design principle is used by providing overstrength for those capacity-protected components.

20.6 Seismic Design Approaches

20.6.1 ATC/MCEER Guidelines [37]

20.6.1.1 Seismic Loads

Seismic loads are represented by the design response spectrum curve for a damping ratio of 5% (Figure 20.13):

$$S_a = \begin{cases} 0.6 \frac{S_{DS}}{T_0} T + 0.4 S_{DS} & \text{for } T \leq T_0 = 0.2 T_s \\ S_{DS} & \text{for } T_0 < T \leq T_s = \frac{S_{D1}}{S_{DS}} \\ \frac{S_{D1}}{T} & \text{for } T > T_s \end{cases} \quad (20.1)$$

$$S_{DS} = F_a S_s \quad (20.2)$$

$$S_{D1} = F_v S_1 \quad (20.3)$$

TABLE 20.1 Recommended LRFD Guidelines. Design Earthquakes and Seismic Performance Objectives [37]

Probability of exceedance for design earthquake ground motions ^a		Performance level ^b	
		Life safety	Operational
Rare earthquake (MCE) 3% PE in 75 years/1.5 mean deterministic	Service ^c Damage ^d	Significant disruption Significant	Immediate Minimal
Expected earthquake 50% PE in 75 years	Service Damage	Immediate Minimal	Immediate Minimal to none

^a The upper-level earthquake considered in the *Guidelines* is designated the Maximum Considered Earthquake or MCE. In general the ground motions or national MCE ground motion maps have a probability of exceedance (PE) of approximately 3% PE in 75 years. However, adjacent to highly active faults, ground motions on MCE maps are bounded deterministically as described in the Commentary for Article 3.2 [46]. When bounded deterministically, MCE ground motions have a probability of exceedance higher than 3% PE in 75 years not to exceed 1.5 times the mean deterministic values. The performance objective for the expected earthquake is either explicitly included as an elastic design for the 50% PE in 75-year force level or results implicitly from design for the 3% PE in 75-year force level.

^b *Performance levels:* These are defined in terms of their anticipated performance objectives in the upper level earthquake. Life safety — In an MCE event, the bridge should not collapse but partial or complete replacement may be required. Since a dual level design is required, the life safety performance level will have immediate service and minimal damage for the expected design earthquake; Operational — For both rare and expected earthquakes, the bridge should be immediate service and minimal damage.

^c *Service levels:* Immediate — Full access to normal traffic shall be available to traffic following an inspection of the bridge; Significant disruption — Limited access (reduced lanes, light emergency traffic) may be possible after shoring; however, the bridge may need to be replaced.

^d *Damage levels:* None — Evidence of movement may be present but no notable damage; Minimal — Some visible signs of damage. Minor inelastic response may occur, but postearthquake damage is limited to narrow flexural cracking in concrete and the onset of yielding in steel. Permanent deformations are not apparent, and any repairs could be made under nonemergency conditions with the exception of superstructure joints; Significant — Although there is no collapse, permanent offsets may occur and damage consisting of cracking, reinforcement yield, and major spalling of concrete and extensive yielding and local buckling of steel columns, global and local buckling of steel braces, and cracking in the bridge deck slabs at shear studs on the seismic load path is possible. These conditions may require closure to repair the damage. Partial or complete replacement of columns may be required in some cases. For sites with lateral flow due to liquefaction, significant inelastic deformation is permitted in the piles, whereas for all other sites the foundations are capacity-protected and no damage is permitted in the pile. Partial or complete replacement of the columns and piles may be necessary if significant lateral flow occurs. If replacement of columns or other components is to be avoided, the design approaches producing minimal or moderate damage such as seismic isolation or the control and reparability design concept should be assessed.

where S_{DS} is the design earthquake response spectral acceleration at short periods, S_{D1} is the design earthquake response spectral acceleration at 1-s period, S_s is the 0.2-s period spectral acceleration on Class B rock from national ground motion maps [45], S_1 is the 1-s period spectral acceleration on Class B rock from national ground motion maps [45], F_a is the site coefficient (Table 20.3) for the short-period portion of the design response spectrum curve, and F_v is the site coefficient (Table 20.4) for the long-period portion of the design response spectrum curve.

For Site Class F, which is not included in the Table 20.5, such as soils vulnerable to potential failure or collapse under seismic loading, such as liquefiable soils, quick and highly sensitive clays, and collapsible weakly cemented soils, site-specific geotechnical investigation and dynamic site response analyses shall be performed [37].

The effects of vertical ground motion may be ignored if the bridge site is located more than 50 km from an active fault. If the bridge is located within 10 km of an active fault, site-specific response spectra and acceleration time histories including vertical ground motions shall be considered.

TABLE 20.2 Caltrans Seismic Performance Criteria [24]

Ground motions at the site	Level of damage and postearthquake service	
	Ordinary bridge	Important bridge
Functional — evaluation ground motion	Service: immediate Damage: repairable	Service: immediate Damage: minimal
Safety — evaluation ground motion	Service: limited Damage: significant	Service: immediate Damage: repairable

Definition

Important bridge: A bridge meets one or more of the following requirements:

- Required to provide postearthquake life safety; such as access to emergency facilities.
- Time for restoration of functionality after closure would create a major economic impact.
- Formally designed as critical by a local emergency plan.

Ordinary bridge: Any bridge not classified as an important bridge.

Functional — evaluation ground motion (FEGM): This ground motion may be assessed either deterministically or probabilistically. The determination of this event is to be reviewed by a Caltrans-approved consensus group.

Safety — evaluation ground motion (SEGM): This ground motion may be assessed either deterministically or probabilistically. The deterministic assessment corresponds to the maximum credible earthquake (MCE). The probabilistic ground motion for the safety evaluation typically has a long return period (approximately 1000 to 2000 years).

MCE: The largest earthquake that is capable of occurring along an earthquake fault, based on current geologic information as defined in the 1996 Caltrans Seismic Hazard Map.

Service levels

- *Immediate:* Full access to normal traffic is available almost immediately following the earthquake.
- *Limited:* Limited access (e.g., reduced lanes, light emergency traffic) is possible with days of the earthquake. Full service is restorable within months.

Damage levels

- *Minimal:* Essentially elastic performance.
- *Repairable:* Damage that can be repaired with a minimum risk of losing functionality.
- *Significant:* A minimum risk of collapse, but damage that would require closure to repair.

F	a.0	a.0	a.0	a.0	a.0

^a Site-specific geotechnical investigation and dynamic site response analysis shall be performed. For purpose of defining seismic hazard levels, Type E values may be used for Type F soils.

Note: Use straight line interpolation for intermediate values of S_s .

TABLE 20.5 Recommended LRFD *Guidelines* — Site Classification [37]

Site class	\bar{v}_s (m/s)	\bar{N} or \bar{N}_{ch} (blows/0.3 m)	\bar{s}_u (kPa)
E	<180	<15	<50
D	180 to 360	15 to 50	50 to 100
C	360 to 760	>50	>100
B	760 to 1500	—	—
A	>1500	—	—

Notes:

\bar{v}_s is the average shear wave velocity for top 30 m of a site.

\bar{N} is the average standard penetration test blow count for top 30 m of a site.

\bar{N}_{ch} is the average standard penetration test blow count for cohesionless layers of top 30 m of a site.

\bar{s}_u is the average undrained shear strength of cohesive layers for top 30 m of a site.

Seismic force effects from different vibration modes shall be combined. For modal response closely spaced in frequency and ground motion in one direction, the complete quadratic combination (CQC) method shall be used. For combining the contribution of orthogonal and uncorrelated ground motion components to a single seismic load case, the square root sum of the squares (SSRC) method or 100 to 40% rule shall be used.

For a bending moment, the combination rules are as follows:

SSRC combination:

$$M_x = \sqrt{(M_x^T)^2 + (M_x^L)^2 + (M_x^V)^2} \tag{20.4}$$

100 to 40% combination:

$$M_x^{LC1} = 1.0M_x^T + 0.4M_x^L + 0.4M_x^V \tag{20.5}$$

$$M_x^{LC2} = 0.4M_x^T + 1.0M_x^L + 0.4M_x^V \tag{20.6}$$

$$M_x^{LC3} = 0.4M_x^T + 0.4M_x^L + 1.0M_x^V \tag{20.7}$$

For circular columns, the vector moments and axial forces shall be obtained for biaxial design:

SSRC combination:

- For bridges with skew angle less than 10°, the maximum of $\sqrt{M_x^2 + (0.4M_y)^2}$ and $\sqrt{M_y^2 + (0.4M_x)^2}$ with the maximum axial load $\pm P$
- For bridges with skew angle greater than 10°, $\sqrt{M_x^2 + M_y^2}$ with the maximum axial load $\pm P$

100 to 40% combination:

- The maximum of $\sqrt{(M_x^{LC1})^2 + (M_y^{LC1})^2}$ and $\sqrt{(M_x^{LC2})^2 + (M_y^{LC2})^2}$ and $\sqrt{(M_x^{LC3})^2 + (M_y^{LC3})^2}$ with the maximum axial load $\pm P$

where subscripts x and y represent two horizontal axes, $x-x$ and $y-y$, respectively; superscripts L , T , and V indicate the longitudinal, transverse, and vertical directions, respectively; and superscripts LC1, LC2, and LC3 are load cases 1, 2, and 3, respectively.

20.6.1.2 Seismic Design and Analysis Procedures (SDAP)

Depending on the seismic hazard levels specified in Table 20.6, each bridge shall be designed, analyzed, and detailed in accordance with Table 20.6.

20.6.1.2.1 Single-Span Bridges

Single-span bridges need not be analyzed for seismic loads and design requirements are limited to the minimum seat widths and connection forces, which shall not be less than the product of $F_a S_s / 2.5$ and the tributary permanent load.

20.6.1.2.2 SDAP A1 and A2

For low seismicity areas, only minimum seat widths and connection design forces for bearings and minimum shear reinforcement in concrete columns and piles in the seismic design requirement (SDR) 2 are deemed necessary for the life safety performance objective. The primary purpose is to ensure that the connections between the superstructure and its supporting substructures remain intact during the design earthquake. SDAP A1 and A2 require that the horizontal design connection forces in the restrained directions shall not be taken to be less than 0.1 and 0.25 times the vertical reactions due to tributary permanent loads and assumed existing live loads, respectively.

TABLE 20.6 Recommended LRFD Guidelines — SHL, SDAP, and SDR [37]

Seismic hazard level (SHL)	Seismic design and analysis procedure (SDAP) and seismic design requirements (SDR)					
	$S_{D1} (F_v S_1)$	$S_{DS} (F_a S_s)$	Life safety		Operational	
			SDAP	SDR	SDAP	SDR
I	$0.15 < S_{D1} \leq 0.15$	$0.15 < S_{DS} \leq 0.15$	A1	1	A2	2
II	$0.15 < S_{D1} \leq 0.25$	$0.15 < S_{DS} \leq 0.35$	A2	2	C/D/E	3
III	$0.25 < S_{D1} \leq 0.40$	$0.35 < S_{DS} \leq 0.60$	B/C/D/E	3	C/D/E	5
IV	$0.40 < S_{D1}$	$0.60 < S_{DS}$	C/D/E	4	C/D/E	6

20.6.1.2.3 SDAP B — No-Analysis Approach

The no-analysis approach allows for the bridge to be designed for all nonseismic requirements without a seismic demand analysis and the capacity design principle is used for all components connected to columns. For geotechnical design of the foundations, the moment overstrength capacity of columns that frame into the foundation, $M_{po} = 1.0M_n$, where M_n is nominal moment capacity of a column. SDAP B applies only to regular bridges meeting the following restrictions:

- The maximum span length is less than both 80 m and 1.5 times the average span length.
- The maximum skew angle is less than 30° .
- The ratio of the maximum interior bent stiffness to the average bent stiffness of the bridge is less than 2.
- The subtended angle in the horizontally curved bridges is less than 30° .
- For frames in which the superstructure is continuous over the bents and some bents do not participate in the ERS, $F_v S_1 (N_{bent}/N_{ers}) < 0.4 \cos \alpha_{skew}$, where N_{bent} and N_{ers} are total number of bents in the frame and number of bents participating in the ERS in the longitudinal direction, respectively; and α_{skew} is the skew angle of the bridge.
- $F_v S_1 < 0.4 \cos \alpha_{skew}$.
- The bridge site has a low potential for liquefaction and the piers are not seated on spread footing.
- For concrete column and pile bents, column axial load, $P_e < 0.15f'_c A_g$ (f'_c is specified minimum concrete compression strength and A_g is gross cross-sectional area of column); longitudinal reinforcement ratio, $\rho_l > 0.008$; column transverse dimension, $D > 300$ mm; and maximum column moment–shear ratio, $M/VD < 6$.
- For concrete wall piers with low volumes of longitudinal steel, $P_e < 0.1f'_c A_g$; $\rho_l > 0.0025$; wall thickness or smallest cross-sectional dimension, $t > 300$ mm; and $M/Vt < 10$.
- For steel pile bents framing into concrete caps, $P_e < 0.15P_y$ (P_y is axial yield force of steel pile); pile dimension about the weak axis bending at the ground level, $D_p > 250$ mm; and $L/b < 10$ (L is the length from point of maximum moment to the inflexion point of the pile when subjected to a pure transverse load and b is the flange width; for a cantilever column in a pile bent configuration, L is equal to the length above ground to the top of the bent plus 3 pile diameters).
- For timber piles framing into concrete caps or steel moment–frame columns, $P_e < 0.1P_c$ (and P_c is axial compression capacity of the pile or the column); $D_p > 250$ mm; and $M/VD_p < 10$.

20.6.1.2.4 SDAP C — Capacity Spectrum Design Method

The capacity spectrum design method combines a demand and capacity analysis and is conceptually the same as the Caltrans displacement-based design method. The primary difference is that the SDAP C begins with nonseismic design and then assesses the adequacy of the displacement. The key equations is the relationship between the seismic coefficient C_s and displacement, Δ :

$$C_s \Delta = \left(\frac{F_v S_1}{2\pi B_L} \right)^2 g \quad (20.8)$$

$$C_s = \frac{F_a S_s}{B_S} \quad (20.9)$$

where B_L is the response reduction factor for long period structures as specified in Table 20.7, B_S is the response reduction factor for short period structures as specified in Table 20.7, g is the acceleration due to gravity (9.8 m/s^2), and Δ is the lateral displacement of the pier; taken as 1.3 times the yield displacement of the pier when the long period equation governs.

The lesser of Equations 20.8 and 20.9 shall be used to assess C_s for two-level earthquakes. The required lateral strength of the bridge is $V_n = C_s W$ where W is the weight of the bridge responding

TABLE 20.7 Recommended LRFD *Guidelines* — Capacity Spectrum Response Reduction Factors for Bridge with Ductile Piers [37]

Earthquake	Performance level	B_s	B_L
50% PE in 75-year	Life safety	1	1
	Operational	1	1
3% PE in 75-year/1.5 mean deterministic	Life safety	2.3	1.6
	Operational	1	1

to earthquake ground motion. The procedure applies only to bridges that behave essentially as a single degree-of-freedom system and very regular bridges satisfying the following requirements:

- The number of spans per frame does not exceed six.
- The number of spans per frame is at least three, unless seismic isolation bearings are utilized at the abutments.
- The maximum span length is less than both 60 m and 1.5 times the average span length in a frame.
- The maximum skew angle is less than 30° and skew of piers or bents differs by less than 5° in the same direction.
- The subtended angle in the horizontally curved bridges is less than 20°.
- The ratio of the maximum bent or pier stiffness to the average bent stiffness is less than 2, including the effects of foundation.
- The ratio of the maximum lateral strength (or seismic coefficient) to the average bent strength is less than 1.5.
- Abutment shall not be assumed to resist the significant forces in both the transverse and longitudinal directions. Pier wall substructures must have bearings to permit transverse movement.
- For concrete column and pile bents, $P_e \leq 0.2f'_c A_g$; $\rho_l > 0.008$; and $D > 300$ mm.
- Piers and bents must have pile foundations when the bridge site has a potential for liquefaction.

20.6.1.2.5 SDAP D — Elastic Response Spectrum Method

The elastic response spectrum method uses either the uniform load or multimode method of analysis by considering cracked section properties. The analysis shall be performed for the governing design earthquakes, either the 50% PE (probability of exceedence) in 75-year or the 3% PE in 75-year/1.5 mean deterministic earthquake. Elastic forces obtained from analyses shall be modified using the response modification factor R .

20.6.1.2.6 SDAP E — Elastic Response Spectrum Method with Displacement Capacity Verification

SDAP E is a two-step design procedure. The first step is the same as SDAP D and the second step is to perform a two-dimensional nonlinear static (push over) analysis to verify substructure displacement capacity.

20.6.1.3 Response Modification Factor R

It is generally recognized that it is uneconomical, sometimes impractical, and impossible to design a bridge to resist large earthquake elastically. Columns are assumed to deform inelastically where seismic forces exceed their design levels, which is established by dividing the elastically computed force effects by the response modification factor R . The R -factors specified in the following were based on an evaluation of existing test data, engineering judgement, and the equal displacement principle as shown in Figure 20.14. It is used in principle for the conventional ductile design.

For substructures

$$R = 1 + (R_B - 1) \frac{T}{T^*} \leq R_B \quad (20.10)$$

FIGURE 20.14 Basis for conventional ductile design [37].

TABLE 20.8 Recommended LRFD Guidelines — Base Response Modification Factor for Substructures, R_B (ATC/MCEER Joint Venture, 2001)

Substructure element	Performance objective			
	Life safety		Operational	
	SDAP D	SDAP E	SDAP D	SDAP E
Wall-type pier — large dimension	2.0	3.0	1.0	1.5
Columns — single and multiple	4.0	6.0	1.5	2.5
Pile bents and drilled shafts — vertical piles — above ground	4.0	6.0	1.5	2.5
Pile bents and drilled shafts — vertical piles — 2 diameters below ground level — no owners approval required	1.0	1.5	1.0	1.0
Pile bents and drilled shafts — vertical piles — in ground — owners approval required	N/A	2.5	N/A	1.5
Pile bents with batter piles	N/A	2.5	N/A	1.5
Seismically isolated structures	1.5	1.5	1.0	1.5
Steel-braced frame — ductile components	3.0	4.5	1.0	1.5
Steel-braced frame — normally ductile components	1.5	2.0	1.0	1.0
All elements for expected earthquake	1.3	1.3	0.9	0.9

Notes:

1. The substructure design forces resulting from the elastic analysis divided by the appropriate R -factor for SDAP E can not be reduced below 70% at the R -factored reduced forces or the 50% PE in 75-year design forces as part of the pushover analysis.
2. There may be design situation (e.g., architecturally oversized column) where a designer opts to design the column for an $R=1$ (i.e., elastic design). In concrete columns the associate elastic design shear may be obtained from the elastic analysis forces using an R -factor of 0.67 or by calculating the design shear by the capacity design procedures using a flexural overstrength factor of 1.0. In steel-braced frame if an $R=1.0$ is used the connection design forces shall be obtained using an $R=0.67$. If an $R=1.0$ is used in any design the foundation shall be designed for elastic forces plus the SDR detailing requirements are required for concrete piles (i.e., minimum shear requirements).
3. Unless specifically stated, the R -factor applies to both steel and concrete.
4. N/A means that owners approval is required and thus the use of SDAP E is required.

where R_B is the base response modification factor specified in Table 20.8, T is the natural period of the structure, $T^* = 1.25T_s$ where T_s is as defined in Section 20.6.1.1.

For connections (superstructure to abutment; expansion joints within a span of the superstructure, columns, piers, or pile bents to cap beam or superstructure; and column or piers to foundations), an R -factor of 0.8 shall be used for those cases where capacity design principles are not used to develop the design forces to design the connections. It is assumed that if the $R < 1.5$, columns should remain essentially elastic for design earthquake; if $1.5 < R < 3.0$, columns should be repairable; if $R > 3.0$ significant plastic hinging may occur and the column may not be repairable; however, collapse is still prevented.

20.6.1.4 Capacity Design Principle

The main objective of the capacity design principle is to ensure the desirable mechanisms can dissipate significant amounts of energy and inelastic deformation (plastic hinging) occurs at expected locations (at top and bottom of columns) where they can be readily inspected and repaired. To achieve this objective, the overstrength force effects developed from the plastic hinges in columns shall be dependably resisted by column shear and adjoining elements such as cap beams, spread footing, pile cap, and foundations. The moment overstrength capacity (M_{po}) can be assessed using one of the following approaches:

$$\bullet M_{po} = \begin{cases} 1.5M_n & \text{for concrete column} \\ 1.2M_n & \text{for steel column, } M_n \text{ based on expected yield strength} \\ 1.3M_n & \text{for concrete filled steel tubes} \\ 1.5M_n & \text{for steel piles in weak axis bending and for steel members} \\ & \text{in shear (e.g., eccentrically braced frames)} \\ 1.0M_n & \text{for geotechnical design force in SDR3} \end{cases} \quad (20.11)$$

- For reinforce concrete columns [46]

$$M_{po} = M_{bo} \left[1 - \left(\frac{P_e - P_b}{P_{to} - P_b} \right)^2 \right] \quad (20.12)$$

where

P_e = axial compression load based on gravity load and seismic (framing) action

P_b = axial compression capacity at the maximum nominal (balanced) moment on the section

$$= 0.425 \beta_1 f'_c A_g$$

β_1 = compression stress block factor ≤ 0.85

P_{to} = axial tensile capacity of the column = $-A_{st}f_{su}$

A_{st} = area of longitudinal reinforcement

f_{su} = ultimate tensile strength of the longitudinal reinforcement

$$M_{bo} = K_{shape} A_{st} f_{su} D' + P_b D \left(\frac{1 - \kappa_0}{2} \right) \quad (20.13)$$

D' = pitch circular diameter of the reinforcement in a circular section or the out-to-out dimension of the reinforcement in a rectangular section, this generally may be assumed as $= 0.8D$

$$K_{shape} = \begin{cases} 0.32 & \text{for circular sections} \\ 0.375 & \text{for square sections with 25\% of the longitudinal} \\ & \text{reinforcement placed in each face} \\ 0.25 & \text{for walls with strong axis bending} \\ 0.5 & \text{for walls with weak axis bending} \end{cases} \quad (20.14)$$

κ_0 = a factor related to the centroid of compression stress block and should be taken as 0.6 and 0.5 for circular and rectangular sections, respectively.

It should be pointed out that Equations 20.12 and 20.13 are rearranged in the simpler format given above.

- For reinforced concrete column, a moment–curvature section analysis taking into account the expected strength, confined concrete properties, and strain hardening effects of longitudinal reinforcement.
- For a steel column, nominal flexural resistance (M_n) shall be determined either in accordance with the AASHTO-LRFD [38] or

$$M_n = 1.18M_{px} \left[1 - \frac{P_u}{A_g F_{ye}} \right] \leq M_{px} \tag{20.15}$$

A_g = gross cross-sectional area of a steel column
 F_{ye} = expected specified minimum yield strength of steel
 M_{px} = plastic moment under pure bending calculated using F_{ye}
 P_u = factored axial compression load

20.6.1.5 Plastic Hinge Zones

The plastic hinge zones (L_p) for typical concrete and steel columns, pile bents, and drilled shaft and zones of a columns above a footing or above an oversized in-ground drilled shaft shall be the maximum of the following:

For reinforced concrete columns

$$L_p = \text{maximum of } \begin{cases} D_{\max} \\ \frac{L}{6} \\ D \left(\cot \theta + \frac{\tan \theta}{2} \right) \\ 1.5 \left(0.08 \frac{M}{V} + 4000 \varepsilon_y d_b \right) \\ \frac{M}{V} \left(1 - \frac{M_y}{M_{po}} \right) \\ 450 \text{ mm} \end{cases} \tag{20.16}$$

where

D = transverse column dimension in the direction of bending
 D_{\max} = maximum cross-sectional dimension of a column
 d_b = diameter of longitudinal reinforcement
 L = clear height of a column
 M = maximum column moment
 V = maximum column shear
 M_y = column yield moment
 ε_y = yield strain of longitudinal reinforcement
 θ = principal crack angle
 $= \tan^{-1}((1.6/\Lambda)(\rho_v/\rho_t)(A_v/A_g))^{0.25}$ with $\theta \geq 25^\circ$ and $\theta \geq \tan^{-1}(D'/L)$
 A_v = shear area of concrete which may be taken as $0.8A_g$ and $b_w d$ for a circular section and a rectangular section, respectively
 ρ_v = ratio of transverse reinforcement
 ρ_t = volumetric ratio of longitudinal reinforcement
 Λ = fixity factor taken as 1 for fixed-pinned and 2 for fixed-fixed ends

For steel columns:

$$L_p = \text{maximum of } \begin{cases} \frac{L}{8} \\ 450 \text{ mm} \end{cases} \tag{20.17}$$

For a flared column, the plastic hinge zone shall be extended from the top of column to a distance equal to the maximum of the above criteria below the bottom of the flare. The areas within the

plastic hinge zones shall be detailed to assure ductile element behavior (e.g., providing confinement reinforcement in concrete columns or inelastic local buckling behavior in steel columns).

20.6.2 Caltrans Seismic Design Criteria

20.6.2.1 Seismic Loads

For ordinary bridges, safety-evaluation ground motion is based on deterministic assessment corresponding to the MCE, the largest earthquake, which is capable of occurring based on current geologic information. A set of ARS curves developed by ATC-32 are adopted as standard horizontal ARS curves in conjunction with the peak rock acceleration from the Caltrans Seismic Hazard Map 1996 to determine the horizontal earthquake forces. Figure 20.15 shows typical ARS curves. Vertical acceleration shall be considered for bridges with nonstandard structural components, unusual site conditions, and/or close

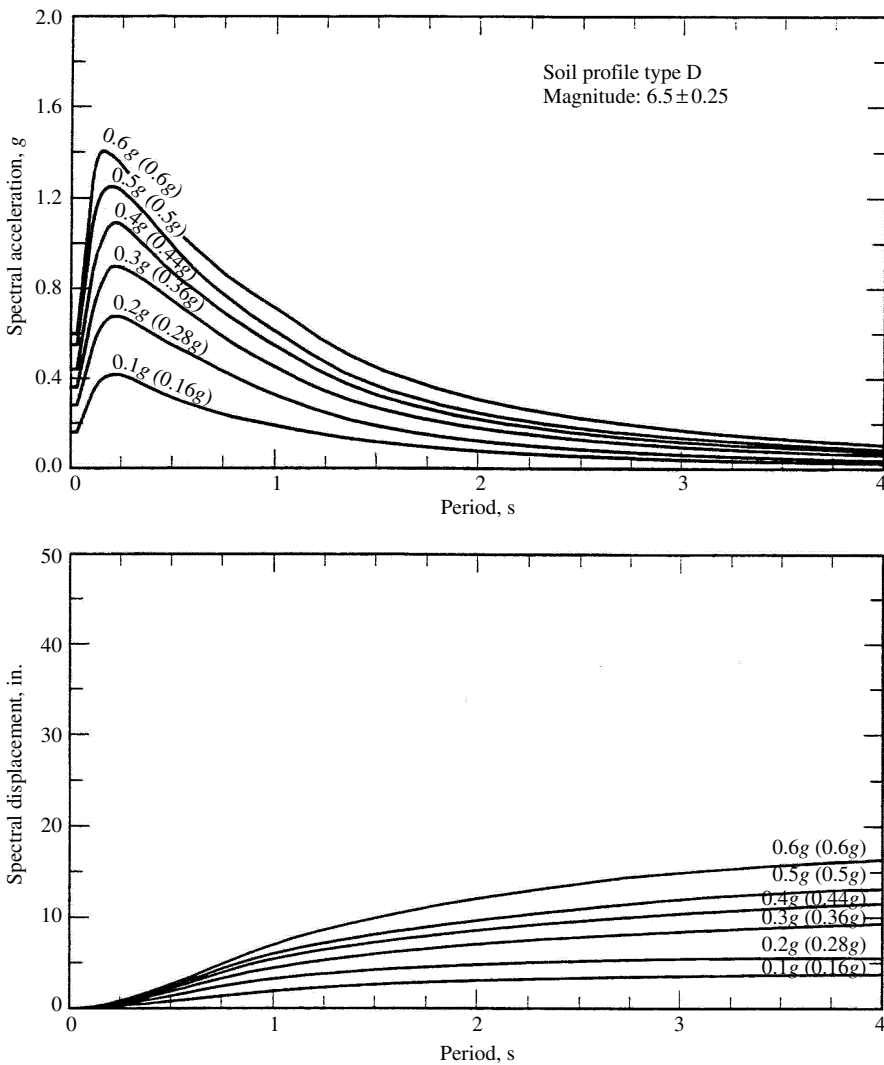

FIGURE 20.15 Typical Caltrans ARS curves [35].

Note: Peak ground acceleration values not in parentheses are for rock (soil profile type B) and peak ground acceleration values in parentheses are for soil profile type D.

proximity to earthquake faults and can be approximated by an equivalent static vertical force applied to the superstructure.

For structures within 15 km from an active fault, the spectral ordinates of the appropriate standard ARS curves shall be increased by 20%. For long period structures ($T \geq 1.5$ s) on deep soil sites (depth of alluvium ≥ 75 m) the spectral ordinates of the appropriate standard ARS curves shall be increased by 20% and the increase applies to the portion of the curves with periods greater than 1.5 s.

20.6.2.2 Design Approaches

The displacement-based design approach is used to ensure that the structural system and its individual components have enough displacement capacities to withstand the deformation imposed by the design earthquake. Using displacements rather than forces as a measurement of earthquake damages allows a structure to fulfill the required functions.

The displacements of the global system and the local ductile system shall satisfy the following requirement:

$$\Delta_D \leq \Delta_C \quad (20.18)$$

where Δ_D is the displacement demand determined by the global analysis, the stand-alone analysis, or the larger of the two if both types of analyses are necessary and Δ_C is the displacement capacity when any plastic hinge capacity reaches its ultimate capacity.

In a displacement-based analysis, proportioning of the structure is made first based on strength and stiffness requirements. The appropriate seismic analysis is performed and the resulting displacements are compared to the displacement capacity, which is dependent on the formation and rotational capacity of plastic hinges and can be evaluated by an inelastic static pushover analysis. This procedure has been used widely in seismic bridge design in California since 1994. Figure 20.16 shows the design flowchart for the ordinary standard bridges.

20.6.2.3 Displacement Demands on Bridges and Ductile Components

Seismic demands on bridge systems and ductile components are measured in terms of displacements rather than forces. Displacement demands shall be estimated from either equivalent static analysis (ESA) or elastic dynamic analysis (EDA, i.e., elastic response spectrum analysis) for typical bridge periods of 0.7 to 3 s. Attempts should be made to design bridges with dynamic characteristics (mass and stiffness) so that the fundamental period falls within the region between 0.7 and 3 s where the equal displacement principle applies. For short period bridges, linear elastic analysis typically underestimates displacement demands. In these cases, the inability to accurately predict displacements can be overcome by either designing the bridge to perform elastically, multiplying the elastic displacement from analysis by an amplification factor, or using seismic isolation and energy dissipation devices to limit seismic response. For long period ($T > 3$ s) bridges, a linear elastic analysis generally overestimates displacements and a linear elastic displacement response spectrum analysis should be used.

20.6.2.4 Force Demands on Capacity-Protected Components

Seismic demands on capacity-protected components, such as superstructures, bent caps, and foundations, are measured in terms of forces rather than displacements. Force demands for capacity-protected components shall be determined by the joint-force equilibrium considering plastic hinging capacity of the ductile component multiplied by an overstrength factor of 1.2. The overstrength factor accounts for the possibility that the actual ultimate plastic moment strength of the ductile component exceeds its estimated idealized plastic capacity based on the expected properties. This overstrength factor (1.2) is utilized not only to determine the demands on the capacity-protected members, but is also used to determine shear demands on the columns themselves.

20.6.2.5 Seismic Capacity

20.6.2.5.1 General

Strength and displacement capacities of a ductile flexural element shall be evaluated by moment–curvature analysis based on the expected material properties and anticipated damages. The impact the second-order

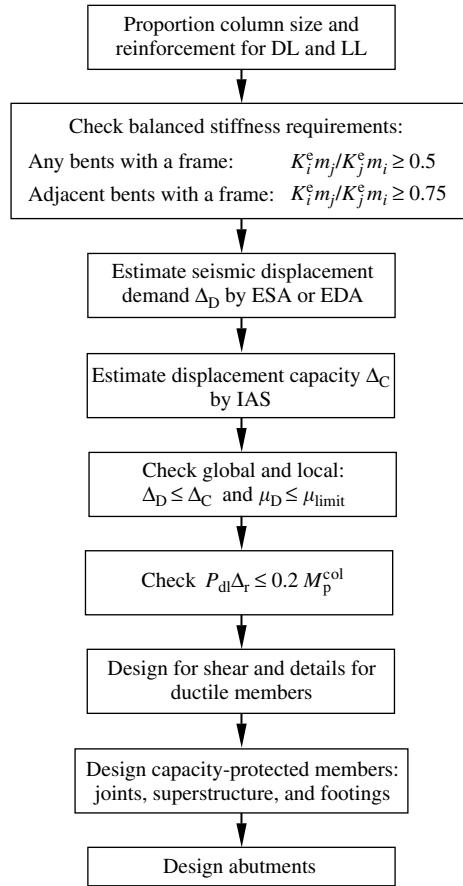

FIGURE 20.16 Caltrans seismic procedure for ordinary standard bridges.

$P-\Delta$ effect on the strength and displacement capacities of all members subjected to combined bending and compression shall be considered. Components may require redesign if the $P-\Delta$ effect is significant.

20.6.2.5.2 Displacement Capacity

The displacement capacity of a bridge system shall be evaluated by an inelastic static analysis (i.e., a static push over analysis). The rotational capacity of all plastic hinges shall be limited to a safe performance level. The plastic hinge regions shall be designed and detailed to perform with minimal strength degradation under cyclic loading.

The displacement capacity of a local member can be evaluated by its rotational capacity. The displacement capacity of a prismatic cantilever member (Figure 20.17) can be calculated as

$$\Delta_c = \Delta_Y^{col} + \Delta_p \tag{20.19}$$

$$\Delta_Y^{col} = L^2/3 \times \phi_Y \tag{20.20}$$

$$\Delta_p = \theta_p \times \left(L - \frac{L_p}{2} \right) \tag{20.21}$$

$$\theta_p = L_p \times \phi_p \tag{20.22}$$

$$\phi_p = \phi_u - \phi_Y \tag{20.23}$$

FIGURE 20.17 Displacement of a cantilever member [35].

FIGURE 20.18 Idealized moment-curvature curve [35].

where

- L = distance from the point of maximum moment to the point of contraflexure
- L_p = equivalent analytical plastic hinge length as defined in Section 20.8.2.6
- Δ_p = idealized plastic displacement capacity due to rotation of the plastic hinge
- Δ_Y^{col} = idealized yield displacement of the column at the formation of the plastic hinge
- ϕ_Y = idealized yield curvature defined by an elastic-perfectly plastic representation of the cross-section's $M-\phi$ curve, see Figure 20.18
- ϕ_p = idealized plastic curvature capacity (assumed constant over L_p)

ϕ_u = curvature capacity at the failure limit state, defined as the concrete strain reaching ϵ_{cu} or the main column reinforcing steel reaching the reduced ultimate strain ϵ_{su}^R
 θ_p = plastic rotation capacity of an equivalent plastic hinge

However, it should be pointed out that Equation 20.19 might overestimate the displacement capacity for a reinforced concrete column [47]. Column slenderness, high compression axial loads, and a low percentage of reinforcement all may contribute to the overestimating of the displacement capacity. Special attention, therefore, should be paid to the estimation of displacement capacity. It was recommended [47] that the $P-\Delta$ effect should be taken into account in calculating lateral load-carrying capacity and the displacement capacity, especially for medium-long and long columns. The lateral displacement capacity Δ_c can be chosen as the displacement that corresponds to the condition when lateral load carrying capacity degrades to a certain acceptable level, say a minimum of 80% of the peak resistance (Figure 20.19) or peak load [47–49].

20.6.2.5.3 Shear Capacity

Shear capacity of concrete members shall be calculated using nominal material properties as

$$\phi V_n = \phi (V_c + V_s) \tag{20.24}$$

$$\phi = 0.85 \tag{20.25}$$

$$V_c = v_c(0.8A_g) \tag{20.26}$$

Concrete shear capacity is influenced by flexural and axial loads and is calculated separately for regions within the plastic hinge zone and regions outside this zone. In the plastic hinge zone, concrete shear capacity is modified based on the level of confinement and the displacement ductility demand (Figure 20.20).

FIGURE 20.19 Lateral load–displacement curve [36].

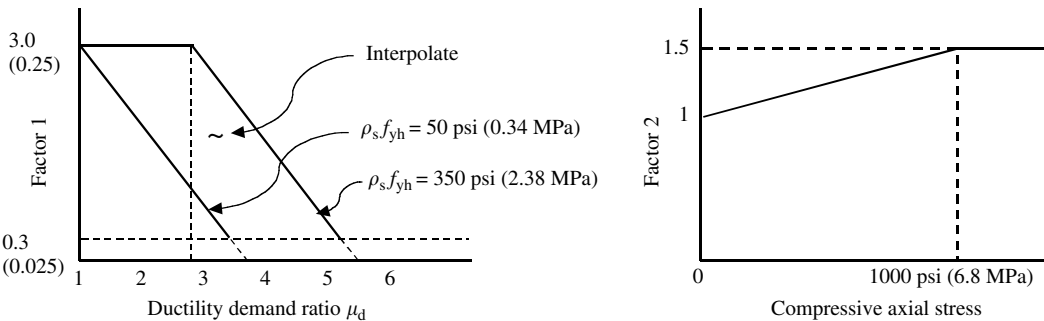

FIGURE 20.20 Shear factors [35].

- Inside the plastic hinge zone

$$v_c = \text{Factor 1} \times \text{Factor 2} \times \sqrt{f'_c} \leq 0.33\sqrt{f'_c} \quad (\text{MPa}) \quad (20.27)$$

- Outside the plastic hinge zone

$$v_c = 0.25 \times \text{Factor 2} \times \sqrt{f'_c} \leq 0.33\sqrt{f'_c} \quad (\text{MPa}) \quad (20.28)$$

$$\text{Factor 1} = 0.025 \leq \frac{\rho_s f_{yh}}{12.5} + 0.305 - 0.083\mu_d < 0.25 \quad (20.29)$$

$$\text{Factor 2} = 1 + \frac{P_c}{13.8 A_g} \leq 1.5 \quad (20.30)$$

To ensure reliable capacity in the plastic hinge regions, all column lateral reinforcements are required to be butt welded or spliced hoops capable of resisting the ultimate capacity of the reinforcing steel.

- For confined circular or interlocking core sections:

$$V_s = \frac{\pi n A_b f_{yh} D'}{2s} \quad (20.31)$$

- For pier wall in weak direction

$$V_s = \frac{A_v f_{yh} d}{s} \quad (20.32)$$

where A_b is the area of an individual interlock spiral or hoop bar, A_v is the total area of shear reinforcement perpendicular to flexural tension reinforcement, D' is the cross-section dimension of confined concrete core measured between the centerline of the peripheral hoop or spiral bars, f_{yh} is the specified minimum yield strength of transverse reinforcement, d is the area of shear reinforcement perpendicular to flexural tension reinforcement, n is the number of individual interlock spirals or hoops core section, and s is the spacing of transverse reinforcement.

20.7 Seismic Analysis and Modeling

20.7.1 Equivalent Static Analysis

The ESA method specified in Caltrans SDC [35] can be used for simpler structures, which have balanced spans and similar bent stiffness. Low skew and seismic response are primarily captured by the fundamental mode of vibration. In the ESA method, the fundamental period is determined using tributary mass and stiffness at each bent. The applied seismic force is the product of the period dependent ARS coefficient and the tributary weight.

20.7.2 Elastic Response Spectrum Analysis (ERSA)

The ERSA including uniform load method and multimode dynamic analysis method is a linear elastic spectral analysis with the appropriate response spectrum. An adequate number of modes considered to capture a minimum of 90% mass participation shall be used for complex structures.

The uniform load method specified in ATC/MCEER *Guidelines* [37] is essentially an ESA method that uses a uniform lateral load distribution to approximate the effect of seismic loads. It may be used for both transverse and longitudinal directions if structures satisfy the requirements in [Table 20.9](#).

TABLE 20.9 Recommended LRFD *Guidelines* — Requirement for Uniform Load Method [37]

Parameter	Value				
Number of spans	2	3	4	5	6
Maximum subtended angle for a horizontally curved bridge	20°	20°	30°	30°	30°
Maximum span length ratio from span to span	3	2	2	1.5	1.5
Maximum bent/pier stiffness ratio from span to span, excluding abutments	—	4	4	4	2

In both ESA and ERSA analyses, “effective” stiffness of the components shall be used in order to obtain realistic evaluation for the structure’s period and displacement demands. The effective stiffness of ductile components shall represent the component’s actual secant stiffness near first yield of rebar. The effective stiffness shall include the effects of concrete cracking, reinforcement, and axial load for concrete components; residual stresses, out-of-straightness, and axial load for steel components; and the restraints of the surrounding soil for piles. For ductile concrete column members, effective moments of inertia, I_{eff} , shall be based on cracked section properties and can be determined from the initial slope of the $M-\phi$ curve between the origin and the point designating first yield of the main column reinforcement. The torsional moment of inertia of concrete column I_{eff} may be taken as 0.2 times I_{gross} . For capacity-protected concrete members, I_{eff} shall be based on their level of cracking. For a conventionally reinforced concrete box girder superstructure, I_{eff} can be estimated between 0.5 and 0.75 times I_{gross} , the moment of inertia of a gross section. For prestressed concrete superstructures, I_{eff} is assumed 1.0 times I_{gross} .

The following are major considerations in seismic analysis and design practice:

- A beam–element model with three or more lumped masses for each member is usually used [25,26].
- Larger cap stiffness is often used to simulate a stiff deck.
- Compression and tension models are used to simulate the behavior of expansion joints. In the tension model, superstructure joints including abutments are released longitudinally but the restrainers are modeled as truss elements. In the compression model, all restrainers are considered to be inactive and all joints are locked longitudinally.
- Simplistic analysis models should be used for initial assessment of structural behavior. The results of more sophisticated models shall be compared for reasonableness with the results obtained from the simplistic models. The rotational and translational stiffness of abutments and foundations modeled in the seismic analysis must be compatible with their structural and geotechnical capacity. The energy dissipation capacity of the abutments should be considered for bridges whose response is dominated by the abutments [50].
- For elastic response spectrum analysis, the viscous damping ratio inherent in the specified ground spectra is usually 5%.
- For time history analysis, in lieu of measurements, a damping ratio of 5% for both concrete and timber constructions and 2% for welded and bolted steel construction may be used.
- For one- or two-span continuous bridges with abutment designed to activate significant passive pressure in the longitudinal direction, a damping ratio of up to 10% may be used in longitudinal analysis.
- Soil-spring elements should be used to the soil–foundation–structure interaction. Adjustments are often made to meet force–displacement compatibility, particularly for abutments. The maximum capacity of the soil behind abutments with heights larger than 2.5 m may be taken as 370 kPa and will be linearly reduced for the backwall height less than 2.5 m.

- Pile footing with pile cap and spread footing with soil types A and B [37] may be modeled as rigid. If footing flexibility contributes more than 20% to pier displacement, foundation springs shall be considered.
- For pile bent/drilled shaft, estimated depth to fixity or soil-spring based on idealized p - y curves should be used.
- Force–deformation behavior of a seismic isolator can be idealized as a bilinear relationship with two key variables: second slope stiffness and characteristic strength. For design, the force–deformation relationship can be represented by an effective stiffness based on the secant stiffness and a damping coefficient. For more detailed information, references can be made ATC/MCEER *Guidelines* and AASHTO Guide Specifications [37,51] and a comprehensive chapter by Zhang [52].

20.7.3 Nonlinear Dynamic Analysis

The nonlinear dynamic analysis (NDA) procedure is normally used for the 3% PE in 75-year earthquake. A minimum of three ground motions including two horizontal components and one vertical component shall be used and the maximum actions for those three motions shall be used for design. If more than seven ground motions are used, the design action may be taken as the mean action of ground motions. The result of an NDA should be compared with an ERSA as a check for a reasonableness of the nonlinear model.

20.7.4 Global and Stand-Alone Analysis

The global analysis specified in Caltrans SDC [35] is an EDA considering the entire bridge modeled from abutment to abutment. It is often used to determine displacement demands on multiframe structures. The stand-alone analysis is an elastic dynamic analysis considering only one individual frame. To avoid having individual frames dependent on the strength and stiffness of adjacent frames, the separate stand-alone model for each frame must meet all requirements of the SDC.

20.7.5 Inelastic Static Analysis — Push Over Analysis

Inelastic Static Analysis (ISA), commonly referred to as the “push over analysis,” shall be used to determine the displacement capacity of a bridge system. IAS shall be performed using expected material properties for modeled members. ISA can be categorized into three types of analysis: (1) elastic–plastic hinge, (2) refined plastic hinge, and (3) distributed plasticity.

The simplest method, elastic–plastic hinge analysis, may be used to obtain an upper bound solution. The most accurate method, distributed plasticity analysis, can be used to obtain a better (more refined) solution. Refined plastic hinge analysis is an alternative that can reasonably achieve both computational efficiency and accuracy.

In an elastic–plastic hinge (lumped plasticity) analysis, material inelasticity is taken into account using concentrated “zero-length” plastic hinges, which maintain plastic moment capacities and rotate freely. When the section reaches its plastic capacity, a plastic hinge is formed and element stiffness is adjusted [53,54]. For regions in a framed member away from the plastic hinge, elastic behavior is assumed. It does not, however, accurately represent the distributed plasticity and associated P - δ effects. This analysis predicts an upper bound solution.

In the refined plastic hinge analysis [55], a two-surface yield model considers the reduction of plastic moment capacity at the plastic hinge due to the presence of axial force and an effective tangent modulus accounts for the stiffness degradation due to distributed plasticity along a frame member. This analysis is similar to the elastic–plastic hinge analysis in efficiency and simplicity and also accounts for distributed plasticity.

Distributed plasticity analysis models the spread of inelasticity through the cross-sections and along the length of the members. This is also referred to as plastic zone analysis, spread-of-plasticity analysis, and elasto-plastic analysis by various researchers. In this analysis, a member needs to be subdivided into several elements along its length to model the inelastic behavior more accurately. Two main approaches have been successfully used to model plastification of members in a second-order distributed plasticity analysis:

- Cross-sectional behavior is described as an input for the analysis by means of moment–thrust–curvature (M – P – ϕ) and moment–thrust–axial strain (M – P – ϵ) relations, which may be obtained separately from a moment–curvature analysis or approximated by closed-form expressions [56].
- Cross-sections are subdivided into elemental areas and the state of stresses and strains are traced explicitly using the proper stress–strain relations for all elements during the analysis.

20.7.6 Moment–Curvature Analysis

The main purpose of moment–curvature analysis is to study the section behavior. The following assumptions are usually made:

- Plane section before bending remains plane after bending.
- Shear and torsional deformations are negligible.
- Stress–strain relationships for concrete and steel are given [35].
- For reinforced concrete, a perfect bond between concrete and steel rebar exists.

The mathematical formulas used in the section analysis are (Figure 20.21)

Compatibility equations

$$\phi_x = \epsilon/y \quad (20.33)$$

$$\phi_y = \epsilon/x \quad (20.34)$$

Equilibrium equations

$$P = \int_A \sigma \, dA = \sum_{i=1}^n \sigma_i A_i \quad (20.35)$$

$$M_x = \int_A \sigma y \, dA = \sum_{i=1}^n \sigma_i y_i A_i \quad (20.36)$$

$$M_y = \int_A \sigma x \, dA = \sum_{i=1}^n \sigma_i x_i A_i \quad (20.37)$$

For a reinforced concrete member, the cross-section is divided into an appropriate number of equivalent concrete and steel elements or filaments representing the concrete and reinforcing steel as shown in Figure 20.21. Each concrete and steel layer or filament is assigned its corresponding stress–strain relationships. Confined and unconfined stress–strain relationships are used for the core concrete and for the cover concrete, respectively.

For a structural steel member, the section is divided into steel layers or filaments and a typical steel stress–strain relationship is used for tension and compact compression elements, and an equivalent stress–strain relationship with reduced yield stress and strain can be used for a noncompact compression element.

The analysis process starts by selecting a strain for the extreme concrete (or steel) fiber. Using this selected strain and assuming a section neutral axis (NA) location, a linear strain profile is constructed and the corresponding section stresses and forces are computed. Section force equilibrium is then checked for the given axial load. By changing the location of the NA, the process is repeated until

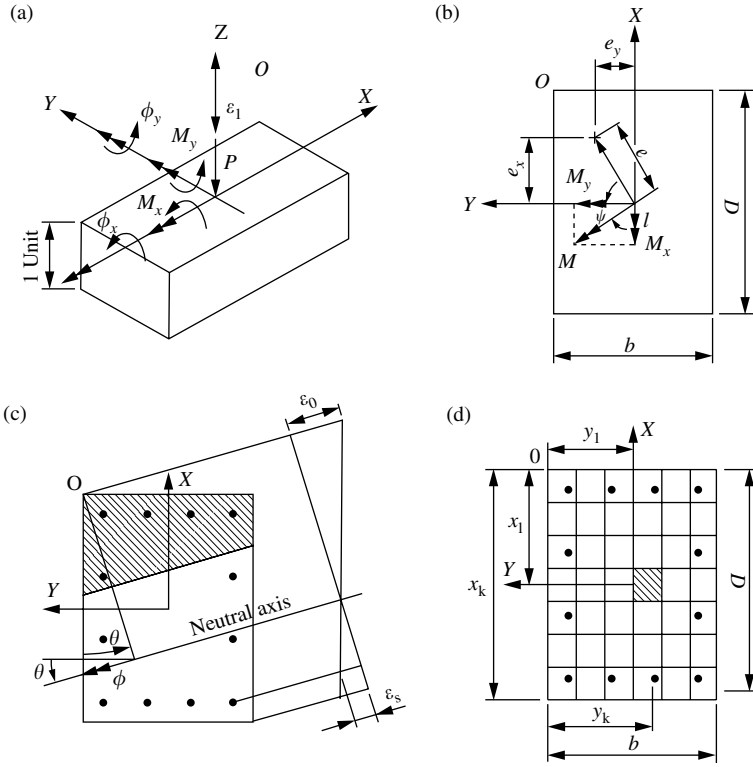

FIGURE 20.21 Section analysis modeling.

equilibrium is satisfied. Once the equilibrium is satisfied, and for the assumed strain and the given axial load, the corresponding section moment and curvature are computed by Equations 20.36 and 20.37.

A moment–curvature ($M-\phi$) diagram for a given axial load is constructed by incrementing the extreme fiber strain and finding the corresponding moment and the associated curvature. An interaction diagram ($M-P$) relating axial load and ultimate moment is constructed by incrementing the axial load and finding the corresponding ultimate moment using the above procedure.

For a reinforced concrete section, the yield moment is usually defined as the section moment at onset of yielding of the tension reinforcing steel. The ultimate moment is defined as the moment at peak moment capacity. The ultimate curvature is usually defined as the curvature when the extreme concrete fiber strain reaches ultimate strain or when the reinforcing rebar reaches its ultimate (rupture) strain (whichever take place first). Figure 20.22a shows typical $M-P-\phi$ curves for a reinforced concrete section.

For a simple steel section, such as rectangular, circular-solid, and thin-walled circular section, a closed-form of $M-P-\phi$ can be obtained using the elastic–perfectly plastic stress–strain relations [56]. For all other commonly used steel section, numerical iteration techniques are used to obtain $M-P-\phi$ curves. Figure 20.22b shows typical $M-P-\phi$ curves for a wide-flange section.

20.7.7 Random Vibration Approach

The random vibration approach is a well-recognized and advanced seismic-response analysis method for linear multisupport-structural systems and long-span structures [57,58]. This approach provides a statistical measure of the response, which is not controlled by an arbitrary choice of the input motions, and also significantly reduces the response evaluation to that of a series of linear one-degree systems in

FIGURE 20.22 Typical moment–thrust–curvature curves: (a) reinforced concrete section and (b) steel section.

a way that fully accounts for the multiple-support input and the space–time correlation structure of the ground motion [58].

Although the random vibration approach has been adopted by the Eurocode [59] and widely used by Chinese engineers, it has not been accepted as a practical method of analysis for complex long-span structures by U.S. practicing engineers due to computation difficulties [57].

During 1990s, Lin and coworkers [60–64] have developed a new series of algorithms, that is, the pseudo-excitation method (PEM) series, on structural stationary/nonstationary random response analysis. The PEM is an accurate and extremely efficient method to solve complicated random vibration problems. The cross-correlation terms between all participating modes and between all excitations are all included in the responses. Most recently, the PEM has been used to analyze several long-span bridges in China. Cheng [65] analyzed the Hunan Yue-Yang Cable-stayed Bridge with a total length of 5700 m and a main span of 880 m, in which 2700 degrees of freedom, 15 multisupport ground motions, and 200 modes were used. Fan et al. [66] used PEM to analyze the Second Yangtze River Bridge at Nancha, a cable stay bridge with a total length of 1238 m and a main span of 628 m, in which 300 modes in the fast CQC (i.e., PEM) analysis and 12 multisupport ground motions were

used. The computations showed that the “wave passage effect” may cause the differences of some demands up to 40%.

20.8 Seismic Detailing Requirements

20.8.1 ATC/MCEER Guidelines [37]

20.8.1.1 Minimum Seat Requirements

In SDRs 1 and 2, the minimum seat width is

$$N_{\min} = \left[0.1 + 0.0017L + 0.007H + 0.05\sqrt{H} \sqrt{1 + \left(2\frac{B}{L}\right)^2} \right] \frac{(1 + 1.25F_v S_1)}{\cos \alpha} \quad (20.38)$$

$$\frac{B}{L} \leq \frac{3}{8} \quad (20.39)$$

where L is the distance between joints (m), H is the height of the tallest pier between joints (m), and B is the width of the superstructure (m).

In SDRs 3 to 6, the minimum seat width is either Equation 20.38 or 1.5 times the displacement of the superstructure at the seat according to the following equation:

$$\Delta = R_d \Delta_e \quad (20.40)$$

$$R_d = \begin{cases} \left(1 - \frac{1}{R}\right) \frac{T^*}{T} + \frac{1}{R} & \text{for } T < T^* \\ 1 & \text{for } T \geq T^* \end{cases} \quad (20.41)$$

where Δ_e is the displacement demand from the seismic analysis.

20.8.1.2 P-Δ Requirements

In SDRs 3 to 6, the displacement of a pier or bent in the longitudinal and transverse directions determined by Equation 20.40 shall satisfy

$$\Delta \leq 0.25C_s H = 0.25 \left(\frac{V_n}{W} \right) H \quad (20.42)$$

where V_n is the lateral nominal shear strength of the pier, W is the dead load of the pier, and H is the height of the pier from the point of fixity for foundation.

The basis of this requirement is that maximum displacement is such that the reduction in resisting force is limited to a 25% reduction from the lateral strength assuming no postyield stiffness. The inequality in Equation 20.42 is to keep the bridge pier from being significantly affected by P-Δ moments.

20.8.1.3 Minimum Displacement Capacity Requirements

For SDAP E, the following equation shall be satisfied:

$$\Delta_c \geq 1.5\Delta \quad (20.43)$$

where Δ_c is lateral displacement capacity of the pier or bent. It is defined as the displacement at which the first component reaches its maximum deformation. The factor of 1.5 on displacement demand recognizes the approximation of the modeling and analysis.

20.8.1.4 Structural Steel Design Requirements

20.8.1.4.1 Limiting Width-to-Thickness Ratios

In SDRs 2 to 6, the width-to-thickness ratio of compression elements of the columns in ductile MRF and single-column structures shall satisfy the limiting ratios specified in [Table 20.10](#). Full penetration flange and web welds are required at beam-to-column connections.

TABLE 20.10 Recommended LRFD *Guidelines* — Limiting Width-to-Thickness Ratios [37]

Description of element	Width-to-thickness ratio, b/t	Limiting width-to-thickness ratio, λ_p	Limiting ratio, k
Flanges of I-shaped sections and channels in compression	$b_f/2t_f$	$\frac{135}{\sqrt{F_y}}$	0.3
Webs in combined flexural and axial compression	h_c/t_w	For $\frac{P_u}{\phi_b P_y} \leq 0.125$	For $\frac{P_u}{\phi_b P_y} \leq 0.125$
		$\frac{1365}{\sqrt{F_y}} \left(1 - \frac{1.54 P_u}{\phi_b P_y} \right)$	$3.05 \left(1 - \frac{1.54 P_u}{\phi_b P_y} \right)$
		For $\frac{P_u}{\phi_b P_y} \leq 0.125$	For $\frac{P_u}{\phi_b P_y} \leq 0.125$
		$\frac{500}{\sqrt{F_y}} \left(2.33 - \frac{P_u}{\phi_b P_y} \right) \geq \frac{665}{\sqrt{F_y}}$	$1.12 \left(2.33 - \frac{P_u}{\phi_b P_y} \right) \geq 1.48$
Hollow circular sections (pipes)	D/t	$\frac{8950}{F_y}$	$\frac{200}{\sqrt{F_y}}$
Unstiffened rectangular tubes	b/t	$\frac{300}{\sqrt{F_y}}$	0.67
Longitudinally stiffened plates in compression	b/t	$\frac{145}{\sqrt{F_y}}$	0.32

Notes:

1. b_f and t_f are the width and thickness of an I-shaped section and h_c is the depth of that section and t_w is the thickness of its web.
2. Limits λ_p is for format $b/t \leq \lambda_p$.
3. Limits k is for format $b/t \leq k\sqrt{E/F_y}$.

TABLE 20.11 Recommended LRFD *Guidelines* — Limiting Slenderness Ratio [37]

Description of members	Limiting slenderness ratio KL/r	Limiting length, L (m)
Unsupported distance for potential plastic hinge zone of columns		$\frac{17250r_y}{F_y}$
Ductile compression bracing members	$\frac{2600}{\sqrt{F_y}}$	
Nominally ductile bracing members	$\frac{3750}{\sqrt{F_y}}$ limit is waived if members designed as tension-only bracing	

20.8.1.4.2 Limiting Slenderness Ratio

In SDRs 2 to 6, Table 20.11 summarizes the limiting slenderness ratio (KL/r) for various steel members. Recent studies found that more stringent requirement for slenderness ratios may be unnecessary, provided that connections are capable of conveying at least the member’s tension capacity. The ratios shown in Table 20.11 reflect those relaxed limits.

20.8.1.4.3 Limiting Axial Load Ratio

High axial load in a column usually results in the early deterioration of strength and ductility.

The ratio of factored axial compression due to seismic load and permanent loads to yield strength ($A_g E_y$) for columns in ductile MRFs and single-column structures shall not exceed 0.4 for SDR 2 and SDRs 3 to 6, respectively.

20.8.1.4.4 Plastic Rotation Capacities

In SDRs 3 to 6, the plastic rotational capacity shall be based on the appropriate performance level and may be determined from tests and a rational analysis. The maximum plastic rotational capacity θ_p should be conservatively limited to 0.035, 0.005, and 0.01 radians for life safety, operational performance, and in ground hinges and piles, respectively.

20.8.1.5 Concrete Design Requirements

20.8.1.5.1 Limiting Longitudinal Reinforcement Ratios

The ratio of longitudinal reinforcement to the gross cross-section shall not be less than 0.008 and not more than 0.04.

20.8.1.5.2 Shear Reinforcement

The shear strength shall be determined by either an implicit approach or an explicit approach. In the end regions, the explicit approach assumes that the shear-resisting mechanism is provided by the strut-tie model (explicit approach) such that

$$\phi V_s \geq V_u - (V_p + V_c) \quad (20.44)$$

$$V_p = \frac{\Lambda}{2} P_e \frac{D'}{L} \quad (20.45)$$

$$V_c = \begin{cases} 0.05 \sqrt{f'_c} b_w d & \text{for plastic hinge zone} \\ 0.17 \sqrt{f'_c} b_w d & \text{for outside plastic hinge zone} \end{cases} \quad (20.46)$$

$$V_s = \begin{cases} \frac{\pi A_{bh}}{2s} f_{yh} D'' \cot \theta & \text{for circular section} \\ \frac{A_v}{s} f_{yh} D'' \cot \theta & \text{for rectangular section} \end{cases} \quad (20.47)$$

where

P_e = compressive axial force including seismic effects

D' = pitch circle diameter of the longitudinal reinforcement in a circular column, or the distance between the outermost layers of bars in a rectangular column

L = column length

Λ = fixity factor defined in Section 20.6.1.5

b_w = web width of the section

d = effective depth of the section

A_{bh} = area of one circular hoop/spiral rebar

A_{sh} = total area of transverse reinforcement in one layer in the direction of the shear force

D'' = centerline section diameter/width of the perimeter spiral/hoops

θ = principal crack angle defined in Section 20.6.1.5

FIGURE 20.23 Column single spiral details [37].

FIGURE 20.24 Column tie details [37].

20.8.1.5.3 Transverse Reinforcement in Plastic Hinge Zones

Figures 20.23 to 20.25 illustrate the typical transverse reinforcement. For confinement in plastic hinge zones, the ratio of transverse reinforcement, ρ_s , shall not be less than

$$\rho_{s \min} = 0.008 \frac{f'_c}{U_{sf}} \left[\alpha_{\text{shape}} \left(\frac{P_e}{f'_c A_g} + \rho_t \frac{f_y}{f'_c} \right) \left(\frac{A_g}{A_{cc}} \right)^2 - 1 \right] \tag{20.48}$$

$$\rho_s = \begin{cases} \frac{4A_{bh}}{D's} & \text{for circular sections} \\ \frac{A_{sh}}{sB'} + \frac{A'_{sh}}{sD''} & \text{for rectangular sections} \end{cases} \tag{20.49}$$

where

- A_{cc} = area of column core concrete, measured to the centerline of the perimeter hoop or spiral
- A_{sh} = total area of transverse reinforcement in one layer into the direction of the applied shear

FIGURE 20.25 Column interlocking spiral details [37].

- A'_{sh} = total area of transverse reinforcement in one layer perpendicular to the direction of the applied shear
- B'' = core dimension of tied column in the direction of the applied shear
- D'' = core dimension of tied column perpendicular to the direction of the applied shear
- D' = center-to-center diameter of perimeter hoop for spiral
- f_y = minimum specified yield strength of rebars
- s = vertical spacing of transverse reinforcement, not exceeding 100 mm
- U_{sf} = strain energy capacity of transverse reinforcement (= 110 MPa)
- α_{shape} = 12 and 15 for circular sections and rectangular section, respectively

To restrain buckling of longitudinal reinforcement in plastic hinges, the transverse reinforcement shall satisfy the following requirements:

For circular section

$$\rho_s = 0.016 \left(\frac{D}{s} \right) \left(\frac{s}{d_b} \right) \rho_t \left(\frac{f_y}{f_{yh}} \right) \tag{20.50}$$

For rectangular section

$$A_{bh} = 0.09 A_b \left(\frac{f_y}{f_{yh}} \right) \tag{20.51}$$

where D is the diameter of the circular column, d_b is the diameter of longitudinal reinforcement bars being restrained by hoop or spiral, f_y is the minimum specified yield strength of longitudinal reinforcement bars, f_{yh} is the minimum specified yield strength of transverse reinforcement bars, A_b is the area of longitudinal reinforcement bars being restrained by hoop or spiral, A_{bh} is the area of hoops or spiral or ties restraining the longitudinal steel, and s is the vertical spacing of transverse reinforcement restraining the longitudinal steel.

The transverse reinforcement shall be provided in the plastic hinge zones defined in Section 20.6.1.5. The spacing the transverse reinforcement shall meet

$$s \leq \begin{cases} 6d_b \\ 0.25 \text{ (minimum member dimension)} \\ 150 \text{ mm} \end{cases} \tag{20.52}$$

20.8.1.5.4 Joint Reinforcement

- Moment-resisting integral connections shall be designed to resist the maximum plastic moment.
- The principal tension stress p_t and compression stress p_c shall be calculated by

$$\frac{p_t}{p_c} = \frac{f_h + f_v}{2} \mp \sqrt{\left(\frac{f_h + f_v}{2} \right)^2 + v_{hv}^2} \tag{20.53}$$

where f_h is the average axial stress in the horizontal direction within the plans of the connection under consideration (positive is compressive stress) (MPa), f_v is the average axial stress in the vertical direction within the plans of the connection under consideration (positive is compressive stress) (MPa), and v_{hv} is the average shear stress within the plans of the connection (MPa).

- The principal compression stress p_c shall not exceed $0.25f'_c$.
- When the principal tension stress $p_t \leq 0.29\sqrt{f'_c}$ for circular columns or columns with intersecting spirals, the volumetric ratio of transverse reinforcement in the form of spirals or hoops to be continued into the cap or footing ρ_s shall not be less than $0.29\sqrt{f'_c}/f_{yh}$ where f_{yh} is yield stress of horizontal hoop/tie reinforcement in the joint.
- When the principal tension stress $p_t > 0.29\sqrt{f'_c}$ the additional reinforcement shown in Figure 20.26 shall be provided as follows:
 - On each side column, vertical stirrups: $A_{jv} = 0.16A_{st}$.
 - Inside joint: the required vertical tie: $A_{jt} = 0.08A_{st}$.
 - Longitudinal reinforcement: $A_{jt} = 0.08A_{st}$.
 - Column hoop or spiral reinforcement into the cap: $\rho_s \geq 0.4A_{st}/l_{ac}^2$.
where A_{st} is the total area of longitudinal steel anchored in the joint and l_{ac} is the length of column reinforcement embedded into the joint.

20.8.1.5.5 Plastic Rotation Capacities

In SDRs 3 to 6, the plastic rotational capacity shall be based on the appropriate performance level and may be determined from tests and a rational analysis. The maximum plastic rotational capacity θ_p should be conservatively limited to 0.035 (0.05), 0.01, and 0.02 radians for life safety (for liquefiable pile foundation), operational performance, and in ground hinges, respectively. For the life safety performance, the plastic hinge of a column shall be calculated by

$$\theta_p = 0.11 \frac{L_p}{D'} (N_f)^{-0.5} \quad (20.54)$$

$$2 \leq N_f = 3.5(T_n)^{-1/3} \leq 10 \quad (20.55)$$

where

N_f = number of cycles of loading expected at maximum displacement amplitude for liquefiable soil, take $N_f = 2$

L_p = effective plastic hinge length

$$L_p = \begin{cases} 0.08 \frac{M}{V} + 4400\varepsilon_y d_b & \text{for common columns} \\ L_g + 8800\varepsilon_y d_b & \text{for columns with isolation gap} \end{cases} \quad (20.56)$$

ε_y = yield strain of longitudinal reinforcement

L_g = gap length between the flare and adjacent element

D' = distance between outer layers of the longitudinal reinforcement

d_b = diameter of the main longitudinal reinforcement bars

20.8.2 Caltrans SDC

20.8.2.1 Minimum Seat Width Requirements

To prevent unseating of superstructures at hinges, piers, and abutments, the seat width shall be available to accommodate the anticipated thermal movement, prestressing shortening, concrete creep and

FIGURE 20.26 Additional cap beam bottom reinforcement for joint force transfer [37].
 Note: I_d = development length.

shrinkage, and the relative longitudinal earthquake displacement, and shall not exceed the following minimum seat requirements [35]:

For seat width at hinges

$$N_{\min} = \text{larger of } \begin{cases} \Delta_{ps} + \Delta_{cr+sh} + \Delta_{temp} + \Delta_{eq} + 100 \\ 600 \text{ mm} \end{cases} \quad (20.57)$$

where Δ_{eq} is total relative displacement between frames.

For seat width at abutments

$$N_{\min} = \text{larger of } \begin{cases} \Delta_{ps} + \Delta_{cr+sh} + \Delta_{temp} + \Delta_{eq} + 100 \\ 760 \text{ mm} \end{cases} \quad (20.58)$$

where Δ_{ps} , Δ_{cr+sh} , Δ_{temp} , and Δ_{eq} are relative displacement due to prestressing, concrete creep and shrinkage, and earthquake, respectively (mm).

20.8.2.2 P-Δ Effects

The $P-\Delta$ effects tend to increase the displacement and decrease the lateral load-carrying capacity of a bridge column. These effects can typically be ignored if the moment ($P_{DL}\Delta$) is less than or equal to 20% of the column plastic moment, that is, $P_{DL}\Delta \leq 0.2M_p^{col}$.

20.8.2.3 Minimum Displacement Ductility Capacity

To ensure the dependable ductile behavior of all columns regardless of seismic demand, a minimum local displacement ductility capacity of $\mu_c = \Delta_c/\Delta_Y \geq 3$ is required and target local ductility of $\mu_c \geq 4$ is recommended. The local displacement ductility capacity shall be calculated for an equivalent member that approximates a fixed base cantilever element.

20.8.2.4 Maximum (Target) Displacement Ductility Demand

The engineers are encouraged to limit displacement ductility demands, defined as $\mu_D = \Delta_D/\Delta_Y$ to the values shown in Table 20.12.

TABLE 20.12 Caltrans Limiting Displacement Ductility Demand Values [35]

Item	Limiting $\mu_D = \Delta_D/\Delta_Y$
Single column bents supported on fixed foundations	4
Multicolumn bents supported on fixed or pinned footings	5
Pier walls (weak direction) supported on fixed or pinned footings	5
Pier walls (strong direction) supported on fixed or pinned footings	1

20.8.2.5 Minimum Lateral Strength

Although providing ductile detailing is essential for achieving the expected performance requirements, each column shall be designed to have a minimum lateral flexural to resist a lateral force of 0.1g or 0.1 times P_{dl} .

20.8.2.6 Structural Steel Design Requirements (Guide) [36]

20.8.2.6.1 Limiting Width-to-Thickness Ratios

For capacity-protected components, width–thickness ratios of compression elements shall not exceed the limiting value λ_r as specified in Table 20.13. For ductile components, width–thickness ratios shall not exceed the λ_p as specified in Table 20.13. Welds located in the expected inelastic region of ductile components are preferably complete penetration welds. Partial penetration groove welds are not recommended in these regions. If the fillet welds are only practical solution for an inelastic region, quality control and quality assurance inspection procedures for the fracture critical members shall be followed (Figure 20.27).

20.8.2.6.2 Limiting Slenderness Ratio

The slenderness parameter λ_c for compression members and λ_b for flexural members shall not exceed the limiting values, λ_{cp} and λ_{bp} , as specified in Table 20.14, respectively.

20.8.2.6.3 Limiting Axial Load Ratio

High axial load in a column usually results in the early deterioration of strength and ductility. The ratio of factored axial compression due to seismic load and permanent loads to yield strength ($A_g F_y$) for columns in ductile moment-resisting frames and single-column structures shall not exceed 0.3.

20.8.2.6.4 Shear Connectors

Shear connectors shall be provided on the flanges of girders, end cross-frames, or diaphragms to transfer seismic loads from the concrete deck to the abutments or pier supports. The cross-frames or diaphragms at the end of each span are the main components to transfer the lateral seismic loads from the deck down to the bearing locations. Recent tests on a 0.4 scale experimental steel girder bridge (18.3 m long) conducted by University of Nevada, Reno [69] indicated that too few shear connectors between the girders and deck at the bridge end did not allow the end cross-frame to reach its ultimate capacity.

20.8.2.7 Concrete Design Requirements

20.8.2.7.1 Limiting Longitudinal Reinforcement Ratios

The ratio of longitudinal reinforcement to the gross cross-section shall not be less than 0.01 and 0.005 for columns and pier walls, respectively, and not more than 0.04.

20.8.2.7.2 Transverse Reinforcement in Plastic Hinge Zones

For confinement in plastic hinge zones (larger of 1.5 times cross-sectional dimension in the direction of bending and the regions of column where the moment exceeds 75% of overstrength plastic moment, M_p^{col}), transverse reinforcement shall not be less than [27]

For spiral and hoops ($\rho_s = 4A_{bh}/D's$)

$$\rho_{s,min} = \begin{cases} 0.45 \frac{f'_c}{f_y} \left(\frac{A_g}{A_c} - 1 \right) \left(0.5 + \frac{1.25P_e}{f'_c A_g} \right) & \text{for } D \leq 0.9 \text{ m} \\ 0.12 \frac{f'_c}{f_y} \left(0.5 + \frac{1.25P_e}{f'_c A_g} \right) & \text{for } D > 0.9 \text{ m} \end{cases} \quad (20.59)$$

For ties

$$A_{sh,min} = \text{larger of } \begin{cases} 0.3sh_c \frac{f'_c}{f_y} \left(\frac{A_g}{A_c} - 1 \right) \left(0.5 + \frac{1.25P_e}{f'_c A_g} \right) \\ 0.12sh_c \frac{f'_c}{f_y} \left(0.5 + \frac{1.25P_e}{f'_c A_g} \right) \end{cases} \quad (20.60)$$

TABLE 20.13 Caltrans Limiting Width–Thickness Ratios [36]

No.	Description of elements	Examples	Width–thickness ratios	λ_r	λ_p
<i>Unstiffened elements</i>					
1	Flanges of I-shaped rolled beams and channels in flexure	Figure 20.27a Figure 20.27c	b/t	$\frac{370}{\sqrt{F_y - 69}}$	$\frac{137}{\sqrt{F_y}}$

7	Webs in combined flexural and axial compression	Figures 20.27a, c, d, f	h/t_w	$\frac{2550}{\sqrt{F_y}} \times \left(1 - \frac{0.74P}{\phi_b P_y}\right)$	For $P_u \leq 0.125\phi_b P_y$ $\times \frac{1365}{\sqrt{F_y}} \left(1 - \frac{1.54P}{\phi_b P_y}\right)$ For $P_u > 0.125\phi_b P_y$ $\times \frac{500}{\sqrt{F_y}} \left(2.33 - \frac{P}{\phi_b P_y}\right)$ $\geq \frac{665}{\sqrt{F_y}}$
8	Longitudinally stiffened plates in compression	Figure 20.27e	b/t	$\frac{297\sqrt{k}}{\sqrt{F_y}}$	$\frac{197\sqrt{k}}{\sqrt{F_y}}$
9	Round HSS in axial compression or flexure		D/t	$\frac{7930}{F_y}$	$\frac{8950}{F_y}$

n = number of equally spaced longitudinal compression flange stiffeners.

I_s = moment of inertia of a longitudinal stiffener about an axis parallel to the bottom flange and taken at the base of the stiffener.

Notes:

- Width–thickness ratios shown in **Bold** are from AISC-LRFD (1999) [67] and AISC-Seismic Provisions (1997) [68]. F_y is MPa.
- k = buckling coefficient specified by Article 6.11.2.1.3a of AASHTO-LRFD [38]. For $n = 1$, $k = (8I_s/bt^3)^{1/3} \leq 4.0$; for $n = 2, 3, 4$, and 5 , $k = (14.3I_s/bt^3n^4)^{1/3} \leq 4.0$.

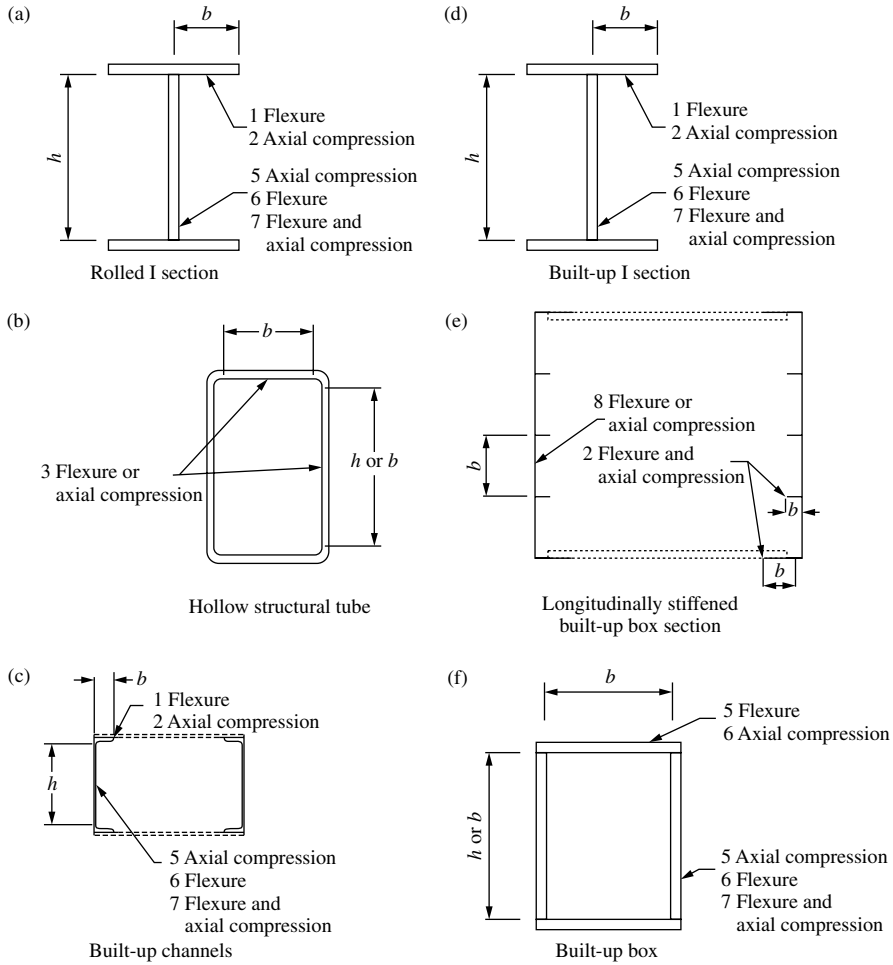

FIGURE 20.27 Selected steel cross-sections [36].

TABLE 20.14 Caltrans Limiting Slenderness Parameters [36]

Member classification	Limiting slenderness parameters	
Ductile		
Compression member	λ_{cp}	0.75
Flexural member	λ_{bp}	$17240/F_y$
Capacity protected		
Compression member	λ_{cp}	1.5
Flexural member	λ_{bp}	$1970/\sqrt{F_y}$

Notes:

$\lambda_c = (KL/r\pi)\sqrt{(F_y/E)}$ (slenderness parameter for compression members).

$\lambda_b = L/r_y$ (slenderness parameter for flexural members).

λ_{cp} = limiting slenderness parameter for compression members.

λ_{bp} = limiting slenderness parameter for flexural members.

K = effective length factor of a member.

L = unsupported length of a member (mm).

r = radius of gyration (mm).

r_y = radius of gyration about the minor axis (mm).

F_y = specified minimum yield strength of steel (MPa).

E = modulus of elasticity of steel (200,000 MPa).

where A_{sh} is the total cross-sectional area of tie reinforcement including supplementary cross-tie within a section having limits of s and h_c , h_c is the core dimension of tied column in direction under consideration (out-to-out of ties), s is the vertical spacing of transverse reinforcement, and D' is the center-to-center diameter of perimeter hoop for spiral.

The spacing the transverse reinforcement in the plastic hinge zones shall meet

$$s \leq \begin{cases} 6d_b \\ 0.2 D_{min} \\ 220 \text{ mm} \end{cases} \quad (20.61)$$

where D_{min} is the least cross-section dimension for columns and one-half of the least cross-section dimension of piers and d_b is the diameter of the main column reinforcement.

20.8.2.7.3 Joint Proportion and Reinforcement [35,70]

- Moment-resisting integral connections shall be designed to resist the overstrength capacity $1.2 \times M_p^{col}$ and associated shear.
- The principal tension stress p_t and compression stress p_c shall not exceed $1.0\sqrt{f'_c}$ and $0.25, f'_c$, respectively. The bent cap width shall not be less than the cross-section dimension of the column in the direction of bending plus 600 mm.
- When the principal tension stress $p_t \leq 0.29\sqrt{f'_c}$ for circular columns or columns with intersecting spirals, the volumetric ratio of transverse reinforcement in the form of spirals or hoops to be continued into the cap or footing ρ_s shall not be less than $0.29\sqrt{f'_c}/f_{yh}$.

FIGURE 20.28 Example cap joint shear reinforcement — skews 0 to 20° [35].

FIGURE 20.29 Location of horizontal joint shear reinforcement [35].

- When the principal tension stress $p_t > 0.29\sqrt{f'_c}$ the additional reinforcement as shown in Figure 20.28 and Figure 20.29 shall be provided and well distributed within $D/2$ from the face of the column. All joint shear reinforcement shall be as follows:
 - On each side column, vertical stirrups: $A_s^{jv} = 0.2A_{st}$.
 - Horizontal stirrups or tiles: $A_s^{jh} = 0.1A_{st}$.
 - Longitudinal side reinforcement: $A_s^{sf} \geq 0.1A_{cap}$, where A_{cap} is area of bent cap top or bottom flexural steel.
 - Column hoop or spiral reinforcement into the cap: $\rho_s \geq 0.4A_{st}/l_{ac}^2$.
 - Horizontal reinforcement shall be stitched across the cap in two or more intermediate layers. The reinforcement shall be shaped as hairpins, spaced vertically at not more than 460 mm. The hairpins shall be 10% of column reinforcement. Spacing shall be denser outside the column than that used within the column.
 - For bent caps skewed greater than 20° , the vertical J-bars hooked around longitudinal deck and bent cap steel shall be 8% of column steel (see Figure 20.30). The J-bars shall be alternatively 600 and 750 mm long and placed within a width of column dimension either side of the column centerline.
 - All vertical column bars shall be extended as high as practically possible without interfering with the main cap bars.

20.8.2.7.4 Effective Plastic Hinge Length

The effective plastic hinge length is used to evaluate the plastic rotation of columns.

$$L_p = \begin{cases} 0.08 L + 0.022 f_{ye} d_b \geq 0.044 f_{ye} d_b & \text{for columns and Type II shafts} \\ G + 0.044 f_{ye} d_b & \text{for horizontally isolated flared columns} \\ D^* + 0.06 H' & \text{for noncased Type I shafts} \end{cases} \quad (20.62)$$

where f_{ye} is the expected yield stress of longitudinal reinforcement, L is the member length from the maximum moment to the point of contraflexure, H' is the length of pile shaft/column from the ground surface to point of contraflexure, above ground, and D^* is the lesser cross-section dimension of shafts.

FIGURE 20.30 Example cap joint shear reinforcement — Skews > 20° [35].

20.9 Seismic Design Practice in Japan

20.9.1 Introduction

Seismic design methods for highway bridges in Japan have been developed and improved based on the lessons learned from the various past bitter experiences after the Kanto Earthquake (M7.9) in 1923. By introducing various provisions such as soil liquefaction considerations and unseating prevention devices to prevent bridges from serious damage, only a few highway bridges suffered complete collapse of superstructures in the recent past earthquakes.

However, the Hyogo-ken-Nanbu (Kobe) Earthquake (M7.3) of January 17, 1995, caused destructive damage to highway bridges. Collapse and near-collapse of superstructures occurred at nine sites and other destructive damages occurred at 16 sites [71,72]. The earthquake revealed that there were a number of critical design issues that should be reevaluated and revised in the seismic design and seismic strengthening of bridges.

Just after the earthquake, the “Committee for Investigation on the Damage of Highway Bridges Caused by the Hyogo-ken-Nanbu Earthquake” was established in the Ministry of Construction (currently Ministry of Land, Infrastructure and Transport (MLIT)) to investigate the damage and to clarify the factors that affected the damage. The committee published the intermediate investigation report in March 1995, and the final one in December 1995 [71]. Besides the investigation of damage of highway bridges, the Committee approved the “Guide Specifications for Reconstruction and Repair of Highway Bridges which Suffered Damage due to the Hyogo-ken-Nanbe Earthquake” on February 27,

1995, and the Ministry of Construction adopted on the same day that the reconstruction and repair of highway bridges that suffered damage during the Hyogo-ken-Nanbu Earthquake should be made according to the “Guide Specifications.” Then, the Ministry of Construction decided on May 25, 1995, that the “Guide Specifications” should be tentatively used in all sections of Japan as emergency measures for seismic design of new highway bridges and seismic strengthening of existing highway bridges until the Design Specifications of Highway Bridges were revised.

Based on the lessons learned from the Hyogo-ken-Nanbu Earthquake through the various investigations, the seismic design specifications for highway bridges were significantly revised in 1996 [73–75]. The intensive earthquake motion with a short distance from the inland earthquakes with Magnitude 7 class as the Hyogo-ken-Nanbu Earthquake has been considered in the design.

After that, the revision works of the design specifications of highway bridges have been continuously made. The revised specifications were targeted to use the performance-based design concept and to enhance the durability of bridge structures for a long-term use, as well as the inclusion of the improved knowledge on the bridge design and construction methods after the 1996 specifications. The 2002 design specifications of highway bridges were issued by the Ministry of Land, Infrastructure and Transport on December 27, 2001, and were published with commentary from the Japan Road Association (JRA) in March 2003 [76,77].

20.9.2 Performance-Based Design Specifications

The 2002 JRA design specifications [76] are based on the performance concept for the purpose to respond the international harmonization of design codes and the flexible applications of new structures and new construction methods. The performance-based design concept is that the necessary performance requirements and the verification policies are clearly specified. The JRA specifications employ the style to specify both the requirements and the acceptable solutions including the detailed performance verification methods which are design methods and details in the 1996 design specifications [73]. For example, the analysis method to evaluate the response against the loads is placed as one of the verification methods or acceptable solutions. Therefore, designers can propose new ideas or select other design methods with the necessary verification.

The code structure of the JRA Seismic Design Specifications is as shown in Figure 20.31. The static and dynamic verification methods of the seismic performance as well as the evaluation methods of the

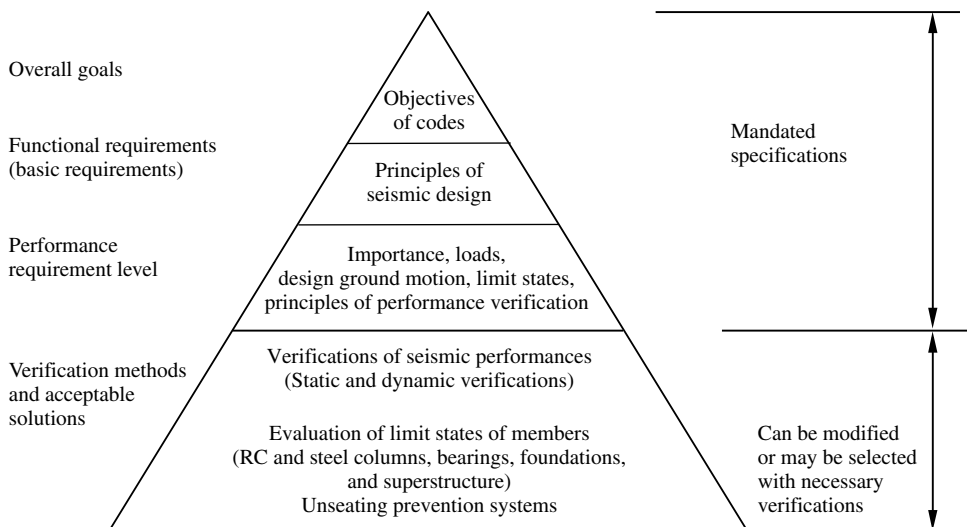

FIGURE 20.31 Code structure of JRA seismic design specification.

strength and ductility capacity of the bridge members are placed as the verification methods and the acceptable solutions, which can be modified by the designers with the necessary verifications.

20.9.3 Basic Principles of Seismic Design

Table 20.15 shows the performance matrix including the design earthquake ground motion and the seismic performance level (SPL) provided in the JRA Seismic Design Specifications. The two-level ground motions are the moderate ground motions induced in the earthquakes with high probability to occur (Level 1 earthquake) and the intensive ground motions induced in the earthquakes with low probability to occur (Level 2 earthquake).

The Level 1 earthquake provides the moderate earthquake ground motions considered in the conventional elastic design method. For the Level 2 earthquake, two types of intensive ground motions are considered. The first is the ground motions that are induced in the interplate-type earthquakes with a magnitude of around 8. The ground motion at Tokyo in the 1923 Kanto Earthquake is a typical target of this type of ground motion. The second is the ground motion developed in earthquakes with magnitude of around 7 at a very short distance. The ground motion at Kobe during the Hyogo-ken-Nanbu Earthquake is a typical target of this type of ground motion. The first and the second ground motions are named as Type-I and Type-II ground motions, respectively.

Figure 20.32 shows the acceleration response spectra of the design ground motions. It is specified that the site-specific design ground motions shall be considered if the ground motion can be appropriately estimated based on the information on the earthquake including past history and the location and detailed condition of the active faults, ground conditions including the condition from the faults to the construction sites. The site-specific design ground motion shall be developed by utilizing necessary and accurate information on the earthquake and ground conditions as well as the verified evaluation methodology of the fault-induced ground motions. However, such detailed information in the regions of Japan is very limited so far. Therefore, continuous investigation and research on this issue as well as the reflection on the practical design of highway bridges is expected.

20.9.4 Ground Motion and Seismic Performance Level

The seismic design of bridges is according to the performance matrix as shown in Table 20.15. The bridges are categorized into two groups depending on their importance: standard bridges (Type-A bridges) and important bridges (Type-B bridges). The SPL depends on the importance of bridges. For the moderate ground motions induced in the earthquakes with high probability of occurrence, both A and B bridges shall behave in an elastic manner essentially without structural damage (SPL: 1). For the intensive ground motions induced in the earthquakes with low probability of occurrence, the Type-A bridges shall prevent critical failure (SPL: 3), while the Type-B bridges shall perform with limited damage (SPL: 2).

SPLs 1 to 3 are based on the viewpoints of “safety,” “functionability,” and “repairability” of bridge structures during and after the earthquakes. Table 20.16 shows the basic concept of these three viewpoints of the SPL.

TABLE 20.15 Seismic Performance Matrix (Design Ground Motion and Seismic Performance Level)

Type of design ground motions	Standard bridges (Type-A)	Important bridges (Type-B)
Level 1 earthquake: ground motions with high probability of occurrence	SPL 1: prevent damage	
Level 2 Earthquake: ground motions with low probability of occurrence Interplate earthquakes (Type-I) Inland earthquakes (Type-II)	SPL 3: prevent critical damage	SPL 2: limited damage for function recovery

Note: SPL, seismic performance level.

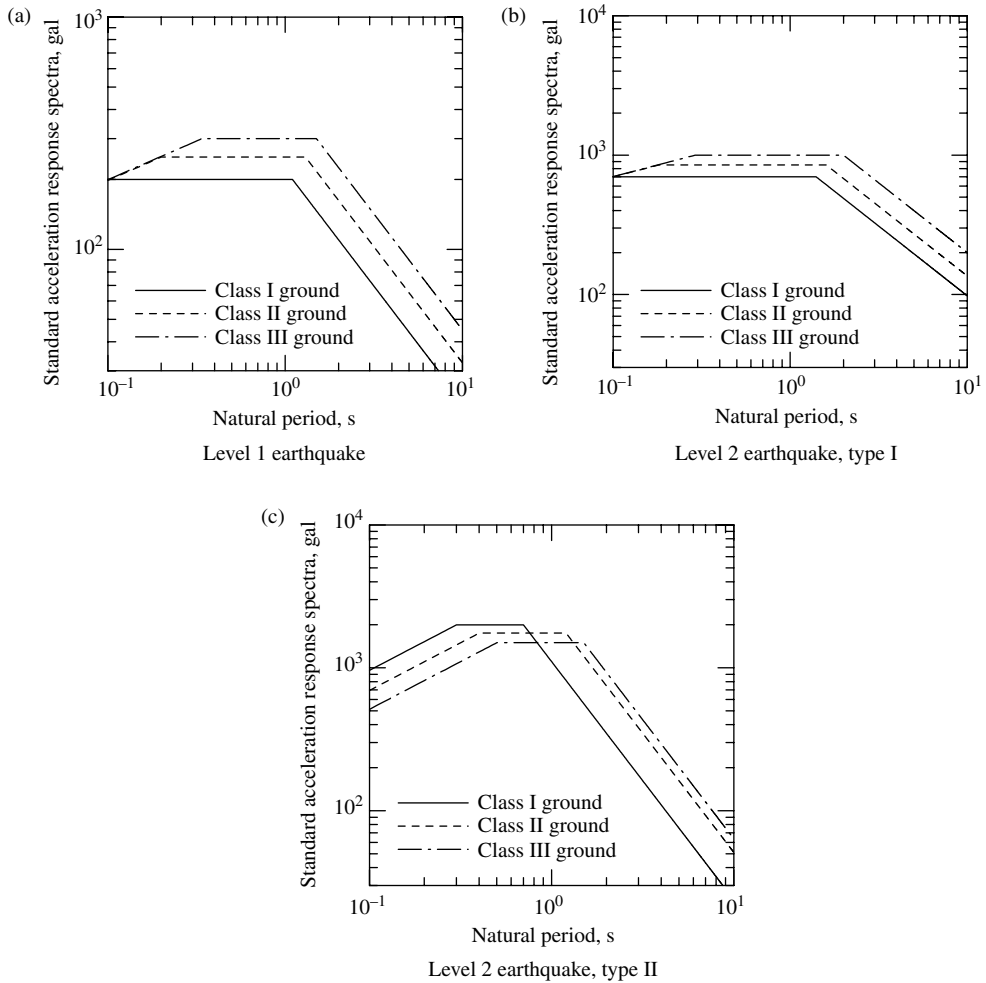

FIGURE 20.32 Design acceleration spectrum. (Class I ground: stiff ground, Class II ground: medium ground, Class III ground: soft ground.)

TABLE 20.16 Key Issues of Seismic Performance

SPL	Safety	Functionability	Repairability	
			Short term	Long term
SPL 1, Prevent damage	Safety against unseating of superstructure	Same function as before earthquake	No need of repair for function recovery	Simple repair
SPL 2, Limited damage for function recovery	Safety against unseating of superstructure	Early function recovery can be made	Function recovery can be made by temporary repair	Relatively easy permanent repair work can be made
SPL 3, Prevent critical damage	Safety against unseating of superstructure	—	—	—

20.9.5 Verification Methods of Seismic Performance

20.9.5.1 Seismic Performance Level and Limit States

In the JRA specifications [76], the determination principles of the limit state to attain the necessary seismic performance are clearly specified. For example, the basic principles to determine the limit state for SPL 2 is: (1) the plastic hinges shall be developed at the expected locations and the capacity of plastic hinges shall be determined so that the damaged members can be repaired relatively easily and quickly without replacement of main members; (2) the plastic hinges shall be developed at the portions with appropriate energy absorption and with quick reparability; (3) considering the structural conditions, the members with plastic hinges shall be appropriately arranged and the limit states of members with plastic hinges shall be determined appropriately. Based on the basic concept, the arrangement of members with plastic hinges and the limit states of members for ordinary bridge structures are specified in the commentary.

20.9.5.2 Verification Methods of Seismic Performance

It is the fundamental policy that the response of the bridge structures against design earthquake ground motions shall be verified by specified method not to exceed the specified limit states.

Table 20.17 shows the applicable verification methods of seismic performance. In the seismic design of highway bridges, it is important to increase the strength and the ductility capacity to appropriately resist the intensive earthquakes. The verification methods are based on static and dynamic analyses. In the JRA specifications, the static lateral force coefficient method with elastic design, ductility design method, and dynamic analysis are specified and these design methods shall be selected based on the configurations of bridge structures.

The static verification methods including the lateral force design method and the ductility design method are applied for the bridges with simple configuration with predominant single mode during the earthquakes. The dynamic verification method is applied for the bridges with complicated configuration; in such cases the applicability of the static verification methods is restricted. In the JRA specifications, the applicability of the dynamic analysis is expanded and the dynamic verification method is limited mainly with appropriate design consideration.

TABLE 20.17 Applicable Verification Methods of Seismic Performance Depending on Earthquake Response Characteristics of Bridge Structures

Dynamic characteristics; SPL to be verified	Bridges with simple configuration	Bridges with multi-plastic hinges and without verification of applicability of energy constant rule	Bridges with limited application of static analysis	
			With multimode response	Bridges with complicated configuration
SPL 1	Static verification	Static verification	Dynamic verification	Dynamic verification
SPL 2/SPL 3	Static verification	Dynamic verification	Dynamic verification	Dynamic verification
Example of bridges	Other bridges	(1) Bridges with rubber bearings to distribute inertia force of superstructures (2) Seismically isolated bridges (3) Rigid frame bridges (4) Bridges with steel columns	(1) Bridges with long natural period (2) Bridge with high piers	(1) Cable-stayed bridges, suspension bridges (2) Arch bridges (3) Curved bridges

Glossary

- Capacity-protected component** — A component expected to experience minimum damage and to behave essentially elastic during the design earthquakes.
- Concentrically braced frame (CBF)** — A diagonally braced frame in which all members of the bracing system are subjected primarily to axial forces.
- Connections** — A combination of joints used to transmit forces between two or more members.
- Design earthquake** — Earthquake loads represented by acceleration response spectrum (ARS) curves specified in design specifications or codes.
- Displacement ductility** — Ratio of ultimate-to-yield displacement.
- Ductile component** — A component expected to experience repairable damage during the FEE and significant damage but without failure during the SEE.
- Ductility** — Ratio of ultimate-to-yield deformation.
- Eccentrically braced frame (EBF)** — A diagonally braced frame that has at least one end of each bracing member connected to a link.
- Expected nominal strength** — Nominal strength of a component based on its expected yield strength.
- Functional evaluation earthquake (FEE)** — A lower level design earthquake that has relatively small magnitude but may occur several times during the life of the bridge. It may be assessed either deterministically or probabilistically. The determination of this event is to be reviewed by a Caltrans-approved consensus group.
- Joint** — An area where member ends, surfaces, or edges are attached.
- Link** — In EBF, the segment of a beam that is located between the ends of two diagonal braces or between the end of a diagonal brace and a column. Under lateral loading, the link deforms plastically in shear thereby absorbing energy. The length of the link is defined as the clear distance between the ends of two diagonal braces or between the diagonal brace and the column face.
- Liquefaction** — Seismically induced loss of shear strength in loose, cohesionless soil that results from a build up of pore pressure as the soil tries to consolidate when exposed to seismic vibrations.
- Maximum credible earthquake (MCE)** — The largest earthquake that is capable of occurring along an earthquake fault, based on current geologic information as defined by the 1996 Caltrans Seismic Hazard Map.
- Moment-resisting frame (MRF)** — A frame system in which seismic forces are resisted by shear and flexure in members and connections in the frame.
- Nominal strength** — The capacity of a component to resist the effects of loads, as determined by computations using specified material strength, dimensions, and formulas derived from acceptable principles of structural mechanics or by field tests or laboratory test of scaled models, allowing for modeling effects, and differences between laboratory and field conditions.
- Overstrength capacity** — The maximum possible strength capacity of a ductile component considering actual strength variation between the component and adjacent components. It is estimated by an overstrength factor of 1.2 times expected nominal strength.
- Plastic hinge** — A concentrated “zero length” hinge that maintains its plastic moment capacity and rotates freely.
- Plastic hinge zone** — A region of structural components that are subject to potential plastification and thus must be detailed accordingly.
- Seismic performance criteria** — The levels of performance in terms of postearthquake service and damage that are expected to result from specified earthquake loadings.
- Safety evaluation earthquake (SEE)** — An upper level design earthquake that has only a small probability of occurring during the life of the bridge. It may be assessed either deterministically or probabilistically. The deterministic assessment corresponds to the maximum credible earthquake. The probabilistically assessed earthquake typically has a long return period (approximately 1000 to 2000 years).

Ultimate displacement — The lateral displacement of a component or a frame corresponding to the expected damage level, not to exceed the displacement when the lateral resistance degrades to a minimum of 80% of the peak resistance.

Upper bound solution — A solution calculated on the basis of an assumed mechanism that is always at best equal to or greater than the true ultimate load.

Yield displacement — The lateral displacement of a component or a frame at the onset of forming the first plastic hinge.

Davis, CA*

Performance-based design (PBD) has emerged as the new paradigm in seismic engineering. The concept of PBD is not limited to the field of seismic design, though the material covered in this chapter focuses primarily on recent developments in earthquake engineering. Performance-based seismic engineering (PBSE) is still an evolving methodology; hence, the information presented in this chapter should not be

interpreted as an existing design specification or an adopted standard. Rather, the contents of this chapter should be viewed as an introduction to an emerging concept for seismic design of building systems.

There are several completed and ongoing efforts to develop performance-based seismic design methodologies. Published documents such as ATC-40 (1996), FEMA-350 (2000), and FEMA-356 (2000) embody key aspects of PBD; however, they were each developed with limited objectives. FEMA-350 applies to new steel moment frames only. ATC-40 and FEMA-356 contain guidelines for the evaluation and rehabilitation of existing buildings; the former is limited to the evaluation of existing reinforced concrete buildings, while the latter covers all building types and is, therefore, referred to as a “prestandard” suggesting that it may resemble the model of a PBD code.

The purpose of this chapter is to provide readers with an overview of existing procedures that attempt to incorporate performance-based concepts in seismic design of new structures or evaluation of existing structures. Several potential approaches to accomplishing the goals of PBD will be discussed and an illustrative example that applies each conceptual framework in the evaluation of a hypothetical design will be presented so as to offer a basis for comparing the relative merits and potential drawbacks of each approach. Much of the emphasis will be placed on buildings since they constitute the largest stock of structures in the built environment, though the procedures outlined here can be extended with minimal effort to other structural systems.

21.1 Some Issues in Current Seismic Design

The first question that comes to mind when introducing a new methodology is the obvious one: why do we need a new procedure? What is inherently wrong or inadequate in the existing provisions for design that warrants a new look at the entire process? Hence, the task of introducing PBSE is more easily accomplished by highlighting the limitations and drawbacks of existing seismic design procedures.

Since the early development of seismic design codes, global response modification factors (or R -factors) have remained at the core of seismic force formulas. The main purpose of the force-reduction factors used in seismic design is to simplify the analysis process so that elastic methods can be used to approximately predict the expected inelastic demands in a structure subjected to the design loads. They account for reductions in seismic force values due to a variety of factors including system inherent ductility, overstrength, and redundancy. Of these, only the ductility component of the R -factor is generally implied in the design provisions because systems with larger expected ductility have the lowest reduction factors. Current codes also specify a displacement amplification factor C_d that quantifies the expected inelastic displacement of the system. Both R and C_d factors are global response measures that do not provide an assessment of structural performance at the component level. There is growing awareness that force-based design using R and C_d factors has serious shortcomings. For instance, these factors are independent of the building period and ground motion characteristics. Additionally, the same R -factor is used for moment-resisting reinforced concrete (RC), steel, and braced frames. It is clear that a single global response modifier cannot capture the progressive distribution of nonlinearities between various structural elements, the resulting redistribution of seismic demands inside the structure, and the changes that occur during the course of the seismic motion. In addition to differences in seismic demands and failure mechanisms, the damage distribution is also likely to vary from one structure to the other even though they have all been designed for the same R -value. A coherent description of the meaning and basis of establishing force-reduction factors is outlined in two papers by Uang (1991) and Uang and Bertero (1991). Figure 21.1 shows the base-shear versus roof displacement response of a typical building structure. The vertical axis in Figure 21.1 shows the base shear coefficient, which is the total shear normalized by the seismic weight of the building (V/W). The design base shear coefficient of the building is C_s , while the corresponding elastic strength is C_e . As is evident from the response of the structure, the yield strength of the building is C_y (assuming a bilinear idealization as shown). First yielding in a member in the system should typically commence at C_s , though material overstrength and member sizing

FIGURE 21.1 Conceptual basis behind use of *R*-factors.

may delay initial yielding beyond this value. Hence, the actual force-reduction factor or response modification factor as defined in IBC (2000) can be defined as follows:

$$R = \frac{C_e}{C_s} = \frac{C_e}{C_y} \cdot \frac{C_y}{C_s} \tag{21.1}$$

The ratio C_e/C_y can be viewed as the response modification factor related to ductility (R_{μ}), while the ratio C_y/C_s contains two components: overstrength (R_{Ω}) and redundancy (R_R). Hence, the *R*-factor can be broken down into three main components as indicated in Equation 21.2:

$$R = R_{\mu} R_{\Omega} R_R \tag{21.2}$$

Numerous factors influence each of the modifiers that appear in Equation (21.2). For example, the postyield strain (or stiffness) can affect both R_{μ} and R_{Ω} . The use of higher material strengths than those specified in the design, satisfying minimum code requirements for detailing, etc., the presence of nonstructural components, and the oversizing of members have an impact primarily on R_{Ω} and R_R . The product $R_{\Omega}R_R$ is likely to have greater variability for RC than for steel structures. It is clearly difficult to isolate the different components of the reduction factor and thereby provide engineers with an understanding of the demands imposed not only on the overall system but also on individual components in the system and the margin of safety against failure.

Since the total lateral force or base shear is the primary design parameter, the current code format is regarded as a “strength-based” design procedure. The idea of distributing strength throughout the structure rather than relying on a single base-shear parameter is recognized in the concept of capacity design (Park and Paulay 1976), which forms the basis of the New Zealand building code. The realization that displacements are more critical than forces initiated the move toward displacement-based design (Moehle 1992, 1996; Priestley and Calvi 1997; Chopra and Goel 2001). Procedures to enhance displacement-based methods yet retain the simplicity of a response spectrum to characterize the hazard were developed by Fajfar and Gasperic (1996). Other interesting research on the shortcomings of existing procedures and the promise of new ideas to advance seismic design methodologies was presented at a workshop in Slovenia (Fajfar and Krawinkler 1997).

While displacement (or deformation) based criteria still remain at the core of ongoing developments to improve the state of practice, the need to correlate measures of performance with measures of demand

has ushered the need for performance-based principles to be integrated into the design process. Following the observed damage in the 1989 Loma Prieta earthquake and the aftermath of the seismic events in Northridge and Kobe, a national effort was launched to reevaluate the principles governing modern seismic design, which culminated in the release of FEMA-356. Two developments that laid the foundation for the Federal Emergency Management Agency (FEMA) document include the prior effort that led to ATC 3-06 (1978) and a parallel effort that produced Vision 2000 (SEAOC 1995). ATC-3-06 marked a significant improvement in seismic provisions with the recognition of a seismic hazard in terms of a mean annual frequency (or return period). The specified return period of 475 years (or a 10% probability of exceedance in 50 years) and associated information (effective peak acceleration (EPA), effective peak velocity (EPV)) facilitated the development of a design spectrum. Vision 2000, an effort initiated and supported by the Structural Engineers Association of California (SEAOC), was concerned with developing a framework for seismic design that explicitly addressed issues beyond life safety to include damageability and functionality.

21.2 Introduction to PBSE

The concepts of hazard and performance level are implied in the provisions of standard building codes such as International Building Code (IBC). The *SEAOC Blue Book*, regarded as the commentary for the Uniform Building Code (now IBC) provisions, clearly identifies the following performance objectives:

- No damage for minor levels of ground motion.
- No structural damage but some nonstructural damage for moderate ground motions.
- Structural and nonstructural damage but no collapse for major levels of ground motion (which include the strongest credible earthquake at the site).

Despite the recognition of three damage states implied in modern codes, life safety has historically been the principle concern in seismic design. Furthermore, there are no explicit procedures or processes that allow an engineer to evaluate the expected performance of the final design or assess the margin of safety provided by satisfying code requirements. Recent experience has shown that property damage and related losses resulting from minor to moderate earthquakes is significant. Nonstructural considerations and business losses can dominate the cost–benefit ratio in a life-cycle cost analysis (Krawinkler 1997). Hence, emphasis on nonstructural issues and business interruption losses must become part of the equation in a holistic treatment of seismic design. This and other concerns discussed in the previous section have led researchers and engineers to rethink the principles and process governing modern seismic design. The various alternative strategies proposed by numerous individual and group research efforts have collectively led to the evolution of performance-based concepts that allow the design of buildings (or the rehabilitation of existing buildings) with due consideration to different design objectives and varying levels of risk and loss. While current design methodology relies considerably on empirical formulations and prescriptive procedures that require only minimal design checks (such as drift limits following the sizing of sections), PBD methodology calls for a detailed demand evaluation of the building model under simulated earthquake loads to assess if the design objective has been achieved. The assessment is intended to project the potential damage and associated losses, which in turn allows all stakeholders (from the building owner to insurers and the building occupants) to specify desired levels of performance, which then becomes the basis of design for the structural engineer. While this entails a more significant responsibility on the part of the design professional, it also means that greater flexibility is possible in the design — in terms of new design alternatives and techniques (the use of seismic protection devices is one example) that can be utilized to achieve the expected performance objective.

21.2.1 Elements of a Typical Performance-Based Methodology

The first definitive document that laid the basis for PBD in seismic engineering is FEMA-356 (2000), which essentially synthesizes two earlier reports, FEMA-273 and FEMA-274, and deals with seismic

rehabilitation of existing buildings. A parallel effort that resulted in the publication of ATC-40 (1996) is limited to RC buildings but is more comprehensive in its treatment. At least one other guideline that builds on FEMA-273 is the result of the FEMA-sponsored SAC project that produced FEMA-350 (2000). Other notable research that addresses issues in performance-based engineering includes ongoing efforts at the Mid-America Earthquake (MAE) and Pacific Earthquake Engineering Research (PEER) centers.

The contents of this chapter are based on the concepts and procedures outlined in the various documents and guidelines cited above. All performance-based methodologies share common elements. Though the details of implementation may vary from one methodology to the next, the basic objectives of the each approach are essentially the same. An attempt is made in the following sections to classify the key components of a typical PBD methodology in three collective steps:

- Step 1. a.* Define a performance objective that incorporates a description of both the hazard and the expected level of performance.
 - b.* Select a trial design.
- Step 2.* Determine seismic demands on the system and its components through an analysis of a mathematical model of the structure.
- Step 3.* Evaluate performance (at the system and component levels) to verify if the performance objective defined in Step 1 has been met. If performance levels are not satisfactory, revise design and return to Step 2.

A brief overview of the three-step process is outlined in the following sections.

21.2.1.1 Quantifying Performance Objectives

Stated simply, a performance objective specifies the desired seismic performance target for the structure. A performance objective consists of two parts: a level of performance that is typically expressed in terms of a *damage state* or *decision variable* and a *hazard level* that describes the expected seismic load at the site. Some examples of performance levels include: collapse prevention, life safety (preservation of human life), and immediate occupancy of the building following the design seismic event. Alternatively, a performance level can be expressed in terms of its economic impact (dollar loss or downtime). A commonly used description of hazard is the probability of the event in a given duration, for example, 10% probability of the design seismic loads being exceeded in 50 years. The intent of this notion of a performance objective is conveyed in Figure 21.2, which quantifies the allowable damage or loss as

FIGURE 21.2 Defining performance objectives.

a function of the intensity of the earthquake load. As suggested earlier, a hazard level denotes the severity of the earthquake. A minor hazard level would represent an event with a higher probability of being exceeded during the life of the structure, while an increased hazard level representing a more severe event would indicate a reduced probability for the same duration. Damage states may be quantified in numerous ways, but two of the most common approaches are physical damage states based on the degree of inelastic response of members and expected losses including economic and indirect losses.

Since a structural system is composed of both primary and secondary elements, the specification of a performance level can be distinguished depending on the structural function. Hence, the structural performance level can be different from the nonstructural performance level for a given performance objective.

21.2.1.1.1 Description of Hazard

Earthquake ground motions, or the characteristics of the expected ground motions, are generally used in conjunction with a performance objective. Given the uncertainty in predicting ground motions, the task of establishing a site-specific design event is a difficult but critical part of any PBD methodology. The description of the hazard is meant to represent the seismic threat given knowledge of the potential earthquake sources at the site. This is typically accomplished through a probabilistic seismic hazard assessment that results in a hazard curve describing mean annual frequency of exceeding a certain spectral acceleration magnitude.

The specification of ground shaking is inevitably linked to two factors: (1) site geology and related site characteristics, which may be classified by soil profile or other soil parameters such as shear wave velocity, undrained shear strength, etc. and (2) site seismicity, which includes information on the seismic source. Ultimately, the design earthquake needs to be quantified in terms of a response spectrum as shown in Figure 21.3. The spectrum is characterized by three critical points: the peak ground acceleration (PGA) S_0 , the region of maximum spectral demands (S_m between T_m and T_n), and finally a description of the spectral demands beyond T_n .

To allow for a range of performance objectives, it is necessary to define more than a single hazard level. The prevalent thinking in most PBD guidelines is to consider at least three levels:

- *Hazard level I (or a basic service level earthquake).* Earthquakes representing this level of hazard are expected to occur more frequently, and therefore, the likelihood of such an event during the life of the structure is high. Probabilistically speaking, this event is typically equated with a 50% probability of being exceeded in 50 years or a mean return period of 72 years.
- *Hazard level II (or a design level earthquake).* This is generally the design level event. Earthquakes at this level of hazard are normally assumed to have a 10% probability of being exceeded in 50 years.

FIGURE 21.3 Key parameters in design response spectrum.

- *Hazard level III (or a maximum credible level earthquake).* Finally, it will be necessary to define a maximum credible event at the site. Such an event can be used to enable higher performance objectives (particularly for critical facilities). Here, the event is assumed to have only a 2% probability of being exceeded in 50 years.

21.2.1.2 Estimation of Demand

Once a performance objective has been defined, the next task is to determine if the design of the structure meets the stated performance objective. This means that a mathematical model of the structure is subjected to the seismic design loads (as specified by the hazard at the site in the previous step) and the demands on the system and its components are evaluated. The task of estimating seismic demand involves the determination of deformations and forces in both structural and nonstructural elements in the structure.

The prediction of deformation demands is a crucial and challenging aspect of a PBD approach. Currently, the only requirement in design that examines demand is the check on drift limitations, which is accomplished by linear elastic methods. Though some of the proposed PBD approaches suggest the use of linear methods to determine demands, there is concern that the introduction of a simplified technique into an otherwise advanced and comprehensive process will prove to be the undoing of the methodology. Errors in estimating the demand can propagate through the process and lead to misleading conclusions on the performance of the structure. Hence, for PBD methodology to become acceptable to engineers and simultaneously pass the scrutiny of researchers, there has to be consensus on an analytical approach (linear or nonlinear and static or dynamic) to evaluate seismic demands.

The process of estimating seismic demands can be subdivided into two primary tasks: developing a model of the structure wherein all structural components and essential nonstructural components are adequately represented and carrying out an analysis of the model subjected to loads that characterize the hazard level. The model may be simple or complex and is dependent on the computational tool (software) that will be used in the analysis.

The deformation demands in a structure and its elements are dependent on a variety of factors:

- *The characteristics of the seismic input.* A response spectrum is valid for static methods including modal analysis, while ground motions (recorded or simulated) are required for time history analyses.
- *Modeling of elements.*
- *Consideration of nonstructural components.*
- *Accurate estimation of material properties.*
- *Modeling of material behavior.* This relates to modeling the nonlinear response characteristics of the elements of the structure, particularly the nature of energy dissipation (hysteresis) of members. Consideration of cyclic degradation is critical to the assessment of performance and must be incorporated in the analytical model.
- *Method of analysis.* This refers to the four possible methods that can be used to estimate forces and deformations in the structural model. Static methods can be used if the seismic input is specified in terms of a response spectrum while transient methods employing a time-integration scheme must be used for ground motion input. In either case, the system of equations may be solved using a constant stiffness matrix resulting in a linear solution, or advanced techniques to incorporate material or geometric nonlinearities can be utilized.

The seismic input will already be defined in the first step in terms of either a response spectra or a set of actual ground motions that satisfy certain criteria. The modeling of structural elements that includes the specification of material-dependent force–deformation behavior is limited by the analytical tool being used to evaluate the model. Most PBD approaches utilize an element-by-element discretization of the building and specify modeling characteristics based on moment and rotation at the ends of the element with due consideration to interaction with axial and shear forces. Assuming an acceptable mathematical

model of the system is developed, the next step is to carry out an analysis of the model. This brings us to a crucial phase in the process. What kind of analysis is appropriate to accurately estimate the imposed seismic demands? Since the motivation for moving away from traditional seismic design is to abandon linear force based methods, it can be argued that the analysis has to be nonlinear. In this context, pushover methods or nonlinear static approaches have gained considerable popularity since they avoid the difficulties and uncertainties associated with time-history analyses. However, it must not be overlooked that an earthquake is a dynamic event and the reliability of using static methods to predict dynamic behavior must be carefully evaluated before prescribing its use in a performance-based evaluation. FEMA-356 prescribes the use of both linear and nonlinear methods, though certain restrictions are placed on linear and static approaches. ATC-40 restricts the analytical solution to nonlinear methods only. All four methods of analysis are discussed later in this chapter, including limitations and potential issues on their application in PBSE.

21.2.1.3 Assessment of Performance

This can be regarded as the third and final phase of a performance-based evaluation. If the estimation of seismic demands is a critical phase in a PBD methodology that must be carried out cautiously with attention to detail, then the next stage in a performance-based evaluation wherein the estimated demands are transformed into performance measures is probably the most contentious. In this phase of the evaluation, demand values such as displacement, drift, and plastic rotation need to be interpreted on a damage scale D ($0 < D < 1$) that encompasses the complete range from elastic undamaged response to near or total collapse.

The question that needs to be addressed here is, what is the most convenient yet rational manner to translate response quantities from a structural analysis into qualitative measures of performance? Much of the work that has been conducted in the area of damage modeling becomes relevant in this context. Currently, only the PEER methodology (to be discussed later in this chapter) uses damage measures explicitly in its formulation. The approach that is favored by engineers (if FEMA-356 is used as a frame of reference) is the use of so-called acceptance criteria that demystify the demand-to-damage transformation through simple subjective but quantitative guidelines. The need to improve and fine-tune these guidelines is well recognized, but the process is well defined and deterministic.

Response quantities estimated from the analysis of the building model in Step 2 need to be compared to acceptable or allowable limits that are termed “acceptance criteria.” These limits can be specified both at the global level in terms of interstory drift limits and at the local level in terms of component demand limits. The limits are a function of performance levels. Hence, to achieve a higher performance level for a given hazard level, the acceptability criteria will be more stringent.

The introduction of acceptance criteria for different performance levels represents a significant departure from traditional seismic design and is obviously the singular step in the overall process that qualifies the term “performance based” in the terminology of structural design. To develop acceptance criteria for a range of element types, it is necessary to have access to information on physically observed damage states during laboratory testing of components and subassemblies. FEMA-356 and ATC-40 provide an initial compilation of such data based on the input of experts and must be regarded as a preliminary guideline for use in the evaluation of existing structures. What is important is that the framework now exists to establish new acceptance limits and engineers have the flexibility to develop their own data using the results of experimental research.

An alternative approach to assessing performance is to describe it in a probabilistic sense given the fact that it is difficult to establish quantitative or deterministic estimates of the consequences of demand limits or damage states. For this reason, FEMA-350 proposes “confidence levels” on the demand estimates that result in a probabilistic description of the performance level. Ongoing work in PEER and MAE attempts to further expand this description using concepts in probability theory. The result is the evolution of cumulative distribution functions or fragility curves that characterize the conditional probability of a decision, damage, or demand variable as a function of the seismic hazard.

To wrap up the introduction to the three-step methodology, it is necessary to return to one of the fundamental objectives that advanced the art of PBSE, namely, the consideration of losses from structural and nonstructural damage. The basic framework of FEMA-356 or ATC-40 does not explicitly link acceptance criteria to expected losses, but it is possible to generate estimates of potential losses given a known damage state. Some of the ongoing research in PBSE (Miranda and Aslani 2003; Krawinkler and Miranda 2004) attempts to address this issue. For example, the PEER methodology explicitly includes decision variables (such as dollar loss, downtime, or other quantifiable economic impact) in its performance-based formulation and will be briefly discussed later in this chapter.

21.3 Performance-Based Methodologies: Deterministic Approach

The precursors to performance-based design in seismic engineering, as suggested earlier in this chapter, can be found in two separate published reports: ATC-40 and FEMA-356. However, both documents arose from the urgent need to develop systematic guidelines for seismic rehabilitation of buildings. The effort to produce ATC-40 was prompted by the stock of pre-1970s cast-in-place concrete buildings in California. The lack of guidelines to assist engineers to rehabilitate these relatively nonductile buildings resulted in the ATC-40 project. Given the narrow focus of ATC-40, it provides a fairly detailed and in-depth look at different perspectives in performance-based design and evaluation. FEMA-356, on the other hand, was a much larger effort and covers all building types: steel, concrete, masonry, wood, and structures incorporating isolation or energy dissipating devices. Though both documents employ a similar format for describing performance objectives, only ATC-40 endorses the capacity spectrum method (CSM) as a basis for evaluating structural performance.

We begin with the common thematic elements in ATC-40 and FEMA-356, namely, the classification of performance levels leading to the specification of performance objectives.

21.3.1 Classifying Performance Levels

Structural and nonstructural performance levels are generally combined to yield the overall building performance level. At the structural level, the following major performance levels are used:

- Immediate occupancy (IO) level requires the building to be safe for unlimited egress, ingress, and occupancy.
- Damage control is described as a performance range from IO to life safety level rather than a specific performance level.
- Life safety (LS) level of performance suggests structural damage without partial or total collapse of structural members, which might pose a risk to life.
- Limited safety, like damage control, is another performance range that lies between LS and the structural stability limit.
- Structural stability level can be viewed as an alternative definition of collapse prevention (CP) wherein the structure is still capable of maintaining gravity loads though structural damage is severe and the risk of falling hazards is high.

Each structural performance level is associated with a damage state that can be observed or quantified. For example, FEMA-356 describes the expected damage at LS performance level for concrete frames as “extensive damage to beams,” “hinge formation” in ductile secondary elements with crack widths less than $\frac{1}{8}$ in., and permanent drifts up to 1%. At CP performance level, concrete frames could experience permanent drifts up to 4%, while steel frames may see drift (transient or permanent) magnitudes of 5%. Both FEMA-356 and ATC-40 (which applies to concrete structures only) contain detailed descriptions of damage for different element types (columns, beams, structural walls, etc). It must be reiterated that the damage measures are based on the expected performance of existing buildings. The magnitudes of

TABLE 21.1 Major Performance Levels Recommended in ATC-40 and FEMA-356

Nonstructural performance levels	Structural performance levels		
	I: immediate occupancy	III: life safety	V: structural stability (collapse prevention)
A: operational	I-A: operational	NR	NR
B: immediate occupancy	I-B: immediate occupancy	III-B	NR
C: life safety	I-C	III-C: life safety	V-C
E: not considered	NR	NR	V-E: structural stability

Note: NR, not recommended.

these measures can be adjusted if experimental data are available to support alternative performance ranges.

Nonstructural performance levels include the performance of components such as elevators, piping, fire sprinkler systems, and heating, ventilation, and air conditioning (HVAC) equipment and building contents such as computers, bookshelves, and art objects. Nonstructural performance levels can be defined as follows:

- Operational performance level requires the postearthquake damage state of all nonstructural elements to remain functional and in operation.
- IO performance level allows for minor disruption due to shifting and damage of components, but all nonstructural components are generally in place and functional.
- LS performance level allows for damage to components but does not include failure of items heavy enough to pose a risk of severe injuries or secondary hazards from damage to high-pressure toxic and fire-suppressing piping.
- Reduced hazard is a postearthquake damage state that considers risk to groups of people from falling heavy objects such as cladding and heavy ceilings.
- Finally, it is also possible to include what is called a “not considered” performance level. This performance level is provided to cover those nonstructural elements that have not been evaluated as having an impact on the overall structural response. In fact, it is common for computer models evaluating seismic demands to ignore the presence of nonstructural elements.

When structural and nonstructural performance levels are combined, the resulting building performance level is established. Table 21.1 shows how such a performance level is determined. Note that only a few selected performance levels are displayed in Table 21.1. In the context of Table 21.1, if a building performance level of III-C were selected, this would require LS performance level at both structural and nonstructural elements.

21.3.2 Defining Performance Objectives

To prescribe a set of performance objectives, ATC-40 defines the following three hazard levels: (1) a serviceable earthquake (SE) with a 50% probability of being exceeded in 50 years, (2) a design earthquake (DE) with a 10% probability of being exceeded in 50 years, and (3) a maximum earthquake (ME) with a 5% chance of being exceeded in 50 years. FEMA-356, on the other hand, specifies four hazard levels in which the earthquake event has the following probabilities: 50% in 50 years, 20% in 50 years, 10% in 50 years, and 2% in 50 years.

A performance objective is now defined by selecting a building performance objective (Table 21.1) for a given hazard level. A possible set of combinations is displayed in Table 21.2 for three hazard levels and three performance levels, making a total of nine possible combinations. For example, a possible performance objective would be to achieve an overall building performance level of III-C for a DE event which translates into LS performance for a 10%/50-year earthquake (or **b** in Table 21.2). It is also

TABLE 21.2 Defining Performance Objectives

Hazard level	Target building performance levels		
	Immediate occupancy	Life safety	Structural stability or collapse prevention
10%/50 years	<i>a</i>	<i>b</i>	<i>c</i>
5%/50 years	<i>d</i>	<i>e</i>	<i>f</i>
2%/50 years	<i>g</i>	<i>h</i>	<i>i</i>

possible to create dual or multiple performance objectives by selecting different performance levels and different hazard levels. An example of this would be achieving I-B performance level for a DE event but satisfying III-C for an ME earthquake (this would correspond to *a* and *e* in Table 21.2).

Both ATC-40 and FEMA-356 prescribe a basic safety objective (BSO), which comprises a dual-level performance objective. In ATC-40, this would entail satisfying III-C (LS performance level) for a DE and also achieving V-E (structural stability) for an ME event. In FEMA-356, the BSO criterion requires LS performance for a 10% in 50-year event and CP performance level for a 2% in 50-year earthquake. With reference to Table 21.2, the BSO in ATC-40 is *b + f* and in FEMA-356 it is *b + i*.

21.3.3 Design Response Spectra and Ground Motions

The selection of a performance objective, as just described, involves the specification of a hazard level. Unless ground motion time histories are used in a dynamic time-history analysis, it is customary to specify the hazard in terms of a response spectrum. The generation of the ground motion hazard spectrum is a function of several parameters, most of which pertain to site characteristics.

Site-specific hazard analysis is recommended for very soft soils that are vulnerable to failure under seismic action such as liquefiable soil, highly sensitive clays, high-plasticity clays with depths exceeding 25 ft and $PI > 75$, and soft- to medium-stiff clays with depths exceeding 120 ft. Soil properties are based on average values for the top 100 ft (30 m) of soil profile. Site-specific studies are also required for special and critical structures located near an active fault. Even if a site-specific hazard spectrum is developed, both FEMA-356 and ATC-40 place limits on the values of site response coefficients C_A and C_V .

In all other cases, an elastic response spectrum as shown in Figure 21.4 can be constructed from known values of C_A and C_V . Typical soil profile types are described in Table 21.3.

21.3.3.1 Generating the Design Spectrum Using ATC-40 Provisions

The site response coefficient C_A is simply the effective peak acceleration (EPA) at the site while the coefficient C_V when divided by the period defines the acceleration in the constant velocity domain. ATC-40 provides the following three options when developing the elastic design spectra:

1. Site specific hazard analysis.
2. Spectral contour maps developed by U.S. Geological Survey (USGS).
3. Site seismic coefficients given in Table 21.4.

If the USGS contour maps (developed for rock sites) are used, then the following modifications are prescribed for buildings on S_B soil sites: $C_A = 0.4S_{MS}$, $C_V = S_{M1}$, where S_{MS} is the spectral acceleration at 0.3 s (short-period range) and S_{M1} is the spectral acceleration at 1.0 s (velocity-sensitive range).

To use Table 21.4, it is first necessary to determine the shaking intensity, which is defined as the product of three quantities: $Z * E * N$ = zone factor \times earthquake hazard level \times near source factor. Using the shaking intensity value, the corresponding site response coefficients C_A and C_V are obtained for a known soil profile. The response spectrum can now be easily generated as indicated in Figure 21.4.

The potential for liquefaction and landsliding at a site are also important considerations when evaluating a structure for earthquake hazards. ATC-40 provides some guidelines for determining when

FIGURE 21.4 ATC-40 and FEMA-356 representation of the 5% damped design response spectrum.

TABLE 21.3 Average Soil Properties Used to Establish Soil Profile

Soil profile type	Soil profile name	Shear wave velocity (m/s)	Standard penetration test (blows/30 cm)	Undrained shear strength (kPa)
SA	Hard rock	>1520	n/a	n/a
SB	Rock	760–1520	n/a	n/a
SC	Very dense soil	365–760	> 50	> 2
SD	Stiff soil	180–365	15–150	1–2

Note: n/a, not applicable.

TABLE 21.4 ATC-40 Specifications for Developing Hazard Spectrum

Soil profile		Shaking intensity, ZEN					
		0.075	0.150	0.200	0.300	0.400	>0.400
SB	CA	0.08	0.15	0.20	0.30	0.40	1.0 * ZEN
	CV	0.08	0.15	0.20	0.30	0.40	1.0 * ZEN
SC	CA	0.09	0.18	0.24	0.33	0.40	1.0 * ZEN
	CV	0.13	0.25	0.32	0.45	0.56	1.4 * ZEN
SD	CA	0.12	0.22	0.28	0.36	0.44	1.1 * ZEN
	CV	0.18	0.32	0.40	0.54	0.64	1.6 * ZEN

Notes: Z = zone factor (IBC-2000: e.g., Zone 4 = 0.4g); E = 0.5 (SE), 1.0 (DE), and 1.25 (Zone 4) and 1.50 (Zone 3) (ME); N = near source factor (typically, N = 1 for faults not capable of producing events with maximum moment magnitude $M > 6.5$ and faults with slip rates less than 2 mm/year). Linear interpolation is permitted for intermediate values.

a more detailed study of these hazards is warranted. In both cases, the expected EPA is used to establish the likelihood of ground failure given the liquefaction potential or the geologic group at the site.

21.3.3.2 FEMA-356 Provisions for Generating the Design Spectrum

National Earthquake Hazards Reduction Program (NEHRP) seismic maps (also available at <http://eqhazmaps.usgs.gov>) provide peak acceleration plots for 5% damped response spectrum at two characteristic periods (short duration: 0.2 s, long duration: 1 s). These maps are referenced to site class B and must be adjusted for the applicable site class through the following equations:

$$S_{xs} = F_a S_s \tag{21.3}$$

$$S_{x1} = F_v S_1 \tag{21.4}$$

where S_{xs} is the design short-period spectral response parameter, S_{x1} is the design spectral response acceleration parameter at 1 s, F_a and F_v are the site coefficients (provided in FEMA-356), S_s is the short-period spectral response parameter, and S_1 is the spectral response acceleration parameter at 1 s.

The site-specific response spectrum is then generated using the following equations:

$$S_a = (S_{xs}/B_s)(0.4 + 3T/T_n) \quad \text{for } 0 < T \leq T_m \quad (21.5)$$

$$S_a = (S_{xs}/B_s) \quad \text{for } T_m < T \leq T_n \quad (21.6)$$

$$S_a = (S_{x1}/B_1 T) \quad \text{for } T > T_n \quad (21.7)$$

where

$$T_n = (S_{x1} B_s)/(S_{xs} B_1) \quad (21.8)$$

and B_s and B_1 are damping coefficients, quantified in FEMA-356 as a function of effective damping in the system. The resulting response spectrum is conceptually similar to ATC-40 and is shown in [Figure 21.4](#).

21.3.4 Ground Motions

Both ATC-40 and FEMA-356 contain provisions for using acceleration time histories in conjunction with transient response analyses. A minimum of three ground motion sets must be used. The selected ground motions are expected to have magnitude, fault distances, and source mechanisms that are comparable to the ground-shaking hazard at the building site. FEMA-356 requires that the data sets be scaled in such a manner that the average value of the square root of sum of squares (SRSS) spectra (that are generated for each data set) does not fall below 1.4 times the 5% damped spectrum for the DE for periods between $0.2T$ and $1.5T$ (where T is the fundamental period of the structure).

When only three time history sets (one horizontal and one vertical component for two-dimensional [2D] systems and all three components for a 3D model) are used in the evaluation process, the maximum value of each response parameter should be considered. If seven or more records are used, then both FEMA-356 and ATC-40 permit mean response estimates to be considered to assess design acceptability.

ATC-40 actually provides a list of ten earthquake data sets for two scenarios: sites that are farther than 10 km from the source and sites that are within 5 km from the source to be considered near-fault events. The ground motions listed in ATC-40 are free-field motions recorded on firm soil sites with magnitude greater than 5.5 and a PGA exceeding 0.2g. A subset of these records is used in the design example presented later in this chapter. It is expected that the listed ground motions be scaled such that the average value of the spectra matches the site response spectrum in the period range of interest (an effective period range near the performance point of the structure — see ensuing discussion on CSM for a definition of the performance point).

21.4 Evaluating Seismic Demands

The estimation of seismic demands requires the development of a mathematical model of the building. The model should incorporate all components that influence the mass, stiffness, and strength of the building, particularly in the inelastic regime of the response. Hence, issues like soil–structure interaction must be carefully evaluated before a decision is made to include or exclude the soil–foundation system in the final model. The model should properly account for gravity loads that comprise dead loads and other permanent fixtures. Consideration of live loads is also necessary if the presence of additional gravity loads is likely to create a situation resulting in adverse seismic response or the shifting of the location of the plastic hinge.

A structural model also includes specification of the expected behavior of all of the elements used to develop the building model. A linear elastic analysis requires only the estimation of the effective stiffness of each element, whereas a nonlinear analysis demands a more concerted effort to establish the expected local behavior of every element in the overall structural model. The guidelines summarized in the next section are partly based on recommendations collectively provided in ATC-40, FEMA-356, and FEMA-350.

21.4.1 Modeling Guidelines

The development of analytical models must account for all possible aspects of behavior while still working within the limitations of the analytical tools being used to carry out the evaluation of seismic demands. Both commercial and noncommercial software is available to assist engineers in estimating seismic demands, and the modeling requirements vary from one tool to the next. Most programs employ simple hinge-based inelastic models with multilinear characterization of force–deformation behavior. In general, it is necessary to model three commonly recognized aspects of cyclic behavior: stiffness degradation, strength deterioration, and pinching response. Hysteretic models that incorporate some or all of these behavioral aspects have been proposed by numerous researchers (Kunnath et al. 1997; Sivaselan and Reinhorn 2000). There is also a large body of work on degrading force–deformation models developed by Japanese researchers, many of which are summarized in a report by Umemura and Takizawa (1982).

A general hysteretic model that incorporates all three elements is shown in Figure 21.5. This basic model, which is implemented in the inelastic damage analysis of RC structures (IDARC) (Kunnath et al. 1992; Kunnath 2004) series of programs, uses several control parameters to establish the rules under which inelastic loading reversals take place. A variety of hysteretic properties can be achieved through the combination of a nonsymmetric trilinear curve and certain control parameters that characterize the shape of the force–deformation loops. For example, α , which can be expressed as a function of the deformation, controls the amount of stiffness loss; ϕ and χ control the initiation and degree of pinching respectively; and the slope s and the change in expected peak strength (M to M^*) control the softening due to system deterioration. A sample simulation of observed behavior using this model is shown in Figure 21.6. The hysteresis curves in this case were obtained from tests of a precast concrete connection with a hybrid combination of mild steel and posttensioning steel (Cheok et al. 1998). However, the specification of hysteretic rules in an actual analysis is rather empirical and should be based on available experimental data. Even so, a parametric study to evaluate the sensitivity of these parameters is necessary.

FIGURE 21.5 General-purpose hysteretic model.

FIGURE 21.6 Simulation of observed hysteretic behavior.

The degree of degeneration is a function of the connection detail. Welded steel moment connections or well-detailed RC members may display stable hysteresis with little degradation of strength in the performance range of the element. Bolted connections or concrete sections with inadequate details may exhibit pinching behavior. Shear dominated members will experience rapid decay in strength after yielding. In general, it is necessary to know in advance the expected behavior of an element when using force–deformation type models. Complete cyclic description of behavior, as illustrated in Figure 21.5 and Figure 21.6, is essential for nonlinear time-history methods only. For nonlinear static approaches, only the force–deformation envelope is needed. FEMA-356 and ATC-40 specify three types of force–deformation envelopes for use with nonlinear static analyses. These are displayed in Figure 21.7. A Type I envelope is meant to represent the expected behavior of a well-detailed ductile connection with a well-defined postyield range (a to b), a region of gradual decay (b to c), and a nonnegligible residual strength that is capable of supporting gravity loads in the regime (c to d). A Type II curve is similar to Type I with the exception that an element modeled as Type II cannot be relied upon to support gravity loads beyond “b.” An important characterization in FEMA is the classification of members as being force controlled or deformation controlled. Members modeled as Type I are generally deformation-controlled members while Type II elements can be classified as deformation controlled only if the ductility at peak strength (b/a) is greater than 2.0. A Type III curve is representative of brittle failure and is, therefore, always a force-controlled element.

An additional detail that is outlined in FEMA-350 is the identification and specification of the interstory drift angle and the associated plastic hinge locations. The idea is that frames should be detailed in such a manner that the required interstory drift angle can be accommodated through a combination

FIGURE 21.7 Envelope patterns recommended in ATC-40 and FEMA-356 for use in nonlinear analysis methods to estimate seismic demands.

of elastic deformation and the development of plastic hinges at known locations within the frame. For example, the use of details such as haunches or reduced beam sections can force yielding in the beam but away from the column face. Figure 21.8 demonstrates this concept. The interstory drift angle, as specified in FEMA-350, is equal to the sum of the plastic drift and that portion of the elastic interstory drift resulting from flexural deformation of the individual members. Interstory drift resulting from axial deformations of columns is not included.

21.4.1.1 P-Δ Effects

The consequence of secondary moments resulting from excessive lateral displacements can have a major impact on the performance of a building in the postyield range of the response. P-Δ effects alter the postyield stiffness of a structure, and with increasing deformation demands the net effect of P-Δ softening can lead to rapid deterioration and collapse of the system. FEMA-356 recognizes both static and dynamic P-Δ effects. For linear procedures, it is required to evaluate a stability coefficient given by

$$\theta_i = \frac{P_i \delta_i}{V_i h_i} \tag{21.9}$$

where P_i is the weight of structure acting on story level i , V_i is the total lateral shear force acting on story level i , h_i is the height of story level i , and δ_i is the lateral drift of story i .

If the stability coefficient is less than 0.1 in all stories, then P-Δ effects can be ignored in the analysis. For values of the coefficient between 0.1 and 0.33, the seismic effects are to be magnified by a factor $1/(1 - \theta_i)$, and for values in excess of 0.33, the system is considered unstable and should be redesigned.

Even if nonlinear procedures are used, a magnification factor (C_3) is used in FEMA-356 for static methods because dynamic P-Δ effects are recognized as being different from static effects. Static P-Δ should be incorporated in pushover analysis, while both static and dynamic P-Δ can be automatically incorporated in nonlinear dynamic procedures.

21.4.1.2 Other Effects and Considerations

In general, it is expected that a building be modeled as a 3D assembly of elements. However, most structures tend to be fairly regular with assumptions of symmetry commonly employed in routine analysis. Some modeling issues that must be resolved before finalizing a building model for use in demand prediction include the following:

- The assumption of rigid diaphragms, which allows axial deformations in floor beams to be ignored and simplifies the resulting system of equations that need to be solved.
- Any out-of-plane offsets in those vertical elements that resist lateral forces must be accounted for when estimating demands on floor diaphragms.

FIGURE 21.8 Definition of interstory drift angle.

- Consideration of actual and accidental horizontal torsion: FEMA-356 lists specific criteria for considering the effects of horizontal torsion.

Normally, it is adequate to consider seismic input in each principal direction of the building only. However, for irregular buildings, concurrent seismic effects in two orthogonal directions must be accounted for by combining 100% of the design effects in one direction with 30% of the design effects in the orthogonal direction. Similarly, the need to consider vertical seismic input arises only in special circumstances such as cantilevered or prestressed elements and those components in which gravity load demands are excessive.

Other considerations not discussed in this section include

- Foundation and SFSI interaction effects.
- Variability in ground motion.
- Modeling of secondary and nonstructural components.
- Introduction and modeling of seismic protection devices such as isolators, dampers, and other energy dissipating devices.

A description of the details that take into consideration the consequence of the above effects is beyond the scope of this chapter.

21.4.2 Methods of Analysis

The estimation of demands can be accomplished using a variety of available procedures. In this section, discussion will be limited to a generic set of evaluation methods that best lend themselves to an assessment within a performance-based framework. The primary objective is to determine forces and deformations both at the global and at the local level when the structure is subjected to seismic loads that characterize the hazard at the building site. As such, there are four possible methods to analyze a mathematical model of a building structure. They may be classified into two broad categories depending on the treatment of the response or the treatment of the loads. The former category results in the distinction between linear and nonlinear methods of analysis, while the latter distinguishes static and dynamic application of the seismic loads.

Linear static and dynamic procedures (LSP and LDP). These procedures are recommended for regular buildings where issues such as torsion and high-mode effects are negligible. The expectation is that the computed displacements using linear equivalent elastic stiffness are approximately equal to the actual displacements that may occur inelastically under the design loads. FEMA-356 lists specific criteria to limit the use of such procedures. For example, it states that linear methods should not be used if the demand to capacity ratio (also called m -factors) for any element in the structure exceeds 2.0. Even if m -factors exceed 2.0, linear procedures may still be used for regular buildings. Section 2.4.1.1 of FEMA-356 outlines criteria for in-plane and out-of-plane discontinuities in the lateral force resisting system and also for irregularities arising from weak stories or torsional strength. Linear procedures are not recommended in ATC-40.

Nonlinear static and dynamic procedures (NSP and NDP). Nonlinear procedures are generally applicable for all buildings with the exception that NSP is limited to buildings where high-mode effects are small. Again, the FEMA document has explicit guidelines to determine if higher modes play an important role in the response: high-mode effects are deemed significant if the shear in any story resulting from a modal analysis considering modes required to obtain 90% mass participation exceeds the corresponding story shear considering first-mode response only by a factor of 1.3.

The LSP is the simplest procedure described in FEMA-356. LSP is an equivalent lateral load analysis procedure that attempts to represent the seismic loading as a static force. The reason for retaining a linear static approach in a performance-based guideline is debatable, but the motivation stems from the simplicity of the method and the current familiarity among engineers with force-based design. It is also felt that such an approach may still be valid for a large group of regular structures. The total lateral load applied to the structure is calculated from

$$V = C_1 C_2 C_3 C_m S_a W \quad (21.10)$$

where V is the total base shear, C_1 , C_2 , and C_3 are modification factors to account for the effects of inelasticity, system degradation, and P - Δ effects, respectively, C_m is an effective mass factor to account for high-mode participation, and S_a is the spectral acceleration at the fundamental period of the structure. The seismic weight of the structure, W , includes 25% of live load in addition to dead loads. The fundamental period, T , of the structure can be computed using an eigenvalue analysis or through an empirical equation, given by the following expression:

$$T = C_t (H_n)^\beta \quad (21.11)$$

where H_n is the height of the building measured from base to roof, and coefficient C_t and power β depend on the structural system. The fundamental period is a critical parameter in the evaluation procedure for both static procedures (LSP and NSP), since they can change the applied lateral force in the linear procedure or alter the target displacement in the nonlinear procedure (discussed in [Section 21.5.2](#)). The total shear computed in Equation 21.10 is distributed over the building height as follows:

$$F_x = \frac{w_x h_x^k}{\sum w_i h_i^k} V \quad (21.12)$$

where w_i is the portion of weight at floor level i , w_x is the portion of weight at floor level x , H_i is the height from base to floor level i , H_x is the height from base to floor level x , and $k = 1.0$ for $T < 0.5$ s and 2.0 for $T \geq 2.5$ s.

The summation in the denominator of Equation 21.12 is carried over all stories, and the coefficient k in the period range from 0.5 and 2.5 s is established through linear interpolation. Note that a reduction factor is not applied to the computed base shear. Hence, the demands will exceed the strength capacity of those components that are expected to yield under the design earthquake loads. The resulting demand-to-capacity ratios are evaluated at the component level.

The LDP involves a linear elastic dynamic analysis using a response spectrum approach or direct time-history evaluation to determine the building response. Linear elastic stiffness properties of elements and equivalent viscous damping at or near the yield level are to be used in the analysis. An unmodified elastic spectrum is utilized in a response spectrum analysis. Peak forces and deformations are estimated using an SRSS or complete quadratic combination (CQC) of modal quantities. For time-history methods, if less than seven earthquake records are used, the maximum response quantities are to be used in the evaluation procedure. For seven or more records, an average value of the response is adequate. As mentioned previously, FEMA-356 requires that each record be scaled such that the average value of the SRSS of the 5% damped spectrum does not fall below 1.4 times the design spectrum value (also constructed for 5% damping) between $1.2T$ and $1.5T$ (where T is the fundamental building period).

The NSP or pushover analysis takes into consideration material nonlinearities. The concept gained prominence after its introduction in the CSM by Freeman (1978). The nonlinear static method is also called the displacement coefficient method in that the expected demand (target displacement) of a single degree-of-freedom (SDOF) system is modified by a set of coefficients to approximate the multiple DOF response. The procedure involves selecting a control node (typically the center of mass at the roof level of the building) and subjecting the structural model to monotonically increasing lateral loads till a target displacement is reached. The lateral load applied to the building to achieve the control node target displacement can be distributed in several ways. The choice of a lateral load pattern can have a significant influence on the calculated response. FEMA-356 suggests that at least two patterns be used: a uniform pattern that results in lateral forces proportional to the total mass of each floor level and a modal pattern, which should be selected from the following two options: (1) when more than 75% of the total mass participates in the fundamental mode, a lateral load pattern represented by Equation 21.12 is used and (2) a lateral load pattern that is proportional to the story shear distribution, calculated by combining modal responses from a response spectrum analysis wherein at least 90% modal mass participation is incorporated, is used. The target displacement is established from the following equation:

$$\delta_t = C_0 C_1 C_2 C_3 S_d \left[\frac{T_e^2}{4\pi^2} \right] g \quad (21.13)$$

where δ_t is the target displacement (note that response quantities are determined when the roof displacement reaches this target displacement), C_0 is a modification factor relating spectral displacement estimated for an equivalent SDOF system to the likely roof displacement of a multistory structure, and the remaining coefficients C_1 to C_3 have the same meaning as previously defined for linear procedures. The effective fundamental period T_e is determined from

$$T_e = T_i (K_i / K_e)^{0.5} \quad (21.14)$$

where T_i is the elastic fundamental period, K_i is the elastic lateral stiffness, and K_e is the secant stiffness at 60% of the yield strength of the building.

Pushover methods have been the subject of numerous studies following numerous questions about the validity of using static procedures to predict dynamic demands. Modified and advanced pushover techniques are available in the literature and are discussed later in this chapter following the design example.

The NDP refers to a complete nonlinear dynamic time history analysis and is generally regarded as the most accurate method of demand evaluation. A complete nonlinear description, in terms of force–deformation behavior at a cross-section (either using hysteretic models or from direct integration of stresses derived from nonlinear constitutive relationships), of all elements expected to experience inelastic deformations should be developed. No fewer than three ground motion sets (comprising of two horizontal components and a vertical component, if necessary) need to be considered. The selected time histories should have magnitude, fault distance, and source mechanisms that are equivalent to the design ground motion at the site. More detailed criteria are specified in FEMA-356 if simulated motions are used. Similar to the linear dynamic procedure, mean response quantities can be used if seven or more

records are utilized in the simulations, and peak response quantities should be used if fewer than seven ground motions are used in the evaluation.

21.5 Assessing Performance: The Development of Acceptance Criteria

The third and final step in a general PBD process is to determine if the demands computed in step 2 using one of the four methods described in the previous section are within the acceptance criteria that satisfy the performance level defined as part of the overall performance objective in step 1 of the procedure. The current thinking in FEMA-356 is that the performance of a component in the system is critical to the overall performance of the building. Consequently, acceptance criteria are specified at the element level. The resulting responses from the analysis of the structural model of the building system are classified as force-controlled (zero or limited ductility) or deformation-controlled actions. It is also necessary to distinguish primary and secondary components.

21.5.1 Linear Procedures

For linear procedures (LSP and LDP), deformation-controlled design actions should include the combined effects of earthquake and gravity loads as follows:

$$Q_{UD} = Q_G \pm Q_E \quad (21.15)$$

where Q_{UD} is the deformation-controlled design action, Q_G is the action due to gravity loads, and Q_E is the action due to earthquake forces.

In the case of force-controlled actions (defined as actions in components where nonlinear deformations are not permitted or are limited), the following expression is used in FEMA-356:

$$Q_{UF} = Q_G \pm \frac{Q_E}{C_1 C_2 C_3 J} \quad (21.16)$$

where Q_{UF} is the force-controlled design action, Q_G is the action due to gravity loads, Q_E is the action due to earthquake forces, C_i are the amplification coefficients introduced in the previous section, and J is the smallest demand-to-capacity ratio of components delivering forces to the component (≥ 1); alternatively, $J = 2$ in high seismic zones, 1.5 in moderate seismic zones, and 1.0 in zones, of low seismicity.

Note that both the positive and the negative signs that appear in Equations 21.15 and 21.16 should be considered when determining the design actions, and the worst-case scenario should be used in the evaluation. Following the analysis using either an LSP or an LDP, the demand-to-capacity ratio (or m -factors) for each component is established as follows:

$$m = \frac{Q_{UD}}{\kappa Q_{CE}} \quad (21.17)$$

where Q_{CE} is the expected capacity of the component (typically the yield capacity of the section considering possible interaction with other actions) and κ is the knowledge factor that accounts for the uncertainty in estimating the material properties of the section (this factor is unity for new designs).

The demand-to-capacity ratio for force-controlled elements is limited to unity: elements with limited ductility (less than 2.0) are also classified as force-controlled elements within the scope of FEMA-356 guidelines. For deformation-controlled elements (those elements where inelastic action is expected and permitted), a set of acceptance (or allowable) limits need to be developed for different components. Typically, such values come from an evaluation of experimental data supplemented by analytical studies. FEMA-356 provides an initial set of numbers that are recommended for existing buildings. However, the FEMA tables also contain recommended values for well-detailed sections that can form the basis of

TABLE 21.5 Typical Acceptance Criteria for Primary Components in a Fully Restrained Steel Frame Building

Component	<i>m</i> -Factors for linear procedures			Plastic rotation angle for nonlinear methods		
	IO	LS	CP	IO	LS	CP

acceptance criteria for new design. A sample of typical *m*-factors for both steel and concrete members is shown in Table 21.5 and Table 21.6.

21.5.2 Nonlinear Procedures

Acceptance criteria for nonlinear procedures, both in ATC-40 and in FEMA-356 are based on peak demands without explicit consideration of cumulative effects resulting from cyclic effects. To some extent, cyclic degrading effects can be implicitly included in the specification of the backbone envelope. To process the results of a nonlinear analysis, it is essential to define response measures that form the basis of acceptance criteria. Currently, the response measure of choice is the rotation demand at the plastic hinge. If a concentrated hinge model is used in the analysis, this is a relatively direct response quantity. However, if a spread-plastic model or a fiber-section model is used to represent material nonlinearities in the element, then the computation of plastic rotations is not straightforward. Either a plastic hinge length needs to be defined to integrate curvature estimates or alternative procedures need to be developed to estimate the plastic rotation demand. FEMA-356 and FEMA-350 define deformations in terms of chord rotations as shown in Figure 21.9.

If the FEMA definition of element rotation is used, then two possibilities exist for defining the plastic rotation. The first approach is to track the moment–rotation behavior at every connection and then compute the difference between the peak rotation and the recoverable rotation (see Figure 21.10). In a nonlinear time-history analysis, the recoverable rotation is more completely defined because member behavior is explicitly defined using constitutive material models or hysteresis models. For nonlinear static procedures, the recoverable rotation may be estimated using the initial stiffness path as the unloading path. Alternatively, the yield rotation can be predetermined using conventional concepts in structural mechanics. For example, FEMA suggests the following expression for steel frame members:

$$\theta_y = \frac{Z f_{ye} L}{6EI} \left(1 - \frac{P}{P_{ye}} \right) \tag{21.18}$$

FIGURE 21.9 Definition of chord rotations to be used in calculating plastic rotation demands.

FIGURE 21.10 Defining plastic rotations for seismic loading.

where Z is the plastic section modulus, f_{ye} is the yield stress of the material, L is the length of the member, EI is the flexural rigidity, P is the axial force in member (may be taken as zero for beams), and P_{ye} is the expected axial capacity ($A_g f_{ye}$).

However, Equation 21.18 is derived on the assumption that the inflection point occurs at the midpoint of the element. If this is not the case, then the yield rotation should be computed using the following expression:

$$\theta_y = \frac{M_y^2 \ell}{3(M_y + M_2) EI} \tag{21.19}$$

where M_2 is the moment at one end of the member ($M_2 < M_y$), ℓ is the length of member, E is the elastic modulus, I is the moment of inertia, and M_y is the yield moment of the section. In FEMA-356, M_2 is assumed to be equal to M_y . This assumption is reasonably true for beams in moment frame structures but is generally not valid for columns.

In the case of RC section, the determination of yield rotation presents significantly greater challenges. For purely flexural elements, it may be adequate to determine the yield moment and then assume an equivalent flexural rigidity so as to establish the yield curvature. The yield rotation is then calculated by assuming a plastic hinge length. There are widely accepted guidelines for assigning effective stiffness values to RC components. FEMA-356, for example, recommends the following: $0.5EI_g$ for beams and columns with gravity compressive loads $< 0.3A_g f'_c$, $0.7EI_g$ for columns with gravity compressive loads $> 0.5A_g f'_c$, $0.8 EI_g$ for uncracked shear walls, and $0.5EI_g$ for walls with visible cracking. The interaction of flexure and axial loads must be considered in developing nonlinear modeling parameters. The interaction of shear and flexure (in the presence of axial forces) is an issue that is still the subject of ongoing research.

Typical limits on plastic rotation demands for different performance levels, as specified in FEMA-356, are also shown in [Table 21.5](#) and [Table 21.6](#) for steel and RC frame buildings.

Ultimately, the intent of the above discussion is to make readers aware of the possible complexities in modeling and evaluating the expected demands at various connections and elements in the structural system. While simple representations of nonlinear behavior lead to more comprehensible results, it is necessary to gain confidence in the computed demands. The desired confidence can be achieved with sensitivity studies on the impact of uncertain variables on the computed demand estimates. For this reason, it is not surprising that FEMA-350 takes a probabilistic approach to PBD. Similarly, ongoing work at PEER evolves around a probabilistic format. Both these methodologies are discussed later in this chapter.

21.5.3 ATC-40 and Capacity Spectrum Procedures

ATC-40 advocates the use of the CSM to evaluate the overall adequacy of design of a structural system. The term “capacity spectrum” refers to an altered form of the capacity or pushover curve for the building. As discussed earlier, a pushover curve provides a representation of both the displacement and the force capacity of a building in terms of roof drift and base shear, respectively. The quantities computed to develop the pushover curve should be recast into spectral displacements and spectral accelerations using simple concepts in structural dynamics. Such a format is conventionally referred to as the acceleration–displacement response spectrum or (ADRS) format (Mahaney et al. 1993). The ATC-40 methodology involves a simple conceptual procedure wherein the reformatted capacity curve is compared to the seismic demand curve, which is also expressed in a similar format. In the context of ATC-40 and capacity spectrum procedures, it should be noted that Reinhorn (1997) proposes an interesting variation on CSM to evaluate the seismic response of buildings. Recently, Fajfar (1999) advanced CSM to incorporate the so-called N2 method into the formulation. These and other related developments on CSM are beyond the scope of this chapter.

21.5.3.1 Determining Capacity

The capacity of a structure is a function of the capacity of its individual components and the interaction of its elements. The preferred method of choice in ATC-40 to establish system capacity is the nonlinear static or pushover procedure in which a mathematical model of the structure is subjected to a lateral force incrementally or iteratively till a capacity curve is obtained. Unlike the pushover procedure in FEMA-356 wherein the lateral load is applied until a target displacement is obtained, in the CSM, the model is pushed till a stability limit is reached. The objective in CSM is to determine the “performance” point of the structure that identifies the demand corresponding to the hazard at the site specified in terms of a response spectrum.

The capacity curve is essentially a pushover curve, and consequently, the NSP procedure of FEMA-356 can be used to develop the curve. If the nonlinear behavior of each element is modeled explicitly, then the resulting base shear versus roof displacement plot is the required capacity curve. However, with the realization that many engineers may only have access to a linear analysis program, ATC-40 also recommends a simplified procedure. In the simplified approach, an elastic analysis is used to approximate the inelastic behavior of the building. The procedure to accomplish this is as follows: a lateral load is applied on the structure, and the magnitude of the lateral load is increased till some element (or a group of elements) reaches approximately 90% of its capacity. At this stage, the analysis is stopped, and the stiffness properties of these elements are set to a very small value or the elements are removed from the model. The lateral loads are reapplied incrementally as before till another set of elements approach their strength capacities. The base shear and roof displacement are recorded at the end of each phase of the analysis, and cumulative values represent points on the capacity curve. The process continues till a stability limit is reached. [Figure 21.11a](#) displays the process of combining the results of each phase of analysis. [Figure 21.11b](#) shows the same capacity curve, identified in the diagram as Curve #1.

FIGURE 21.11 Generating the capacity curve using linear solution methods (ATC-40).

ATC-40 also recommends changing the lateral load pattern to reflect the displaced shape of the building at the end of each phase of the analysis.

It is also possible to consider degrading effects in the simplified procedure described above by reinitializing the analysis at the end of each phase and plotting a new capacity curve. Each new curve begins with a degraded system that accounts for the state of elements at the end of each phase. Figure 21.11b provides a conceptual view of three such capacity curves. The final capacity curve is drawn by connecting the final point on the previous curve to a new point on the next capacity curve at the next displacement increment so as to produce a saw-tooth response as shown in Figure 21.11b.

21.5.3.1.1 Conversion to ADRS Format

The capacity curve obtained either by the simplified process described in the previous section or by a detailed nonlinear analysis technique is transformed into ADRS format. The following relationships provide the conversion to ADRS format:

$$S_{a,n} = \alpha_n(V_n/W) \text{ (expressed in units of } g) \tag{21.20}$$

$$S_{a,n} = \frac{\Delta_{c,n}}{\beta_n \Phi_{c,n}} \tag{21.21}$$

$$\alpha_n = \frac{\sum_{i=1}^N w_i \Phi_{i,n}^2}{(\sum_{i=1}^N w_i \Phi_{i,n})^2} \tag{21.22}$$

$$\beta_n = \frac{\sum_{i=1}^N w_i \Phi_{i,n}}{\sum_{i=1}^N w_i \Phi_{i,n}^2} \tag{21.23}$$

where $S_{a,n}$ is the spectral acceleration for mode n , $S_{d,n}$ is the spectral displacement for mode n , V_n is the base shear for mode n , W is the seismic weight of the building, w_i is the seismic weight of the floor at level i , $\phi_{i,n}$ is the modal amplitude at level i for mode n , and $\Delta_{c,n}$ and $\Phi_{c,n}$ are the displacement and modal amplitude of control node for mode n .

The theoretical basis for making the conversion is outlined in the Appendix A.

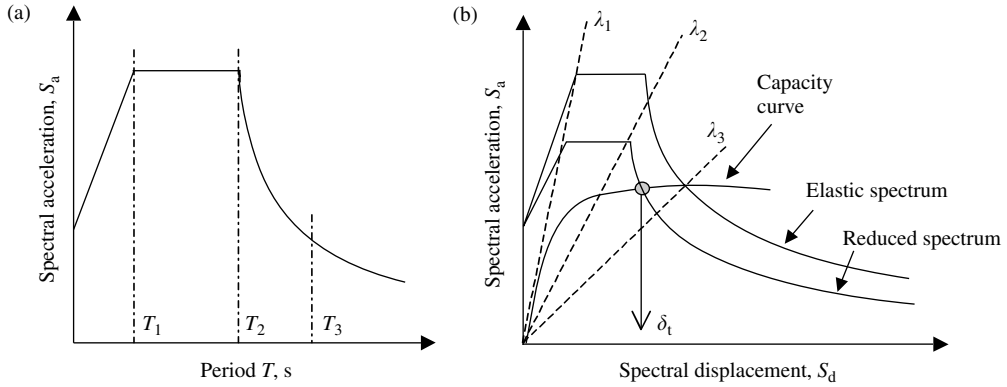

FIGURE 21.12 Generating the ADRS demand and capacity spectrum.

21.5.3.2 Determining Demand

The next step in CSM is to convert the response spectrum (which represents the demand side of the equation) into ADRS format as well, thereby permitting a comparison of demand versus capacity. The design response spectrum is usually expressed in terms of spectral acceleration and period as shown in Figure 21.12a. Since a response spectrum results from the analysis of an SDOF system, the following relationships between pseudospectral acceleration and spectral displacement can be used:

$$S_d = \frac{S_a T^2}{(2\pi)^2} \tag{21.24}$$

$$\frac{S_a}{S_d} = \lambda = \left(\frac{2\pi}{T}\right)^2 \tag{21.25}$$

Hence, it is possible to convert the spectral coordinates for every value of the period T_i into spectral displacements. The resulting curve is in ADRS format and the radial lines shown in Figure 21.12b represent λ values for corresponding T_i values. The capacity curve obtained in the previous step can now be superimposed on the demand curve. If the elastic design spectrum is used to create the demand spectrum, the overlay is valid only if the structural response is also elastic. Hence, the next step in the process is to reduce the elastic response spectrum to an inelastic spectrum using the concept of equivalent damping. Using the fundamental principles of structural mechanics, the equivalent damping ζ_d associated with dissipated energy during inelastic response is given by

$$\zeta_d = \frac{1}{(\Omega/\omega)} \frac{1}{4\pi} \frac{E_D}{E_S} \tag{21.26}$$

where (Ω/ω) is the ratio of the forcing frequency to the natural frequency of the system, E_D is the energy dissipated through hysteretic behavior, and E_S is the strain energy at the maximum displacement. If it is assumed that the peak response is associated with the resonant frequency, then the ratio $\Omega/\omega = 1.0$.

The ATC-40 methodology for estimating the equivalent viscous damping is derived for a bilinear capacity curve, therefore, it is necessary to transform the capacity curve into bilinear form. Figure 21.13 shows a bilinear capacity curve and the energy dissipated in a single cycle given the maximum displacement demand and the corresponding spectral acceleration (S_{dmp} , S_{am}). The equivalent damping corresponding to the dissipated energy can be computed using Equation 21.26 and reduced to the following form:

$$\zeta_d = \frac{0.637(S_{ay}S_{dm} - S_{dy}S_{am})}{S_{am}S_{dm}} \tag{21.27}$$

FIGURE 21.13 Bilinear representation of capacity curve and peak demand parameters.

Note that the elastic design spectrum already incorporates 5% damping, hence the equivalent damping (Equation 21.27) from inelastic behavior must be added to the elastic viscous damping. For behavior other than bilinear hysteresis, a modification factor κ is introduced. The final damping value incorporating elastic damping, equivalent inelastic damping, and general hysteretic behavior is given by

$$\zeta_{eq} = \kappa \zeta_d + 0.05 \tag{21.28}$$

Finally, the elastic spectrum is transformed into a reduced spectrum for the damping ratio given by Equation 21.28. ATC-40 provides the following spectral reduction factors, which are derived using the well-known Newmark–Hall relationships:

$$SR_A = \frac{3.21 - 0.68 \ln(100\zeta_{eq})}{2.12} \tag{21.29}$$

$$SR_V = \frac{2.31 - 0.41 \ln(100\zeta_{eq})}{1.65} \tag{21.30}$$

where SR_A is the reduction factor in the constant acceleration region of the spectrum and SR_V is the reduction factor in the constant velocity region. There are imposed limits on the above reduction factors depending on the expected shape of the hysteresis loops.

21.5.3.2.1 Performance Point

The CSM methodology attempts to predict the expected peak displacement given a demand response spectrum. A trial displacement value δ_t (Figure 21.12b) and the corresponding spectral acceleration is selected on the capacity curve. The equivalent viscous damping associated with these spectral magnitudes can now be estimated using Equation 21.27. The 5% damped elastic spectrum is transformed into a reduced inelastic spectrum using Equations 21.20 and 21.21. The demand and capacity curves in ADRS format are overlaid. If the trial displacement is within 5% of the displacement at the intersection of the demand and capacity curves, the performance point has been located. Figure 21.12b shows a case where the trial displacement is the performance point.

21.5.3.3 Performance Assessment

Once the performance point has been established, the acceptability of the design can be assessed by comparing the demand to the acceptance criteria. ATC-40 global acceptance criteria for different performance levels are listed in Table 21.7. Component acceptance criteria are essentially similar to FEMA-356 specifications.

TABLE 21.7 Global Acceptance Criteria for Use with ATC-40 CSM

Parameter	Performance level		
	IO	Damage control	LS
Maximum interstory drift	0.010	0.01–0.02	0.02
Maximum inelastic drift	0.005	0.005–0.015	No limit

21.6 Performance-Based Methodologies: Probabilistic Approaches

21.6.1 The SAC-FEMA Project and FEMA-350

The discovery of numerous brittle fractures of beam-to-column connections in fully restrained steel moment frames following the 1994 Northridge Earthquake dramatically altered a widely held conviction that welded-steel moment-frame buildings are among the most ductile systems contained in the building code. The observed damage was not limited to any particular class of steel structures: varying degrees of brittle fracture were reported in buildings ranging from 1 to 26 stories in height and in a range of ages from 30-year-old buildings to structures being constructed at the time of the earthquake.

The need to reevaluate both existing code provisions and construction practice in welded-steel frames led to the organization of the SAC Joint Venture in 1994, which eventually produced FEMA-350 (2000), a performance-based guideline for the design of new steel structures. The basic procedure described in FEMA-350 is similar to that in FEMA-356 with the major exception that the eventual acceptance criteria assume a probabilistic format. Additionally, it also provides specific qualification criteria for various types of connections that are beyond the scope of this chapter.

The conceptual basis of the FEMA-350 evaluation methodology, outlined in a paper by Cornell et al. (2002), can be expressed in probabilistic terms as follows:

$$P(D > PL) = \int P_{D > PL}(x)h(x) dx \quad (21.31)$$

$P(D > PL)$ is the probability that the damage exceeds a specified performance level within a given duration (say, t years). $P_{D > PL}(x)$ is the probability that the damage exceeds a specified performance level, as a function of x , given that the ground motion intensity is level x . $h(x)dx$ is the probability of experiencing a ground motion of level x to $(x + dx)$ in a duration of t years.

The steps involved in evaluating the performance of a building using the above concept are summarized here:

1. As with any performance-based process, the performance objective consisting of a hazard level and a performance level is first defined. FEMA-350 lists only two primary hazard levels based on current specifications in FEMA-302: a maximum considered earthquake (MCE), which corresponds to a 2% probability of being exceeded in 50 years, and a DE, which is specified as having an intensity equal to two thirds of MCE. Recall that the DE in ATC-40 was defined as an event with a 10% chance of being exceeded in 50 years. More importantly, only two performance levels are considered: IO and CP. To this extent, FEMA-350 is a limited application of PBD concepts. However, this is an acknowledgment of the lack of available data to classify additional performance limit states.
2. A hazard spectrum or a set of ground motions that meet the criteria specified in the performance objective is developed. The procedure for generating a site-specific response spectrum (similar to

Figure 21.3) is identical to FEMA-356. For probabilistic-based assessment, the ground motion intensity is expressed in terms of the 5% spectral acceleration (S_a) magnitude at the fundamental period of the building. Procedures for determining S_a for other exceedance probabilities are outlined in FEMA-356.

3. The next step in the process is to establish seismic demands that are established from a static or dynamic analysis of a mathematical model of the building — a process not different from that described earlier in this chapter. However, FEMA-350 clearly defines the scope of each analytical method to carry out the task of demand estimation. A table listing the applicability of each method (LSP, NSP, LDP, and NDP) is provided for guidance. For example, if IO performance level is being evaluated and the fundamental period (T) of the structure is less than 3.5 times the characteristic period of the design response spectrum (T_n), then any of the four methods of analysis is valid, but if $T > 3.5T_n$, then static methods are not permitted. Similarly, if CP performance level is being considered for a regular structure with $T < 3.5T_n$ and strong column conditions (sum of column moment capacity is greater than sum of beam moment capacity at connection) exist throughout the frame, then all four methods of analysis are permitted while only nonlinear methods are allowed for irregular structures. Additionally, the demand values of interest are somewhat different from those used in FEMA-356. The following comprise the demand quantities of interest in FEMA-350: interstory drift angles, column compression, and column splice tensile demands.
4. Following the determination of the global and local demand measures, median estimates of structural capacity are established. These capacity parameters include system level measures such as interstory drift capacity and component level measures such as column compressive capacity. FEMA-350 recommends using an incremental dynamic analysis (IDA) to estimate interstory drift capacity, while statistical analyses of available experimental data, as described later in this section, can be utilized for component measures of capacity.
5. Finally, a demand and resistance factor design format is used to determine the confidence level associated with the probability that a building will have less than a specified exceedance probability for a desired performance level. The confidence index is determined through evaluation of the factored-demand-to-capacity ratio given by the equation:

$$\lambda = \frac{\gamma\gamma_a D}{\phi C} \quad (21.32)$$

where C is the estimated capacity of the structure for the primary demand measures, namely, interstory drift, column compression, and column splice tensile demand; D is the estimated demand for the structure, obtained from the structural analysis of a building model for the corresponding demand measure; γ is a factor that accounts for the variability inherent in the prediction of demand related to structural modeling assumptions and specification of ground motion parameters; γ_a is a factor that accounts for the bias and uncertainty inherent in the method of analysis used to estimate demands; and ϕ is a resistance factor that accounts for the uncertainty and variability inherent in the prediction of structural capacity as a function of ground-shaking intensity.

The confidence level of the performance evaluation is then back-calculated from the following equation:

$$\lambda_L = \exp(-b\beta_{UT}[K_x - 0.5k\beta_{UT}]) \quad (21.33)$$

where b is a coefficient relating an incremental change in the seismic demand measure to an incremental change in the intensity measure of the ground motion, determined from the demand hazard curve; β_{UT} is a parameter to account for uncertainties in demand and capacity calculated from $\sqrt{(\sum \beta_{ui}^2)}$, where β_{ui} are the standard deviations of the natural logarithms of the variations in demand and capacity, outlined in subsequent sections; k is the slope of the hazard curve (in ln–ln coordinates) at the hazard level of interest; and

K_x is the standard Gaussian variate associated with probability x of not being exceeded as a function of standard deviation measures (obtained readily from standard probability tables).

FEMA-350 includes a table that provides the solution of the above equation for various values of k , λ , and β_{UT} .

The overall confidence level is controlled by the lowest λ value for each of the demand measures (interstory drift, column compression, and column splice tensile demand). The various parameters needed to evaluate the confidence measure are summarized in the following.

21.6.1.1 Slope of the Hazard Curve

A plot of the probability of exceedance (or annual rate of exceedance) of a spectral amplitude versus the spectral value (at a period typically corresponding to the fundamental period of the structure), plotted on a log–log scale, is represented by the following functional form in the hazard range of interest:

$$\nu(S_a) = k_0(S_a)^{-k} \quad (21.34)$$

where k is the slope of the hazard curve and $\nu(S_a)$ is the probability of an event having a spectral amplitude greater than S_a . Hazard curves can be developed from seismic hazard maps provided by the USGS and are assessable at <http://eqhazmaps.usgs.gov>.

21.6.1.2 Demand Variability Factor (γ)

This factor accounts for the variability in the prediction of demand measures such as interstory drift ratio and column splice tension demands. This is determined from the following expression:

$$\gamma = \exp\left(\frac{k}{2b}\beta_{DR}^2\right) \quad (21.35)$$

where k and b are the same parameters described in Equation 21.33, and β_{DR} is the standard deviation of the natural logarithms of the selected response measure developed from nonlinear time-history analyses of a mathematical model of the building subjected to a suite of ground motions, all of which are scaled to match the 5% damped spectral response acceleration of the hazard spectrum.

21.6.1.3 Analysis Uncertainty Factor (γ_a)

This represents the bias associated with the analytical method (LSP, LDP, or NSP) used to determine the demand measure. It is computed from the following equation:

$$\gamma_a = C_B \exp\left(\frac{k}{2b}\beta_{DU}^2\right) \quad (21.36)$$

where C_B is the bias factor given by the ratio of the demand predicted by nonlinear time-history analysis to the demand predicted by the chosen analytical method. In this case, β_{DU} represents the uncertainty that results from variability in the model parameters such as material strength, assumed damping, hysteretic behavior, and soil–foundation interaction modeling. A series of analyses with different structural models (that account for critical model uncertainties) are carried out using a single ground motion, and statistical measures of dispersion are obtained. β_{DU} is the standard deviation of the natural logarithm of the selected response parameter.

21.6.1.4 Resistance Factor (ϕ)

This factor accounts for the uncertainty in the estimation of the system or component capacity. The resistance factor will have the following general form:

$$\phi = \phi_R \phi_U = \phi_R \exp\left(\frac{k}{2b}\beta^2\right) \quad (21.37)$$

where ϕ_U is the factor accounting for uncertainty in the relationship between laboratory findings and behavior in real buildings (when considering component effects) or the uncertainty in analytical predictions (when considering system response measures such as global drift capacity). FEMA-350 suggests a value of $\beta = 0.2$ for component response measures and a period-dependent value for system response measures. ϕ_R is the randomness inherent in the computation of the resistance factor and is expressed in a form identical to ϕ_U . When computing the resistance factor for component response, β corresponds to the logarithmic standard deviation of the capacity measure based on observed data from laboratory testing. When estimating the resistance factor at the system level, β corresponds to the logarithmic standard deviation of the global stability limit determined from an IDA, as described later.

21.6.2 Simplified Evaluation Method (FEMA-350)

The overall procedure outlined in the Section 21.6.1 is the detailed method that requires numerous simulations of response data and careful statistical analysis of capacity measures. To facilitate routine engineering assessment of regular buildings, FEMA-350 also provides a set of tables to approximately evaluate the uncertainty parameters needed to establish the confidence index parameter. These uncertainty and variability factors are approximate estimates derived from a limited subset of parametric studies based on typical characteristics of regular buildings. Hence, they incorporate a certain degree of conservativeness. Whenever possible, the detailed method described earlier in this section should be used to improve the reliability of the performance evaluation.

A summary of a selected subset of uncertainty factors for special moment frames is shown in Table 21.8 and Table 21.9. Once the uncertainty factors are known, the factored demand-to-capacity index λ can be established for a particular demand measure. Finally, the confidence level of the computed “factored” demand-to-capacity ratio is determined using another table provided in FEMA-350. Table 21.10 shows a slice of the FEMA-350 listing; here, the values tabulated are valid only for midrise frames (4 to 12 stories) at CP performance level. To assess the adequacy of the design, the calculated confidence levels are compared to minimum acceptance criteria. Table 21.11 lists the FEMA criteria for global interstory drift and column compression.

TABLE 21.8 Typical Uncertainty Factors Recommended in FEMA-350 to be Used in Assessing Global Interstory Drift in Special Moment Frames

		Low-rise (<4 stories)	Mid-rise (4–12 stories)	High-rise (>12 stories)	
γ_a	LSP	IO	0.94	1.15	1.12
		CP	0.70	0.97	1.21
NSP	IO	1.13	1.45	1.36	
	CP	0.89	0.99	0.95	
γ	IO	1.50	1.40	1.40	
	CP	1.30	1.20	1.50	
ϕ	IO	1.00	1.00	1.00	
	CP	0.90	0.85	0.75

	Immediate occupancy (IO) (%)	Collapse prevention (CP) (%)
Global behavior limited by interstory drift	50	90
Column compression behavior	50	90

21.6.3 Incremental Dynamic Analysis

The global stability limit corresponds to the CP limit state and is determined using an IDA as proposed by Vamvatsikos and Cornell (2002). An IDA curve is developed from the following procedure:

1. A suite of accelerograms (a minimum of ten records is recommended) is selected representative of the site and hazard level for which the CP level (or global stability limit) is desired. Artificially synthesized records may be used, but it is preferable to choose recorded ground motions that represent the expected hazard at the site in terms of source mechanism, fault distance, and geological characteristics.
2. For each earthquake record, conduct a series of time-history analyses by uniformly scaling the accelerogram each time so as to induce increasing levels of inelasticity in the structure and thereby characterize the behavior of the system from its elastic limit to its failure state.
3. Plot the magnitude of the spectral acceleration of the 5% damped response spectrum of the earthquake record at the fundamental period $S_a(T_0)$ versus the control node (typically the roof) displacement (Δ). Note that the spectral values will scale linearly during the scaling process. The resulting plot is called the IDA curve. Repeat the process for each of the selected ground motions thereby constructing a set of IDA curves.
4. The scale factors used to generate the IDA curve must be carefully selected to capture the elastic, postyield, and collapse limit states. The number of analyses required to develop an IDA curve will vary from one structure to the next; however, Vamvatsikos and Cornell (2002) suggest that the global drift capacity be defined at a point where the slope of the S_a - Δ curve drops below 20% of the elastic slope. Additionally, FEMA-350 places a limit of 10% on the global drift capacity.
5. Establish the distribution of spectral magnitudes at the global drift capacity to facilitate the computation of the logarithmic standard deviation of the drift capacity, β . The global resistance factor is then determined using

$$\phi_R = \exp\left(\frac{k}{2b}\beta^2\right) \tag{21.38}$$

where k and b are the same parameters described in previous expressions.

21.6.4 The PEER PBD Methodology

The methodology in development at the PEER center may be regarded as a holistic approach to PBD in that it involves a measure of performance that is relevant to stakeholders.

A probabilistic framework is used to assess the performance of the structure. This framework is based on a similar format used in the SAC Steel Frame project (Cornell et al. 2002) described in the previous section. While the original formulation by Cornell and coworkers was cast in demand versus capacity format and expressed the performance objective function as the probability of exceeding a certain performance level, the methodology developed for PEER extends this concept to include decision variables and damage measures. A conceptual description of the PEER methodology, using the total probability theorem, is expressed as follows:

$$\nu(DV) = \iiint G(DV|DM) dG(DM|EDP) dG(EDP|IM) d\lambda(IM) \quad (21.39)$$

where $\nu(DV)$ is the probabilistic description of the decision variable (expressed in terms of the mean annual probability of repair or replacement cost, net dollar loss, downtime, etc.), DM represents the damage measure (an index value that expresses the state of damage resulting from a given demand), EDP represents the engineering demand parameter (drift, plastic rotation, etc.), and IM represents the intensity measure (characterizing the hazard). The expression of the form $P(A|B)$ is essentially a cumulative distribution function or the conditional probability that A exceeds a specified limit for a given value of B . The term of the form $dP(A|B)$ is the derivative with respect to A of the conditional probability ($A|B$).

One of the objectives of the PEER methodology is to incorporate all significant sources of uncertainty that arise in the specification of the ground motion, the material properties, and the modeling and evaluation process. The methodology also insists on a rigorous evaluation utilizing state-of-the-art tools for both the prediction of demand and the probabilistic assessment of each random variable. Hence, it would generally be expected that the evaluation be based on nonlinear time-history analyses using a suite of ground motions since it offers more options for the treatment of uncertainties. However, it does not preclude any particular method of analysis as long as the inherent bias and system uncertainties are quantified and probabilistic descriptions of the demand measures are established.

A brief description is now provided of the variables that appear in Equation 21.39.

21.6.4.1 Hazard Description (IM)

This refers to the hazard curve that expresses the annual frequency or exceedance probability of the design seismic event in a specified duration. In developing the hazard model, a rigorous seismic hazard analysis must be carried out that takes into consideration the seismic source, recurrence, and attenuation relations. Once a hazard model is developed, a set of ground motions must be synthesized (artificially) or selected from available records that satisfy the magnitude–distance combinations and geologic and fault characteristics at the site. An intensity measure must then be selected that quantifies the hazard. The idea of introducing an intensity measure to characterize the hazard provides a framework to develop fragility functions. A simple choice of intensity measure would be the PGA. Another option would be the 5% damped spectral acceleration at the characteristic period of the structure ($S_a(T_0)$) since it introduces an additional parameter in the description. There could potentially be numerous such measures with increasing complexity. The goal in selecting a measure of earthquake intensity is to minimize the variability in the performance assessment arising from ground motion parameters.

21.6.4.2 Engineering Demand Parameter (EDP)

The nonlinear analysis of a mathematical model of the structural system produces a wealth of information. The process of selecting one or more demand measures to characterize the performance of the system is not an easy task. The PEER methodology does not identify any specific demand measure since the choice of an appropriate demand parameter is a function of both the system and the desired performance objectives. A performance objective, for example, that attempts to minimize losses in a moderate earthquake might depend on the damage to nonstructural elements. In this case, the demand

measure of interest may be interstory drift or peak floor acceleration. On the other hand, if the performance objective were linked to global measures such as LS or CP, it would be prudent to select demand measures that provide a more rational evaluation of the damage states of components. The treatment of modeling uncertainties is important in the process of establishing demands.

21.6.4.3 Damage Measure (DM)

Relevant measures of damage are identified for both structural and nonstructural components. However, unlike deterministic approaches where performance limits are specified for different damage states, the damage description in a probabilistic framework takes the form of a fragility function. The likelihood of a certain damage state is conditioned on a structural response measure or EDP. Similar to the development of acceptance criteria in FEMA-356, a damage model in the PEER framework is expected to rely on damage data from field observations and laboratory testing. Since the database of experimental information is limited, analytical simulations wherein calibrated models can be utilized to generate fragility curves for different variables can aid the development of damage fragilities. Again, this approach provides a means to incorporate material and model uncertainties into the evaluation process.

21.6.4.4 Decision Variable (DV)

The final phase of the PEER methodology involves loss modeling. The terminology that is introduced in this context is a decision variable that is expected to measure system performance in terms of cost estimates, such as mean annual dollar loss (repair costs), or the probability that the damage resulting from the seismic event will result in a specified downtime (loss of operability) and similar economic measures.

The PEER methodology offers distinct advantages over existing PBD frameworks. First, it recognizes the need to incorporate uncertainties in every phase of the process. This enables an assessment of the sensitivity of critical decision variables to uncertain input parameters. Approaches to evaluating system uncertainties and reducing the number of variable parameters that need to be considered have been investigated by Haukaas and Der Kiureghian (2002) and Porter (2002). Second, it provides an explicit probabilistic expression of the system performance in terms of economic measures that are more intelligible to stakeholders. Finally, the methodology is a generic representation of input and output that permits maximum flexibility to the user to define model parameters.

21.7 PBD Application: An Illustrative Example

The basic procedures outlined in this chapter are now applied to a sample six-story steel building to illustrate the application of performance-based concepts in routine seismic evaluation and design. The intention here is to merely demonstrate the process rather than establish a valid design that conforms to a specific performance-based format. As reiterated in several instances in this chapter, PBD is an evolving methodology that still lacks final details on acceptance criteria and loss estimates associated with different damage states. In fact, this example will also serve to illustrate potential unresolved issues in the current state-of-the-art.

For the purpose of this illustration, it will be assumed that the site of the building is located in an active seismic zone in Southern California. The building has a regular and symmetric plan 120 ft². The primary lateral load resisting system is a moment frame around the perimeter of the building. Moment continuity of each of the perimeter frames is interrupted at the ends where a simple shear connection is used to connect to the weak column axis. The plan view of the building and the elevation of a typical perimeter frame are shown in [Figure 21.14](#). The interior frames were designed as gravity frames and consist of simple shear connections only. It will be further assumed that the columns of the perimeter frames are supported on foundation beams and rigid pile groups that permit the structure to be modeled as fully restrained at the supports.

FIGURE 21.14 Building plan and elevation of typical moment frame considered in sample problem.

21.7.1 Performance Objective

The building will be designed for an event with a 10% probability of being exceeded in 50 years. This is referred to as the DE in ATC-40 or a BSE-1 hazard level in FEMA-356. In the present example, a performance level corresponding to LS for all primary structural elements is selected. Secondary or nonstructural performance is not considered in this example. Hence, the performance objective for the trial design is to achieve LS performance in all components when the building is subjected to a DE with the specified probability of occurrence (10% in 50 years).

It is now necessary to define the design event. Since both static and dynamic methods will be used to estimate demands, it is necessary to define a response spectrum and to develop a set of acceleration time histories. To construct the hazard spectrum, the soil profile, the geological characteristics, and source mechanism at the site need to be established. The following values will be assumed to generate the spectrum: seismic zone 4, firm soil with a shear wave velocity exceeding 1000 m/s and the closest distance to a seismic source capable of producing large-magnitude events to be 10 km. The spectral acceleration at a 1.0-s period for site class B is taken as 0.48g. Note that both the short-period and the long-period

spectral acceleration values can be determined from USGS seismic maps. This results in the following parameters:

ATC-40:

$$C_A = 0.40g$$

$$C_V = 0.48g$$

$$T_n = C_V / 2.5 C_A = 0.48 \text{ s}$$

$$T_m = 0.2 T_n = 0.096 \text{ s}$$

$$S_t = C_V = 0.48g$$

FEMA-356:

$$S_{xs} = 1.0g$$

$$S_{x1} = S_{m1} = 0.48g$$

$$S_t = S_{x1} = 0.48g$$

Using the parameters defined above, the hazard spectrum for the building site corresponding to a design event with a 10% chance of being exceeded in 50 years is developed and is shown in Figure 21.15.

21.7.2 PBD and Assessment

The next step in the process is to select preliminary sections for the building elements. This stage of the design is similar to current practice wherein preliminary sizing of members must precede the analysis of the building under the imposed seismic loads. In the present example, we will focus on the performance-based design and evaluation of a typical perimeter frame which is designated to carry half the lateral load in each direction. The initial selection of members is shown in Table 21.12. Section properties are

FIGURE 21.15 Design spectrum for building site.

5	W24 × 84	W14 × 90
3-4	W24 × 84	W14 × 132
2	W27 × 102	W14 × 176
1	W30 × 116	W14 × 176

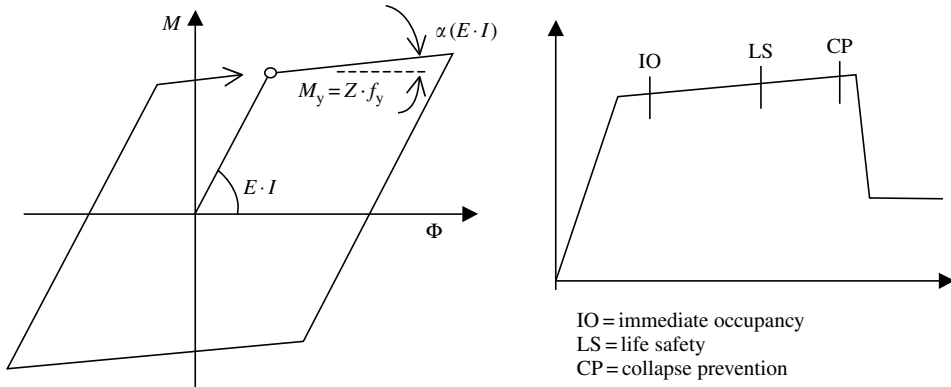

FIGURE 21.16 Prescribed force–deformation behavior of members and monotonic behavior identifying different performance limit states.

computed assuming a yield stress of 414 MPa (60 ksi). Using nominal dimensions for the floor slab and standard weights for nonstructural elements, the floor weights are estimated as 6227 kN (1400 kip) at the first level, 5338 kN (1200 kip) at the second through fifth level, and 7562 kN (1700 kip) at the roof level, resulting in a total building weight of approximately 33,805 kN (7600 kip). A 2D model of the frame was developed to estimate seismic demands. The computer program OpenSees (2003) was used for the analytical simulations since it provided the capability to carry out nonlinear static and dynamic analyses.

Nonlinearity in members is modeled using a bilinear force–deformation behavior in view of the fact that fully restrained connections are used and no brittle fracture is expected. The performance regime of the components will, therefore, lie in the ascending slope of the force–deformation envelope, and softening behavior need not be considered. The expected cyclic behavior of the each yielding section and the monotonic envelope identifying the different performance limit states is qualitatively displayed in Figure 21.16.

Beginning with the trial design (Figure 21.14), the performance of the building is evaluated by determining the demands in each component and comparing these demands to performance-based acceptance criteria. However, as discussed in previous sections of this chapter, there are different approaches to estimating demands and consequently, different assessment criteria to evaluate the performance of the structure. Different methods will be presented in the following sections so as to make readers aware of the predicament that will face engineers when making a decision on which method to use in a given situation. Hopefully, some of the observations and comments offered in this example will assist in clarifying some of these issues.

27.7.2.1 Method I: Deterministic Assessment — LSP (FEMA-356)

The so-called “pseudo” lateral load to be applied on the frame is determined from Equation 21.10. The fundamental period of the building (established from an eigenvalue analysis of the frame model) is 1.45 s. The coefficients needed to evaluate the total lateral load *V* are

- $C_1 = 1.0$ (since $T > T_n$)
- $C_2 = 1.0$ for linear procedures
- $C_3 = 1.0$ (assuming $P-\Delta$ effects can be ignored)
- $C_m = 1.0$ (since $T > 1$ s)
- $S_a = 0.48/1.45 = 0.33g$

This results in a total lateral force of $V = 6672$ kN (1500 kip) to be applied on each perimeter frame in each direction. The lateral load is distributed over the building height using the expression given in Equation 21.12. The resulting moments on the structural components are recorded, and the peak *m*-factors are evaluated. Recall that the *m*-factor is the ratio of the peak moment to the moment capacity

(defined here as the yield moment and computed by taking the product of the yield stress of the material and the plastic section modulus) of the beam. A typical summary of such an evaluation is shown in Table 21.13 for all the beam elements on the first level of the building.

This process is carried through all the beams and columns in the structure. The resulting *m*-factors for the entire frame are exhibited in Figure 21.17.

These *m*-factors are then compared to the acceptance criteria listed in FEMA-356 to check if the desired performance level has been satisfied. The limits on *m*-factors for different performance levels are a function of certain section characteristics as identified previously in Table 21.5. For the beams on the first level for which *m*-factor computations were listed in Table 21.13, the following section characteristics are established:

$$b_f = 267 \text{ mm (10.5 in.)}, \quad t_f = 21.6 \text{ mm (0.85 in.)}, \quad t_w = 14.5 \text{ mm (0.57 in.)}, \quad h = 762 \text{ mm (30 in.)}$$

$$\frac{b_f}{2t_f} = 61.8, \quad \frac{52}{\sqrt{f_{yc}}} = 6.71, \quad \frac{h}{t_w} = 50.6, \quad \frac{418}{\sqrt{f_{yc}}} = 54$$

The above numbers, using Table 21.5, require that for IO performance the *m*-factors be less than 2.0. Since this is true for all beams in the first-story level, they satisfy IO criteria. This performance limit is summarized in Figure 21.18 along with the performance limit states for all elements in the building. As displayed in Figure 21.18, several columns fail LS performance level at the third and fifth floor levels. The notation CP indicates that the element meets the criteria for CP but fails LS performance levels. Since the objective of the design was to ensure LS performance, the result of this evaluation indicates that the

desired performance objective has not been met. It is, therefore, necessary to redesign the frame and go through an iterative process till the design objective is satisfied.

21.7.2.2 Method II: Deterministic Assessment — NSP (FEMA-356)

The same frame will now be evaluated using a pushover analysis to determine expected demands. The building model is subjected to a monotonically increasing inverted triangular lateral load pattern till the roof drift reaches the target value. The target roof displacement is estimated using the following coefficients:

- C_0 : 1.42 (From table 3.2 of FEMA-356)
- C_1 : 1.0 since $T_e > T_S$ (from Hazard Spectra)
- C_2 : 1.0 (from table 3.3 of FEMA-356)
- C_3 : 1.0 for positive postyield stiffness

The spectral acceleration at the fundamental period T : 1.45 s is 0.33g. This results in a target displacement of 260 mm (10.22 in.). When the building model is pushed using an inverted triangular lateral load distribution till the roof displacement reaches this value, none of the elements reach their yield value. This means that the plastic rotation demands are zero and, consequently, all elements (beams and columns) satisfy IO performance levels. This is contrary to the findings using linear static analysis.

21.7.2.3 Method III: Deterministic Assessment — LDP (FEMA-356)

A linear dynamic analysis can be accomplished in two ways: using a response spectrum approach or resorting to a full time-history analysis. In this example, the demands were determined using a response spectrum analysis. The moment demands in each element are tabulated, similar to the summary table described for LSP, and the resulting m -factors are calculated. A sample set of values for all the column elements in the first-story level are shown in Table 21.14. For columns, it is also necessary to compute axial force levels since acceptance criteria for columns are a function of the axial demands in the column (see Table 21.14).

TABLE 21.14 Peak Demands in Columns on First Story Using LDP

FIGURE 21.19 Computed m -factors using LDP.

The m -factors determined in the table are shown in Figure 21.19 along with the demand-to-capacity values for the remaining elements. Using the criteria listed in FEMA-356, the acceptance levels corresponding to these m -factors are established. As can be seen from the m -factors, most values are below unity, which means that the demands are generally below the yield capacity of the corresponding components. The demand-to-capacity ratios for a few columns are marginally greater than 1.0. Overall, all elements in the structure pass the criteria for IO. This is consistent with the findings using the NSP.

21.7.2.4 Method IV: Deterministic Assessment — NDP (FEMA-356)

The most rigorous procedure to estimate demands is to carry out a complete nonlinear time-history analysis using a set of ground motions. To accomplish this, a subset of seven earthquake ground motions recommended in ATC-40 is used. Basic seismic parameters of the selected record set are listed in Table 21.15.

As required in FEMA-356, the ground motions are scaled such that the average value of the SRSS spectra does not fall below 1.4 times the 5% damped spectrum for the DE for periods between $0.2T$ and $1.5T$. The spectra for the scaled records along with the original design spectra and the scaled design spectra (wherein the ordinates of the original spectrum are scaled by a factor of 1.4) are shown in Figure 21.20.

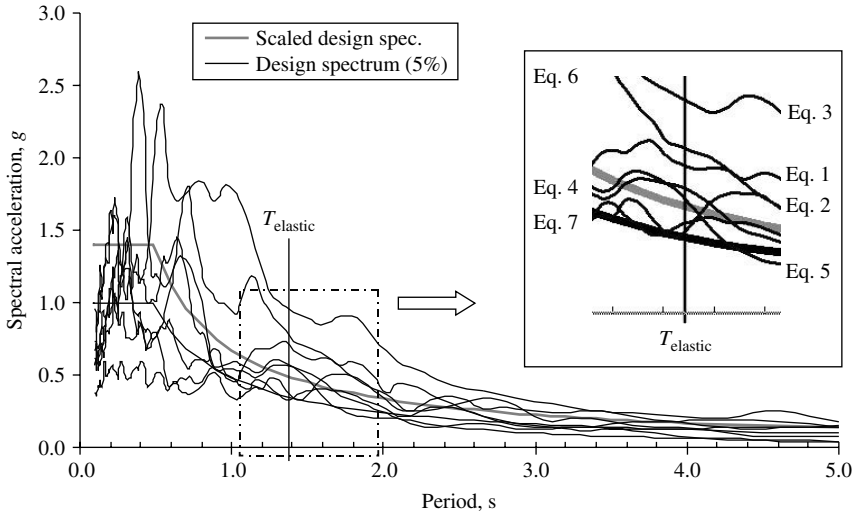

FIGURE 21.20 Original design spectrum, scaled spectrum, and spectra of selected ground motions after scaling.

Component demands from each time-history analysis are recorded, and the maximum values from each earthquake are used to estimate plastic rotation demands. Since seven records were used in the simulation, both FEMA-356 and ATC-40 stipulate that mean values of the peak demands are an adequate measure of the seismic demand. Table 21.16 summarizes the peak and average plastic rotation demands on the columns in the first story for all seven earthquakes. Table 21.16 also shows the maximum demands. This observation is crucial to our understanding of the process governing the choice of earthquake records for an NDP evaluation. If, for example, only three records were used in the evaluation, and Earthquake no. 3 was among the three records, then the seismic demands on the structure would be controlled by the peak values rather than the mean estimates. The maximum demands are considerably different from the mean values, suggesting that engineers should use caution when opting to select mean demands when evaluating performance limits.

In the present case, since all seven data points are used, performance limit states are going to be evaluated on the basis of mean demand estimates. The resulting performance of the building is shown in Figure 21.21. Though only the mean values were used, the NDP results indicate that several columns do not pass IO criteria but do pass LS criteria. Since LS performance is achieved for all elements, the trial design is acceptable.

FIGURE 21.21 Performance assessment of frame based on LDP evaluation (see notation in Figure 21.18).

21.7.2.5 Method V: Probabilistic Assessment — LSP (FEMA-350)

The previous four methods provided a deterministic assessment of the building performance. The same design will now be evaluated in a probabilistic manner using the criteria in FEMA-350. The process itself is not probabilistic, though the final evaluation results in a nondeterministic evaluation of the computed demands. We begin with the LSP. The steps involved in predicting demands are similar to method I. The total lateral force is applied as an inverted triangular load using the distribution given by Equation 21.11, and the resulting moment demands in each component are tabulated. These demands are then factored by the uncertainty factors (see Table 21.8) to establish the factored demand value $\gamma\gamma_a D$. Acceptable capacity values are then determined (see typical capacity limits given in Table 21.9) and modified by a capacity reduction factor (shown in Table 21.8), to account for the inherent uncertainty in establishing such limits. The factored demand-to-capacity ratio, λ , is used to establish a confidence level. The computed confidence levels for global interstory drift are tabulated in Table 21.17. The acceptability of the estimated confidence level is specified in FEMA-350 as follows:

Recommended Minimum Confidence Levels (%)		
	IO	CP
Global behavior limited by interstory drift	50	90
Local connection behavior limited by interstory drift	50	50
Column compression behavior	50	90
Column splice tension behavior	50	50

TABLE 21.17 Confidence Levels from Factored Demand and Capacity Estimates (LSP)

Story level	IS drift	$(\gamma\gamma_a)D$		λ		Confidence level	
		IO	CP	IO	CP	IO	CP
0							
1	0.014	0.023	0.027	1.15	0.31	35	99
2	0.014	0.022	0.026	1.11	0.31	47	99
3	0.017	0.028	0.033	1.40	0.38	10	99
4	0.016	0.026	0.030	1.29	0.35	20	99
5	0.015	0.024	0.028	1.19	0.33	30	99
6	0.009	0.014	0.017	0.72	0.20	98	99

TABLE 21.18 Computed Confidence Levels Using NSP

Story level	IS drift	$(\gamma\gamma_a)D$		λ		Confidence level	
		IO	CP	IO	CP	IO	CP
0							
1	0.037	0.074	0.088	3.71	1.04	< 10	69
2	0.029	0.059	0.070	2.95	0.82	< 10	87
3	0.043	0.087	0.103	4.34	1.21	< 10	55
4	0.035	0.072	0.085	3.58	1.00	< 10	72
5	0.026	0.052	0.062	2.62	0.73	< 10	92
6	0.010	0.021	0.025	1.05	0.29	< 52	99

Based on the recommended acceptance criteria, it is deduced that the confidence level associated with preventing building collapse at the computed drift values is extremely high (actually, this value is at its upper limit). However, the confidence level on IO performance is unacceptable. The minimum recommended value in FEMA-350 is 50%, while the confidence levels based on computed interstory drift are well below these limits for the first five story levels. Unfortunately, FEMA-350 does not specify confidence levels for LS performance. It will be necessary to use the detailed approach to establish the confidence level for this performance state. Consequently, it will not be feasible to evaluate the performance objective of this example using FEMA-350.

21.7.2.6 Method VI: Probabilistic Assessment — NSP (FEMA-350)

Though we have seen that FEMA-350 cannot be used to evaluate LS performance using the approximate method, the evaluation is extended in this section to include NSPs. The intent here is to provide a comparison of the performance evaluation using the same guideline (in this case FEMA-350) but employing different analytical methods to estimate seismic demands. It was shown earlier that the FEMA-356 evaluation using LSP resulted in unacceptable performance, while all the remaining procedures indicated satisfactory performance for the stated design objective.

Results of the evaluation using a pushover analysis (or NSP) are given in Table 21.18. The confidence levels are unacceptable for IO performance at all levels and for CP performance at the third story-level. It is observed that the confidence levels are generally lower than those estimated using LSP. This is interesting because the drift values using NSP are identical for both FEMA-356 and FEMA-350. However, FEMA-356 determines acceptance criteria using local component demands only while FEMA-350 uses a multilevel acceptance criterion. In the present case, global interstory drift was used to evaluate the building performance.

21.7.2.7 Method VII: Capacity Spectrum Based Evaluation (ATC-40)

The next evaluation methodology that will be discussed is the CSM outlined in ATC-40. The first step is to establish the capacity curve, which in this case is simply the pushover curve for the building. However, unlike the process discussed in Method II, no target displacement is used. Instead, the lateral loads are applied incrementally until a stability point is reached (impending $P-\Delta$ collapse). Since a nonlinear computer program is employed for the analysis, the approximate technique (Figure 21.11) discussed earlier does not apply. The pushover curve, which is obtained in terms of base shear and roof displacement, is converted into ADRS format (Equations 21.20 and 21.21). The next step is to select a trial performance point. Before doing this, it is instructive to overlay the 5% damped spectrum, also transformed into ADRS format, with the capacity curve to get a sense of the demand region. Figure 21.22 shows the original demand spectrum and the pushover capacity spectrum. The intersection of the demand and capacity curves occurs at approximately 180 mm (7.1 in.). At this level of displacement, the system is still elastic and the effective period is still 1.45 s. This implies that the intersection point is indeed the performance point since introducing additional damping will only reduce the demand. This result is consistent with the finding using Method II, which also concluded that all members will remain in the elastic range when the structure is subjected to design lateral forces.

21.7.2.8 Method VIII: PEER Probabilistic Framework for Performance Assessment

The final evaluation method to be considered is the PEER probabilistic approach. The first step in the PEER methodology calls for a site-specific analysis to develop the probabilistic hazard curve. As outlined in the detailed FEMA-350 procedure, it will be necessary to determine the slope of the hazard curve to carry out the integration implied in the PEER methodology (Equation 21.39). This means that we need to define at least two hazard levels. In this case, the following hazard levels are selected: events with a 10% probability of being exceeded in 50 years and events with a 2% probability of being exceeded in 50 years. To create a new hazard level beyond that specified in the design objective, the design spectrum for the 10%/50 hazard is scaled by a factor of 1.5 to produce the 2%/50 hazard spectrum. Earlier, a set of seven records corresponding to a 10%/50 hazard level was used in the FEMA-356 NDP evaluation. The same seven records are scaled in a manner consistent with the criteria specified in ATC-40 and FEMA-356 to produce records for the evaluation of the building model for 2%/50 hazard. The design spectral curves and the mean and median of the seven records for both hazard levels are displayed in Figure 21.23.

FIGURE 21.22 Capacity spectrum analysis of the building using ATC-40.

FIGURE 21.23 Mean and median spectra of scaled ground motions for both hazard levels.

FIGURE 21.24 Probabilistic hazard curve developed for building location.

The intensity measure selected to characterize the hazard of each earthquake is the spectral acceleration at the fundamental period, $S_a(T)$. Ground motions for each hazard level now need to be scaled so as to match the magnitude of the spectral accelerations of the hazard spectrum at the fundamental period. To remain reasonably consistent with the FEMA-356 NDP evaluation, the median curves are used to represent the hazard spectra. Recall that in the NDP evaluation, the ground motions were scaled such that the average value of the SRSS spectra does not fall below 1.4 times the spectral magnitudes of the DE for periods between $0.2T$ and $1.5T$. The resulting hazard curve, plotted in log-log scale, is shown in Figure 21.24. It is evident that an expression of the following form, as suggested in Equation 21.34, can be developed:

$$v(S_a) = k_0(S_a)^{-k}$$

Next, the expected demands in the system, both at the global and at the local level, need to be estimated. The NDP is selected as the analysis method to estimate these demands. The model of the building is subjected to a total of 14 earthquake records, seven for each hazard level. The peak interstory drifts resulting from the nonlinear dynamic analyses are summarized in Figure 21.25.

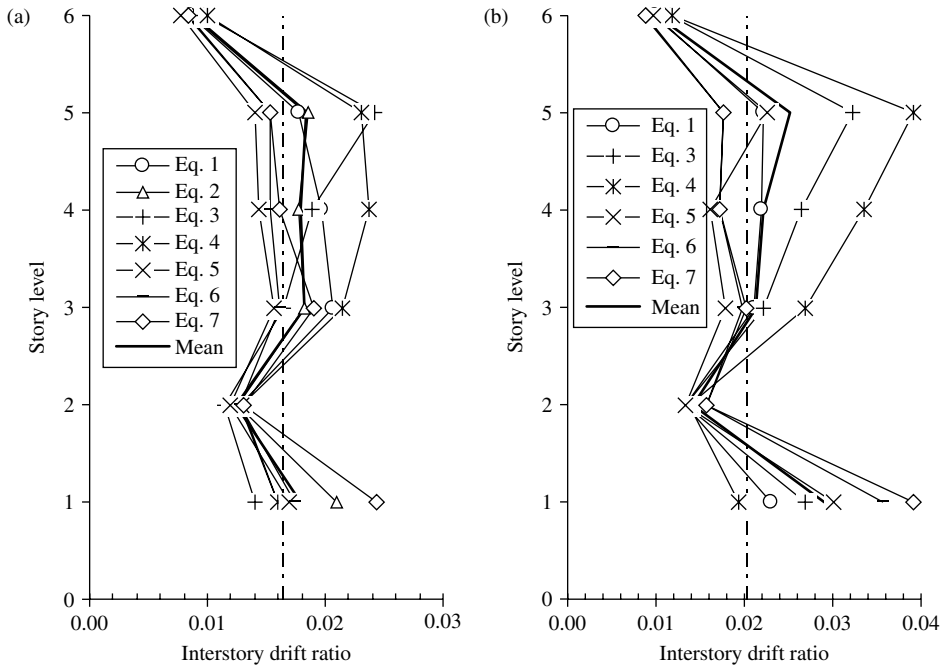

FIGURE 21.25 Interstory drift across building height for both hazard levels.

For the FEMA NDP evaluation, only the peak plastic rotation demands were needed to assess the performance of the system. In the PEER approach, the choice of a demand measure is left to the discretion of the user. For example, we could choose to use peak plastic rotations in any component at a given story level. However, in this case, the peak interstory drift ratios (IDR) are utilized to evaluate performance. In general, it would be advisable to evaluate system performance using several demand measures ranging from global measures such as drift to local measures such as plastic rotation demand. The distribution of the IDR as a function of the intensity measure is shown in Figure 21.26. Only the peak IDRs for each analysis are used to generate this plot. It is now possible to develop a drift hazard curve of the following form:

$$e^{\mu_{\ln[x|S_a]}} = a(S_a)^b \tag{21.40}$$

where $\mu_{\ln[x|S_a]}$ is the mean value of the natural logarithm of the IDRs associated with the given intensity measure and a and b are constants to be evaluated through curve-fitting the data.

The objective in this phase of the evaluation is to estimate the probability of occurrence of a peak IDR conditioned on a given spectral ordinate, as follows:

$$P(x|IM = S_a) = \Phi\left(\frac{\ln(x) - \mu_{\ln[x]}}{\sigma_{\ln[x|S_a]}}\right) \tag{21.41}$$

where x is the peak IDR, IM is the intensity measure which has been selected as $S_a(T)$, $\mu_{\ln[x]}$ is as defined previously, and $\sigma_{\ln[x|S_a]}$ is the standard deviation of the natural logarithm of the IDRs at the same intensity measure. If the drift demand is considered to be a random variable, and the drift hazard curve is established as described in Equation 21.40, Luco and Cornell (1998) show that the annual exceedance probability can be estimated from

$$v(x) = k_0 \left[\left(\frac{x}{a} \right)^{1/b} \right]^{-k} \exp \left[0.5k^2 \left(\frac{\sigma_{\ln[x|S_a]}}{b} \right)^2 \right] \tag{21.42}$$

FIGURE 21.26 Distribution of peak interstory drift as a function of earthquake intensity measure.

FIGURE 21.27 Interstory drift hazard.

All terms in the above expression have been previously defined. Since we have two distributions of the IDRs for two hazard levels, separate standard deviations are available for each hazard. However, for the design example under consideration, the dispersion associated with the 10%/50 year hazard is utilized to construct the plots of exceedance probability shown in Figure 21.27.

The information presented in Figure 21.27 is only an intermediate step in the PEER methodology. Next, we need to establish a damage definition given a demand value. There are obviously many ways to do this. For the purpose of this study, we will examine the use of IDA to identify critical limit states and use these limits to define a measure of damage. For example, IDA curves are recommended in FEMA-350 to determine the collapse limit state of the building. In this example, the IDA curve is used to specify several possible limit states. In the IDA analysis, each of the seven earthquake records is scaled repeatedly

to produce a range of demand values from the elastic state to near collapse. The collapse limit state in most applications is a stability limit state. When using a nonlinear computer program with ability to incorporate $P-\Delta$ effects, this limit state corresponds to numerical instability (or inability to converge within the specified tolerance) arising from $P-\Delta$ softening.

Results of the IDA evaluation are displayed in Figure 21.28. For each analysis, both the roof drift and the peak interstory drift values are recorded. In many cases, failure may be triggered by local soft stories, and damage states are more discernable when examining story drift measures rather than global response measures. An interesting feature of IDA is that it provides a sense of the complexity of inelastic dynamic response. Scaling the accelerogram does not necessarily result in increased demands. Each earthquake produces a different pattern of demands. Hence, it is necessary to consider a statistically significant sample of earthquake records to extract meaningful information from an IDA.

Since the primary objective of this example is to demonstrate the methodology rather than offer a complete evaluation of the building, the IDA curves presented in Figure 21.28 will now be evaluated to define performance limit states. The response of the system is essentially in the elastic range up to about 1% peak interstory drift (at any level). However, damage to the contents in the building may occur at lower drift limits. A deviation from the initial linear portion of the curve is evident around 2% for most records. Earthquake No. 2 produces considerable softening in the system beyond 2% interstory drift. Based on these qualitative observations, the following limit states are defined:

- *Immediate occupancy limit state.* IDR of 1.0%.
- *Life safety limit state.* IDR of 3.0%.

Assuming that the above IDR values represent the mean estimates and using the dispersion (standard deviation) in the IDR data at the above two limit states, the damage probabilities conditioned on the IDRs are determined and displayed in Figure 21.29a. It is important to reiterate that the above limit states are rather arbitrary and correspond to global response measures only. Detailed evaluation of demands at the component (and nonstructural component) level is necessary to develop more rational limit states in an actual building evaluation. For the present example, therefore, if the above limit states are defined, it is possible to assess the building performance from a probabilistic standpoint. If the PEER methodology is carried through as suggested in Equation 21.33, it is also necessary to define a decision variable. A careful examination of the different variables that appear in the

FIGURE 21.28 IDA curves for the six-story frame using the records listed in Table 21.15 (peak IDR at stability limit is identified as 0.07).

PEER equation indicates that it may not be necessary to integrate across three separate variables. For example, a demand measure may be translatable directly into a decision variable since damage parameters and decision variables are closely interlinked. In this illustration, the evaluation will not be carried through to the level of a decision variable (meaning a quantified economic loss measure) as intended in the PEER methodology primarily because the task of defining and calibrating such variables is beyond the scope of this chapter. Instead, the damage fragility will be established by considering the individual probabilities of damage and demand in the following manner:

$$P(\text{DM}|S_a) = \int P(\text{DM}|x)P(x|S_a) dx \tag{21.43}$$

The variable x in the above expression is the IDR. $P(\text{DM}|x)$ is plotted in Figure 21.29a. Combining this with $P(x|IM)$ and carrying out the assessment indicated by Equation 21.43 results in the fragility curves shown in Figure 21.29b. The results indicate that the likelihood of exceeding 1% drift (which we have defined to correspond to IO performance criteria) is almost certain if the spectral acceleration of the ground motion (based on constructing a 5% damped elastic spectrum of the accelerogram) exceeds about 0.6g at a fundamental period of approximately 1.39 s. The required magnitude of the spectral acceleration at the fundamental period of the building for LS performance is about twice as much.

21.7.3 Notes and Observations

The primary purpose of the illustrative exercises presented previous subsections was to highlight issues in the current state-of-the-art in performance-based seismic design. There are clearly many unresolved issues, particularly pertaining to acceptance criteria and method of analysis. For example, in the sample evaluations discussed here, the findings were inconsistent for different methods. Using the same design spectrum, the demands from different methods produced different performance levels. With reference to FEMA-356, it is observed that in this case the linear static method was the most conservative. The remaining three methods indicated satisfactory behavior with the performance objective being achieved. However, the results from LDP and NSP indicated an essentially elastic response, while demands from NDP showed inelastic behavior in some elements though the demands were within LS levels. Analysis using ATC-40 and CSMs was similar to FEMA-356 NSP. In the case of FEMA-350, which is written in a format conforming to modern code specifications, no criteria are specified for LS performance.

FIGURE 21.29 Fragility functions showing damage probabilities for two performance states: (a) damage probability conditioned on IDR and (b) damage probability conditioned on intensity measure.

Note: IO and LS limit states correspond to 1% and 3% IDR, respectively.

However, an interesting observation here is that an evaluation using NSP was less conservative than that with LSP, which is contrary to a similar comparison using FEMA-356. The results of the evaluation using the PEER methodology cannot be directly compared to the results of the previous procedures. Yet, it is possible to arrive at a nondeterministic understanding of the response: if we were to use the spectral acceleration of $0.58g$ corresponding to the 10%/50 year hazard, then the probability of achieving IO performance level is low (in other words, there is a high probability that the 0.01 IDR threshold for IO performance will be exceeded). This is based on the conclusion from the IDA curve that suggests a 0.01 peak IDR to correlate with IO performance level (or likely elastic limit). However, the likelihood of more severe damage states decreases dramatically (for example, Life Safety performance at the 10%/50 year hazard level is easily achieved since the probability of exceeding 3% drift corresponding to LS performance is nearly zero). Ideally, it should also be possible to develop loss estimates associated with different damage states. The reader is referred to the work of Miranda and Aslani (2003) and Krawinkler and Miranda (2004) for a more in-depth treatment of this subject.

21.8 Concluding Remarks

While much progress has been made in the last decade to develop processes and procedures that incorporate performance-based concepts in design and evaluation of structural systems, the findings and observations presented in the previous section raise important issues that point to the need for additional research and the development and validation of methodologies that minimize uncertainty and maximize confidence. The ongoing work at PEER is clearly a major advancement that deserves attention. Another ongoing effort is the FEMA-sponsored ATC-58 project, which has been charged with developing the next-generation performance-based seismic design procedures and guidelines. The objective of the ATC endeavor is to “express performance directly in terms of the quantified risks” in a format that is comprehensible to the decision maker. The project is expected to be conducted in two phases: in the first phase a set of procedures will be developed using probabilistic methods to assist an engineer to evaluate either an existing building or the proposed design of a new building utilizing terminology defined by decision makers; in the second phase a complimentary set of guidelines for use by stakeholders will be developed.

Since PBEE seeks to define a range of damage states, considerable work remains to be done to develop advanced computational tools that predict seismic demands of a complete soil–foundation–structure system reliably. Precise modeling guidelines should accompany such tools. Work is needed to quantify damage states and to develop models that transform damage states into loss estimates. Methods of analysis need to be validated with more rigor, particularly simplified methods that can be used in lieu of fully nonlinear time-history evaluations. Pushover procedures, which work well for low-rise, regular structures must be enhanced so that they can be used for a wider range of structural configurations. The work of Gupta and Kunnath (2000) and Chopra and Goel (2002) are important developments in this area. But more importantly, the propagation of uncertainties must be incorporated through the demand and assessment process. The degree of sophistication or level of detail will depend on the application, on whether the structure is classified as being ordinary or critical, and numerous other factors.

The success of a new seismic design methodology lies in the success of its implementation in building practice. Based on patterns in other earthquake innovations (e.g., base isolation and load and resistance factor design (LRFD)) May (2000) suggests that it may take at least two decades for ideas to move from the initial onset of preliminary guidelines (such as FEMA-356 and FEMA-350) to widespread adoption. Some of the key obstacles to advancing and implementing performance-based earthquake engineering (PBEE) cited by May include uncertainties in the methodology and its benefits, costs associated with adopting the methodology, complexity of the methodology in comparison to current code format, and issues related to validating and facilitating the adoption of the methodology. Another factor that can impact the development of PBEE is the interest of stakeholders in the success of the methodology. Steps to mitigate these barriers are essential to hasten the adoption of PBEE.

In conclusion, it must be reiterated that the intent of this chapter is to provide readers with a glimpse of evolving views on PBSE so that they can be better prepared as the first performance-based code for

seismic design becomes a reality in the future. At a time when performance-based concepts were still being debated, Krawinkler (1997) noted that PBEE “appears to promise engineered structures whose performance can be quantified and conform to the owner’s desires. If rigorously held to this promise, performance-based engineering will be a losing cause.” This prediction can be regarded as ominous or enlightening depending on the perspective of the reader. Rather than offer an unpromising indictment, Krawinkler’s purpose was to underscore the myriad of uncertainties associated with the overall process. In fact, he continues by saying that “significant improvements beyond the status quo will not be achieved without a new and idealistic target to shoot for. We need to set this target high and strive to come close to its accomplishment . . . Performance based seismic engineering is the best target available and we need to focus on it.” The real challenge in PBSE is not simply to better predict seismic demands or improve our loss-assessment methodology, but it is “in contributing effectively to the reduction of losses and the improvement of safety.” (Cornell and Krawinkler 2000).

Appendix A

Conceptual Basis of Pushover Analysis and CSM

In this section, a few conceptual details on some of the processes and methods discussed in this chapter are outlined. These concepts should aid the reader in comprehending the basis of both pushover analysis and CSMs. Figure 21.A1 shows an idealized model of a four-story frame. In a standard computer analysis of the 2D frame model, each node will be assigned three DOFs corresponding to axial, shear, and bending deformations. However, the primary degree of interest in pushover analysis and CSMs is the lateral floor DOF since it is generally assumed that floors are rigid and a SDOF is adequate to represent the drift at a story level. When constructing the system stiffness matrix, all three DOFs are used; however, only the floor DOFs are retained (the remaining DOFs are condensed, not eliminated or ignored).

The idea behind static pushover methods is to characterize the nature of seismic loads acting on the frame. The response of the frame to any dynamic load is a combination of the dynamic modes of vibration of the system. Hence, it is instructive to begin with fundamental concepts in modal analysis of structures. As is well known, any vector of order n can be expressed by a set of n independent vectors. In this case, the independent eigenvectors resulting from the solution of the eigenvalue problem serve as appropriate vectors to express the floor displacements of a multistory building. The variable n refers to the number of DOFs which in this case is the number of floor levels for the reasons cited:

$$\{u_i\}_m = \sum_{m=1}^N \Phi_m q_m = [\Phi]\{q\} \quad (21.A1)$$

where $\{u_i\}$ is the displacement vector, $\{q\}$ is the normal or modal coordinates, $[\Phi]$ is the matrix of eigen vectors, and m and i are the mode number and floor level, respectively.

Let us now consider the equilibrium relationship for a multi-DOF system:

$$[m]\{\ddot{u}\} + [c]\{\dot{u}\} + [k]\{u\} = -[m]\{1\}\ddot{u}_g(t) \quad (21.A2)$$

where $[m]$, $[c]$, and $[k]$ are the mass, damping, and stiffness matrices, respectively; $\{u\}$, $\{\dot{u}\}$, and $\{\ddot{u}\}$ are the displacement, velocity, and acceleration vectors, respectively; $\{1\}$ is a vector of unit values; and $\ddot{u}_g(t)$ is the imposed ground motion acceleration.

Utilizing the modal decomposition given in Equation 21.A1 and applying orthogonality relationships, the equilibrium expression reduces to the following form:

$$\ddot{q}_n + 2\zeta\omega_n\dot{q}_n + \omega_n^2 q_n = -\Gamma_n\ddot{u}_g(t) \quad (21.A3)$$

where $\Gamma_n = ([\Phi]^T[m]\{1\})/M_n$, in which $M_n = [\Phi]^T[m][\Phi]$.

FIGURE 21.A1 Typical multistory frame model with reduced DOFs.

Actually, a more informative way of expressing the right-hand side of Equation 21.A2 is to consider independent modal contributions as presented by Chopra (2001):

$$[m]\{\ddot{u}\} + [c]\{\dot{u}\} + [k]\{u\} = - \sum_{n=1}^N R_n \ddot{u}_g \quad (21.A4)$$

Comparing Equation 21.A4 to Equation 21.A2 and following through with the modal transformation that results in Equation 21.A3, it can be shown that

$$\{R\} = \sum R_n = \Gamma_n m \Phi_n \quad (21.A5)$$

Each term in the above expansion contains the modal contribution of the respective mode. Another way of visualizing Equation 21.A5 is to consider the load vector on the right-hand side of Equation 21.A2 as follows:

$$[m]\{t\} \ddot{u}_g = \{R\} f(t) \quad (21.A6)$$

where $\{R\}$ is a load distribution vector. For a general loading function $\{p(t)\} = \{\mathbf{r}\} f(t)$, the vector $\{\mathbf{r}\}$ represents a displacement transformation vector resulting from a unit support displacement. For earthquake loading, this simply becomes a vector with unit values. The external loading can obviously vary as a function of time in terms of both amplitude and spatial distribution. The objective of deriving an expression of the form given by Equation 21.A6 is to separate the spatial distribution from the time-varying amplitude function. This concept is not new and has been discussed in standard textbooks in dynamics (Clough and Penzien 1993).

The next step is to introduce features of the earthquake loading. Since the procedure being developed is a static procedure, the most appropriate form of earthquake loading that can be considered is a response spectrum. The spatial distribution of lateral forces to be used in conjunction with a pushover analysis is approximated in terms of the peak modal contributions as follows:

$$\{f_n\} = \Gamma_n [m] \{\Phi_n\} S_a(\zeta_n, T_n) \quad (21.A7)$$

where S_a is the spectral acceleration for the given earthquake loading at a frequency corresponding to the period T and damping ratio ζ for mode n .

The modal forces computed using Equation 21.A7 will represent the contributions to mode n only. Equation 21.A7 represents the most general form of the lateral force vector to be used in a pushover

analysis. If $n = 1$, only the first mode contributions are considered. In the approach proposed by Chopra and Goel (2002), it is assumed that the inelastic response can also be approximated by modal superposition because the n th mode is expected to be dominant even for inelastic systems. Other modal combination techniques (Kunnath 2004) and even adaptive lateral force distributions have been proposed (Gupta and Kunnath 2000) based on interesting variations in applying the load represented by Equation 21.A7. These concepts are beyond the scope of this chapter.

To understand the concept of a capacity spectrum and the ADRS conversion, it is necessary to return to Equations 21.A1 to 21.A3 and follow through with the general modal analysis procedure. The peak response of an SDOF system subjected to a given ground motion can be obtained from a response spectrum of the ground motion. Equation 21.A3 describes a set of n SDOF systems with each expression providing the solution to a specific mode. The total response is obtained through the transformation given by Equation 21.A1.

Assuming $S_d(\zeta_n, \omega_n)$ to represent the maximum displacement of an SDOF system with frequency ω_n and damping ratio ζ_n when subjected to the ground motion $\ddot{u}_g(t)$, the peak displacement response of the system represented in Equation 21.A3 is given by

$$\{q_n\}_{\max} = \Gamma_n S_d(\zeta_n, \omega_n) \quad (21.A8)$$

The peak story displacements can now be determined using Equation 21.A1 as follows:

$$\begin{Bmatrix} u_1 \\ u_2 \\ \vdots \\ u_n \end{Bmatrix}_{\max} = \Gamma_1 S_d(\zeta_1, \omega_1) \begin{Bmatrix} \Phi_{11} \\ \Phi_{21} \\ \vdots \\ \Phi_{n1} \end{Bmatrix} + \Gamma_2 S_d(\zeta_2, \omega_2) \begin{Bmatrix} \Phi_{12} \\ \Phi_{22} \\ \vdots \\ \Phi_{n2} \end{Bmatrix} + \cdots + \Gamma_n S_d(\zeta_n, \omega_n) \begin{Bmatrix} \Phi_{1n} \\ \Phi_{2n} \\ \vdots \\ \Phi_{nn} \end{Bmatrix} \quad (21.A9)$$

The above expression contains the contributions of all modes. Let us assume that only the peak displacement at a particular DOF is needed. For example, if DOF n represents the roof level, and only the first-mode contribution is considered, then the following expression is obtained:

$$u_{n,\max} = \Gamma_1 S_d(\zeta_1, \omega_1) \Phi_{n1} \quad (21.A10)$$

This equation is used to convert the roof displacement resulting from a pushover analysis to the first-mode spectral displacement in the capacity spectrum procedure.

To establish the equivalent first-mode spectral acceleration from the base shear, the peak displacement

$$\{f_n\}_{\max} = \omega_n^2 [m] \{u_n\}_{\max} \quad (21.A11)$$

$$\{f_n\}_{\max} = \omega_n^2 [m] \Gamma_n S_d(\zeta_n, \omega_n) [\Phi] \quad (21.A12)$$

$$\begin{aligned} \{f_n\}_{\max} &= \Gamma_n S_a(\zeta_n, \omega_n) [m] [\Phi] \\ &= \left\langle \Gamma_1 S_a(\zeta_1, \omega_1) \begin{Bmatrix} m_1 \Phi_{11} \\ m_2 \Phi_{21} \\ \dots \end{Bmatrix} + \Gamma_2 S_a(\zeta_2, \omega_2) \begin{Bmatrix} m_1 \Phi_{12} \\ m_2 \Phi_{22} \\ \dots \end{Bmatrix} + \cdots \right\rangle \end{aligned} \quad (21.A13)$$

If only the first-mode contribution is considered

$$\{f_n\}_{\max} = \Gamma_1 S_a(\zeta_1, \omega_1) \begin{Bmatrix} m_1 \Phi_{11} \\ m_2 \Phi_{21} \\ \dots \end{Bmatrix} \quad (21.A14)$$

The base shear is the sum of story forces, hence the first-mode contribution to the base shear is given by

$$V = \Gamma_1 S_a(\zeta_1, \omega_1) \sum_{i=1}^n m_i \Phi_{i1} \quad (21.A15)$$

Acknowledgments

I would like to acknowledge the assistance and contributions of Erol Kalkan in preparing the design example presented in this chapter. Conversations with Helmut Krawinkler on performance-based engineering and with Eduardo Miranda on the PEER methodology, provided new perspectives that have aided my thought process in the preparation of this chapter.

22.1 Modern Techniques in Steel Frame Construction

22.1.1 Constructability

One of the main considerations in planning a building project is to have the building ready and occupied as early as possible. In order to reduce the time over which the investment is tied up in construction and maximize the return of investment through the use of the building, the design needs to consider the constructability aspects of the construction.

Speed in construction is achieved through a number of factors, some of which are listed below:

- Simple building design to avoid complicated site works.
- Design for minimum delay in construction.
- Maximize use of prefabricated and precast elements to avoid delays on site.

- Reduce the number of operations on the critical path.
- Complete all the designs before starting work on site.

Complicated geometry and building layout design should be avoided where possible. This is especially critical in crowded city sites where access and storage of materials may be a problem. Repetition of work means that the work can be done in a much faster process. The more repetition in elements, the quicker the site team goes through the process of familiarization.

In a steel framed building the positioning of services may need careful consideration at the design stage to allocate service zones. Hence, conflict of interests between various professions can be avoided.

Steel offers the best framing material for prefabrication. With the use of metal decks, the concept of fast track construction is introduced. The metal decking can be placed easily and used as the slab reinforcement. Trough deck stud welding for composite action reduces beams weights and depths. It also helps ensure that the floor slab can be used as a diaphragm to transfer lateral loads to bracing frames or stiff cores. Lightweight fire protection can be applied at a later stage, taking it off the critical path.

22.1.2 Prefabrication and Ease of Construction

Steel members and plates can be shop-fabricated using computer-controlled machinery, which have less chance of mistakes. On site the assembly is mainly carried out by a bolting procedure. Lateral-load-resisting systems should be located at the lifts, stair towers, etc., to provide stability throughout, rather than a rigid unbraced frame where temporary bracing may be required during erection.

Structural members delivered to site should be lifted directly and fixed into position, avoiding storage on site. Steel stairs, erected along with the frame, give immediate access for quicker and safer erection.

Metal decking may be lifted in bundles and no further craning is required as it is laid by hand and fixed by welded studs. This gives both a working and safety platform against accidents.

Secondary beams should be placed close enough to suit the deck, so that temporary propping can be avoided, and the deck could be concreted immediately.

22.1.3 Steel–Concrete Composite Design

Considerable benefit is gained by composition of the slab with the steel beam with possible weight savings of up to 30%. An effective width of slab is assumed to carry the compressive stresses leaving virtually the whole of the steel beam in tension creating a T-beam effect. Interaction between the slab and the beam is generated by “through deck” stud welding on to the beam flange.

22.1.4 Deflection and Cambering

Where the floors are unpropped, the deflection due to wet construction requires consideration to avoid the problem of ponding.

Dead load deflections exceeding 15 to 20 mm can be easily offset by cambering, which is best achieved by cold rolling the beam. This is a specialized operation as the camber is permanent because of stress redistribution due to controlled yielding. This will depend upon a number of factors and the advice of the specialist should be sought.

Because cambering can add 10 to 20% to the basic steel cost, this should be compared with the cost of a deeper and stiffer beam section provided that the increase in building height does not compromise additional cladding costs.

22.1.5 Fire Resistance

In the event of fire the metal deck unit would cease to function effectively due to loss of strength. However, additional strength can be provided by the added wire mesh for up to 1 h fire rating.

For higher period of fire resistance or for exceptionally high imposed loads, heavier reinforcement in the form of bars placed within the deck through can be used. Up to 4 h fire rating can be obtained using

this method based upon fire engineering calculations with the deck units serving only as a permanent formwork.

For beams and columns, fire resistance may be provided by lightweight systems, which are quick to apply and economic. Normally cement-based spays are applied to beams and boards around columns. For tall buildings, steel columns may be encased or circular steel columns infilled with high-strength concrete to enhance resistance against compression and fire.

22.2 Classification of Multistory Frames

It is useful to define various frame systems to simplify the modeling of multistory frames. For more complicated three-dimensional structures involving the interaction of different structural systems, simple models are useful for preliminary design and for checking computer results. These models should capture the behavior of individual subframes and their effects on the overall structures.

This section describes what a framed system represents, defines when a framed system can be considered to be braced by another system, defines what is meant by a bracing system, and provides the difference between sway and nonsway frames. Various structural schemes for multistory building construction are also given.

22.2.1 Moment Frames

A moment frame derives its lateral stiffness mainly from the bending rigidity of frame members interconnected by rigid joints. The joints shall be designed in such a manner that they have enough strength and stiffness and negligible deformation. The deformation must be small enough to have any significant influence on the distribution of internal forces and moments in the structure or on the overall frame deformation.

An unbraced rigid frame should be capable of resisting lateral loads without relying on an additional bracing system for stability. The frame, by itself, has to resist the design forces, including gravity and lateral forces. At the same time, it should have adequate lateral stiffness against sidesway when it is subjected to horizontal wind or earthquake loads. Even though the detailing of the rigid connections results in a less economic structure, rigid unbraced frame systems perform better in load reversal situation or in earthquakes. From the architectural and functional points of view, it can be advantageous not to have any triangulated bracing systems or solid wall systems in the building.

22.2.2 Simple Frames

A simple frame refers to a structural system in which the beams and columns are pin connected and the system is not capable of resisting any lateral loads. The stability of the entire structure must be provided by attaching the simple frame to some forms of bracing systems. The lateral loads are resisted by the bracing systems while the gravity loads are resisted by both the simple frame and the bracing system.

In most cases, the lateral load response of the bracing system is sufficiently small such that second-order effects may be neglected for the design of the frames. Thus, the simple frames that are attached to the bracing system may be classified as nonsway frames. [Figure 22.1](#) shows the principal components — simple frame and bracing system — of such a structure.

There are several reasons for adopting pinned connections in the design of steel multistory frames:

1. Pin-jointed frames are easier to fabricate and erect. For steel structures, it is more convenient to join the webs of the members without connecting the flanges.
2. Bolted connections are preferred compared to welded connections, which normally require weld inspection, weather protection, and surface preparation.
3. It is easier to design and analyze a building structure that can be separated into system resisting vertical loads and system resisting horizontal loads. For example, if all the girders are simply

FIGURE 22.1 Simple braced frame.

supported between the columns, the sizing of the simply supported girders and the columns is a straightforward task.

4. It is more cost-effective to reduce the horizontal drift by means of bracing systems added to the simple framing than to use unbraced frame systems with rigid connections.

Actual connections in structures do not always fall within the categories of pinned or rigid connections. Practical connections are semirigid in nature and therefore the pinned and rigid conditions are only idealizations. Modern design codes allow the design of semirigid frames using the concept of wind moment design (type 2 connections). In wind moment design, the connection is assumed to be capable of transmitting only part of the bending moments (those due to the wind only). Recent development in the analysis and design of semirigid frames can be obtained from Chen et al. (1996). Design guidance is given in Eurocode 3 (EC3) (1992a,b).

22.2.3 Bracing Systems

Bracing systems provide lateral stability to the overall framework. It may be in the form of triangulated frames, shear wall/cores, or rigid-jointed frames. It is common to find bracing systems represented as shown in Figure 22.2. They are normally located in buildings to accommodate lift shafts and staircases.

In steel structures, it is common to have triangulated vertical truss to provide bracing (see Figure 22.2a). Unlike concrete structures where all the joints are naturally continuous, the most direct way of making connections between steel members is to hinge one member to the other. For a very stiff structure, shear wall or core wall is often used (Figure 22.2b). The efficiency of a building to resist lateral forces depends on the location and the types of the bracing systems employed and the presence or otherwise of shear walls, and cores around lift shafts and stair wells.

22.2.4 Braced versus Unbraced Frames

Building frame systems can be separated into vertical load-resistance and horizontal load-resistance systems. The main function of a bracing system is to resist lateral forces. In some cases the vertical load-resistance system also has some capability to resist horizontal forces. It is necessary, therefore, to identify

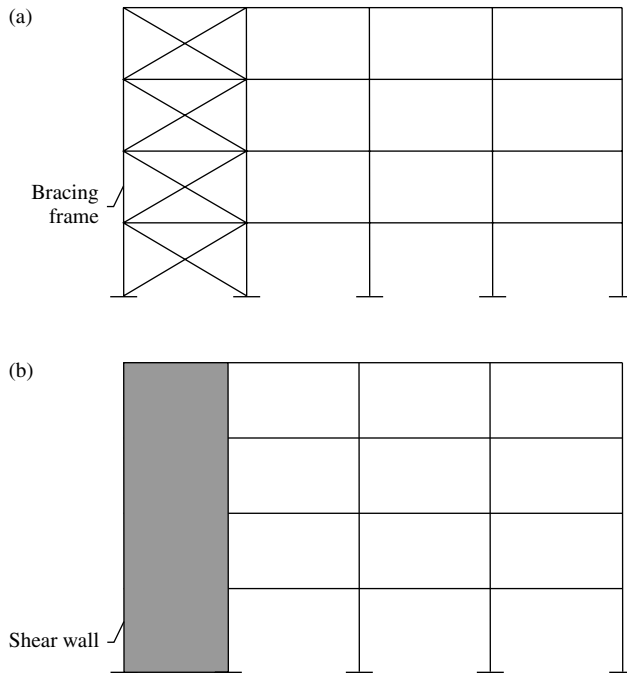

FIGURE 22.2 Common bracing systems: (a) vertical truss system and (b) shear wall.

FIGURE 22.3 Frames split into two subassemblies.

the sources of resistance and to compare their behavior with respect to the horizontal actions. However, this identification is not that obvious since the bracing is integral within the structure. Some assumptions need to be made in order to define the two structures for the purpose of comparison.

Figure 22.3 and Figure 22.4 represent the structures that are easy to define, within one system, two subassemblies identifying the bracing system and the system to be braced. For the structure shown in Figure 22.3, there is a clear separation of functions in which the gravity loads are resisted by the hinged subassembly (Frame B) and the horizontal loads are resisted by the braced assembly (Frame A). In contrast, for the structure in Figure 22.4, since the second subassembly (Frame B) is able to resist horizontal actions as well as vertical actions, it is necessary to assume that practically all the horizontal actions are carried by the first subassembly (Frame A) in order to define this system as braced.

According to EC3 (1992a,b), a frame may be classified as braced if its sway resistance is supplied by a bracing system in which its response to lateral loads is sufficiently stiff for it to be acceptably accurate to assume all horizontal loads are resisted by the bracing system. The frame can be classified as braced if the bracing system reduces its horizontal displacement by at least 80%.

FIGURE 22.4 Mixed frames split into two subassemblies.

For the frame shown in Figure 22.3, the hinged frame (Frame B) has no lateral stiffness and Frame A (truss frame) resists all lateral load. In this case, Frame B is considered to be braced by Frame A. For the frame shown in Figure 22.4, Frame B may be considered to be a braced frame if the following deflection criterion is satisfied:

$$\left(1 - \frac{\Delta_A}{\Delta_B}\right) \geq 0.8 \quad (22.1)$$

where Δ_A is the lateral deflection calculated from the truss frame (Frame A) alone and Δ_B is the lateral deflection calculated from Frame B alone.

Alternatively, the lateral stiffness of Frame A under the applied lateral load should be at least five times larger than that of Frame B:

$$K_A \geq 5K_B \quad (22.2)$$

where K_A is the lateral stiffness of Frame A and K_B is the lateral stiffness of Frame B.

22.2.5 Sway versus Nonsway Frames

A frame can be classified as nonsway if its response to in-plane horizontal forces is sufficiently stiff for it to be acceptable to neglect any additional internal forces or moments arising from horizontal displacements of the frame. In the design of a multistory building frame, it is convenient to isolate the columns from the frame and treat the stability of columns and the stability of frames as independent problems. For a column in a braced frame it is assumed that the columns are restricted at their ends from horizontal displacements and therefore are only subjected to end moments and axial loads as transferred from the frame. It is then assumed that the frame, possibly by means of a bracing system, satisfies global stability checks and that the global stability of the frame does not affect the column behavior. This gives the commonly assumed *nonsway frame*. The design of columns in a nonsway frame follows the conventional beam–column capacity check approach and the column effective length may be evaluated based on the column end restraint conditions. Interaction equations for various cross-section shapes have been developed through years of research in the field of beam–column design (Chen and Atsuta 1976).

Another reason for defining “sway” and “nonsway frames” is the need to adopt conventional analysis in which all the internal forces are computed on the basis of the undeformed geometry of the structure. This assumption is valid if second-order effects are negligible. When there is an interaction between overall frame stability and column stability, it is not possible to isolate the column. The column and the frame have to act interactively in a “sway” mode. The design of sway frames has to consider the frame sub-assembly or the structure as a whole. Moreover, the presence of “inelasticity” in the columns will render some doubts on the use of the familiar concept of “elastic effective length” (Liew et al. 1991, 1992).

On the basis of the above considerations, a definition can be established for sway and nonsway frames as

A frame can be classified as nonsway if its response to in-plane horizontal forces is sufficiently stiff for it to be acceptably accurate to neglect any additional internal forces or moments arising from horizontal displacements of its nodes.

British Code: BS5950: Part 1 (1990) provides a procedure to distinguish between sway and nonsway frames as follows:

1. Apply a set of notional horizontal loads to the frame. These notional forces are to be taken as 0.5% of the factored dead plus vertical imposed loads and are applied in isolation, that is, without the simultaneous application of actual vertical or horizontal loading.
2. Perform a first-order linear elastic analysis and evaluate the individual relative sway deflection δ for each story.
3. If the actual frame is unclad, the frame may be considered to be nonsway if the interstory deflection satisfies the following limit:

$$\delta < \frac{h}{4000}$$

where h is the story height for every story.

4. If the actual frame is clad but the analysis is carried out on the bare frame, then in recognition of the fact that the cladding will substantially reduce deflections, the condition is reflected and the frame may be considered to be nonsway if

$$\delta < \frac{h}{2000}$$

where h is the story height for every story.

5. All frames not complying with the criteria in (3) or (4) are considered to be sway frames.

EC3 (1992a,b) also provides some guidelines to distinguish between sway and nonsway frames. It states that a frame may be classified as nonsway for a given load case if $P_{cr}/P \geq 10$ for that load case, where P_{cr} is the elastic critical buckling value for sway buckling and P is the design value of the total vertical load. When the system buckling load factor is ten times more than the design load factor, the frame is said to be stiff enough to resist lateral load and it is unlikely to be sensitive to sidesway deflections. AISC LRFD (1993) does not give specific guidance on frame classification. However, for frames to be classified as nonsway in AISC LRFD format, the moment amplification factor, B_2 , has to be small (a possible range is $B_2 \leq 1.10$) so that sway deflection would have negligible influence on the final value obtained from the beam-column capacity check.

22.2.6 Classification of Multistory Buildings

The selection of appropriate structural systems for tall buildings must satisfy both the strength and stiffness requirements. The structural system must be adequate to resist lateral and gravity loads that cause horizontal shear deformation and overturning deformation. Other important issues that must be considered in planning the structural schemes and layout are the requirements for architectural details, building services, vertical transportation, and fire safety, among others. The efficiency of a structural system is measured in terms of their ability to resist higher lateral load, which increases with the height of the frame (Iyengar et al. 1992). A building can be considered as tall when the effect of lateral loads is reflected in the design. Lateral deflections of tall buildings should be limited to prevent damage to both structural and nonstructural elements. The accelerations at the top of the building during frequent windstorms should be kept within acceptable limits to minimize discomfort to the occupants (see Section 22.5).

Figure 22.5 shows a chart which defines, in general, the limits to which a particular framing system can be used efficiently for multistory building projects. The various structural systems in Figure 22.5 can be broadly classified into two main types: (1) medium-height buildings with shear-type deformation predominant and (2) high-rise cantilever structures such as framed tubes, diagonal tubes, and braced trusses. This classification of system forms is based primarily on their relative effectiveness in resisting lateral loads. At one end of the spectrum in Figure 22.5 is the moment resisting frames, which are efficient for buildings of 20 to 30 stories, and at the other end is the tubular systems with high cantilever

FIGURE 22.5 Categorization of tall building systems.

efficiency. Other systems are placed with the idea that the application of any particular form is economical only over a limited range of building heights.

An attempt has been made to develop a rigorous methodology for the cataloguing of tall buildings with respect to their structural systems (Council on Tall Buildings and Urban Habitat 1995). The classification scheme involves four levels of framing division: primary framing system, bracing subsystem, floor framing, and configuration and load transfer. While any cataloguing scheme must address the preeminent focus on lateral load resistance, the load-carrying function of the tall building subsystems is rarely independent. An efficient high-rise system must engage vertical gravity load-resisting elements in the lateral load subsystem in order to reduce the overall structural premium for resisting lateral loads. Further readings on design concepts and structural schemes for steel multistory buildings can be found in Liew (2001) and the design calculations and procedure for building frame structures using the AISC LRFD procedure are given in ASCE (1987).

Some degree of independence can be distinguished between the floor framing systems and the lateral-load-resisting systems, but the integration of these subassemblies into the overall structural scheme is crucial. Section 22.3 provides some advice for selecting composite floor systems to achieve the required stiffness and strength and also highlights the ways where building services can be accommodated within normal floor zones. Several practical options for long-span construction are discussed and their advantages and limitations are compared and contrasted. Design considerations for floor diaphragm are discussed. Section 22.4 provides some advice on the general principles to be applied when preparing a structural scheme for multistory steel and composite frames. The design procedure and construction considerations that are specific to steel gravity frames, braced frames, moment-resisting frames, and the design approaches to be adopted for sizing multistory building frames are given. The potential use of steel-concrete composite material for high-rise construction is presented. Section 22.5 deals with the

issues related to wind-induced effects on multistory frames. Dynamic effects due to along wind, across wind, and torsional response are considered with examples.

22.3 Floor Systems

22.3.1 Design Consideration

Floor systems in tall buildings generally do not differ substantially from those in low-rise buildings. However, the following aspects need to be considered in design:

1. Weight to be minimized
2. Self-supporting during construction
3. Mechanical services to be integrated in the floor zone
4. Adequate fire resistance
5. Buildability
6. Long spanning capability
7. Adequate floor diaphragm

Modern office buildings require large floor span in order to create greater space flexibility for the accommodation of greater variety of tenant floor plans. For building design, it is necessary to reduce the weight of the floors so as to reduce the size of columns and foundations and thus permit the use of larger space. Floors are required to resist vertical loads and they are usually supported by secondary beams. The spacing of the supporting beams must be compatible with the resistance of the floor slabs.

The floor systems can be made buildable using prefabricated or precast elements of steel and reinforced concrete in various combinations. Floor slabs can be precast concrete slab or composite slabs with metal decking. Typical precast slabs are 4 to 7 m, thus avoiding the need of secondary beams. For composite slabs, metal deck spans ranging from 2 to 7 m may be used depending on the depth and shape of the deck profile. However, the permissible spans for steel decking are influenced by the method of construction; in particular, it depends on whether temporary propping is provided. Propping is best avoided as the speed of construction is otherwise diminished for the construction of tall buildings.

Sometimes openings in the webs of beams are required to permit passage of horizontal services, such as pipes (for water and gas), cables (for electricity, telecommunications, and electronic communication), and ducts (air conditioning), etc.

In addition to strength, floor spanning systems must provide adequate stiffness to avoid large deflections due to live load, which could lead to damage of plaster and slab finishers. Where the deflection limit is too severe, precambering with an appropriate initial deformation equal and opposite to that due to the permanent loads can be employed to offset part of the deflection. In steel construction, steel members can be partially or fully encased in concrete for fire protection. For longer period of fire resistance, additional reinforcement bars may be required. Various long-span flooring systems in [Section 22.3.4](#) offer solutions to integrate building service into the structural depth leading to potential savings in weight and cladding cost.

22.3.2 Composite Floor Systems

Composite floor systems typically involve structural steel beams, joists, girders, or trusses linked via shear connectors with a concrete floor slab to form an effective T-beam flexural member resisting primarily gravity loads. The versatility of the system results from the inherent strength of the concrete floor component in compression and the tensile strength of the steel member. The main advantages of combining the use of steel and concrete materials for building construction are:

- Steel and concrete may be arranged to produce an ideal combination of strength, with concrete efficient in compression and steel in tension.

- Composite flooring is lighter in weight than pure concrete.
- The construction time is reduced since casting of additional floors may proceed without having to wait for the previously cast floors to gain strength. The steel decking system provides positive-moment reinforcement for the composite floor and requires only a small amount of reinforcement to control cracking and for fire resistance.
- The construction of a composite floor does not require highly skilled labor. The steel decking acts as a permanent formwork. Composite beams and slabs can accommodate raceways for electrification, communication, and air distribution systems. The slab serves as a ceiling surface to provide easy attachment of a suspended ceiling.
- The composite floor system produces a rigid horizontal diaphragm, providing stability to the overall building system while distributing wind and seismic shears to the lateral-load-resisting systems.
- Concrete provides thermal protection to steel at elevated temperature. Composite slabs of 2 h fire rating can be easily achieved for most building requirements.

The floor slab can be formed by the following methods:

- a flat-soffit reinforced concrete slab (Figure 22.6a);
- precast concrete planks with cast *in situ* concrete topping (Figure 22.6b);
- precast concrete slab with *in situ* grouting at the joints (Figure 22.6c);
- a metal steel deck tops with concrete, either composite or noncomposite (Figure 22.6d).

The composite action of the metal deck results from side embossments incorporated into the steel sheet profile.

22.3.3 Composite Beams and Girders

Steel and concrete composite beams may be formed by shear connectors connecting the concrete floor to the top flange of the steel member. Concrete encasement will provide fire resistance to the steel member.

FIGURE 22.6 Composite beams with: (a) flat-soffit reinforced concrete slab, (b) precast concrete planks and cast *in situ* concrete topping, (c) precast concrete slab and *in situ* concrete at the joints, and (d) metal steel deck supporting concrete slab.

FIGURE 22.7 (a) Composite floor plan. (b) Stress distribution in a composite cross-section.

FIGURE 22.8 Web opening with horizontal reinforcements.

Alternatively, direct sprayed-on cementitious and board-type fireproofing materials may be used economically to replace the concrete insulation on the steel members. The most common arrangement found in composite floor systems is a rolled or built-up steel beam connected to a formed steel deck and concrete slab (Figure 22.6d). The metal deck typically spans unsupported between steel members while also providing a working platform for concreting work.

Figure 22.7a shows a typical building floor plan using composite steel beams. The stress distribution at working loads in a composite section is shown schematically in Figure 22.7b. The neutral axis is normally located very near to the top flange of the steel section. Therefore, the top flange is lightly stressed. From a construction point of view, a relatively wide and thick top flange must be provided for proper installation of shear stud and metal decking. However, the increased fabrication costs must be evaluated, which tend to offset the saving from material efficiency.

A number of composite girder forms allowing passage of mechanical ducts and related services through the depth of the girder (Figure 22.8). Successful composite beam design requires the consideration of various serviceability issues such as long-term (creep) deflections and floor vibrations. Of particular concern is the occupant-induced floor vibrations. The relatively high flexural stiffness of most composite floor framing systems results in relatively low vibration amplitudes and therefore is effective in reducing perceptibility. Studies have shown that short to medium span (6 to 12 m) composite floor beams perform quite well and are rarely found to transmit annoying vibrations to the occupants. Particular care is required for long-span beams more than 12 m in range.

22.3.4 Long-Span Flooring Systems

Long spans impose a burden on the beam design in terms of larger required flexural stiffness for serviceability design. Besides satisfying both serviceability and ultimate strength limit states, the proposed system must also accommodate the incorporation of mechanical services within normal floor

zones. Several practical options for long-span construction are available and they are discussed in the following sections.

22.3.4.1 Beams with Web Openings

Standard castellated beams can be fabricated from hot-rolled beams by cutting along a zigzag line through the web. The top and bottom half-beams are then displaced to form castellations (Figure 22.9). Castellated composite beams can be used effectively for lightly serviced building. Although composite action does not increase the strength significantly, it increases the stiffness and hence reduces deflection and the problem associated with vibration. Castellated beams have limited shear capacity and are best used as long-span secondary beams where loads are low or where concentrated loads can be avoided. Its use may be limited due to the increased fabrication cost and the fact that the standard castellated openings are not large enough to accommodate the large mechanical ductwork common in modern high-rise buildings.

Horizontal stiffeners may be required to strengthen the web opening and they are welded above and below the opening. The height of the opening should not be more than 70% of the beam depth and the length should not be more than twice the beam depth. The best location of the openings is in the low shear zone of the beams. This is because the webs do not contribute much to the moment resistance of the beam.

22.3.4.2 Fabricated Tapered Beams

The economic advantage of fabricated beams is that they can be designed to provide the required moment and shear resistance along the beam span in accordance with the loading pattern along the beam. Several forms of tapered beams are possible. A simply supported beam design with a maximum bending moment at the mid-span would require that they all effectively taper to a minimum at both ends (Figure 22.10). A rigidly connected beam would have minimum depth toward the mid-span. To make best use of this system, services should be placed toward the smaller depth of the beam cross-sections. The spaces created by the tapered web can be used for running services of modestly size (Figure 22.10).

A hybrid girder can be formed with the top flange made of lower-strength steel in comparison with the steel grade for the bottom flange. The web plate can be welded to the flanges by double-sided fillet welds. Web stiffeners may be required at the change of section when taper slope exceeds approximately 6°. Stiffeners are also required to enhance the shear resistance of the web, especially when the web slenderness ratio is too high. A tapered beam is found to be economical for spans up to 20 m. Further information on the design of fabricated beams with tapered webs can be found in Owens (1989).

FIGURE 22.9 Composite castellated beams.

FIGURE 22.10 Tapered composite beam.

FIGURE 22.11 Haunched composite beam.

22.3.4.3 Haunched Beams

Haunched beams are designed by forming a rigid moment connection between the beams and columns. The haunch connections offer restraints to beam and it helps to reduce mid-span moment and deflection. The beams are designed in a manner similar to continuous beams. Considerable economy can be gained in sizing the beams using continuous design that may lead to a reduction in beam depth up to 30% and deflection up to 50%.

The haunch may be designed to develop the required moment that is larger than the plastic moment resistance of the beam. In this case, the critical section is shifted to the tip of the haunch. The depth of the haunch is selected based on the required moment at the beam-to-column connections. The length of the haunch is typically 5 to 7% the span length for nonsway frames or 7 to 15% for sway frames. Service ducts can pass below the beams (Figure 22.11).

Haunched composite beams are usually used in the case where the beams frame directly into the major axis of the columns. This means that the columns must be designed to resist the moment transferred from the beam to the column. Thus, a heavier column and a more complex connection would be required in comparison with a structure designed based on the assumption that the connections are pinned. The rigid frame action derived from the haunched connections can resist lateral loads due to wind without the need of vertical bracing. Haunched beams offer higher strength and stiffness during the steel erection stage thus making this type of system particular attractive for long-span construction. However, haunched connections behave differently under positive and negative moments, as the connection configuration is not symmetrical about the bending axis.

The rationale of using the haunched beam approach is explained as follows. In continuous beam design, the moment distribution of a continuous beam would show that the support moment is generally larger than the mid-span moment up to the ratio of 1.8. The effective cross-sections of typical steel-concrete composite beams under hogging and sagging moment can be determined according to the usual stress block method of design. It can be observed that the hogging moment capacity of the composite section at the support is smaller than the sagging moment capacity near the mid-span.

Therefore, there is a mismatch between the required greater support resistance and the much larger available sagging moment capacity.

When elastic analysis is used in the design of continuous composite beams, the potential large sagging moment capacities available from composite action can never be realized. One way to overcome this problem is to increase the moment resistance at the support (and hence utilize the full potential of larger sagging moment) by providing haunches at the supports. An optimum design can be achieved by designing the haunched section to develop the required moment at the support and the composite section to develop the required sagging moment. If this can be achieved in practice, the design does not require inelastic force redistribution and hence elastic analysis is adequate. However, analysis of haunched composite beams is more complicated because the member is nonprismatic (i.e., cross-section property varies along the length). The analysis of such beams requires the evaluation of section properties such as beam's stiffness (EI) at different cross-sections. The analysis/design process is more involved because it requires the evaluation of serviceability deflection and ultimate strength limit state of nonprismatic members. Some guides on haunched beam design can be found in Lawson and Rackham (1989).

22.3.4.4 Parallel Beam System

The system consists of two main beams with secondary beams run over the top of the main beams (see Figure 22.12). The main beams are connected to either side of the column. They can be made continuous over two or more spans supporting on stubs attached to the columns. This will help in reducing the construction depth and thus avoiding the usual beam-to-column connections. The secondary beams are designed to act compositely with the slab and may also be made to span continuously over the main

FIGURE 22.12 (a) Parallel composite beam system. (b) Parallel beam connection.

beams. The need to cut the secondary beams at every junction is thus avoided. The parallel beam system is ideally suited for accommodating large service ducts in orthogonal directions (Figure 22.12). A small saving in steel weight is expected from the continuous construction because the primary beams are noncomposite. However, the main beam can be made composite with the slab by welding beam stubs to the top flange of the main beam and connected to the concrete slab through the use of shear studs. The simplicity of connections and ease of fabrication make this long-span beam option particularly attractive. Competitive pricing can be obtained from the fabricator. Further details on parallel beam approach can be found in Brett and Rushton (1990).

22.3.4.5 Composite Trusses

Trusses are frequently used in multistory buildings for very long-span supports. The openings created in the truss braces can be used to accommodate large services. Although the cost of fabrication is higher in relation to the material cost, truss construction can be cost-effective for a very long span when compared to other structural schemes. One disadvantage of the truss configuration is that fire protection is labor intensive and sprayed protection systems cause a substantial mess to the services that pass through the web opening (see Figure 22.13).

Several forms of truss arrangement are possible. The three most common web framing configurations in floor truss and joist designs are (1) Warren truss, (2) modified Warren truss, and (3) Pratt truss, as shown in Figure 22.14. The efficiency of various web members in resisting vertical shear forces may be affected by the choice of a web-framing configuration. For example, the selection of a Pratt web over a Warren web may effectively shorten compression diagonals resulting in more efficient use of these members.

Experience has shown that both Pratt and Warren configurations of web framing are suitable for short-span trusses with shallow depths. For truss with spans greater than 10 m, or effective depths larger than 700 mm, a modified Warren configuration is generally preferred. The Warren and modified Warren trusses are more popular for building construction since they offer larger web openings for services between bracing members.

FIGURE 22.13 Composite truss.

FIGURE 22.14 Truss configurations: (a) Warren truss, (b) modified Warren truss, and (c) Pratt truss.

The resistance of a composite truss is governed by (1) yielding of the bottom chord, (2) crushing of the concrete slab, (3) failure of the shear connectors, (4) buckling of top chord during construction, (5) buckling of web members, and (6) instability occurring during and after construction. To avoid brittle failures, ductile yielding of the bottom chord is the preferred failure mechanism. Thus, the bottom chord should be designed to yield prior to crushing of concrete slab. The shear connectors should have sufficient capacity to transfer the horizontal shear between the top chord and the slab. During construction, adequate plan bracing should be provided to prevent top chord buckling. When considering composite action, the top steel chord is assumed not to participate in the moment resistance of the truss, since it is located very near to the neutral axis of the composite truss and, thus, contributes very little to the flexural capacity. However, the top chord has two functions: (1) it provides an attachment surface for the shear connectors and (2) it resists the forces in the end panel without reliance on composite action unless shear connectors are placed over the seat or along a top chord extension. Thus, the top chord must be designed to resist the compressive force equilibrating the horizontal force component of the first web member. In addition, the top chord also transfers the factored shear force to the support and thus must be designed accordingly.

The bottom chord shall be continuous and may be designed as an axially loaded tension member. The bottom chord shall be proportioned to yield before the concrete slab, web members, or the shear connectors fail.

The shear capacity of the steel top and bottom chords and concrete slab can be ignored in the evaluation of the shear resistance of a composite truss. The web members should be designed to resist vertical shear. Further references on composite trusses can be found in ASCE Task Committee (1996) and Neals and Johnson (1992).

22.3.4.6 Stub Girder System

The stub girder system involves the use of short beam stubs that are welded to the top flange of a continuous, heavier bottom girder member, and connected to the concrete slab through the use of shear studs. Continuous transverse secondary beams and ducts can pass through the openings formed by the beam stub. The natural openings in the stub girder system allow the integration of structural and service zones in two directions (Figure 22.15), permitting story-height reduction when compared with some other structural framing systems.

Ideally, stub girders span about 12 to 15 m in contrast to the conventional floor beams, which span about 6 to 9 m. The system is very versatile, particularly with respect to secondary framing spans with beam depths being adjusted to the required structural configuration and mechanical requirements. Overall girder depths vary only slightly, by varying the beam and stub depths. The major disadvantage of the stub girder system is that it requires temporary props at the construction stage and these props have to be retained until the concrete has gained adequate strength for composite action. However, it is possible to introduce additional steel top chord, such as a T-section, which acts in compression to

FIGURE 22.15 Stub girder system.

develop the required bending strength during construction. For span length greater than 15 m, stub girders become impractical, because the slab design becomes critical.

In the stub girder system, the floor beams are continuous over the main girders and splice at the locations near the points of inflection. The sagging moment regions of the floor beams are usually designed compositely with the deck–slab system, to produce savings in structural steel as well as to provide stiffness. The floor beams are bolted to the top flange of the steel bottom chord of the stub girder and two shear studs are usually specified on each floor beam, over the beam–girder connection for anchorage to the deck–slab system. The stub girder may be analyzed as a Vierendeel girder, with the deck–slab acting as a compression top chord, the full length steel girder as a tensile bottom chord, and the steel stubs as vertical web members or shear panels.

22.3.4.7 Prestressed Composite Beams

Prestressing of the steel girders is carried out such that the concrete slab remains uncracked under the working loads and the steel is utilized fully in terms of stress in the tension zone of the girder.

Prestressing of steel beam can be carried out using a precambering technique as depicted in Figure 22.16. First, a steel girder member is prebent (Figure 22.16a) and is then subjected to preloading in the direction against the bending curvature until the required steel strength is reached (Figure 22.16b). Second, the lower flange of the steel member, which is under tension, is encased in a reinforced concrete chord (Figure 22.16c). The composite action between the steel beam and the concrete slab is developed by providing adequate shear connectors at the interface. When the concrete gains adequate strength, the steel girder is prestressed by stress relieving the precompressed tension chord (Figure 22.16d). Further composite action can be achieved by supplementing the girder with *in situ* or prefabricated reinforcement concrete slabs and this will produce a double composite girder (Figure 22.16e).

The major advantages of this system are that the steel girders are encased in concrete on all sides, no corrosion and fire protection are required on the sections. The entire process of precambering and prestressing can be performed and automated in a factory. During construction, the lower concrete chord cast in the works can act as the formwork. If the distance between two girders is large, precast planks can be supported by the lower concrete chord as permanent formwork.

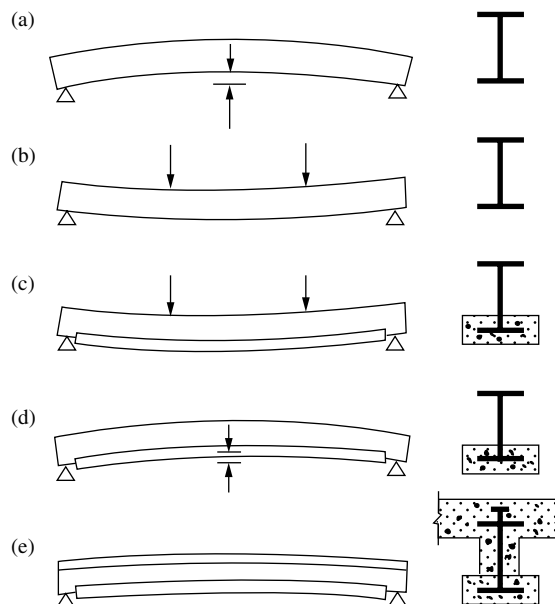

FIGURE 22.16 Process of prestressing using precambering technique.

Prestressing can also be achieved by using tendons that can be attached to the bottom chord of a steel composite truss or the lower flange of a composite girder to enhance the load-carrying capacity and stiffness of long-span structures (Figure 22.17). This technique has been found to be popular for bridge construction in Europe and the United States, although less common for building construction.

22.3.5 Comparison of Floor Spanning Systems

The conventional composite beams are the most common forms of floor construction for a large number of building projects. Typically, they are highly efficient and economic with bay sizes in the range of 6 to 12 m. There is, however, much demand for larger column free areas where, with a traditional composite approach, the beams tend to become excessively deep, with unnecessary increases in the overall building height and the consequent increases in cladding costs. Spans exceeding 12 m are generally achieved by choosing an appropriate structural form that integrates the services within the floor structure, thereby reducing the overall floor zone depths. Although a long-span solution may entail a small increase in structural costs, the advantages of greater flexibility and adaptability in service and the creation of column-free space often represent the most economic option over the design life of the building. Figure 22.18 compares the various structural options of a typical range of span lengths used in practice.

FIGURE 22.17 Prestressing of composite steel girders with tendons.

FIGURE 22.18 Comparison of composite floor systems.

22.3.6 Floor Diaphragms

Typically, beams and columns rigidly connected for moment resistance are placed in orthogonal directions to resist lateral loads. Each plane frame would assume to resist a portion of the overall wind shear, which is determined from the individual frame stiffness in proportion to the overall stiffness of all frames in that direction. This is based on the assumption that the lateral loads are distributed to the various frames by the floor diaphragm. In order to develop proper diaphragm action, the floor slab must be attached to all columns and beams that participate in lateral-force resistance. For building relying on bracing systems to resist all lateral loads, the stability of a building depends on rigid floor diaphragm to transfer wind shears from their point of application to the bracing systems such as lattice frames, shear walls, or core walls.

The use of composite floor diaphragms in place of in-plane steel bracing has become an accepted practice. The connection between slab and beams are often through shear studs that are welded directly through the metal deck to the beam flange. The connection between beams of adjacent deck panels is crucial and often through interlocking of panels overlapping each other. The diaphragm stresses are generally low and can be resisted by floor slabs that have adequate thickness for most buildings.

Plan bracing is necessary when the diaphragm action is not adequate. Figure 22.19a shows a triangulated plan bracing system that resists lateral load on one side and spans between the vertical walls. Figure 22.19b illustrated the case where the floor slab has adequate thickness and it can act as diaphragm resisting lateral loads and transmitting the forces to the vertical walls. However, if there is an abrupt

change in lateral stiffness or where the shear must be transferred from one frame to the other due to the termination of lateral bracing system at certain height, large diaphragm stresses may be encountered and they must be accounted for through proper detailing of slab reinforcement. Also, diaphragm stresses may be high where there are large openings in the floor, in particular at the corners of the openings.

The rigid diaphragm assumption is generally valid for most high-rise buildings (Figure 22.20a); however, as the plan aspect ratio (b/a) of the diaphragm linking two lateral systems exceeds 3 in 1 (see the illustration in Figure 22.20b), the diaphragm may become semirigid or flexible. For such cases, the wind shears must be allocated to the parallel shear frames according to the attributed area rather than relative stiffness of the frames.

From the analysis point of view, a diaphragm is analogous to a deep beam with the slab forming the web and the peripheral members serving as the flanges as shown in Figure 22.20b. It is stressed principally in shear, but tension and compression forces must be accounted for in design.

A rigid diaphragm is useful to transmit torsional forces to the lateral-load-resistance systems to maintain lateral stability. Figure 22.21a shows a building frame consisting of three shear walls resisting lateral forces acting in the direction of Wall A. The lateral load is assumed to act as a concentrated load with a magnitude F on each story. Figure 22.21b and c shows the building plan having dimensions of L_1 and L_2 . The lateral-load-resisting system is represented in the plan by solid lines that represent Wall A, Wall B, and Wall C. Since there is only one lateral resistance system (Wall A) in the direction of

FIGURE 22.21 (a) Lateral-force-resisting system in a building. (b) Rigid diaphragm. (c) Flexible diaphragm.

TABLE 22.1 Details of Typical Flooring Systems and their Relative Merits

Floor system	Typical span length (m)	Typical depth (mm)	Construction time	Degree of lateral restraint to beams	Degree of diaphragm action	Usage
<i>In situ</i> concrete	3–6	150–250	Medium	Very good	Very good	All categories but not often used in multistory buildings
Steel deck with <i>in situ</i> concrete	2.5–3.6 unshore; >3.6 shore	110–150	Fast	Very good	Very good	All categories especially in multistory office buildings
Precast concrete	3–6	110–200	Fast	Fair–good	Fair–good	All categories with crane requirements
Prestressed concrete	6–9	110–200	Medium	Fair–good	Fair–good	Multistory buildings and bridges

the applied load, the loading condition creates a torsion (Fe) and the diaphragm tends to rotate as shown by the dashed lines in Figure 22.21b. The lateral-load-resistance systems in Wall B and Wall C will provide the resistance forces to stabilize the torsional force by generating a couple of shear resistance as

$$V_B = V_C = \frac{Fe}{L_2}$$

Figure 22.21c illustrates the same condition except that a flexible diaphragm is used. The same torsional tendency exists, but the flexible diaphragm is unable to generate a resisting couple in Wall B and Wall C and the structure will collapse as shown by the dashed lines. To maintain stability, a minimum of two vertical bracings in the direction of the applied force is required to eliminate the possibility of any torsional effects.

The adequacy of the floor to act as a diaphragm depends very much on its type. Precast concrete floor planks without any prestressing offer limited resistance to the racking effects of diaphragm action. In such cases, supplementary bracing systems in plan, such as those shown in Figure 22.19a, are required for resistance of lateral forces. Where precast concrete floor units are employed, sufficient diaphragm action can be achieved by using a reinforced structural concrete topping, so that all individual floor planks are combined to form a single floor diaphragm. Composite concrete floors, incorporating permanent metal decking, provide excellent diaphragm action provided that the connections between the diaphragm and the peripheral members are adequate. When composite beams or girders are used, shear connectors will usually serve as boundary connectors and intermediate diaphragm-to-beam connectors. By fixing the metal decking to the floor beams, an adequate floor diaphragm can be achieved during the construction stage.

It is essential at the start of the design of structural steelworks to consider the details of the flooring system to be used, since these have a significant effect on the design of the structure. Table 22.1 summarizes the salient features of the various types of flooring systems in terms of their diaphragm actions.

22.4 Design Concepts and Structural Schemes

22.4.1 Introduction

Multistory steel frames consist of columns and beams interconnected to form a three-dimensional structure. A building frame can be stabilized either by some forms of bracing systems (braced frames) or by itself (unbraced frames). All building frames must be designed to resist lateral load to ensure overall stability. A common approach is to provide a gravity framing system with one or more lateral bracing systems attached to it. This type of framing system, which is generally referred to as simple braced frames, is found to be cost-effective for multistory buildings of moderate height (up to 20 stories).

For gravity frames, the beams and columns are pinned connected and the frames are not capable of resisting any lateral loads. The stability of the entire structure is provided by attaching the gravity frames to some forms of bracing systems. The lateral loads are resisted mainly by the bracing systems while the gravity loads are resisted by both the gravity frame and the bracing system. For buildings of moderate height, the bracing system's response to lateral forces is sufficiently stiff such that second-order effects may be neglected for the design of such frames.

In moment-resisting frames, the beams and columns are rigidly connected to provide moment resistance at joints, which may be used to resist lateral forces in the absence of any bracing systems. However, moment joints are rather costly to fabricate. In addition, it takes longer time to erect a moment frame than a gravity frame.

A cost-effective framing system for multistory buildings can be achieved by minimizing the number of moment joints, replacing field welding by field bolting, and combining various framing schemes with appropriate bracing systems to minimize frame drift. A multistory structure is most economical and efficient when it can transmit the applied loads to the foundation by the shortest and most direct routes. For ease of construction, the structural schemes should be simple enough, which implies repetition of member and joints, adoption of standard structural details, straightforward temporary works, and minimal requirements for an inter-related erection procedure to achieve the intended behavior of the completed structure. Sizing of structural members should be based on the longest spans and largest attributed roof and floor areas. The same sections should be used for similar but less onerous cases.

Scheme drawings for multistory building design should include the following:

1. General arrangement of the structure including column and beam layout, bracing frames, and floor systems.
2. Critical and typical member sizes.
3. Typical cladding and bracing details.
4. Typical and unusual connection details.
5. Proposals for fire and corrosion protection.

This section offers advice on the general principles to be applied when preparing a structural scheme for multistory steel and composite frames. The aim is to establish several structural schemes that are practicable, sensibly economic, and functional to the changes that are likely to be encountered as the overall design develops. The section begins by examining the design procedure and construction considerations that are specific to steel gravity frames, braced frames, and moment-resisting frames and the design approaches to be adopted for sizing tall building frames. The potential use of steel-concrete composite material for high-rise construction is then presented. Finally, the design issues related to braced and unbraced composite frames are discussed.

22.4.2 Frame and Member Stability

There are many parameters and behavioral effects that influence the stability of steel-framed structures. The extent to which these factors are modeled in analysis will affect the criteria that one applies in design of the frame, its members, and connections. Three basic aspects of behavior, geometric nonlinearities, imperfection effects, and member limit states, will ultimately govern frame deformations under applied loads and the resulting internal load effects.

22.4.2.1 Geometric Nonlinearities and Imperfection Effects

Modern stability design provisions are based on the premise that the member forces are calculated by second-order elastic analyses, where equilibrium is satisfied on the deformed structure. When stability effects are significant, consideration must be given to initial geometric imperfections. Many code provisions for calibrating the stability requirements are based on initial geometric imperfections conservatively assumed as equal to the maximum fabrication and erection tolerances permitted by the Code. For columns and frames, this would normally imply a member out-of-straightness

equal to $0.001L$, where L is the member length between brace or framing points, and a frame out-of-plumb equal to $0.002H$, where H is the story height.

Many of the code's specified analysis/design approaches are calibrated against inelastic distributed-plasticity analyses that account for yielding through the member cross-section and along the member length. Thermal residual stresses in I- or H- (wide flange) shape members are assumed to have maximum values of $0.3F_y$, which are linearly varying across the flanges and uniform tension in the web.

22.4.2.2 Member Limit States

Member strength may be controlled by any one of the following limit states: cross-section yielding, local buckling, flexural buckling, and torsional–flexural buckling. Most of the structural analyses envisioned for routine design use do not model limit states associated with local buckling of cross-section or torsional–flexural buckling of member. Therefore, these limits must be considered in separate member design checks. For inelastic analyses, the effect of cross-section yielding is incorporated directly in the analysis; for elastic analyses, the cross-section strength can be checked by an interaction equation that approximates the P – M yield surface. Whether or not the analysis captures in-plane flexural buckling depends on the extent to which the maximum moments are affected by distributed plasticity and member imperfections. Concerns as to whether the analysis captures these effects suggest the need to apply a member check for in-plane flexural buckling, even when an accurate second-order analysis is used. A major consideration for the in-plane flexural buckling check relates to the assumed buckling length used in calculating the design compression strength.

22.4.2.3 Second-Order Analysis

In practice, there are alternative approaches one can employ for conducting second-order analyses, some of which are more rigorous than others. The difference between simplified and rigorous analyses depends on the extent to which P – δ effects due to curvature of the member relative to its chord are modeled and whether the problem is “linearized” to expedite the solution. Rigorous second-order analyses are those that accurately model all significant second-order effects such as to include solution of the governing differential equation, either through stability functions or computer frame analysis programs that model these effects.

Not all modern commercial computer programs are capable of rigorous analyses. Methods that modify first-order analysis results through second-order amplifiers are in some cases accurate enough to constitute a rigorous analysis, but this depends on the magnitude of second-order effects and other characteristics of the problem. A common type of approximate analyses are those that only capture P – Δ due to member end translations (e.g., interstory drift) but fail to capture P – δ effects. Where P – δ effects are significant, errors arise in approximate methods that do not accurately account for the effect of P – δ moments on amplification of both local member moments and the calculated global displacements.

22.4.2.4 Direct Analysis Approach

The direct analysis approach is developed with the goal to accurately model frame stability effects and thereby eliminate the need for calculating effective buckling lengths for column designs. The new provisions in the 2005 AISC Standard involve reducing the nominal elastic stiffness and applying a notional load to the frame. The notional load approach can be found in steel standards such as Eurocode, but many aspects of the proposed provisions given in the new 2005 AISC Standard address known shortcomings of conventional notional load approaches in other standards.

In the reduced stiffness approach, the reduction on the flexural stiffness EI can be applied by modifying E in the analysis. For computer programs that perform semiautomated design checks, one should be sure that the elastic modulus should not be reduced in design equations, which involve E to evaluate the design strength. The reduced stiffness and notional load requirements only pertain to analysis of the strength limit state and they do not apply to analysis of other serviceability conditions.

Notional load is applied to represent the destabilizing effect of geometric imperfections and other effects such as yielding, nonidealized boundary, and loading conditions. Notional loads are applied as

lateral loads at each floor level and specified in terms of the gravity loads applied at that floor level. The notional load magnitude of 0.002 corresponds to a frame out-of-plumb equal to $0.002H$ (where H is the story height). Notional loads shall be applied in the direction that adds to the destabilizing effects under the specified strength load combination.

22.4.3 Gravity Frames

Gravity frames refer to structures that are designed to resist only gravity loads. The bases for designing gravity frames are as follows:

1. The beam and girder connections transfer only vertical shear reactions without developing bending moment that will adversely affect the members and the structure as a whole.
2. The beams may be designed as a simply supported member.
3. Columns must be fully continuous. The columns are designed to carry axial loads only. Some codes of practice (e.g., BS5950 1990) require the column to carry nominal moments due to the reaction force at the beam end, applied at an appropriate eccentricity.
4. Lateral forces are resisted entirely by bracing frames or by shear walls, lift, or staircase closures through floor diaphragm action.

22.4.3.1 General Guides

The following points should be observed in the design of gravity frames:

1. Provide lateral stability to gravity framing by arranging suitable braced bays or core walls deployed symmetrically in orthogonal directions, or wherever possible, to resist lateral forces.
2. Adopt a simple arrangement of slabs, beams, and columns so that loads can be transmitted to the foundations by the shortest and most direct load paths.
3. Tie all the columns effectively in orthogonal directions at every story. This may be achieved by the provision of beams or ties that are placed as close as practicable to the columns.
4. Select a flooring scheme that provides adequate lateral restraint to the beams and adequate diaphragm action to transfer the lateral load to the bracing system.
5. For tall building construction, choose a profiled-steel-decking composite floor construction if uninterrupted floor space is required and/or height is at a premium. As a guide, limit the span of the floor slab to 2.5 to 3.6 m, the span of the secondary beams to 6 to 12 m, and the span of the primary beams to 5 to 7 m. Otherwise, choose a precast or an *in situ* reinforced concrete floor, limiting their span to 5 to 6 m and the span of the beams to 6 to 8 m approximately.

22.4.3.2 Structural Layout

In building construction, greater economy can be achieved through a repetition of similarly fabricated components. A regular column grid is less expensive than a nonregular grid for a given floor area. In addition, greater economies can be achieved when the column grids in plan are rectangular in which the secondary beams should span in the longer direction and the primary beams in the shorter direction as shown in Figure 22.22a and b. This arrangement reduces the number of beam-to-beam connections and the number of individual members per unit area of supported floor (Owens and Knowles 1992).

In gravity frames, the beams are assumed to be simply supported between columns. The effective beam span to depth ratio (L/D) is about 12 to 15 for steel beams and 18 to 22 for simply supported composite beams. The design of the beam is often dependent on the applied load, the type of beam system employed, and the restrictions on structural floor depth. The floor-to-floor height in a multistory building is influenced by the restrictions on overall building height and the requirements for services above and below the floor slab. Naturally, flooring systems involving the use of structural steel members that act compositely with the concrete slab achieve the longest spans.

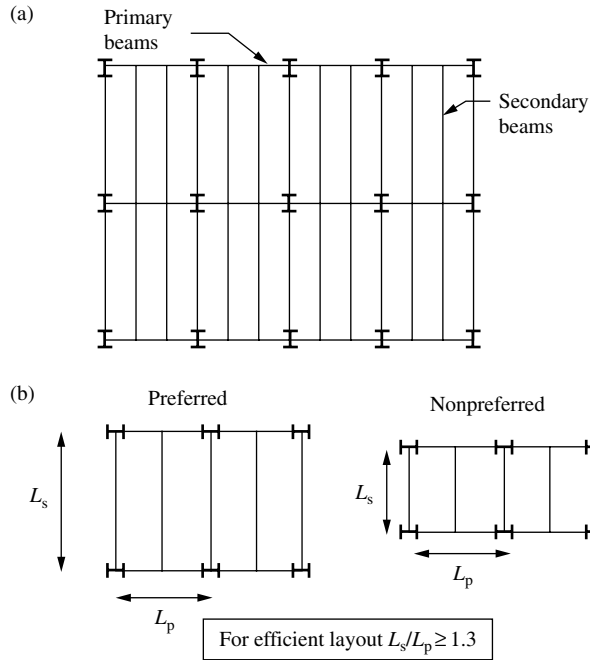

FIGURE 22.22 (a) Rectangular grid layout. (b) Preferred and nonpreferred grid layouts.

22.4.3.3 Analysis and Design

The analysis and design of a simple braced frame must recognize the following points:

1. The members intersecting at a joint are pin connected.
2. The columns are not subjected to any direct moment transferred through the connection, but nominal moments due to eccentricity of the beam reaction forces should be considered. The design axial force in the column is predominately governed by floor loading and the tributary areas.
3. The structure is statically determinate. The internal forces and moments are therefore determined from a consideration of statistics.
4. Gravity frames must be attached to a bracing system so as to provide lateral stability to the part of the structure resisting gravity load. The frame can be designed as a nonsway frame and the second-order moments associated with frame drift can be ignored.
5. The leaning column effects due to column sidesway must be considered in the design of the frames that participate in sidesway resistance.

Since the beams are designed as simply supported beams between their supports, the bending moments and shear forces are independent of beam size. Therefore, initial sizing of beams is a straightforward task. Beam or girder members supporting more than 40 m² of floor at one story should be designed for a reduced live load in accordance with ASCE (1990).

Most conventional types of floor slab construction will provide adequate lateral restraint to the compression flange of the beam. Consequently, the beams may be designed as laterally restrained beams without the moment resistance being reduced by lateral-torsional buckling.

Under service loading, the total central deflection of the beam or the deflection of the beam due to unfactored live load (with proper precambering for dead load) should satisfy the deflection limits as given in Table 22.2.

TABLE 22.2 Recommended Deflection Limits for Steel Building Frames

<i>Beam deflections from unfactored imposed loads</i>	
Beams carrying plaster or brittle finish	Span/360 (with maximum of $\frac{1}{4}$ to 1 in.)
Other beams	Span/240
Edge beams supporting cladding	Span/500
<i>Beam deflection due to unfactored dead and imposed loads</i>	
Internal beams with ceilings	Span/200
Edge beams supporting cladding	Span/350
<i>Column deflections from unfactored imposed and wind loads</i>	
Column in single-story frames	Height/300
Column in multistory frames	Height of story/300
Column supporting cladding that is sensitive to large movement	Height of story/500
<i>Frame drift under 50 years wind load</i>	
Frame drift	Frame height/450 to frame height/600

In some occasions, it may be necessary to check the dynamic sensitivity of the beams. When assessing the deflection and dynamic sensitivity of secondary beams, the deflection of the supporting beams must also be included. Whether it is the strength, deflection, or dynamic sensitivity that controls the design will depend on the span-to-depth ratio of the beam. Figure 22.18 gives typical span ranges for beams in office buildings for which the design would be optimized for strength and serviceability. For beams with their span lengths exceeding those shown in Figure 22.18, serviceability limits due to deflection and vibration will most likely be the governing criteria for design.

The required axial forces in the columns can be derived from the cumulative reaction forces from those beams that frame into the columns. Live load reduction should be considered in the design of columns in a multistory frame (ASCE 1990). If the frame is braced against sidesway, the column node points are prevented from lateral translation. A conservative estimate of column effective length, KL , for buckling considerations is $1.0L$, where L is the story height. However, in cases where the columns above and below the story under consideration are underutilized in terms of load resistance, the restraining effects offered by these members may result in an effective length of less than $1.0L$ for the column under consideration. Such a situation arises where the column is continuous through the restraint points and the columns above and below the restraint points are of different length.

An example of such cases is the continuous column shown in Figure 22.23 in which Column AB is longer than Column BC and hence Column AB is restrained by Column BC at the restraint point B. A buckling analysis shows that the critical buckling load for the continuous column is $P_{cr} = 5.89EI/L^2$, which gives rise to an effective length factor of $K = 0.862$ for Column AB and $K = 1.294$ for Column BC. Column BC has a larger effective length factor because it provides restraint to Column AB, whereas Column AB has a smaller effective length factor because it is restrained by column BC during buckling. Figure 22.24 summarizes the reductions in effective length that may be considered for columns in a frame with different story heights having various values of a/L ratios (Owens and Knowles 1992).

22.4.3.4 Simple Connections

Simple connections should be designed and detailed to allow free rotation and to prevent excessive transfer of moment between the beams and columns. Such connections should comply with the classification requirement for a “nominally pinned connection” in terms of both strength and stiffness. Computer program for connection classification has been made available in a book by Chen et al. (1996); their design implications for semirigid frames are discussed in Liew et al. (1993a).

FIGURE 22.23 Buckling of a continuous column with intermediate restraint.

Column	Frame	0.2	0.4	a/L 0.6	0.8	1.0
EI		0.76	0.82	0.88	0.94	1.0
EI		0.57	0.65	0.75	0.87	1.0
EI		0.74	0.79	0.84	0.91	1.0

FIGURE 22.24 Effective length factors of continuous braced columns.

Simple connections are designed to resist vertical shear at the beam end. Depending on the connection details adopted, it may also be necessary to consider an additional bending moment resulting from the eccentricity of the bolt line from the supporting face. Often the fabricator is told to design connections based on the beam end reaction for one-half uniform distributed load (UDL). Unless the concentrated

FIGURE 22.25 Simple beam-to-column connections.

load is located very near to the beam end, UDL reactions are generally conservative. Because of the large reaction, the connection becomes very strong and may require a large number of bolts. Thus, it would be a good practice to design the connections for the actual forces used in the design of the beam. The engineer should give the design shear force for every beam to the steel fabricator so that a more realistic connection can be designed, instead of requiring all connections to develop the shear capacity of the beam. Figure 22.25 shows the typical connections that can be designed as simple connections. When the beam reaction is known, capacity tables developed for simple standard connections can be used for detailing such connections (AISC 1990).

22.4.4 Bracing Systems

Bracing frames provide the lateral stability to the entire structure. It has to design to resist all possible kinds of lateral loading due to external forces, for example, wind forces, earthquake forces, and “leaning forces” from the gravity frames. The wind or the equivalent earthquake forces on the structure, whichever are greater, should be assessed and divided into a number of bracing bays resisting the lateral forces in each direction.

22.4.4.1 Structural Forms

Steel braced systems are often in a form of vertical truss that behaves like cantilever elements under lateral loads developing tension and compression in the column chords. Shear forces are resisted by the bracing members. The truss diagonalization may take various forms, as shown in Figure 22.26. The design of such structures must take into account the manner in which the frames are erected, the distribution of lateral forces, and their side sway resistance.

FIGURE 22.26 (a) Diagonal bracing, (b) cross-bracing, (c) K-bracing, (d) eccentric bracing, (e) braces connected to beam, (f) bracing connection to either beam or column, and (g) X-bracing connections.

In the single braced forms, where a single diagonal brace is used (Figure 22.26a), it must be capable of resisting both tensile and compressive axial forces caused by the alternate wind load. Hollow sections may be used for the diagonal braces as they are stronger in compression. In the design of diagonal braces, gravity forces may tend to dominate the axial forces in the members and due consideration must be given in the design of such members. It is recommended that the slenderness ratio of the bracing member (L/r) must not be greater than 200 to prevent the self-weight deflection of the brace limiting its compressive resistance.

In a cross-braced system (Figure 22.26b), the brace members are usually designed to resist tension only. Consequently, light sections such as structural angles and channels or tie rods can be used to provide a very stiff bracing. The advantage of the cross-braced system is that the beams are not

subjected to significant axial force, as the lateral forces are mostly taken up by the bracing members.

For K-trusses, the diagonals do not participate extensively in carrying column load and can thus be designed for wind axial forces without gravity axial force being considered as a major contribution. A K-braced frame is more efficient in preventing sidesway than a cross-braced frame for equal steel areas of braced members used. This type of system is preferred for longer bay width because of the shorter length of the braces. A K-braced frame is found to be more efficient if the apexes of all the braces are pointing in the upward direction (Figure 22.26c).

For an eccentrically braced frame, the center line of the brace is positioned eccentrically to the beam–column joint, as shown in Figure 22.26d. The system relies, in part, on flexure of the short segment of the beam between the brace–beam joint and the beam–column joint. The forces in the braces are transmitted to the column through shear and bending of the short beam segment. This particular arrangement provides a more flexible overall response. Nevertheless, it is more effective against seismic loading because it allows for energy dissipation due to flexural and shear yielding of the short beam segment.

22.4.4.2 Drift Assessment

The story drift Δ of a single story diagonally braced frame, as shown in Figure 22.27, can be approximated by the following equation:

$$\begin{aligned} \Delta &= \Delta_s + \Delta_f \\ &= \frac{HL_d^3}{A_dEL^2} + \frac{Hh^3}{A_cEL^2} \end{aligned} \tag{22.3}$$

where Δ is the interstory drift, Δ_s is the story drift due to the shear component, Δ_f is the story drift due to the flexural component, A_c is the area of the chord, A_d is the area of the diagonal brace, E is the modulus of elasticity, H is the horizontal force in the story, h is the story height, L is the length of the braced bay, and L_d is the length of the diagonal brace.

The shear component Δ_s in Equation 22.3 is caused mainly by the axial deformation of the diagonal brace. The deformation associated with girder compression has been neglected in the calculation of Δ_s because the axial stiffness of the girder is very much larger than the stiffness of the brace. The elongation of the diagonal braces gives rise to shear deformation of the frame, which is a function of the brace length, L_d , and the angle of the brace (L_d/L). A shorter brace length with a smaller brace angle will produce a lower story drift.

The flexural component of the frame drift is due to tension and compression of the windward and leeward columns. The extension of the windward column and shortening of the leeward column cause

FIGURE 22.27 Lateral displacement of a diagonally braced frame.

flexural deformation of the frame, which is a function of the area of the column and the ratio of the height to bay length (h/L). For a slender bracing frame with large h/L ratio, the flexural component can contribute significantly to the overall story drift.

Low-rise braced frame deflects predominately in shear mode while high-rise braced frames tend to deflect more in flexural mode.

22.4.4.3 Design Considerations

Frames with braces connecting columns may obstruct locations of access openings such as windows and doors, and so they should be placed where such access is not required, for example, around elevators, service, and stair wells. The location of the bracing systems within the structure will influence the efficiency with which the lateral forces can be resisted. The most appropriate position for the bracing systems is at the periphery of the building (Figure 22.28a) since this arrangement provides greater

FIGURE 22.28 Location of bracing systems: (a) exterior braced frames, (b) internal braced core, and (c) bracing arrangements to be avoided.

torsional resistance. Bracing frames should be situated where the center of lateral resistance is approximately equal to the center of shear resultant on plan. Where this is not possible, torsional forces will be induced and they must be considered when calculating the load carried by each braced system.

When core braced systems are used, they are normally located in the center of the building (Figure 22.28b). The torsional stability is then provided by the torsional rigidity of the core brace. For tall building frames, a minimum of three braced bents are required to provide transitional and torsional stability. These bents should be carefully arranged so that their planes of action do not meet at one point so as to form a center of rotation. The bracing arrangement shown in Figure 22.28c should be avoided.

The flexibility of different bracing systems must be taken into account in the analysis, since the stiffer braces will attract a larger share of the applied lateral load. For tall and slender frames, the bracing system itself can be a sway frame and a second-order analysis is required to evaluate the required forces for ultimate strength and serviceability checks.

Lateral loads produce transverse shears, over turning moments and sidesway. The stiffness and strength demands on the lateral system increase dramatically with height. The shear increases linearly, the overturning moment as a second power and sway as a fourth power of the height of the building. Therefore, apart from providing the strength to resist lateral shear and overturning moments, the dominant design consideration (especially for tall buildings) is to develop adequate lateral stiffness to control sway.

For serviceability verification, it requires that both the interstory drifts and the lateral deflections of the structure as a whole must be limited. The limits depend on the sensitivity of the structural elements to shear deformations. Recommended limits for typical multistory frames are given in Table 22.2. When considering the ultimate limit state, the bracing system must be capable of transmitting the factored lateral loads safely down to the foundations. Braced bays should be effective throughout the full height of the building. If it is essential for bracing to be discontinuous at one level, provision must be made to transfer the forces to other braced bays. Where this is not possible, torsional forces may be induced and they should be allowed for in design (see Section 22.3.6).

Figure 22.29 shows an example of a building that illustrates the locations of vertical braced trusses provided at the four corners to achieve lateral stability. Diaphragm action is provided by a lightweight aggregate concrete slab that acts compositely with metal decking and floor beams. The floor beam-to-column connections are designed to resist shear force only as shown in the figure.

FIGURE 22.29 Simple building frame with vertical braced trusses located at the corners.

22.4.5 Moment-Resisting Frames

In cases where bracing systems would disturb the functioning of the building, rigidly jointed moment-resisting frames can be used to provide lateral stability to the building, as illustrated in Figure 22.30a. The efficiency of development of lateral stiffness depends on bay span, number of bays in the frame, number of frames, and the available depth in the floors for the frame girders. For buildings with heights not more than three times the plan dimension, the moment frame system is an efficient form. Bay dimensions in the range of 6 to 9 m and structural height up to 20 to 30 stories are commonly used. However, as the building height increases, deeper girders are required to control drift, thus the design becomes uneconomical.

When a rigid unbraced frame is subjected to lateral load, the horizontal shear in a story is resisted predominantly by the bending of columns and beams. These deformations cause the frame to deform in a shear mode. The design of these frames is controlled therefore by the bending stiffness of individual members. The deeper the member, the more efficiently the bending stiffness can be developed. A small part of the frame sidesway is caused by the overturning of the entire frame resulting in shortening and elongation of the columns at opposite sides of the frame. For unbraced rigid frames up to 20 to 30 stories, the overturning moment contributes for about 10 to 20% of the total sway, whereas shear racking accounts for the remaining 80 to 90% (Figure 22.30b). However, the story drift due to overall bending tends to increase with height, while that due to shear racking tends to decrease.

22.4.5.1 Drift Assessment

Since shear racking accounts for most of the lateral sway, the design of such frames should be directed toward minimizing the sidesway due to shear. The shear displacement Δ in a typical story in a multistory frame, as shown in Figure 22.31, can be approximated by the equation

$$\Delta_i = \frac{V_i h_i^2}{12E} \left(\frac{1}{\sum(I_{ci}/h_i)} + \frac{1}{\sum(I_{gi}/L_i)} \right) \tag{22.4}$$

where Δ_i is the shear deflection of the i th story, E is the modulus of elasticity, I_c , I_g are second moments of area for columns and girders, respectively, h_i is the height of the i th story, L_i is the length of girder in the i th story, V_i is the total horizontal shear force in the i th story, $\sum(I_{ci}/h_i)$ is the sum of the column stiffness in the i th story, and $\sum(I_{gi}/L_i)$ is the sum of the girder stiffness in the i th story.

Examination of Equation 22.4 shows that sidesway deflection caused by story shear is influenced by the sum of column and beam stiffnesses in a story. Since for multistory construction span lengths are generally larger than the story height, the moment of inertia of the girders needs to be larger to match the

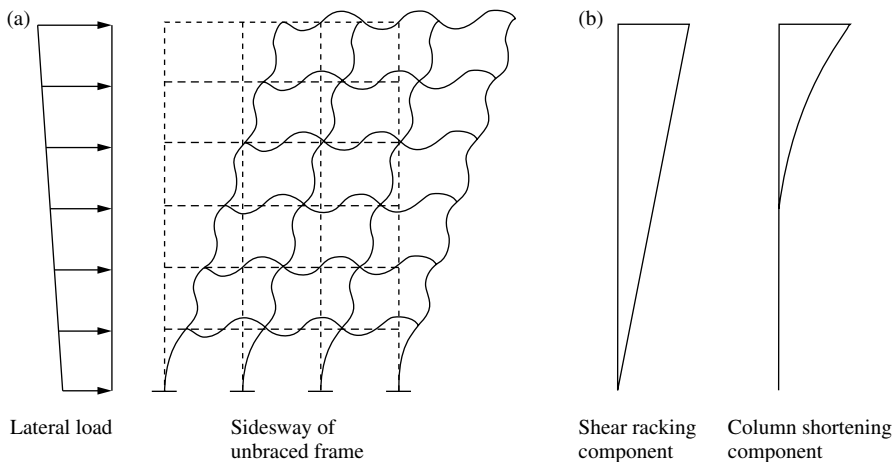

FIGURE 22.30 Sidesway resistance of a rigid unbraced frame.

FIGURE 22.31 Story drift due to (a) bending of columns and (b) bending of girders.

column stiffness, as both of these members contribute equally to the story drift. As the beam span increases, considerably deeper beam sections will be required to control frame drift.

Since the gravity forces in columns are cumulative, larger column sizes are needed in lower stories as the frame height increases. Similarly, story shear forces are cumulative and, therefore, larger beam properties in lower stories are required to control lateral drift. Because of limitations in available depth, heavier beam members will need to be provided at lower floors. This is the major shortcoming of unbraced frames because considerable premium for steel weight is required to control lateral drift as building height increases.

Apart from the beam span, height-to-width ratios of the building play an important role in the design of such structures. Wider building frames allow a larger number of bays (i.e., larger values for story summation terms $\sum(I_{ci}/h_i)$ and $\sum(I_{gi}/L_i)$ in Equation 22.4 with consequent reduction in frame drift. Moment frames with closed spaced columns that are connected by deep beams are very effective in resisting sidesway. This kind of framing system is suitable for use in the exterior planes of the building.

22.4.5.2 Moment Connections

Fully welded moment joints are expensive to fabricate. To minimize labor cost and to speed up site erection, field bolting instead of field welding should be used. Figure 22.32 shows several types of bolted or welded moment connections that are used in practice. Beam-to-column flange connections can be shop-fabricated by welding of a beam stub to an end plate or directly to a column. The beam can then be erected by field bolting the end plate to the column flanges or splicing beams (Figure 22.32c and d).

An additional parameter to be considered in the design of columns of an unbraced frame is the “panel zone” between the column and the transverse framing beams. When an unbraced frame is subjected to lateral load, additional shear forces are induced in the column web panel as shown in Figure 22.33. The shear force is induced by the unbalanced moments from the adjoining beams causing the joint panel to deform in shear. The deformation is attributed to the large flexibility of the unstiffened column web. To prevent shear deformation so as to maintain the moment joint assumption as assumed in the global analysis, it may be necessary to stiffen the panel zone using either a doubler plate or a diagonal stiffener

FIGURE 22.32 Rigid connections: (a) bolted and welded connection with doubler plate; (b) bolted and welded connection with diagonal stiffener; (c) bolted end-plate connection; and (d) beam-stub welded to column.

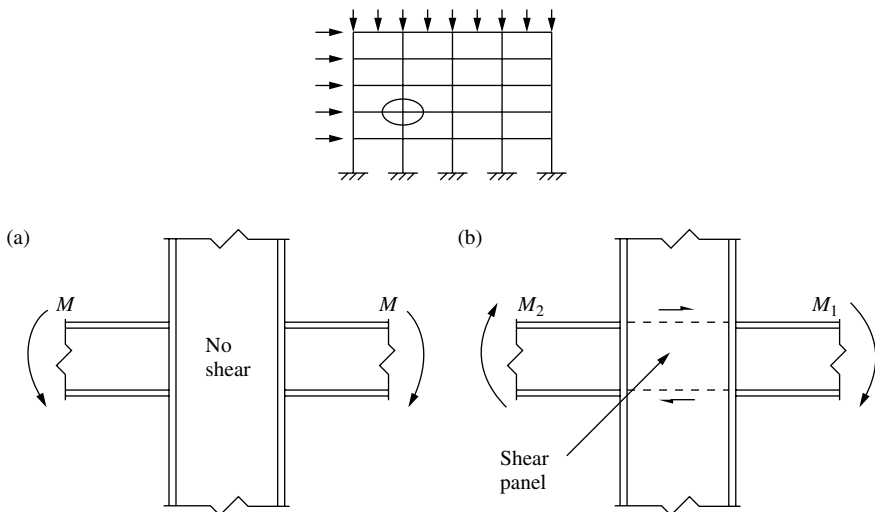

FIGURE 22.33 Force acting on a panel joint: (a) balanced moment due to gravity load and (b) unbalanced moment due to lateral load.

as shown in the joint details in [Figure 22.32a](#) and b. Otherwise, a heavier column with larger web area is required to prevent excessive shear deformation and this is often the preferred method as stiffeners and doublers can add significant costs to fabrication.

The engineer should not specify full-strength moment connections unless they are required for ductile frame design for high seismic loads. For wind loads and for conventional moment frames where beams and columns are sized for stiffness (drift control) instead of strength, full-strength moment connections are not required. Even so, many designers will specify full-strength moment connections, adding to the cost of fabrication. Designing for actual loads has the potential to reduce column weight or reduce the stiffener and doubler plate requirements.

If the panel zone is stiffened to prevent inelastic shear deformation, the conventional structural analysis based on the member center-line dimension will generally overestimate the frame displacement. If the beam–column joint sizes are relatively small compared to the member spans, the increase in frame stiffness using member center-line dimension will be offset by the increase in frame deflection due to panel–joint shear deformation. If the joint sizes are large, a more rigorous second-order analysis, which considers panel zone deformations, may be required for an accurate assessment of the frame response (Liew and Chen 1995).

22.4.5.3 Analysis and Design of Unbraced Frames

Multistory moment frames are statically indeterminate, the required design forces can be determined using either (1) elastic analysis or (2) plastic analysis. Whilst elastic methods of analysis can be used for all kind of steel sections, plastic analysis is only applicable for frames whose members are of plastic sections so as to enable the development of plastic hinges and to allow for inelastic redistribution of forces.

First-order elastic analysis can be used only in the following cases:

1. Where the frame is braced and not subjected to sidesway.
2. Where an indirect allowance for second-order effects is made through the use of moment amplification factors and the column effective length. EC3 requires only second-order moment or effective length factor to be used in the beam–column capacity checks. However, column and frame imperfections need to be modeled explicitly in the analysis. In AISC LRFD (1993), both factors need to be computed for checking the member strength and stability and the analysis is based on structures without initial imperfections.

The first-order elastic analysis is a convenient approach. Most design offices possess computer software capable of performing this method of analysis on large and highly indeterminate structures. As an alternative, hand calculations can be performed on appropriate subframes within the structure (see [Figure 22.34](#)) comprising a significantly reduced number of members. However, when conducting the analysis of an isolated subframe it is important that

1. The subframe is indeed representative of the structure as a whole.
2. The selected boundary conditions are appropriate.
3. Account is taken of the possible interaction effects between adjacent subframes.
4. Allow for second-order effects through the use of column effective length or moment amplification factors.

Plastic analysis generally requires more sophisticated computer programs, which enable second-order effects to be taken into account. Computer software is now available through recent publications made available by Chen and Toma (1994) and Chen et al. (1996). For building structures in which the required rotations are not calculated, all members containing plastic hinges must have plastic cross-sections.

A basic procedure for the design of an unbraced frame is as follows:

1. Obtain approximate member size based on gravity load analysis of subframes shown in [Figure 22.34](#). If sidesway deflection is likely to control (e.g., slender frames) use Equation 22.4 to estimate the member sizes.

FIGURE 22.34 Subframe analysis for gravity loads: (a) subframe for beam and (b) subframe for column design.

2. Determine wind moments from the analysis of the entire frame subjected to lateral load. A simple portal wind analysis may be used in lieu of the computer analysis.
3. Check member capacity for the combined effects of factored lateral load plus gravity loads.
4. Check beam deflection and frame drift.
5. Redesign the members and perform final analysis/design check (a second-order elastic analysis is preferable at the final stage).

The need to repeat the analysis to correspond to changed section sizes is unavoidable for highly redundant frames. Iteration of Steps 1 to 5 gives results that will converge to an economical design satisfying the various design constraints imposed on the analysis.

22.4.6 Multistory Building Framing Systems

The following subsections discuss four classical systems that have been adopted for tall building constructions, namely (1) core braced system, (2) moment-truss system, (3) outrigger and belt system, and (4) tube system. Tall frames that utilize cantilever action will have higher efficiencies, but the overall structural efficiency depends on the height-to-width ratio. Interactive systems involving moment frame and vertical truss or core are effective up to 40 stories and represent most building forms for tall structures. Outrigger truss and belt truss help to further enhance the lateral stiffness by engaging the exterior frames with the core braces to develop cantilever actions. Exterior framed tube systems with closely spaced exterior columns connected by deep girders mobilize the three-dimensional action to resist lateral and torsional forces. Bundled tubes improve the efficiency of exterior frame tubes by providing internal stiffening to the exterior tube concept. Finally, by providing diagonal braces to the exterior framework, a superframe is formed and can be used for ultratall megastructures.

22.4.6.1 Core Braced Systems

This type of structural system relies entirely on the internal core for lateral load resistance. The basic concept is to provide an internal shear wall core to resist the lateral forces (Figure 22.35). The surround

FIGURE 22.35 Core braced frame: (a) internal core walls with simple exterior framing and (b) beam-to-wall and beam-to-external column connections.

steel framing is designed to carry gravity load only if simple framing is adopted. Otherwise, a rigid framing surrounding the core will enhance the overall lateral-force resistance of the structure. The steel beams can be simply connected to the core walls using a typical corbel detail, by bearing in a wall pocket, or by a shear plate embedded in the core wall through studs. If a rigid connection is required, the steel beams should be rigidly connected to steel columns embedded in the core wall. Rigid framing surrounding the cores are particularly useful in high seismic areas and for very tall buildings that tend to attract stronger wind loads. They act as moment frames and provide resistance to some part of the lateral loads by engaging the core walls in the building.

The core generally provides all torsional and flexural rigidity and strength with no participation from the steel system. Conceptually, the core system should be treated as a cantilever wall system with punched openings for access. The floor framing should be arranged in such a way that it distributes enough gravity loads to the core walls so that their design is controlled by compressive stresses even under wind loads. The geometric location of the core should be selected so as to minimize eccentricities for lateral load. The core walls need to have adequate torsional resistance for possible asymmetry of the core system where the center of the resultant shear load is acting at an eccentricity from the center of the lateral-force resistance.

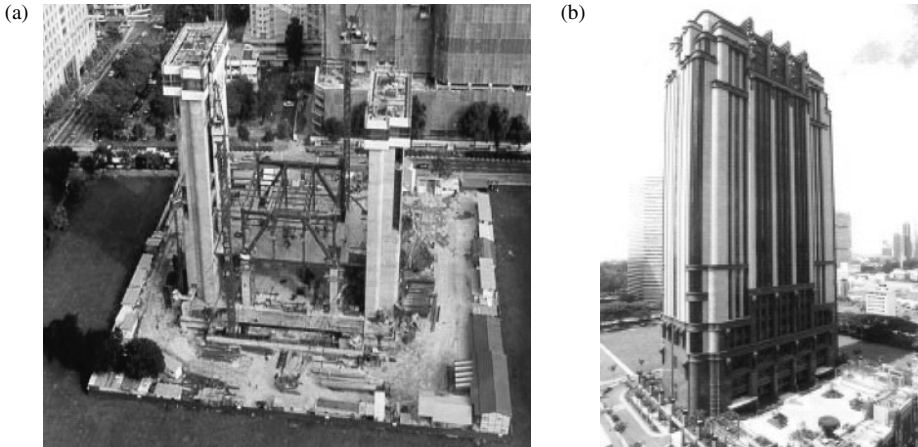

FIGURE 22.36 A steel building braced by two external core walls with large open lobby at the bottom: (a) during construction and (b) after construction.

A simple cantilever model should be adequate to analyze a core-wall structure. However, if the structural form is a tube with openings for access, it may be necessary to perform a more accurate analysis to include the effect of openings. The walls can be analyzed by a finite element analysis using thin-walled plate elements. An analysis of this type may also be required to evaluate torsional stresses when the vertical profile of the core-wall assembly is asymmetrical.

The concrete core walls can be constructed using slip-form techniques, where the core walls could be advanced several floors (typically four to six stories) ahead of the steel framing (see Figure 22.36a). A core-wall system represents an efficient type of structural system up to certain height premium because of its cantilever action. However, when it is used alone, the massiveness of the wall structure increases with height, thereby inhabiting the free planning of interior spaces, especially in the core. The space occupied by the shear walls leads to loss of overall floor area efficiency, as compared to the tube system which could otherwise be used.

In commercial buildings where floor space is valuable, the large area taken up by a concrete column can be reduced by the use of an embedded steel column to resist the extreme loads encountered in tall building. Sometimes, particularly at the bottom open floors of a high-rise structure where large open lobbies or atriums are utilized as part of the architectural design (see Figure 22.36a and b), a heavy embedded steel section as part of a composite column is necessary to resist high load and due to the long unbraced length. A heavy steel section in a composite column is often utilized where the column size is restricted architecturally and where reinforcing steel percentages would otherwise exceed the maximum code allowed values for the design of reinforced concrete columns.

22.4.6.2 Frame–Truss Systems

Vertical shear trusses located around the inner core in one or both directions can be combined with perimeter moment-resisting frames in the facade of a building to form an efficient structure for lateral load resistance. An example of a building consisting of moment frames with shear trusses located at the center of the building is shown in Figure 22.37a. For the vertical trusses arranged in the north–south direction, either the K- or X-form of bracing is acceptable since access to lift shafts is not required. However, K-trusses are often preferred because in the case of X or single brace form bracings the influence of gravity loads is rather significant. In the east–west direction, only the knee bracing is effective in resisting lateral load.

In some cases internal bracing can be provided using concrete shear walls as shown in Figure 22.37b. The internal core walls substitute the steel trusses in K, X, or single brace form, which may interfere with openings that provide access to, for example, elevators.

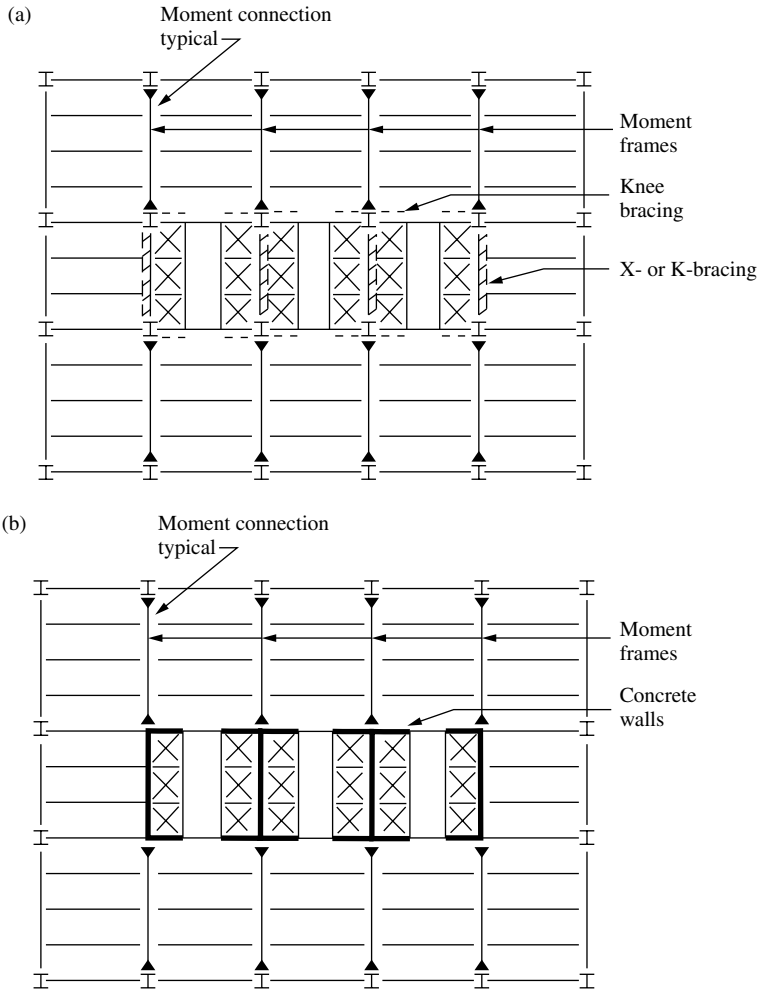

FIGURE 22.37 (a) Moment frames with internal braced trusses. (b) Moment frames with internal core walls.

The interaction of shear frames and vertical trusses produces a combination of two deflection curves with the effect of more efficient stiffness. These moment frame–truss interacting systems are considered to be the most economical steel systems for buildings up to 40 stories. Figure 22.38 compares the sway characteristic of a 20-story steel frame subjected to same lateral forces, but with different structural schemes namely (1) unbraced moment frame, (2) simple-truss frame, and (3) moment–truss frame. The simple-truss frame helps to control lateral drift at the lower stories, but the overall frame drift increases toward the top of the frame. The moment frame, on the other hand, shows an opposite characteristic for sidesway in comparison with the simple braced frame. The combination of moment frame and truss frame provides overall improvement in reducing frame drift; the benefit becomes more pronounced toward the top of the frame. The braced truss is restrained by the moment frame at the upper part of the building, while at the lower part the moment frame is restrained by the truss frame. This is because the slope of frame sway displacement is relatively smaller than that of the truss at the top while the proportion is reversed at the bottom. The interacting forces between the truss frame and moment frame, as shown in Figure 22.39, enhance the combined moment–truss frame stiffness to a level larger than the summation of individual moment frame and truss stiffnesses.

FIGURE 22.38 Sway characteristics of rigid braced frame, simple braced frame, and rigid unbraced frame.

FIGURE 22.39 Behavior of frames subjected to lateral load: (a) independent behavior and (b) interactive behavior.

22.4.6.3 Outrigger and Belt Truss Systems

Another significant improvement of lateral stiffness can be obtained if the vertical truss and the perimeter shear frame are connected on one or more levels by a system of outrigger and belt trusses. Figure 22.40 shows a typical example of such a system. The outrigger truss leads the wind forces of the core truss to the exterior columns providing cantilever behavior of the total frame system. The belt truss in the facade improves the cantilever participation of the exterior frame and creates a three-dimensional frame behavior.

Figure 22.41 shows a schematic diagram that demonstrates the sway characteristic of the overall building under lateral load. Deflection is significantly reduced by the introduction of the outrigger–belt trusses. Two kinds of stiffening effects can be observed: one is related to the participation of the external columns together with the internal core to act in a cantilever mode and the other is related to the stiffening of the external facade frame by the belt truss to act as a three-dimensional tube. The overall stiffness can be increased up to 25% as compared to the shear truss and frame system without such outrigger–belt trusses.

FIGURE 22.40 Outrigger-belt truss system.

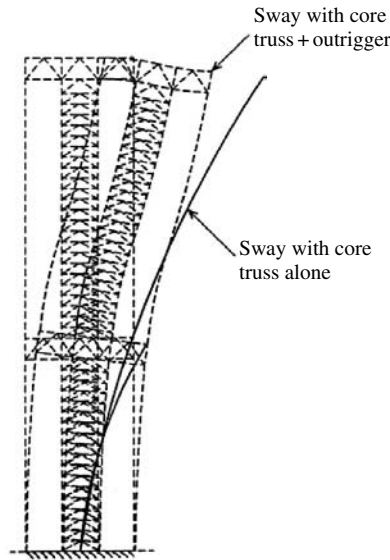

FIGURE 22.41 Improvement of lateral stiffness using outrigger-belt truss system.

The efficiency of this system is related to the number of trussed levels and the depth of the truss. In some cases the outrigger and belt trusses have a depth of two or more floors. They are located in services floors where there are no requirements for wide open spaces. These trusses are often pleasingly integrated into the architectural conception of the facade.

22.4.6.4 Frame Tube Systems

Figure 22.42 shows a typical frame tube system, which consists of a frame tube at the exterior of the building and gravity steel framing at the interior. The framed tube is constructed from wide columns placed at close centers connected by deep beams creating a punched wall appearance. The exterior frame tube structure resists all lateral loads of wind or earthquake whereas the gravity steel framing in the interior resists only its share of gravity loads. The behavior of the exterior frame tube is similar to a

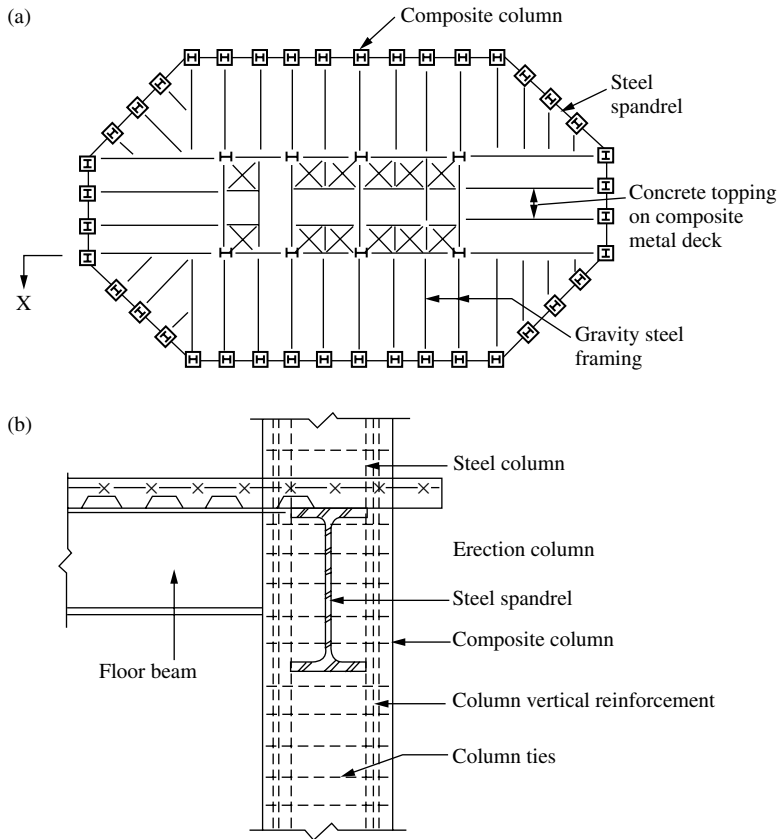

FIGURE 22.42 Composite tubular system: (a) plan view and (b) beam-to-column connection.

hollow perforated tube. The overturning moment under the action of lateral load is resisted by compression and tension of the leeward and windward columns, which are called the flange columns. The shear is resisted by bending of the columns and beams at the two sides of the building parallel to the direction of the lateral load, which are called the web frames.

Deepening on the shear rigidity of the frame tube, there may exist a shear lag across the windward and leeward sides of the tube. As a result of this, not all the flange columns resist the same amount of axial force. An approximate approach is to assume an equivalent column model as shown in Figure 22.43. In the calculation of the lateral deflection of the frame tube it is assumed that only the equivalent flange columns on the windward and leeward sides of the tube and the web frames would contribute to the moment of inertia of the tube.

The use of exterior framed tube has the following distinct advantages: (1) It develops high rigidity and strength for torsional and lateral-load resistance, since the structural components are effectively placed at the exterior of the building forming a three-dimensional closed section. (2) Massiveness of the frame tube system eliminates potential uplift difficulties and produces better dynamic behavior. (3) The use of gravity steel framing in the interior has the advantages of flexibility and enables rapid construction. If a composite floor with metal decking is used, electrical and mechanical services can be incorporated in the floor zone.

Composite columns are frequently used in the perimeter of the building where the closely spaced columns work in conjunction with the spandrel beam (either steel or concrete) to form a

FIGURE 22.43 Equivalent column model for frame tube.

FIGURE 22.44 (a) Encased composite section. (b) Concrete-filled steel column.

three-dimensional cantilever tube rather than an assembly of two-dimensional plane frames. The exterior frame tube significantly enhances the structural efficiency in resisting lateral loads and thus reduces the shear wall requirements. However, in cases where a higher magnitude of lateral stiffness is required (such as for vary tall buildings), internal wall cores and interior columns with floor framing can be added to transform the system into a tube-in-tube system. The concrete core may be strategically located to recapture elevator space and to provide transmission of mechanical ducts from shafts and mechanical rooms.

22.4.7 Steel–Concrete Composite Systems

Steel–concrete composite construction has gained wide acceptance as an alternative to pure steel and pure concrete construction. Composite building systems can be broadly categorized into two forms: one utilizes the core braced system by means of interior shear walls and the other utilizes exterior framing to form a tube for lateral load resistance. Combining these two structural forms will enable taller buildings to be constructed.

22.4.7.1 Composite Column

Composite columns have been used for many decades, with steel-encased sections similar that shown in Figure 22.44a being incorporated in multistory buildings in the United States during the late 19th century. The initial application of composite columns was for fire rating requirements of the steel

section. Later developments saw the composite action fully utilized for strength and stability. Composite action in columns utilizes the favorable tensile and compressive characteristics of the steel and concrete, respectively. These types of columns are still in use today where steel sections are used as erection columns, with reinforced concrete cast around them. One major benefit of this system has been the ability to achieve higher steel percentages than conventional reinforced concrete structures, and the steel erection column allows rapid construction of steel floor systems in steel-framed buildings.

Concrete-filled steel columns, as illustrated in Figure 22.44b, were developed much later during the last century but are still based on the fundamental principle that steel and concrete are most effective in tension and compression, respectively. The major benefits also include constructibility issues, whereby the steel section acts as a permanent and integral formwork for the concrete. These sections were essentially expensive, as the steel section was designed to be hollow, thus requiring large steel plate thickness. This lack of constructional economy has seen the use of concrete-filled steel columns limited in their application through the world. Furthermore, restrictive cross-section sizes have rendered them unsuitable for application in tall buildings where demand on axial strength is high.

22.4.7.2 Composite Connection

For composite frames resisting gravity load only, the beam-to-column connections behave as pinned before the placement of concrete. During construction, the beam is designed to resist concrete dead load and the construction load (to be treated as temporary live load). At the composite stage, the composite strength and stiffness of the beam should be utilized to resist the full design loads. For gravity frames consisting of bare steel columns and composite beams, there is now sufficient knowledge available for the designer to use composite action in the structural element as well as the semirigid composite joints to increase design choices, leading to more economical solutions (Leon and Ammerman 1990; Eurocode 4 1994; Leon 1994).

Figure 22.45a and b shows the typical beam-to-column connections, one using flushed end-plate bolted to the column flange and the other using bottom angle with double web cleats. Composite action in the joint is developed based on the tensile forces developed in the rebars acting with the balancing compression forces transmitted by the lower portion of the steel section that bear against the column flange to form a couple. Properly designed and detailed composite connections are capable of providing moment resistance up to the hogging resistance of the connecting members.

In designing the connections, slab reinforcements placed within a horizontal distance of six times the slab depth are assumed to be effective in resisting the hogging moment. Reinforcement steels that fall outside this width should not be considered in calculating the resisting moment of the connection (see Figure 22.46). The connections to edge columns should be carefully detailed to ensure adequate anchorage of rebars. Otherwise they shall be designed and detailed as simply supported. In a braced

FIGURE 22.45 Composite beam-to-column connections with: (a) flush end plate and (b) seat and double web angles.

FIGURE 22.46 Moment transfer through reinforcement at perimeter columns: (a) connection details and (b) reinforcement detail.

frame a moment connection to the exterior column will increase the moments in the column, resulting in an increase of column size. Although the moment connections restrain the column from buckling by reducing the effective length, this is generally not adequate to offset the strength required to resist this moment.

22.4.7.3 Unbraced Composite Frames

For unbraced frame subjected to gravity and lateral loads, the beam typically bends in double curvature with negative moment at one end of the beam and positive moment on the other end. The concrete is assumed to be ineffective in tension; therefore, only the steel beam stiffness on the negative moment region and the composite stiffness on the positive moment region can be utilized for frame action. The frame analysis can be performed with variable moment of inertia for the beams (see Figure 22.47). Further research is still needed in order to provide tangible guidance for design.

If semirigid composite joints are used in unbraced frames, the flexibility of the connections will contribute to additional drift over that of a fully rigid frame. In general, semirigid connections do not require the column size to be increased significantly over an equivalent rigid frame. This is because the design of frames with semirigid composite joints takes advantage of the additional stiffness in the beams provided by the composite action. The increase in beam stiffness would partially offset the additional flexibility introduced by the semirigid connections.

The moment of inertia of the composite beam I_{cp} may be estimated using a weighted average of moment of inertia in the positive moment region (I_p) and negative moment regions (I_n). For interior spans, approximately 60% of the span is experiencing positive moment and it is suggested that (Leon 1990)

$$I_{cp} = 0.6I_p + 0.4I_n \tag{22.5}$$

where I_p is the lower bound moment of inertia for positive moment and I_n is the lower bound moment of inertia for negative moment. However, if the connections at both ends of the beam are designed and detailed for simply supported, the beam will bend in single curvature under the action of gravity loads and I_p should be used throughout.

The story shear displacement Δ in an unbraced frame can be estimated using a modified expression from Equation 22.4 to account for the connection flexibility

$$\Delta_i = \frac{V_i h_i^2}{12E} \left(\frac{1}{\sum (I_{ci}/h_i)} + \frac{1}{\sum (I_{cpi}/L_i)} \right) + \frac{V_i h_i^2}{\sum K_{con}} \tag{22.6}$$

where Δ_i is the shear deflection of the i th story, E is the modulus of elasticity, I_c is the moment of inertia for columns, I_g is the moment of inertial of a composite girder based on the weighted average method, h_i is the height of the i th story, L_i is the length of girder in the i th story, V_i is the total horizontal shear force

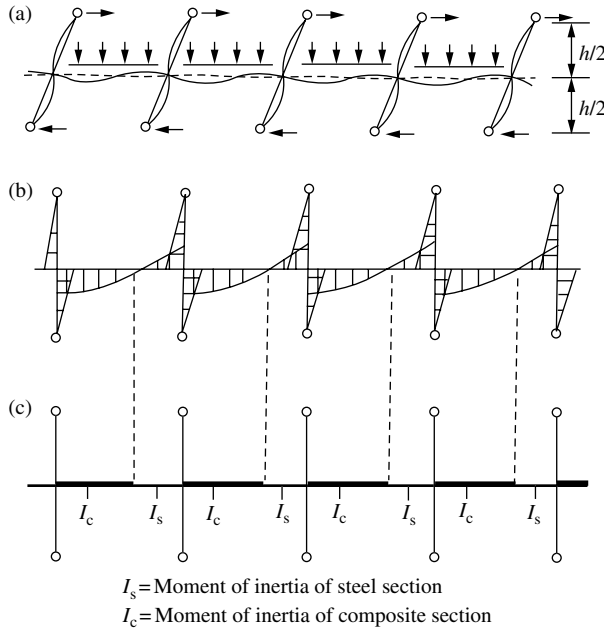

FIGURE 22.47 Composite unbraced frames: (a) story loads and idealization, (b) bending moment diagrams, and (c) composite beam stiffness.

in the i th story, $\sum(I_{c_i}/h_i)$ is the sum of the column stiffnesses in the i th story, $\sum(I_{g_i}/L_i)$ is the sum of the girder stiffnesses in the i th story, and $\sum K_{con}$ is the sum of the connection rotational stiffness in the i th story.

Further research is required to assess the performance of various types of composite connections used in building construction. Issues related to accurate modeling of effective stiffness of composite members and joints in unbraced frames for the computation of second-order effects and drifts need to be addressed.

22.5 Wind Effects on Buildings

22.5.1 Introduction

With the development of lightweight high-strength materials, the recent trend is to build tall and slender buildings. The design of such buildings in nonseismic areas is often governed by the need to limit the wind-induced accelerations and drift to acceptable levels for human comfort and integrity of nonstructural components, respectively. Thus, to check for serviceability of tall buildings, the peak resultant horizontal acceleration and displacement due to the combination of along wind, across wind, and torsional loads are required. As an approximate estimation, the peak effects due to along wind, across wind, and torsional responses may be determined individually and then combined vectorally. A reduction factor of 0.8 may be used on the combined value to account for the fact that in general the individual peaks do not occur simultaneously. If the calculated combined effect is less than any of the individual effects, then the latter should be considered for the design.

The effects of acceleration on human comfort are given in [Table 22.3](#). The factors affecting the human response are

1. Period of building — tolerance to acceleration tends to increase with period.
2. Women are more sensitive than men.

3. Children are more sensitive than adults.
4. Perception increases as you go from sitting on the floor, to sitting on a chair, to standing.
5. Perception threshold level decreases with prior knowledge that motion will occur.
6. Human body is more sensitive to fore-and-aft motion than to side-to-side motion.
7. Perception threshold is higher while walking than standing.
8. Visual cue — very sensitive to rotation of the building relative to fixed landmarks outside.
9. Acoustic cue — Building make sounds while swaying due to rubbing of contact surfaces. These sounds and sounds of the wind whistling focus the attention on building motion even before motion is perceived, and thus lower the perception threshold.
10. The resultant translational acceleration due to the combination of longitudinal, lateral, and torsional motions causes human discomfort. In addition, angular (torsional) motion appears to be more noticeable.

Since the tolerable acceleration levels increase with period of building, the recommended design standard for peak acceleration for 10 year wind in commercial and residential buildings is as depicted in Figure 22.48 (Griffis 1993). Lower acceleration levels are used for residential buildings for the following reasons:

1. Residential buildings are occupied for longer hours of the day and night and are therefore more likely to experience the design wind storm.
2. People are less sensitive to motion when they are occupied with their work than when they relax at home.
3. People are more tolerant of their work environment than of their home environment.
4. Occupancy turnover rates are higher in commercial buildings than in residential buildings.
5. People can be easily evacuated from commercial buildings than residential buildings in the event of a peak storm.

TABLE 22.3 Acceleration Limits for Different Perception Levels

Perception	Acceleration limits
Imperceptible	$a < 0.005g$
Perceptible	$0.005g < a < 0.015g$
Annoying	$0.015g < a < 0.05g$
Very annoying	$0.05g < a < 0.15g$
Intolerable	$a > 0.15g$

FIGURE 22.48 Design standard on peak acceleration for a 10-year return period.

TABLE 22.4 Serviceability Problems at Various Deflection or Drift Indices

Deformation as a fraction of span or height	Visibility of deformation	Typical behavior
$\frac{1}{500}$	Not visible	Cracking of partition walls
$\frac{1}{300}$	Visible	General architectural damage
		Cracking in reinforced walls
		Cracking in secondary members
		Damage to ceiling and flooring
		Facade damage
		Cladding leakage
		Visual annoyance
$\frac{1}{200} - \frac{1}{300}$	Visible	Improper drainage
$\frac{1}{100} - \frac{1}{200}$	Visible	Damage to lightweight partitions, windows, finishes
		Impaired operation of removable components such as doors, windows, sliding partitions

FIGURE 22.49 Schematic diagram for wind-resistant design of structures.

The effects of excessive deflection on building components is described in Table 22.4. Thus, the allowable drift, defined as the resultant peak displacement at the top of the building divided by the height of the building, is generally taken to be in the range $\frac{1}{450}$ to $\frac{1}{600}$.

Figure 22.49 depicts schematically the procedure of estimating the wind-induced accelerations and displacements in a building. The steps involved in this design procedure are described below with numerical examples for situations where the motion of the building does not affect the loads acting on the building. Finally, the situations when a wind tunnel studies is required is listed at the end of this section.

22.5.2 Characteristics of Wind

22.5.2.1 Mean Wind Speed

The velocity of wind (wind speed) at great heights above the ground is constant and is called the gradient wind speed. As shown in Figure 22.50, closer to the ground surface, the wind speed is affected by frictional forces caused by the terrain and thus there is a boundary layer within which the wind speed varies from zero to the gradient wind speed. The thickness of the boundary layer (gradient height) depends on the ground roughness. For example, the gradient height is 457 m for large cities, 366 m for suburbs, 274 m for open terrain, and 213 m for open sea.

The velocity of wind averaged over 1 h is called the hourly mean wind speed. The mean wind velocity profile within the atmospheric boundary layer is described by a power law:

$$\bar{U}(z) = \bar{U}(z_{\text{ref}}) \left(\frac{z}{z_{\text{ref}}} \right)^\alpha \tag{22.7}$$

FIGURE 22.50 Mean wind profiles for different terrains.

TABLE 22.5 Typical Values of Terrain

	z_0	a	d (m)
City centers	0.7	0.33	15–25
Suburban terrain	0.3	0.22	5–10
Open terrain	0.03	0.14	0
Open sea	0.003	0.10	0

in which $\bar{U}(z)$ is the mean wind speed at height z above the ground, z_{ref} is the reference height normally taken to be 10 m, and α is the power law exponent.

An alternative description of the mean wind velocity is by the logarithmic law:

$$\bar{U}(z) = \frac{1}{k} u_* \ln\left(\frac{z-d}{z_0}\right) \tag{22.8}$$

in which u_* is the friction velocity, k is von Karmon’s constant equal to 0.4, z_0 is the roughness length, and d is the height of zero-plane above the ground where the velocity is zero. Generally, zero plane is about 1 or 2 m below the average height of buildings and trees providing the roughness. Typical values of α , z_0 , and d are given in Table 22.5 (ANSI 1982; ESDU 1985).

The roughness affects both the thickness of the boundary layer and the power law exponent. The thickness of the boundary layer and the power law exponent increase with the roughness of the surface. Consequently, the velocity at any height decreases as the surface roughness increases. However, the gradient velocity will be the same for all surfaces. Thus, if the velocity of wind for a particular terrain is known, using Equation 22.7 and Table 22.5 the velocity at some other terrain can be computed.

22.5.2.2 Turbulence

The variation of wind velocity with time is shown in Figure 22.51. The eddies generated by the action of wind blowing over obstacles cause the turbulence. In general, the velocity of wind may be represented in a vector form as

$$U(z, t) = \bar{U}(z)\underline{i} + u(z, t)\underline{i} + v(z, t)\underline{j} + w(z, t)\underline{k} \tag{22.9}$$

where u , v , and w are the fluctuating components of the gust in x , y , z (longitudinal, lateral, and vertical axes) as shown in Figure 22.52 and $\bar{U}(z)$ is the mean wind along the x -axis. The fluctuating component

FIGURE 22.51 Variation of longitudinal component of tubular wind with time.

FIGURE 22.52 Velocity components of turbulent wind.

along the mean wind direction, u , is the largest and is therefore the most important for the vertical structures such as tall buildings, which are flexible along the wind direction. The vertical component w is important for horizontal structures, which are flexible vertically such as long-span bridges.

An overall measure of the intensity of turbulence is given by the root mean square value. Thus, for the longitudinal component of the turbulence

$$\sigma_u(z) = \left[\frac{1}{T_0} \int_0^{T_0} \{u(z, t)^2\} dt \right]^{1/2} \tag{22.10}$$

where T_0 is the averaging period. For the statistical properties of the wind to be independent on which part of the record is being used, T_0 is taken to be 1 h. Thus, the fluctuating wind is a stationary random function, over 1 h.

The value of $\sigma_u(z)$ divided by the mean velocity $\bar{U}(z)$ is called the turbulence intensity

$$I_u(z) = \frac{\sigma_u(z)}{\bar{U}(z)} \tag{22.11}$$

which increases with ground roughness and decreases with height.

The variance of longitudinal turbulence can be determined from

$$\sigma_u^2 = \beta u_*^2 \tag{22.12}$$

where u_* is the friction velocity determined from Equation 22.8 and β , which is independent of the height, is given in Table 22.6 for various roughness lengths.

22.5.2.3 Integral Scales of Turbulence

The fluctuation of wind velocity at a point is due to eddies transported by the mean wind \bar{U} . Each eddy may be considered to be causing a periodic fluctuation at that point with a frequency n . The average size of the turbulent eddies are measured by integral length scales. For eddies associated with longitudinal velocity fluctuation u , the integral length scales are L_u^x, L_u^y, L_u^z describing the size of the eddies in longitudinal, lateral, and vertical directions, respectively. If L_u^y and L_u^z are comparable to the dimension of the structure normal to the wind, then the eddies will envelope the structure and give rise to well-correlated pressures and thus the effect is significant. On the other hand, if L_u^y and L_u^z are small, then the eddies produce uncorrelated pressures at various parts of the structure and the overall effect of the longitudinal turbulence will be small. Thus, the dynamic loading on a structure depends on the size of eddies.

22.5.2.4 Spectrum of Turbulence

The frequency content of the turbulence is represented by the power spectrum, which indicates the power or kinetic energy per unit time, associated with eddies of different frequencies. An expression for the power spectrum is (Taranath 1988)

$$\frac{nS_u(z, n)}{u_*^2} = \frac{200f}{(1 + 50f)^{5/3}} \tag{22.13}$$

where $f = nz/\bar{U}(z)$ is the reduced frequency. A typical spectrum of wind turbulence is shown in Figure 22.53. The spectrum has a peak value at a very low frequency around 0.04 Hz. As the typical range

TABLE 22.6 Values of β for Various Roughness Lengths

z_0 (m)	0.005	0.7	0.30	1.0	2.5
b	6.5	6.0	5.25	4.85	4.0

FIGURE 22.53 Power spectrum of longitudinal turbulence.

for the fundamental frequency of a tall building is 0.1 to 1 Hz, the buildings are affected by high-frequency small eddies characterizing the descending part of the power spectrum.

22.5.2.5 Cross-Spectrum of Turbulence

The cross-spectrum of two continuous records is a measure of the degree to which the two records are correlated. If the records are taken at two points M_1 and M_2 separated by a distance r , then the cross-spectrum of longitudinal turbulent component is defined as

$$S_{u_1 u_2}(r, n) = S_{u_1 u_2}^c(r, n) + i S_{u_1 u_2}^q(r, n) \quad (22.14)$$

where the real and imaginary parts of the cross-spectrum are known as the cospectrum and the quadrature spectrum, respectively. However, the latter is small enough to be neglected. Thus, the cospectrum may be expressed nondimensionally as the coherence and is given by

$$\gamma^2(r, n) = \frac{[S_{u_1 u_2}(r, n)]^2}{S_{u_1}(n) S_{u_2}(n)} \quad (22.15)$$

where $S_{u_1}(n)$ and $S_{u_2}(n)$ are the longitudinal velocity spectra at M_1 and M_2 respectively.

The square root of the coherence is given by the following expression (Davenport 1968):

$$\gamma(r, n) = e^{-\hat{f}} \quad (22.16)$$

where

$$\hat{f} = \frac{n[c_z^2(z_1 - z_2)^2 + c_y^2(y_1 - y_2)^2]^{1/2}}{(\frac{1}{2})[\bar{U}(z_1) + \bar{U}(z_2)]} \quad (22.17)$$

in which y_1, z_1 and y_2, z_2 are the coordinates of points M_1 and M_2 . The line joining M_1 and M_2 is assumed to be perpendicular to the direction of the mean wind. The suggested values of c_y and c_z for engineering calculation are 16 and 10, respectively (Vickery 1970).

22.5.3 Wind-Induced Dynamic Forces

22.5.3.1 Forces Due to Uniform Flow

A bluff body in a two-dimensional flow, as shown in Figure 22.54, is subjected to a net force in the direction of flow (drag force) and a force perpendicular to the flow (lift force). Furthermore, when the

FIGURE 22.54 Drag and lift forces and torsional moment on a bluff body.

resultant force is eccentric to the elastic center, the body will be subjected to torsional moment. For uniform flow these forces and moment per unit height of the object are determined from

$$F_D = \frac{1}{2} \rho C_D B \bar{U}^2 \tag{22.18}$$

$$F_L = \frac{1}{2} \rho C_L B \bar{U}^2 \tag{22.19}$$

$$T = \frac{1}{2} \rho C_T B^2 \bar{U}^2 \tag{22.20}$$

where \bar{U} is the mean velocity of the wind, ρ is the density of air, C_D and C_L are the drag and lift coefficients, C_T is the moment coefficient, and B is the characteristic length of the object such as the projected length normal to the flow.

The drag coefficient for a rectangular building in plan is shown in Figure 22.55 for various depth-to-breadth ratios (ASCE 1987). The shear layers originating from the separation points at the windward corners surround a region known as the wake. For elongated sections, the stream lines that separate at the windward corners reattach to the body to form a narrower wake. This attributes to the reduction in the drag for larger aspect ratios. For cylindrical buildings in plan the drag coefficient is dependent on the Reynolds number as indicated in Figure 22.56.

Unlike the drag force, the lift force and torsional moment do not have a mean value for a symmetric object with a symmetric flow around it, as the symmetrical distribution of mean forces acting in the across wind direction cannot cause a nett force. If the direction of wind is not parallel to the axes of

FIGURE 22.55 Drag coefficient for a rectangular section with different aspect ratios.

FIGURE 22.56 Effects of Reynolds number on drag coefficient of a circular cylinder.

symmetries or if the object is asymmetrical, then there will be a mean lift force and torsional moment. However, due to vortex shedding, fluctuating lift force and torsional moment will be present in both symmetric and nonsymmetric structures. Figure 22.57 shows the mechanism of vortex shedding. Near the separation zones, strong shear stresses impart rotational motions to the fluid particles. Thus, discrete vortices are produced in the separation layers. These vortices are shed alternatively from the sides of the object. The asymmetric pressure distribution created by the vortices around the cross-section leads to an alternating transverse force (lift force) on the object. The vortex shedding frequency in Hz, n_s , is related to a nondimensional parameter called the Strouhal number, S , defined as

$$S = \frac{n_s B}{\bar{U}} \tag{22.21}$$

where \bar{U} is the mean wind speed and B is the width of the object normal to the wind. For objects with rounded profiles such as circular cylinders, the Strouhal number varies with Reynolds number “ Re ” defined as

$$Re = \frac{\rho \bar{U} B}{\mu} \tag{22.22}$$

where ρ is the density of air and μ is the dynamic viscosity of the air. The vortex shedding becomes random in the transition region of $4 \times 10^5 < Re < 3 \times 10^6$ where the boundary layer at the surface of the cylinder changes from laminar to turbulent. Outside this transition range, the vortex shedding is regular producing a periodic lift force. For cross-sections with sharp corners, the Strouhal number is independent of the Reynolds number. The variation of Strouhal number with length-to-breadth ratio of a rectangular cross-section is shown in Figure 22.58.

FIGURE 22.57 Vortex shedding in the wake of a bluff body.

FIGURE 22.58 Strouhal number for a rectangular section.

22.5.3.2 Forces Due to Turbulent Flow

If the wind is turbulent, then the velocity of the wind along the wind direction is described as follows:

$$U(t) = \bar{U} + u(t) \quad (22.23)$$

where \bar{U} is the mean wind and $u(t)$ is the turbulent component along the wind direction. The time dependent drag force per unit height is obtained from Equation 22.18 by replacing \bar{U} by $U(t)$. As the ratio $u(t)/\bar{U}$ is small, the time-dependent drag force can be expressed as

$$f_D(t) = \bar{f}_D + f'_D(t) \quad (22.24)$$

where \bar{f}_D and f'_D are the mean and the fluctuating parts of the drag force per unit height, which are given by

$$\bar{f}_D = \frac{1}{2} \rho \bar{U}^2 C_D B \quad (22.25)$$

$$f'_D = \rho \bar{U} u C_D B \quad (22.26)$$

The spectral density of the fluctuating part of the drag force is obtained from the Fourier transformation of the autocorrelation function as

$$S_{fD}(n) = \rho^2 \bar{U}^2 B^2 C_D^2 S_u(n) \quad (22.27)$$

where $S_u(n)$ is the spectral density of the turbulent velocity and may be obtained from Equation 22.13.

In practice, the presence of the structure distorts the turbulent flow, particularly the small high-frequency eddies. A correction factor known as the aerodynamic admittance function $\chi(n)$ may be introduced (Davenport 1961) to account for these effects. The following empirical formula has been suggested for $\chi(n)$ (Vickery 1970):

$$\chi(n) = \frac{1}{1 + [(2n\sqrt{A})/\bar{U}(z)]^{4/3}} \quad (22.28)$$

where A is the frontal area of the structure. Now with the introduction of the aerodynamic admittance function, Equation 22.27 may be rewritten as

$$S_{fD}(n) = \rho^2 \bar{U}^2 B^2 C_D^2 \chi^2(n) S_u(n) \quad (22.29)$$

It is evident from Equation 22.26 that the fluctuating drag force varies linearly with the turbulence. Thus, large integral length scale and high turbulent intensities will cause strong buffeting and consequently increases the along wind response of the structure. However, the regularity of vortex shedding is affected by the presence of turbulence in the along wind and hence the across wind motion and torsional motion due to vortex shedding decreases as the level of turbulence increases.

22.5.4 Response Due to Along Wind

Tall slender buildings, where the breadth of the structure is small compared to the height, can be idealized as a line-like structure shown in Figure 22.59. Modeling the building as a continuous system, the governing equation of motion for along wind displacement $x(z, t)$ can be written as (Heidebrecht and Smith 1973):

$$m(z)\ddot{x}(z, t) + c(z)\dot{x}(z, t) + EI(z)x''''(z, t) - GA(z)x''(z, t) = f(z, t) \quad (22.30)$$

where m , c , EI , GA are the mass, damping coefficient, flexural rigidity, and shear rigidity, per unit height, respectively. Furthermore, $f(z, t)$ is the fluctuating wind load per unit height given in Equation 22.26.

FIGURE 22.59 Typical deflection mode of a shear wall-frame building.

Expressing the displacement in terms of the normal coordinates

$$x(z, t) = \sum_{i=1}^N \phi_i(z) q_i(t) \tag{22.31}$$

where ϕ_i is the i th vibration mode shape and q_i is the i th normal coordinate. Using the orthogonality conditions of mode shapes, Equation 22.30 can be expressed as (Balendra 1993)

$$m_i^* \ddot{q}_i + c_i^* \dot{q}_i + k_i^* q_i = p_i^*, \quad i = 1 \text{ to } N \tag{22.32}$$

where m_i^* , c_i^* , k_i^* , and p_i^* are the generalized mass, damping, stiffness, and force in the i th mode of vibration. The generalized mass and force are determined from

$$m_i^* = \int_0^H m(z) \phi_i^2(z) dz \tag{22.33}$$

$$\begin{aligned} p_i^* &= \int_0^H f(z, t) \phi_i(z) dz \\ &= \rho C_D B \int_0^H \bar{U}(z) u(z, t) \phi_i(z) dz \end{aligned} \tag{22.34}$$

Equation 22.32 consists of a set of uncoupled equations, each representing a single degree of freedom system. Using the random vibration theory (Robson 1963), the power spectrum of the response in each normal coordinate is given by

$$S_{q_i}(n) = |H_i(n)|^2 S_{p_i^*}(n) \frac{1}{(k_i^*)^2} \tag{22.35}$$

where

$$|H_i(n)| = \frac{1}{([1 - (n/n_i)^2]^2 + 4\zeta_i^2 (n/n_i)^2)^{1/2}} \tag{22.36}$$

and

$$k_i^* = 4\pi^2 n_i^2 m_i^* \tag{22.37}$$

in which n_i and ζ_i are the frequency and damping ratios in the i th mode. The spectral density of the generalized force takes the form

$$S_{p_i^*}(n) = \rho^2 C_D^2 B^2 \chi^2(n) \int_0^H \int_0^H \bar{U}(z_1) \bar{U}(z_2) S_{u_1 u_2}(r, n) \phi_i(z_1) \phi_i(z_2) dz_1 dz_2 \quad (22.38)$$

where $S_{u_1 u_2}(r, n)$ is the cross-spectral density defined in Equation 22.14 with r being the distance between the coordinates z_1 and z_2 . In Equation 22.38, the aerodynamic admittance has been incorporated to account for the distortion caused by the structure to the turbulent velocity.

In view of Equation 22.15, Equation 22.38 may be expressed as

$$S_{p_i^*}(n) = \rho^2 C_D^2 B^2 \chi^2(n) \int_0^H \int_0^H \phi_i(z_1) \phi_i(z_2) \bar{U}(z_1) \bar{U}(z_2) \sqrt{S_{u_1}(n)} \sqrt{S_{u_2}(n)} \gamma(r, n) dz_1 dz_2 \quad (22.39)$$

where $\gamma(r, n)$ is the square root of the coherence given in Equation 22.16 and $S_u(n)$ is the spectral density of the turbulent velocity.

The variance of the i th normal coordinate is obtained from

$$\sigma_{q_i}^2 = \int_0^\infty S_{q_i}(n) dn = \frac{1}{(k_i^*)^2} \int_0^\infty |H_i(n)|^2 S_{p_i^*}(n) dn \quad (22.40)$$

The calculation of the above integral is very much simplified by observing the plot of the two components of the integrand shown in Figure 22.60. The mechanical admittance function is either 1.0 or zero for most of the frequency range. However, over a relatively small range of frequencies around the natural frequency of the system, it attains very high values if the damping is small. As a result, the integrand takes the shape shown in Figure 22.60c. It has a sharp spike around the natural frequency of the system.

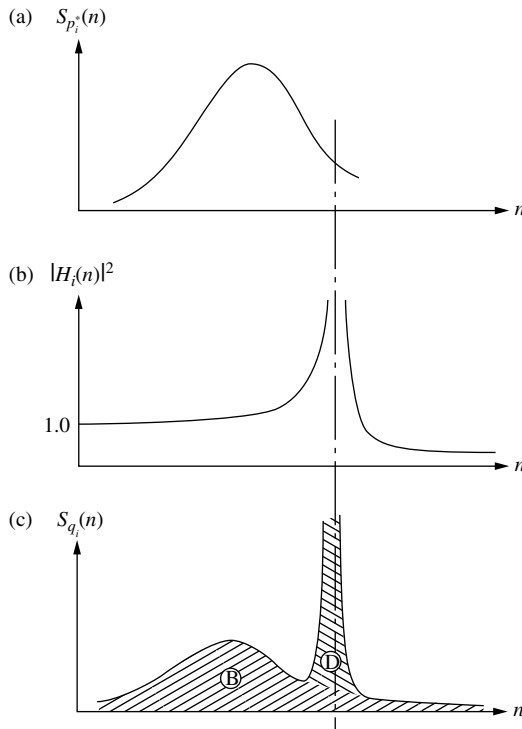

FIGURE 22.60 Schematic diagram for computation of response.

The broad hump is governed by the shape of the turbulent velocity spectrum which is modified slightly by the aerodynamic admittance function. The area under the broad hump is the broad band or non-resonant response, whereas the area in the vicinity of the natural frequency gives the narrow band or resonant response. Thus, Equation 22.40 can be rewritten as

$$\sigma_{q_i}^2 = \frac{1}{(k_i^*)^2} \left[\int_0^{n_i - \Delta n} S_{p_i^*}(n) \, dn + \frac{\pi n_i}{4\zeta_i} S_{p_i^*}(n_i) \right] = \sigma_{Bq_i}^2 + \sigma_{Dq_i}^2 \quad (22.41)$$

in which σ_{Bq_i} and σ_{Dq_i} are the nonresonating and resonating root mean square response of the i th normal coordinate. As the response due to various modes of vibration are statistically uncorrelated, the response of the system is given by

$$\sigma_x^2(z) = \sum_{i=1}^N \phi_i^2(z) \sigma_{Bq_i}^2 + \sum_{i=1}^N \phi_i^2(z) \sigma_{Dq_i}^2 \quad (22.42)$$

which gives the variance and hence the root mean square displacement at various heights.

The total displacement is obtained by including the static deflection due to the mean drag load, which is determined conveniently as follows:

In view of Equation 22.25, the mean generalized force is given by

$$\bar{f}_i = \int_0^H \frac{1}{2} \rho C_D \bar{U}^2(z) B \phi_i(z) \, dz = \frac{1}{2} \rho C_D B \int_0^H \bar{U}^2(z) \phi_i(z) \, dz \quad (22.43)$$

Then, the mean displacement is determined from

$$\bar{x}(z) = \sum_{i=1}^N \phi_i(z) \left[\frac{\bar{f}_i}{(2\pi n_i)^2 m_i^*} \right] \quad (22.44)$$

The root mean square acceleration is obtained from

$$\sigma_{\ddot{x}}(z) = \left[\sum_{i=1}^N (2\pi n_i)^4 \phi_i^2(z) \sigma_{Dq_i}^2 \right]^{1/2} \quad (22.45)$$

The dynamic shear and bending moment at any height is obtained from the vibratory inertia forces in each mode and then by summing the modal contributions.

The probability of the response exceeding certain magnitude is determined using a peak factor on the root mean square response, Davenport (1964) recommended the following expression for 50% probability of exceedence:

$$g_D = \sqrt{[2 \ln(vT_0)]} + \frac{0.577}{\sqrt{[2 \ln(vT_0)]}} \quad (22.46)$$

where g_D is the peak factor, v is the expected frequency at which the fluctuating response crosses the zero axis with positive slope, and T_0 is the period (usually 3600 s) during which the peak response is assumed to occur.

For resonant response, v is equal to the natural frequency and thus the peak factor for the resonant response g_D is obtained by setting $v = n$. For the nonresonating or broadband response the peak factor g_B has been evaluated to be 3.5 (ESDU 1976).

Using these peak factors, the most probable maximum value of the load effect, E , such as displacement, shear, bending moment, are determined as follows:

$$E_{\max} = \bar{E} + [(\bar{g}_B \sigma_{BE})^2 + (\bar{g}_D \sigma_{DE})^2]^{1/2} \quad (22.47)$$

where σ_{BE} and σ_{DE} are the nonresonating and resonating components of the load effect and \bar{E} is the load effect due to mean wind.

EXAMPLE 22.1

A rectangular building of height $H=194$ m is situated in a suburban terrain. The breadth B and width D of the building are 56 m and 32 m, respectively. The period of the building corresponding to the fundamental sway mode is 5.15 s. The values of the mode shape at various heights are given below:

$H(\text{m})$	0	20	40	75	95	135	150	170	194
ϕ	0	0.032	0.096	0.248	0.365	0.611	0.746	0.849	1.0

The generalized mass and damping ratio corresponding to this mode are 18×10^6 kg and 2%, respectively.

Assuming that the mean wind profile follows the power law with a power law coefficient $\alpha=0.22$, determine the maximum drift for a 50-year wind storm of 21 m/s at 10 m height, blowing normal to the breadth of the building. Given that the friction velocity is 2.96 m/s, the drag coefficient C_D is 1.3 and density of air $\rho = 1.2$ kg/m³.

Solution

The mean height of the building $\bar{H} = 97$ m

$$\bar{U}(97) = \bar{U}(10) \left(\frac{97}{10} \right)^{0.22} = 21 \left(\frac{97}{10} \right)^{0.22} = 34.6 \text{ m/s}$$

At mid-height, the reduced frequency

$$f = \frac{n\bar{H}}{\bar{U}(\bar{H})} = \frac{97n}{34.6} = 2.8n$$

From Equation 22.13, the spectrum of turbulent wind is given by

$$S_u(\bar{H}, n) = \frac{2.96^2 \times 200 \times 2.8}{(1 + 50 \times 2.8n)^{5/3}} = \frac{4906}{(1 + 140n)^{5/3}}$$

Resonant displacement

$$n_1 = \frac{1}{5.15} = 0.194 \text{ Hz},$$

$$S_u(\bar{H}, n_1) = \frac{4906}{(1 + 140 \times 0.194)^{5/3}} = 18.8 \text{ m}^2/\text{s}$$

The admittance function, from Equation 22.28, becomes

$$\chi(n) = \frac{1}{1 + ((2n\sqrt{56 \times 194})/34.6)^{4/3}} = \frac{1}{1 + 10.96n^{4/3}}$$

$$\chi(n_1) = 0.45$$

From Equation 22.39

$$S_{p_1^*}(n) = \rho^2 C_D^2 B^2 \chi^2(n) S_u(\bar{H}, n) \frac{[\bar{U}(\bar{H})]^2}{\bar{H}^{2\alpha}} \int_0^H \int_0^H \phi_1(z_1) \phi_1(z_2) z_1^2 z_2^2 \gamma(z_1, z_2, n) dz_1 dz_2$$

The square root of coherence γ is determined from Equation 22.16, considering only the vertical correlation. Thus

$$\begin{aligned} S_{p_1^*}(n_1) &= 1.2^2 \times 1.3^2 \times 56^2 \times (0.45)^2 \times 18.8 \times \frac{(34.6)^2}{97^{0.44}} \times 16,900 \\ &= 7.85 \times 10^{10} \text{ N}^2/\text{Hz} \end{aligned}$$

From Equations 22.41 and 22.42, the variance of resonant displacement at the top of the building is obtained as

$$\begin{aligned} \sigma_D^2 &= \phi_1^2(H) \sigma_{D_{q_1}}^2 = \frac{1}{(k_1^*)^2} \frac{\pi n_1}{4 \zeta_1} S_{p_1^*}(n_1) \\ \sigma_D^2 &= \left(\frac{1}{26.8 \times 10^6} \right)^2 \left(\frac{\pi(0.194)}{4(0.02)} \right) (7.85 \times 10^{10}) 10^6 \text{ mm}^2 \\ \sigma_D &= 28.9 \text{ mm} \end{aligned}$$

Nonresonant displacement

The variance of nonresonant displacement at the top of the building is determined from Equations 22.41 and 22.42 as

$$\begin{aligned} \sigma_B^2 &= \phi_1^2(H) \sigma_{B_{q_1}}^2 = \frac{1}{(k_1^*)^2} \int_0^{n_1 - \Delta n} S_{p_1^*}(n) \, dn \\ &= \frac{565 \times 10^9}{(26.8 \times 10^6)^2} \times 10^6 \text{ mm} \\ \sigma_B &= 28 \text{ mm} \end{aligned}$$

Response to mean wind

From Equation 22.43, the mean generalized force

$$\begin{aligned} \bar{f}_1 &= \frac{1}{2} \rho C_D B \int_0^H \bar{U}^2(z) \phi_1(z) \, dz \\ &= \frac{1}{2} \rho C_D B [\bar{U}(\bar{H})]^2 \left(\frac{1}{\bar{H}} \right)^{2\alpha} \int_0^H z^{2\alpha} \phi_1(z) \, dz \\ &= \frac{1}{2} \times 1.2 \times 1.3 \times 56 \times (34.6)^2 \left(\frac{1}{97} \right)^{0.44} \times 684 \\ &= 4.8 \times 10^6 \text{ N} \end{aligned}$$

The generalized stiffness

$$\begin{aligned} k_1^* &= \left(\frac{2\pi}{5.15} \right)^2 \times 18 \times 10^6 \\ &= 26.8 \times 10^6 \text{ N/m} \end{aligned}$$

Thus, the mean displacement

$$\bar{X} = \frac{4.8 \times 10^6}{26.8 \times 10^6} \times 10^3 = 179 \text{ mm}$$

The peak factor g_D for resonant response is determined from Equation 22.46 as 3.78. Using a peak factor of 3.5 for nonresonant response, the most probable maximum displacement is

$$\begin{aligned} X_{\max} &= \bar{X} + \sqrt{(g_B \sigma_B)^2 + (g_D \sigma_D)^2} \\ &= 179 + \sqrt{(3.5 \times 28)^2 + (3.78 \times 28.9)^2} \\ &= 326 \text{ mm} \end{aligned}$$

The most probable maximum drift would be

$$= \frac{326}{194,000} = \frac{1}{595}$$

The peak acceleration would be

$$\begin{aligned} &= 0.0289 \times 3.78 \times (2\pi)^2 \times (0.194)^2 \\ &= 0.16 \text{ m/s}^2 \text{ (1.6\% g)} \end{aligned}$$

22.5.5 Response Due to Across Wind

For most modern tall buildings, the across wind response is more significant than the along wind response. Across wind vibration of building is caused by the combination of forces from three sources: (1) buffeting by the turbulence in the across wind direction, (2) wake excitation due to vortex shedding, and (3) lock-in, a displacement-dependent excitation.

The across wind force due to lateral turbulence in the approaching flow is generally small compared to the effects due to other mechanisms. Lock-in is the term used to describe large amplitude across wind motion that occurs when the vortex shedding frequency is close to the natural frequency. If the across wind response exceeds a certain critical value, the across wind response causes an increase in the excitation force, which in turn increases the response. The vortex shedding frequency tends to couple with the natural frequency of the structure for a range of wind velocities and the large amplitude response will persist. Lock-in is likely to occur only in the case of structures with relatively low stiffness and low damping, operating near the critical wind velocity given by

$$\bar{U}_{\text{crit}} = \frac{n_0 B}{S} \quad (22.48)$$

in which \bar{U}_{crit} is the critical wind speed, B is the breadth of the structure normal to the wind stream, n_0 (in Hz) is the fundamental natural frequency of the structure in the across wind direction, and S is the Strouhal number.

Buildings should be designed so that lock-in effects do not occur during their anticipated life. If the root mean square displacement at the top of the structure is less than a certain critical value, then lock-in will not occur. For square tall buildings, the critical root mean square displacements σ_{yc} expressed as a ratio with respect to the breadth (σ_{yc}/B) are approximately 0.015, 0.025, and 0.045, respectively (Rosati 1968) for open terrain ($z_0 = 0.07$ m), suburban terrain ($z_0 = 1.0$ m), and city centers ($z_0 = 2.5$ m). For circular sections with diameter D , the value of σ_{yc}/D is approximately 0.006 for suburban terrain.

Thus for buildings the most common cause for across wind motion is the wake excitation. Although the turbulence in the atmospheric boundary layer affects the regularity of vortex shedding, the shed vortices have a predominant period that could be determined from an appropriate Strouhal number. Because the vortex shedding is random, the fluctuating across wind force is effectively broadband as shown in Figure 22.61. The band width and the energy concentration near the vortex shedding frequency depend on the geometry of the building and the characteristics of the approach flow.

FIGURE 22.61 Effects of turbulence intensity and afterbody length on across wind force spectra.

The response due to this across wind random excitation can be determined using the random vibration theory. Idealizing the tall building as a line-like structure, the across wind displacement $y(z, t)$ may be expressed in terms of the normal coordinates $r_i(t)$ as

$$y(z, t) = \sum_{i=1}^N \psi_i(z) r_i(t) \tag{22.49}$$

where $\psi_i(z)$ is the i th vibration mode in the across wind direction and N is the total number of modes considered to be significant. The governing equation of motion in terms of generalized mass, m_i^* , generalized damping, c_i^* , and generalized stiffness, k_i^* , takes the form

$$m_i^* \ddot{r}_i + c_i^* \dot{r}_i + k_i^* r_i = f_i^*(t), \quad i = 1 \text{ to } N \tag{22.50}$$

in which

$$\begin{aligned} m_i^* &= \int_0^H m(z) \psi_i^2(z) dz \\ k_i^* &= (2\pi n_i)^2 m_i^* \\ c_i^* &= 2\zeta_i \sqrt{m_i^* k_i^*} \\ f_i^*(t) &= \int_0^H f(z, t) \psi_i(z) dz \end{aligned} \tag{22.51}$$

where H is the height of the building, $m(z)$ is the mass per unit length, n_i is the frequency of the i th mode in the across wind direction, ζ_i is the damping ratio in the i th mode, $f(z, t)$ is the across

wind force per unit height, and $f_i^*(t)$ is the generalized across wind force in the i th mode. The spectral density of each normal coordinate can be determined from

$$S_{r_i}(n) = \frac{|H_i(n)|^2}{(k_i^*)^2} S_{f_i^*}(n) \quad (22.52)$$

where $|H_i(n)|$ is the mechanical admittance function and $S_{f_i^*}$ is the power spectral density of the generalized across wind force.

The variance of the normal coordinate r_i is given by

$$\sigma_{r_i}^2 = \int_0^\infty S_{r_i}(n) \, dn \quad (22.53)$$

Hence, the variance of the across wind displacement is obtained from

$$\sigma_y^2(z) = \sum_{i=1}^N \psi_i^2(z) \sigma_{r_i}^2 \quad (22.54)$$

In Equation 22.53, if the contribution from the nonresonating component is neglected then the root mean square response of the across wind displacement is given by

$$\sigma_y(z) = \left[\sum_{i=1}^N \frac{\psi_i^2(z)}{(2\pi n_i)^4 (m_i^*)^2} \left(\frac{\pi n_i}{4\zeta_i} \right) S_{f_i^*}(n_i) \right]^{1/2} \quad (22.55)$$

For convenient use of the above equation, the generalized force spectra obtained experimentally by Kwok and Melbourne (1981) and Saunders and Melbourne (1975) are presented in Figure 22.62 for various aspect ratios of square and rectangular buildings deflecting in a linear mode.

EXAMPLE 22.2

Consider the building of Example 22.1. If the period of vibration in the across wind direction is 5.2 s, assuming a linear mode determine the acceleration in the across wind direction for a 10-year wind storm of 14 m/s at 10 m height. Given that the generalized mass corresponding to the linear mode is 17.5×10^6 kg and the damping in this mode of oscillation is 2%.

Solution

The building is rectangular with an aspect ratio of

$$H:B:D = 6:1.75:1$$

Since the building is in a suburban terrain, the generalized cross wind force can be determined from Figure 22.62e.

The wind speed at the tip of the building

$$\bar{U}(H) = \bar{U}(10) \times \left(\frac{194}{10} \right)^{0.22} = 26.9 \text{ m/s}$$

The reduced frequency

$$\frac{n_1 B}{\bar{U}(H)} = \frac{0.192 \times 56}{26.9} = 0.40$$

then from Figure 22.62e

$$\begin{aligned} S_{f_i^*}(n_1) &= \left(\frac{0.00018}{0.192} \right) \left(\frac{1}{2} \times 1.2 \times 26.9^2 \times 56 \times 194 \right)^2 \\ &= 2.09 \times 10^{10} \text{ N}^2/\text{Hz} \end{aligned}$$

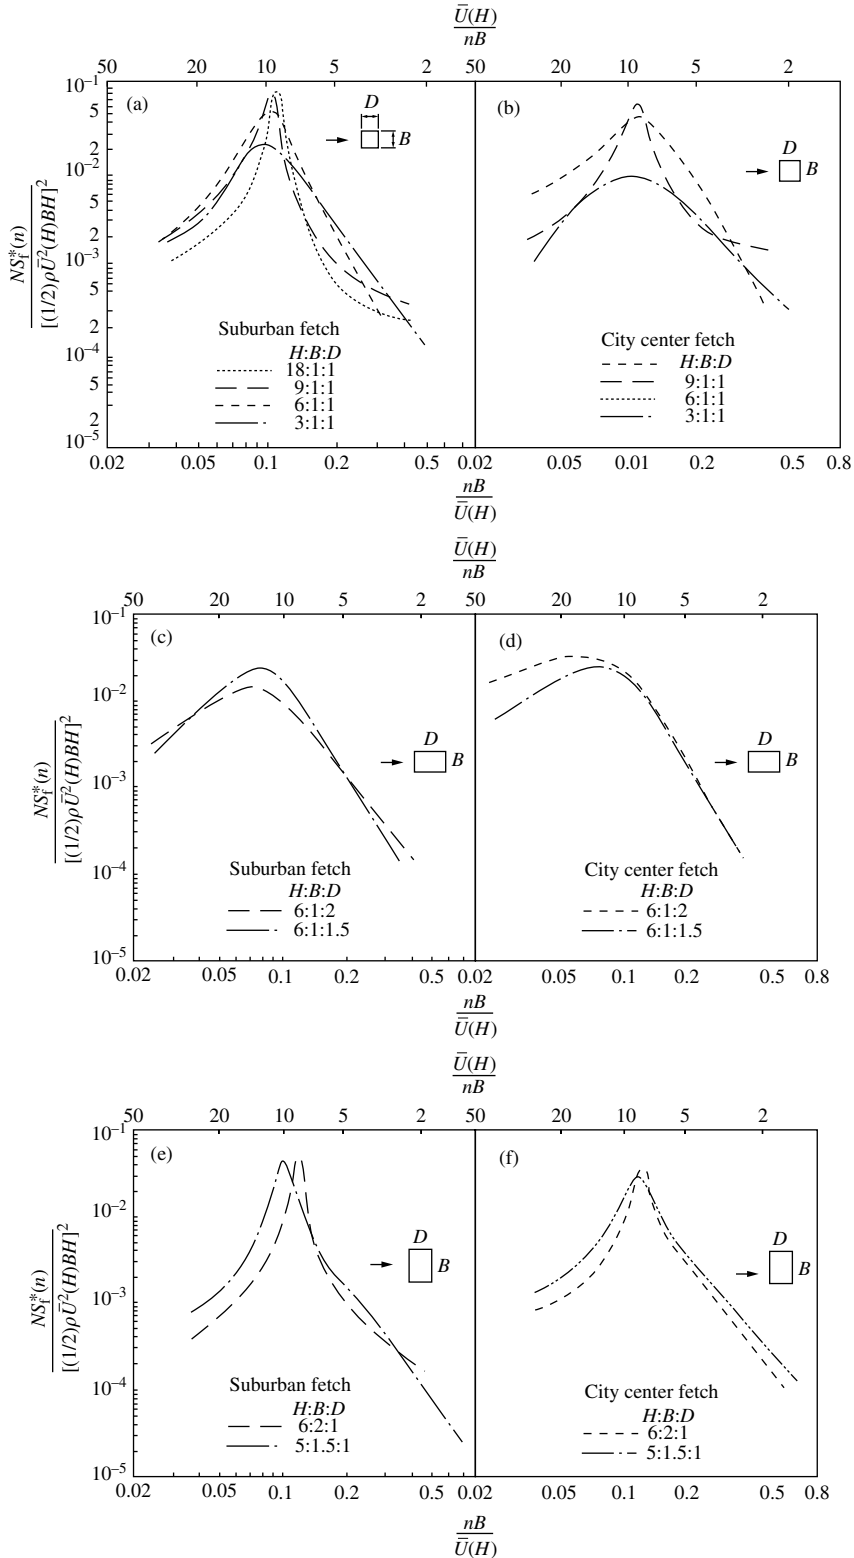

FIGURE 22.62 Generalized force spectra for a square and a rectangular building in suburban and city center fetch.

From Equation 22.55

$$\begin{aligned}\sigma_y(H) &= \left[\left(\frac{\pi \times 0.192}{4 \times 0.02} \right) (2.09 \times 10^{10}) \frac{1}{(2\pi \times 0.192)^4 (17.5 \times 10^6)^2} \right]^{1/2} \\ &= 0.016 \text{ m}\end{aligned}$$

Assuming a peak factor of 4, the peak acceleration in the cross wind direction is

$$4 \times 0.016(2\pi)^2(0.192)^2 = 0.093 \text{ m/s}^2$$

22.5.6 Torsional Response

A building will be subjected to torsional motion when the instantaneous point of application of resultant aerodynamic load does not coincide with the center of mass and the elastic center. The major source for dynamic torque is the flow-induced asymmetries in the lift force and the pressure fluctuation on the leeward side caused by the vortex shedding. Any eccentricities between the center of mass and center of stiffness present in asymmetrical buildings can amplify the torsional effects.

Balendra et al. (1989) have presented a time domain approach to estimate the coupled lateral-torsional motion of buildings due to along wind turbulence and across wind forces and torque due to wake excitation. The experimentally measured power spectra of across wind force and torsional moment (Reinhold 1977) were used in this analysis. This method is useful at the final stages of design as specific details that are unique for a particular building can be easily incorporated in the analytical model. A useful method to assess the torsional effects at the preliminary design stage is given by the following empirical relation (Simiu and Scanlan 1986), which yields the peak base torque induced by wind speed $\bar{U}(H)$ at the top of the building as

$$T_{\text{peak}} = \psi(\bar{T} + g_T T_{\text{rms}}) \quad (22.56)$$

where ψ is a reduction coefficient, g_T is the torsional peak factor equal to 3.8, and \bar{T} and T_{rms} are the mean and root mean square base torques that are given by

$$T_{\text{rms}} = 0.00167 \frac{1}{\sqrt{\zeta_T}} \rho L^4 H n_T^2 U_r^{2.68} \quad (22.57)$$

$$\bar{T} = 0.038 \rho L^4 H n_T^2 U_r^2 \quad (22.58)$$

in which

$$L = \frac{\int |r| ds}{\sqrt{A}} \quad (22.59)$$

$$U_r = \frac{\bar{U}(H)}{n_T L} \quad (22.60)$$

where ρ is the density, H is the height of the building, n_T and ζ_T are the frequency and damping ratio in the fundamental torsional mode of vibration, $|r|$ is the distance between the elastic center and the normal to an element ds on the boundary of the building, and A is the cross-sectional area of the building. The expressions for \bar{T} and T_{rms} are obtained for the most unfavorable directions for the mean and root mean square values of the base torque. In general, these directions do not coincide and furthermore will not be along the direction of the extreme winds expected to occur at the site. As such, a reduction coefficient ψ ($0.75 < \psi \leq 1$) is incorporated in Equation 22.56.

For a linear fundamental mode shape, the peak torsional induced horizontal accelerations at the top of the building at a distance “ a ” from the elastic center is given by (Greig 1980)

$$a\ddot{\theta} = \frac{2ag_T T_{\text{rms}}}{\rho_b B D H r_m^2} \quad (22.61)$$

where $\ddot{\theta}$ is the peak angular acceleration, ρ_b is the mass density of the building, B and D are the breadth and depth of the building, and r_m is the radius of gyration. For a rectangular building with uniform mass density

$$r_m^2 = \frac{1}{12}(B^2 + D^2) \quad (22.62)$$

EXAMPLE 22.3

If the torsional frequency of the building in Example 22.2 is 0.8 Hz, assuming a linear mode and 2% damping ratio, determine the peak acceleration at the corner of the building due to torsional motion for a 10-year wind storm of 14 m/s. Given that the center of rigidity is at the geometric center of the building.

Solution

For a rectangular building

$$\int |r| ds = \frac{1}{2}(B^2 + D^2)$$

Thus, from Equations 22.59 and 22.60

$$L = \frac{1}{\sqrt{BD}}(B^2 + D^2) \frac{1}{2} = 49.1 \text{ m}$$

$$U_r = \frac{\bar{U}(H)}{n_r L} = \frac{26.9}{0.8 \times 49.1} = 0.685$$

From Equation 22.58

$$\begin{aligned} T_{\text{rms}} &= 0.00167 \left(\frac{1}{\sqrt{0.02}} \right) (1.2)(49.1)^4 (194)(0.8)^2 (0.685)^{2.68} \\ &= 3.71 \times 10^6 \text{ N m} \end{aligned}$$

The average density of the building is determined as

$$\rho_b = \frac{3m_1^*}{AH} = \frac{3 \times 17.5 \times 10^6}{56 \times 32 \times 194} = 151 \text{ kg/m}^3$$

Thus, the peak torsional acceleration of the corner for which $a = 32.2$ m is

$$a\ddot{\theta} = \frac{2 \times 32.2 \times 3.8 \times 3.71 \times 10^6}{151 \times 56 \times 32 \times 194 \times 346.7} = 0.05 \text{ m/s}^2$$

22.5.7 Response by Wind Tunnel Tests

There are many situations where analytical methods cannot be used to estimate certain type of wind loads and associated structural response. For example, the aerodynamic shape of the building is rather uncommon or the building is very flexible so that its motion affects the aerodynamic forces acting on the building. In such situations, a more accurate estimate of wind effects on buildings are obtained through aeroelastic model tests in a boundary-layer wind tunnel (Balendra 1993).

The aeroelastic model studies would provide the overall mean and dynamic loads, displacements, rotations, and accelerations. The aeroelastic model studies may be required under the following situations:

1. When the height-to-width ratio exceeds 5.
2. When the structure is light with a density in the order of 1.5 kN/m³.

3. The fundamental period is long in the order of 5 to 10 s.
4. When the natural frequency of the building in the cross wind direction is in the neighborhood of the shedding frequency.
5. When the building is torsionally flexible.
6. When the building is expected to execute strongly coupled lateral-torsional motion.

Glossary

Aeroelastic model — The model which simulates the dynamic properties of buildings to capture the motion-dependent loads.

Along wind response — Response in the direction of wind.

Boundary layer — The layer within which the velocity varies because of ground roughness.

Bracing frames — Frames that provide lateral stability to the overall framework.

Composite beams — Steel beam acting compositely with part of the concrete slab through shear connectors.

Cross wind response — Response perpendicular to the direction of wind.

Drag force — Force in the direction of wind.

Frequency — Number of cycles per second.

Gradient height — Thickness of the boundary layer.

Gradient wind — Wind velocity above the boundary layer.

Generalized force — Force associated with a particular mode of vibration.

Generalized mass — Participating mass in a particular mode of vibration.

Integral length scale — A measure of average size of the eddies.

Lift force — Force perpendicular to the flow.

Lock-in — Situation where the vortex shedding frequency tends to couple with the frequency of the structure.

Long-span systems — Structural systems that span a long distance. The design is likely to be governed by serviceability limit states.

Mode shapes — Free vibration deflection configurations in each frequency of the structure.

Nonresonant response — Response due to eddies whose frequencies are remote from the structural frequency.

Normal coordinates — Coordinates associated with modes of vibration.

Peak factor — Ratio between the peak and root mean square values.

Period — Duration of one complete cycle.

Power spectral density — Kinetic energy per unit time associated with eddies of different frequencies.

Resonant response — Response due to eddies whose frequencies are in the neighborhood of structural frequency.

Rigid frames — Frames resisting lateral load by bending of members that are rigidly connected.

Simple frames — Frames that have no lateral resistance and whose members are pinned connected.

Stiffness — Force required to produce unit displacement.

Sway frames — Frames in which the second-order effects due to gravity load acting on the deformed geometry can influence the force distribution in the structure.

Torsional response — Response causing twisting motion.

Turbulent intensity — Overall measure of intensity of turbulence.

Wake — Region surrounded by the shear layers originating from separation points.

Wake excitation — Excitation caused by the vortices in the wake.

23.1 Introduction

The analysis and design of building steel frames in practice has long been based on simplified assumptions concerning the behavior of beam-to-column connections as two idealized models, fully rigid and ideally pinned, even though the semirigid concept was introduced many years ago. The first model implies displacement and slope continuity between the column and the beam, together with the full transfer of bending moments. The latter one, on the other hand, implies that rotation continuity is nonexistent and, consequently, no bending moment may be transmitted to the column by the beam. Although adoption of such idealized models leads to great simplification in structural analysis and design, it by no means represents the actual behavior of the connections. Consequently, the predicted structural responses may be inaccurate as a result of disregarding the true behavior of beam-to-column connections. To date, numerous experimental investigations on connection behavior have clearly demonstrated that a pinned connection possesses a certain amount of rotational stiffness, while a rigid connection possesses some degree of rotational flexibility. Most beam-to-column connections commonly used in practice actually exhibit semirigid behavior characterized by the moment–rotational relationship as shown in [Figure 23.1](#).

The importance of the semirigid behavior of connections and the semirigid construction of steel framing systems has been recognized in different structural steel design standards in both North American and European communities for a period of time. In general, the process of designing semirigid steel frames involves the following three tasks: assessing the behavior of beam-to-column connections,

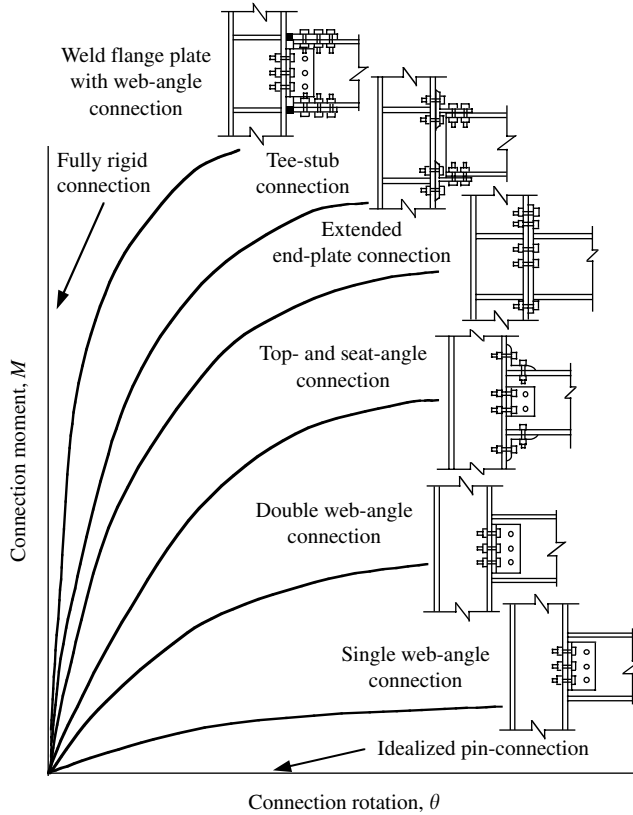

FIGURE 23.1 Moment–rotation behavior for various beam-to-column connections.

incorporating the connection behavior into the structural analysis of the frames, and designing the frames in accordance with the pertained specifications. In this chapter, together with a brief review of different design specifications on semirigid construction, a discussion on each of the three foregoing aspects is presented.

23.2 Semirigid Steel Framing in Design Specifications and Standards

In the United States of America, the *Specification for Allowable Stress Design for Structural Steel Buildings* of the American Institute of Steel Construction (ASD) [1] provides three connection types for construction and associated analysis assumptions: Type 1, commonly designated as “rigid framing or continuous framing”; Type 2, commonly designated as “simple framing”; and Type 3, commonly designated as “semirigid framing.” The rigid frame assumes that beam-to-column connections have sufficient rigidity to maintain the original angles between intersecting members virtually unchanged. The simple framing assumes that the ends of beams are connected for shear only and are free to rotate under load. The semirigid framing assumes that the connections of beams and girders possess a dependable and known moment capacity intermediate in degree between the complete rigidity of Type 1 and complete flexibility of Type 2.

The *Load and Resistance Factored Design Specification for Structural Steel Building* of the American Institute of Steel Construction (LRFD) [2] classifies two types of constructions: Type FR (fully restrained) and Type PR (partially restrained). FR constructions are basically the same as the Type 1

construction in ASD. PR constructions are those where the connections have insufficient rigidity to maintain the original angles between the beams and the columns. Type PR comprises two cases depending on whether connection restraint is ignored or not, which correspond to Types 2 and 3 of ASD, respectively. When connection restraint is considered, it is required that the strength, stiffness, and ductility characteristics of the connections be incorporated into the analysis and design. These characteristics shall be as documented in technical literature or established by analytical or experimental means.

The Canadian standard [3] on *Limit States Design of Steel Structures*, CAN/CSA-S16, stipulates three types of steel framing constructions; rigidly connected and continuous construction, simple construction, and semirigid (partially restrained) construction. The design and construction of semirigid frames is required to comply with the following:

1. The positive and negative moment–rotation relation up to the maximum capacity for a connection is to be established by testing and be either as is published in technical literature or be available from a reputable testing facility.
2. The design of the frame shall be based on either linear analysis using the secant stiffness of the connections at ultimate load or on nonlinear analysis using a nonlinear moment–rotation relationship for connections.
3. The design should consider effects of repeated loading, load reversals, incremental strain in connections, and low-cycle fatigue.

The European standard [4] on *Design of Steel Structures*, commonly called “Eurocode 3,” defines three framing types: continuous, simple, and semicontinuous. The standard precisely distinguishes between these three types of connections and also recognizes that the extent of semirigid action depends to a large extent on the type of structure, such as braced or unbraced frame.

23.3 Behavior and Modeling of Semirigid Connections

A beam-to-column connection is generally subjected to axial and shear forces and bending and torsional moments. The effect of torsion is usually neglected for planar frames. Furthermore, axial and shearing deformations are also neglected since they are small compared to the bending deformation of most connections. Thus, only the rotational deformation of a connection alone is considered in semirigid framing for practical purposes. As shown in Figure 23.2, a beam-to-column connection rotates through an angle θ when a moment M is applied. The angle θ corresponds to the relative rotation of the beam and column at the connection. Therefore, the dominant in-plane behavior of a semirigid connection is represented by its moment–rotation (M – θ) relationship.

Shown in Figure 23.1 is the semirigid moment–rotation (M – θ) behavior of some common beam-to-column connections used in practice. It is obvious from the figure that the behavior of all types of connections falls in between the two extremes of ideally pinned and fully rigid connections.

FIGURE 23.2 Semirigid beam-to-column connections.

The single-angle connection and the weld flange plate with web-angle connection represent very flexible and rather rigid connections, respectively. Also, as shown in Figure 23.1, experimental tests have clearly demonstrated that there is a nonlinear relationship between M and θ for almost all types of connections over the entire loading range. The nonlinearity is mainly because a connection is an assemblage of several components that interact differently at different levels of applied loads. Material discontinuity of the connection subassemblage, local yielding of some components, local buckling of a plate element, and so on, all contribute to the nonlinearity. One of the primary obstacles to implementing semirigid framing in design practice is that the nonlinear M – θ relationship of semirigid connections complicates the evaluation of the structural response of semirigid frames.

The modeling of the M – θ relationship is a fundamental requirement for any consideration of the interaction of connection and member behavior. The most accurate and reliable knowledge of the behavior of a beam-to-column connection is obtained through experimental testing, but this technique is too expensive for design practice and is usually reserved for research purposes only. With the aim to incorporate connection behavior into structural analysis, connection behavior is generally simulated by means of a mathematical representation of the M – θ relationship. It is difficult to model this nonlinear relationship by rigorous and exact mathematical procedures and the connection behavior modeling in practical design is usually approximate in nature with drastic simplifications. Tests of prototype connections are commonly carried out to obtain actual moment–rotation behavior, which is then modeled approximately by means of different mathematical representation. The degree of the refinement of the mathematical representations of the M – θ relationship depends somewhat on the computational capabilities of available design aids.

23.3.1 Linear Model

The simplest connection model is the single-stiffness linear model that is expressed as follows:

$$M = R\theta \tag{23.1}$$

where M is the connection moment and R and θ are the stiffness and rotation of the connection, respectively.

The connection stiffness R in Equation 23.1 can be the initial connection rotational stiffness, R_i , as shown in Figure 23.3. Alternatively, a secant stiffness of the connection, R_s , which corresponds to a rotation of $\theta_0 (= M_u/R_i)$, can be determined from the initial stiffness R_i , the ultimate moment capacity M_u , and the moment–rotation curve of the connection. R_s is recommended instead of R_i as a representative connection

FIGURE 23.3 Various linear models for semirigid connection.

stiffness value because the initial stiffness of the connection does not represent connection response adequately.

To recognize the degradation of connection stiffness under increased load, the secant stiffness, R_b , determined in accordance with the so-called *beam line* method can be used in Equation 23.1. As shown in Figure 23.3, the beam line is defined as the straight line connecting two extreme connection conditions for a uniformly loaded beam, the end restrained moment when the connection is fully rigid and the end rotation when the connection is ideally pinned; that is, the rotation is zero for fully rigid end-connections with a resulting end-restrained moment of $wL^2/12$ and the moment is zero when the ends of the beam are pinned with resulting end rotation of $wL^3/24EI$. The connection stiffness R_b is then determined by the intersection of the beam line and moment–rotation curve of the connection. However, it is evident that the beam line does not represent the attainment of yield stress for any condition other than for a simply supported beam and a fixed ended beam, that is, the two end points of the line. To overcome this shortcoming, the bilinear model of the beam line [5] shown as the dashed line in Figure 23.3 can be used establish a connection stiffness R_B , which corresponds to an end rotation midway between pinned and fully fixed.

23.3.2 Polynomial Model

While the linear model in Equation 23.1 is simple and easy to use, it does not represent the true behavior of the connection. Bilinear and piecewise linear models have been proposed to provide a closer approximation of connection behavior. With the aim of providing a more accurate representation of nonlinear behavior of semirigid connections, nonlinear empirical models based on curve-fitting experimental results are widely employed to replicate and predict the nonlinear M – θ relationship of various types of beam-to-column connections. Shown in Equation 23.2 is an odd-power polynomial model [6]:

$$\theta = C_1(KM) + C_2(KM)^3 + C_3(KM)^5 \quad (23.2)$$

where θ is the connection rotation and M is the moment acting on the connection. Parameter K is a standardization factor determined by the connection type and geometry and C_1 , C_2 , and C_3 are curve-fitting constants obtained by using the method of least squares. The standardization factor and curve-fitting constants for various connections are shown in Table 23.1.

23.3.3 Three-Parameter Power Model

Chen and Kishi [7] adopted the power model developed by Richard and Abbott [8] to represent the moment–rotation characteristics of steel beam-to-column connections. The model is composed of three parameters: initial stiffness R_{ki} , ultimate moment capacity M_u , and a shape parameter n , and can be expressed as in Equation 23.3, taking the shape shown in Figure 23.4.

$$M = \frac{R_{ki}\theta}{\{1 + [\theta/\theta_0]^n\}^{1/n}} \quad (23.3)$$

where θ_0 is equal to M_u/R_{ki} is the reference plastic rotation. From Figure 23.4, it is recognized that the larger the shape parameter n the steeper the curve, which represents more rigid connections. The shape parameter n can be determined by using the least squares method applied to the differences between the predicted moments and the experimental test moments. The tangent connection stiffness R_{kt} and connection rotation can be determined from Equation 23.3 as follows:

$$R_{kt} = \frac{dM}{d\theta} = \frac{R_{ki}}{(1 + [\theta/\theta_0]^n)^{(n+1)/n}} \quad (23.4)$$

$$\theta = \frac{M}{R_{ki}(1 - [M/M_u]^n)^{1/n}} \quad (23.5)$$

TABLE 23.1 Curve-Fitting Constants and Standardization Constants for Polynomial Model (All Size Parameters are in Centimeters)

Connection types	Curve-fitting and standardization constants	
Single web-angle connection		$C_1 = 1.67 \times 10^0$ $C_2 = 8.56 \times 10^{-2}$ $C_3 = 1.35 \times 10^{-3}$ $K = d_a^{-2.4} t_c^{-1.81} g^{0.15}$
Double web-angle connection		$C_1 = 1.43 \times 10^{-1}$ $C_2 = 6.79 \times 10^1$ $C_3 = 4.09 \times 10^5$ $K = d_a^{-2.4} t_c^{-1.81} g^{0.15}$
Header plate connection		$C_1 = 6.14 \times 10^{-3}$ $C_2 = 1.08 \times 10^{-3}$ $C_3 = 6.05 \times 10^{-3}$ $K = t_p^{-1.6} g^{1.6} d_p^{-2.3} t_w^{-0.5}$
Top- and seat-angle connections		$C_1 = 2.59 \times 10^{-1}$ $C_2 = 2.88 \times 10^3$ $C_3 = 3.31 \times 10^4$ $K = d^{-1.5} t_a^{-0.5} l_a^{-0.7} d_b^{-1.1}$
Top- and seat-angle with double web-angle connection		$C_1 = 1.50 \times 10^{-3}$ $C_2 = 5.60 \times 10^{-3}$ $C_3 = 4.35 \times 10^{-3}$ $K = d^{-1.287} t_a^{-1.128} t_c^{-0.415} l_a^{-0.694} (g - 0.5 d_b)^{1.35}$
Extend end-plate connection without column stiffeners		$C_1 = 8.91 \times 10^{-1}$ $C_2 = -1.20 \times 10^4$ $C_3 = 1.75 \times 10^8$ $K = d_g^{-2.4} t_p^{-0.4} t_f^{-1.5}$
Extended end-plate connection with column stiffeners		$C_1 = 2.60 \times 10^{-1}$ $C_2 = 5.36 \times 10^2$ $C_3 = 1.31 \times 10^7$ $K = d_g^{-2.4} t_p^{-0.6}$
T-stub connection		$C_1 = 6.42 \times 10^{-2}$ $C_2 = 1.77 \times 10^2$ $C_3 = -2.03 \times 10^4$ $K = d^{-1.5} t^{-0.5} l_i^{-0.7} d_b^{-1.1}$

FIGURE 23.4 Three-parameter power model of semirigid connection.

Kishi and Chen [9] applied the model to four types of connections: single web-angle connections, double web-angle connections, top- and seat-angle connections, and top- and seat-angle with double web-angle connections. The detailed procedure to evaluate the three parameters R_{ki} , M_u , and n for the four types of connections is described by Chen and Lui [10].

23.3.4 Four-Parameter Power Model

As experimental tests have shown that many semirigid connections do not exhibit the plateau in their $M-\theta$ relationship shown in Figure 23.4 even at large rotation, the four-parameter power model shown in Equation 23.6 and Figure 23.5 has been adopted by a number of researchers [11–13] to simulate the nonlinear moment–rotation relationship of such connections:

$$M = \frac{(R_e - R_p)\theta}{\{1 + [(R_e - R_p)\theta/M_0]^n\}^{1/n}} + R_p\theta \tag{23.6}$$

where, as shown in Figure 23.5, R_e is the initial stiffness of the connection, R_p is the plastic stiffness of the connection, M_0 is a reference moment, and n is a shape parameter. One of the advantages of this model is that it can easily represent simpler models, such as the linear model by setting $R_e = R_p$ and the three-parameter power model by setting $R_p = 0$. The model also approaches a bilinear model when n becomes large.

23.3.5 Connection Database

The connection database considered herein is a collection of experimental test results for different types of steel beam-to-column connections. The data usually collected are the corresponding details and dimensions of the connection, fastener, and connected beam and column. The purpose of the connection database is to provide the necessary information for the determination of the moment–rotation characteristics of beam-to-column connections, which are often required by design standards in facilitating the analysis and design of semirigid framed structures.

As extensive tests had been previously conducted to investigate the moment–rotation characteristics of various types of connections, efforts to establish connection databases were initiated in 1980s. Goverhan [14] collected a total of 230 experimental moment–rotation curves and digitized them to form the corresponding database of connection behavior. Nethercot [15] conducted an extensive literature survey of more than 800 individual tests from over 70 studies. Kishi and Chen [16] expanded and extended Goverhan’s collection to a total 303 tests, which consisted of experimental data published from 1936 to 1985. After that, Kishi and his colleagues revised the database and appended 93 sets of experimental data published from 1986 to 1998.

FIGURE 23.5 Four-parameter power model of semirigid connection.

Three prediction moment–rotation equations were incorporated with Kishi and Chen’s database: the polynomial model shown in Equation 23.2, a modified exponential model [17], and the three-parameter power model shown in Equation 23.3. The validity of either the three-parameter power model or the modified experimental model for practical use was examined by Kishi et al. [18], who concluded that the three-parameter power model adequately describes the experimental test data for modeling the connection moment–rotation behavior for practical use.

23.3.6 Connection Classification

In practice, steel framed structures are to be designed in accordance with one of the three types of steel framing constructions: continuous construction, simple construction, and semirigid construction. Therefore, designers must be knowledgeable as to when the connections can be assumed to be rigid, semirigid, or flexible. The purpose of connection classification is to select a suitable basis on which to conduct the frame analysis and design. Based on the stiffness and strength of a connection, the connection can be classified as follows:

- *Stiffness criterion.* A connection is categorized as rigid, semirigid, and flexible based on the ratio of its rotational stiffness (R) to the stiffness of the beam (EI/L) it connects, RL/EI , where L and EI are the length and bending rigidity of the beam, respectively.
- *Strength criterion.* The most important aspect of the strength of a connection is its relationship to the strength of the connected beam. Based on comparison of the moment resistance (M_n) of a connection to the plastic moment resistance (M_p) of the beam it connects, the connection can be classified as a full strength, partial strength, or flexible connection.

Table 23.2 summarizes three classifications of connections presented by Bjorhovde et al. [19], Eurocode 3 [4], and LRFD [2] based on the foregoing criteria. The initial stiffness of the connection (R_i) was adopted in classifications by Bjorhovde et al. and Eurocode 3, while the secant stiffness of the connection (R_s) was used in the LRFD classification. As shown in Table 23.2, the secant stiffness, R_s , is defined on the basis of either the moment, M_s , or the rotation, θ_s , which would occur under the applied loads. The LRFD classification suggests that two distinct values of secant stiffness should be adopted to characterize the connection behavior under the two limit states of serviceability and ultimate load. The moment resistance of the connection, M_n , can be determined on the basis of an ultimate limit-state model of the connection or from tests. When a semirigid connection does not exhibit a plateau in its moment–rotation relationship, the moment resistance of the connection is defined at the rotation $\theta_n = 0.02$ radians [2,12,13,20].

In addition to the strength and stiffness of the connection, a third important characteristic that should be considered in connection classification is the ductility of the connection. Connection ductility

TABLE 23.2 Summary of Connection Classification Systems

Bjorhovde classification [19]	Eurocode 3 classification [4]	AISC LRFD classification [3]
Stiffness criterion		
<p>Rigid: $R_i \geq EI/2d$</p> <p>Semirigid: $EI/10d < R_i < EI/2d$</p> <p>Flexible: $EI/10d \geq R_i$</p>	<p>Rigid: $R_i/L/EI \geq 25$ (unbraced frame) $R_i/L/EI \geq 8$ (braced frame)</p> <p>Semirigid: $2 < R_i/L/EI < 20$ (unbraced frame) $2 < R_i/L/EI < 8$ (braced frame)</p> <p>Flexible: $R_i/L/EI \leq 2$</p>	<p>Rigid: $R_s/L/EI \geq 20$</p> <p>Semirigid: $2 < R_s/L/EI < 20$</p> <p>Flexible: $R_s/L/EI \leq 2$</p>
Strength criterion		
<p>Rigid: $M_n \geq 0.7M_p$</p> <p>Semirigid: $0.2M_p < M_n < 0.7M_p$</p> <p>Flexible: $M_n \leq 0.7M_p$</p> <p>$M' = M/M_p; \theta' = \theta/\theta_p$ $\theta_p = M_p/(EI/5d)$ $d = \text{depth of beam}$</p>	<p>Full strength: $M_n \geq M_p$</p> <p>Partial strength: $0.25M_p < M_n < M_p$</p> <p>Flexible: $M_n \leq 0.25M_p$</p> <p>$M^* = M/M_p; \theta^* = \theta/\theta_p$ $\theta_p = M_p/(EI/L)$</p>	<p>Full strength: $M_n \geq M_p$</p> <p>Partial strength: $0.2M_p < M_{n_{\theta=0.02}} < M_n < M_p$</p> <p>Flexible: $M_{n_{\theta=0.02}} \leq 0.2M_p$</p> <p>$M_{n_{\theta=0.02}}$ = moment resistance of the connection at a rotation of 0.02 radians</p>

is a key parameter when joint deformations are concentrated in the connection elements, as is the typical case for partial strength connections where the strength of the connected beam exceeds that of the connection. The connection ductility can be represented by its rotational capacity, θ_u , which is defined in the LRFD classification as the value at which the moment resistance of the connection has dropped to $0.8M_n$ or the connection has deformed beyond 0.03 radians. That is, a connection is classified as ductile if its rotation capacity is equal or greater than 0.03 radians, otherwise the connection is considered to be nonductile.

The difference between the LRFD and Eurocode 3 classifications is that the latter one acknowledges the fact that the extent of semirigid action is largely associated with the type of structure, such as a braced or unbraced frame. Therefore, in Eurocode 3 the connections are classified separately with regard to braced and unbraced frames. The Eurocode 3 classification considers the load-carrying capacity of frames, which is more rational. For example, the stiffness boundaries between the rigid and semirigid zones are chosen such that the drop in load carrying capacity, due to semirigid behavior, is not more than 5% (in terms of the Euler buckling load). However, the ductility demand is not considered in Eurocode 3.

As the purpose of connection classification is to facilitate frame design for different limit states, it is necessary that a classification system be able to reflect the connection assumptions used in the frame analysis and design at each limit state. To that purpose, the connections should be classified corresponding not only to the ultimate limit state but also to the serviceability limit state, as a connection may respond differently at the two different limit states.

23.4 Structural Analysis of Semirigid Framed Structures

The structural analysis procedures for semirigid frames presented in this section are based on the following assumptions and idealizations:

1. All members are prismatic and straight.
2. Only the moment–rotation behavior of connections is considered (i.e., axial and shear deformations in a connection are ignored).
3. Members display linear-elastic or second-order elastic behavior, while the connections display nonlinear moment–rotation behavior.
4. Connection dimensions are assumed to be negligible compared to the lengths of the beams and columns; that is, the rotational deformation of a connection is assumed to be concentrated at a point at the end of the semirigid member.
5. The effects of eccentricity at joints are neglected.

23.4.1 End-Fixity Factor of Semirigid Member

Shown in [Figure 23.6](#) is a semirigid member comprising a finite-length beam–column member with a zero-length rotational spring at each end (the symbol @ represents the spring). The connection flexibilities are modeled through rotational springs of stiffness R_1 and R_2 at the two ends of the beam. The relative stiffness of the beam–column member and the rotational end-spring connection is measured by an end-fixity factor defined as follows [21]:

$$r_j = \frac{1}{1 + 3EI/R_jL} \quad (j = 1, 2) \quad (23.7)$$

where R_j is the end-connection spring stiffness and EI/L is the flexural stiffness of the attached member. The fixity factor r_j defines the rotational stiffness of each end-connection relative to that of the attached member. For a pinned connection, the rotational stiffness of the connection is idealized as zero and thus the value of the end-fixity factor is zero ($r_j = 0$). For a rigid connection, the connection rotational stiffness is taken to be infinite and the end-fixity factor has a value of unity ($r_j = 1$). Therefore, a semirigid connection has an end-fixity factor between zero and one ($0 < r_j < 1$).

Upon the introduction of the end-fixity factor, different member-end restraint conditions, such as rigid–pinned, rigid–semirigid, pinned–semirigid, are readily modeled simply by setting the end-fixity factors at the two ends of the member to appropriate values. This comprehensive model of member end-rotational conditions can be employed for the analysis of frames with any combination of pinned, rigid, and semirigid connections.

The end-fixity factor also simplifies the analysis procedure for semirigid framed structures. [Figure 23.7](#) and [Figure 23.8](#) illustrate the variation of mid-span and end moments and mid-span deflection of a uniformly loaded semirigid beam versus the end-fixity factor. Comprehensive formulations for calculation of both end-reactions and span deflections in terms of end-fixity factors for a semirigid member under different types of loads are listed in [Table 23.3](#) and [Table 23.4](#). As will be

FIGURE 23.6 Model of semirigid member.

FIGURE 23.7 Moments of a uniformly loaded beam versus end-fixity factor.

FIGURE 23.8 Deflection of a uniformly loaded beam versus end-fixity factor.

demonstrated subsequently, the formulations of stiffness matrices and effective-length factors of beam-columns can all be expressed in terms of the end-fixity factors. The end-fixity factor has further value in design because it provides a physical interpretation of the extent of rigidity available in a connection. It also provides designers with a convenient way to compare the structural responses of a member with semirigid connections to that with rigid or pinned connections.

By Equation 23.7, the relationship between the end-fixity factor and the connection stiffness is nonlinear, as shown in Figure 23.9. It is observed from the figure that when the connection stiffness is large, very significant changes in stiffness produce only very small changes in the end-fixity factor. Consequently, from Figure 23.7 and Figure 23.8, such changes have a negligible influence on both moments and deflection of the beam. Conversely, from Figure 23.9, with low values of connection stiffness, small increases in the stiffness result in appreciable increases in the end-fixity factor. In this case, as Figure 23.7 and Figure 23.8 show, there is a considerable effect on the bending moments and the deflection. Thus, in practice, when a real pinned connection has some stiffness, a considerable restraining moment may develop to the benefit of the structure. At the other extreme, attempting to achieve further increase in connection stiffness beyond that of a nearly rigid connection is not efficient and economical because it involves only a small change in the end-fixity factor and, consequently, has little effect on the response of structure.

TABLE 23.3 End-Reactions of a Semirigid Member

Member span loads	Member end-reactions
	$M_1 = (wL^2/12)[3r_1(2 - r_2)/(4 - r_1 r_2)]$ $M_2 = (wL^2/12)[3r_2(2 - r_1)/(4 - r_1 r_2)]$ $V_1 = (M_1 + M_2)/L + wL/2$ $V_2 = -(M_1 + M_2)/L + wL/2$
	$M_1 = (wL^2/30)[r_1(7 - 4r_2)/(4 - r_1 r_2)]$ $M_2 = (wL^2/60)[r_2(16 - 7r_1)/(4 - r_1 r_2)]$ $V_1 = (M_1 + M_2)/L + wL/6$ $V_2 = -(M_1 + M_2)/L + wL/3$
	$M_1 = \frac{r_1}{4 - r_1 r_2} \left(\frac{L^2}{60} \right) (n - m) \{ w_a(2 + r_2) [3(n - m)^3 + 15m(n^2 + m^2)] + 10w_a(4 - r_2)(n + 2m) - 30w_a[(n + m)^2 + 2m^2] + w_b(2 + r_2) [3(m - n)^3 + 15n(m^2 + n^2)] + 10w_b(4 - r_2)(m + 2n) - 30w_b[(m + n)^2 + 2n^2] \}$ $M_2 = \frac{r_2}{4 - r_1 r_2} \left(\frac{L^2}{60} \right) (n - m) \{ w_a(2 + r_1) [3(n - m)^3 + 15m(n^2 + m^2)] - 20w_a(1 - r_1)(n + 2m) - 15r_1 w_a [(n + m)^2 + 2m^2] + w_b(2 + r_1) [3(m - n)^3 + 15n(m^2 + n^2)] - 20w_b(1 - r_1)(m + 2n) - 15r_1 w_b [(m + n)^2 + 2n^2] \}$ $V_1 = \frac{(M_1 + M_2)}{L} + \frac{(n - m)L}{6} [w_a(3 - 2m - n) + w_b(3 - m - 2n)]$ $V_2 = -\frac{(M_1 + M_2)}{L} + \frac{(n - m)L}{6} [w_a(2m + n) + w_b(m + 2n)]$
	$M_1 = \frac{r_1}{4 - r_1 r_2} m(1 - m)[2(2 - m) - r_2(1 + m)]PL$ $M_2 = -\frac{r_2}{4 - r_1 r_2} m(1 - m)[2(1 + m) - r_1(2 - m)]PL$ $V_1 = (M_1 + M_2)/L + P(1 - m)$ $V_2 = -(M_1 + M_2)/L + Pm$
	$M_1 = -\frac{r_1}{4 - r_1 r_2} [6(1 - m)^2 - 2 + r_2(3m^2 - 1)]M$ $M_2 = -\frac{r_2}{4 - r_1 r_2} [2(3m^2 - 1) - 3r_1(1 - m)^2 - r_1]M$ $V_1 = -V_2 = (M + M_1 + M_2)/L$

	$\delta_1(\xi) = \delta_M(\xi) + \frac{ML^2\xi}{6EI}(\xi^2 - 6m + 3m^2 + 2) \quad (0 \leq \xi \leq m)$ $\delta_2(\xi) = \delta_M(\xi) - \frac{ML^2(1 - \xi)}{6EI}[(1 - \xi)^2 + 3m^2 - 1] \quad (m < \xi \leq 1)$ $\delta_M(\xi) = \frac{M_1L^2\xi}{6EI}(1 - \xi)(2 - \xi) - \frac{M_2L^2\xi}{6EI}(1 - \xi^2)$

FIGURE 23.9 Relationship between connection stiffness and end-fixity factor.

23.4.2 Manual-Based Approximate Analysis of Semirigid Structures

For simple semirigid framed structures, analysis using the linear connection model defined by Equation 23.1, can be conducted manually as for rigid frames. In this section, a procedure based on a modified moment distribution method is presented for the analysis of semirigid continuous beams and braced frames.

Moment distribution is a method of successive approximations that may be carried out to any desired degree of accuracy. The convergence of the method is guaranteed for stable linear elastic structures under small deformations and displacements. Its primary advantage over other hand-calculation structural analysis procedures, such as the method of consistent deformations and the slope deflection method, is that it eliminates the requirement to solve a set of simultaneous equations to determine the member end moments for statically indeterminate beams or nonsway plane frames in which the joints are restrained against translation.

Upon the introduction of the end-fixity factor defined in Equation 23.7 to take into account semirigid connection behavior based on Equation 23.1, the analysis of semirigid continuous beams and frames can be conducted through minor modification of the conventional moment distribution method for rigid continuous beams and frames, as described in the following:

- *Sign convention.* All loads acting on the members in the mathematical model of a semirigid continuous beam or a plane frame are referenced to the individual local member coordinate system. As indicated in Figure 23.6, positive load acts downward and positive end moment and shear act counter-clockwise and upward, respectively.
- *Member end-reaction moments.* The end moments of a semirigid member due to different types of applied loads are listed in Table 23.3.
- *Member rotational stiffness factor K_{ij} .* For a semirigid member i , with different end-connection stiffnesses R_1 and R_2 determined by Equation 23.1, let the end-fixity factors defined in Equation 23.7 for the ends 1 and 2 be r_1 and r_2 , respectively. The end-stiffness factors K_{i1} and K_{i2} for the member can be expressed as

$$K_{i1} = \frac{3r_1}{4 - r_1r_2} \frac{4EI}{L} \quad (23.8a)$$

$$K_{i2} = \frac{3r_2}{4 - r_1r_2} \frac{4EI}{L} \quad (23.8b)$$

in which $3r_1/(4 - r_1r_2)$ and $3r_2/(4 - r_1r_2)$ are factors accounting for the end-connection flexibility.

- *Distribution factor D_{ij}* . The distribution factor is defined as the stiffness factor of the member divided by the sum of the stiffness factors of all members connecting at the joint,

$$D_{ij} = \frac{K_{ij}}{\sum_{i=1}^n K_{ij}} \quad (j = 1, 2) \quad (23.9)$$

This factor corresponds to the fraction of the total applied moments at a joint that will be resisted by any member i as the joint rotates through an angle ϕ , where n is the number of members connected at the joint.

- *Carry-over factor C_{ij}* . When a moment is applied to the near end of any member whose far end is restrained against rotation during the distribution process, a moment must be applied to the far end by the joint to resist rotation of the member end. This moment is called the carry-over moment and the ratio of the far-end moment to the near-end moment is known as the carry-over factor. The carry-over factors for a semirigid member i are

$$C_{i1} = 0.5r_2 \quad (23.10a)$$

$$C_{i2} = 0.5r_1 \quad (23.10b)$$

Implementation of the mathematical model of the moment distribution method for semirigid continuous beams, or semirigid braced frames in which the joints are restrained against translation, consists of the following steps:

1. Evaluate end-fixity factors r_1 and r_2 according to Equation 23.7 for each member for the given values of connection stiffness R_j ($j = 1, 2$). For cases of pinned and fixed-end connections, assign the end-fixity factor to zero and unity, respectively.
2. Calculate end-stiffness factors K_{ij} ($j = 1, 2$) according to Equations 23.8 for each member i and determine moment distribution factors D_{ij} from Equation 23.9.
3. Compute the end-reaction moments $M_{ij}^{(k)}$ ($j = 1, 2$) due to the applied loads for each member through Table 23.3, assuming that all joints are locked by fictitious rotation restraints, and set index $k = 0$.
4. Sum the member end moments at each joint to determine the unbalanced moment $M^{(k)} = -\sum M_{ij}^{(k)}$ there.
5. Release or “unlock” the joints by removing the fictitious rotation restraint at each joint in turn, assuming that the other joints are still restrained against rotation, and distribute the unbalanced moment at the joint to the near end of each connecting member as $M_{ij}^{(k+1)} = D_{ij} \times M^{(k)}$.
6. Carry the near-end moment of each member over to its other end by multiplying each moment with the carry-over factor, that is, $M_{i1}^{(k+1)} = C_{i2} \times M_{i2}^{(k+1)}$ or $M_{i2}^{(k+1)} = C_{i1} \times M_{i1}^{(k+1)}$.
7. If the unbalanced moment $M^{(k)}$ is small enough to be considered insignificant, then terminate the iteration and proceed to step 8; otherwise, set $k = k + 1$ and return to step 4.
8. Sum the end moments of each member. Calculate the axial forces (for nonsway frames) and the shear forces of the members satisfying equilibrium and determine the reaction forces and moments at the supports based on the joint equilibrium conditions.

EXAMPLE 23.1

For the three-span continuous beam shown in Figure 23.10, all of the end-connections are semirigid except for the connection at joint D, which is rigid ($r = 1$). The secant rotational stiffnesses of the semirigid connections associated with the serviceability and ultimate load states are 1.15×10^{10} and 5.75×10^9 N mm/rad, respectively. The beam is subjected to uniformly distributed dead and live loads, 3.2 and 12.0 kN/m, respectively. The beam is laterally braced and has a W410 \times 39 section with cross-sectional properties $I_x = 126 \times 10^6$ mm⁴ and $Z_x = 730 \times 10^3$ mm³. The yield stress F_y and elastic modulus E of the steel are 345 MPa and 2.0×10^5 MPa, respectively. It is required to employ the modified moment distribution method for semirigid continuous beams to determine the bending moment distribution

FIGURE 23.10 Example 1: three-span semirigid continuous beam.

of the structure and to then check if the flexural strength of the beam is adequate based on LRFD [2]. The mid-span deflection of the beam due to the service load is required to be less than or equal to $L/240$.

For the ultimate load state and connection stiffness 5.75×10^9 N mm/rad, the values of the corresponding end-fixity factor for beams 1 and 3 of length $L = 9000$ mm are

$$r_{1A} = r_{1B} = r_{3C} = \frac{1}{1 + 3EI/RL} = \frac{1}{1 + (3 \times 200 \times 10^3 \times 126 \times 10^6)/(5.75 \times 10^9 \times 9000)} = 0.406$$

and $r_{3D} = 1.0$.

For beam 2, $L = 10,000$ mm

$$r_{2B} = r_{2C} = \frac{1}{1 + 3EI/RL} = \frac{1}{1 + (3 \times 200 \times 10^3 \times 126 \times 10^6)/(5.75 \times 10^9 \times 10,000)} = 0.432$$

Carry-over factors for the beams are

$$C_{1A} = 0.406/2 = 0.203, \quad C_{2B} = C_{2C} = 0.432/2 = 0.216, \quad C_{3D} = 1.0/2 = 0.5$$

Stiffness factors K_{1B} and K_{3C} for beams 1 and 3 are

$$K_{1B} = \frac{3r_{1B}}{4 - r_{1A}r_{1B}} \cdot \frac{4EI}{L} = \frac{3 \times 0.406}{4 - 0.406^2} \cdot \frac{4EI}{9000} = 1.411 \times 10^{-4}EI/\text{mm}$$

$$K_{3C} = \frac{3r_{3C}}{4 - r_{3C}r_{3D}} \cdot \frac{4EI}{L} = \frac{3 \times 0.406}{4 - 0.406 \times 1.0} \cdot \frac{4EI}{9000} = 1.506 \times 10^{-4}EI/\text{mm}$$

Stiffness factors K_{2B} and K_{2C} for beam 2 are

$$K_{2B} = K_{2C} = \frac{3r_{2B}}{4 - r_{2B}r_{2C}} \cdot \frac{4EI}{L} = \frac{3 \times 0.432}{4 - 0.432^2} \cdot \frac{4EI}{10,000} = 1.359 \times 10^{-4}EI/\text{mm}$$

At joint B, the distribution factors for beams 1 and 2 are

$$DF_{1B} = \frac{K_{1B}}{K_{1B} + K_{2B}} = \frac{1.411 \times 10^{-4}EI/\text{mm}}{1.411 \times 10^{-4}EI/\text{mm} + 1.359 \times 10^{-4}EI/\text{mm}} = 0.509$$

$$DF_{2B} = 1 - DF_{1B} = 1 - 0.509 = 0.491.$$

At joint C, the distribution factors for beams 2 and 3 are

$$DF_{2C} = \frac{K_{2C}}{K_{2C} + K_{3C}} = \frac{1.359 \times 10^{-4}EI/\text{mm}}{1.359 \times 10^{-4}EI/\text{mm} + 1.506 \times 10^{-4}EI/\text{mm}} = 0.474$$

$$DF_{3C} = 1 - DF_{2C} = 1 - 0.474 = 0.526.$$

The uniformly distributed factored load of the beam is

$$w_f = 1.2 \text{ dead load} + 1.6 \text{ live load} = 1.2 \times 3.2 \text{ kN/m} + 1.6 \times 12 \text{ kN/m} = 23.04 \text{ kN/m}$$

From Table 23.3, the end-reaction moments of the beams associated with the factored load are

$$M_{1A}^{(0)} = -M_{1B}^{(0)} = \frac{wL^2}{12} \cdot \frac{3r_{1A}(2 - r_{1B})}{4 - r_{1A}r_{1B}} = \frac{23.04(9)^2}{12} \cdot \frac{3 \times 0.406(2 - 0.406)}{4 - 0.406^2} = 78.73 \text{ kN m}$$

End-reaction moments of beam 2 due to the load are

$$M_{2B}^{(0)} = -M_{2C}^{(0)} = \frac{wL^2}{12} \cdot \frac{3r_{2B}(2 - r_{2C})}{4 + r_{2B}r_{2C}} = \frac{23.04(10)^2}{12} \cdot \frac{3 \times 0.432(2 - 0.432)}{4 - 0.432^2} = 102.32 \text{ kN m}$$

End-reaction moments of beam 3 due to the load are

$$M_{3C}^{(0)} = \frac{wL^2}{12} \cdot \frac{3r_{3C}(2 - r_{3D})}{4 + r_{3C}r_{3D}} = \frac{23.04(9)^2}{12} \cdot \frac{3 \times 0.406(2 - 1)}{4 - 0.406 \times 1} = 52.71 \text{ kN m}$$

$$M_{3D}^{(0)} = \frac{wL^2}{12} \cdot \frac{3r_{3D}(2 - r_{3C})}{4 + r_{3C}r_{3D}} = \frac{23.04(9)^2}{12} \cdot \frac{3 \times 1(2 - 0.406)}{4 - 0.406 \times 1} = -206.93 \text{ kN m}$$

The modified moment distribution is conducted as shown in Table 23.5 and the final moment distribution of the beam is shown in Figure 23.10. The maximum span moment of Beam 2 is 201.09 kN m, which is located 5.06 m from joint B. The maximum negative moment at joint D is 193.08 kN m. Since the beam is laterally braced and W410 × 39 is a compact section, the flexural strength of the beam based on LRFD [2] is

$$M_r = \phi_b M_p = 0.9 Z_x F_y = 0.9 \times 730 \times 10^3 \text{ mm}^3 \times 345 \text{ MPa} \times 10^{-6} = 226.67 \text{ kN m} > 201.09 \text{ kN m}$$

Therefore, the flexural strength of the beam is adequate.

To calculate the mid-span deflection of Beam 2 due to the service load $w = 3.2 \text{ kN/m} + 12.0 \text{ kN/m} = 15.2 \text{ kN/m}$, and the connection rotational stiffness $R = 1.15 \times 10^{10} \text{ N mm/rad}$, the corresponding end-fixity factors of the beam are

$$r_{1A} = r_{1B} = r_{3C} = 0.578, \quad r_{3D} = 1.0, \quad \text{and} \quad r_{2B} = r_{2D} = 0.603$$

Following the foregoing procedure, the final moments obtained by the modified moment distribution at joints B and C are $M_{2B} = 81.67 \text{ kN m}$ and $M_{2B} = -73.04 \text{ kN m}$.

TABLE 23.5 Moment Distribution of Three-Span Semirigid Continuous Beam

Joint	A		B		C		D

Therefore, the mid-span deflection of beam 2 can be obtained from the deflection equation shown in Table 23.4 as

$$\begin{aligned}
 |\delta(\xi)| &= \left| \left[\frac{M_1 L^2 \xi}{6EI} (1 - \xi)(2 - \xi) - \frac{M_2 L^2 \xi}{6EI} (1 - \xi^2) - \frac{wL^4 \xi}{24EI} (\xi^3 - 2\xi^2 + 1) \right]_{\xi=0.5} \right| \\
 &= \left| \frac{81.67 \times 10^6 \times 10,000^2 \times 0.5}{6 \times 200 \times 10^3 \times 126 \times 10^6} \times (1 - 0.5)(2 - 0.5) - \frac{-73.04 \times 10^6 \times 10,000^2 \times 0.5}{6 \times 200 \times 10^3 \times 126 \times 10^6} (1 - 0.5^2) \right. \\
 &\quad \left. - \frac{15.2 \times 10,000^4 \times 0.5}{24 \times 200 \times 10^3 \times 126 \times 10^6} (0.5^3 - 2 \times 0.5^2 + 1) \right| \\
 &= |-40.2 \text{ mm}| = 40.2 \text{ mm} < \frac{L}{240} = \frac{10,000}{240} = 41.7 \text{ mm}
 \end{aligned}$$

EXAMPLE 23.2

A one-storey two-bay semirigid braced frame of a low-rise building is shown in Figure 23.11. The spacing between the frames is 10 m. The roof dead load is 1.25 kN/m² and the snow load is 1.82 kN/m². The secant stiffness of the beam-to-column connections obtained from experimental tests associated with the connection rotation $\theta = 0.02$ radians are 2.8×10^{10} N mm/rad and 1.7×10^{10} N mm/rad for beams BC and CE, respectively. The rotational stiffnesses of the column bases are 3.0×10^9 N mm/rad for columns AB and DC and 1.75×10^9 N mm/rad for column EF. The diagonal bracing is to be designed as a tension-only member with pinned ends. It is required to find the bending moment distribution of the frame and axial loads of the columns for the load case of dead load plus live load by using the modified moment distribution method.

Load calculation:

The uniformly distributed nominal dead load is $10 \text{ m} \times 1.25 \text{ kN/m}^2 = 12.5 \text{ kN/m}$
 The uniformly distributed nominal snow load is $10 \text{ m} \times 1.82 \text{ kN/m}^2 = 18.2 \text{ kN/m}$
 Gravity load case (dead load + snow load):

$$w = 1.2D + 1.6L = 1.2 \times 12.5 + 1.6 \times 18.2 = 44.12 \text{ kN/m}$$

Properties of cross-sections:

Beam: W530 × 85, $I_{bx} = 485 \times 10^6 \text{ mm}^4$; Column: W250 × 33, $I_{cx} = 48.9 \times 10^6 \text{ mm}^4$

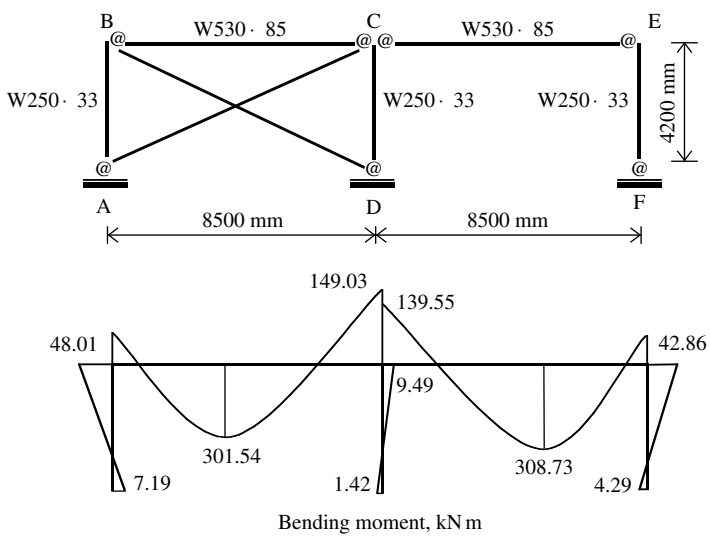

FIGURE 23.11 Example 2: two-bay semirigid braced frame.

End-fixity factor r of beams:

$$r_{BC} = r_{CB} = \frac{1}{1 + (3EI_{bx}/RL)} = \frac{1}{1 + \frac{3(200 \times 10^3)485 \times 10^6}{(2.8 \times 10^{10})8500}} = 0.45$$

$$r_{CE} = r_{EC} = \frac{1}{1 + (3EI_{bx}/RL)} = \frac{1}{1 + \frac{3(200 \times 10^3)485 \times 10^6}{(1.7 \times 10^{10})8500}} = 0.332$$

Carry-over factor for beams:

$$C_{BC} = C_{CB} = r_{BC}/2 = 0.45/2 = 0.225 \quad \text{and} \quad C_{CE} = C_{EC} = r_{CE}/2 = 0.332/2 = 0.166$$

End-fixity factor r of columns:

$$r_{AB} = r_{DC} = \frac{1}{1 + 3EI_{cx}/RL} = \frac{1}{1 + \frac{3(200 \times 10^3)48.9 \times 10^6}{(3 \times 10^9)4200}} = 0.30$$

$$r_{FE} = \frac{1}{1 + 3EI_{cx}/RL} = \frac{1}{1 + \frac{3(200 \times 10^3)48.9 \times 10^6}{(1.75 \times 10^9)4200}} = 0.20$$

$$r_{BA} = r_{CD} = r_{EF} = 1.0$$

Carry over factor for columns:

$$C_{BA} = C_{CD} = r_{AB}/2 = 0.30/2 = 0.15, \quad C_{EF} = r_{FE}/2 = 0.20/2 = 0.10$$

Member stiffness factor:

Beams:

$$K_{BC} = K_{CB} = \frac{3r_{BC}}{4 - r_{BC}r_{CB}} \times \frac{4EI}{L} = \frac{3 \times 0.45}{4 - 0.45^2} \times \frac{4E(485 \times 10^6)}{8500} = 81,137E \times \text{mm}^3$$

$$K_{CE} = K_{EC} = \frac{3r_{CE}}{4 - r_{CE}r_{DE}} \times \frac{4EI}{L} = \frac{3 \times 0.332}{4 - 0.332^2} \times \frac{4E(485 \times 10^6)}{8500} = 58,441E \times \text{mm}^3$$

Columns:

$$K_{AB} = K_{DC} = \frac{3r_{AB}}{4 - r_{AB}r_{BA}} \times \frac{4EI}{L} = \frac{3 \times 0.3}{4 - 1 \times 0.3} \times \frac{4E(485 \times 10^6)}{4200} = 11,328E \times \text{mm}^3$$

$$K_{BA} = K_{CD} = \frac{3r_{BA}}{4 - r_{BA}r_{AB}} \times \frac{4EI}{L} = \frac{3 \times 1.0}{4 - 1.0 \times 0.30} \times \frac{4E(48.9 \times 10^6)}{4200} = 37,761E \times \text{mm}^3$$

$$K_{EF} = \frac{3r_{EF}}{4 - r_{EF}r_{FE}} \times \frac{4EI}{L} = \frac{3 \times 1.0}{4 - 1.0 \times 0.20} \times \frac{4E(48.9 \times 10^6)}{4200} = 36,767E \times \text{mm}^3$$

$$K_{FE} = \frac{3r_{FE}}{4 - r_{FE}r_{EF}} \times \frac{4EI}{L} = \frac{3 \times 0.2}{4 - 1.0 \times 0.20} \times \frac{4E(48.9 \times 10^6)}{4200} = 7353.4E \times \text{mm}^3$$

Distribution factor:

Joint B:

$$DF_{BA} = \frac{K_{BA}}{K_{BA} + K_{BC}} = \frac{37,761E \times \text{mm}^3}{37,761E \times \text{mm}^3 + 81,137E \times \text{mm}^3} = 0.318 \quad \text{and} \quad DF_{BC} = 1 - 0.318 = 0.682$$

Joint C:

$$DF_{CB} = \frac{K_{CB}}{K_{CB} + K_{CD} + K_{CE}} = \frac{81,136E \times \text{mm}^3}{81,136E \times \text{mm}^3 + 37,761E \times \text{mm}^3 + 58,441E \times \text{mm}^3} = 0.458$$

$$DF_{CE} = \frac{K_{CE}}{K_{CB} + K_{CD} + K_{CE}} = \frac{58,441E \times \text{mm}^3}{81,136E \times \text{mm}^3 + 37,761E \times \text{mm}^3 + 58,441E \times \text{mm}^3} = 0.330$$

$$DF_{CD} = 1 - 0.457 - 0.330 = 0.212$$

Joint E:

$$DF_{EC} = \frac{K_{EC}}{K_{EC} + K_{EF}} = \frac{58441E \times \text{mm}^3}{58441E \times \text{mm}^3 + 36767E \times \text{mm}^3} = 0.614$$

$$DF_{EF} = 1 - 0.614 = 0.386$$

End moments of the beams under the gravity load:

$$M_{BC}^{(0)} = -M_{CB}^{(0)} = \frac{wL^2}{12} \cdot \frac{3r_{BC}(2 - r_{CB})}{4 - r_{BC}r_{CB}} = \frac{44.12(8.5)^2}{12} \cdot \frac{3 \times 0.45(2 - 0.45)}{4 - 0.45^2} = 146.37 \text{ kN m}$$

$$M_{CE}^{(0)} = -M_{EC}^{(0)} = \frac{wL^2}{12} \cdot \frac{3r_{CE}(2 - r_{EC})}{4 - r_{CE}r_{EC}} = \frac{44.12(8.5)^2}{12} \cdot \frac{3 \times 0.332(2 - 0.332)}{4 - 0.332^2} = 113.46 \text{ kN m}$$

Following the procedure for the modified moment distribution method, the detailed moment distribution process is shown in Table 23.6 and the final moment distribution of the frame under the gravity loads is shown in Figure 23.11. It can be seen from Figure 23.11 that the bending moment is not distributed symmetrically due to the differences in connection stiffness between the two bays. The maximum span moment for beam BC is located 4.01 m from joint B with a value of 296.25 kN m, while the maximum span for beam CE is located 4.51 m from joint C with a value of 309.10 kN m. The axial loads in the columns are found as

$$P_{fAB} = \frac{wL}{2} + \frac{M_{BC} + M_{CB}}{L} = \frac{44.12 \times 8.5}{2} + \frac{48.01 - 149.03}{8.5} = 175.63 \text{ kN}$$

$$P_{fDC} = wL - \frac{M_{BC} + M_{CB}}{L} + \frac{M_{CE} + M_{EC}}{L} = 44.12 \times 8.5 - \frac{48.01 - 149.03}{8.5} + \frac{139.55 - 42.86}{8.5}$$

$$= 398.28 \text{ kN}$$

$$P_{fDC} = \frac{wL}{2} - \frac{M_{CE} + M_{EC}}{L} = \frac{44.12 \times 8.5}{2} - \frac{139.55 - 42.86}{8.5} = 176.13 \text{ kN}$$

23.4.3 First-Order Nonlinear Analysis of Semirigid Framed Structures

Computer-based analysis of semirigid framed structures can be generally achieved by modifying existing programs of rigid frame analysis in one of two ways. The first method introduces additional “connection elements” that model the beam-to-column connections, while the second method modifies the member stiffness matrix to account for the connection flexibility. The application of the first approach is limited to only computer-based analysis and design and is inconvenient for practical use because the beam-column members are separated from the attached end-connections. Therefore, the second approach is considered to be more general as the analysis and design of such structures can also be facilitated

manually. Most research and engineering applications have adopted the second approach as the means to incorporate semirigid connection behavior into frame analysis and design.

The implementation of the concept of end-fixity factor into frame analysis is straightforward. For an existing rigid frame analysis computer program, only minor modifications to the member stiffness matrix and the evaluation of member end-reactions due to applied member loads are required. The elastic stiffness matrix of a member i with two semirigid end-connections having stiffness moduli R_1 and R_2 , as shown in Figure 23.6, can be represented by the stiffness matrix for the member taken to have rigid end-connections modified by a correction matrix [21]; that is

$$\mathbf{K}_i^{\text{SR}} = \mathbf{S}_i \cdot \mathbf{C}_{e-i} \quad (23.11)$$

where \mathbf{K}_i^{SR} is the stiffness matrix of member i with semirigid end-connections taken into account, \mathbf{S}_i is the stiffness matrix of the member taken to have rigid ends, and \mathbf{C}_{e-i} is the required correction matrix. For a planar beam-column element with six degrees of freedom, the matrices \mathbf{S}_i and \mathbf{C}_{e-i} have the following form:

$$\mathbf{S}_i = \begin{bmatrix} \frac{EA}{L} & 0 & 0 & \frac{-EA}{L} & 0 & 0 \\ & \frac{12EI}{L^3} & \frac{6EI}{L^2} & 0 & \frac{-12EI}{L^3} & \frac{6EI}{L^2} \\ & & \frac{4EI}{L} & 0 & \frac{-6EI}{L^2} & \frac{2EI}{L} \\ & & & \frac{EA}{L} & 0 & 0 \\ \text{sym} & & & & \frac{12EI}{L^3} & \frac{-6EI}{L^2} \\ & & & & & \frac{4EI}{L} \end{bmatrix} \quad (23.12)$$

$$\mathbf{C}_{e-i} = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & \frac{4r_2 - 2r_1 + r_1 r_2}{4 - r_1 r_2} & \frac{-2Lr_1(1 - r_2)}{4 - r_1 r_2} & 0 & 0 & 0 \\ 0 & \frac{6(r_1 - r_2)}{L(4 - r_1 r_2)} & \frac{3r_1(2 - r_2)}{4 - r_1 r_2} & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & \frac{4r_1 - 2r_2 + r_1 r_2}{4 - r_1 r_2} & \frac{2Lr_2(1 - r_1)}{4 - r_1 r_2} \\ 0 & 0 & 0 & 0 & \frac{6(r_1 - r_2)}{L(4 - r_1 r_2)} & \frac{3r_2(2 - r_1)}{4 - r_1 r_2} \end{bmatrix} \quad (23.13)$$

where E is elastic modulus and L , A , and I are the length, cross-sectional area, and moment of inertia of the member, respectively. The end-fixity factors r_1 and r_2 in Equation 23.13 are defined by Equation 23.7. Knowing the semirigid beam-column member stiffness matrix from Equation 23.11 for specified values of end-fixity factors reflecting connection stiffness, the analysis of frames with semirigid connections can then be carried out directly using the conventional displacement method.

To take into account the nonlinear behavior of semirigid connections, an iterative procedure is applied to obtain the solution. In each iteration, the member stiffness matrix \mathbf{K}_i^{SR} is modified using the correction matrix \mathbf{C}_{e-i} with updated end-fixity factors r . In addition, when there are member loads on semirigid members, the equivalent joint loads that facilitate matrix analysis of the structure are updated since member end-reactions are also functions of the end-fixity factors. The secant-stiffness-based iterative procedure for the first-order analysis of semirigid frameworks accounting for the nonlinear

behavior of connections defined by Equation 23.6 is described in the following [where subscript j ($j = 1, 2$) denotes the two ends of semirigid member i]:

- Step 1. Input data, including the nonlinear parameters and initial stiffness R_e defining the specified connections in the connection database. Set the iteration index $k = 0$ and assign connection stiffness $R_{ij}^{(k)} = R_e$.
- Step 2. For each beam-column element i , update the end-fixity factors r_{ij} through Equation 23.7 and compute the corresponding equivalent joint loads. Generate the correction matrix C_{e-i} and member stiffness matrix K_i^{SR} through Equations 23.13 and 23.11, respectively.
- Step 3. Assemble the structure stiffness matrix and solve for the nodal displacements, member forces, and connection moments $M_{ij}^{(k)}$.
- Step 4. Calculate connection rotations $\theta_{ij}^{(k)} = M_{ij}^{(k)} / R_{ij}^{(k)}$ and obtain the corresponding moments $M(\theta_{ij}^{(k)})$ from Equation 23.6.
- Step 5. Check convergence by comparing the connection moments $M_{ij}^{(k)}$ obtained through analysis with the moments $M(\theta_{ij}^{(k)})$ calculated in Step 4; if $|M_{ij}^{(k)} - M(\theta_{ij}^{(k)})| \leq \varepsilon$ (a predefined tolerance), then stop; otherwise, go to Step 6.
- Step 6. Update connection secant stiffnesses $R_{ij}^{(k)} = M(\theta_{ij}^{(k)}) / \theta_{ij}^{(k)}$ and iteration index $k = k + 1$, and return to Step 2.

23.4.4 Second-Order Nonlinear Analysis of Semirigid Framed Structures

The stability of framed structures has long been a concern in the design of such structures. In current design practice, this concern can be addressed by performing the so-called second-order $P-\Delta$ analysis for frames. Unlike the first-order elastic analysis, in which the equilibrium and kinematic relationships of a frame are established with respect to the undeformed geometry of the structure, the second-order elastic analysis is associated with the interaction between forces and deformation of the structure. For that reason, the second-order elastic analysis is referred to as geometrical nonlinear analysis. By inducing additional stresses in the members and by causing the frame members to deform more, the second-order effects ($P-\Delta$ and $P-\delta$), have a destabilizing effect on the structure. For rigid frames, the computer-based second-order elastic analysis is often pursued as an iterative procedure and the stiffness matrix of each member i with rigid ends is expressed as

$$K_i = S_i + G_i \quad (23.14)$$

where S_i is the elastic stiffness matrix and is as shown in Equation 23.12 and G_i is the geometrical stiffness matrix that accounts for the second-order effects and is expressed as

$$G_i = \frac{N}{L} \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ & \frac{6}{5} & \frac{L}{10} & 0 & -\frac{6}{5} & \frac{L}{10} \\ & & \frac{2L^2}{15} & 0 & -\frac{L}{10} & -\frac{L^2}{30} \\ & & & 0 & 0 & 0 \\ \text{sym.} & & & & \frac{6}{5} & -\frac{L}{10} \\ & & & & & \frac{2L^2}{15} \end{bmatrix} \quad (23.15)$$

where N is the axial force in the member (positive when the member is in tension).

Knowing that semirigid frames are more flexible than conventional rigid frames, the stability of semirigid frames becomes even more a concern in the design of such structures. Together with consideration of the nonlinear behavior of connections, the analysis of semirigid frames requires both geometrical nonlinearity (second-order) and material nonlinearity (semirigid connection behavior)

effects to be taken into account. The semirigid member stiffness matrices for second-order elastic analysis can be obtained by modifying the corresponding stiffness matrices of rigid members as follows [22]:

$$\mathbf{K}_i^{\text{SR}} = \mathbf{S}_i \mathbf{C}_{e-i} + \mathbf{G}_i \mathbf{C}_{g-i} \quad (23.16)$$

where the matrices \mathbf{S}_i , \mathbf{C}_{e-i} and \mathbf{G}_i are as defined in Equations 23.12, 23.13, and 23.15, respectively, and \mathbf{C}_{g-i} is the correction matrix for the geometrical stiffness of the semirigid member and is expressed as

$$\mathbf{C}_{g-i} = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & G_{32} & G_{33} & 0 & G_{35} & G_{36} \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & G_{62} & G_{63} & 0 & G_{65} & G_{66} \end{bmatrix} \quad (23.17)$$

where

$$G_{32} = -G_{35} = \frac{-4}{5L(4 - r_1 r_2)^2} (8r_1^2 r_2 - 13r_1 r_2^2 - 32r_1^2 - 8r_2^2 + 25r_1 r_2 + 20)$$

$$G_{33} = \frac{r_1}{5(4 - r_1 r_2)^2} (16r_2^2 + 25r_1 r_2^2 - 96r_1 r_2 + 128r_1 - 28r_2)$$

$$G_{36} = \frac{4r_2}{5(4 - r_1 r_2)^2} (16r_1^2 - 5r_1^2 r_2 + 9r_1 r_2 - 28r_1 + 8r_2)$$

$$G_{62} = -G_{65} = \frac{-4}{5L(4 - r_1 r_2)^2} (8r_1 r_2^2 - 13r_1^2 r_2 - 32r_2^2 - 8r_1^2 + 25r_1 r_2 + 20)$$

$$G_{63} = \frac{4r_1}{5(4 - r_1 r_2)^2} (16r_2^2 - 5r_1 r_2^2 + 9r_1 r_2 + 8r_1 - 28r_2)$$

$$G_{66} = \frac{r_2}{5(4 - r_1 r_2)^2} (16r_1^2 + 25r_1^2 r_2 - 96r_1 r_2 - 28r_1 + 128r_2)$$

in which r_1 and r_2 are end-fixity factors of the member as defined by Equation 23.7 and L is the length of the member.

Since the correction matrices \mathbf{C}_{e-i} and \mathbf{C}_{g-i} that take into account the semirigid connection behavior are in terms of end-fixity factors instead of connection stiffness, the stiffness matrix \mathbf{K}_i^{SR} applies to a beam-column member with any combination of pinned, semirigid, and rigid connections.

The secant-stiffness-based iterative procedure for the second-order analysis of semirigid frames, with nonlinear behavior of connections taken into account, is readily developed through modification of the first-order analysis procedure as described in the following:

- Step 1. Input the data, including the parameters for the specified connections from Equation 23.6. Set the iteration index $k=0$, assign connection stiffnesses $R_{ij}^{(k)} = R_e$, and set member axial forces $N_i^{(k)} = 0$. Generate elastic stiffness matrix from Equation 23.12 for each member.
- Step 2. Set iteration index $k = k + 1$, update the end-fixity factors r_{ij} using Equation 23.7 for each semirigid member i ; evaluate member equivalent joint loads; calculate the correction matrices \mathbf{C}_{e-i} and \mathbf{C}_{g-i} by Equations 23.13 and 23.17, respectively. Evaluate geometrical stiffness matrix \mathbf{G}_i based on Equation 23.15 and the axial force $N_i^{(k-1)}$ from the previous iteration. Generate the member stiffness matrix \mathbf{K}_i^{SR} according to Equation 23.16 for each semirigid member.
- Step 3. Assemble the structure stiffness matrix and solve for nodal displacements, member axial forces $N_i^{(k)}$, and connection moments $M_{ij}^{(k)}$.
- Step 4. Calculate connection rotations $\theta_{ij}^{(k)} = M_{ij}^{(k)} / R_{ij}^{(k)}$ and obtain the corresponding moments $M(\theta_{ij}^{(k)})$ from Equation 23.6.

- Step 5. Check for convergence for specified tolerances ϵ_1 and ϵ_2 by comparing the connection moments $M_{ij}^{(k)}$ obtained through analysis with the moments $M(\theta_{ij}^{(k)})$ calculated in Step 23.4 and by also comparing the member axial forces $N_i^{(k)}$ with the forces $N_i^{(k-1)}$ from the previous iteration; if $|M_{ij}^{(k)} - M(\theta_{ij}^{(k)})| \leq \epsilon_1$ and $|N_i^{(k)} - N_i^{(k-1)}| \leq \epsilon_2$, then stop; otherwise, go to Step 6.
- Step 6. Update connection secant stiffness $R_{ij}^{(k)} = M(\theta_{ij}^{(k)})/\theta_{ij}^{(k)}$ and go back to Step 2.

With the adoption of the end-fixity factor defined in Equation 23.7 and the member stiffness matrix Equation 23.16 accounting for both second-order effects and semirigid connection behavior, it is a straightforward matter to modify linear elastic analysis computer programs for rigid frames to perform second-order analysis of semirigid frames. Figure 23.12 illustrates a program flow chart for the second-order analysis of semirigid frames.

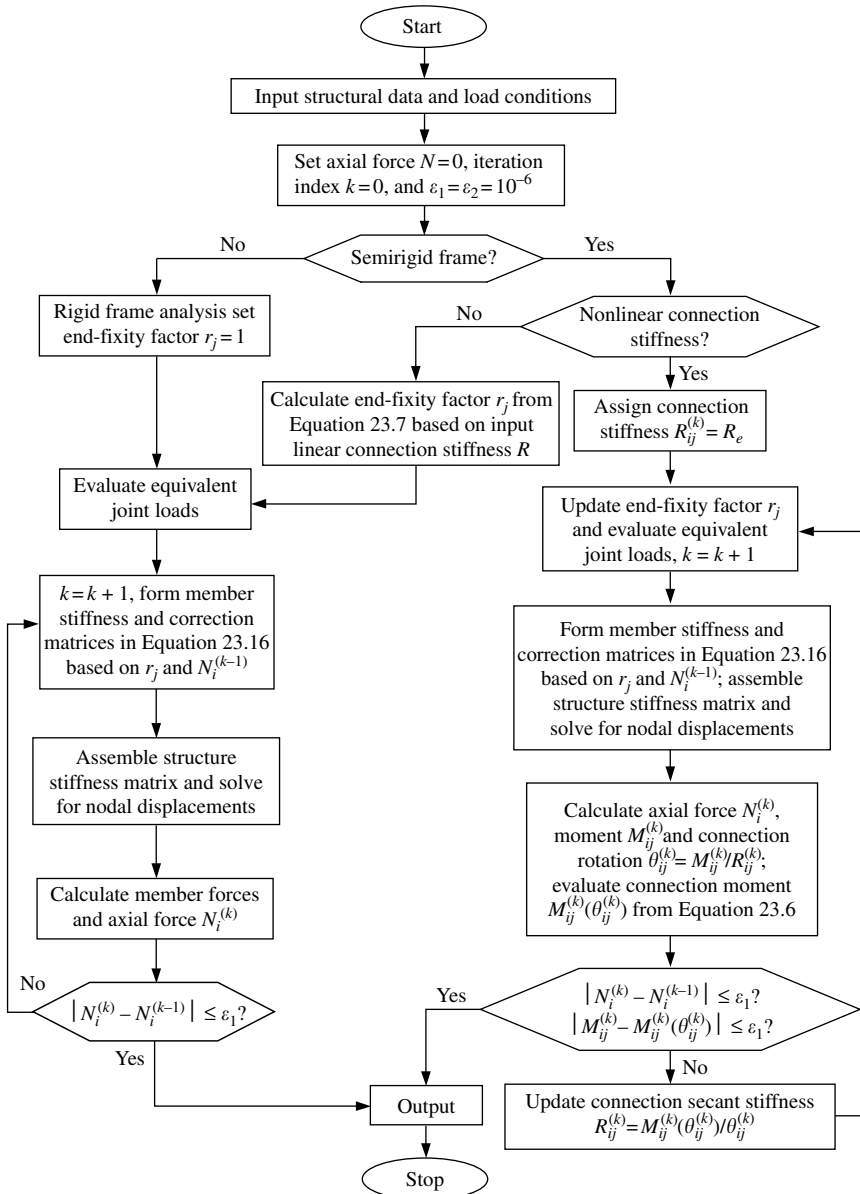

FIGURE 23.12 Flowchart of second-order semirigid frame elastic analysis.

23.4.5 Modification of Column Effective-Length Factor

The determination of column strength is of primary importance in the design of framed structures. The strength and stability of a frame and its columns are interrelated. The effective-length concept for evaluating column strength in rigid frames used to be the primary method to evaluate the stability of columns of frames. According to this concept, the strength of a column is evaluated from that of an equivalent pinned member of length KL , subject to axial load only, by means of a so-called K factor found as

$$K = \sqrt{\frac{P_e}{P_{cr}}} \quad (23.18)$$

where $P_e = \pi^2 EI/L^2$ is the Euler buckling load of the pinned-end column, in which L is the length of the column and I is the moment of inertia of the column section about the axis of bending, and P_{cr} is the buckling load of the end-restrained column. For a laterally braced semirigid column, the corresponding effective-length factor based on Newmark's approximation [23] can be expressed in terms of column end-fixity factors r_1 and r_2 defined in Equation 23.7 as

$$K = \sqrt{\frac{[\pi^2(1-r_1) + 6r_1] \times [\pi^2(1-r_2) + 6r_2]}{[\pi^2(1-r_1) + 12r_1] \times [\pi^2(1-r_2) + 12r_2]}} \quad (23.19)$$

Equation 23.19 yields K factor values having a maximum error of less than 4% compared to corresponding theoretically correct values.

The effective-length factor concept is considered to be an essential part of many analysis procedures, and a corresponding alignment chart approach is recommended by almost all current design standards [1-4]. The idealizations and assumptions associated with the approach are as follows:

1. All beams and columns are purely elastic.
2. All members have constant cross-section.
3. All joints are rigid.
4. For braced (sidesway inhibited or sway prevented) frames, rotations at opposite ends of the restraining beams are equal in magnitude, producing single-curvature bending.
5. For unbraced (sidesway uninhibited or sway permitted) frames, rotations at opposite ends of the restraining beams are equal in magnitude, producing reverse-curvature bending.
6. The stiffness parameters $L\sqrt{P/EI}$ of all columns are equal.
7. Joint restraint is distributed to the column above and below the joint in proportion to the I/L values for the two columns.
8. All columns buckle simultaneously.
9. No significant axial compression force exists in the beams.

Based on the foregoing assumptions, the effective-length factor K of a column in a braced frame is determined from the following equation:

$$\frac{G_U G_L}{4} \left(\frac{\pi}{K}\right)^2 + \frac{G_U + G_L}{2} \left(1 - \frac{\pi/K}{\tan \pi/K}\right) + 2 \left(\frac{\tan \pi/K}{\pi/K}\right) = 1 \quad (23.20)$$

For an unbraced frame, the current Canadian standard CSA S16 [3] takes sway effects into account directly by using $K = 1.0$ for columns and performing a second-order elastic analysis under actual and notional loads (i.e., in lieu of using the traditional effective-length factor to account for frame stability, as is permitted by the American design specifications [1,2]). Following the alignment chart approach, the K factor for a column in an unbraced frame is determined from the following equation:

$$\frac{G_U G_L (\pi/K)^2 - 36}{6(G_U + G_L)} = \left(\frac{\pi/K}{\tan \pi/K}\right) \quad (23.21)$$

In Equations 23.20 and 23.21, G_U and G_L are the stiffness factors for the upper and lower ends of the column, respectively. A stiffness factor G is defined as

$$G = \frac{\sum(I_c/L_c)}{\sum(I_b/L_b)} \quad (23.22)$$

where the summation is taken over all members connected to the joint, I_c is the moment of inertia of the column section corresponding to the plane of buckling, L_c is the unsupported length of the column, I_b is the moment of inertia of the beam/girder section corresponding to the plane of buckling, and L_b is the unsupported length of the beam/girder. Having the stiffness factors G_U and G_L evaluated in accordance with Equation 23.22, the effective-length factor K of a column in a braced or unbraced frame can be obtained from the applicable alignment charts developed from Equations 23.20 and 23.21.

The evaluation of the effective-length factor K for columns in semirigid frames can be conveniently achieved by pursuing the foregoing approach for rigid frames with a necessary modification to account for connection flexibility when calculating a stiffness factor as

$$G = \frac{\sum(I_c/L_c)}{\sum(\alpha_b I_b/L_b)} \quad (23.23)$$

where α_b is a modification factor applied to the moment of inertia I_b of the restraining beams that can be expressed as a function of the end-fixity factors associated with each restraining beam depending on whether the frame is of braced or unbraced frames. For braced semirigid frames

$$\alpha_b = \frac{3r_1(2 - r_2)}{4 - r_1 r_2} \quad (23.24)$$

while for unbraced semirigid frames

$$\alpha_b = \frac{r_1(2 + r_2)}{4 - r_1 r_2} \quad (23.25)$$

where the end-fixity factors r_1 and r_2 in Equations 23.24 and 23.25 correspond to the so called “near end” and “far end,” respectively, of the beam. In the case where the “far end” of the restraining beam is connected to a rotation-restrained support instead of a column, the corresponding modification factors for braced and unbraced semirigid frames are

$$\alpha_b = \frac{6r_1}{4 - r_1 r_2} \quad (23.26)$$

$$\alpha_b = \frac{2r_1}{4 - r_1 r_2} \quad (23.27)$$

As the modification factor α_b is expressed by the end-fixity factors, beams with pinned, semirigid, and rigid connections can all be considered. For instance, Equation 23.24 will yield a value of 1.5 for the modification factor α_b for a beam in a braced frame with a rigid connection at the “near end” ($r_1 = 1$) and a pinned connection at the “far-end” ($r_2 = 0$). If the “near end” connection is a pinned connection ($r_1 = 0$), the corresponding modification factor α_b becomes zero, which indicates the beam does not provide any rotational restraint to the connected column.

Having the modification factor value α_b based on the end-fixity of the restraining beams, the stiffness factors for the upper and lower ends of the column can be calculated according to Equation 23.23. The corresponding column effective-length factor is then obtained from the applicable alignment chart. However, unlike that for the rigid frame case, in which the effective-length factor of a column is

evaluated regardless of the applied loads, the rotational stiffnesses of beam-to-column connections in semirigid frames are interrelated to the loads and, hence, so are the end-fixity factors r_j ($j = 1, 2$) and modification factors α_b . As a frame is loaded, the connection stiffness and, thus, the restraint provided to the columns gradually decreases, causing the column effective-length factor to increase. Consequently, the effective-length factor of the column in a semirigid frame must be evaluated for each applied load case.

EXAMPLE 23.3

The 11-storey unbraced frame shown in Figure 23.13 is analyzed using the second-order elastic analysis approach presented earlier, with the intention to illustrate frame behavior due to the interaction of second-order effects and the semirigid behavior of the beam-to-column connections. All of the beam-to-column connections of the frame are assumed to be identical.

In order to trace the effect of semirigid behavior on geometric second-order effects, nine (9) analyses were conducted for the frame with the end-fixity factor decreasing in decrements of 0.1 from that for a rigid connection ($r = 1.0$) to that for a flexible connection ($r = 0.2$). The frame was analyzed with and without considering second-order effects for each case. The lateral deflection obtained at the roof level for each case is presented in Table 23.7 along with the values of the end-fixity factor, the corresponding

FIGURE 23.13 Example 3: two-bay 11-story semirigid steel frame.

TABLE 23.7 Lateral Deflection of Two-Bay 11-Story Steel Frame

End-fixity factor (r)	Stiffness ratio (RL/EI)	Connection stiffness (N/mm/rad)	Lateral deflection Δ_1 , first-order analysis (mm)	Lateral deflection Δ_2 , second-order analysis (mm)	$\frac{\Delta_2}{\Delta_1}$
1.0	∞	∞	125	140	1.12
0.9	27.00	4.723×10^{11}	145	165	1.14
0.8	12.00	2.099×10^{11}	168	196	1.17
0.7	7.00	1.225×10^{11}	197	237	1.20
0.6	4.50	7.872×10^{10}	235	293	1.25
0.5	3.00	5.248×10^{10}	286	377	1.32
0.4	2.00	3.499×10^{10}	358	514	1.44
0.3	1.29	2.249×10^{10}	478	780	1.66
0.2	0.75	1.312×10^{10}	675	1531	2.27

FIGURE 23.14 Lateral deflection increase due to second-order effects of 11-story frame.

stiffness ratio RL/EI , and the connection stiffness. Figure 23.14 shows that as the end-fixity factor decreases, the lateral deflection due to second-order effects increases significantly, thus intensifying the second-order effects considerably.

Increasing the lateral deflection limit for serviceability, $H/500$, by a factor of 1.35 to account for factored loads gives a roof lateral deflection limit of 125 mm. As shown in Table 23.7, the lateral deflection obtained from the first-order rigid frame analysis ($r=1.0$) is 125 mm, which satisfies the deflection limit. Also note from Table 23.7 that the lateral deflection of the frame is 145 mm for first-order semirigid analysis with the value of end-fixity factor $r=0.9$. This deflection is greater than the 140 mm obtained when second-order effects are considered for the rigid frame case ($r=1.0$). Also note that the value of the stiffness ratio $RL/EI=27$ for $r=0.9$. According to the LRFD and Eurocode 3 connection classifications, connections are classified as rigid when the values of RL/EI are equal or greater than 20 ($r=0.87$) or 25 ($r=0.89$), respectively. Because the value of RL/EI is within the range for rigid connections used in typical building design, this demonstrates that the influence of the beam-to-column connection behavior on frame deflection may be more significant than the second-order effects. In turn, this perhaps suggests that a value of the end-fixity factor less than 1.0 should be used in mid- to high-rise rigid steel frame design where the beam-to-column connections are classified as rigid connections.

It is also observed from Figure 23.14 that for semirigid beams with an end-fixity factor value less than 0.75, an increase in the value of the end-fixity factor due to an increase in connection stiffness would result in appreciable decrease in the lateral deflection of the frame; such an effect can be substantial for flexible beam-to-column connections ($r \leq 0.4$ or $RL/EI \leq 2$, equivalently). However, for nearly rigid connections ($r \geq 0.75$), further increase in the end-fixity factor has a trivial effect on the deflection. A similar phenomenon is also observed for the strength of columns in the frame. Figure 23.15 illustrates

FIGURE 23.15 Interior column strength versus end-fixity factor.

the influence of beam end-fixity on the strength of the interior column (WWF400 × 274) between the third and fourth floors, in which the strength of the column is calculated based on LRFD with steel yield stress 350 MPa. Considering the relationship between the end-fixity factor and connection stiffness shown in Figure 23.9, it is concluded that it is important and economical to consider the semi-rigid behavior of connections in the design of unbraced steel frames having flexible beam-to-column connections.

This study also finds that the buckling load capacity of the frame increases considerably as the end-fixity factors increase from zero to 0.4 for beam-to-column connections. For an unbraced frame having flexible connections having a low value of connection stiffness, even a small increase in the stiffness would result in an appreciable increase in the end-fixity factor, which consequently causes a significant increase in the buckling load capacity. In practice, pinned connections always have some rotational stiffness, which considerably benefits the load capacity of the frame. Conversely, reducing the connection stiffness from rigid connection with full fixity (e.g., from $r=1.0$ to 0.75) will result in an insignificant decrease in the critical buckling loads. This is because large reductions in connection stiffness from rigid frames are shown to have little effect on the frame stability in that a large change to the stiffness of rigid connections will result in only a small change in the end-fixity factor, as shown in Figure 23.9. Consequently, potential savings in connection cost may be achieved from the replacement of rigid connections with semirigid connections. Therefore, considering the behavior of semirigid connections in frame stability can produce more appropriate and economical designs.

Glossary

ASD — Allowable stress design.

LRFD — Load and resistance factor design.

Beam-to-column connection — A connection that connects a beam to a column.

Braced frame — A frame to which lateral translation is prevented by a system of bracing.

Connection rotation capacity — The angular rotation that a connection can undergo prior to local failure.

Effective-length factor — The ratio between the effective length and the unbraced length of a member.

End-fixity factor — The factor that defines the rotational stiffness of an end-connection relative to that of the attached member.

First-order elastic analysis — Structural analysis based on linear elastic deformation, in which equilibrium conditions are formulated with respect to the undeformed structure.

$M-\theta$ relationship — The relationship between moment and rotation of a connection.

$P-\Delta$ effect — Secondary effect of axial loads and lateral deflection on the moments in members.

Rigid frame — A structure in which connections maintain the angular relationship between beam and column members under load.

Second-order elastic analysis — Structural analysis based on second-order elastic deformation, in which equilibrium conditions are formulated with respect to the deformed structure.

Unbraced frame — A frame in which the lateral deflection is not prevented by a system of bracing.

24.1 Introduction to Space Frame Structures

24.1.1 General Introduction

A growing interest in space frame structures has been witnessed worldwide over the last half-century. The search for new structural forms to accommodate large unobstructed areas has always been the main objective of architects and engineers. With the advent of new building techniques and construction materials, space frames frequently provide the right answer and satisfy the requirements for lightness, economy, and speedy construction. Significant progress has been made in the process of development of space frame. A large amount of theoretical and experimental research programs were carried out by many universities and research institutions in various countries. As a result, a great deal of useful information has been disseminated, and fruitful results have been put into practice.

In the past few decades, the proliferation of space frame was mainly due to its great structural potential and visual beauty. New and imaginative applications of space frames are being demonstrated in the total range of building types, such as sports arenas, exhibition pavilions, assembly halls, transportation terminals, airplane hangars, workshops, and warehouses. They have been used not only on long-span roofs, but also on mid- and short-span enclosures as roofs, floors, exterior walls, and canopies. Many

interesting projects have been designed and constructed all over the world using a variety of configurations.

Some important factors that influence the rapid development of space frame can be cited as follows. First of all, the search for large indoor space has always been the focus of human activities. Consequently, sports tournaments, cultural performances, mass assemblies, and exhibitions can be held under one roof. The modern production and the needs of greater operational efficiency also created demand for large space with minimum interference from internal supports. Space frame provides the benefit that the interior space can be used in a variety of ways and thus is ideally suited for such requirements.

Space frames are highly statically indeterminate, and their analysis leads to extremely tedious computation if done by hand. The difficulty of the complicated analysis of such a system has contributed to its limited use. The introduction of the electronic computer has radically changed the whole approach to the analysis of space frames. By using computer programs, it is possible to analyze very complex space structures with great accuracy and less time involved.

Last, the space frame has also the problem of connecting a large number of members (sometimes up to 20) in space through different angles at a single point. The emergence of several connecting methods of proprietary systems has made great improvement in the construction of space frame, which offers simple and efficient means for making connection of members. The exact tolerances required by these jointing systems can be achieved in the fabrication of the members and joints.

24.1.2 Definition of Space Frame

If one looks at technical literature on structural engineering, one finds that the meaning of the *space frame* has been very diverse or even confusing. In a very broad sense, space frame is literally a three-dimensional structure. However, in a more restricted sense, space frame means some type of special structural action in three dimensions. Sometimes, structural engineers and architects fail to convey what they really mean by the term. Thus it is appropriate to define here the term space frame as understood throughout this section. It is best to quote a definition given by a Working Group on Spatial Steel Structures of the International Association on Shell and Spatial Structures [1]:

A space frame is a structure system assembled of linear elements so arranged that forces are transferred in a three-dimensional manner. In some cases, the constituent element may be two-dimensional. Macroscopically a space frame often takes the form of a flat or curved surface.

It should be noted that virtually the same structure defined as space frame here is referred to as *latticed structures* in a state-of-the-art report prepared by the Task Committee on Latticed Structures [2], which states

A latticed structure is a structure system in the form of a network of elements (as opposed to a continuous surface). Rolled, extruded or fabricated sections comprise the member elements. Another characteristic of latticed structural system is that their load-carrying mechanism is three-dimensional in nature.

The American Society of Civil Engineers (ASCE) report also specifies that the three-dimensional character includes flat surfaces with loading perpendicular to the plane as well as curved surfaces. The Report excludes structural systems such as common trusses on building frames, which can appropriately be divided into a series of planar frameworks with loading in the plane of the framework. In this section the terms “space frames” and “latticed structures” are considered synonymous.

A space frame is usually arranged in an array of single, double, or multiple layers of intersecting members. Some authors define space frames only as double-layer grids. A single-layer space frame that has the form of a curved surface is termed as *braced vault*, *braced dome*, or *latticed shell*.

Occasionally, the term *space truss* appears in the technical literature. According to the structural analysis approach, a space frame is analyzed by assuming rigid joints that cause internal torsions and moments in the members, whereas a space truss is assumed as hinged joints and therefore has no internal

member moments. The choice between space frame and space truss action is mainly determined by the joint-connection detailing and the member geometry is no different for both. However, in engineering practice, there are no absolutely rigid or hinged joints. For example, a double-layer flat surface space frame is usually analyzed as hinged connections, while a single-layer curved surface space frame may be analyzed either as hinged or as rigid connections. The term “space frame” will be used to refer to both space frames and space trusses.

24.1.3 Basic Concepts

The space frame can be formed on either a flat or a curved surface. The earliest form of space frame structure is single-layer grid. By adding intermediate grids and including rigid connection to the joist and girder framing system, the single-layer grid is formed. The major characteristic of grid construction is the omnidirectional spread of the load as opposed to the linear transfer of the load in an ordinary framing system. Since such load transfer is mainly by bending, for larger spans the bending stiffness is increased most efficiently by changing to a double-layer system. The load transfer mechanism of a curved surface space frame is essentially different from the grid system that is primarily membrane-like action. The concept of space frame can be best explained by the following example.

It is necessary to design a roof structure for a square building. Figure 24.1a and b shows two different ways of roof framing. The roof system shown in Figure 24.1a is a complex roof composed of planar latticed trusses. Each truss resists the load acting on it independently and transfers the load to the columns on each end. To ensure the integrity of the roof system, usually purlins and bracings are used between trusses. In Figure 24.1b latticed trusses are laid orthogonally to form a system of space latticed grids that will resist the roof load through its integrated action as a whole and transfer the loads to the columns along the perimeters. Since the loads can be taken by the members in three dimensions, the corresponding forces in space latticed grids are usually less than that in planar trusses and hence the depth can be decreased in a space frame.

FIGURE 24.1 Roof framing for a square plan.

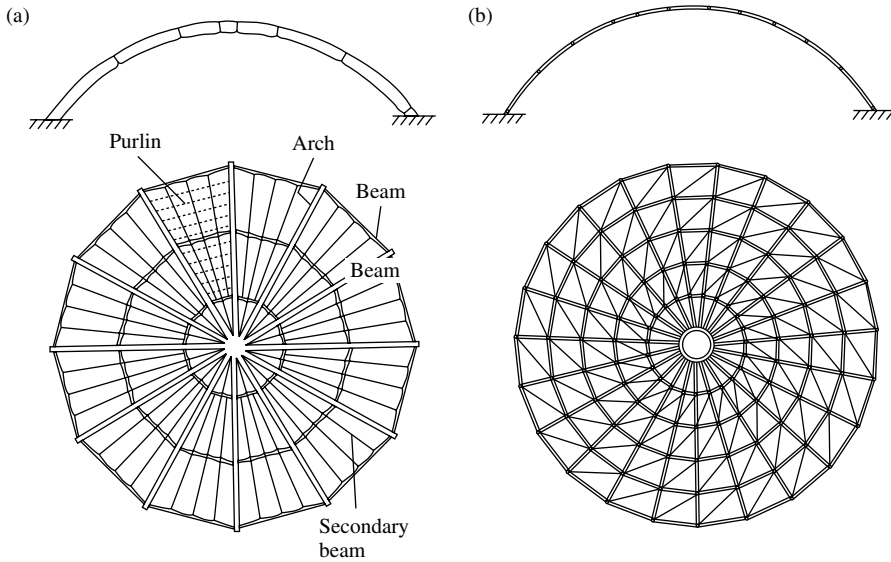

FIGURE 24.2 Roof framing for a Circular Dome.

The same concept can be observed in the design of a circular dome. Again, there are two different ways of framing a dome. The dome shown in Figure 24.2a is a complex of elements like arches, primary and secondary beams, and purlins, which all lie in a plane. Each of these elements constitutes a system that is stable by itself. In contrast, the dome shown in Figure 24.2b is an assembly of a series of longitudinal, meridional, and diagonal members, a form of latticed shell. It is a system whose resisting capacity is ensured only through its integral action as a whole.

The difference between planar structures and space frames can be understood also by examining the sequence of flow of forces. In a planar system, the force due to the roof load is transferred successively through the secondary elements, the primary elements, and then finally to the foundation. In each case, loads are transferred from the elements of lighter class to the elements of heavier class. As the sequence proceeds, the magnitude of the load to be transferred increases, so does the span of the element. Thus, elements in a planar structure are characterized by their distinctive ranks, not only by the size of their cross-sections but also by the importance of the task assigned to them. In contrast, in a space system there is no sequence of load transfer, and all elements contribute to the task of resisting the roof load in accordance with the three-dimensional geometry of the structure. For this reason, the ranking of the constituent elements similar to planar structures is not observed in a space frame.

24.1.4 Advantages of Space Frames

1. One of the most important advantages of a space structure is its lightweight. This is mainly due to the fact that material is distributed spatially in such a way that the load transfer mechanism is primarily axial — tension or compression. Consequently, all material in any given element is utilized to its full extent. Furthermore, most space frames are now constructed with steel or aluminum, which decreases considerably their self-weight. This is especially important in the case of long-span roofs, which led to a number of notable examples of applications.
2. The units of space frames are usually mass produced in the factory so that they can take full advantage of the industrialized system of construction. Space frames can be built from simple prefabricated units, which are often of standard size and shape. Such units can be easily transported and rapidly assembled on site by semi-skilled labor. Consequently, space frames can be built at a lower cost.

3. A space frame is usually sufficiently stiff in spite of its lightness. This is due to its three-dimensional character and to the full participation of its constituent elements. Engineers appreciate the inherent rigidity and great stiffness of space frames and their exceptional ability to resist unsymmetrical or heavy concentrated load. Possessing greater rigidity, the space frames allow also greater flexibility in layout and positioning of columns.
4. Space frames possess a versatility of shape and form and can utilize a standard module to generate various flat space grids, latticed shell, or even free-form shapes. Architects appreciate the visual beauty and the impressive simplicity of lines in space frames. A trend is very noticeable in which the structural members are left exposed as a part of the architectural expression. Desire for openness for both visual impact as well as the ability to accommodate variable space requirements always calls for space frames as the most favorable solution.

24.1.5 Preliminary Planning Guidelines

In the preliminary stage of planning a space frame to cover a specific building, a number of factors should be studied and evaluated before proceeding to structural analysis and design. These include not only structural adequacy and functional requirements but also the esthetic effect desired.

1. In its initial phase, structural design consists of choosing the general form of the building and the type of space frame appropriate to this form. Since a space frame is assembled of straight, linear elements connected at nodes, the geometrical arrangement of the elements — surface shape, number of layers, grid pattern, etc. — needs to be studied carefully in the light of various pertinent requirements.
2. The geometry of the space frame is an important factor to be planned, which will influence both the bearing capacity and the weight of the structure. The *module* size is developed from the overall building dimensions, while the *depth* of the grid (in the case of double-layer), the size of cladding, and the position of the supports will also have a pronounced effect upon it. For curved surface, the geometry is also related to the curvature, or more specifically to the rise of the span. A compromise between these various aspects usually has to be made to achieve a satisfactory solution.
3. In a space frame, connecting joints play an important role, both functional and esthetic, which derives from their rationality during construction and after completion. Since joints have a decisive effect on the strength and stiffness of the structure and compose around 20 to 30% of the total weight, joint design is critical to space frame economy and safety. These are quite a few proprietary systems that are used for space frame structures. They should be selected on the basis of quality, cost, and erection efficiency. In addition, custom-designed space frames have been developed, especially for long-span roofs. Regardless of the type of space frame, the essence of any system is the jointing system.
4. At the preliminary stage of design, the choosing of the type of space frames has to be closely related with the constructional technology. The space frames do not have such a sequential order of erection for planar structures and require special consideration on the method of construction. Usually, a complete falsework has to be provided so that the structure can be assembled in the high position. Alternatively, the structure can be assembled on the ground, and a certain technique can be adopted to lift the whole structure, or its major part, to the final position.

24.2 Double-Layer Grids

24.2.1 Types and Geometry

Double-layer grids, or flat surface space frames, consist of two planar networks of members forming the top and bottom-layers parallel to each other and interconnected by vertical and inclined web members. Double-layer grids are characterized by hinged joints with no moment or torsional resistance; therefore,

FIGURE 24.3 Basic elements of double-layer grids.

all members can only resist tension or compression. Even in the case of connection by comparatively rigid joints, the influence of bending or torsional moment is insignificant.

Double-layer grids are usually composed of basic elements such as

1. Planar latticed truss.
2. A pyramid with a square base that is essentially a part of an octahedron.
3. A pyramid with a triangular base (tetrahedron).

The basic elements used for various types of double-layer grids are shown in Figure 24.3.

Several types of double-layer grids can be formed by these basic elements. They are developed by varying the direction of the top and bottom-layers with respect to each other and also by the positioning of the top-layer nodal points with respect to the bottom-layer nodal points. Additional variations can be introduced by changing the size of the top-layer grid with respect to the bottom-layer grid. Thus, internal openings can be formed by omitting every second element in a normal configuration. According to the form of basic elements, double-layer grids can be divided in two groups, *latticed grids* and *space grids*. The latticed grids consist of intersecting vertical latticed trusses and form a regular grid. Two parallel grids are similar in design, with one layer directly over the top of another. Both top and bottom grids are directionally the same. The space grids consist of a combination of square or triangular pyramids. This group covers the so-called offset grids, which consist of parallel grids having an identical layout with one grid offset from the other in plane but remaining directionally the same, as well as the so-called “differential” grids in which two parallel top and bottom grids are of a different layout but are chosen to coordinate and form a regular pattern [3].

The type of double-layer grid can be chosen from the following most commonly used framing systems, which are shown in Figure 24.4a through j. In Figure 24.4, top chord members are depicted with heavy solid lines, bottom chords are depicted with light solid lines, and web members are depicted with dashed lines, while the upper joints are depicted by hollow circles and the bottom joints by solid circles. Different types of double-layer grids are grouped and named according to their composition, and the names in the parentheses indicate those suggested by other authors.

- Group 1: composed of latticed trusses
 - A. *Two-way orthogonal latticed grids (square on square) (Figure 24.4a)*. This type of latticed grid has the advantage of simplicity in configuration and in joint detail. All chord members are of the same length and lie in two planes that intersect at 90° to each other. Because of its weak torsional strength, horizontal bracings are usually established along the perimeters.
 - B. *Two-way diagonal latticed grids (Figure 24.4b)*. The layout of the latticed grid is exactly the same as in type 1, except that it is offset by 45° from the edges. The latticed trusses have different spans along two directions at each intersecting joint. Since the depth is all the same, the stiffness of each latticed truss varies according to its span. The latticed trusses of shorter span may be considered as a kind of support for latticed trusses of longer span, hence more spatial action is obtained.

FIGURE 24.4 Framing system of double-layer grids.

3. *Three-way latticed grids (Figure 24.4c)*. All chord members intersect at 60° to each other and form equilateral triangular grids. It is a stiff and efficient system that is adaptable to odd shapes like circular and hexagonal plans. The joint detail is complicated by numerous members intersecting at one point, with 13 members in extreme cases.
 4. *One-way latticed grids (Figure 24.4d)*. It is composed of a series of mutually inclined latticed trusses to form a folded shape. There are only chord members along the spanning direction, therefore one-way action is predominant. As in type 1, horizontal bracings are necessary along the perimeters to increase the integral stiffness.
- Group 2A: composed of square pyramids
 5. *Orthogonal square pyramid space grids (square on square offset) (Figure 24.4e)*. This is one of the most commonly used framing patterns with top-layer square grids offset over bottom-layer grids. In addition to the equal length of both top and bottom chord members, if the angle between the diagonal and chord members is 45° , then all members in the space grids will have the same length. The basic element is a square pyramid that is used in some proprietary systems as prefabricated units to form this type of space grid.
 6. *Orthogonal square pyramid space grids with openings (square on square offset with internal openings, square on larger square) (Figure 24.4f)*. The framing pattern is similar to that of type 5, except that the inner square pyramids are removed alternatively to form larger grids in the bottom-layer. This modification will reduce the total number of members and consequently the weight. It is also visually effective as the extra openness of the space grids network produces an impressive architectural effect. Skylights can be used with this system.
 7. *Differential square pyramid space grids (square on diagonal) (Figure 24.4g)*. This is a typical example of differential grids. The two planes of the space grids are at 45° to each other, which will increase the torsional stiffness effectively. The grids are arranged orthogonally in the top-layer and diagonally in the bottom-layer. It is one of the most efficient framing systems with shorter top chord members to resist compression and longer bottom chords to resist tension. Even with the removal of a large number of members, the system is still structurally stable and esthetically pleasing.
 8. *Diagonal square pyramid space grids (diagonal square on square with internal openings, diagonal on square) (Figure 24.4h)*. This type of space grid is also of the differential layout but with a reverse pattern from type 7. It is composed of square pyramids connected at their apices with fewer members intersecting at the node. The joint detail is relatively simple since there are only six members connecting at the top chord joint and eight members at the bottom chord joint.
 - Group 2B: composed of triangular pyramids
 9. *Triangular pyramid space grids (triangle on triangle offset) (Figure 24.4i)*. Triangular pyramids are used as basic elements and connected at their apices, thus forming a pattern of top-layer triangular grids offset over bottom-layer grids. If the depth of the space grids is equal to $\sqrt{\frac{2}{3}}$ chord length, then all members will have the same length.
 10. *Triangular pyramid space grids with openings (triangle on triangle offset with internal openings) (Figure 24.4j)*. Like type 6, the inner triangular pyramids may also be removed alternatively. As in the figure shown, triangular grids are formed in the top-layer, while triangular and hexagonal grids are formed in the bottom-layer. The pattern in the bottom-layer may be varied depending on the ways of removal. This type of space grids has a good open feeling, and the contrast of the patterns is effective.

24.2.2 Type Choosing

In the preliminary stage of design, it is most important to choose an appropriate type of double-layer grid that will have direct influence on the overall cost and speed of construction. It should be determined comprehensively by considering the shape of building plan, size of span, supporting conditions,

magnitude of loading, roof construction, and architectural requirements. In general, the system should be chosen so that the space grid is built of relatively long tension members and short compression members.

In choosing the type, the steel weight is one of the important factors for comparison. If possible, the cost of the structure should also be taken into account, which is complicated by the different costs of joint and member. By comparing the steel consumption of various types of double-layer grids with rectangular plan and supported along perimeters, it was found that the *aspect ratio* of the plan, defined here as the ratio of longer span to shorter span, has more influence than the span of the double-layer grids. When the plan is square or nearly square (aspect ratio = 1 to 1.5), two-way latticed grids and all space grids of group 2A, that is, types 1, 2, and 5 through 8, could be chosen. Of these types, the diagonal square pyramid space grid or differential square pyramid space grid has the minimum steel weight. When the plan is comparatively narrow (aspect ratio = 1.5 to 2), then those double-layer grids with the orthogonal grid system in the top-layer will consume less steel than those with the diagonal grid system. Therefore, two-way orthogonal latticed grids, orthogonal square pyramid space grids, and also those with openings and differential square pyramid space grids, that is, types 1, 5, 6, and 7, could be chosen. When the plan is long and narrow, the one-way latticed grid is the only choice. For square or rectangular double-layer grids supported along perimeters on three sides and free on the other side, the selection of the appropriate types for different cases is essentially the same. The boundary along the free side should be strengthened by increasing either the depth or the number of layers. An individual supporting structure like truss or girder along the free side is not necessary.

In case the double-layer grids are supported on intermediate columns, one could choose from two-way orthogonal latticed grids, orthogonal square pyramid space grids, and also those with openings, that is, types 1, 5, and 6. If the supports for multispans double-layer grids are combined with those along perimeters, then two-way diagonal latticed grids and diagonal square pyramid space grids, that is, types 2 and 8, could also be used.

For double-layer grids with circular, triangular, hexagonal, and other odd shapes supporting along perimeters, types with triangular grids in the top-layer, that is, types 3, 9, and 10, are appropriate for use.

The recommended types of double-layer grids are summarized in Table 24.1 according to the shape of the plan and their supporting conditions.

24.2.3 Method of Support

Ideal double-layer grids would be square, circular, or other polygonal shapes with overhanging and continuous supports along perimeters. This approaches more of a plate type of design, which minimizes the maximum bending moment. However, the configuration of building has a great number of varieties, and the support of the double-layer grids can take the following locations:

1. *Support along perimeters.* This is the most commonly used support location. The supports of double-layer grids may directly rest on the columns or on ring beams connecting the columns or

TABLE 24.1 Type Choosing for Double-Layer Grids

Shape of the plan	Supporting condition	Recommended types
Square, rectangular, aspect ratio = 1–1.5	Along perimeters	1, 2, 5–8
Rectangular, aspect ratio = 1.5–2	Along perimeters	1, 5–7
Long strip, aspect ratio > 2	Along perimeters	4
Square, rectangular	Intermediate support	1, 5, 6
Square, rectangular	Intermediate support combined with support along perimeters	1, 2, 5, 6, 8
Circular, triangular, hexagonal, and other odd shapes	Along perimeters	3, 9, 10

- exterior walls. Care should be taken that the module size of grids should match the column spacing.
2. *Multicolumn supports.* For single-span buildings, like sports hall, double-layer grids can be supported on four intermediate columns as shown in Figure 24.5a. For buildings like workshops, usually multispans columns in the form of grids as shown in Figure 24.5b are used. Sometimes the column grids are used in combination with supports along perimeters as shown in Figure 24.5c. Overhangs should be employed where possible in order to provide some amount of stress reversal to reduce the interior chord forces and deflections. For those double-layer grids supported on intermediate columns, it is best to design with overhangs, which are taken as quarter to one third of the midspan. Corner supports should be avoided if possible, since this cause large forces in the edge chords. If only four supports are to be provided, then it is more desirable to locate them in the middle of the sides rather at the corners of the building.
 3. *Support along perimeters on three sides and free on the other side.* For buildings of rectangular shape, it is necessary to have one side open, such as in the case of airplane hangar or for future extension. Instead of establishing the supporting girder or truss on the free side, triple-layer grids can be formed by simply adding another layer of several module widths (Figure 24.6). For shorter spans, this can also be solved by increasing the depth of the double-layer grids. The sectional area of the members along the free side will increase accordingly.

The columns for double-layer grids must support gravity loads and possible lateral forces. Typical types of support on multicolumns are shown in Figure 24.7. Usually, the member forces around the support will be excessively large, and some means of transferring the loads to column is necessary. It may carry the space grids down to the column top by an inverted pyramid as shown in Figure 24.7a or by triple-layer grids as shown in Figure 24.7b, which can be employed to carry skylights. If necessary, the inverted pyramids may be extended down to the ground level as shown in Figure 24.7c. The spreading out of the concentrated column reaction on the space grids reduces the maximum chord and web member forces adjacent to the column supports and reduces the effective spans. The use of a vertical strut on column tops as shown in Figure 24.7d enables the space grids to be supported on top chords, but the vertical strut and the connecting joint have to be very strong. The use of crosshead beams on

FIGURE 24.5 Multicolumn supports.

FIGURE 24.6 Triple-layer grids on the free side.

column tops as shown in Figure 24.7e produces the same effect as the inverted pyramid but usually costs more in material and special fabrication.

24.2.4 Design Parameters

Before any work can proceed on the analysis of a double-layer grid, it is necessary to determine the depth and the module size. The depth is the distance between the top and bottom-layers and the module is the distance between two joints in the layer of the grid (see Figure 24.8). Although these two parameters seem simple enough to determine, yet they will play an important role in the economy of the roof design. There are many factors influencing these parameters, such as the type of double-layer grid, the span between the supports, the roof cladding, and the proprietary system used. In fact, the depth and module size are mutually dependent, which is related by the permissible angle between the center line of web members and the plane of the top and bottom chord members. This should be less than 30° , or the forces in the web members and the length will be relatively excessive, or greater than 60° , or the density of the web members in the grid will become too high. For some of the proprietary systems, the depth and module are standardized.

The depth and module size of double-layer grids are usually determined by practical experience. In some of the papers and handbooks, figures on these parameters are recommended, and one may find that the difference is quite large. For example, the span–depth ratio varies from 12.5 to 25, or even more. It is usually considered that the depth of space frame can be relatively small when compared with more conventional structures. This is generally true because double-layer grids produce smaller deflections under load. However, depths that are small in relation to span will tend to use smaller modules, and hence a heavier structure will result. In the design, almost unlimited possibilities exist in practice for the choice of geometry. It is best to determine these parameters through structural optimization.

FIGURE 24.7 Supporting columns.

FIGURE 24.8 Depth and module.

Work has been done on the optimum design of double-layer grids supported along perimeters. In an investigation by Lan [4], seven types of double-layer grids were studied. The module dimension and depth of the space frame are chosen as the design variables. The total cost is taken as the objective function, which includes the cost of members and joints as well as of roofing systems and enclosing walls. Such assumption makes the results realistic to a practical design. A series of double-layer grids of different types spanning from 24 to 72 m were analyzed by optimization. It was found that the optimum design parameters were different for different types of roof system. The module number generally increases with the span, and the steel purlin roofing system allows larger module sizes than that of reinforced concrete. The optimum depth is less dependent on the span and a smaller depth can be used for steel purlin roofing system. It should be observed that a smaller member density will lead to a grid with relatively few nodal points and thus the least possible production costs for nodes, erection expense, etc.

Through regression analysis of the calculated values by optimization method where the costs are within the 3% optimum, the following empirical formulas for optimum span–depth ratio are obtained. It was found that the optimum depths are distributed in a belt and all the span–depth ratios within this range will have optimum effect in construction.

For roofing system composed of reinforced concrete slabs

$$L/d = 12 \pm 2 \quad (24.1)$$

and for roofing system composed of steel purlins and metal decks

$$L/d = (510 - L)/34 \pm 2 \quad (24.2)$$

where L is the short span and d is the depth of the double-layer grids.

Few data could be obtained from the past works. Regarding the optimum depth for steel purlin roofing systems, Geiger suggested the span–depth ratio to be varied from 10 to 20 with less than 10% variation in cost. Motro recommended a span–depth ratio of 15. Curves for diagonal square pyramid space grids (diagonal on square) were given by Hirata et al., and an optimum ratio of 10 was suggested. In the earlier edition of the *Specifications for the Design and Construction of Space Trusses* issued in China, the span–depth ratio is specified according to the span. These figures were obtained through the analysis of the parameters used in numerous design projects. A design handbook for double-layer grids also gives graphs for determining upper and lower bounds of module dimension and depth. The relation between depth and span obtained from Equation 24.2 and the relevant source is shown in Figure 24.9. For short and medium spans, the optimum values are in good agreement with those obtained from experience. It is noticeable that the span–depth ratio should decrease with the span, yet an increasing tendency is found from experience, which gives irrational large values for long spans.

In the revised edition of the *Specifications for the Design and Construction of Space Trusses* issued in China, appropriate values of module size and depth for commonly used double-layer grids simply supported along the perimeters are given. Table 24.2 shows the range of module numbers of the top chord and the span–depth ratios prescribed by the *Specifications*.

24.2.5 Cambering and Slope

Most double-layer grids are sufficiently stiff so that camber is often not required. Cambering is considered when the structure under load appears to be sagging and the deflection might be visually undesirable. It is suggested that the cambering be limited to $\frac{1}{300}$ of the shorter span. As shown in Figure 24.10, cambering is usually done in (a) cylindrical, (b) ridge, or (c) spherical shape. If the grid is being fabricated on site by welding, then almost any type of camber can be obtained as this is just a matter of setting the joint nodes at the appropriate levels. If the grid components are fabricated in the factory, then it is necessary to standardize the length of the members. This can be done by keeping either the top or the bottom-layer chords at the standard length and altering the others either by adding a small amount to the length of each member or subtracting a small amount from it to generate the camber required.

FIGURE 24.9 Relation between depth and span of double-layer grids.

TABLE 24.2 Module Number and Span-Depth Ratio

Type of double-layer grids	Reinforced concrete slab roofing system		Steel purlin roofing system	
	Module number	Span-depth ratio	Module number	Span-depth ratio
1, 5, 6	$(2-4) + 0.2L$	10-14	$(6-8) + 0.07L$	$(13-17) - 0.03L$
2, 7, 8	$(6-8) + 0.08L$			

Notes:

1. L denotes the shorter span in meters.
2. When the span is less than 18 m, the number of modules may be decreased.

FIGURE 24.10 Ways of cambering.

FIGURE 24.11 Ways of forming roof slope.

Sometimes cambering is suggested so as to ensure that the rainwater drains off the roof quickly to avoid ponding. This does not seem to be effective especially when cambering is limited. To solve the water run-off problem in those locations with heavy rains, it is best to form a roof slope by the following methods (Figure 24.11):

1. Establishing short posts of different heights on the joints of top-layer grids.
2. Varying the depth of grids.
3. Forming a slope for the whole grid.
4. Varying the height of supporting columns.

24.2.6 Methods of Erection

The method chosen for erection of a space frame depends on its behavior of load transmission and constructional details, so that it will meet the overall requirements of quality, safety, speed of construction, and economy. The scale of the structure being built, the method of jointing the individual elements, and the strength and rigidity of the space frame until its form is closed must all be considered. The general methods of erecting double-layer grids are as follows. Most of them can also be applied to the construction of latticed shells.

1. *Assembly of space frame elements in the air.* Members and joints or prefabricated subassembly elements are assembled directly on their final position. Full scaffoldings are usually required for this type of erection. Sometimes only partial scaffoldings are used if cantilever erection of space frame can be executed. The elements are fabricated at the shop and transported to the construction site, and no heavy lifting equipment is required. It is suitable for all types of space frame with bolted connections.
2. *Erection of space frame by strips or blocks.* The space frame is divided on its plan into individual strips or blocks. These units are fabricated on the ground level, then hoisted up into its final position and assembled on the temporary supports. With more work being done on the ground, the amount of assembling work at high elevation is reduced. This method is suitable for those double-layer grids where the stiffness and load-resisting behavior will not change considerably after dividing into strips or blocks, such as two-way orthogonal latticed grids, orthogonal square pyramid space grids, and the those with openings. The size of each unit will depend on the hoisting capacity available.
3. *Assembly of space frame by sliding element in the air.* Separate strips of space frame are assembled on the roof level by sliding along the rails established on each side of the building. The sliding units may slide one after another to the final position and then be assemble together or assembled successively during the process of sliding. Thus, the erection of space frame can be carried out simultaneously with the construction work underneath, which leads to saving of construction time and cost of scaffoldings. The sliding technique is relatively simple, requiring no special lifting equipment. It is suitable for orthogonal grid systems where each sliding unit will remain geometrically nondeferrable.
4. *Hoisting of whole space frame by derrick masts or cranes.* The whole space frame is assembled at ground level so that most of the assembling work can be done before hoisting. This will result in increased efficiency and better quality. For short and medium spans, the space frame can be hoisted up by several cranes. For long-span space frame, derrick masts are used as the support and electric winches as the lifting power. The whole space frame can be translated or rotated in the air

and then seated on its final position. This method can be employed to all types of double-layer grids.

5. *Lifting up the whole space frame.* This method also has the benefit of assembling space frame at ground level, but the structure cannot move horizontally during lifting. Conventional equipment used is hydraulic jacks or lifting machines for lift-slab construction. An innovative method has been developed by using the center hole hydraulic jacks for slipforming. The space frame is lifted up simultaneously with the slipforms for reinforced concrete columns or walls. This lifting method is suitable for double-layer grids supported along perimeters or on multipoint supports.
6. *Jacking-up the whole space frame.* Heavy hydraulic jacks are established on the position of columns that are used as supports for jacking-up. Occasionally, roof claddings, ceilings, and mechanical installations are also completed with the space frame at the ground level. They are appropriate for use in space frame with multipoint supports, the number of which is usually limited.

24.3 Latticed Shells

24.3.1 Form and Layer

The main difference between double-layer grids and latticed shells is the form. For double-layer grid, it is simply a flat surface. For latticed shell, the variety of forms is almost unlimited. A common approach to the design of latticed shells is to start with the consideration of the form — a surface curved in space. The geometry of basic surfaces can be identified, according to the method of generation, as surface of translation and surface of rotation. A number of variations of form can be obtained by taking segments of the basic surfaces or by combining or adding them. In general, the geometry of surface has a decisive influence on essentially all characteristics of the structure: the manner in which it transfers loads, its strength and stiffness, the economy of construction, and the esthetic quality of the completed project.

Latticed shells can be divided into three distinct groups forming singly curved, synclastic, and anticlastic surfaces. A barrel vault (cylindrical shell) represents a typical developable surface, having a zero curvature in the direction of generatrices. A spherical or elliptical dome (spheroid or elliptic paraboloid) is a typical example of synclastic shell. A hyperbolic paraboloid is a typical example of anticlastic shell.

Besides the mathematical generation of surface systems, there are other methods for finding shapes of latticed shell. Mathematically, the surface can be defined by a high-degree polynomial with the unknown coefficients determined from the known shape of the boundary and the known position of certain points at the interior required by the functional and architectural properties of the space. Experimentally, the shape can be obtained by loading a net of chain wires or a rubber membrane or a soap membrane in the desired manner. In each case the membrane is supported along a predetermined contour and at predetermined points. The resulting shape will produce a minimal surface, which is characterized by a least surface area for a given boundary and also constant skin stress. Such an experimental model helps to develop a first understanding about the nature of structural forms.

The inherent curvature in latticed shell will give the structure greater stiffness. Hence, latticed shell can be built in single layer, which is a major difference from the double-layer grid. Of course, latticed shell may also be built in double-layer. Although single- and double-layer latticed shells are similar in shape, the structural analysis and connecting detail are quite different. The single-layer latticed shell is a structural system with rigid joints, while the double-layer latticed shell has hinged joints. In practice, single-layer latticed shells of short span with lightweight roofing may also be built with hinged joints. The members and connecting joints in a single-layer shell of large span will resist not only axial forces as in a double-layer shell but also the internal moments and torsions. Since the single-layer latticed shells are easily liable to buckling, the span should not be too large. There is no distinct limit between single and double layers, which will depend on the type of shell, the geometry and size of the framework, and the section of members.

24.3.2 Braced Barrel Vaults

The braced barrel vault is composed of member elements arranged on a cylindrical surface. The basic curve is a circular segment; occasionally, a parabola, ellipse or funicular line may also be used. Figure 24.12 shows the typical arrangement of a braced barrel vault. Its structural behavior depends mainly on the type and location of supports, which can be expressed as L/R , where L is the distance between the supports in longitudinal direction and R is the radius of curvature of the transverse curve.

If the distance between the supports is long and usually edge beams are used in the longitudinal direction (Figure 24.12a), the primary response will be beam action. For $1.67 < L/R < 5$, the barrel vaults are called long shells, which can be visualized as beams with curvilinear cross-sections. The beam theory with the assumption of linear stress distribution may be applied to barrel vaults that are of symmetrical cross-section and under uniform loading if $L/R > 3$. This class of barrel vault will have longitudinal compressive stresses near the crown of the vault, longitudinal tensile stresses toward the free edges, and stresses toward the supports.

As the distance between transverse supports becomes closer, or as the dimension of the longitudinal span becomes smaller than the dimension of the shell width, such that $0.25 < L/R < 1.67$, the primary response will be arch action in the transverse direction (Figure 24.12b). The barrel vaults are called short shells; their structural behavior is rather complex and dependent on their geometrical proportions. The force distribution in the longitudinal direction is not linear anymore, but in a curvilinear manner, trusses or arches are usually used as the transverse supports.

When a single braced barrel vault is supported continuously along its longitudinal edges on foundation blocks, or the ratio of L/R becomes very small, that is, < 0.25 (Figure 24.12c), the forces are carried directly in the transverse direction to the edge supports. Its behavior may be visualized as the response of parallel arches. Displacement in the radial direction is resisted by circumferential bending stiffness. This type of barrel vault can be applied to buildings like airplane hangars or gymnasias where the wall and roof are combined together.

There are several possible types of bracing that have been used in the construction of single-layer braced barrel vaults. Figure 24.13 shows five principle types:

1. Orthogonal grid with single bracing of Warren truss (a).
2. Orthogonal grid with single bracing of Pratt truss (b).
3. Orthogonal grid with double bracing (c).
4. Lamella (d).
5. Three way (e).

The first three types of braced barrel vaults can be formed by composing latticed trusses with difference in the arrangement of bracings (Figure 24.13a–c). In fact, the original barrel vault was introduced by Foppl. It consists of several latticed trusses, spanning the length of the barrel and supported on the gables. After connection of the longitudinal booms of the latticed trusses, they became a part of the braced barrel vault of the single-layer type.

FIGURE 24.12 Braced barrel vaults.

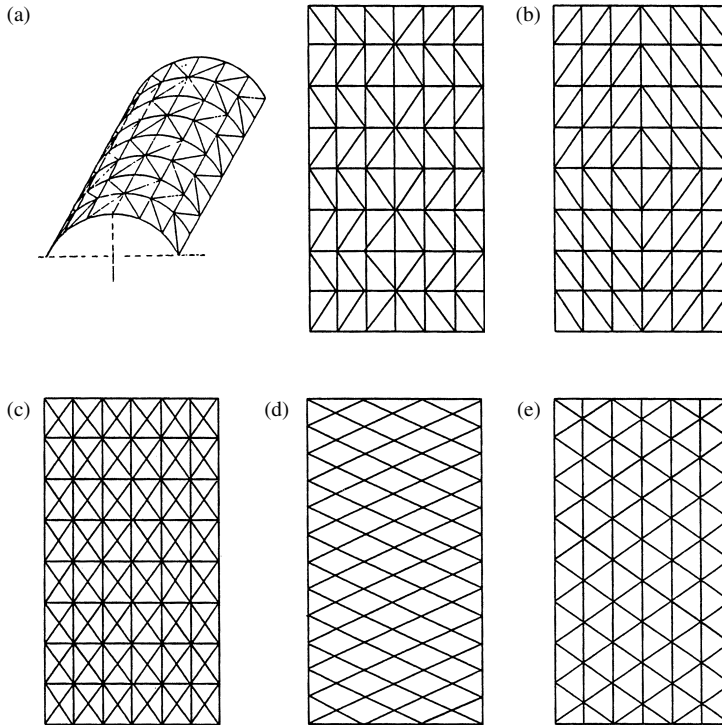

FIGURE 24.13 Types of bracing for braced barrel vaults.

The popular diamond-patterned lamella type of braced barrel vault consists of a number of interconnected modular units forming a rhombus-shaped grid pattern (Figure 24.13d). Each unit, which is twice the length of the side of a diamond, is called a *lamella*. Lamella roofs proved ideal for prefabricated construction as all the units are of standard size. They were originally constructed of timber, but with the increase of span, steel soon became the most frequently used material.

To increase the stability of the structure and to reduce the deflections under unsymmetrical loads, purlins were employed for large-span lamella barrel vaults. This created the three-way grid type of bracing and became very popular (Figure 24.13e). The three-way grid enables the construction of such a system using equilateral triangles composed of modular units, which are of identical length and can be connected with simple nodes.

Research investigations have been carried out on braced barrel vaults. One aspect of this research referred to the influence of different types of bracing on the resulting stress distribution. The experimental tests on the models proved that there are significant differences in the behavior of the structures, and the type of bracing has a fundamental influence on the strength and load-carrying capacity of the braced barrel vaults. The three-way single-layer barrel vaults exhibited a very uniform stress distribution under uniformly distributed load and much smaller deflections in the case of unsymmetrical loading than for any of the other type of bracing. The experiments also showed that large-span single-layer braced barrel vaults are prone to instability, especially under the action of heavy unsymmetrical loads, and that the rigidity of joints can exert an important influence on the overall stability of the structure.

For double-layer braced barrel vaults, if two- or three-way latticed trusses are used to form the top and bottom-layers of the latticed shell, the grid pattern is identical as shown in Figure 24.13 for single-layer shells. If square or triangular pyramids are used, either the top-layer grid or the bottom-layer grid may follow the same pattern as shown in Figure 24.13.

The usual height to width ratio for long shells varies from $\frac{1}{3}$ to $\frac{1}{6}$. When the barrel vault is supported along the longitudinal edges, the height can be increased to half to one fifth of the chord width. For long

shells, if the longitudinal span is larger than 30 m, or for barrel vaults supported along longitudinal edges with transverse span larger than 25 m, double-layer grids are recommended. The thickness of the double-layer barrel vault is usually from $\frac{1}{20}$ to $\frac{1}{50}$ of the chord width.

24.3.3 Braced Domes

Domes are one of the oldest and well-established structural forms and have been used in architecture since the earliest times. They are of special interest to engineers as they enclose a maximum amount of space with a minimum surface and have proved to be very economical in terms of consumption of constructional materials. The stresses in a dome are generally membrane and compressive in the major part of the shell except circumferential tensile stresses near the edge and small bending moments at the junction of the shell and the ring beam. Most domes are surfaces of revolution. The curves used to form the synclastic shell are spherical, parabolic, or elliptical, covering circular or polygonal areas. Out of a large variety of possible types of braced domes, only four or five types proved to be frequently used in practice. They are shown in Figure 24.14.

1. Ribbed domes (a)
2. Schwedler domes (b)
3. Three-way grid domes (c)
4. Lamella domes (d and e)
5. Geodesic domes (f)

Ribbed dome is the earliest type of braced dome that has been constructed (Figure 24.14a). A ribbed dome consists of a number of identical meridional solid girders or trusses, interconnected at the crown by a compression ring. The ribs are also connected by concentric rings to form grids in trapezium shape. The ribbed dome is usually stiffened by a steel or reinforced concrete tension ring at its base.

FIGURE 24.14 Braced domes.

A Schwedler dome also consists of meridional ribs connected together to a number of horizontal polygonal rings to stiffen the resulting structure so that it will be able to take unsymmetrical loads (Figure 24.14b). Each trapezium formed by intersecting meridional ribs with horizontal rings is subdivided into two triangles by a diagonal member. Sometimes the trapezium may also be subdivided by two cross-diagonal members. This type of dome was introduced by a German engineer J.W. Schwedler in 1863. The great popularity of Schwedler domes is due to the fact that, on the assumption of pin-connected joints, the structure can be analyzed as statically determinate. In practice, in addition to axial forces, all the members are also under the action of bending and torsional moments. Many attempts have been made in the past to simplify their analysis, but precise methods of analysis using computers have finally been applied to find the actual stress distribution.

The construction of three-way grid dome is self-explanatory, which may be imagined as a curved form of three-way double-layer grids (Figure 24.14c). It can also be constructed in single layer for the dome. The Japanese “diamond dome” system by Tomoegumi Iron Works belongs to this category. The theoretical analysis of three-way grid domes shows that even under unsymmetrical loading the forces in this configuration are very evenly distributed leading to economy in material consumption.

A lamella dome is formed by intersecting two-way ribs diagonally to form a rhombus-shaped grid pattern. As in lamella braced barrel vault, each lamella element has a length that is twice the length of the side of a diamond. The lamella dome can further be distinguished into parallel and curved domes. For parallel lamella as shown in Figure 24.14d, the circular plan is divided into several sectors (usually six or eight), and each sector is subdivided by parallel ribs into rhombus grids of the same size. This type of lamella dome is very popular in the United States. It is sometimes called a Kiewitt dome, after its developer. For curved lamella as shown in Figure 24.14e, rhombus grids of different sizes, gradually increasing from the center of the dome, are formed by diagonal ribs along the radial lines. Sometimes, for the purpose of establishing purlins for roof decks, concentric rings are introduced, and a triangular network is generated.

The geodesic dome was developed by the American designer Buckminster Fuller, who turned architects’ attention to the advantages of braced domes in which the elements forming the framework of the structure are lying on the great circle of a sphere. This is where the name “geodesic” came from (Figure 24.14f). The framework of these intersecting elements forms a three-way grid comprising virtually equilateral spherical triangles. In Fuller’s original geodesic domes, he used an icosahedron as the basis for the geodesic subdivision of a sphere; then, the spherical surface is divided into 20 equilateral triangles as shown in Figure 24.15a. This is the maximum number of equilateral triangles into which a sphere can be divided. For domes of larger span, each of these triangles can be subdivided into six triangles by drawing medians and bisecting the sides of each triangle. It is therefore possible to form 15 complete great circles regularly arranged on the surface of a sphere (see Figure 24.15b). Practice shows that the primary type of bracing, which is truly geodesic, is not sufficient since it would lead to an excessive length for members in geodesic dome, therefore a secondary bracing has to be introduced. To obtain a more or less regular network of the bracing bars, the edges of the basic triangle are divided modularly. The number of modules into which each edge of the spherical icosahedron is divided depends mainly on the size of the dome, its span, and the type of roof cladding. This subdivision is usually referred to as “frequency,” as depicted in Figure 24.15c. It must be pointed out that during such a subdivision the resulting triangles are no longer equilateral. The members forming the skeleton of the dome show slight variation in their length. As the frequency of the subdivision increases, the member length reduces, the number of components as well as the number of types of connecting joints increase. Consequently, this reflects in the increase of the final price of geodesic dome and is one of the reasons why geodesic domes, in spite of their undoubted advantages for smaller spans, do not compare equally well with other types of braced domes for larger span.

The rise of a braced dome can be as flat as one seventh of the diameter or as high as three fourths of the diameter, which will constitute the greater part of a sphere. For diameters larger than 60 m, double-layer grids are recommended. The ratio of the thickness to the diameter of double-layer braced dome is in the range of $\frac{1}{30}$ to $\frac{1}{60}$; for long spans the thickness can be as small as $\frac{1}{100}$ of the diameter.

FIGURE 24.15 Geodesic subdivision.

The subdivision of the surface of the braced dome can also be carried out using the following three methods. The first method is based on the surface of revolution, and the first set of lines of division are drawn as the meridional lines from the apex. Next, circumferential rings are added. This results in a ribbed dome and further a Schwedler dome. Alternately, the initial set may be taken as a series of spiral arcs, resulting in dividing the surface into triangular units as uniform as possible. This is achieved by drawing great circles in three directions as shown in the case of grid dome. A noteworthy type of division of a braced dome is the parallel lamella dome, which is obtained by combining the first and second methods described above. The third type of subdivision results from projecting the edges of in-polyhedra onto the spherical surface and then inscribing a triangular network of random frequency into this basic grid. Geodesic dome represents an application of this method, with the basic field derived from the isosahedron further subdivided into equilateral triangles.

24.3.4 Hyperbolic Paraboloid Shells

The hyperbolic paraboloid or hyper is a translational surface formed by sliding a concave paraboloid called generatrix parallel to itself along a convex parabola called directrix, which is perpendicular to the generatrix (Figure 24.16a). By cutting the surface vertically, parabolas can be obtained, and cutting horizontally will give hyperbolas. Such a surface can also be formed by sliding a straight line along two other straight lined skewed with respect to each other (Figure 24.16b). The hyperbolic paraboloid is a doubly ruled surface; it can be defined by two families of intersecting straight lines, which form in plan projection a rhombic grid. This is one of the main advantages of a hyperbolic paraboloid shell. Although it has a double curvature anticlastic surface, it can be built by only using linear structural members. Thus, single-layer hyper shells can be fabricated from straight beams and double-layer hyper shells from linear latticed trusses. The single hyper unit shown in Figure 24.16 is suitable for use in the building of square, rectangular, or elliptic plan. In practice, there exist an infinite number of ways of combining hyper units to enclose a given building space.

A shallow hyperbolic paraboloid under uniform loading acts primarily as a shear system, where the shear forces, in turn, cause diagonal tension and compression. The behavior of the surface can be visualized as thin compression arches in one direction and tension cables in the perpendicular direction. In reality, additional shear and bending may occur along the vicinity of the edges.

24.3.5 Intersection and Combination

The basic forms of latticed shells are single-curvature cylinders, as well as double-curvature sphere and hyperbolic paraboloids. Many interesting new shapes can be generated by intersecting and combining of these basic forms. The art of intersection and combination is one of the important tools in the design of latticed shells. To fulfill the architectural and functional requirements, the load-resisting behavior of the structure as a whole and also its relation to the supporting structure should be taken into consideration.

For cylindrical shells, a simply way is to intersect through the diagonal as shown in Figure 24.17a. Two types of groined vaults on square plan can be formed by combining the corresponding intersected curve surfaces shown in Figure 24.17b and c. Likewise, combination of curved surfaces intersected from a cylinder produces a latticed shell on a hexagonal plan as shown in Figure 24.17d.

For spherical shells, segments of the surface are used to cover planes other than circular, such as triangular, square, and polygonal as shown in Figure 24.18a–c, respectively. Figure 24.18d shows a latticed shell on a square plan by combining the intersected curved surfaces from a sphere.

It is usual to combine a segment of cylindrical shell with hemispherical shells at two ends as shown in Figure 24.19. This form of latticed shell is an ideal plan for indoor track fields and ice skating rink.

Different solutions for assembling single hyperbolic paraboloid units to cover a square plan are shown in Figure 24.20. The combination of four equal hyper units produces different types of latticed shell supported on a central column as well as two or four columns along the outside perimeter. These basic blocks, in turn, can be added in various ways to form the multibay buildings.

24.4 Structural Analysis

24.4.1 Design Loads

24.4.1.1 Dead Load

The design dead load is established on the basis of the actual loads that may be expected to act on the structure of constant magnitude. The weight of various accessories — cladding, supported lighting, heat and ventilation equipment — and the weight of space frame comprise the total dead load. An empirical

FIGURE 24.20 Combination of hyperbolic paraboloids.

formula is suggested to estimate the dead weight g of double-layer grids:

$$g = \frac{1}{200} (\zeta \sqrt{q_w L}) \text{ kN/m}^2 \tag{24.3}$$

where q_w indicates all dead and live loads acting on double-layer grid except its self-weight (in kN/m^2); L is the shorter span (in m); and ζ is a coefficient, 1.0 for steel tubes and 1.2 for mill sections.

24.4.1.2 Live Load, Snow, or Rain Load

Live load is specified by the local building code and compared with the possible snow or rain load; the larger one should be used as the design load. Each space frame is designed with uniformly distributed snow load and further allowed for drifting depending on the shape and slope of the structure. Often more than one assumed distribution of snow load is considered. It was recommended by ISO for the determination of snow loads on simple curved roofs, pointed arches, and domes. The intensity of snow load as specified in *Bases for Design of Structures: Determination of Snow Loads on Roofs* [5] is reproduced as Figure 24.21. For domes of circular plan form, an axially symmetrical balanced load may be given as the corresponding balanced arch load. The drift load may likewise be given by the corresponding arch drift load along the plan diameter being parallel to the wind direction multiplied by a reduction factor $(1 - a/r)$ where r is the plan radius and a is the horizontal distance from the wind direction diameter to any parallel plan chord. The snow loads can be calculated by the following formulas:

Windward side

$$s = s_b \tag{24.4a}$$

Leeward side

$$s = s_b + s_d \tag{24.4b}$$

Balanced load part

$$\begin{aligned} s_b &= s_0 C_e C_t \mu_b \\ \mu_b &= \sqrt{\cos(C_m 1.5\beta)} \quad \text{for } (C_m 1.5\beta) \leq 90^\circ \\ \mu_b &= 0 \quad \text{for } (C_m 1.5\beta) > 90^\circ \end{aligned} \tag{24.5}$$

Drifted load part

$$\begin{aligned} s_b &= s_0 C_e C_t (\mu_b \mu_d) \\ \mu_d &= (2.2 C_e - 2.1 C_e^2) \sin(3\beta) \quad \text{for } \beta \leq 60^\circ \\ \mu_d &= 0 \quad \text{for } \beta > 60^\circ \end{aligned} \tag{24.6}$$

where s_0 is the characteristic snow load on the ground (in kN/m^2), μ_b is the slope reduction coefficient, μ_d is the drift load coefficient, C_e is the exposure reduction coefficient, C_t is the thermal reduction coefficient, and C_m is the surface material coefficient.

FIGURE 24.21 Snow loads on simple curved roofs and domes.

The exposure coefficient, C_e , defines the balanced load on a flat horizontal roof of a cold building as a fraction of the characteristic load on the ground. For regions where there are not sufficient sinter climatological data available, it is recommended to set $C_e = 0.8$. However, the designer should always assess whether calm weather conditions (i.e., $C_e = 10$) during the snowfall season might yield more severe conditions for the structure. The thermal coefficient, C_t , is introduced to account for the reduction of snow load on roofs with high thermal transmittance, in particular glass-covered roofs, from melting caused by heat loss through the roof. For such cases C_t may take values less than unity. For all other cases, $C_t = 1.0$ applies. The surface material coefficient, C_m , defines a reduction of the snow load on roofs made of surface material with low surface roughness. It varies between 1.333, for slippery, unobstructed surfaces, to 1.0, for other surfaces. Detailed methods for the determination of these coefficients are given in the annexes of the Standard.

Rain load may be important in the tropical climate especially if the drainage provisions are insufficient. Ponding results when water on a double-layer grid flat roof accumulates faster than it runs off, thus causing excessive load on the roof.

24.4.1.3 Wind Load

The wind loads usually represent a significant proportion of the overall forces acting on barrel vaults and domes. A detailed comparison of the available codes concerning wind loads has revealed quite a large difference between the practices adopted by various countries. Pressure coefficients for arched roof springing from ground surface that can be used for barrel vault design are shown in Figure 24.22 and Table 24.3. For arched roof resting on an elevated structure like enclosure walls, the pressure coefficients are shown in Table 24.4. It should be noticed that ANSI is no longer used in practice in the United States. The ASCE has issued *Minimum Design Loads for Buildings and Other Structures* (SEI/ASCE 7-02). In Chapter C6 “Wind Loads,” detailed provisions for determining wind loads are given.

The wind pressure distribution on buildings is also recommended by the European Committee for Standardization as European Prestandard [6]. The pressure coefficients for arched roof and spherical domes, either resting on the ground or on elevated structure, are presented in graphical forms in Figure 24.23 and Figure 24.24 respectively.

It can be seen that significant variations in pressure coefficients from different codes of practice exist for three-dimensional curved space frames. This is due to the fact that these coefficients are highly dependent on Reynolds number, surface roughness, wind velocity profile, and turbulence. It may be concluded that the codes of practice are only suitable for preliminary design purposes, especially for the important long-span space structures and those lattice shells with peculiar shapes. It is therefore necessary to undertake further wind tunnel tests in an attempt to establish more accurately the pressure distribution over the roof surface. For such tests, it is essential to simulate the velocity profile and turbulence of the natural wind and the Reynolds number effects associated with curved surface.

24.4.1.4 Temperature Effect

Most space frames are subject to thermal expansion and contraction due to changes in temperature and thus may be subject to axial loads if restrained. Potential temperature effect must be considered in the design especially when the span is comparatively large. The choice of support locations — perimeter, intermediate columns, etc. — and types of support — fixed, slid, or free rotation and translation — as

FIGURE 24.22 Wind pressure on an arched roof.

well as the geometry of members adjacent to the support, all contribute to minimizing the effect of thermal expansion. The temperature effect of a space frame may be calculated by the ordinary matrix displacement method of analysis, and most computer programs provided such a function.

For double-layer grid, if it satisfies one of the following requirements, the calculation for temperature effect may be exempted:

1. The joints on supports allow the double-layer grid to move horizontally.
2. Double-layer grids of less than 40 m span are supported along perimeters by independent reinforced concrete columns or brick pilasters.
3. The displacement at the top of the column due to a unit force is greater or equal to the value calculated according to the following formula:

$$\delta = \frac{L}{2\xi EA} \left(\frac{E\alpha\Delta_t}{0.05[\sigma]} - 1 \right) \quad (24.7)$$

where L is the span of the double-layer grid in the direction of checking temperature effect, E is the modulus of elasticity, A is the arithmetic mean value of the cross-sectional area of members in the supporting plane (top or bottom-layer), α is the coefficient of thermal expansion, Δ_t is the temperature difference, $[\sigma]$ is the allowable stress of steel, and ξ is a coefficient: when the chords in the supporting plane are arranged in orthogonal grids, $\xi = 1$, in diagonal grids, $\xi = 2$, and in three-way grids, $\xi = 2$.

24.4.1.5 Construction Loads

During construction, structures may be subjected to loads different from the design loads after completion, depending on the sequence of construction and method of scaffoldings. For example, a space frame may be lifted up at points different from the final supports or it may be constructed in blocks or strips. Therefore, the whole structure, or a portion of it, should be checked during various stages of construction.

24.4.2 Static Analysis

There are generally two different approaches in use for the analysis of space frames. In the first approach the structure is analyzed directly as a general assembly of discrete members, that is, *discrete method*.

FIGURE 24.23 Wind pressure coefficients for arched roof.

Notes: (a) For $0 \leq h/d \leq 0.5$, $c_{pe,10}$ is obtained by linear interpolation; (b) for $0.2 \leq h/d \leq 0.3$ and $h/d \geq 0.5$, two values of $c_{pe,10}$ have to be considered; and (c) the diagram is not applicable for slat roofs.

In the second approach the structure is represented by an equivalent continuum like a plate or shell, that is, *continuum analogy method*.

The advent of computers has radically changed the whole approach to the analysis and design of space frames. It has also been realized that matrix methods of analysis provide an extremely efficient means for rapid and accurate treatment of many types of space structures. In the matrix analysis, a structure is represented as a discrete system, and all the usual equations of structural mechanics are written conveniently in matrix form. Thus, matrix analysis is particularly suitable to computer formulation, with an automatic sequence of operations. A number of general purpose computer programs like STRUDL, SAP, and ANSYS have been developed and are available to designers.

The two common formulations of the matrix analysis are the stiffness method and the flexibility method. The stiffness method is also referred to as displacement method, since the displacements of the redundant members are treated as unknowns. The flexibility method (or force method) treats the forces in the members as unknowns. Of these two methods, the displacement method is widely used in most computer programs.

FIGURE 24.24 Wind pressure coefficients for spherical domes.

Note: $c_{pe,10}$ is constant along arcs of circles, intersections of the sphere and of planes perpendicular to the wind; it can be determined as a first approximation by linear interpolation between the values in A, B, and C along the arcs of circles parallel to the wind. In the same way the value of $c_{pe,10}$ in A if $0 < h/d < 1$ and in B or C if $0 < h/d < 0.5$ can be obtained by linear interpolation in the figure.

In the *displacement method*, the stiffness matrix of the whole structure is obtained by adding appropriately the stiffness matrices of the individual elements. Supports are then introduced since the displacements at these points are known. A set of simultaneous equations are solved for displacements. From the joint displacements the member elongation can be found and, hence, the member forces and reaction at supports.

The matrix displacement method is by far the most accurate method for the analysis of space frames. It can be used without any limit on the type and shape of the structure, the loadings, the supporting conditions, or the variation of stiffness. The effect of temperature or uneven settlement of supports can be also analyzed conveniently by this method. For design work, a special purpose computer program for space frames is preferred, otherwise the input of generating nodal coordinates and member connectivity plus loading information will be a tremendous amount of work. Some sophisticated computer programs provide the functions of automatic design, optimization, and drafting.

Double-layer grids can be analyzed as pin connected, and rigidity of the joints does not change the stress by more than 10 to 15%. In the displacement method, bar elements are used with three unknown displacements in the x , y , and z directions at each end. For single-layer reticulated shells with rigid joints, bar elements are used and the unknowns are doubled, that is, three displacements and three rotations. Under specific conditions, single-layer braced domes may be analyzed as pin connection joints with reasonable accuracy if the rise of the dome is comparatively large and under symmetric loading.

When using a computer, the engineer must know the assumptions on which the program is based, the particular conditions for its use (boundary conditions for example), and the manner of introducing the input data. In the static analysis of space frames, care should be taken on the following issues.

24.4.2.1 Support Conditions

A fixed support (bolted or welded) in construction should not be treated as a completely fixed node in analysis literally. As a matter of fact, most space frames are supported on columns or walls that have a lateral flexibility. Upon the acting of external loads, there will be lateral displacements on the top of columns. Therefore, it is more reasonable to assume the support as horizontally movable rather than fixed, or as an elastic support by considering the stiffness of the supporting column.

24.4.2.2 Criteria for the Number of Reanalyses

Usually, a set of sectional areas are assumed for members, and the computer will proceed to analyze the structure to obtain a set of member forces. Then, the members are checked to see if the assumed areas are appropriate. If not, the structure should be reanalyzed until the forces and stiffness will completely match with each other. However, such extended reanalyses by the stiffness method will induce a high concentration of stiffness and, hence, a great difference of member sections, which is unacceptable for practical use. Therefore, it is necessary to limit the number of reanalyses. In practice, certain criteria are specified such that the reanalyses will terminate automatically. One of the criteria suggested is the number of modified members should be less than 5% of the total number of members. Usually, three or four runs will produce a satisfactory result.

24.4.2.3 Checking of Computer Output

It is dangerous for an engineer to rely on the computer output as being infallible. Always try to estimate and anticipate results approximately. A simple manual calculation by the approximate method and comparing it with the computer output will be beneficial. By doing so, at least one can get an order of magnitude for the results. In this operation, intuition also plays an important role. At the same time, simple checks should be done to test the reliability of the computer program, such as the equilibrium of forces at nodes and equilibrium of total loading with the summation of reactions. A check on the deflections along certain axes of the structure would also be helpful. The size and location of any large deflection should be noted. All deflections should be scanned to look for possible bad solutions caused due to improper modeling of the structure. This check is made easily if the program has the ability to produce a deformed geometry plot.

A *continuum analogy method* may also be used for the static analysis of space frames. This is to replace a latticed structure by an equivalent continuum that exhibits equivalent behavior with respect to strength and stiffness. The equivalent rigidity is used for the stress and displacement analysis in the elastic range, particularly for stability and dynamic analysis. It is also useful for providing an understanding of the overall behavior of the structure. By using equivalent rigidity, the thickness, elastic moduli, and Poisson's ratio are determined for the equivalent continuum, and the fundamental equations that govern the behavior of the equivalent continuum are established as in the usual continuum theory. Therefore, the methods of solution and the results of the theory of plates and shells are directly applicable. Thus, certain types of latticed shells and double-layer grids can be analyzed by treating them as a continuum and applying the shell or plate analogy. This method has been found to be satisfactory where the loading is uniform and the load transfer is predominantly through membrane action.

Some difficulties may occur in the application of continuum analogy method. The boundary conditions of the continuum cannot be entirely analogous to the boundary condition of the discrete prototype. Also, some of the effects that are relatively unimportant in the case of continua may be significant in the case of space frames. Two of these merit mention. The effect of shear deformation in elastic plates and shells is essentially negligible, whereas the contributions of web members connecting the layers of a space frame can be significant to the total deformation. Similarly, the correct continuum model of a rigidly connected space frame must allow for the possibility of rotation of joints independent

of the rotations of normal sections. Such models are more complex than the usual ones, and few solutions of the governing equations exist.

It is useful to compare the discrete method and continuum analogy method. The continuum analogy method can only be applied to regular structures, while the discrete method can handle arbitrary structural configuration. The computational time is much less for an equivalent shell analysis than for a stiffness method analysis. The work involved in a continuum analogy method includes calculating the equivalent rigidity, calculating the forces in the equivalent continuum and finally calculating the forces in the members. This will go through a discrete–continuum–discrete process and hence involves further approximation. To summarize, the continuum analogy method is most valuable at the stage of conceptual and preliminary design, while the discrete method should be used for a working design.

24.4.3 Earthquake Resistance

One of the important issues that must be taken into consideration in the analysis and design of space frames is the earthquake excitation in case the structure is located in a seismic area. The response of the structure to earthquake excitation is dynamic in nature, and usually a dynamic analysis is necessary. The analysis is complicated due to the fact that the amplitude of ground accelerations, velocities, and motions is not clearly determined. Furthermore, the stiffness, mass distribution, and damping characteristics of the structure will have a profound effect on its response: the magnitude of internal forces and deformations.

The dynamic behavior of a space frame can be studied first through the vibration characteristics of the structure, which is represented by its natural frequencies. The earthquake effects can be reflected in response amplification through interaction with the natural dynamic characteristics of the structures. Thus, double-layer grids can be treated as a pin-connected space truss system, and its free vibration is formulated as an equation of motion for a freely vibrating undamped multi-degree-of-freedom system. By solving the generalized eigenvalue problems, the frequencies and vibration modes are obtained.

A series of double-layer grids of different types and spans were taken for dynamic analysis [7]. The calculation results show some interesting features of the free vibration characteristics of the space frames. The difference between the frequencies of the first ten vibration modes is so small that the frequency spectrums of space frames are rather concentrated. The variation of any design parameter will lead to the change of frequency. For instance, the boundary restraint has a significant influence on the fundamental period of the space frame: the stronger the restraint, the smaller the fundamental period.

The fundamental periods of most double-layer grids range from 0.37 to 0.62 s which is less than that of planar latticed trusses of comparable size. This fact shows clearly that the space frames have a relatively higher stiffness. Investigating into the relationship of fundamental periods of different types of double-layer grids with span, it is found that fundamental period increases with the span, that is, the space frames will be more flexible for longer span. The response of space frame with shorter span will be stronger.

The vibration modes of double-layer grids could be classified mainly as vertical modes and horizontal modes that appear alternately. In most cases, the first vibration modes are vertical. The vertical modes of different types of double-layer grids demonstrate essentially the same shape, and the vertical frequencies for different space frames of equal span are very close to each other. It was found that the forces in the space frame due to vertical earthquake are mainly contributed by the first three symmetrical vertical modes. Certain relations could be established between the first three frequencies of the vertical mode as follows:

$$\omega_{v2} = (2 - 3.5)\omega_{v1} \quad (24.8)$$

$$\omega_{v3} = (4 - 4.6)\omega_{v2} \quad (24.9)$$

where ω_{v1} , ω_{v2} , and ω_{v3} are the first, second, and third vertical frequencies, respectively.

The simplest way to estimate the earthquake effect is a quasi-static model, in which the dynamic action of the ground motion is simulated by a static action of equivalent loads. The manner in which the equivalent static loads are established is introduced in many seismic design codes of different countries. In the region where the maximum vertical acceleration is 0.05g, usually the earthquake effect is not the governing factor in design and it is not necessary to check the forces induced by vertical or horizontal

earthquake. In the area where the maximum vertical acceleration is 0.1g or greater, a factor of 0.08 to 0.2, depending on different codes, is used to multiply the gravitational loads to represent the equivalent vertical earthquake load. It should be noticed that in certain seismic codes, the live load that forms a part of gravitational loads is reduced by 50%. The values of vertical seismic forces in the members of double-layer grids are higher near the central region and decrease gradually toward the perimeters. Thus, the ratio between the forces in each member due to vertical earthquake and static load is not constant over the whole structure. The method of employing equivalent static load serves only as an estimation of the vertical earthquake effect and provides an adequate level of safety.

Due to the inherent horizontal stiffness of double-layer grids, the forces induced by horizontal earthquake can be resisted effectively. In the region of 0.1g maximum acceleration, if the space grids are supported along perimeters with short or medium span, it is not required to check the horizontal earthquake. However, for double-layer grids of longer span or if the supporting structure underneath is rather flexible, seismic analysis in the horizontal direction should be done. In the case of latticed shells with curved surface, the response to horizontal earthquake is much stronger than in double-layer grids depending on the shape and supporting condition. Even in the region with maximum vertical acceleration of 0.05g, the horizontal earthquake effect on latticed shells should be analyzed. In such an analysis, the coordinating action of space frame and the supporting structure should be considered. A simple way of coordination is to include the elastic effect of the supporting structure. This is represented by the elastic stiffness provided by the support in the direction of restraint. The space frame is analyzed as if the supports have elastic restraints horizontally. For more accurate analysis, the supporting columns are taken as member with bending and axial stiffness and analyzed together with the space frame. In the analysis, it is also important to include the inertial effect of the supporting structure, which has influence on the horizontal earthquake response of the space frame.

In the case of more complex structures or large span, dynamic analysis such as response spectrum method for modal analysis should be used. Such a method gives a good estimate of the maximum response during which the structure behaves elastically. For space frames, the vertical seismic action should be considered. However, few recorded data on the behavior of such a structure under vertical earthquake exist. In some seismic design codes, the magnitude of the vertical component may be taken as 50 to 65% of the horizontal motions. It is recommended to use 10 to 20 vibration modes for the space frames when applying the response spectrum method.

For space frames with irregular and complicated configuration or important long-span structures, time-history analysis method should be used. The number of acceleration records or synthesized acceleration curves for time-history analysis is determined according to intensity, near or far earthquake, and site category. In usual practice, at least three records are used for comparison. This method is an effective tool to calculate the earthquake response when large, inelastic deformations are expected.

The behavior of latticed structures under dynamic loads or, more specifically, the performance of latticed structures due to earthquake was the main concern of structural engineers. An ASCE Task Committee on Latticed Structures under Extreme Dynamic Loads was formed to investigate this problem. One of the objectives was to determine if dynamic conditions have historically been the critical factor in the failure of lattice structures. A short report on "Dynamic Considerations in Latticed Structures" [8] was submitted by the Task Committee in 1984. Eight major failures of latticed roof structures were reported, but notably none of them was due to earthquake.

Since the ASCE report was published, valuable information on the behavior of space frame during earthquake has been obtained through two seismic events. In 1995, the Hanshin area of Japan suffered a strong earthquake, and many structures were heavily damaged or destroyed. However, comparing with other types of structures, most of the damage to space frames located in that area was relatively minor [9]. It is worthwhile to mention that two long-span sports arenas of space frame construction were built on an artificial island in Kobe, and no major structural damage was found. On the other hand, serious damage to a latticed shell was found on the roof structure of a hippodrome stand where many members were buckled. The cause of the damage is not due to the strength of the space frame itself but the failure of the supporting structure. Another example of serious damage to double-layer grids in the roof

structure of a theater occurred in 1985, when a strong earthquake struck the Kashigor District of Sinkiang Uygur Autonomous Region in China [10]. Failure was caused by a flaw in the design as the elastic stiffness and inertial effect of the supporting structures were completely ignored. Behavior of space frame structures under strong earthquake has generally been satisfactory from a strength point of view. Experience gained from strong earthquakes shows that the space frames demonstrate an effective spatial action and consequently a reasonably good earthquake resistant behavior.

24.4.4 Stability

Although a great amount of research work has been carried out to determine the buckling load of latticed shells, the available solutions are not satisfactory for practical use. The problem is complicated by the effect of geometric nonlinearity of the structure and also the influence of the joint system according to which the members can be considered as pin connected, partially or completely restrained at the nodes. The following points are important in the buckling analysis of latticed shells [11]:

1. Decision on which kind of nonlinearity is to be used — only geometrical nonlinearity with the elastic analysis or geometrical and material nonlinearities with the elastic–plastic analysis.
2. Choosing the physical model — equivalent continuum or discrete structure.
3. Choosing the computer model and numerical procedure for tracing the nonlinear response for precritical behavior, collapse range, and postcritical behavior.
4. Study of factors that influence load-carrying capacity — buckling modes, density of network, geometrical and mechanical imperfections, plastic deformations, rigidity of joints, load distributions, etc.
5. Experimental investigations to provide data for analysis (rigidity of joints, postbuckling behavior of individual members, etc.) and confirmation of theoretical values.

Generally speaking, there are three types of buckling that may occur in latticed shells:

1. Member buckling (Figure 24.25a)
2. Local or dimple buckling at a joint (Figure 24.25b)
3. General or overall buckling of the whole structure (Figure 24.25c)

Member buckling occurs when an individual member becomes unstable, while the rest of the space frame (members and nodes) remains unaffected. The buckling load P_{cr} of a straight prismatic bar under axial compression is given by

$$P_{cr} = \alpha \frac{\pi^2 E_e I}{l^2}, \quad \alpha = \alpha(c_1, c_2, w_0, e, m) \quad (24.10)$$

where E_e is the effective modulus of elasticity that coincides with Young's modulus in the elastic range, I is the moment of inertia of member, and l is the length of the member. The coefficient α takes different values depending on the parameter in the parentheses. The quantities c_1 and c_2 characterize the rotational stiffness of the joints, w_0 is the initial imperfection, e is the eccentricity of the end compressive forces, and m indicates the end shear forces and moments. A reduced length l_0 should be used in place of l when the ratio of the joint diameter to member length is relatively large. On the basis of Equation 24.10, the design code for steel structures in different countries provides methods for estimating member buckling, usually by introducing the slenderness ratio $\lambda = l/r$, where r is the radius of gyration of the member's section.

FIGURE 24.25 Different types of buckling.

The *local buckling* of space frame consists of a snap-through buckling, which takes place at one joint. Snap-through buckling is characterized by a strong geometrical nonlinearity. Local buckling is apt to occur when the ratio of t/R (where t is the equivalent shell thickness and R is the radius of curvature) is small. Similarly, local buckling of a space frame is likely to occur in single layer latticed shells.

Local buckling is greatly affected by the stiffness of and the loads on the adjacent members. Consider the pin-connected structure shown in Figure 24.26. Buckling load q_{cr} in terms of uniform normal load per unit area can be expressed as

$$\frac{AEI}{12R^3} \leq q_{cr} \leq \frac{AEI}{6R^3} \tag{24.11}$$

where A is the cross-sectional area of the member, E is the modulus of elasticity, and R is the radius of an equivalent spherical shell through points B–A–B.

In practice, different types of joints used in the design will possess different flexural strengths; thus, the actual behavior of the joint and member assembly should be incorporated in determining the local buckling load. An approximate formula was proposed by Lind [12] and is applicable to triangular networks having all elements of the same cross-sections. For the uniform load, the critical load is

$$Q_{cr} = \frac{E_t}{1 + \alpha^2/8\pi^2} \left(0.47 \frac{Al^3}{R^3} + 3 \frac{BI}{R} \right), \quad \alpha = l^2/rR \tag{24.12}$$

where E_t is the tangent modulus of elasticity, R is the radius of curvature of the framework midsurface, r is the radius of gyration, and B is the nondimensional bending stiffness of the grid given in Table 24.5. For the concentrated load, the following two formulas are presented:

$$W_{cr} = \frac{3EAh^3}{l^3} \left[\frac{8B}{\alpha^2} + 0.241 \left(1 - 5.95 \frac{8B}{\alpha^2} \right) \right] \tag{24.13}$$

which is valid for $\alpha > 9$, and

$$W_{cr} = 0.0905EA \left(\frac{l}{R} \right)^3 \tag{24.14}$$

for a regular pin-jointed triangular network.

FIGURE 24.26 Local buckling of a pin-connected structure.

TABLE 24.5 Equivalent Bending Stiffness B

α	$\frac{1}{32}$	$\frac{1}{16}$	$\frac{1}{8}$	$\frac{1}{4}$	$\frac{1}{2}$	1	2	4	8	16	32	64
B	0.868	0.873	0.886	0.950	1.176	1.85	3.15	4.83	6.48	7.35	7.80	7.90

The *overall buckling* occurs when a relatively large area of the space frame becomes unstable and a relatively large number of joints are involved in the buckle. For most cases, in overall buckling of a space frame, the wave length is significantly greater than the member length. Local buckling often plays the role of a trigger for overall buckling.

The type of buckling collapse of a space frame is greatly influenced by the following factors: its Gaussian curvature, whether it is single- or double-layer system, the degree of statical indeterminacy, and the manner of supporting and loading. Generally speaking, a shallow shell of positive Gaussian curvature, like a dome, is more prone to overall buckling than a cylindrical shell of zero Gaussian curvature. Recent research reveals that hyperbolic paraboloid shell is less vulnerable to overall buckling and the arrangement of the grids has a considerable influence on the stability and stiffness of the shell. It is best to arrange the members along the direction of compressive forces. Single-layer space frame exhibits greater sensitivity to buckling than the double-layer structure. Moreover, various types of buckling behavior may take place simultaneously in a complicated relation. For double-layer grids, in most cases, it is sufficient to examine the member collapse that may occur in the compressive chord members.

The theoretical analysis of buckling behavior may be approached by two methods: continuum analogy analysis and discrete analysis. Since almost all space frames are constructed from nearly identical units arranged in a regular pattern, it is generally accepted that the analysis on the basis of the equivalent continuum serves as an important tool in the investigation of the buckling behavior of space frames. Numerous analytical and experimental studies on the buckling of continuous shells have been performed, and the results can be applied to the latticed shells.

The buckling formula for a spherical shell subjected to a uniformly distributed load normal to the middle surface can be expressed as

$$q_{cr} = kE \left(\frac{t}{R} \right)^2 \quad (24.15)$$

where t is the thickness and R is the radius of the shell.

Different values of the coefficient k were obtained by various investigators:

- 1.21 ([13], based on classical linear theory)
- 0.7 (experiments on very carefully prepared models)
- 0.366 ([14], based on nonlinear elastic theory)
- 0.228 and 0.246 ([15], for $\mu = 0$ and 0.3, respectively).

For a triangulated dome, where an equivalent thickness is used, Wright [16] derived the formula by using

$$\begin{aligned} E &= AE/3rl, \quad t = 2\sqrt{3}r, \quad k = 0.4 \\ q_{cr} &= 1.6E \frac{Ar}{lR^2} \end{aligned} \quad (24.16)$$

The critical load for overall buckling may also be expressed as the following formula for comparison:

$$q_{cr} = k' \frac{E}{R^2} t_m^{1/2} t_b^{3/2} \quad (24.17)$$

where t_m is the effective in-plane thickness, t_b is the effective bending thickness, and the values of k' are

- 0.377 [16]
- 0.365 [17]
- 0.247 [15]
- 0.294 [18]

Discrete Analysis is a more powerful tool to study the whole process of instability for space frames. As shown in [Figure 24.27](#), a structure may lose its stability when it has reached a "limit point," where

FIGURE 24.27 Instability points.

the stiffness is lost completely. On the other hand, a structure, such as a dome, may lose its stability by a sudden buckling into a mode of deformation before the limit point, which occurs at a distinct *critical point* — the “bifurcation point” on the load path. It should be noted that the initial imperfection of the structure will greatly reduce the value of critical load, and certain types of space frame are very sensitive to the presence of imperfection.

In the stability analysis, usually the characteristic at a certain special state is investigated, that is, the stability mode and critical load are analyzed as an eigenvalue problem. The researchers are now more interested to study the whole process of nonlinear stability. As a result of the development of the computer matrix method, numerical analyses of the large system have become straightforward. Therefore, the discrete analysis of a space frame, itself a discrete structure, is very suitable for the study of stability problems. Major problems encountered in the nonlinear stability process are mathematical and mechanical modeling of the structure, numerical technique for solving nonlinear equations, and tracing method for the nonlinear equilibrium path. A great many research works have been carried out in the above area.

The Newton–Raphson method or the modified Newton–Raphson method is the fundamental method for solving the nonlinear equilibrium equations and has proved to be one of the most effective methods. The purpose of tracing the nonlinear equilibrium path is as follows: (a) to provide equilibrium analysis for the prebuckling state, (b) to determine the critical point, such as the limit point or bifurcation point, on the load path and its critical load, and (c) to trace the postbuckling response. On the basis of the increment-iteration process for finite element method, techniques for the analysis of nonlinear equilibrium path and its tracing tactics have made significant progress in recent years. Numerical methods used for the construction of equilibrium path associated with nonlinear problems, like load incremental method, constant arc-length method, displacement control method, etc., were developed by different authors. Since each technique has its advantages and disadvantages in the derivation of fundamental equations, accuracy of solution, computing time, etc., the selection of an appropriate method has a profound influence on the efficiency of computation. In the present stage of development, complicated equilibrium path can be traced with the aid of the above technique. Computer programs have been developed for the whole process of nonlinear stability and can be used for the design of various types of latticed shells.

24.5 Jointing Systems

24.5.1 General Description

The jointing system is an extremely important part of a space frame design. An effective solution of this problem may be said to be fundamental to successful design and construction. The type of jointing

depends primarily on the connecting technique, whether it is bolting, welding, or applying special mechanical connectors. It is also affected by the shape of the members. This usually involves a different connecting technique depending on whether the members are circular or square hollow sections or rolled steel sections. The effort expended on research and development of jointing systems has been enormous, and many different types of connectors have been proposed in the past decades.

The joints for the space frame are more important than the ordinary framing systems because more members are connected to a single joint. Furthermore, the members are located in a three-dimensional space, and hence the force transfer mechanism is more complex. The role of the joints in a space frame is so significant that most of the successful commercial space frame systems utilize proprietary jointing systems. Thus, the joints in a space frame are usually more sophisticated than the joints in planar structures, where simple gusset plates will suffice.

In designing the jointing system, the following requirements should be considered. The joints must be strong and stiff, simple structurally and mechanically, and easy to fabricate without recourse to more advanced technology. The eccentricity at a joint should be kept to a minimum, and yet the joint detailing should provide for the necessary tolerances that may be required during the construction. Finally, joints of space frames must be designed to allow for easy and effective maintenance.

The cost of the production of joints is one of the most important factors affecting the final economy of the finished structure. Usually, the steel consumption of the connectors will constitute 15 to 30% of the total. Therefore, a successful prefabricated system requires joints that must be repetitive, mass produced, simple to fabricate, and able to transmit all the forces in the members interconnected at the node.

All connectors can be divided into two main categories: the purpose-made joint and the proprietary joint used in the industrialized system of construction. The purpose-made joints are usually used for long-span structure where the application of standard proprietary joints is limited. An example of such a joint is the cruciform gusset plate for connecting rolled steel sections shown in Figure 24.28.

A survey around the world will reveal that there are over 250 different types of jointing system suggested or used in practice, and there are some 50 commercial firms trying to specialize in the manufacture of proprietary jointing systems for space frames. Unfortunately, many of these systems have not proved to be very successful mainly because of the complexity of the connecting method. Table 24.6, Table 24.7, and Table 24.8 give a comprehensive survey of the jointing systems all over the world. All the connection techniques can be divided into three main groups: (a) with a node, (b) without a node, and (c) with prefabricated units.

24.5.2 Proprietary System

Some of the most successful prefabricated jointing systems are summarized in Table 24.9. This is followed by further description of each system.

24.5.2.1 Mero

The Mero connector, introduced some 50 years ago by Dr. Mengerlinghausen, proved to be extremely popular and has been used for numerous temporary and permanent buildings. Its joint consists of a node that is a spherical hot-pressed steel forging with flat facets and tapped holes. Members are circular hollow sections with cone-shaped steel forgings welded at the ends, which accommodate connecting bolts. Bolts are tightened by means of a hexagonal sleeve and dowel pin arrangement, resulting in a completed joint such as that shown in Figure 24.29. Up to 18 members can be connected at a joint with no eccentricity. The manufacturer can produce nodes of different sizes with diameters ranging from 46.5 to

FIGURE 24.29 Mero system.

FIGURE 24.30 Dimensions of spherical node.

350 mm, the corresponding bolts ranging from M12 to M64 with a maximum permissible force of 1413 KN. A typical space module of the Mero system is a square pyramid (half an octahedron) with both chord and diagonal members of the same length, 'a'; angles extended are 90 or 60°. Thus, the depth of the space module is $a/\sqrt{2}$, and the vertical angle between diagonal and chord member is 54.7°.

The Mero connector has the advantage that the axes of all members pass through the center of the node, eliminating eccentricity loading at the joint. Thus, the joint is only under the axial forces. Then, tensile forces are carried along the longitudinal axis of the bolts and resisted by the tube members through the end cones. The compressive forces do not produce any stresses in the bolts; they are distributed to the node through the hexagonal sleeves. The size of the connecting bolt of compression members based on the diameter calculated from its internal forces may be reduced by 6 to 9 mm.

The diameter of a steel node may be determined by the following equation (Figure 24.30):

$$D \geq \sqrt{\left(\frac{d_2}{\sin \theta} + d_1 \cot \theta + 2\xi d_1\right)^2 + \eta^2 d_1^2} \tag{24.18}$$

However, to satisfy the requirements of the connecting face of the sleeve, the diameter should be checked by the following equation:

$$D \geq \sqrt{\left(\frac{\eta d_2}{\sin \theta} + \eta d_1 \cot \theta\right)^2 + \eta^2 d_1^2} \tag{24.19}$$

where D is the diameter of the steel ball (mm), θ is the smaller intersecting angle between two bolts (rad), d_1 and d_2 are the diameters of the bolts (mm), ξ is the ratio between the inserted length of the bolt into the steel ball and the diameter of the bolt, and η is the ratio between the diameter of the circumscribed circle of the sleeve and the diameter of the bolt. ξ and η may be determined by the design tension values or compression strength of the bolt, respectively. Normally, $\xi = 1.1$ and $\eta = 1.8$. The diameter of the steel ball should be taken as the larger of the values calculated from Equations 24.18 and 24.19.

The Mero connector was originally developed for double-layer grids. Due to the increasing use of nonplanar roof forms, it is required to construct the load-bearing space frame integrated with the cladding element. A new type of jointing system called Mero Plus System was developed so that a variety of curved and folded structures are possible. Square or rectangular hollow sections are used to match the particular requirements of the cladding so that a flush transition from member to connecting node can be executed. The connector can transmit shear force, resist torsion and, in special cases, resist bending moment. There are four groups in this system, which are described as follows.

24.5.2.1.1 Disk Node (Type TK)

This a planar ring-shaped node connecting 5 to 10 members of square or rectangular sections. A single bolt is used to connect the node and member, and depth of node is equal to member section depth. Such

FIGURE 24.31 Disk node (type TK).

FIGURE 24.32 Bowl node (type NK).

FIGURE 24.33 Cylinder node (type ZK).

a jointing system can transmit shear force and resist rotation (Figure 24.31). In the following discussion the U-angle is designated as the angle between two members connected to the same node. Also, the V-angle is the angle between the member axis and the normal in the plane of the node, which is a measure of curvature. For disk node, the U-angle varies from 30 to 80°, and the V-angle varies from 0 to 10°. This type of jointing system is essentially pin-jointed connections and be suitable for latticed shells made of triangular meshes.

24.5.2.1.2 Bowl Node (Type NK)

This is a hemispherical node connecting top chord and diagonal members. A single bolted connection from node to member is used. The top chord members of square or rectangular sections can be loaded in shear and are fitted flush to the nodes. Bowl nodes are used for double-layer planar and curved surfaces, in particular buildings irregular in plan or pyramid in shape. The diagonals and lower chords are constructed in ordinary Mero system with circular tubes and spherical nodes (Figure 24.32).

24.5.2.1.3 Cylinder Node (Type ZK)

This is a cylindrical node with multiple bolted connection, which can transmit bending moment (Figure 24.33). Usually, the node can connect 5 to 10 square or rectangular sections that can take transverse loading. Connection angle varies from 30 to 100° for U-angle and from 0 to 10° for V-angle. Cylinder nodes are used in singly or doubly curved surface of latticed shells with trapezoidal meshes where flexural rigid connections are required.

24.5.2.1.4 Block Node (Type BK)

This is a block- or prism-shaped solid node connecting members of square or rectangular sections. The U-angle varies from 70 to 120°, and the V-angle varies from 0 to 10°. It can be used for singly or doubly curved surfaces with pin-jointed or rigid connections where the number of members is small. The structure is of simple geometry and small dimensions (Figure 24.34).

FIGURE 24.34 Block node (type BK).

FIGURE 24.35 Space deck system.

24.5.2.2 Space Deck

The Space Deck System, introduced in England in the early 1950s, utilizes pyramidal units that are fabricated in the shop, as shown in Figure 24.35. The four diagonals made of rods or bars are welded to the corners of the angle frame and joined to a fabricated boss at the apex. It is based on square pyramid units that form a configuration of square on square offset double-layer space grids. The units are field-bolted together through the angle frames. The apexes of the units are connected in the field by using tie bars made from high-tensile steel bars. Camber can be achieved by adjusting the tie bar lengths, since right- and left-hand threading is provided in the boss. The Space Deck System is usually used for buildings of span less than 40 m with a standard module and depth, both of 1.2 m; a minimum structural depth of 0.75 m is also provided. For higher design loading and larger spans, alternative production modules of 1.5 and 2.0 m with the same depth as the module are also available.

24.5.2.3 Triodetic

The joint for the Triodetic System, developed in Canada, consists of an extruded aluminum connector hub with serrated keyways. Each member end is pressed to form a coined edge that fits into the hub keyway. The joint is completed when the members are inserted into the hub, washers are placed at each end of the hub, and a screw bolt is passed through the center of the hub, as shown in Figure 24.36. The triodetic connector can be used for any type of three-dimensional space frame. Originally, only aluminum structures were built in this system, but now, space frames are erected using galvanized steel tubes and aluminum hubs. Triodetic double-layer grids have been used up to 33-m clear span. The basic module can be almost any size up to approximately 2.7 m^2 . The depth is usually 70% of the module size.

24.5.2.4 Unistrut

The Unistrut System was developed in the United States in the early 1950s. Its joint consists of a connector plate that is press-formed from steel plate. The members are channel-shaped, cold-formed sections and are fastened to the connector plate by using a single bolt at each end. The connectors for the top and bottom-layers are identical, and therefore the Unistrut double-layer grids consist only of four components, that is, the connector plate, the strut, the bolt, and the nut (see Figure 24.37). The maximum span for this system is approximately 40 m with standard modules of 1.2 and 1.5 m. The name of Moduspan has also been used for this system.

24.5.2.5 Oktaplatte

The Oktaplatte System utilizes hollow steel spheres and circular tube members that are connected by welding. The node is formed by welding two hemispherical shells together, which are made from steel plates either by hot or cold pressing. The hollow sphere may be reinforced with an annular diaphragm. This type of node was popular at the early stage of development of space frames. It is also useful for the long-span structures where other proprietary systems are limited by their bearing capacity. Hollow spheres with diameter up to 500 mm are used. It can be applied to single-layer latticed shells as the joint can be considered as semi- or fully rigid. The whole jointing system and the hollow sphere with its parts are shown in Figure 24.38.

FIGURE 24.36 Triodetic system.

FIGURE 24.37 Unistrut system.

FIGURE 24.38 Oktaplatte system.

The allowable bearing strength of hollow spheres can be calculated by the following empirical formulas:

Under compression

$$N_c = \eta_c \left(6.6td - 2.2 \frac{t^2 d^2}{D} \right) \frac{1}{K} \text{ (tons)} \tag{24.20}$$

Under tension

$$N_t = \eta_t (0.6td\pi) [\sigma] \tag{24.21}$$

where D is the diameter of the hollow sphere (cm), t is the wall thickness of the hollow sphere (cm), d is the diameter of the tubular member (cm), $[\sigma]$ is the allowable tensile stress, η_c and η_t are the amplification factors due to the strengthening effect of the diaphragm, taken as 1.4 and 1.1, respectively, and K is a factor of safety.

24.5.2.6 Unibat

The Unibat System, developed in France, consists of pyramidal units by arranging the top-layer set on a diagonal grid relative to the bottom-layer. The short length of the top chord members results in less material being required in these members to resist the applied compressive and bending stresses. The standard units are connected to the adjacent units by means of a single high-tensile bolt at each upper corner. The bottom-layer is formed by a two-way grid of circular hollow sections, which are interconnected with the apex of pyramidal units by a single vertical bolt (Figure 24.39). Numerous multistory buildings, as well as large-span roofs over sports buildings, have been built using the Unibat System since 1970.

24.5.2.7 Nodus

The Nodus System was developed in England in the early 1970s. Its joint consists of half-casing, which is made of cast steel and has machined grooves and drilled holes, as shown in Figure 24.40. The chord connections are made of forged steel, have machined teeth, and are full-strength welded to the member ends. The teeth and grooves have an irregular pitch to ensure proper engagement. The forked connectors are made of cast steel and are welded to the diagonal members. In the completed joint, the centroidal axes of the diagonals intersect at a point that generally does not coincide with the corresponding intersecting points of the chord members. This eccentricity produces some amount of local bending in the chord members and the joint components. Destructive load tests performed on typical joints usually result in failures due to bending of the teeth in the main half-casing. The main feature of the Nodus jointing system is that all fabrication is carried out in the workshop so that only the simplest erection techniques are necessary for the assembly of the structure on-site.

24.5.2.8 NS Space Truss

The NS Space Truss System was introduced around 1970 by the Nippon Steel Corporation. It originated from the space truss technology developed for the construction of the huge roof at the symbol zone for Expo '70 in Japan. The NS Space Truss System has a joint consisting of thick spherical steel shell connectors open at the bottom for bolt insertion. The structural members are steel hollow sections having specially shaped end cones welded to both ends of the tube. End cones have threaded bolt holes. Special high-strength bolts are used to join the tubular members to the spherical shell connector. The NS nodes enable several members to be connected to one node from any direction without any eccentricity of internal forces. The NS Space Truss System has been used successfully for many large-span double- and triple-layer grids, domes, and other space structures. The connection detail of the NS node is shown in Figure 24.41.

FIGURE 24.39 Unibat system.

FIGURE 24.40 Nodus system.

FIGURE 24.41 NS space truss.

24.5.3 Bearing Joints

Space frames are supported on columns or ring beams through bearing joints. These joints should possess enough strength and stiffness to transmit the reactions at the support safely. Under the vertical loading, bearing joints are usually under compression. In some double-layer grids with diagonal layout, bearing joints at corners may resist tension. In latticed shells, both vertical and horizontal reactions are acting on the bearing joints.

The restraint of the bearing joint has a distinct influence on the joint displacement and member forces. The construction detail of bearing support should conform to the restraint assumed in the design as near as possible. If this requirement is not satisfied, the magnitude or even the sign of the member forces may be changed.

The axes of all connecting members and the reaction should be intersected at one point at the support where a hinged joint is used. This will allow free rotation of the joint. From an engineering standpoint, the space frame may be fixed in the vertical direction, while in the horizontal direction, it may be fixed either tangential or normal to the boundary or both. The way the space frame is fixed often depends on the temperature effect. If the bearing support can allow a horizontal motion normal to the boundary, then the member forces due to the temperature variation can be neglected. In such a case, the bearing should be constructed so that it can slide horizontally. For those space frames with large-span or complicated configuration, especially curved surface structures supported on a sloped base, care should be exercised to ensure a reliable bearing support.

Typical details for bearing joints are shown in Figure 24.42. The simplest form of bearing is to establish the joint on a flat plate and anchored by bolts as shown in Figure 24.42a and b. This joint seems to be fixed at the support, but in structural analysis it has to be incorporated with the supporting structure, such as columns or walls that have a lateral flexibility. Figure 24.42c shows the joint resting on a curved bearing block, which allows rotation along the curved surface. This type of construction is considered as a hinged joint. If a laminated elastomeric pad is used under the joint as shown in Figure 24.42d, a new type of bearing joint is formed. Due to the shear deformation of the elastomeric pad, the joint can produce both rotation and horizontal movements. It is very effective to accommodate the horizontal deformation caused by temperature variation or earthquake action.

FIGURE 24.42 Bearing joints.

Glossary

Aspect ratio — Ratio of longer span to shorter span of a rectangular space frame.

Braced (barrel) vault — A space frame composed of member elements arranged on a cylindrical surface.

Braced dome — A space frame composed of member elements arranged on a spherical surface.

Continuum analogy method — A method for the analysis of space frame where the structure is analyzed by assuming it as an equivalent continuum.

Depth — Distance between the top and bottom-layers of a double-layer space frame.

Discrete method — A method for the analysis of space frame where the structure is analyzed directly as a general assembly of discrete members.

Double-layer grids — A space frame consisting of two planar networks of members forming the top and bottom-layers parallel to each other and interconnected by vertical and inclined members.

Geodesic dome — A braced dome in which the elements forming the network lie on the great circle of a sphere.

Lamella — A unit used to form diamond-shaped grids, the size being twice the length of the side of the diamond.

Latticed grids — Double-layer grids consist of intersecting vertical latticed trusses to form regular grids.

Latticed shell — A space frame consisting of curved networks of members built either in single or in double layer.

Latticed structure — A structural system in the form of a network of elements whose load-carrying mechanism is three-dimensional in nature.

Local buckling — A snap-through buckling that takes place at one point.

Module — Distance between two joints in the layer of grid.

Overall buckling — Buckling that takes place in a relatively large area where a large number of joints are involved.

Space frame — A structural system in the form of a flat or curved surface assembled of linear elements so arranged that forces are transferred in a three-dimensional manner.

Space grids — Double-layer grids consisting of a combination of square or triangular pyramids to form offset or differential grids.

Space truss — A three-dimensional structure assembled of linear elements and assumed as hinged joints in structural analysis.

Further Reading

An introduction to the practical design of space structures is presented in *Horizontal-span Building Structures* by W. Schueller. It covers a wide range of topics, including the development, structural behavior, simplified analysis, and application of different types of space structures.

For further study of continuum analogy method of space frames, *Analysis and Design of Space Frames by the Continuum Method* by L. Kollar and I. Hegedus provides a good reference.

The quarterly journal *International Journal of Space Structures* reports advances in the theory and practice of space structures. Special issues treating individual topics of interest were published, such as *Stability of Space Structures* (ed. V. Gioncu) Vol. 7, No. 4, 1992 and *Prefabricated Spatial Frame Systems* by A. Hanaor, Vol. 10, No. 3, 1995.

Conferences and symposiums are organized by IASS (International Association for Shell and Spatial Structures) annually. The proceedings document the latest development in this field and provide a wealth of information on theoretical and practical aspects of space structures. The proceedings of conferences recently held are as follows:

1. *Spatial Structures at the Turn of Millennium*, IASS Symposium 1991, Copenhagen.
2. *Innovative Large Span Structures*, IASS-CSCE International Congress 1992, Toronto.
3. *Public Assembly Structures from Antiquity to the Present*, IASS Symposium 1993, Istanbul.
4. *Nonlinear Analysis and Design for Shell and Spatial Structures*, Seiken-IASS Symposium 1993, Tokyo.
5. *Spatial, Lattice and Tension Structures*, IASS-ASCE International Symposium 1994, Atlanta.
6. *Spatial Structures: Heritage, Present and Future*, IASS Symposium 1995, Milan.
7. *Conceptual Design of Structures*, IASS International Symposium 1996, Stuttgart.
8. *Design, Construction, Performance and Economics*, IASS International Symposium 1997, Singapore.

9. *Lightweight Structures in Architecture and Engineering*, IASS Symposium 1998, Sydney.
10. *Shell and Spatial Structures: from Recent Past to the Next Millennium*, 40th Anniversary Congress of IASS 1999, Madrid.
11. *Bridging Large Spans, from Antiquity to the Present*, IASS-MSU Symposium 2000, Istanbul.
12. *Theory, Design and Realization of Shell and Spatial Structures*, IASS Symposium 2001, Nagoya.
13. *Lightweight Structures in Civil Engineering*, IASS Symposium 2002, Warsaw.

Journal of IASS is published three times a year and it covers design, analysis, construction, and other aspects of technology of all types of shell and spatial structures.

25.1 Introduction

A bridge is a structure that crosses over a river, bay, or other obstruction and permits the smooth and safe passage of vehicles, trains, and pedestrians. An elevation view of a typical bridge is shown in [Figure 25.1](#). A bridge structure can be divided into an upper part (the superstructure), which consists of the deck,

FIGURE 25.1 Elevation view of a typical bridge.

the floor system, and the main trusses or girders, and a lower part (the substructure), which consists of piers, columns, footings, piles, and abutments. The superstructure provides horizontal spans and carries traffic loads directly. The substructure supports the horizontal spans elevating above the ground surface. The bridges can be classified into the following categories:

1. *Classification by materials (superstructures)*

Steel bridges. Bridges using a wide variety of structural steel components and systems: decks, girders, trusses, arches, stayed, and suspension cables.

Concrete bridges. Bridges using reinforced and prestressed concrete.

Timber bridges. Bridges using wood when the span is relatively short.

Metal alloy bridges. Bridges using metal alloys such as aluminum alloy and stainless steel.

Advanced composite bridges. Bridges using advanced composite materials or fiber reinforced plastics composites.

Stone bridges. Bridges using stone; in ancient times stone was the most common material used to construct magnificent arch bridges.

2. *Classification by objectives*

Highway bridges. Bridges carrying vehicle traffic.

Railway bridges. Bridges carrying trains.

Combined bridges. Bridges carrying vehicles and trains.

Pedestrian bridges. Bridges carrying pedestrian traffic.

Aqueduct bridges. Bridges supporting pipelines with channeled waterflow.

Bridges can alternatively be classified into movable for ships to pass the river, or fixed and permanent, or temporary categories.

3. *Classification by structural systems (superstructures)*

I-girder (beam) bridges. The main girders consist of either plate girders (plate assemblages of top and bottom flanges and a web) or rolled I-shapers. I-sections can effectively resist bending and shear.

Box-girder bridges. The main girders consist of a single or multiple box beams fabricated from steel plates and formed from concrete, which resist not only bending and shear but also torsion effectively.

T-beam bridges. A number of reinforced concrete T-beams are placed side by side to support the live load.

Composite girder bridges. The concrete deck slab works in conjunction with the steel girders to support loads as a united beam. The steel girder takes mainly tension, while the concrete slab takes the compression component of the bending moment.

Grillage girder bridges. The main girders are connected transversely by floor beams to form a grid pattern, which shares the loads with the main girders.

Othotropic deck bridges. The deck consists of a steel deck plate and rib stiffeners.

Truss bridges. The bar members are arranged in a continuous pattern based on structural rigidity of triangles. Truss members are theoretically considered to be connected with pins at their ends. Each member resists an axial force, either in compression or tension. Figure 25.1 shows a Warren truss bridge with vertical members, which is a “through bridge,” that is, the deck slab is placed through the lower part of the bridge.

Arch bridges. The arch is a vertically curved structure that resists load mainly in axial compression.

Cable stayed bridges. The girders are supported by highly strengthened cables slopping directly from one or more towers. These are most suited to bridge long distances.

Suspension bridges. The girders are supported by vertical or near-vertical hangers, which are, in turn, supported by the main suspension cables extending over towers from anchorage to anchorage. The load is transmitted mainly by tension in cables. This design is suitable for longest bridges.

4. Classification by support conditions

Figure 25.2 shows three different support conditions for girder and truss bridges.

Simply supported bridges. The main girders or trusses are supported by a movable hinge at one end and a fixed hinge at the other end.

Continuously supported bridges. Girders or trusses are supported continuously by more than three hinges, resulting in a structurally indeterminate system. These tend to be more economical since the fewer expansion joints will have less service and maintenance problems. Settlements at the supports shall be avoided.

Gerber bridges (cantilever bridges). A continuous bridge is rendered determinate by placing intermediate hinges between the supports.

Rigid frame bridges. The girders are rigidly connected to the substructures.

In this chapter, main structural features of common types of steel and concrete bridges for short and mid-long spans are discussed. Cable-supported long-span bridges are addressed in Chapter 26. The recently published Bridge Engineering Handbook (Chen and Duan 2000) provides a unique, comprehensive, state-of-the-art, and state-of-the-practice reference work and resource book covering the major area of bridge engineering. For a more detailed look at design procedures, references should be made to the books of Troitsky (1994), Xanthakos (1994, 1995), Toniais (1995), and Barker and Puckett (1997).

FIGURE 25.2 Supporting conditions of girder bridges: (a) simple girder; (b) continuous girder; and (c) Gerber girder.

25.2 Conceptual Design

Bridge design is a combination of art—creation, science—natural laws, and technology—engineering reality. The conceptual design is the first step, which the designers must take, to visualize and imagine the bridge in order to determine its fundamental function and performance before any theoretical analysis and detailing design can be proceeded. The design process includes considerations of important factors, such as selection of bridge systems, materials, proportions, dimensions, foundations, esthetics, and surrounding landscape and environment.

25.2.1 Planning — Fulfillment of its Function

The first principle is planning a bridge to optimally meet the specified functions. A bridge project will start with planning the fundamental design conditions. To meet the specific purposes, a bridge may have different alignments: straight, skewed, and horizontally curved (Figure 25.3). A straight bridge is easy to design and construct but often needs longer spans. A skewed bridge or a horizontally curved bridge is commonly required for expressways or railroads where the road line must be kept straight or horizontally curved, even at the cost of a more difficult design. The width of a bridge is dependent of the traffic requirements. For a highway bridge, its width is usually determined by the width of the traffic lanes and the sidewalk width, and often the same dimension as that of the approaching road.

25.2.2 Bridge Types — Challenging Spans

The type of bridges is usually determined by factors such as design loads, surrounding geographical features, soil and foundations, passing line and its width, the length and span of the bridge, esthetics, the requirement for clearance below the bridge, transportation of the construction materials, erection procedures, construction cost and period. Table 25.1 shows the span lengths appropriate to each type of bridge.

25.2.3 Proportioning — Golden Mean and Image of Human Body

The geometry proportioning of a bridge structure is to establish the relationships between horizontal superstructures and supporting substructures, between the depth and span of the beams, between the height, length, and width of the opening, and between sizes of individual members. The ideal bridge is structurally straightforward and elegant. The golden mean provides the key to squaring the circle. The image of a beautiful human body provides the harmonious proportion — all measurements and their relationship are found all numerical relationships (Leonhardt 2000).

FIGURE 25.3 Bridge lines.

TABLE 25.1 Types of Bridges and Applicable Span Length

Bridge type	Span range (m)	Leading bridge and span length
Prestressed concrete girder	10–300	Stolmasundet, Norway, 301 m
Steel I/box girder	15–376	Sfalassa Bridge, Italy, 376 m
Steel truss	40–550	Quebec, Canada, 549 m
Steel arch	50–550	Shanghai Lupu, China, 550 m
Concrete arch	40–425	Wanxian, China, 425 m (steel tube filled concrete)
Cable stayed	110–1100	Sutong, China, 1088 m
Suspension	150–2000	Akaski-Kaikyo, Japan, 1991 m

FIGURE 25.4 Firth of Forth Bridge and bridge model in U.K. (1980).

A structure designed in harmony with one other not only appeals to our hereditary sense of beauty, but also behaves a smooth load transfer path. Figure 25.4 shows the Firth of Forth Bridge built in Scotland, U.K., in 1890 and the bridge model. This bridge is a gain steel railway bridge with a main span of 521 m. The bridge designer Baker stated (Collins 2001) that

When a load is put on the central girder by a person setting on it, the men’s arms and the anchor ropes come into the tension, and the men’s bodies and the sticks come into compression. The chairs are representative of the circular granite piers. Imagine of chairs one third of a mile apart and the men’s head as high as the cross of St. Paul’s, their arms represented by the huge lattice steel girders and the sticks by the tubes 12 ft (3.6 m) in diameter at the base, and a very good notion of the structure is obtained.

25.2.4 Esthetics — Harmonizing Surroundings

A bridge is required not only to fulfill its function as a thoroughfare, but must use its structure and form to blend, harmonize, and enhance its surroundings. Although there are different views regarding esthetic practice in bridge engineering, the following guidelines presented by Svensson (1998) may be useful:

- “Choice of a clean and simple structural system,” like a beam, a frame, an arch, or a suspended structure, the bridge must look trustworthy and stable.
- “Good proportion in all three dimensions” between the structural members or between length and depth of bridges openings.

- “Good order of all the lines of edges of a structures,” which determine the appearance. One should limit the number of directions that cause unrest, confusion, and worried feelings. For the transition from straight lines to curved lines, the curvature should steadily increase like a second-order parabola.
- The compatible integration of a structure into its environment, into the landscape of city. This is specially important with regard to the scale of the structure compared to the scale of the surroundings.
- The choice of the materials has considerable influence on the esthetic effects.
- Simplicity and restriction to the pure structural shape is important.
- Pleasing appearance can be enhanced by color.
- The space above the bridge should be shaped in such a way that the driver experiences the bridge and gets a comfortable feeling.
- A structure must be designed that the flow of forces is evident to the causal observer.
- Moderate esthetic lighting can enhance the appearance of a bridge at night.

Figure 25.5 shows a conceptual design of Ruck-a-Chucky Bridge crossing American River about 17 km from the Auburn Dam in California. This horizontally curved cable-stayed bridge spanning 396 m was designed to anchor cables in the hillsides. Although the bridge was never built, the design fits the topography, the surrounding environment, and is a real well-conceived design (Lin 2001; Ruck-a-Chucky 2003). It was awarded by *Progressive Architecture* magazine in 1979. For more detailed discussion about esthetics, references are made to Leonhardt (1984, 2000), Billington (1983, 2000), and TRB (1991).

25.2.5 Bridge-Type Selection — Comprehensive Decision

The selection of bridge types is a complex task to achieve the owner’s objectives. Table 25.2 shows a sample evaluation matrix, which may be used to select the bridge types. For the items listed in Table 25.2, a priority factor may be assigned from 1 to 5 (1 = low, 2 = standard, 3 = high, 4 = very high, and 5 = extremely high). The quality rating can be on a scale of 1 to 5 (1 = poor, 2 = fair, 3 = good, 4 = very good, and 5 = excellent). The weighted rating is obtained by multiplying the priority factor with the quality-rating

FIGURE 25.5 Conceptual design of Ruck-a-Chucky Bridge (courtesy of T.Y. Lin).

factor and summed for each bridge alternative. The bridge type with the highest total score shall be the best candidate.

The collapse of a portion of upper and lower decks of the eastern portion (Figure 25.6) of the San Francisco-Oakland Bay Bridge (SFOBB) in the 1989 Loma Prieta Earthquake, California, demonstrated the critical need for seismic safety on bridges in San Francisco Bay Area. California Department of Transportation (SFOBB 2003) determined that it is more cost-effective to replace the existing east span with a new bridge than it would be to seismically retrofit the existing structure (Figure 25.6). Figure 25.7 to Figure 25.10 show four structure alternatives for the new SFOBB east signature span across the shipping channel. The Engineering and Design Advisory Panel (SFOBB 2003) for the new SFOBB east span adopted the following guidelines:

- The bridge should integrate into the site and surrounding environment by reflecting the grand scale of San Francisco Bay, by harmonizing with the existing western span of the bridge, and by landing gracefully on the Oakland shore and Yerba Buena Island.

FIGURE 25.7 San Francisco-Oakland Bay Bridge east span — cable-stayed alternative 1.

FIGURE 25.8 San Francisco-Oakland Bay Bridge east span — cable-stayed alternative 2.

- The replacement bridge should, by contrast or similarity, complement the existing Bay Bridge suspension span. One bridge should not diminish the visual quality or importance of the other.
- The new bridge should be visually memorable and convey a sense of gateway to Oakland.
- Views from the bridge when traveling toward Oakland should consider Oakland's central business district and waterfront.
- The bridge should provide a measure of visual continuity for motorists.
- The girders, piers, and rails should generally appear slender and provide for views by motorists on the bridge.
- Guardrails and handrails should be designed for maximum transparency to maintain views while meeting safety criteria.
- Night lighting on the bridge is an important consideration.

The single-tower self-anchored asymmetrical suspension span (180 m + 385 m) with a steel tower and a steel orthotropic deck (Figure 25.10) was the final selection from the above four alternatives (Nader et al. 2001). The bridge is under construction and expected to open to traffic in 2007.

FIGURE 25.9 San Francisco-Oakland Bay Bridge east span — suspension alternative 1.

FIGURE 25.10 San Francisco-Oakland Bay Bridge east span — suspension alternative 2 (selected).

Figure 25.11 shows a comparison of the four design alternatives evaluated for Minato Oh-Hashi in Osaka, Japan. The truss frame design was selected.

25.3 Final Design

The final design is to produce a set of constructible, biddable, and cost-effective construction documents. The design process involves structural analysis, member and detailing design, and preparation of a set of construction documents including plans, drawings, and special provisions. Structural analysis shall consider the appropriate material properties, member joints, and boundary conditions. The members and joints shall be proportioned to carry various possible loads (dead loads, live loads, wind loads, earthquake loads, etc.) in accordance with the requirements of design standards and codes, such as AASHTO (2004) for highway bridges and AREMA (2003) for railway bridges in the United States or JRA (2002) in Japan, or project-specific design criteria. For major bridges, project-specific design criteria are usually needed and shall be developed (Caltrans 2002). A well-prepared construction document shall be biddable and constructable and cost-effective.

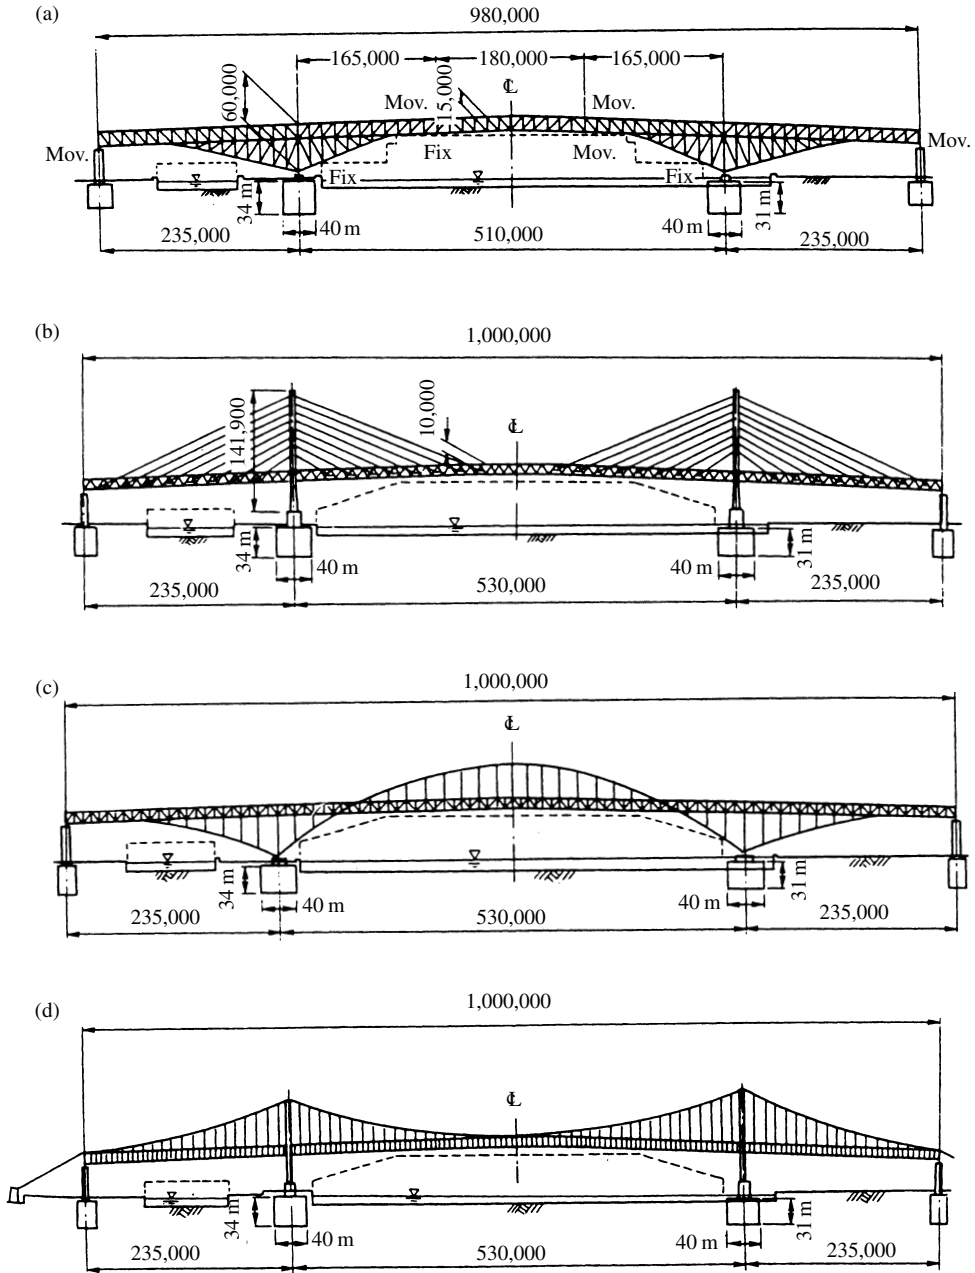

FIGURE 25.11 Design comparison of Minato Oh-Hashi, Japan: (a) K-truss bridge (this was selected); (b) cable-stayed bridge; (c) arch bridge; and (d) suspension bridge (HEPC 1975).

25.4 Steel Girder Bridges

25.4.1 Introduction

Steel has higher strength, ductility, and toughness than many other structural materials such as concrete or wood, and thus makes a vital material for bridge structures. In addition to the conventional steel, there are many types of high-performance steel (HPS) developed recently for the bridge application.

FIGURE 25.12 High-performance steel with low yield ratio (from Kozai Club, Japan, with permission).

HPS can be defined as having an optimized balance of their properties, such as strength, weldability, toughness, ductility, corrosion resistance, and formability, to give maximum performance in bridge structures while remaining cost-effective (Mistry 2002). The two main differences compared to conventional weathering steels are improved weldability and toughness. Other properties such as corrosion resistance and ductility will be essentially the same. There are two HPS grades, ASTM A 709 HPS 70W and HPS 50W, available for bridge structures in the United States. There are 91 HPS bridges built in the United States so far (FHWA 2003). HPS has very high strength, with constant yield point, narrow range of yield point, low yield ratio, excellent ductility, and ultrathickness. Figure 25.12 shows the performance mechanism of the steel with low yield ratio that provides higher ductility at plastic hinges.

Girder bridges are structurally the simplest and the most common. They consist of a floor slab, girders, and bearings, which support and transmit gravity loads to the substructure. Girders resist bending moments and shear forces and are used to span short distances. Steel girders are classified as plate and box girders.

Figure 25.13 shows the structural composition of plate and box girder bridges and the load transfer path. In plate girder bridges, the live load is directly supported by the slab and then by the main girders. In box girder bridges, the forces are taken first by the slab, then supported by the stringers and floor beams in conjunction with the main box girders, and finally taken to the substructure and foundation through the bearings.

Girders are classified as noncomposite or composite, that is, whether the steel girders act in tandem with the concrete slab (using shear connectors) or not. Since composite girders make use of best properties of both steel and concrete, they are often the rational and economic choice. Less frequently noncomposite I-shapes are used for short-span noncomposite bridges.

25.4.2 Plate Girder (Noncomposite)

The plate girder is the most economical shape designed to resist bending and shear and the moment of inertia is the greatest for a relatively low weight per unit length. Figure 25.14 shows a plan of a typical plate girder bridge with four main girders spanning 30 m and a width of 8.5 m.

The gravity loads are supported by several main plate girders, each manufactured by welding three plates: top and bottom flanges and a web. Figure 25.15 shows a piece of plate girder and its fabrication

FIGURE 25.13 Steel girder bridges: (a) plate girder bridge and (b) box girder bridge (Nagai 1994).

process. The web and the flanges are cut from the steel plate and welded. The piece is fabricated in shop and transported to the construction site for erection.

The design procedure for plate girders, primarily the sizing of the three plates, is discussed as follows:

1. *Web height.* The web height is the fundamental design factor affecting the weight and cost of the bridge. If the height is too small, the flanges need to be large and the dead weight increases. The height (D) is determined empirically by dividing the span length (L) by a “reasonable” factor. Common ratios are $D/L = \frac{1}{18}$ to $\frac{1}{20}$ for highway bridges and a little smaller for railway bridges. The web height also influences the flexural stiffness of bridge. Greater heights generally produce greater stiffness. However, if the height is too large, the web may become unstable and must have its thickness supplemented or stiffeners added. These measures increase the weight and the cost. In addition, plate girders with excessively deep web and small flanges are vulnerable to buckle laterally.
2. *Web thickness.* The web primarily resists shear forces that are not usually significant when the web height is properly designed. The shear force is generally assumed to be distributed uniformly across the web instead of using the exact equation of beam theory. The web thickness (t) is determined such that thinner is better as long as buckling is prevented. Since the web does not contribute much to the bending resistance, thin webs are most economical but the possibility of buckling increases. Therefore, a noncompact web thickness is usually selected and stiffened by transverse (vertical) and longitudinal (horizontal) stiffeners. It is not primarily strength but rather stiffness that controls the design of webs.

FIGURE 25.14 General plans of a typical plate girder bridge: (a) side view; (b) plan; and (c) cross-section (Tachibana and Nakai 1996).

FIGURE 25.15 Fabrication of plate girder piece.

FIGURE 25.16 Local buckling of compression flange.

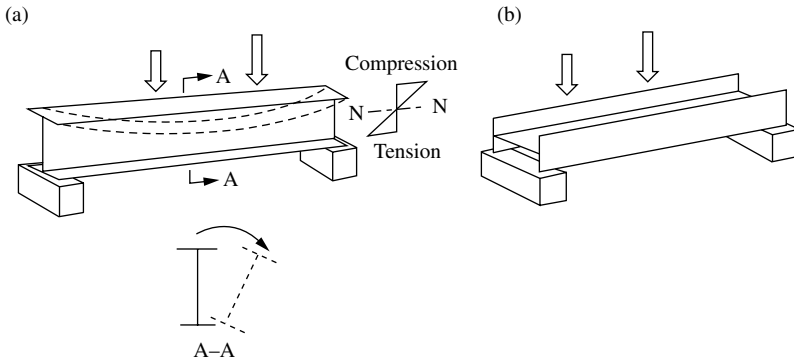

FIGURE 25.17 Lateral torsional buckling: (a) strong axis bending (torsional buckling) and (b) weak axis bending (no torsional buckling).

3. *Area of flanges.* After the sizes of the web are determined, the flanges are then designed. The flanges work mostly in bending and the required area is calculated approximately using equilibrium conditions imposed on the internal and external bending moments. A selection of strength for the steel material is principally made at this stage in the design process.
4. *Width and thickness of flanges.* The width and thickness can be determined by ensuring that the area of the flanges falls under the limiting width-to-thickness ratio, b/t (Figure 25.16), as specified in design codes. If the flanges are too thin (i.e., the width-to-thickness ratio is too large), the compression flange may buckle or the tension flange may be distorted by heat of welding. Thus, the thickness of both flanges must be checked. Since plate girders have little torsional resistance, special attention should be paid to lateral torsional buckling. To prevent this phenomenon, the compression flange must have sufficient width to resist “out-of-plane” bending. Figure 25.17 shows the lateral torsional buckling that may occur by bending with respect to strong axis.

After determining the member sizes, calculations of the resisting moment capacity are made to ensure code requirements are satisfied. If these fail, the above steps must be repeated until the specifications are met.

A few other important factors in the design of girder bridges will be explained in the following:

1. *Web stiffeners.* The transverse (vertical) and longitudinal (horizontal) stiffeners are usually needed (Figure 25.18) when a web is relatively thin. Bending moment produces compression and tension in the web, separated by a neutral axis. The longitudinal (horizontal) stiffener prevents bending buckling of web and is therefore attached to the compression side of the web (the top half for a simply supported girder). Since the bending moment is the largest near the midspan for a simply

FIGURE 25.18 Stiffeners of web: (a) buckling of web and (b) stiffeners of web.

supported girder, the longitudinal (horizontal) stiffeners are usually located here. The longitudinal stiffeners are not recommended due to its poor fatigue resistance. Transverse (vertical) stiffeners, on the other hand, prevent shear buckling and provide postelastic shear buckling capacity by the tension field action. The most transverse (vertical) stiffeners are placed near the support since the largest shear force occurs at those locations. Bearing stiffeners are also required at the supports to combat large reaction forces, which are designed independently just as any other compression member would be. Buckling patterns of a web are shown in Figure 25.18. If the web is not too deep nor its thickness is too small, no stiffeners are necessary and fabrication costs are reduced.

2. *Variable sections.* The variable cross-sections may be used to save material and cost where the bending moment is smaller, that is, near the end of the span (see Figure 25.15). However, this reduction increases the manpower required for welding and fabrication. The cost of manpower and material must be balanced and traded off. In today's industrial climate, manpower is more important and costly than the material. Therefore, the change of girder section may not be economic. Likewise, thick plates are often specified to eliminate the number of stiffeners needed, thus to reduce the necessary manpower.

25.4.3 Composite Girder

If two beams are simply laid one upon the other as shown in Figure 25.19a, they act separately and only share the load depending on their relative flexural stiffness. In this case, slip occurs along the boundary between the beams. However, if the two beams are connected and slip prevented as shown in Figure 25.19b, they act as a unit, that is, a composite girder. For composite plate girder bridges, the steel girder and the concrete slab are joined by shear connectors. In this way, the concrete slab becomes integral with the girder and usually takes most of the compression component of the bending moment while the steel plate girder takes the tension. Composite girders are much more effective than the simply tiered girder.

Let us consider the two cases shown in Figure 25.19 and note the difference between tiered beams and composite beams. Both have the same cross-sections and are subjected to a concentrated load at mid-span. The moment of inertia for the composite beam is four times that of the tiered beams, thus the resulting vertical deflection is one fourth. The maximum bending stress in the outer (top or bottom) fiber is a half that of the tiered beam configuration.

The corresponding stress distributions are shown in Figure 25.20. Points "S" and "V" are the center of area of the steel section and the composite section, respectively. According to beam theory, the strain distribution is linear but the stress distribution has a step change at the boundary between the steel and concrete.

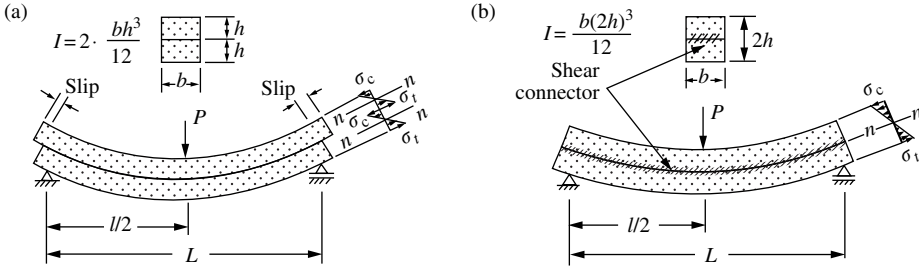

FIGURE 25.19 Principle of tiered beam and composite beam: (a) tiered beam and (b) composite beam (Tachibana and Nakai 1996).

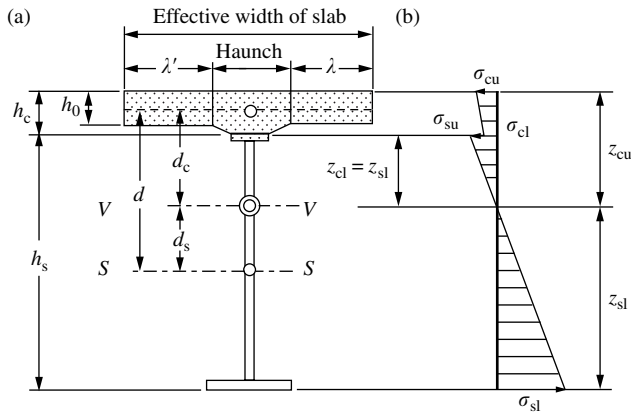

FIGURE 25.20 Section of composite girder: (a) composite girder section and (b) stress distribution (Tachibana and Nakai 1996).

Three types of shear connectors, studs, horse shoes, and steel blocks, are shown in Figure 25.21. Studs are most commonly used since they are easily welded to the compression flange by the electric resistance welding, but the weld inspection is a cumbersome task. If the weld on a certain stud is poor, the stud may shear off and trigger a totally unforeseen failure mode. Other types are considered to maintain more reliability.

Shear connectors are needed most near the ends of the span where the shear force is largest. This region is illustrated in Figure 25.19a, which shows the maximum shift due to slip occurs at ends of tiered beams. It is this slip that is restrained by the shear connectors.

25.4.4 Grillage Girder

When girders are placed in a row and connected transversely by floor beams, the truck loads are distributed by the floor beams to the girders. This system is called as “grillage girder.” If the main girders are plate girders, no stiffness in torsion is considered. On the other hand, box girders and concrete girders can be analyzed assuming stiffness is available to resist torsion. Floor beams increase the torsional resistance of the whole structural system of bridge.

Let us consider the structural system shown in Figure 25.22a to observe the load distribution in a grillage system. This grillage has three girders with one floor beam at midspan. In this case, there are three nodal forces at the intersections of the girders and the floor beam but only two equilibrium equations ($V = 0$ and $M = 0$). Thus, it becomes one degree statically indeterminate. If we disconnect the intersection

FIGURE 25.21 Type of shear connectors: (a) stud; (b) horse shoe; and (c) steel block (Nagai 1994).

FIGURE 25.22 Grillage girders: (a) one-degree indeterminate system and (b) statically determinate system (Tachibana and Nakai 1996).

between the main girder B and the floor beam and apply a pair of indeterminate forces “X” at point “b.” Once the force X is found, the sectional forces in the girders can be calculated. This structural system is commonly applied to the practical design of plate girder bridges.

25.4.5 Widely Spaced Plate Girder

To compete with concrete bridges, a new design concept of steel bridge has been developed by minimizing the number of girders and pieces of fabrication blocks, thus reducing the construction cost. The space between girders is taken wide and the lateral bracing is neglected. An example of the bridge is shown in Figure 25.23, which has only two girders with the space 5.7 m and the prestressed concrete slab deck thickness of 320 mm.

25.4.6 Box Girder

Structural configuration of box girders is illustrated in Figure 25.24. Since the box girder is a closed section, its torsional resistance is high with no loss of strength in bending and shear. On the other hand, plate girders are open sections generally only considered effective in resisting bending and shear. Orthotropic decks — steel plates with longitudinal and transverse stiffeners — are often used for decks on box girder or thin-walled structures instead of a concrete slab (Figure 25.24b) for long-span bridges.

Torsion is resisted in two parts: pure torsion (St Venant torsion) and warping torsion. The pure torsional resistance of I-plate girders is negligible. However, for closed sections such as a box girder, the pure torsional resistance is considerable, making them particularly suited for horizontally curved bridges or long-span bridges. On the other hand, the warping torsion for box section is negligible. The I-section girder has some warping resistance but it is not so large compared to the pure torsion of closed sections.

FIGURE 25.23 Widely spaced girder bridge (Chidorinosawagawa Bridge, Japan, from Kawasaki Heavy Ind., Ltd., with permission).

FIGURE 25.24 Box girder: (a) with reinforced concrete deck and (b) with steel deck (Nagai 1994).

25.4.7 Fabrication

Gas flame cutting is generally used to cut steel plates to designated dimensions. Fabrication by welding is conducted in shop where the bridge components are prepared before being assembled (usually bolted) on the construction site.

25.4.7.1 Welding

Welding is the most effective means of connecting steel plates. The properties of steel change when heated and this change is usually for the worse. Molten steel must be shielded from the air to prevent oxidization. Welding can be categorized by the method of heating and the shielding procedure. Shielded metal arc welding (SMAW), submerged arc welding (SAW), CO₂ gas metal arc welding (GMAW), tungsten arc inert gas welding (TIG), metal arc inert gas welding (MIG), electric beam welding, laser beam welding, and friction welding are common methods.

The first two welding procedures mentioned above, SMAW and SAW, are used extensively in bridge construction due to their high efficiency. These both use an electric arc that is generally considered the most efficient method of applying heat. SMAW is done by hand and is suitable for welding complicated joints but less efficient than SAW. SAW is generally automated and can be very effective for welding simple parts such as the connection between flange and web of plate girders. A typical placement of these welding methods is shown in Figure 25.25. TIG and MIG use an electric arc for heat source and inert gas for shielding.

FIGURE 25.25 Welding methods: (a) shielded metal arc welding; (b) submerged arc welding; and (c) gas metal arc welding (Nagai 1994).

FIGURE 25.26 Types of welding joints: (a) fillet weld and (b) groove weld (Tachibana 1996).

An electric beam weld must not be exposed to air; therefore, must be laid in a vacuum chamber. A laser beam weld can be placed in air but is less versatile than other types of welding. It cannot be used on thick plates but is ideal for minute or artistic work. Since the welding equipment necessary for heating and shielding is not easy to handle on a construction site, all welds are usually laid in the fabrication shop.

The heating and cooling processes during welding induce residual stresses to the connected parts. The steel surfaces or parts of the cross-section at some distance from the hot weld cool first. When the area close to the weld then cools, it tries to shrink but is restrained by the more solidified and cooler parts. Thus, tensile residual stresses are trapped in the vicinity of the weld while the outer parts are put into compression.

There are two types of welded joints: fillet and groove welds (Figure 25.26). The fillet weld is placed at the junction of two plates, often between a web and a flange. It is a relatively simple procedure with no machining required. The groove weld, also called a butt weld, is suitable for joints requiring greater strength. Depending on the thickness of adjoining plates, the edges are beveled in preparation for the weld to allow the metal to fill the joint. Various groove weld geometries for full penetration welding are shown in Figure 25.26b.

Inspection of welding is an important task since an imperfect weld may well have catastrophic consequences. It is difficult to find faults such as an interior crack or a blow hole by observing only the surface of a weld. Many nondestructive testing procedures are available which use various devices, such as x-ray, ultrasonic waves, color paint, or magnetic particles. These all have their own advantages and disadvantages. For example, the x-ray and the ultrasonic tests are suitable for interior faults but require expensive equipment. Use of color paint or magnetic particles, on the other hand, is a less-expensive alternative but only detects surface flaws. The x-ray and ultrasonic tests are used in common bridge construction, but ultrasonic testing is becoming increasingly popular for both its “high tech” and its economical features.

25.4.7.2 Bolting

Bolting does not require the skilled workmanship needed for welding and is thus a simpler alternative. It is applied to the connections worked on a construction site. Some disadvantages, however, are incurred: (1) splice plates are needed and the force transfer is indirect; (2) screwing-in of the bolts creates noise; and (3) esthetically bolts are less appealing. In special cases that need to avoid these disadvantages, the welding may be used even for site connections.

FIGURE 25.27 Slip-critical and bearing-type connections: (a) slip-critical connection; (b) bearing-type connection; and (c) behavior of bolt connections (Nagai 1994).

FIGURE 25.28 Tension-type connection.

There are three types of high-tensile-strength bolted connections: the slip-critical connection, the bearing-type connection (Figure 25.27), and the tensile connection (Figure 25.28). The slip-critical (friction) connection is most commonly used in bridge construction as well as other steel structures because it is simpler than a bearing-type connection and more reliable than a tension connection. The force is transferred by the friction generated between the base plates and the splice plates. The friction resistance is induced by the axial compression force in the bolts.

The bearing-type bolt transfers the force by bearing against the plate as well as making some use of friction. The bearing-type bolt can transfer larger force than the friction bolts but are less forgiving with respect to the clearance space often existing between the bolt and the plate. These require that precise holes be drilled and at exact spacings. The force transfer mechanism for these connections is shown in Figure 25.27. In the beam-to-column connection shown in Figure 25.26, the bolts attached to the column are tension bolts while the bolts on the beam are slip-critical bolts.

The tension bolt transfers force in the direction of bolt axis. Tension type of bolt connection is easy to connect on site but difficulties arise in distributing forces equally to each bolt, resulting in reduced

reliability. Tension bolts may also be used to connect box members of the towers of suspension bridges where compression forces are larger than the tension forces. In this case, the compression is shared with butting surfaces of the plates and the tension is carried by the bolts.

25.4.7.3 Fabrication in Shop

Steel bridge components are fabricated into members in the shop yard and then transported to the construction site for assembly. Ideally, all constructional work would be completed in the shop to get the highest quality in the minimum construction time. The larger and longer the members can be, the better, within the restrictions set by transportation limits and erection tolerances. When crane ships for erection and barges for transportation can be used, one block can weigh as much as a thousand tons and be erected as a whole on the quay. In these cases the bridge is made of a single continuous block and much of the hassle usually associated with assembly and erection is avoided.

25.4.7.4 Erections

The designer must consider the loads, which occur during construction, generally different from those occurring during service. Steel bridge components are particularly prone to buckling during

FIGURE 25.29 Erection methods: (a) truck crane and bent erection; (b) launching erection; (c) cable erection; and (d) cantilever erection (JMCA 1991).

construction. The erection plan must be made prior to the main design and must be checked for strength and stability for every possible load case that may arise during erection. Truck crane and bent erection (or staging erection), launching erection, cable erection, cantilever erection, and large block erection (or floating crane erection) are several techniques (see [Figure 25.29](#)). An example of the large block erection is shown in [Figure 25.46](#), in which a 186 m–4500 ton center block is transported by barge and lifted.

25.4.7.5 Painting

Steel must be painted to protect it from rusting. There is a wide variety of paints and the life of a steel structure is largely influenced by its quality. In areas near the sea, the salty air is particularly harmful to exposed steel. The cost of painting is high but is essential to the continued good condition of the bridge. The color of the paint is also an important consideration in terms of its public appeal or esthetic quality.

25.5 Concrete Girder Bridges

25.5.1 Introduction

For modern bridges, both structural concrete and steel give satisfactory performance. The choice between the two materials depends mainly upon the cost of construction and maintenance. Generally, concrete structures require less maintenance than steel structures, but since the relative cost of steel and concrete is different from country to country, and may even vary throughout different parts of the same country, it is impossible to put one definitively above the other in terms of “economy.”

In this section, the main features of common types of concrete bridge superstructures are briefly discussed. Concrete bridge substructures will be discussed in [Section 25.6](#).

25.5.2 Reinforced Concrete Bridges

[Figure 25.30](#) shows the typical reinforced concrete sections commonly used in highway bridge superstructures.

25.5.2.1 Slab

A reinforced concrete slab ([Figure 25.30a](#)) is the most economical bridge superstructure for spans of up to approximately 40 ft (12.2 m). The slab has simple details, standard formwork, and is neat, simple, and pleasing in appearance. Common spans range from 16 to 44 ft (4.9 to 13.4 m) with structural-depth-to-span ratios of 0.06 for simple spans and 0.045 for continuous spans.

25.5.2.2 T-Beam (Deck Girder)

The T-beams ([Figure 25.30b](#)) are generally economic for spans of 40 to 60 ft (12.2 to 18.3 m), but does require complicated formwork, particularly for skewed bridges. Structural-depth-to-span ratios are 0.07 for simple spans and 0.065 for continuous spans. The spacing of girders in a T-beam bridge depends on the overall width of the bridge, the slab thickness, and the cost of the formwork and may be taken as 1.5 times the structural depth. The most commonly used spacings are between 6 and 10 ft (1.8 to 3.1 m).

25.5.2.3 Cast-In-Place Box Girder

Box girders like the one shown in [Figure 25.30c](#), are often used to span 50 to 120 ft (15.2 to 36.6 m). Its formwork for skewed structures is simpler than that required for the T-beam. Due to excessive dead load deflections, the use of reinforced concrete box girders over simple spans of 100 ft (30.5 m) or more may uneconomical. The depth-to-span ratios are typically 0.06 for simple spans and 0.055 for continuous spans with the girders spaced at 1.5 times the structural depth. The high torsional resistance of the box girder makes it particularly suitable for curved alignments, such as the ramps onto freeways. Its smooth flowing lines are appealing in metropolitan cities.

FIGURE 25.30 Typical reinforced concrete sections in bridge superstructures: (a) solid slab; (b) T-beam; and (c) box girder.

25.5.2.4 Design Consideration

A reinforced concrete highway bridge should be designed to satisfy the specification or code requirements, such as the AASHTO-LRFD (2004) requirements for all appropriate service, fatigue, strength, and extreme event limit states. In the AASHTO-LRFD (2004), service limit states include cracking and deformation effects, and strength limit states consider the strength and stability of a structure. A bridge structure is usually designed for the strength limit states and is then checked against the appropriate service and extreme event limit states.

25.5.3 Prestressed Concrete Bridges

Prestressed concrete, using high-strength materials, makes it an attractive alternative for long-span bridges. It has been widely used in bridge structures since the 1950s.

25.5.3.1 Slab

Figure 25.31 shows FHWA (1990) standard types of precast prestressed voided slabs and their sectional properties. While a cast-in-place prestressed slab is more expensive than reinforced concrete slab, a precast prestressed slab is economical when many spans are involved. Common spans range from 20 to 50 ft (6.1 to 15.2 m). Structural-depth-to-span ratios are 0.03 for both simple and continuous spans.

25.5.3.2 Precast I-Girder

Figure 25.32 shows AASHTO (FHWA 1990) standard types of I-beams. Figure 25.33 and Figure 25.34 show Caltrans standard “I”-girder “Bulb-Tee” girders (Caltrans 2001), respectively. These compete with steel girders and generally cost more than reinforced concrete with the same depth-to-span ratios. The formwork is complicated, particularly for skewed structures. These sections are applicable to spans 30 to 120 ft (9.1 to 36.6 m). Structural-depth-to-span ratios are 0.055 for simple spans and 0.05 for continuous spans.

25.5.3.3 Box Girder

Figure 25.35 shows FHWA (1990) standard types of precast box sections. Figure 25.36 shows Caltrans standard precast “Bathtub” girder (Caltrans 2001). The shape of a cast-in-place prestressed concrete box girder is similar to the conventional reinforced concrete box girder (Figure 25.31c). The spacing of the

FIGURE 25.33 Caltrans precast standard "I"-girder (Caltrans 2001).

girders can be taken as twice the structural depth. It is used mostly for spans of 100 to 600 ft (30.5 to 182.9 m). Structural depth-to-span ratios are 0.045 for simple spans and 0.04 for continuous spans. These sections are used frequently for simple spans of over 100 ft (30.5 m) and are particularly suitable for widening in order to control deflections. About 70 to 80% of California's highway bridge system is composed of prestressed concrete box girder bridges.

25.5.3.4 Segmental Concrete Bridge

The segmentally constructed concrete bridges have been successfully developed by combining the concepts of prestressing, box girder, and the cantilever construction (Podolny and Muller 1982; AASHTO 1999). The first prestressed segmental box girder bridge was built in West Europe in 1950. California's Pine Valley Bridge as shown in Figure 25.37 and Figure 25.38 (composed of three spans of 340 ft (103.6 m), 450 ft (137.2 m), and 380 ft (115.8 m) with the pier height of 340 ft (103.6 m)) is the first cast-in-place segmental bridge built in the United States in 1974.

The prestressed segmental bridges with precast or cast-in-place segmental can be classified by the construction methods (1) balanced cantilever, (2) span-by-span, (3) incremental launching,

FIGURE 25.34 Caltrans precast standard "Bulb-Tee" girder (Caltrans 2001).

and (4) progressive placement. The selection between cast-in-place and precast segmental and among various construction methods is dependent of project features, site conditions, environmental and public constraints, construction time for the project, and equipment available. Table 25.3 lists the range of the application of segmental bridges by the span lengths (Podolny and Muller 1982).

25.5.3.5 Design Consideration

Compared to reinforced concrete, the main design features of prestressed concrete are that stresses for concrete and prestressing steel and deformation of structures at each stage, that is, during construction, stressing, handling, transportation, and erection as well as during the service life, and stress concentrations need to be investigated in accordance with the design specifications and codes.

25.5.4 Corrugated Steel Web Bridges

The corrugated steel web bridge is used in prestressed concrete to reduce the weight and increase the span length. The corrugated web also has the advantages that it does not take the axial force by accordion effect, thus introducing prestressing force in the concrete more effectively. An example of the bridge is shown in Figure 25.39.

25.6 Concrete Substructures

25.6.1 Introduction

Bridge substructures transfer traffic loads from the superstructure to the footings and foundations. Vertical intermediate support — piers or bents and end supports — abutments, are included.

25.6.2 Bents and Piers

25.6.2.1 Pile Bents

Pile extension as shown in Figure 25.40a is used for slab and T-beam bridges. It is usually used to cross streams when debris is not a problem.

25.6.2.2 Solid Piers

Figure 25.40b shows a typical solid pier used mostly when stream debris or fast currents are present. These are used for long spans and can be supported by spread footings or pile foundations.

25.6.2.3 Column Bents

Column bents (Figure 25.40c) are generally used on the dry land structures and supported by spread footings or pile foundations. Multicolumn bents are desirable for bridges in seismic zones. The single-column bent, such as a T-bent (Figure 25.40d), modified T-bent, C-bent (Figure 25.40e), or outrigger bent (Figure 25.40f) may be used when the location of the columns is restricted and changes of the alignment are impossible. To achieve a pleasing appearance at minimum cost using standard column shapes, Caltrans (1990) developed "Standard Architectural Columns" (Figure 25.41). Prismatic sections of Column Types 1 and 1W, with one-way flares of Column Types 2 and 2W, and with two-way flares of Column Types 3 and 3W may be used for various highway bridges.

25.6.3 Abutments

Abutments are the end supports of a bridge. Figure 25.42 shows the typical abutments used for highway bridges. The seven types of abutments can be divided into two categories: open and closed ends. Selection of an abutment type depends on the requirements for structural support, movement, drainage, road approach, and earthquakes.

25.6.3.1 Open End Abutments

Open end abutments include diaphragm abutments and short seat abutments. These are the most frequently used abutments and are usually the most economical, adaptable, and attractive. The basic structural difference between the two types is that seat abutments permit the superstructure to move

Column type 1 Shaft t ft (m)	Column types 2 and 3				
	Shaft t ft (m)	Top height ft (m)	Dimension, ft (m)		
			a	b	c
4 (1.219)	4 (1.219)	12 (3.658)	2 (0.610)	6 (1.829)	1 (0.305)
5.5 (1.676)	5.5 (1.676)	16.5 (5.029)	2.75 (0.838)	8.25 (2.515)	1.375 (0.419)

Notes:

1. Square shape S section is only for Column type 1.
2. Flare curve is parabolic and dimension C is only for Column type 3.

FIGURE 25.41 Caltrans standard architectural columns: (a) Column types 1, 2, 3; (b) Column types 1W, 2W, 3W; (c) side view; and (d) front view (Caltrans 1990).

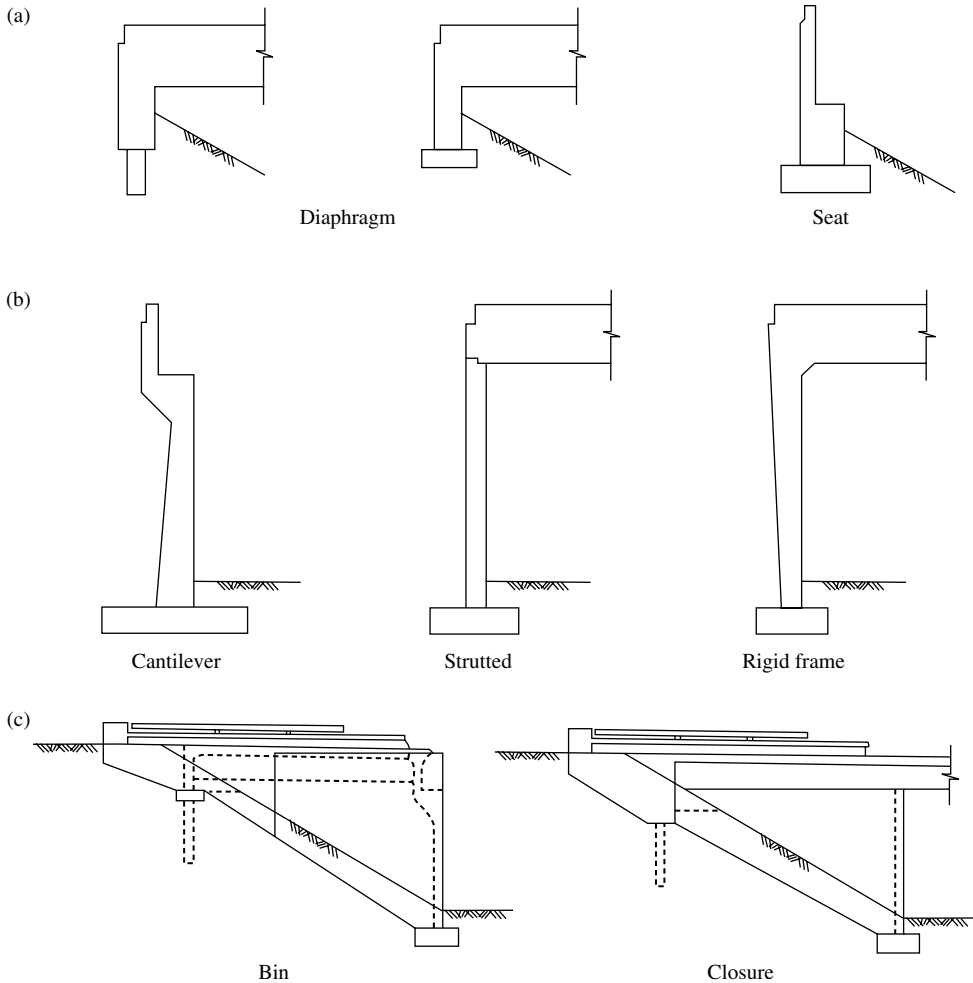

FIGURE 25.42 Typical types of abutments: (a) open end; (b) closed end — backfilled; and (c) closed end — cellular (Caltrans 1990).

independently from the abutment while the diaphragm abutment does not. Since they have lower height of abutment walls, there is less settlement in the road approaches than that experienced by higher backfilled closed abutments. These also provide more economical widening than closed abutments.

25.6.3.2 Closed End Abutments

Closed end abutments include cantilever, struted, rigid frame, bin, and closure abutments. These are less commonly used, but are used for bridge widenings of the same kind, unusual sites, or in tightly constrained urban locations. Rigid frame abutments are generally used with tunnel-type single-span connectors and overhead structures that permit passage through a roadway embankment. Because the structural supports are adjacent to traffic these have a high initial cost and present a closed appearance to approaching traffic.

25.6.4 Design Consideration

During the recent 1989 Loma Prieta and the 1994 Northridge Earthquakes in the United States and the 1995 Kobe Earthquake in Japan, major damages have been found in substructures. Special attention,

therefore, must be paid to seismic effects and the detailing of the ductile structures. Boundary conditions and soil–foundation–structures interaction in seismic analyses should also be carefully considered. Chapter 20 addresses the seismic considerations.

25.7 Truss Bridges

25.7.1 Introduction

The structural layout of a truss bridge is shown in Figure 25.43 for a through bridge with the deck located at the level of lower chords. The floor slab, which carries the live load, is supported by the floor system of stringers and cross beams. The load is transmitted to the main trusses at nodal connections, one on each side of the bridge, through the floor system and finally to the bearings. Lateral braces, which also are a truss frame, are attached to the upper and lower chords to resist horizontal forces such as wind and earthquake loads as well as torsional moments. The portal frame at the entrance provides transition of horizontal forces from the upper chords to the substructure.

Truss bridges can take the form of a deck bridge as well as a through bridge. In this case, the concrete slab is mounted on the upper chords and the sway bracing is placed between the vertical members of two main trusses to provide lateral stability.

A truss is composed of upper and lower chords, joined by diagonal and vertical members (web members). This frame action corresponds to beam action in that the upper and lower chords perform like flanges and the diagonal braces behave in much the same way as the web plate. The chords are mainly in charge of bending moment while the web members take the shear force. Trusses are an assembly of bars, not plates, and thus are comparatively easier to erect on site and are often the choice for long bridges.

25.7.2 Type of Truss

Figure 25.44 shows some typical trusses. A Warren truss is the most common and is a frame composed of isosceles triangles, where the web members are either in compression or tension. The web members of a Pratt truss are vertical and diagonal members where the diagonals are inclined toward the center and resist only tension. The Pratt truss is suitable for steel bridges since it is tension that is most effectively resisted. It should be noted, however, that vertical members of Pratt truss are in compression. A Howe truss is similar to the Pratt except that the diagonals are inclined toward the ends, leading to axial compression forces, and the vertical members resist tension. Wooden bridges

FIGURE 25.43 Truss bridge (Nagai 1994).

FIGURE 25.44 Types of trusses: (a) Warren truss (straight upper chord); (b) Warren truss (curved upper chord); (c) Warren truss with vertical members; (d) Pratt truss; (e) Howe truss; and (f) K-truss.

FIGURE 25.45 Nodal joints of truss bridge (JASBC 1985).

often make use of the Howe truss since the connections of the diagonals in wood prefer compression. A K-truss, so named since the web members form a “K,” is most economical in large bridges because the short member lengths reduce the risk of buckling.

25.7.3 Structural Analysis and Secondary Stress

The truss is a framed structure of bars, theoretically assumed to be connected by hinges, forming stable triangles. Trusses contain triangle framed units to keep it stable. Its members are assumed to resist only

FIGURE 25.46 Lifting erection of Minato Oh-Hashi, Japan (Gerber bridge 1974) (HEPC 1994).

tensile or compressive axial forces. A statically determinate truss can be analyzed using equilibrium equations only. If more than the least number of members required for stability are provided, the truss becomes indeterminate and can no longer be solved using only the equilibrium equations. The displacement compatibility must be added. An internally and/or externally indeterminate truss is best solved using a computer software.

In practice, truss members are connected to gusset plates with high-strength bolts (see [Figure 25.45](#)), not rotation-free hinges, simply because these are much easier to fabricate. The “pinned” condition of theory is not reflected in the field. This discrepancy results in “secondary stresses” (bending stresses) in the members. Secondary stresses are found by a structural analysis of a rigid frame and are usually less than 20% of the primary (axial) stresses. If the truss members are properly designed, that is the slenderness ratios of the truss bars are sufficiently large with no buckling, then secondary stresses can conveniently and reliably be disregarded.

25.7.4 Gerber Truss Bridge

Figure 25.46 is a photo of a Gerber truss bridge during the erection of the central part, which is Minato Oh-Hashi in Japan. Its plan view is shown in [Figure 25.11](#). A Gerber truss has intermediate hinges between the supports to create a statically determinant structural system. In the case of Minato Oh-Hashi, the soil condition at the bottom of the harbor was found not stiff and solid and the Gerber truss proved the wisest choice.

25.8 Rigid Frame Bridges (Rahmen Bridges)

25.8.1 Introduction

The members are rigidly connected in “Rahmen” structures or “rigid frames.” Unlike the truss and the arch bridges that will be discussed in the following subsection, all the members are subjected to both axial force and bending moments. [Figure 25.47](#) shows various types of Rahmen bridges.

The members of a rigid frame bridge are much larger than those in a typical building. Consequently, stress concentrations occur at the junctions of beams and columns that must be carefully designed using

FIGURE 25.47 Type of Rahmen bridges: (a) portal frame; (b) π -Rahmen; (c) V-leg Rahmen; and (d) Vierendeel Rahmen.

finite element analyses or experimental verification. The supports of Rahmen bridges are either hinged or fixed, making it an externally indeterminate structure, and it is therefore not suitable when the foundation is likely to sink. The reactions at supports are horizontal and vertical forces at hinges, and with the addition of a bending moment at a fixed base.

25.8.2 Portal Frame

A portal frame is the simplest design (Figure 25.47a) and is widely used for the piers of elevated highway bridges because the space underneath can be effectively used for other roads or parking lots. These piers were proved in the 1995 Kobe Earthquake in Japan to be more resilient, that is, to retain more strength and absorb more energy than single-column piers.

25.8.3 π -Rahmen (Strutted Beam Bridge)

The π -Rahmen design is usually used for bridges in mountainous regions where the foundation is firm and it can pass over a deep valley with a relatively long span or for bridges crossing over expressways (Figure 25.47b). As shown in the structural layout of π -Rahmen in Figure 25.48, the two legs support the main girders, inducing axial compression in the center span of the girder. Live load on the deck is transmitted to the main girders through the floor system. Intermediate hinges may be inserted in the girders to make Gerber girders. A V-leg Rahmen bridge is similar to a π -Rahmen bridge but can span longer distances with no axial force in center span of the girder (Figure 25.47c).

25.8.4 Vierendeel Bridge

The Vierendeel bridge is a rigid frame whose upper and lower chords are connected rigidly to the vertical members (Figure 25.47d). All the members are subjected to axial and shear forces as well as bending

FIGURE 25.48 Rahmen bridge (JASBC 1985).

moments. This is internally a highly indeterminate system. Analysis of the Vierendeel frame must consider secondary stresses. It is more stiff than Langer or Lohse arch bridges in which some members take only axial forces.

25.9 Arch Bridges

25.9.1 Introduction

An arch rib acts like a circular beam restrained not only vertically but also horizontally at both ends and thus results in vertical and horizontal reactions at the supports. The horizontal reaction causes axial compression in addition to bending moments in the arch rib. The bending moments caused by the horizontal force balances those due to gravity loads. Comparing with the axial force, the effect of the bending moment is usually small. That is why the arch is often made of materials that have high compressive strength such as concrete, stone, or brick.

25.9.2 Type of Arch

An arch bridge includes the road deck and the supporting arch. Various types of arches are shown in Figure 25.49. In the figure, the thick line represents the members carrying bending moment, shear, and axial forces. The thin line represents members taking axial forces only. Arch bridges are classified into the deck and the through-deck types according to the location of the road surface as shown in Figure 25.49. Since the deck in both type of bridges is sustained by either vertical columns or hangers to the arch, structurally the same axial force action, either compression or tension, is in effect in the members. The difference is that the vertical members of deck bridges take compressive forces and the hangers of through-deck bridges take tension. The live load acts on the arch only indirectly.

A basic structural type for an arch is a two-hinged arch (see Figure 25.49a). The two-hinge arch has one degree of indeterminacy externally because there are four end reactions. If one hinge is added at the crown of the arch, creating a three-hinge arch, it is rendered determinate. If the ends are clamped, turning it into a fixed arch, it becomes indeterminate to the third degree. The tied arch is subtended by two hinges by a tie and simply supported (Figure 25.49b). The tied arch is externally determinate but internally has one degree of indeterminacy. The floor structures hang from the arch and are isolated from the tie. Other type of arch bridges will be discussed later in more detail.

25.9.3 Structural Analysis

Almost all bridge design analyses, in this age of super computing power, use finite element methods. The analysis of an arch is basically the same as that for a frame. The web members are analyzed as truss bars

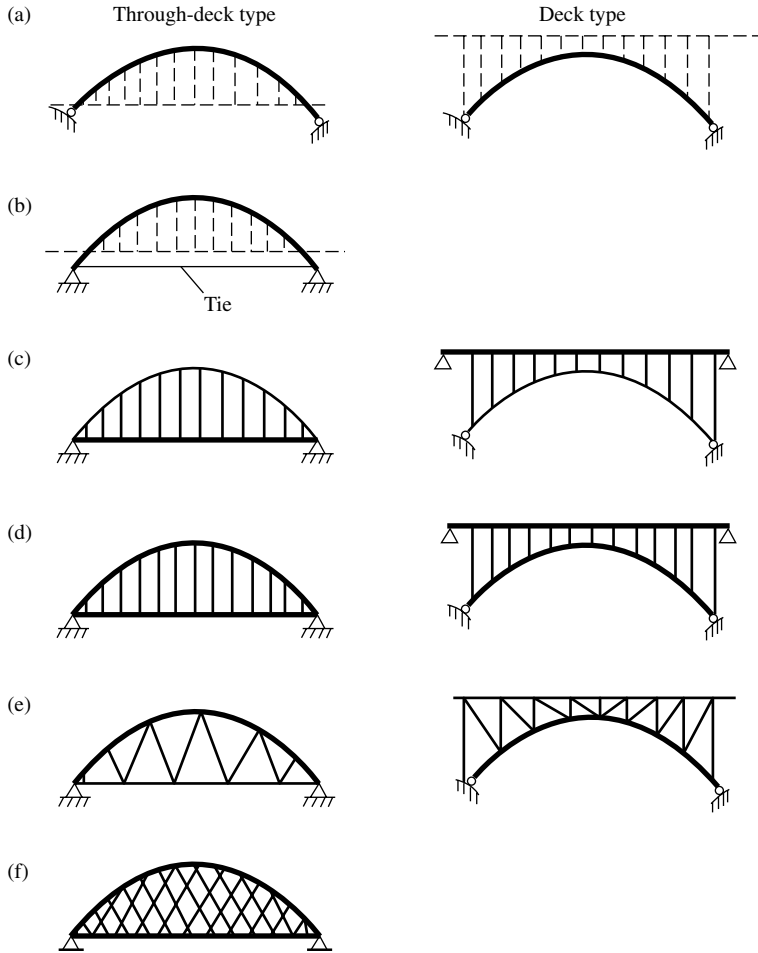

FIGURE 25.49 Type of arch bridges: (a) two-hinge arch; (b) tied arch; (c) Langer arch; (d) Lohse arch; (e) trussed arch; and (f) Nielsen arch (Shimada 1991).

that take only axial forces. The arch rib and the girders are analyzed as either trusses or beam-columns depending on the type of arch considered. Beam-columns take axial and shear forces and bending moments. An arch rib is usually made up of straight piecewise components, not curved segments, and it is so analyzed.

25.9.4 Langer Bridge

The Langer arch is analyzed by assuming that the arch rib takes only axial compression (Figure 25.49c). The arch rib is thin, but the girders are deep and resist moment and shear as well as axial tension. The girders of the Langer bridge are regarded as being strengthened by the arch rib. Figure 25.50 shows structural components of a Langer bridge.

If diagonals are used in the web, it is called a trussed Langer. The difference of the trussed Langer against a standard truss is that the lower chord is a girder instead of just a bar. The Langer bridge is also determinate externally and indeterminate internally. The deck-type bridge of the Langer is often called a “reversed” Langer.

FIGURE 25.50 Langer arch bridge (JASBC 1985).

25.9.5 Lohse Bridge

Lohse bridge is very similar to the Langer bridge except the Lohse bridge carries its resistance to bending in the arch rib as well as the girder (Figure 25.49d). By this assumption, the Lohse bridge is stiffer than the Langer. The distribution of bending moments in the arch rib and the girder depends on the stiffness ratio of the two members, which is the designer's decision. The Lohse arch bridges may be thought of as tiered beams (see Figure 25.19) connected by vertical members. The vertical members are assumed to take only axial forces. Esthetically, the Lohse is more imposing than the Langer, and is therefore suited to urban areas while the Langer fits into mountain areas.

25.9.6 Trussed Arch and Nielsen Arch Bridges

Generally, diagonal members are not used in arch bridges thus avoiding difficulty in structural analysis. However, recent advancements in computer technology have changed this outlook. New types of arch bridges, such as the trussed arch in which diagonal truss bars are used instead of vertical members or the Nielsen Lohse design in which tension rods are used for diagonals, have now been introduced (see Figure 25.49e and f). Diagonal web members increase the stiffness of a bridge more than the vertical members.

All the members of the truss bridge take only axial forces. On the other hand, the trussed arch bridge, however, may resist bending in the arch rib, the girder, or both. Since the diagonals of the Nielsen Lohse bridge carry only axial tension, they are prestressed by the dead load to compensate for the compression force due to the live load.

25.10 Floor System

25.10.1 Introduction

The floor system of a bridge usually consists of a deck carried by girders. The deck directly supports the live load. Floor beams as well as stringers shown in Figure 25.51 form a grillage and transmit the load from the deck to the main girders. The floor beams and stringers are used for framed bridges, that is, truss, Rahmen, and arch bridges (see Figure 25.43, Figure 25.48, and Figure 25.50), in which the spacing of the main girders or trusses is large. In an upper deck type of plate girder bridge the deck is directly supported by the main girders and often there is no floor system because the main girders run in parallel and close together.

FIGURE 25.51 Floor system: (a) truss bridge and (b) box girder bridge (Nagai 1994).

The floor system is classified as suitable for either highway or railroad bridges. The deck of a highway bridge is designed for the wheel loads of trucks using plate bending theory in two dimensions. Often in design practice, however, this plate theory is reduced to equivalent one-dimensional beam theory. The materials used are also classified into concrete, steel, or wood.

The recent influx of traffic flow has severely fatigued existing floor systems. Cracks in concrete decks and connections of floor system are often found in old bridges that have been in service for many years.

25.10.2 Decks

25.10.2.1 Concrete Deck

A reinforced concrete deck slab is most commonly used in highway bridges. It is the deck that is most susceptible to damage caused by the flow of traffic, which continues to increase over the years. Urban highways are exposed to heavy traffic and forced to be repaired frequently.

Recently, a composite deck slab was developed to increase the strength, ductility, and durability of decks without increasing their weight or affecting the cost and duration of construction. In a composite slab, the bottom steel plate serves both as a part of the slab and the form work for pouring the concrete. There are many ways of combining the steel plate and the reinforcement. A typical example is shown in [Figure 25.52](#). This slab is prefabricated in the yard and then the concrete is poured on site after girders have been placed. A precast prestressed deck may reduce the time required to complete construction.

25.10.2.2 Orthotropic Deck

For long spans, the orthotropic deck is used to minimize the weight of the deck. The orthotropic deck is a steel deck plate stiffened with longitudinal and transverse ribs as shown in [Figure 25.53](#). The steel deck also works as the upper flange of the supporting girders. The pavement or wearing surfacing on the steel deck should be carefully finished to prevent water from penetrating through the pavement and causing the steel deck to rust.

25.10.3 Pavement

The pavement on the deck provides both a smooth driving surface and prevents rain water from seeping into the reinforcing bars and steel deck below. A layer of waterproofing may be inserted between the pavement and the deck. Asphalt is most commonly used to pave highway bridges. Its thickness is usually 5 to 10 cm on highways and 2 to 3 cm on pedestrian bridges.

FIGURE 25.52 Composite deck (JASBC 1988).

FIGURE 25.53 Orthotropic deck (JASBC 1985).

25.10.4 Stringers

The stringers support the deck directly and transmit the loads to floor beams as can be seen in [Figure 25.51](#). They are placed in the longitudinal direction just like the main girders are in a plate girder bridge and thus provide much the same kind of support.

The stringers must be sufficiently stiff in bending to prevent cracks forming in the deck or on the pavement surface. The design codes usually limit the vertical displacement caused by the weight of a truck.

25.10.5 Floor Beams

The floor beams are placed in the transverse direction and connected by high-strength bolts to the truss frame or arch as shown in [Figure 25.51](#). The floor beams support the stringers and transmit the loads to main girders, trusses, or arches. In other words, the main truss or arch receives the loads indirectly via the floor beams. The floor beams also provide transverse stiffness to bridges and thus improve the overall torsional resistance.

25.11 Bearings, Expansion Joints, and Railings

25.12.1 Introduction

Aside from the main components such as the girders or the floor structure, some other parts such as bearings (shoes), expansion joints, guard railings, drainage paths, lighting, and sound-proofing walls also make up the structure of a bridge. Each plays a minor part but provides an essential function. Drains flush rain water off and wash away dust. Guard railings and lights add to the esthetic quality of the design as well as providing their obvious original functions. A sound-proofing wall may take away from the beauty of the structure but might be required by law in urban areas to isolate the sound of traffic from the surrounding residents. In the following section, bearings, expansion joints, and guard railings are discussed.

25.11.2 Bearings

Bearings (shoes) support the superstructure (the main girders, trusses, or arches) and transmit the loads to the substructure (abutments or piers). The bearings connect the upper and lower structures and carry the whole weight of the superstructure. The bearings are designed to resist these reaction forces by providing support conditions that are fixed or hinged. The hinged bearings may be movable or immovable; that is, horizontal movement is restrained or unrestrained (horizontal reaction is produced or not). The amount of the horizontal movement is determined by calculating the elongation due to a temperature change.

During the 1995 Kobe earthquake in Japan, many bearings were found to have sustained extensive damage due to stress concentrations, which are the weak spots along the bridge. The bearings may play the role of a fuse to keep damage from occurring at vital sections of the bridge, but the risk of the superstructure falling down goes up. The girder-to-girder or girder-to-abutment connections prevent the girders from collapsing during strong earthquakes.

Many types of bearings are available and some are shown in [Figure 25.54](#) and briefly explained in the following:

1. *Line bearings*. The contacting line between the upper plate and the bottom round surface provides rotational capability as well as sliding. These are used in small bridges.
2. *Plate bearings*. The bearing plate has plane surface on the top side which allows sliding and a spherical surface on the bottom allowing rotation. The plate is placed between the upper and lower shoes.
3. *Hinged bearings (pin bearings)*. A pin is inserted between the upper and lower shoes allowing rotation but no translation in the longitudinal direction.
4. *Roller bearings*. Lateral translation is unrestrained by using single or multiple rollers for hinged bearings or spherical bearings.

FIGURE 25.54 Types of bearings: (a) line bearing; (b) plate bearing; (c) hinged bearing; (d) multiple roller bearing; (e) single roller bearing; (f) spherical bearing; and (g) pendel bearing (JASBC 1984).

5. *Spherical bearings (pivot bearings)*. Convex and concave spherical surfaces allow rotation in all directions and no lateral movement. The two types are: a point contact for large differences in the radii of each sphere and a surface contact for small differences in their radii.
6. *Pendel bearings*. An eye bar connects the superstructure and the substructure by a pin at each end. Longitudinal movement is permitted by inclining the eye bar; therefore, the distance of the pins at ends should be properly determined. These are used to provide a negative reaction in cable-stayed bridges. There is no resistance in transverse direction.
7. *Wind bearings*. This type of bearings provides transverse resistance for wind and is often used with pendel bearings.
8. *Elastomeric bearings*. The flexibility of elastomeric or lead rubber bearings is that they allow both rotation and horizontal movement. Figure 25.55 explains a principle of rubber-layered bearings by

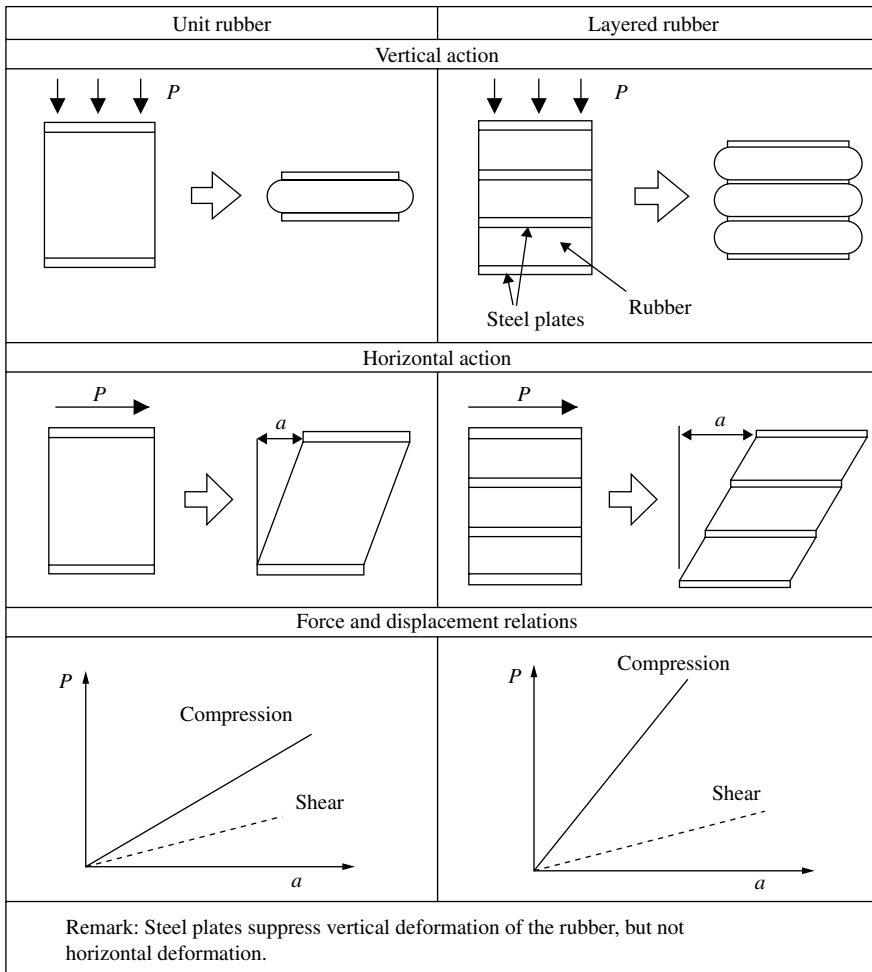

FIGURE 25.55 Properties of elastomeric bearings (Bridgestone Co.).

comparing with a unit rubber. A layered rubber is stiff, unlike a unit rubber, for vertical compression since the steel plates placed between the rubber restrain the vertical deformation of the rubber, but flexible for horizontal shear force like a unit rubber. The flexibility absorbs horizontal seismic energy and are ideally suited to resist earthquake actions. After the disaster of the 1995 Kobe Earthquake in Japan the elastomeric rubber bearings are becoming more and more popular, but whether they effectively sustain severe vertical actions without damage is not certified.

9. *Seismic isolation bearings.* Many different types of seismic isolation bearings are available, such as elastomeric isolators and sliding isolators. When installed on the bridge piers and abutments, the isolation bearings serve both vertical bearing devices for gravity loads and lateral isolation devices for seismic load. The basic purpose of isolation devices is to change the fundamental mode of vibration so that the structure is subjected to lower earthquake force. However, reduction in force may be accompanied by an increase in displacement demand that shall be accommodated within the isolation system and any adjacent structures.

FIGURE 25.56 Types of expansion joints (JASBC 1984): (a) blind slit type; (b) slit plate type; (c) angle joint type; (d) postfitting butt type; (e) rubber joint type; (f) steel covered type; (g) steel finger type (cantilevered); and (h) steel finger type (supported).

A selection from these types of bearings is made according to the size of bridge and the magnitude of predicted downward or upward reaction forces.

25.11.3 Expansion Joints

Expansion joints are provided to allow a bridge to adjust its length under changes in temperature or deformation by external loads. They are designed according to expanding length and material as classified in Figure 25.56. Steel expansion joints are most commonly used. A defect is often found at the boundary between the steel and the concrete slab where the disturbing jolt is given to drivers as they pass over the junction. To solve this problem, rubber joints are used on the road surface to provide a smooth transition for modern bridge construction (see Figure 25.56e) or continuous girders are more commonly adopted than simple girders.

25.11.4 Railings

Guard railings are provided to ensure vehicles and pedestrians do not fall off from the bridge. They may be a hand rail for pedestrians, a heavier guard for vehicles, or a common railing for both. These are made from materials such as concrete, steel, or aluminum. The guard railings are located prominently and are thus open to the critical eye of the public. It is important that they do not only keep traffic within boundaries but also add to the esthetic appeal of the whole bridge (Figure 25.57).

FIGURE 25.57 Pedestrian railing (JASBC 1985): (a) railing images waves and (b) Kanazawa Kakkei Oh-Hashi, Kanagawa, Japan (1982).

Acknowledgments

Many of the figures in this section are copied from other textbooks and journals. The authors would like to express sincere gratitude to these original authors. Special thanks go to Professor N. Nagai of Nagaoka Institute of Science and Technology, Professors Y. Tachibana and H. Nakai of Osaka City University, Japan Association of Steel Bridge Construction, American Association of State Highway and Transportation Officials, and California Department of Transportation for their generosity.

Glossary

Abutment — An end support for a bridge structure.

Arch bridge — A bridge that includes the road deck and the supporting arch.

Bridge — A structure that crosses over a river, bay, or other obstruction, permitting the smooth and safe passage of vehicles, trains, and pedestrians.

Cable-stayed bridge — A bridge in which the superstructure is hanging from the diagonal cables that are tensioned from the tower.

Cast-in-place concrete — Concrete placed in its final position in the structure while still in a plastic state.

- Composite girder** — A steel girder connected to a concrete deck so that they respond to force effects as a unit.
- Deck (slab)** — A component, with or without wearing surface, directly supporting wheel loads.
- Floor system** — A superstructure, in which the deck is integral with its supporting components, such as floor beams and stringers.
- Girder** — A structural component whose primary function is to resist loads in flexure and shear. Generally, this term is used for fabricated section.
- Girder bridge** — A bridge superstructure that consist of a floor slab, girders, and bearings.
- Influence line** — A continuous or discretized function over a section of girder whose value at a point, multiplied by a load acting normal to the girder at that point, yields the force effect being sought.
- Lever rule** — The static summation of moments about one point to calculate the reaction at the second point.
- LRFD (load and resistance factor design)** — A method of proportioning structural components (members, connectors, connecting elements, and assemblages) such that no applicable limit state is exceeded when the structure is subjected to all appropriate load combinations.
- Precast member** — Concrete element cast in a location other than its final position.
- Prestressed concrete** — Concrete components in which the stresses and deformations are introduced by application of prestressing forces.
- Rigid frame bridge** — A bridge in which the superstructure and substructure members are rigidly connected.
- Segmental bridge** — A bridge in which primary load-supporting members are composed of individual members called segments post-tensioned together to act as a monolithic unit under loads.
- Substructure** — Structural parts of the bridge that provide the horizontal span.
- Superstructure** — Structural parts of the bridge that support the horizontal span.
- Suspension bridge** — A bridge in which the superstructure is suspended by two main cables and anchored to end blocks.
- Truss bridge** — A bridge superstructure that consist of a floor system and main trusses.

26.1 Introduction

26.1.1 Features of Cable-Supported Bridges

Cable-supported bridges or cable-suspended bridges are defined as bridges whose decks are supported by flexible cables. They are, in principle, classified into a suspension type where the bridge deck is continuously supported by stretched catenary cable(s), a cable-stayed type where the deck is discretely and directly suspended by straight stay cables, and their combined type. Suspension and stayed structures are applied to roof and buildings too.

Although the load bearing mechanisms are different, suspension and cable-stayed bridges have in common the following features:

1. They generally consist of cables, bridge deck incorporated with solid-web girder or truss, and towers.
2. They are advantageous for spanning long distances as seen in [Figure 26.1](#) because cables are subject to only tension and steel wires consisting of a cable have very high tensile strength, although they may also be used economically on short- and medium-span pedestrian bridges.
3. The entire structure is much more flexible than other types of structures having equivalent span length.
4. The complete structure can be mostly erected without intermediate staging from the ground.
5. The main structure is elegant and neatly expresses its function owing to its transparent appearance.

FIGURE 26.1 Transition of maximum span length of bridges in the 20th century.

Since the cable-supported bridges are mostly used outside the span range of the standard bridge specifications and are quite flexible compared with other structural types, their design specifications are often provided peculiarly.

26.1.2 Historical Sketch of Modern Cable-Supported Bridges

The history of cable-supported bridges is very long because the concept of suspending a bridge deck by cables might be easily thought of. However, construction of reliable structures of these sorts had to wait until the age of the industrial revolution when strong and homogeneous wrought iron, and later steels, were manufactured. Since then, techniques of suspension bridge construction have made steady progress despite frequent accidents, whereas early attempts to construct bridges as cable-stayed systems were not successful probably due to lack of technical and analytical understanding.

Roebings' Brooklyn Bridge (486 m span) built in 1883 marked the beginning of the golden age of modern suspension bridges in the United States spanning the next half a century. With the successive construction of the Williamsburg (1903; 488 m), Benjamin Franklin (1926; 533 m), Ambassador (1929; 564 m), George Washington (1931; 1067 m), Golden Gate (1937; 1280 m), and Verrazano Narrows (1965; 1298 m) bridges, the United States stood at the vanguard of long-span suspension bridge technology. In the mid-1950s, 15 of the longest span suspension bridges in the world were in the United States. Among them, the Manhattan Bridge built in 1909 is featured as the first suspension bridge designed on the basis of the deflection theory. It provides a contrast to the neighboring Williamsburg Bridge, built only 6 years earlier by using the elastic theory, when slenderness of stiffening truss is compared. The George Washington Bridge was epoch-making because its main span length exceeded 1 km for the first time, almost doubling the previous record. Not to speak of the technological excellence, the Golden Gate Bridge is featured by its Art Deco style towers and iron oxide red color that harmonize so well with the magnificent site. In 1940, the Tacoma Narrows Bridge, then the world's third-longest suspension bridge, collapsed due to dramatic flutter oscillation caused by a gale. The lesson from this tragedy was reflected in the design of the Mackinac Strait and the Verrazano Narrows bridges afterwards in different styles.

From around 1960, a wave of long-span suspension bridges moved to western Europe. In particular, the unprecedented ideas of streamlined box girder and inclined hangers adopted first for the design of the Severn Bridge in the United Kingdom, completed in 1966, were further applied to the Humber Bridge, the world's longest span bridge at the time of completion in 1981, and the first Bosphorus bridge (Kemal Ataturk Bridge), designed by the same group. Later, in the last quarter of the 20th century, the construction of long-span suspension bridges boomed in Japan and the Scandinavian countries, and then in China. Such chronological trends as mentioned above may be recognized from Table 26.1a.

Among the recent suspension bridges in the Far East, the Seto Bridges in Japan (1988) and the Tsin Ma Bridge in Hong Kong (1997) are featured as long-span suspension bridges carrying both road and substantial rail traffics. Particularly in the former, new techniques such as innovative track structures and new design and fabrication provisions against fatigue were first developed. The longest span of a suspension bridge

has reached nearly 2 km in the 20th century, while the Messina Strait Bridge in Italy, which will also carry both road and rail and is awaiting construction, is expected to have the formidable span length of 3300 m.

Although the concept of cable-stayed bridge was known since ancient times, the first outstanding application of stay cables was realized by Roebling in his Niagara suspension bridge in the mid-1850s, carrying rail and road. The same system was used for the Brooklyn Bridge also though these stays were not effective structural components. More than a half century later, F. Dischinger proposed the combined system of suspension and stay cables in 1938 but did not use it for actual construction.

The construction of modern cable-stayed bridges was led by German engineers after the Second World War. In particular, three large bridges, Nord, Knie, and Oberkassel, built from 1956 to 1972 for the city of Duesseldorf crossing the River Rhine, were a dramatic display of the new form. Following these early German designs, cable-stayed bridges spread rapidly throughout the world, marked especially by a variety of forms chosen for esthetic and technical reasons. As seen in Figure 26.1, the development of record span length of this type has been very rapid. The longest span exceeds 800 m in the late 1990s, and now is expected to exceed 1000 m by 2010 (see Table 26.1b). As far as the number of long-span cable-stayed bridges is concerned, Japan and China have taken lead; in 2010, China will have eight among the top ten longest bridges.

Since the tower and girder of a cable-stayed bridge are mostly subject to bending and compression, concrete structures have been widely used from the early stage, even for spans as long as 500 m or more. On the other hand, its application to short-span pedestrian bridges has been also very widespread, being appreciated for its esthetic value and economical advantage.

26.2 Structural Cables

26.2.1 Steel Wires

Cables are naturally the most important element of a cable-supported bridge. Although eye-bar chain was used in the early days and now the use of new composite materials is going to increase for small-span bridges, the material most frequently employed in modern bridge cables is cold-drawn high-strength steel wires, which have a diameter of 3 to 7 mm and ultimate tensile strength of 1.5 to 1.9 GPa.

As shown in Figure 26.2, the tensile strength of the steel wires used in suspension bridge cables increased up to 1.8 GPa in constructing the world's longest bridge, Akashi Kaikyo, which was completed in 1998 by adding an appropriate amount of silicon. On the other hand, the wire element of the seven-wire strand as used extensively for prestressed concrete, consisting of a straight core wire surrounded by a single layer of long-pitch six wires, has already had a higher tensile strength between 1.8 and 1.9 GPa.

FIGURE 26.2 Tensile strength of galvanized steel wires.

26.2.2 Basic Feature of Wire Cable

A wire cable has to be composed of a large number of single wires to meet the strength requirement. A certain number of wires is often shop-assembled to form a prefabricated strand, subsequently at the site as basic elements for the final cable by being bundled into generally a circular cross-section.

Cable strands are classified into the wire rope formed by helically twisted wires and the parallel-wire strand (PWS), as shown in Table 26.2. A strand rope is manufactured by further twisting spiral rope strands around a single straight core strand. Mechanical properties of a cable go down in order of the PWS, the spiral rope, and the strand rope (see Table 26.3), while order of ease of handling is the reverse. Due to the inferiority of mechanical properties, the strand rope is rarely used in bridge cables. Stay cables used in cable-stayed bridges have more diversity as will be mentioned in the next section.

The cables in a cable-stayed bridge are all inclined. The actual stiffness of such an inclined cable is lower than that of the cable material itself because of sag due to its own weight. The equivalent Young's modulus of an inclined cable is expressed by

$$E_{\text{eff}} = \frac{E_0}{1 + \gamma^2 l^2 E_0 / (12\sigma^3)} \tag{26.1}$$

where E_0 is Young's modulus of the straight cable, γ is the weight of the unit length cable, l is the horizontally projected length of the cable, and σ is the tensile stress in the cable [1]. Although this

TABLE 26.2 Types of Suspension Bridge Cables

Name	Shape of section	Structure
Parallel wire strand		Wires are hexagonally bundled in parallel
Strand rope		Six strands made of several wires are closed around a core strand
Spiral rope		Wires are stranded in several layers mainly in opposite lay directions
Locked coil rope		Deformed wires are used for the outside layers of spiral rope

^b Value for a circumscribed hexagon.

reduction of the stiffness is practically negligible in most cases, it must be properly considered for a very long cable or during some construction stage.

The sectional area of cables is determined on the basis of the maximum cable tension. The safety factor of structural cables has been normally 2.0 to 2.5 for the guaranteed tensile strength, while that of main cables of long-span suspension bridges may be a little lower. This depends on the ratio of the dead load stress to the total stress, the nature of secondary stress, and the existence of fatigue stress.

26.2.3 Types of Bridge Cables

26.2.3.1 Spiral Rope

Spiral ropes have been used for main cables of many short- and medium-span suspension bridges, hanger ropes of almost all suspension bridges, and stay cables of some cable-stayed bridges mainly in the United Kingdom. When a large sectional area is required as in the case of main cables for a medium-span suspension bridge, a certain number of spiral rope strands are arranged in parallel and usually compacted in one cable. In order to remove nonelastic elongation of the spiral rope strand caused by the compaction of the strand, prestressing is performed before erection. Because spiral ropes are self-compacting, it is not required to wrap or provide with bands around the cable if a strand is separately arranged.

26.2.3.2 Locked-Coil Rope

Locked-coil ropes (LCRs) are a family of spiral ropes, but noncircular or deformed wires are arranged in the outside layers of the strand as seen in [Table 26.2](#). The strength of the wires in an LCR is lower (1370 to 1570 MPa), while a nominal modulus of elasticity of an LCR strand is slightly higher than that of a normal spiral rope. The Z-shaped wires of the outer layers make the LCR strand more compact owing to a very small void ratio inside the strand, more water-tight, and less sensitive to side pressures at saddles and anchorages, whereas an LCR is not easy to handle when compared to normal spiral ropes due to its bending stiffness.

The LCR has been widely used in steel cable-supported bridges in Europe, and even in the main cables of suspension bridges with a main span of up to 850 m. Its maximum size so far is approximately 1250 m in length and 180 mm in diameter.

26.2.3.3 Parallel-Wire Cable

A parallel-wire main cable of a large suspension bridge is made either by the air-spinning method where the total cable section is assembled on site from individual wires or by the prefabricated parallel-wire strand (PPWS) method where the PPWS fabricated at the shop is coiled around the reel and transported to the site. The diameter of the individual wire used in suspension bridge main cables is about 5 mm.

A PPWS with covering sheath is widely used in cable-stayed bridges. A parallel-wire bundle of prestressing wires with a diameter of about 5 or 7 mm is incorporated as a stay cable with a polyethylene pipe filled by cement grout as corrosion protection and with HiAm anchor sockets as the end fittings. These parallel-wire cables have been widely used in both concrete and steel cable-stayed bridges.

26.2.3.4 Ultra-Long Lay Cable

The idea of an ultra-long lay cable strand was initiated in the 1980s as the improved variant of PWS parallel-wire cables. Twisting the wires up to 3 to 4° enables the wire bundle to ease reeling and make the strand self-compacting under axial tension without spoiling the mechanical properties. These cable strands were designated as “New PWS” in Japan and as “HiAm-SPWC” in Europe. The New PWS is also featured by extruding high-density polyethylene (HDFE) cover directly onto the wire bundle so that no void will exist between the outer wires and the surrounding cover. The strand is assembled by

7 mm wires and the thickest one comprises 421 wires. The longest stay cable of this type is 460 m long with an outer diameter of 165 mm, as used in the Tatar Bridge.

26.2.3.5 Parallel-Strand Cable

The seven-wire strand that has been extensively used as tendon for a prestressed concrete structure is the simplest and most prevalent stay cable of prestressed concrete cable-stayed bridges. As the pitch of twisted wires is relatively long, the stiffness of the strand is close to that of a straight wire strand and its breaking strength is even higher. For cables, the strand is normally made from 5 mm wires and its nominal diameter is 12.7 or 15.2 mm and these strands are arranged in parallel to form a stay cable. The number of the seven-wire strands varies from 7 to 127 depending on the required design force.

There are a number of strand or cable systems using the seven-wire strands according to corrosion protection, assembling method, and end-fitting techniques, for example, Freyssinet, Dywidag, VSL, Stronghold, SEEE, ASP (at-site prefabricated cable system), and so on. The parallel-strand cables are either shop-fabricated or site-fabricated, and sometimes their combination like SEEE. Cost saving is attained by the site-fabrication of stay cables with individual strands pushed through a preinstalled sheath. The corrosion protection will be illustrated later in [Section 26.2.5](#). These types of cables have also been applied recently to steel or steel/concrete hybrid cable-stayed bridges.

26.2.3.6 Bar Stay Cable

A bar stay cable consists of round steel bars with a diameter of 26 to 36 mm, being covered by a steel pipe, the inside of which is filled with cement grout. The external steel tube is considered in the cable cross-section when live load is applied. Since the length of a bar cannot be long, coupling is normally needed. This type of stay member is scarcely used, particularly for large cable-stayed bridges.

26.2.4 End Fittings of Cable

Bridge cables are connected and anchored to the anchoring substructures or other structural members such as the girder and towers through the end fittings.

26.2.4.1 Strand Shoes

For parallel-wire cables erected by the air-spinning method, the anchoring is generally made by looping the wires around a strand shoe disc that is semicircular or circular and is fixed to the anchor frame through anchoring rods.

26.2.4.2 Metallic Alloy Sockets

For prefabricated strands, either parallel-wire cables or wire ropes, both ends of the strands are fitted by metallic alloy sockets. The socket consists of a thick-walled steel cylinder with a conical cavity, in which the disentangled end of the strand is inserted and the molten metallic alloy is filled. The wedge action of the hardened alloy serves the force transmission. The sockets are supported by the anchor fittings or other anchoring members. The metallic alloy should be provided with large bonding force for wires, low melting temperature, superplasticity, and favorable creep properties. Zn–Cu alloy with 2% Cu is usually used for suspension bridge main cables.

26.2.4.3 Sockets for Stay Cables

The Zn–Cu alloy used in suspension bridges is also popular in the socket of the stay cables, although Zn–Al alloy has been employed in Germany. In the case of cables of the cable-stayed bridges, the fatigue under repeated stress due to vehicle loading and the fretting corrosion due to the abrasion of metals, which occur at the entrance of the socket, are the problems to be considered. As exemplified in

the following, a variety of high-fatigue-resistant sockets have been developed for the stay cables (Figure 26.3):

1. *HiAm anchor socket*. The anchoring mechanism is mainly arch action of wires and steel balls in the conical hole of the steel socket.

FIGURE 26.3 Examples of high-fatigue-resistant socket: (a) HiAm anchor socket; (b) DINA anchor head; and (c) NS anchor socket. (Adapted from M. Ohashi, *Cables for Cable-Stayed Bridges*, in *Cable-Stayed Bridges — Recent Developments and their Futures*, M. Ito et al., Eds., Elsevier, Amsterdam, 125, 1991, with permission.)

2. *NS socket*. This consists of a hot poured Zn–Cu alloy cone and epoxy resin at the mouth of the socket. The epoxy resin prevents fretting corrosion, buffers stress concentration, and reduce unfavorable thermal effect of the molten alloy.
3. *DINA anchor head*. It consists of button heads of wires, a steel anchor head, and epoxy resin. One of its advantages is the short length that can be accommodated into a small space.

Furthermore, various stay-cable anchorages such as Freyssinet, Dywidag, VSL, Stronghold, and SEEE, evolved from the post-tension systems, have been applied to the cable-stayed bridges.

26.2.5 Corrosion Protection

Cable corrosion is caused by water and ion invasion from outside and by dew resulting from the alternating dry and humid conditions inside the cable void. The corrosion protection system usually consists of at least two barriers: the internal barrier immediately adjacent to the main tension element and the external barrier or covering that is exposed to the outside environment and often the blocking compound that is the corrosion inhibiting or water repelling material used to fill the voids inside the covering [2,3]. The internal barrier for steel wires is usually a zinc galvanized barrier, but mainly in North America, epoxy coating of individual wires or seven-wire strands has been widely used on stay cables.

26.2.5.1 Parallel-Wire Main Cables of Suspension Bridges

The conventional method of corrosion protection for the main cables of most long-span suspension bridges has been a covering over the zinc-galvanized parallel wires by layers of paste, wrapping with galvanized soft wires, and painting, all of which aim at preventing water from permeating into the cable, as seen in Figure 26.4a. The paste materials have usually been red lead, polymer organic lead, zinc dust, or the recent lead-acid calcium, while the paint has been futsal acid, rubber chloride, or polyurethane.

FIGURE 26.4 Corrosion protection of suspension-bridge cable: (a) conventional system and (b) new system for the Akashi Kaikyo Bridge.

However, the above-mentioned system was found unsatisfactory under highly humid environments because the conventional types of paste are not effective in protecting against water and corrosion inside the cable occurs irrespective of the effectiveness of the paste if moisture exists in the cable. Accordingly, new corrosion protection technologies have been introduced in the recent Japanese suspension bridges. One is the use of a combination of aluminum triphosphate and organic lead paste and wrapping with S-shaped deformed steel wires adopted in the Hakucho Bridge (1998), and the other is the system consisting of, in addition to the conventional wire wrapping, the wrapping with neoprene rubber sheet instead of paste, as shown in [Figure 26.4b](#); the adoption of a dehumidified air-injection device has also been used, which was used in the Akashi Kaikyo (1998) and Kurushima (1999) bridges. The rubber sheet may be replaced by fiberglass acrylic sheet. In the latter, double layers of butane-contained rubber and denatured silicone were used at the cable band portion.

26.2.5.2 Wire Ropes

The wires for spiral ropes are zinc galvanized and the voids are filled with a sealing compound such as metalcoat, which is a suspension of aluminum flakes incorporated into a hydrocarbon resin carrier suitably diluted with a solvent for ease of application.

LCRs used in Japanese cable-stayed bridges are manufactured from galvanized wires, applying a minimum amount of lubricating oil during rope closing to avoid any concern about future stains of the surface. The outer surfaces are usually painted after the dead load has been fully applied. In European practice, the inner voids of the zinc-galvanized wires are filled by polyurethane with zinc dust or linseed oil with red lead, and outer surface of the rope is coated with polyurethane. Metalcoat is also sometimes applied as the second barrier during its fabrication.

26.2.5.3 Covering of Stay Cables

Covering the strand or cable as the external barrier has been common to other stay cables than helical wire ropes. One of the methods was to wrap a foamed polyethylene tape with glass fiber reinforced plastic covering over the PWS. In the early 1970s this was executed by hand-lay-up method on site, but later prefabricated-segment method was developed to improve the workability of the hand-lay-up method. This is to fabricate fiber-reinforced plastic (FRP) segments in the shop and just to connect them on site to form the complete covering. In this method, however, an installation of catwalk was indispensable for the erection, some expansion joints had to be placed on the covering at certain intervals, and repairing works were needed in some cable-stayed bridges after the age of 20 years or so.

The covering by a metal tube made of steel, stainless steel, or aluminum alloy has been often applied to stay cables of concrete cable-stayed bridges although steel pipes have to be further coated. Installation of metal pipes should be done at the erection site and their stiffness may cause some difficulty in handling during erection when a cable is long.

Use of a FRP or polyethylene (PE) tube was initiated in 1960s. HDPE, which is a widely used material, is selected to resist weathering, high pressure, high temperature, and external injury. At the same time, 2 to 3% carbon is mixed to protect the sheath from ultraviolet rays. Now, HDPE tubes are most popular for both parallel-wire cables and parallel-strand cables, and either shop- or site-fabricated. When heavier corrosion protection is needed, a double-layer PE tube is used to prevent the cracks on the outer surface from reaching the main tension elements.

In the cases of “New PWS” and seven-wire strands, the covering is completely shop-fabricated by a directly extruded HDPE sheath after coating wires with corrosion protection compound. In the former, any further work for corrosion protection is not required at the site. Even if the PE covering is injured, the durability of the cable can be retained for some duration because the wires are galvanized. The repairing of the injured PE envelope can be easily done. The inspection of the cable will also be possible by tearing off a part of the PE covering and by watching the cable from the torn PE window. Although the original color of the PE covering is black due to the mixed carbon, cable coloring techniques have been developed. One is to extrude a colored thin fluoro-polymer on the black PE layer; another method is a paint coating system that consists of an application of primer made from adhesive components for

PE envelope and for the finish coat, and a baking of the primer with a far-infrared ray. The finish coat is usually done by fluoro-olefin paint. The light color is preferred not only for good looks but also for reducing the temperature effect. Supplementary wrapping with colored Tedler tapes is an alternative.

26.2.5.4 Blocking Compound

Cement grout has been the most popular blocking compound for its alkaline properties providing an active corrosion protection to the steel wires. Cement mortar is injected after the stay cables are erected on the bridge when the cable is under full dead load stress to suppress the formation of cracks in the grout, because the presence of cracks may be associated with the potential for fretting corrosion of steel wires. However, cracks may still occur due to shrinkage of cement mortar and stress repetition under cyclic live loading.

Another problem of cement grout combined with galvanized steel wires is a fear of hydrogen brittleness caused by reaction of zinc and cement milk. In order to avoid it, the nongalvanized wires or the galvanized wires coated with polyester to isolate zinc from cement milk have been used in this case. Another measure is to substitute normal Portland cement by polymer cement, the advantages of which are that it is far more ductile, does not shrink after grouting nor bleed during placing, does not require special technique and equipment, and that it can be used in combination with galvanized wire without a fear of chemical reaction between the zinc layer and the cement. On the other hand, its disadvantages are relatively high materials cost and temperature-dependent viscosity and hardening. Cement grout plasticized with polyurethane was used in some bridges.

An example of alternatives to cementitious grout once used by the Honshu Shikoku Bridge Authority in Japan was synthetic resin material based on polybutadiene. This two-component material has very low viscosity during pouring, is very flexible after hardening, and has such low density as about a half of that of cement grout. But the material and execution costs were high and it is highly temperature dependent and flammable. Epoxy resin is specified in the American Society for Testing and Materials provisions as a filling material into the interstices of epoxy-coated seven-wire prestressing strands.

Other blocking compounds are grease used on PWS or prestressing strands and wax for parallel-strand cables. The petroleum is injected in a liquid state at temperatures of 85 to 105°C, which solidifies upon cooling. However, it shrinks during the cooling process and cracks may develop. A soft petroleum base wax that can be applied at ambient temperature on the monostrand system seems promising [4]. It has a melting point over 260°C and displaces any moisture on the surface of steel. In any case, grease and wax are to be used in combination with other corrosion protection measures. It is noted that the nongrout type PWS, which is completely fabricated in the shop, is now available.

26.2.6 Vibration Control

Wind-induced vibrations of stay cables have revealed themselves after the introduction of multistay systems with thin and long cables covered by PE sheath having a smooth surface. The long hangers of a suspension bridge using similar cables are also vulnerable to vibrations under wind. Among several kinds of wind-induced vibrations considered on cables, those where special care should be taken are vortex excitation, wake galloping, and rain/wind-induced vibration. Although tentative or approximate stability criteria for typical vibratory phenomena have been proposed [5], these wind-induced vibrations are dependent on the local terrain features and the peculiar conditions of the respective structural elements.

The following measures are generally considered to suppress the wind-induced vibrations of cables when the responses are not acceptable:

1. Increase of structural stiffness and natural frequency.
2. Increase of structural damping.
3. Modification of the cable surface.

Points (1) and (2) are categorized as mechanical or structural means, while point (3) is the aerodynamic means to weaken the exciting mechanisms by disturbing or reducing wind-induced dynamic

forces acting on the cable. However, because the exciting mechanisms of different vibratory phenomena differ, the countermeasures shall fit for the phenomenon concerned.

Occurrence of wake galloping depends on the spacing of neighboring parallel cables. Very small spacing or quite wide spacing, more than six times the cable diameter, can remarkably moderate the response. If these conditions cannot be satisfied for other design reasons or when undesirable wake galloping is observed after erection, the cable vibration can be suppressed by connecting both cables by a few spacers or small mechanical dampers.

One of the common countermeasures that has been often adopted is to connect the cables with secondary thin cables which may terminate at a cable or at the deck (tie-down cable). Even with a few and small stabilizing ropes, cable movement can be restrained. The natural frequencies of each cable and thus the resistance to dynamic excitation can be raised by shortening the effective free length of the primary cables. Such elements may be also sources of additional damping. But even if the size of stabilizing ropes is significantly smaller than that of the primary cables, they may affect the appearance of the structure to some extent. Furthermore, the rupture of these interconnecting ropes or the fatigue failure of the connection fittings have been reported in several bridges. Viscoelastic bushings or special clamps with damping devices in the joint of the both cables can reduce fatigue and provide additional damping.

Increase of structural damping is effective in suppressing the amplitude of buffeting, vortex excitation, and rain/wind-induced vibration and in raising the critical wind speed for the onset of galloping. It is first recommended to place such damping material as neoprene ring or high-damping rubber between the cable and the steel exit pipe at the pylon and deck anchorage. Use of damping material results in the additional benefit of reduced local bending moment in the cable. Further additional damping, if necessary, can be provided by mechanical damping devices. Very simple and small tuned mass dampers represented by the classical Stockbridge damper that has been prevailing on transmission power lines were applied to stay cables or diagonal hangers of some European cable-supported bridges, but is not very popular now for esthetic reasons.

When rather high additional damping is required, the most prevalent method in cable-stayed bridges is to install a dash-pot type viscous damper between the stay cable and the bridge deck. Shock absorbers similar to those used in automobiles or hydraulic oil dampers are the examples. These dampers shall not spoil the appearance of the bridge. The mechanical dampers utilizing shear-viscous material can be more compact. The attached position of these dampers influences the mode shape and the dampening effect of the cables. It is not easy to make a compromise between the requirement to lower the damper position and the efficacy of the damper when the cable is long.

The aerodynamic countermeasures for the round cables are to modify the sheath surface. The idea of helical fins often used on circular stacks to prevent vortex excitation will be also effective against rain vibration, but care shall be taken on the appearance. The idea of axial protuberances in the form of longitudinal ribs on the HDPE tube surface was developed in the Higashi Kobe Bridge in Japan (Figure 26.5a), aiming at preventing the rain vibration. A similar idea was later seen in the more simpler HDPE sheaths with fine grooves. Further on the Tatara Bridge, HDPE sheaths are provided a pattern-indented surface with roughness of 1% applied disorderly in a convex or a concave pattern (Figure 26.5b). The effect of these surface modifications is linked to influence the water rivulets. However, it should be noted that these means are not necessarily effective in suppressing vortex excitation and that the drag coefficient may be increased. In case of the Tatara Bridge, however, the drag coefficient in the supercritical Reynolds number range could be reduced to 0.6.

26.2.7 Use of Composite Materials

A fiber-reinforced polymer composite or a FRP is a matrix of polymeric material reinforced by fibers or other reinforcement that has a discernible aspect ratio of length to thickness. Reinforcements are fibers made from glass, carbon, or aramid, and the polymer resin can be either thermoset or thermoplastic. Thermosets are typically used for construction applications and can be polyester, vinyl ester, phenolic, or epoxy. FRP composites have been used in a variety of engineering products.

FIGURE 26.5 High-density polyethylene sheath of (a) the Higashi Kobe and (b) the Tataru bridges.

TABLE 26.4 Mechanical Properties of Different Cable Materials

Material	Specific gravity	Tensile strength (MPa)	Young's modulus (MPa)	Failure strain
Steel	7.85	1750–1900	200	6
Aramid fiber	1.35	1400–1800	50–70	2–4
Glass fiber	1.85	600–900	30	2
Carbon fiber	1.55	1900–2300	120–400	0.6–1.9

FRP composites have many advantages as structural materials such as high strength, relatively high elastic modulus, light weight, long-term durability, high dielectric strength, low axial thermal expansion, low maintenance, design flexibility, tailored esthetic appearance, and low tooling and installed costs. On the other hand, their demerits are the rupture without yielding, low elastic modulus of some kinds of the materials, anisotropic properties, low shear and impact resistance, and high material cost that may be gradually improved by the progress of manufacturing technology and widespread use.

Although the use of FRP composites is now becoming popular in structural engineering, carbon fiber-reinforced plastic (CFRP) as a cable material seems the most ideal application. Actually, CFRP stay cables have already been employed on several cable-stayed bridges for pedestrian use. In the far future, CFRP or some other FRPs may be used for the main cables of suspension bridges and greatly increase the limiting span length. The mechanical properties of different cable materials are shown in Table 26.4.

CFRP cables are produced as assemblies of the wires made up of carbon fibers and an epoxy resin matrix. The design considerations for cables made of unidirectional CFRP wires are similar to those for steel cables, with a few exceptions due to the highly anisotropic nature of the material. So far, CFRP stay cables have been made by twisting CFRP wires. Although twisted fiber rope makes coiling possible, resulting in ease in handling, care must be taken on the strength loss of the wires in a bundle and friction between wires. Since the decrease in cable strength is also brought by side

pressure and bending, the diameter of a reel and the radius of curvature of the saddle should not be small. As the strength of epoxy resin deteriorates by the effect of ultraviolet radiation, the CFRP cables shall be protected by covering.

The trial design of a super-long-span suspension bridge for which CFRP main cables are used indicates that the bending moment and vertical deflection of the stiffening girder significantly increase due to the light weight of the structure [6], while the dimensions of towers and foundations can be greatly reduced. It is recommended to reduce the sag/span ratio of the main cables.

26.3 Suspension Bridges

26.3.1 Structural System

26.3.1.1 Components of a Suspension Bridge

A suspension bridge typically consists of the following components (Figure 26.6):

1. Main cables that suspend the bridge deck.
2. Main towers that support the main cables. Sometimes lower subtowers are positioned between the main tower and the cable anchorage to lead the cable to the anchorage.
3. Stiffening girder, either solid-web girder or truss, being incorporated with the bridge deck.
4. Hangers or suspenders that connect the bridge deck with the main cables.
5. Anchorages that anchor the main cable. They are usually massive concrete blocks, in which the anchor frame is embedded.

In very special situations occasionally encountered in short-span bridges, some components other than the main cables and the bridge deck may be omitted.

26.3.1.2 Classification

The structural system of suspension bridges may be classified by the following factors:

Number of spans. A suspension bridge may be single-span, two-span, three-span, or multispan. The number of main towers is one for two-span, two for single- and three-span, and more than two for multispan bridges (Figure 26.7). Two-span suspension bridges have been rare because they are less efficient as recognized from Equation 26.2. Single-span suspension bridges have straight backstays. Three-span suspension bridges are the most popular, in particular for long-span bridges and the ratio of side spans to main span is mostly 0.2 to 0.5. Although multispan suspension bridges have been rare because of great flexibility, their applicability is being studied for the future straits crossings [7]. The major concerns about multispan suspension bridges are the design of intermediate towers and cable erection.

FIGURE 26.6 Suspension bridge.

FIGURE 26.7 Single-, three-, and multispan suspension bridge (from top).

Continuity of stiffening girder. The stiffening girders are typically either simply supported on each span or continuous over two or more spans. The former is called two-hinged and commonly used for road bridges. Although continuous girder with intermediate supports is not economical as also recognized from Equation 26.2, it is advantageous for a rail bridge to improve runnability of trains. Furthermore, in the Great Belt Bridge, which is a road bridge with a center span of 1624 m, the girder is continuously supported by the cable system through three spans. The economical design was attained in this case by omitting the vertical support of the girder at the towers and fixing the main cables to the stiffening girder by clamps at the midspan.

Arrangement of hangers. Hangers are either vertical or diagonal. The latter makes the entire suspended structure a kind of truss incorporated with the main cables and the bridge deck.

Method of cable anchoring. The main cables of a suspension bridge are either externally anchored to the anchor blocks or self-anchored to the stiffening girder. Although the latter is rare, a more detailed description will be made in the following.

26.3.1.3 Self-Anchored Suspension Bridge [8]

Self-anchored suspension bridges do not require massive end anchor blocks. Instead, the main cables are anchored to the stiffening girder. Accordingly, the girder is subject to large axial force in addition to bending and shear, and the girder must be placed before the main cables are erected. Therefore, this type of structure is limited to moderate spans. Recent examples of the self-anchored suspension bridge are the Konohana Bridge in Japan (1990, three spans), the Yongjong Bridge in Korea (2000, three-span double-deck truss), and the replaced San Francisco Oakland Bay East Bridge (two spans). The first two bridges have 300 m center span, whereas the span of the Bay Bridge will be 385 m long. The Konohana Bridge is a monocable type, while two main cables of the other two bridges are converged at the peaked tower top.

26.3.2 Analysis of Suspension Bridges

Because a suspension bridge is very flexible and the bridge deck is suspended from the main cables by thin hangers, a different approach from other types of bridge structures should be taken in its analysis.

26.3.2.1 Behavior under Vertical Loads

The overall behavior of a suspension bridge is given by the deflection theory where the vertical deflection of cables due to live load is considered in the equilibrium of the structure. The premised assumptions in this case are (1) the cable is completely flexible, (2) the stiffening girder is horizontal and straight, (3) the original form of the main cable is a parabola, (4) all dead loads are sustained by the main cable, and (5) the hangers are inextensible and closely spaced. Thus, the bending moment $M(x)$ of the stiffening girder under live load is given by

$$M(x) = M_0(x) - H_p y(x) - (H_w + H_p) v(x) \quad (26.2)$$

where $M_0(x)$ is the bending moment due to the live load in a beam without cables, having the same span length, $y(x)$ is the ordinate of the cable, measured from the straight line connecting cable supports, $v(x)$ is the vertical deflection due to live load, H_w and H_p are the horizontal components of cable tension due to dead load and live load, respectively.

It is understood from the above equation that the stiffening girder of a suspension bridge subject to vertical live load can be replaced by the beam shown in Figure 26.8, and the bending moment in the stiffening girder decreases with increase of cable tension and deflection. The longer the span length is, the more conspicuous this effect becomes. In other words, the cable tension very much contributes to the stiffness of a suspension bridge, and since almost all dead loads are sustained by the main cable, the stiffening girder of a suspension bridge is not necessary to be so stiff even if the span is long.

26.3.2.2 Behavior under Horizontal Load

Lateral forces caused by wind or earthquake in horizontal direction are to be transmitted from the stiffening girder to the main cables through flexible hangers because the deformation of the girder is larger than that of the main cables due to the difference of the horizontal loads and their stiffness. This effect is more pronounced as seen in Figure 26.9 in the center region of the span owing to large inclination of hangers. Consequently, the lateral bending moment induced in the girder is not so large in the region of the mid-span.

26.3.2.3 Design Analysis

Equation 26.2 indicates the nonlinearity between live load and the bridge responses. In long-span suspension bridges, however, $H_w + H_p$ can be assumed nearly constant because H_w is much larger than H_p , and therefore the analysis becomes quasilinear and the influence line analysis can be used on the conservative side (the linearized deflection theory) [9]. This simplified treatment is useful in a very early stage of preliminary design.

More accurate analysis shall be performed at the subsequent design stages including detailed design. With the progress of computer application nowadays, the finite displacement analysis for the entire

FIGURE 26.8 The equivalent beam of a suspension bridge.

FIGURE 26.9 Transverse deformation of a suspension bridge under wind load.

suspension bridge structure is available taking into account the discreteness and elongation of hangers, deformation of towers, and so on.

26.3.3 Design Procedure

After the type of structural system and the span arrangement are decided, the design of suspension bridge superstructure is performed according to the procedure shown in Figure 26.10 [10].

26.3.3.1 Design Loads

Accurate evaluation of dead load is important in suspension bridge design because its contribution to the main components of the bridge is large. Design live load can be reduced from a probabilistic viewpoint with increasing span length and road width. The dynamic magnification due to running vehicles is usually negligible for design of the main cables, towers, and stiffening girder of a large suspension bridge owing to its long span and low natural frequencies.

The dynamic analysis is inevitable in seismic and wind-resistant design of flexible suspension bridges. Although the seismic forces induced in the superstructure are relatively small due to its long natural period, attention should be paid on possible large displacement of the stiffening girder and great forces transferred to the supports under seismic loading. Aerodynamic stability often dominates the design of a suspension bridge and some appropriate cures may be needed (cf. Chapter 9 of Section II) [11].

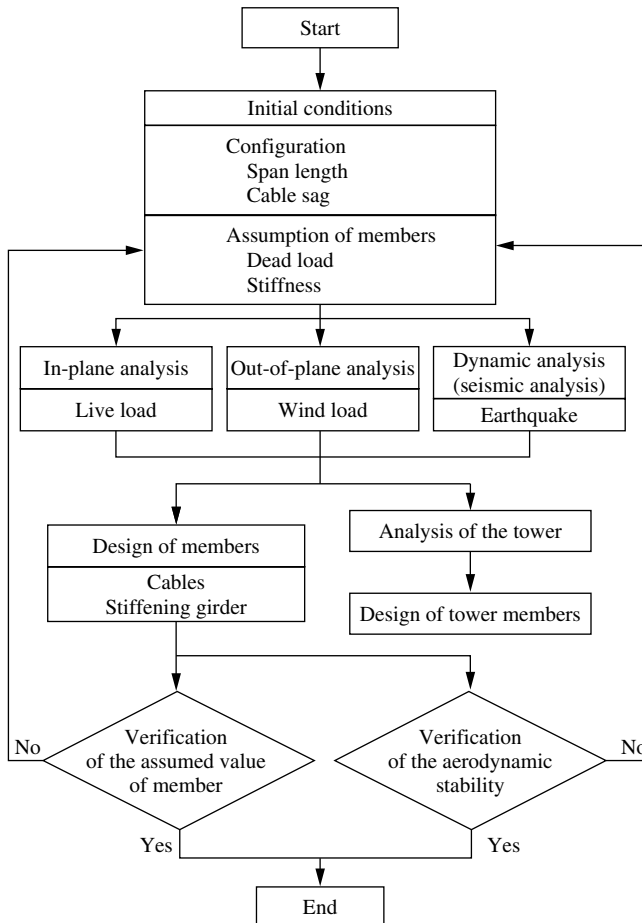

FIGURE 26.10 Design process of a suspension bridge superstructure.

26.3.3.2 Main Cables

The final form of the main cable of a suspension bridge is a parabola. Sag/span ratio is determined to optimize construction cost of the entire bridge, and sometimes in consideration of the aerodynamic stability as it affects the dynamic characteristics of the entire structure. In general, the sag/span ratio is around $\frac{1}{10}$ irrespective of span length.

As mentioned in [Section 26.2.2](#), the parallel-wire cable is exclusively used in very long-span bridges, whereas the spiral ropes or LCRs have been sometimes adopted in moderate- or short-span suspension bridges.

26.3.3.3 Hangers

Hanger cables are arranged to be either vertical or diagonal (forming a truss). The latter aimed at increasing the damping properties and stiffness of the structure, and was first adopted in the Severn Bridge in the United Kingdom in 1966, followed by two large suspension bridges in Europe. But it was abandoned afterwards due to the fatigue injuries in the Severn Bridge.

The spiral or strand ropes have been widely used on the hangers of suspension bridges. Exceptions are the LCRs as in the Little Belt Bridge in Denmark and the PWS in the latest Japanese suspension bridges (Akashi and Kurushima). The hangers are connected to the main cable either by pin or by laying around the cable.

26.3.3.4 Main Towers

To meet the condition that the longitudinal movement of the main cable at the tower top should be theoretically allowed in a suspension bridge, towers are classified into rigid (saddle on rollers at the tower top), rocking (hinged at the tower base), and flexible types. Nowadays, the rocking type and flexible type are used in short-span and long-span bridges, respectively. In the case of the intermediate tower(s) of a multispan suspension bridge, the main cables may be fixed by anchoring them to the top of the rigid tower. The tower height above the deck is governed by the sag of the main cable.

Except the A-shaped tower used on some self-anchored suspension bridges or pedestrian bridges, the main towers consist of basically two vertical shafts connected to each other with horizontal struts at the top and underneath the bridge deck. Between these struts and between the lower strut and tower base, two shafts are often connected by additional strut(s) (portal-type tower) or diagonal members (braced-type tower). The vertical shafts can be slightly inclined. The member axis of inclined shafts typically coincides with the center line of the main cable at the tower top.

The main towers of suspension bridges may be made of either steel or concrete. Although almost all stiffening girders are steel structures, reinforced concrete towers have been prevalent in the recent European and Chinese bridges. Since the flexible towers are subject to both compression and bending, strength as well as elastic stability analysis shall be carefully conducted.

The steel tower shaft has a closed section consisting of stiffened plates. The outline of the cross-section is a rectangular, T-, or cross-shape. The latter two shapes are composed of multicells. The tower base where axial force, lateral force, and bending moment are transmitted into the foundation is either grillage (bearing transmission type) or embedded type (shear transmission type). On the other hand, the shaft of concrete towers has a rectangular hollow section. Since the main towers of a suspension bridge is outstanding and symbolic, esthetic consideration should be taken into account in its configuration.

26.3.3.5 Stiffening Girder (Bridge Deck)

The role of the stiffening girder is not only to give stiffness to the entire structure but to distribute the loads applied after the completion and transfer them to the main cables through hangers. However, since the stiffness provided by cable tension is quite large in long-span suspension bridges and almost all the dead load is sustained by the main cables, the rigidity of the stiffening girder may be not so large even if the span length is long. On the other hand, because the torsional rigidity of the stiffening girder is significant to ensure the flutter stability of a suspension bridge under wind, it is intended to constitute closed box effects structurally even if the girder is a trussed structure, by providing with both upper and

lower lateral bracings. The ratio of fundamental natural frequencies in torsion and in bending is recommended to be 2.0 or higher.

Although short-span bridges are often provided with I-girders, the stiffening girder of a long-span suspension bridge is usually either a truss girder or a box girder. Its design is mainly governed by the function such as traffic requirement, the necessary stiffness, and aerodynamic stability, as well as the site conditions of erection and maintenance. Selecting an aerodynamically stable cross-section has usually priority. Use of either streamlined box section or the section with openings such as a truss of small solidity factor and steel open-grating floor will meet this requirement. Three typical examples of the stiffening girder are shown in Figure 26.11. Although a truss girder has been used on double-deck

FIGURE 26.11 Examples of stiffening girder of modern suspension bridge: (a) Severn Bridge; (b) Tsing Ma Bridge and (c) Akashi Kaikyo Bridge.

bridges, adoption of big fairings on both sides of the cross-section and longitudinal openings on upper and lower decks features the Tsing Ma Bridge in Hong Kong (Figure 26.11b).

Even if the stiffening girder is simply supported, both supports are designed as movable shoes in long-span suspension bridges; that is, the stiffening girder is suspended by tower links at the tower and end links at the abutment. The wind bearings preventing transverse displacement of the girder are installed on the horizontal strut of the tower and on the abutment. When no vertical support is provided at the tower, the lateral support at the tower can be accomplished by applying vertical sliding bearings between the girder and the inner surfaces of the tower shafts as in the case of the Great Belt Bridge.

In many long-span suspension bridges, the stiffening girder is fixed to the main cables at the center of main span by either rigid clamps or diagonal stays, which are called the center tie and the center diagonal stay, respectively. These aim at constraining the asymmetric vibration mode of torsion and the relative longitudinal displacement between the cables and the girder, resulting in the reduction of secondary bending stress in short hangers and the increase of longitudinal restoring force of the girder. In the case of the diagonal stay, it may be proportioned to fail at a certain service limit state.

26.3.4 Stress Ribbon Bridge

Stress ribbon bridges are a kind of earth-anchored suspension bridges (Figure 26.12). The stretched cables are encased in the concrete slab which is used as the bridge deck. As understood from Equation 26.2, the cable tension due to the dead load and prestressing, in addition to bending rigidity of the deck slab, contribute to the stiffness of the entire bridge. Although the sagged form is inevitable in the stress ribbon bridge, the maximum longitudinal slope is limited from the function of the bridge. On the other hand, very large tensile force in the cable is associated with increase of the cost. Therefore, this type of structure has been applied so far to the pedestrian bridges having short or moderate span length, although the structure is efficient, very slender, and elegant. In their design, care should be taken in forming a smooth transition between the slab and the abutments [12].

26.3.5 Erection

26.3.5.1 Towers

The control of erection accuracy in holding verticality is very important in tower construction. Steel towers are erected by using tower cranes and creeper traveler cranes. When open water area is available, floating cranes are sometimes used together. Because very tall and slender steel towers are vulnerable to wind-induced vibrations, in particular during the free standing stage of erection, some damping devices

FIGURE 26.12 An example of stress ribbon bridge.

FIGURE 26.13 Operating principle of aerial spinning. (Source: Honshu-Shikoku Bridge Authority, Technology of the Seto-Ohashi Bridge, Japan, 1989, with permission.)

are often installed. In the case of the Akashi Kaikyo Bridge, a set of tuned mass dampers are left as permanent fixtures inside the shafts. In constructing concrete towers, the towers are slip-formed in a continuous operation, employing self-climbing forms, tower cranes, and concrete-pumping buckets.

26.3.5.2 Main Cables

The erection of parallel-wire main cables of a suspension bridge is executed by either aerial spinning (AS) method or prefabricated strand (PPWS) method. In the former, the total cable section is assembled on site from individual 5 mm wires pulled across an anchorage to the other anchorage over the tower saddles. The conventional sag-control method spans individual wires in free-hang condition and the sag of each wire is individually adjusted to ensure the wires to be of equal length (Figure 26.13). The problem of this method was the sensitiveness of the quality of the cables and the erection period to such site working conditions as wind environment and spinning equipment.

A new method that is called the tension-control method was developed in Japan (Figure 26.14) and has been applied not only to the Japanese bridges but also to the Second Bosphorus and Great Belt bridges. Although adjustment of individual strands is still required, the idea of this method is to keep the tension in the wire constant during cable spinning to obtain uniform wire lengths.

On the other hand, the PPWS method was introduced to reduce the labor and the weather sensitivity and consequently to speed up erection work. Although the limitation of this method may lie in the weight of the strand and the size of the reel, it was successfully applied to the world's longest Akashi Kaikyo Bridge, requiring strands with a length of 4000 m and a strand plus reel weight of 95 tons.

Now that the AS and PPWS methods have been improved step by step and experience has been gained, the method undertaken depends on the cost and period of construction at the specific site or area.

FIGURE 26.14 Operating principle of tension control method. (Source: Honshu-Shikoku Bridge Authority, Technology of the Seto-Ohashi Bridge, Japan, 1989, with permission.)

26.3.5.3 Stiffening Girder

The erection of the stiffening girder in the main span of a suspension bridge proceeds either from the mid-span to the both towers (girder-section method) or vice versa (cantilevering method). The former is typically applied to the box-type girder. The prefabricated blocks of the girder are transported to the site by deck barges and tugboats and lifted up to the designated position. Then the blocks are connected with hinges and finally welded or bolted together. In the case of the Kurushima Kaikyo bridges in Japan, a self-controlled barge maintaining its position by means of computer monitoring and a quick-joint system shortening the erection time were developed and used to cope with the fast and complex tidal currents at the site.

On the other hand, the cantilevering method is typically adopted when the open sea area cannot be utilized for erection or when a trussed stiffening girder is to be erected. Preassembled panels of the truss girder are erected by cantilevering them from the towers and anchorage blocks. If the situation allows, some large blocks are erected by floating cranes.

The connections of the girder section during erection is temporarily hinged or rigidly connected. In the former case, the joints are loosely connected until all sections are positioned. It enables simple and easy analysis of the behavior of the structure under erection and usually temporary reinforcement of the members is not needed, while the countermeasures against wind instability should be taken if necessary. In the rigid-connection method, full-splice joints are immediately completed as each girder block is erected into place. This keeps the girder smooth and rigid, resulting in high construction accuracy. But temporary reinforcement of the girders and hangers to resist transient excessive stresses or controlled operation to avoid overstress will be sometimes required.

26.4 Cable-Stayed Bridges

26.4.1 Layout of Structural System

A cable-stayed bridge is considered a girder elastically supported at the anchoring points of stay cables, but the girder is subjected to not only bending and shear but also axial forces due to the horizontal component of tension in stay cables (Figure 26.15). The degree of static indeterminacy increases with increasing number of stay cables. The jacking devices arranged at the cable anchorages can not only adjust for relaxation in the cables or errors in the cable length but also modify the cable forces, and hence the prestressing by cables can improve the dead load stress distribution in the girder.

The wide design possibility is available in cable-stayed bridges because of a variety of alternatives for configuration, structural system, and relative stiffness of each element. This is the reason why

FIGURE 26.15 The equivalent beam of a cable-stayed bridge.

FIGURE 26.16 Typical cable-stayed bridges: (a) partially earth-anchored two-span bridge and (b) three-span bridge with intermediate piers in the side span.

cable-stayed bridges can be applied to not only very long-span bridges but also to short-span pedestrian bridges. In contrast to a suspension bridge, a cable-stayed bridge is typically a closed structural system; in other words, mostly a self-anchored system. Since a cable-stayed bridge can be built usually without massive anchor block and temporary staging, it is particularly advantageous in areas where the soil condition is not so good.

As compared with a suspension bridge, the stiffness of a cable-stayed bridge is greater because the cables are straight though the limit span length of the former may be longer than the latter.

26.4.1.1 Alignment of Bridge

Although most bridges are straight or skewed, a cable-stayed bridge can be designed as a curved bridge. The Katsushika Harp Bridge in Tokyo has the bridge axis forming an S-shape curve because of the complex site conditions from the adjacent rivers and road alignment. The anchors of single-plane stay cables were positioned symmetrically with respect to the tower, so as to minimize the transverse bending moment in the tower. The girder of a curved bridge should be torsion-stiff.

26.4.1.2 Span Allocation

Although the three-span structure is most prevalent, two-span layouts are widely acceptable in a cable-stayed bridge. Even the asymmetric span allocation can be designed economically and be esthetically pleasing. When the side spans are very short, all or some of the stay cables may be earth-anchored (Figure 26.16a). The earth-anchored stay cables make the whole structure stiffer and hence more advantageous in planning super-long-span cable-stayed bridges.

If the situation allows, it is advantageous to provide the intermediate piers in the side spans (Figure 26.16b) or to extend the suspended side spans continuously toward further one or a few spans in order to increase the stiffness of the entire structure.

On the other hand, multispan cable-stayed bridges are also attractive. Examples are the Maracaibo Bridge (cantilevered multispan P/C bridge, 235 m span) in Venezuela built in 1962, the Mezcala Bridge (167 + 311.4 + 299.5 + 191 m) in Mexico built in 1994, the Ting Kau Bridge (127 + 448 + 475 + 127 m) in Hong Kong built in 1998, the Rion Antirion Bridge (286 + 3 × 560 + 286 m) in Greece built in 2004, and the Millau Viaduct (204 + 6 × 342 + 204 m) in France also built in 2004.

26.4.1.3 Multiple-Span Bridge

When a cable-stayed bridge has more than three spans, the bending moment in the intermediate towers may be very large or the structure will be subject to large deformations under the action of live load. In order to cope with the problem, various alternative methods (Figure 26.17) such as using rigid frame towers (Rion-Antirion Bridge), tying the tower tops of each other with horizontal cables, tying the tower tops to the girder and tower intersection point at the adjacent towers (Tsing Kau Bridge), adding additional tie-down piers at span centers, or crossing cables at mid-spans can be employed [13]. Since these methods has merits and demerits, an appropriate measure shall be selected depending upon the conditions of the respective bridge.

26.4.1.4 Cable Arrangement

In the longitudinal direction, stay cables are arranged to be single-plane or two-plane. In the former, cable anchorages at the girder are positioned at the central reserve and the girder should be torsion-stiff. But the single-plane arrangement has such advantages as the reduced size of substructures and the better visual impression given to both users and viewer, while it has naturally shorter limiting span length

FIGURE 26.17 Alternate solutions for multispan cable-stayed bridges (from top: rigid intermediate pylons; head-cables connecting tower tops; cables connecting tower top and an adjacent pylon at the deck level; overlapped stays in the mid-span area). (Adapted from Virlogeux, M., *Struct. Eng. Int.*, IABSE, 1, 61, 2001, with permission.)

compared with a two-plane cable system: currently the Tsurumi Bridge in Yokohama, Japan, has the maximum span length of 510 m. On the other hand, the double-plane system may be formed either as two vertical planes or as twin inclined planes connected from the edge of the deck to either an A frame or inverted Y frame tower. Inclined stays increase the stiffness and stability, particularly in torsion, of the structure and are advantageous for very long spans.

Viewing from the transverse direction, the cable arrangement can be classified into harp, fan, and radial types (Figure 26.18). Although the fan-type system is popular because of the advantages in proportioning bridge components, the harp-type cable system is sometimes preferred for either pleasing appearance or more constraint upon longitudinal displacement of the bridge deck.

The use of a small number of stay cable(s) with large diameter has shifted to a multistay system since the end of the 1960s. The closely spaced multistay system has such advantages that additional bending moment in the girder is reduced, a stay cable is individually replaceable, and the anchorage details become more compact and simple.

26.4.1.5 Extradosed Prestressed Concrete Bridge

In an extradosed prestressed concrete bridge, the concept of which was first proposed by a French engineer U. Mathivat, the cables behave as external prestressing with a large eccentricity and the girder provides a significant part of the global load carrying capacity of the superstructure, whereas a typical cable-stayed bridge has a more flexible deck and relies on the stay cables to provide the global vertical load carrying capacity for the structure. In appearance, however, it is difficult to distinguish an extradosed bridge (e.g., Figure 26.19) from a cable-stayed bridge. Its apparent feature is lower towers and thick deck as compared with a cable-stayed bridge.

Extradosed bridges are used to span normally 100 to 200 m, but the Kiso River Bridge (160 + 3 × 275 + 160 m) and the Ibi River Bridge (154 + 4 × 271.5 + 157 m) near Nagoya, Japan, could span about 275 m by using the steel box girders in the middle part of main span.

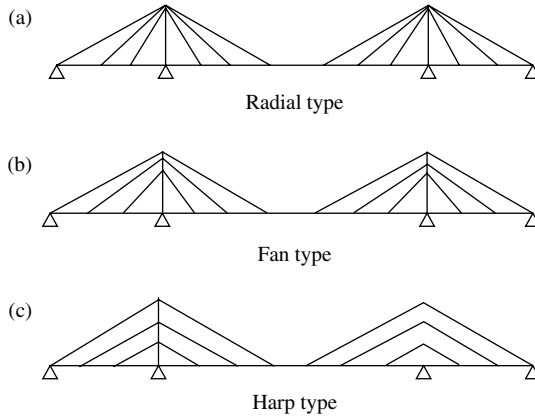

FIGURE 26.18 Stay-cable layout.

FIGURE 26.19 Extradosed bridge.

26.4.2 Configuration and Design of Structural Components

26.4.2.1 Stay Cables

Since the types, corrosion protection, and vibration control of cables were already mentioned in Section 26.2, just the anchoring techniques of cables in cable-stayed steel bridges will be reviewed herein.

The structural details to anchor stay cables at the main girder or the tower shall be designed so as to smoothly transmit cable tension to the main structural component, to be as simple and compact as possible, to be easy in fabrication and maintenance, and to have good appearance. Care shall be also taken on the fatigue and secondary stresses of both cables and anchorages. Although the types of structural details are manifold, the typical ones are given in the Sections 26.4.2.1.1 and 26.4.2.1.2.

26.4.2.1.1 The Stay Anchor at the Girders

1. Spray saddle/anchor girder type — The combination of spray saddle and anchor girder has been used for thick cables, but is not prevailing now.
2. Anchor girder (block) type — The anchor girder or the anchor block is inserted in the main girder by welding or bolting.
3. Bracket type — The bracket that anchors the stay cable is projected outside the main girder.
4. Pipe anchor type — The pipe that anchors the stay cable is incorporated with the web of a main girder.
5. Gusset type — The cable socket is connected to the gusset extended from the web of a main girder.

26.4.2.1.2 The Stay Anchor at the Tower

In the earlier bridges having a small number of thick stay cables, the hinged or fixed saddle over which cables are continuous was used. But nowadays, use of thin stay cables is prevailing and the typical types of anchorage are as follows:

1. Saddle type (e.g., Zarate-Brazo Largo Bridge, Yokohama Bay Bridge).
2. Anchor girder type (e.g., Speyer Bridge, Tempoan Bridge).
3. Bearing plate type (e.g., Kurt-Schumacher Bridge, Torikai-Ninnaji Bridge).
4. Pin-socket type (e.g., Stroemsund Bridge, John O'Connell Memorial Bridge).

26.4.2.2 Towers

Since the action of stay cables becomes inefficient with decreasing inclination, the stay inclination is usually taken as 25 to 65°, or the tower height of a cable-stayed bridge is around $\frac{1}{4}$ to $\frac{1}{5}$ of the main span and hence much taller than that of a suspension bridge with equivalent scale.

Almost all towers of the recent cable-stayed bridges are made of concrete though steel towers were used on the earlier steel bridges and presently almost all Japanese bridges have steel girders. Now concrete towers can be used for very long-span cable-stayed bridges such as the Normandy Bridge over the Seine (850 m span) and the Su-Tong Yangtze River Bridge (the world's longest span 1088 m) now under construction in China, with advances in concrete construction and formwork technology. In the Stonecutters Bridge (1018 m span) now under construction in Hong Kong, the top one third of 290 m high single-pylon tower will be a composite steel/concrete structural section. The steel skin will be fabricated from stainless steel for reasons of appearance and durability.

Development of bending moment in pylons was prevented in the earlier bridges by the use of rocker or sliding saddles and pinned tower feet, but those of recent bridges except for very short spans are mostly made integral with the pier or sometimes with the girder.

Wider choice is available in the tower form of a cable-stayed bridge as compared with a suspension bridge. This feature is advantageous in view of esthetical design. The tower form in general has distinctive characters, attaining increasing levels of refinement and rationality as time passes. Needless to say, the design of the tower must adapt to the stay cable layouts and to the topography and geology of the bridge site, and carry the forces economically.

FIGURE 26.20 Various forms of cable-stayed bridge tower.

The typical forms of cable-stayed bridge towers are shown in Figure 26.20. The single pylon adapting to a single-plane cable system has to be usually situated within the central median of the roadway and hence an additional width of deck is required for the necessary clearance to traffic. The inverted Y-shape tower is used for both single-plane and double-plane cable systems, while A- or inverse V-shape towers adapt to a double-plane cable system. The H-shape tower is the most logical form structurally for a two-plane cable system. In the case of the A or inverted Y towers, the spacing of two shafts under the deck is often narrowed to reduce the size of the foundation. These diamond-shape towers have been used for long-span cable-stayed bridges such as the Tataru (Japan), Yangpu (China), and Baytown (United States), but the visual aspect of securing the strength of the portion under the deck should be carefully pursued.

26.4.2.3 Bridge Deck

In cable-stayed bridges, the solid-web girders precede the truss girders except for double-deck designs for both structural and esthetic reasons. These girders or bridge deck are subjected to not only bending and torsional moments as well as shear forces but also axial forces. The closer spacing of cables in a multistay system allows a more slender bridge deck. Although the stability of the girder as a beam-column is generally not yet a serious problem owing to elastic and almost continuous support by stay cables so far, the overall stability of the structure must be checked by using a nonlinear, second-order analysis for super-long-span cable-stayed bridges [14].

As for the cross-section of the steel girder in a cable-stayed bridge, there seems two ways at the moment. One is a single or double box as seen in many long-span cases. Orthotropic steel plate deck is incorporated with the steel girder and the circumscribed shape of the cross-section is usually trapezoidal or hexagonal, mainly for aerodynamic reason. Another way is the use of shallow-plated edge girders connected with cross-girders. For wider bridges and longer span bridges than 500 m, Leonhardt and Zeller [15] suggest the use of similar cross-sections of all steel structures with an orthotropic steel deck, and that no box girder is needed and simple edge beams are sufficient. However, a box girder with high torsional rigidity should be used when the stay cables are arranged in a single plane along the center line of the bridge deck.

The use of a composite steel/concrete girder on cable-stayed bridges may be categorized into the latter. Prefabricated or *in situ* concrete slabs are connected with longitudinal edge girders and cross-beams in steel by stud shear connectors. The compressive forces from the stay cables can be sustained by the concrete slab. The Yangpu Bridge in Shanghai with a long main span of 602 m is provided with double-web edge girders. Figure 26.21 shows two typical examples of steel girders used in large cable-stayed bridges.

One trapezoidal or two rectangular box designs are most popular in prestressed concrete cable-stayed bridges. But as in the case of the composite girder mentioned above, the longitudinal edge beams

FIGURE 26.21 Examples of steel girder of cable-stayed bridge: (a) composite girder of the Nanpu Bridge and (b) steel box girder of the Tatara Bridge.

connected by the transverse beams and incorporated with the stay anchors are sometimes employed. Even in the prestressed concrete girders, wind nose may be added to the cross-section when the span is long.

When the ratio of the side span to main span length is small, the use of steel girders in the main span and continuously extended concrete girders in the side spans is one of the solutions to attain the rational and economical design. If the situation allows, it is advantageous to provide with intermediate supports for the side-span girders in this case.

Most of the truss girders for cable-stayed bridges are employed in double-deck cases, as exemplified in several Japanese designs. Among them, the Hitsuishijima and Iwakurojima bridges (Figure 26.22) were designed to carry four lanes of roadway traffic on the upper deck and ordinary type railway tracks as well as double Shinkansen rail tracks on the lower deck. Yokohama Bay Bridge, which carries six lanes of roadway traffic on the respective decks, is unique in that the upper chord of its truss is a shallow steel box section stiffening the girder system and concealing power and communication cables. The truss girder of the Higashi-Kobe Bridge is shallow and of Warren type without vertical members, so it appears slender for a double-deck road bridge.

26.4.2.4 Vertical Support of Girder

A variety of supporting conditions have been adopted in modern cable-stayed bridges [16] because the selection of the supporting conditions for longitudinal movement is rather adaptable owing to the existence of stay cables and flexible towers. Less constraint in the bridge axis direction yields longer natural periods of the corresponding motion and thus reduces the seismic inertia forces. However, less constraint on the longitudinal movement of the girder may cause large bending moment in the towers and larger displacement of the girder. The effect of temperature change should be also taken into account. Figure 26.23 illustrates the potential combinations of supporting conditions for three span cases that are most prevalent in long span cable-stayed bridges.

FIGURE 26.22 Typical cross-section of the Seto Bridge.

Type (a) or (e) in the figure, where one support is made as a fixed hinge and all other supports are longitudinally movable, have been widely used for bridges with medium or short span length because temperature effects are released and the seismic force applied to the substructure is relatively small. With increasing span length, design and construction of the pier fixed to the girder become difficult due to the increase of seismic reaction. The supporting condition (e) has been preferred to (a) in Japanese bridges because the expansion of the girder end under temperature change is smaller and the size of the tower foundation is relatively large for reasons other than earthquake effect. The supporting condition (a) may, however, be preferable when the height of the tower below the bridge deck is large and the end support is on the abutment.

When large clearance height is required, the bridge deck is often provided with fixed hinges at both flexible towers as in (c) or is rigidly connected to these towers. The stresses due to temperature change can be released owing to the flexibility of the towers and seismic reactions can be sustained by both tower piers. Some difficulties may arise, however, in giving the towers both the flexibility to absorb deformation of the girder due to temperature change and the stiffness to cope with seismic effects. The additional thrust induced in the girder should be also borne in mind in this case.

Prevalent in long-span cable-stayed steel bridges in Japan are the various devices connecting the girder elastically with towers or abutments ((b), (d), or (h) in Figure 26.23). In the Meikoh-West bridge and some other bridges, elastic restraint was provided by attaching horizontal cables between the girder and the tower, while large Belleville springs were fitted to the rocker bearings at each end pier of the Hitsuishijima and Iwakurojima bridges. The purpose of these devices was to reduce and distribute seismic forces, to control the longitudinal movement of the girder, and also to find a compromise with temperature effect.

The advantage of all movable support types, (f) and (g) in Figure 26.23, is to reduce the seismic inertial force of the girder by attaining very long natural periods of longitudinal sway motion. The so-called floating type (g), where the vertical support at the tower is omitted, leads to a noticeable reduction of the bending moment in the girder at the towers. However, care should be given to excessive displacement of the girder and proneness of instability of the towers. In the Higashi-Kobe Bridge, newly developed vane-type dampers were installed on the end piers as stopping devices against unexpectedly severe earthquakes. The use of short tower links in the Yokohama Bay Bridge or thick rubber shoes on the side span of the Ikuchi Bridge was also aimed at optimizing seismic design under the given conditions.

FIGURE 26.23 Different supporting systems of cable-stayed bridge.

26.4.3 Erection of Cable-Stayed Bridges

Different from an earth-anchored suspension bridge, the erection of which proceeds from anchorages and towers, to cable, and then stiffening girder, the different main components of the self-anchored cable-stayed bridges may be erected in parallel. During cantilever erection of the girder from the tower

toward mid-span, the stay cables will have to be installed and tensioned every time an anchor point at the girder is reached. In some cases, even the construction of the pylons will proceed in parallel with the erection of the girder and stay cables. More detailed description on the erection of cable-stayed bridges are given in the book by Gimsing [17].

The construction methods used on the towers of cable-stayed bridges are typically not different from those of suspension bridges. For smaller or moderate size of steel towers, the erection may be carried out by traveler crane or floating crane with tall boom.

27.1 Introduction

Hyperbolic cooling towers are large, thin shell reinforced concrete structures that contribute to environmental protection and to power generation efficiency and reliability. As shown in [Figure 27.1](#), they may dominate the landscape but they possess a certain esthetic eloquence due to their doubly curved form. The operation of a cooling tower is illustrated in [Figure 27.2](#). In a thermal power station, heated steam drives the turbogenerator that produces electric energy. To create an efficient heat sink at the end of this process, the steam is condensed and recycled into the boiler. This requires a large amount of cooling water, whose temperature is raised and then recooled in the tower.

In a so-called “wet” natural draft cooling tower, the heated water is distributed evenly through channels and pipes above the fill. As the water flows and drops through the fill sheets, it comes into contact with the rising cooler air. Evaporative cooling occurs and the cooled water is then collected in the water basin to be recycled into the condenser. The difference in density of the warm air inside and the colder air outside creates the natural draft in the interior. This upward flow of warm air, which leads to a continuous stream of fresh air through the air inlets into the tower, is protected against atmospheric turbulence by the reinforced concrete shell. The cooling tower shell is supported by a truss or framework of columns bridging the air inlet to the tower foundation.

There are also “dry” cooling towers that operate simply on the basis of convective cooling. In this case, the water distribution, the fill, and the water basin are replaced by a closed piping system around the air inlet, resembling, in fact, a gigantic automobile radiator. While dry cooling towers are doubtless superior

FIGURE 27.1 Computer vision of the lignite power plant at Niederaussem.

FIGURE 27.2 Thermal power plant with cleaned flue gas injection.

from the point of view of environmental protection, their thermal efficiency is only about 30% of comparable wet towers. If the flue gas is cleaned by a washing technology, it is frequently discharged into the atmosphere by the cooling tower upward flow. This saves reheating of the cleaned flue gas and the construction of a smoke stack (see Figure 27.2).

Figure 27.3 summarizes the historical development of natural draft cooling towers. Technical cooling devices first came into use at the end of the 19th century. The well-known hyperbolic shape of cooling towers was introduced by two Dutch engineers, Van Iterson and Kuyper, who in 1914 constructed the first hyperbolic towers, which were 35 m high. Soon, capacities and heights increased until around 1930,

FIGURE 27.3 Historical development of natural draft cooling towers.

FIGURE 27.4 Cooling tower, Gundremmingen, Germany.

when tower heights of 65 m were achieved. The first such structures to reach higher than 100 m were the towers of the High Marnham Power Station in Britain.

In the 1970s, cooling towers for nuclear power plants exceeded elevations of 160 m, having key dimensions as given in Figure 27.4. The increase of efficiency at French nuclear stations led to tower heights close to 190 m, demonstrated by the highest cooling tower for nearly one decade in Civaux, France.

After the German reunification, a generation of new power plants in the lignite belt of the former East Germany replaced the old equipment there, with all having cooling towers with heights close to 180 m. Recently in Niederraussem, near Cologne, Germany, a lignite power station with 965 MW of net capacity and achieving a degree of efficiency of 43% started energy production. The Niederraussem cooling tower with a height of 200 m presently is the world's highest [1]. For all of these new tall towers, the shell is proportionally thinner than an egg.

In the near future, if a renewal program for nuclear power stations in the United States begins, the expected cooling tower heights will easily exceed 200 m, both for better control of thermal pollution and for savings of nuclear fuel.

27.2 Components of a Natural Draft Cooling Tower

The most prominent component of a natural draft cooling tower is the huge, towering shell. This shell is supported by diagonal, meridional, or vertical columns bridging the air inlet. The columns, made of high-strength reinforced concrete, are either prefabricated or cast *in situ* into moveable steel forms (Figure 27.5). After the erection of the ring of columns and the lower edge member, the climbing formwork is assembled and the stepwise climbing construction of the cooling tower shell wall or veil begins (Figure 27.6). Fresh concrete and reinforcement steel are supplied to the working site by a central

FIGURE 27.5 Fabrication of supporting columns.

FIGURE 27.6 Climbing construction of the shell.

crane anchored to the completed parts of the shell and are placed in lifts up to 2 m high (Figure 27.7). After sufficient strength has been gained, the complete forms are raised for the next lift.

To enhance the durability of the concrete and to provide sufficient cover for the reinforcement, the cooling tower shell thickness should not be less than 16 to 18 cm. The shell itself should be sufficiently stiffened by upper and lower edge members. In order to achieve sufficient resistance against instability, large cooling tower shells may be stiffened by additional internal or external rings. These stiffeners may also be used for repair or rehabilitation of deficient shells.

Wet cooling towers have a water basin with a cold water outlet at the base. These are both large engineered structures, able to handle up to $50 \text{ m}^3/\text{s}$ of water circulation, as indicated in Figure 27.8. The fill construction inside the tower is a conventional frame structure and is always prefabricated. It carries the water through a large piping system, the spray nozzles, and the fill package. Often, dripping traps are applied on the upper surfaces of the fill to keep water losses through the uplift stream under 1%. Finally, noise protection elements around the inlet decrease the noise caused by the continuously dripping water, as illustrated in Figure 27.2.

27.3 Damage, Failures, and Loss of Durability

Today's natural draft cooling towers are safe and durable structures if properly designed and constructed. Nevertheless, it should be recognized that this high-quality level has been achieved only after the lessons learned from a series of collapsed or heavily damaged towers have been incorporated into the relevant body of engineering knowledge.

FIGURE 27.7 Formwork and steel reinforcement of shell wall.

FIGURE 27.8 Water basin.

While cooling towers have been the largest existing shell structures for many decades, their design and construction were formerly carried out simply by following the existing “recognized rules of craftsmanship,” which had never envisaged constructions of this type and scale. This changed radically, however, in the wake of the Ferrybridge failures in 1965 [2]. On November 1, 1965, three of eight 114 m high cooling towers collapsed during a Beaufort 12 gale in an obviously identical manner (Figure 27.9).

FIGURE 27.9 Collapse of Ferrybridge Power Station shell.

Within a few years of this spectacular accident, the response phenomena of cooling towers had been studied in detail, and safety concepts with improved design rules were developed. These international research activities gained further momentum after the occurrence of failures in Ardeer (Britain) in 1973, Bouchain (France) in 1979, and Fiddler's Ferry (Britain) in 1984, the last case clearly displaying the influence of dynamic and stability effects.

In surveying these failures, one can recognize at least four common circumstances:

1. The maximum design wind speed was often underestimated, so that the safety margin for the wind load was insufficient.
2. Group effects leading to higher wind speeds and increased vortex shedding influence on downstream towers were neglected.
3. Large regions of the shell were reinforced only in one central layer (in two orthogonal directions) or the double layer reinforcement was insufficient.
4. The towers had no upper edge members or the existing members were too weak to stiffen the structure against dynamic wind actions.

Two towers in the United States, at Willow Island, West Virginia, and at Port Gibson, Mississippi, were heavily damaged during their construction stage, the latter by a tornado-initiated crane impact. The Port Gibson tower repair included the addition of ring stiffeners [3]. Another tower in Poland collapsed without any definitive explanation having been published up to now, but probably because of large imperfections.

In addition to these cases, cracking of many cooling towers has been observed, often due to ground motions following underground coal mining or just because of faulty design and construction.

One of the main European design mistakes was in the amount of circumferential reinforcement, too low to resist shell bending due to wind dynamics, thermal, and hydrated effects. Such deficiencies can lead to extensive, even progressive vertical crack-damage on the outer shell faces [4]. Obviously, any

visible crack in a cooling tower shell is an indication of deterioration of its safety, reliability, and durability. Corrosion of concrete with low resistance to SO_x and NO_x contents in the air around fossil fuel plants adds severely to this degradation. It is thus imperative to conform to a design and construction concept that guarantees sufficiently safe and reliable structures over a predetermined lifetime.

Although power plant construction over much of the industrialized west has slowed in the last decade, research and development on the structural aspects of hyperbolic cooling towers has continued [5,6] and a new wave of construction for these impressive structures seems to be approaching. Engineers face this challenge with confidence in their improved analytical tools, in their ability to employ improved materials, and in their valuable experience in construction.

27.4 Geometry

The main elements of a cooling tower shell in the form of a hyperboloid of revolution are shown in Figure 27.10. This form falls into the class of structures known as thin shells. The cross-section as shown depicts the ideal profile of a shell generated by rotating the hyperboloid $R=f(Z)$ about the vertical (Z) axis. The coordinate Z is measured from the throat while z is measured from the base. All dimensions in the R - Z plane are specified on a reference surface, theoretically the middle surface of the shell but possibly the inner or outer surface. Dimensions through the thickness $h(Z)$ are then referred to this surface. There are several variations possible on this idealized geometry such as a cone-toroid with an upper and lower cone connected by a toroidal segment, two hyperboloids with different curves meeting at the throat, and an offset of the curve describing the shell wall from the axis of rotation. Classically, the columns are arranged as V- or X-frameworks, the latter for very high air inlets; vertical (meridional) columns now popular and were used for the world's highest tower shown later in Figure 27.17.

FIGURE 27.10 Hyperbolic cooling tower.

Referring to Figure 27.10, the equation of the generating curve is given by

$$4R^2/d_T^2 - Z^2/b^2 = 1 \quad (27.1)$$

where d_T is the diameter at the throat and b is a characteristic dimension of the shell that may be evaluated from the diameters d_H and d_U by

$$b = d_T Z_H / \sqrt{(d_H^2 - d_T^2)} \quad (27.2)$$

or from

$$b = d_T Z_U / \sqrt{(d_U^2 - d_T^2)} \quad (27.3)$$

if the upper and lower curves are different. The dimension b is related to the slope of the asymptote of the generating hyperbola (see Figure 27.10) by

$$b = 2d_T/c \quad (27.4)$$

For a cooling tower shell where the axis of the generating hyperboloid is offset from the axis of the cooling tower shell middle surface by a constant radial distance R_o , Equations 27.1–27.4 are modified slightly. However, the former equations may be used directly if the dimension b in Equations 27.2 and 27.3 is calculated using the values of d_H and d_T referred to the axis of the hyperboloid. Then, R_o is added to the value of R calculated by Equation 27.1 to determine the total radial distance from the axis of the cooling tower to the middle surface of the shell at any vertical coordinate Z . Such a shell is known in Figure 27.3, where the value of $R_o = -1.0370$ m for the part of the shell below the throat.

27.5 Loading

Hyperbolic cooling towers may be subjected to a variety of loading conditions. Most commonly, these are dead load (D), wind load (W), earthquake load (E), temperature variations (T), construction loads (C), and settlement (S). For the proportioning of the elements of the cooling tower, the effects of the various loading conditions should be factored and combined in accordance with the applicable codes or standards. If no other codes or standards specifically apply, the factors and combinations given in ASCE 7 [7] are appropriate.

Dead load consists of the self-weight of the shell wall and the ribs and the superimposed load from attachments and equipment. Wind loading is extremely important in cooling tower design for several reasons. First, the amount of reinforcement, beyond a prescribed minimum level, is often controlled by the *net difference* between the *tension* due to wind loading and the dead load *compression*, and is therefore especially sensitive to variations in the wind-produced tension. Second, the quasistatic velocity pressure on the shell wall is sensitive to the vertical variation of the wind, as it is for most structures, and also to the circumferential variation of the wind around the tower, which is peculiar to cylindrical bodies. While the vertical variation is largely a function of the regional climatic conditions and the ground surface irregularities, the circumferential variation is strongly dependent on the roughness properties of the shell wall surface. There are also additional wind effects such as internal suction, dynamic amplification, and group configuration.

The external wind pressure acting at any point on the shell surface is computed as [5,8]

$$q(z, \theta) = q(z)H(\theta)(1 + g) \quad (27.5)$$

where $q(z)$ is the effective velocity pressure at a height z (Figure 27.10) above the ground level, $H(\theta)$ is the coefficient for circumferential distribution of external wind pressure, and $1 + g$ is the gust response factor, and g is the peak factor.

As mentioned above, $q(z)$ should be obtained from applicable codes or standards such as Ref. [7].

The circumferential distribution of the wind pressure is denoted by $H(\theta)$ and is shown in Figure 27.11. The key regions are the windward meridian, $\theta = 0^\circ$, the maximum side suction, $\theta \approx 70^\circ$, and the back suction, $\theta \geq 90^\circ$. These curves were determined by laboratory and field measurements as a function of

FIGURE 27.11 Types of circumferential pressure distribution.

Execution	Roughness parameter kla_R	Pressure min c_{pa}	Pressure distribution
With ribs	0.025–0.100	-1.0	K 1.0
	0.016–0.025	-1.1	K 1.1
	0.010–0.016	-1.2	K 1.2
	0.006–0.010	-1.3	K 1.3
Without ribs	Smooth	-1.5	K 1.5
		-1.6	K 1.6

FIGURE 27.12 Surface roughness and type of pressure distribution.

the roughness parameter k/a_R as shown in Figure 27.12, in which k is the height of the rib and a_R is the mean distance between the ribs measured at about one-third of the height of the tower. Note that the coefficient along the windward meridian $H(\theta)$ reflects the so-called *stagnation pressure* while the side suction is, remarkably, significantly affected by the surface roughness k/a_R . As will be discussed in Section 27.6.2, the meridional forces in the shell wall and hence the required reinforcing steel are very sensitive to $H(\theta)$. In turn, the costs of construction are affected. Thus, the design of the ribs, or of alternative roughness elements, is an important consideration. For quantitative purposes, the equations of the various curves are given in Table 27.1 and tabulated values at 5° intervals are available [4].

The circumferential distribution of the external wind pressure may be presented in another manner that accents the importance of the asymmetry. If the distribution $H(\theta)$ is represented in a Fourier cosine series of the form

$$H(\theta) = \sum_{n=0}^{n=\infty} A_n \cos n\theta \tag{27.6}$$

the Fourier coefficients A_n for a distribution most similar to the curve for K 1.4 are as follows [5]:

n	A_n
0	-0.3922
1	0.2602
2	0.6024
3	0.5046
4	0.1064
5	-0.0948
6	-0.0186
7	0.0468

Representative modes are shown in Figure 27.13. The $n=0$ mode represents uniform expansion and contraction of the circumference, while $n=1$ corresponds to beam-like bending about a diametrical axis resulting in translation of the cross-section. The higher modes $n > 1$ are peculiar to shells in that they produce undulating deformations around the cross-section with no net translation. The relatively large Fourier coefficients associated with $n=2, 3, 4, 5$ indicate that a significant portion of the loading will cause shell deformations in these modes. In turn, the corresponding local forces are significantly higher than a beam-like response would produce.

To account for the internal conditions in the tower during operation, it is common practice to add an axisymmetric internal suction coefficient $H=0.5$ to the external pressure coefficients $H(\theta)$. In terms of the Fourier series representation, this would increase A_0 to -0.8922 .

TABLE 27.1 Equations for $H(\theta)$

Curve	Minimum pressure	Sector I	II	III	α_w

FIGURE 27.13 Harmonic components of the radial displacement.

The dynamic amplification of the effective velocity pressure is represented by the parameter g in Equation 27.5. This parameter reflects the resonant part of the response of the structure and may be as much as 0.2, depending on the dynamic characteristics of the structure. However, when the basis of $q(z)$ includes some dynamic portion such as the fastest-mile-of-wind, $(1 + g)$ is commonly taken as 1.0.

Cooling towers are often constructed in groups and close to other structures, such as chimneys or boiler houses, which may be higher than the tower itself. When the spacing of towers is closer than 1.5 times the base diameter or two times the throat diameter, or when other tall structures are nearby, the wind pressure on any single tower may be altered in shape and intensity. Such effects should be studied carefully in boundary-layer wind tunnels in order not to overlook dramatic increases in the wind loading.

Earthquake loading on hyperbolic cooling towers is produced by ground motions transmitted from the foundation through the supporting columns and the lintel into the shell. If the base motion is assumed to be uniform vertically and horizontally, the circumferential effects are axisymmetrical ($n=0$) and anti-symmetrical ($n=1$), respectively (see Figure 27.13). In the meridional direction, the magnitude and distribution of the earthquake-induced forces is a function of the mass of the tower and the dynamic properties of the structure (natural frequencies and damping) as well as the acceleration produced by the earthquake at the base of the structure. The most appropriate technique for determining the loads applied by a design earthquake to the shell and components is the response spectrum method, which, in turn, requires a free vibration analysis to evaluate the natural frequencies [8–10]. It is common to use elastic spectra with 5% of critical damping. The supporting columns and foundation are critical for this loading condition and should be modeled in appropriate detail [9,10]. Just as for the wind load case, earthquake loading may produce tensile forces opposite to the dead load compression, so the net effect may be quite sensitive.

Temperature variations on cooling towers arise from two sources: operating conditions and sunshine on one side. Typical operating conditions for Central European and North American climatic conditions are

FIGURE 27.14 Central crane during construction attached to shell wall.

an external temperature of -15°C and internal temperature of $+30^{\circ}\text{C}$. This is an axisymmetrical effect, $n = 0$ in Figure 27.13. For sunshine, a temperature gradient of 25°C constant over the height and distributed as a half-wave around one-half of the circumference is appropriate. This loading would require a Fourier expansion in the form of Equation 27.6 and higher harmonic components, $n > 1$, to be considered.

For power plants operating as the base supply (e.g., nuclear plants) and situated in cold winter regions, the inner cooling tower faces may be wetted by condensed vapor for several months. Such hydrated actions may cause swelling of the inner concrete, the intensity of which is dependent on the properties of gravel and cement. Without detailed concrete investigations, an additional thermal gradient of $\sim 10^{\circ}\text{C}$ (warmer at the inner face) may account for this deteriorating effect.

Construction loads are generally caused by the fixing devices of climbing formwork, by tower crane anchors, and by attachments for material transport equipment as shown in Figure 27.14. These loads must be considered on the portion of the shell extant at the phase of construction.

Nonuniform settlement due to varying subsoil stiffness may be a consideration. Such effects should be modeled considering the interaction of the foundation and the soil.

27.6 Methods of Analysis

27.6.1 Response Behavior

Thin shells may resist external loading through forces acting parallel to the shell surface, forces acting perpendicular to the shell surface, and moments. While the analysis of such shells may be formulated

within the three-dimensional theory of elasticity, there are reduced theories that are two-dimensional and are expressed in terms of force and moment *intensities*. These intensities are traditionally based on a reference surface, generally the middle surface, and are forces and moments per unit length of the middle surface element upon which they act: they are called *stress resultants* and *stress couples*, respectively, and are associated with the three directions — circumferential, θ^1 ; meridional, θ^2 ; and normal, θ^3 . In Figure 27.15, the extensional stress resultants, n_{11} and n_{22} , the in-plane shearing stress resultants, $n_{12} = n_{21}$, and the transverse shear stress resultants, $q_{12} = q_{21}$, are shown in the left diagram along with the components of the applied loading in the circumferential, meridional, and normal directions, p_1 , p_2 , and p_3 , respectively. The bending stress couples, m_{11} and m_{22} , and the twisting stress couples, $m_{12} = m_{21}$, are shown in the right diagram along with the displacements v_1 , v_2 , and v_3 in the respective directions.

Historically, doubly curved thin shells have been designed to resist applied loading primarily through the extensional and shearing forces in the “plane” of the shell surface, as opposed to the transverse shears and bending and twisting moments, which predominate in flat plates loaded normally to their surface. This is known as *membrane action*, as opposed to *bending action*, and is consistent with an accompanying theory and calculation methodology having the advantage of being statically determinate. This methodology was well suited for the precomputer age and enabled many large thin shells, including cooling towers, to be rationally designed and economically constructed [5]. Because the conditions that must be provided at the shell boundaries in order to insure membrane action are not always achievable, shell bending should be taken into account, even for shells designed by membrane theory. Remarkably, the accompanying bending often is confined to narrow regions in the vicinity of the boundaries and other discontinuities and may have only a minor effect on the shell design, such as local thickening and additional reinforcement. Many clever and insightful techniques have been developed over the years to approximate the effects of local bending in shells designed by the membrane theory.

As we have passed into and advanced in the computer age, it is no longer appropriate to use the membrane theory to analyze such extraordinary thin and massive shells, except perhaps for preliminary design purposes. The finite element method is widely accepted as the standard contemporary analysis technique and the attention shifts to the level of sophistication required. Usually, the more sophisticated the analysis, more data are required. Consequently, a model may evolve through several stages, starting with a relatively simple version that enables the structure to be sized, to the most complex version that may depict such phenomena as the sequence of progressive collapse of the as-built shell under various static and dynamic loading scenarios, the incremental effects of the progressive stages of construction, the influence of the operating environment, aging and deterioration on the structure, etc. The techniques described in the following paragraphs form a hierarchical progression from the relatively simple to the very complex, depending on the objective of a particular analysis.

In modeling cooling tower shells using the finite element method, there are a number of options. For the shell wall, a variety of ring elements, triangular elements, and quadrilateral elements have been used. Early on, flat elements adapted from two-dimensional elasticity and plate formulations were used to

FIGURE 27.15 Surface loads, stress resultants, stress couples, and displacements.

approximate the doubly curved surface. Such elements present a number of theoretical and computational problems and are *not* recommended for the analysis of shells. Currently, shell elements degenerated from three-dimensional solid elements are very popular. These elements have been utilized in both ring and quadrilateral forms.

The column region at the base of the shell presents a special modeling challenge. For static analysis, the lower boundary is often idealized as a uniform support at the lintel level. Then, a portion of the lower shell and the columns is considered in a subsequent analysis to account for the concentrated actions of the columns, which may penetrate only a relatively short distance into the shell wall. For dynamic analysis, it is important to include the column region along with the veil in the model. An equivalent shell element has proved useful in this regard if ring elements are used to model the shell [9,10]. It may also be desirable to include some of the foundation elements, such as a ring beam at the base and even the supporting piles in a dynamic or settlement model. Figure 27.16 shows such a finite element model for the final tower design with approximately 51,000 degrees of freedom, shown here in a five times coarser resolution.

27.6.2 Linear Elastic Analysis

The linear static analysis method is based on the classical bending theory of thin shells. While this theory has been formulated for many years, solutions for doubly curved shells have not been readily achievable until the development of computer-based numerical methods, most notably the finite element method. The outputs of such an analysis are the stress resultants and couples, defined in Figure 27.15, over the entire shell surface and the accompanying displacements. The analysis is based on the initial geometry, linear elastic material behavior, and a linear kinematic law. Representative results of such analyses for a

FIGURE 27.16 Finite element mesh for tower design including shell, supports, and foundation.

FIGURE 27.17 Prototype of cooling tower at Niederaussem.

large cooling tower (Figure 27.17) are shown in Figures 27.18 to 27.24 for some of the important loading conditions discussed in Section 27.5. The finite element model used considers the shell to be fixed at the top of the columns and, thus, does not account for the effect of the concentrated column reactions. Also, in considering the analyses under the individual loading conditions, it should be remembered that the effects are to be factored and combined to produce design values.

The dead load analysis results in Figure 27.18 and Figure 27.19 indicate that the shell is always under compression in both directions, except for a small circumferential tension near the top. This is a very desirable feature of this geometrical form and the result of a complex shape finding process [6,11].

In Figures 27.20 to 27.22, the results of an analysis for a quasistatic wind load using the K1.0 distribution from Figure 27.11 are shown. Large tensions in both the meridional and circumferential directions are present. The regions of tension may extend a considerable distance along the circumference from the windward meridian, and the magnitude of the forces is strongly dependent on the distribution selected. In contrast to bluff bodies, where the magnitude of the extensional force along the meridian would be essentially a function of the overturning moment, the cylindrical-type body is also strongly influenced by the circumferential distribution of the applied pressure, a function of the surface roughness. The major effect of the shearing forces is at the level of the lintel where they are transferred into the columns. The internal suction effects, Figure 27.23 and Figure 27.24, are significant only in the circumferential direction.

For the service temperature case shown in Figure 27.25 and Figure 27.26, the main effects are bending in the lower region of the shell wall.

27.6.3 Stability

The analysis of hyperbolic cooling towers for instability or buckling is a subject that has been investigated for several decades [12]. Shell buckling is a complex topic to treat analytically in any case, due to the influence of imperfections; for reinforced concrete, it is even more difficult. While the governing

FIGURE 27.18 Circumferential forces n_{11D} under deadweight.

FIGURE 27.19 Meridional forces n_{22D} under deadweight.

FIGURE 27.20 Circumferential forces n_{11W} under wind load.

FIGURE 27.21 Meridional forces n_{22W} under wind load.

FIGURE 27.22 Shear forces n_{12W} under wind load.

FIGURE 27.23 Circumferential forces n_{11S} under internal suction.

equations may be generalized to treat instability by using nonlinear strain–displacement relations and thereby introducing the geometric stiffness matrix, the correlation between the resulting analytical solutions and the possible failure of a reinforced concrete cooling tower is questionable.

Nevertheless, it has been common to analyze cooling tower shells for instability under an unfactored combination of dead load plus wind load plus internal suction. The corresponding instability buckling pattern is shown in [Figure 27.27](#).

FIGURE 27.24 Meridional forces n_{22S} under internal suction.

FIGURE 27.25 Circumferential bending moments m_{11T} under service temperature.

Interaction diagrams calibrated from experimental studies based on bifurcation buckling are also available [4,5,13]. Additionally, there are empirical methods based on wind tunnel tests that consider a snap-through buckle at the upper edge at each stage of construction [4]. These formulas are proportional to h/R and are convenient for establishing an appropriate shell thickness profile. If buckling safety is evaluated based on such a linear buckling analysis or an experimental investigation, the buckling safety

FIGURE 27.26 Meridional bending moments m_{22T} under service temperature.

FIGURE 27.28 Layered model for reinforced concrete shell.

FIGURE 27.29 Nonlinear material properties of reinforced concrete.

factor for realistic material parameters should exceed 5.0. Presently, however, the use of bifurcation buckling analyses should be confined to preliminary proportioning and to wall strengthening around shell openings, since more rational procedures based on nonlinear analysis have been developed to predict the collapse of reinforced concrete shells, as discussed in the following section.

27.6.4 Nonlinear Analysis

Advances in the analyses of reinforced concrete have produced the capability to analyze shells taking into account the layered composition of the cross-section as shown in Figure 27.28. Using realistic material properties for steel and for concrete, including tension stiffening in the form shown in Figures 27.29 to 27.32,

FIGURE 27.30 Elastic-plastic material law for steel.

FIGURE 27.31 Biaxial failure envelope of Kupfer/Hilsdorf/Rüsch.

load-deflection relationships may be constructed for appropriate load combinations. These relationships progress from the linear elastic phase to initial cracking of the concrete through spreading of the cracks until collapse.

Results from a nonlinear study of a shell using a shell geometry given in Figure 27.33, a finite element mesh shown in Figure 27.34, and a reinforcement as specified in Figure 27.35 are presented in Figures 27.36 to 27.41. The wind load factor λ is plotted against the maximum lateral displacement at different heights on the shell in Figure 27.36 and the deformed shape for the collapse load is shown in Figure 27.37. Also, the pattern of cracking corresponding to the initial yielding of the reinforcement is indicated in Figure 27.38. For reinforced concrete shells, this type of analysis represents the state-of-the-art and provides a realistic evaluation of the capacity of such shells against extreme loading [13]. Also, durability assessments can be performed by this concept, from which particularly weak and crack-endangered regions of the shell can be identified and further reinforced [6].

FIGURE 27.32 Additional modulus of elasticity due to tension stiffening.

FIGURE 27.33 Cooling tower geometry with injection holes and shell thickness.

FIGURE 27.34 Finite element mesh for prototype cooling tower Niederaussem.

Figure 27.39 and Figure 27.40 show the additional weakening and cracking of the shell by wind effects W acting on the tower during a cold winter night ($\Delta T = 45^\circ\text{C}$).

It is possible to obtain an estimate of the wind load factor, λ , from the results of a linear elastic analysis, even from a calculation based on membrane theory. This estimate is computed as cracking load for the shell under a combination of $D + \lambda W$ and is predicated on the notion that the reinforcement may add only a modest amount of capacity to the tower beyond the cracking load [15]. The amount of reinforcement in the wall is often controlled by a specified minimum percentage, augmented by that required to resist the net tension due to the factored load combinations. The steel provided is often less than the capacity of the concrete in tension, which is presumed to be lost when the concrete cracks. Therefore, the cracking load represents most of the ultimate capacity of the tower.

The maximum meridional tension location under the wind loading is identified, for example, as the value of $n_{22} = 863 \text{ kN/m}$ in Figure 27.21. The dead load at this location is obtained from Figure 27.19 as -701 kN/m . Taking the concrete tensile capacity as 2400 kN/m^2 and the wall thickness as 16 cm, the tensile strength is 384 kN/m . Therefore, we have

$$-701 + \lambda 863 = 384 \quad (27.7)$$

giving $\lambda = 1.26$ as the *lower bound* on the ultimate strength of the tower. Note that this value characterizes the end of the elastic response phase of the tower. What follows then is the long redistribution phase by secondary concrete cracking and yielding of the reinforcement, which nearly might double λ up to failure. Or, λ might not increase very much, depending on the amount of reinforcement in the critical regions.

27.6.5 Dynamic Analysis

The dynamic analysis of cooling towers is usually associated with design for earthquake-induced forces. The most efficient approach is the response spectrum method, but a time-history analysis may be appropriate if nonlinearities are to be included [2,8]. For large shells the dynamic response due to wind

FIGURE 27.35 Reinforcement in shell and supports for prototype tower.

is often investigated, at least to determine the positions of the nodal lines and areas of particularly intensive vibrations. In any case the first step is to carry out a free vibration analysis. This analysis represents the modes of free vibration associated with each natural frequency, f , or its inverse the natural period T , as the product of a circumferential mode proportional to $\sin n\theta$ or $\cos n\theta$ and a longitudinal mode along the z -axis [9,10]. Some results are shown in Figure 27.41, which demonstrate the lowest vibration modes of a tower without and then with holes for flue gas inlets. Such inlets require great strengthening of the injection area. Further representative results are shown in Figure 27.42 and Figure 27.43, as discussed below.

As an illustration, the cooling tower from Figure 27.4 is again considered. Some key circumferential and longitudinal modes for a fixed-base boundary condition are shown in Figure 27.42. Also, the effects of different cornice stiffnesses are demonstrated. This model may be regarded as preliminary in that the relatively soft column supports are not properly represented, but it illustrates the salient characteristics of the modes of vibration. Most interesting are the frequency curves in Figure 27.43 for the first ten harmonics. Note that the natural frequencies decrease with increasing n until a minimum is reached whereupon they increase, a characteristic behavior for cylindrical-type shells. Also, the stiffening of the cornice tends to raise the minimum frequency, which is desirable for resistance to dynamic wind. Longitudinally, the cornice stiffness effect is significant for odd modes only, as shown in Figure 27.42.

FIGURE 27.36 Load–displacement diagrams for load combination $D + \lambda W$.

FIGURE 27.37 Displacement plot for load combination $D + \lambda W$ (exaggeration: 40).

Specifically for earthquake effects and other coherent excitations, only the first mode participates in a linear analysis for uniform horizontal base motion and the respective values for $n = 1$ should be entered into the design response spectrum.

Results from a seismic analysis of a cooling tower are presented in Figures 27.44 to 27.47. The cooling tower of Figure 27.4 is subjected to a horizontal base excitation based on Figure 27.44, leading to

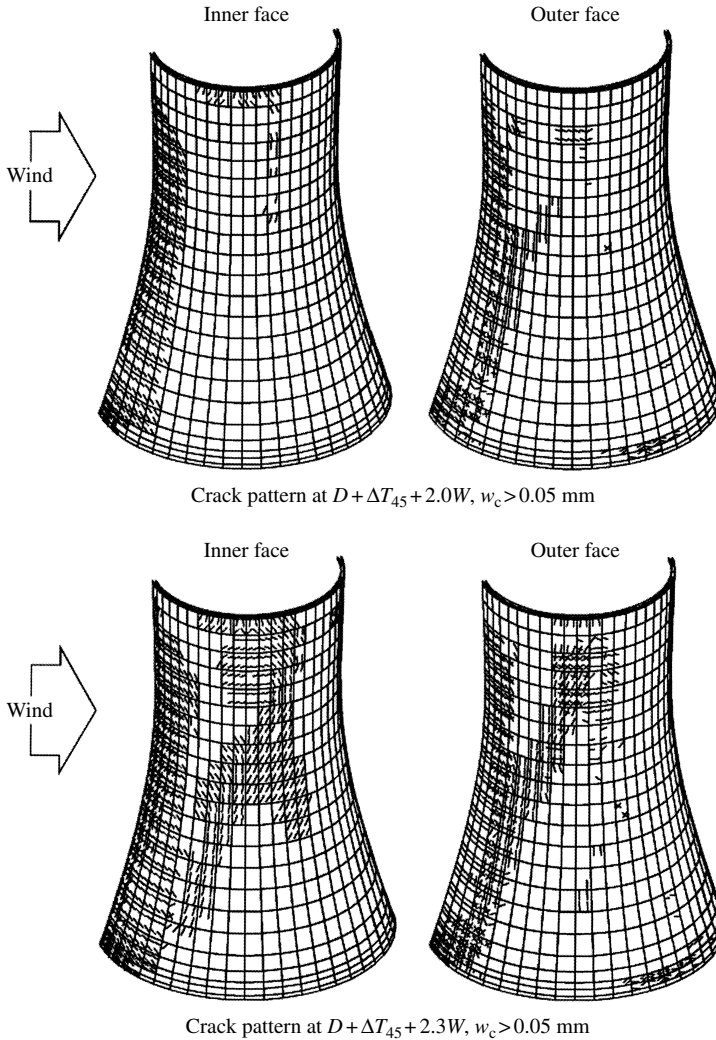

FIGURE 27.38 Different crack patterns for load combination $D + \lambda W$.

a first circumferential mode ($n = 1$) response. A response spectrum analysis provides the lateral displacements w of the tower axis, the meridional forces n_{22} , and the shear forces n_{12} , as shown on the indicated figures. In general, cooling tower shells have proven to be reasonably resistant against seismic excitations, but obviously the most critical region is the connection between the columns and the lintel as portrayed in Figure 27.48.

27.7 Design and Detailing of Components

The dimensioning of the tower components should follow the requirements of the applicable codes of practice. In Ref. [5], limit states of serviceability and of failure are presented to provide sufficient safety. In the limit states of serviceability, a total safety factor concept is applied and the following load combinations are recommended:

$$D + W, \quad D + W + T, \quad D + W/3 + T + E, \quad D + 0.70W + T$$

FIGURE 27.39 Load–displacement diagrams for load combination $D + \Delta T_{45} + \lambda W$.

the latter for checking crack widths. Here, T is taken for standard temperature service conditions. In the failure limit state design, partial safety factors are used for the following load combinations:

$$\gamma_D G + \gamma_W W, \quad \gamma_D G + \gamma_W W + \gamma_T T$$

The structural elements of the tower should be constructed with a suitable grade of concrete following the provisions of applicable codes and standards. The design of the mixture should reflect the site conditions for placement of the concrete and the external and internal environment of the tower.

The shell wall should be of a thickness that will permit two layers of reinforcement in two perpendicular directions to be covered by a minimum of 3 cm of concrete, and should be no less than 16 cm thick [2,4,8]. The buckling considerations mentioned in Section 27.6.3 have proven to be convenient and evidently acceptable criteria for setting the minimum wall thickness, subject to a nonlinear analysis. The formula

$$q_c = 0.052E(h/R)^{2.3} \tag{27.8}$$

where E is the modulus of elasticity has been used to estimate the critical shell buckling pressure, q_c [4,12]. Then, $h(z)$ is selected to provide a factor of safety of at least 5.0 with respect to the maximum velocity pressure along the windward meridian, $q(z)(1 + g)$. Also, the cornice should have a minimum stiffness of

$$I_x/d_H = 0.0015 \text{ m}^3 \tag{27.9}$$

where I_x is the moment of inertia of the uncracked cross-section about the vertical axis and d_H is shown in Figure 27.10 [4]. Some typical forms of the cornice cross-section are shown in Figure 27.49.

The elements of the cooling tower should be reinforced with deformed steel bars so as to provide for the tensile forces and moments arising from the controlling combination of factored loading cases. The shell walls may be proportioned as rectangular cross-sections subjected to axial forces and bending. As mentioned above, a mesh of two orthogonal layers of reinforcement should be provided in the shell walls, generally in the meridional and circumferential directions [8]. In each direction, the inner and outer layers should generally be the same, except near the edges where the bending may require an

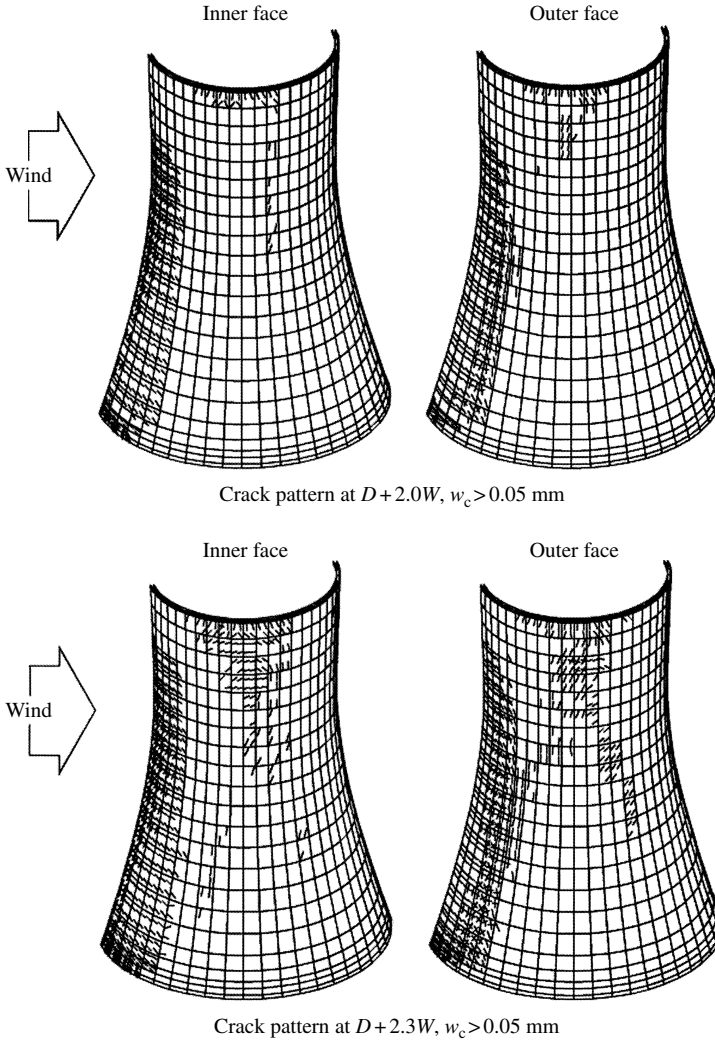

FIGURE 27.40 Different crack patterns for load combination $D + \Delta T_{45} + \lambda W$.

unsymmetrical mesh. It is preferable to locate the circumferential reinforcement outside of the meridional reinforcement except near the lintel, where the meridional reinforcement should be on the outside to stabilize the circumferential bars [16]. A typical heavily reinforced segment of the lintel, also showing the anchorage of the column reinforcement into the shell, is depicted in Figure 27.50.

A summary of the most important minimum construction tolerance values for the shell wall reinforcement is given in Figure 27.51 [2,4,8]. The bars should not be smaller than 8 mm diameter, ϕ , and, for meridional bars, not smaller than 10 mm. Further, a minimum of 0.35 to 0.45%, depending on the admissible cracking, should be used in each direction. The minimum cover, as mentioned previously, should be 3 cm, the maximum spacing of the bars, e , should be 20 cm, and the splices should be staggered as specified for the construction of walls in the applicable codes or standards. Particular attention should be given to splices in tensile zones.

The supporting columns should ideally be proportioned for the forces and moments computed from an analysis in which they are represented as discrete members, using the appropriate factored loading

FIGURE 27.41 Lowest natural vibration modes with/without flue gas inlets.

FIGURE 27.42 Natural frequencies for different cornice stiffnesses for the cooling tower in Figure 27.4.

combinations [9]. If the column region has not been modeled discretely, but rather by a continuum approximation, the columns may be proportioned to resist the tributary factored forces and moments at the interface with the lintel, as computed from the shell analysis. The effective length may be taken as unity. Particular attention should be directed toward splices of the column bars when net tension is present. Since large bars will be involved, welded or mechanical splices capable of transmitting tension forces are recommended in such regions.

It is possible to add discrete circumferential stiffeners to the shell to increase the stability or to restore capacity that may have been lost due to cracking or other deterioration [3] (see Figure 27.10). Such stiffeners can generally be included in a finite element model of the shell wall and should be

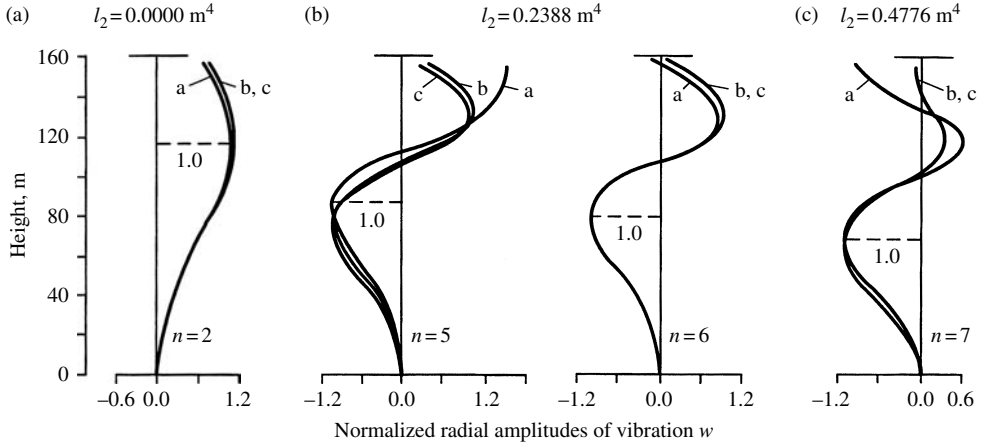

FIGURE 27.43 Normalized natural vibration modes for the cooling tower in Figure 27.4.

FIGURE 27.44 Seismic response spectrum.

proportioned for the forces computed from such an analysis. The eccentricity of the stiffeners with respect to the circumferential axis should be considered when the stiffeners are only on one side of the shell. This technique is discussed further in Section 27.9 and some applications are given there.

The foundations should be proportioned for the factored forces induced by the column reactions or from the computed forces if the foundation is included in the model with the shell and columns. Reinforcement detailing and cover should be in accordance with the applicable codes or standards. Several improved forms for cooling tower foundations have been suggested. Figure 27.52 shows a flat ring footing suitable for uniform soil conditions, while Figure 27.53 portrays a stiff ring beam foundation appropriate for soil conditions that are nonuniform around the circumference. An example of an individual pier on bedrock is given in Figure 27.54.

FIGURE 27.45 First axial mode seismic response.

FIGURE 27.46 Second axial mode seismic response.

27.8 Construction

Tolerances for tall concrete cooling tower shells have been debated for many years and reasonable values should take into consideration what is achievable and what is measurable. It should be noted that state-of-the-art finite element models are capable of analyzing the as-built shell as well as the design configuration, so that the effects of those irregularities arising during construction, or even those discovered later, may be quantitatively studied and sometimes corrected.

It is recommended that the actual wall thickness be no less than the design thickness and exceed this thickness by not more than 10%. The imperfections of the shell wall middle surface should not exceed one-half of the wall thickness or 10 cm. Deviations from the design geometry occurring during the construction should be corrected gradually, limiting the angular change in either direction to 1.5%. The column heads should be within 0.005 times the column height or ± 6.0 cm of the design position, and

FIGURE 27.47 SRSS superposition of first and second axial modes.

FIGURE 27.48 Column to lintel connection.

FIGURE 27.49 Suitable forms of the cornice.

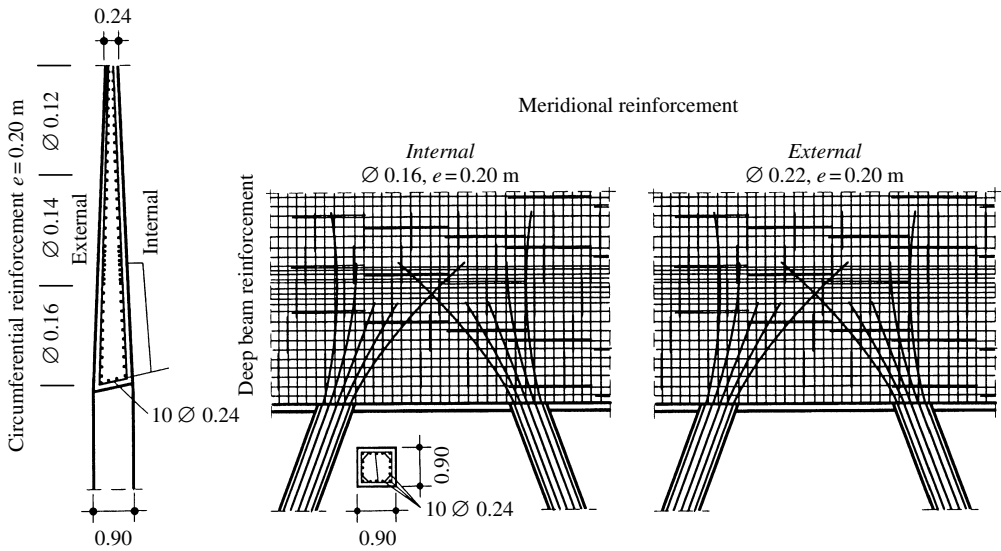

FIGURE 27.50 Lintel reinforcement.

foundation structures should also be within ± 6.0 cm of the design location [2,4,8]. Tolerances for the reinforcement are discussed in Section 27.7.

Formwork and scaffolding systems are generally proprietary and are provided by the constructor. Nevertheless, their influence on the shell quality is of utmost importance and diligent attention of the engineer is required. In general, the system should be designed to provide safety to operating personnel and to produce a sound structure. The working platforms should be designed for realistic loading and scaffolding systems used for continuous material transport should be designed and built taking into account the resulting loads.

FIGURE 27.51 Important minimum construction values.

FIGURE 27.52 Flat ring foundation.

The connections and joints between individual scaffolding units should be designed and built to act independently in case of collapse, so that the loss of one unit would not affect the adjacent units. Furthermore, at least two independent safety devices should be in place to prevent collapse of the scaffolding.

The shell wall should be designed to resist the anchor loads of the scaffolding, based on the actual strength of the concrete that is expected to be available when the anchors are loaded. Continuous monitoring of the concrete strength during the climbing process is essential.

27.9 Durability

Cooling tower shells, particularly in fossil fuel power plants, are subjected to a relatively severe environment over their lifetime, which may span several decades, and special care must be taken in order to provide a durable structure. The tower is subjected to the physical loads produced by wind, temperature,

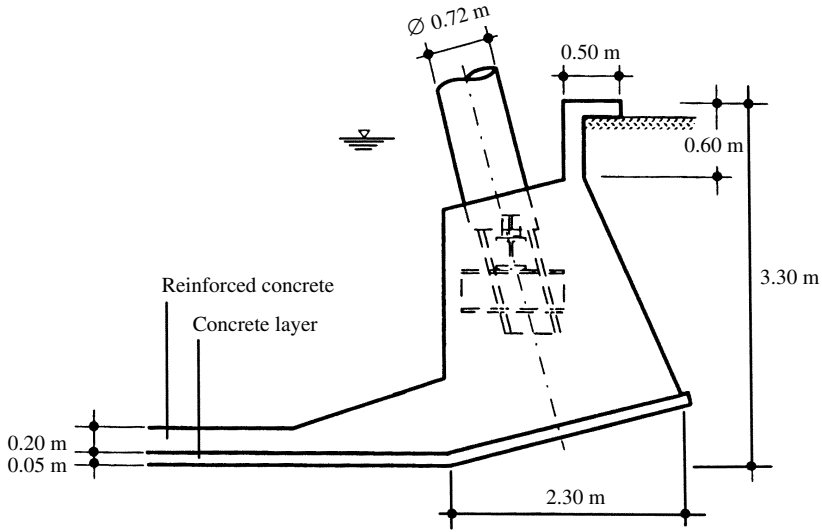

FIGURE 27.53 Ring beam foundation.

FIGURE 27.54 Individual reinforced concrete foundation on concrete base.

and moisture acting on concrete which may still be drying and hardening. Over the lifetime of the structure, it may be exposed to severe frost action in a saturated state, chemical attacks due to noxious substances in the atmosphere and in the water and water vapor, biological attacks due to microorganisms, and possibly additional chemical attacks due to reintroduced cleaned flue gases.

The concrete should be of high-quality approved materials including fly ash. It should have the following properties:

- High resistance against chemical attacks
- High early strength

- High structural density
- High resistance against frost

Cooling towers are often located in plants with extremely aggressive air due to its SO_x and NO_x content. This can cause severe durability problems resulting from concrete corrosion, both on the outer and inner shell surfaces. If cleaned flue gas is discharged via the cooling tower, corrosion protection of the inner surface is vital.

As a proper countermeasure against concrete corrosion, coating of the tower surfaces by synthetic resin has been proven successfully. In such a case, the concrete surface shall be of high quality, smooth, and essentially free of shrink holes. Air bubbles exceeding 4 mm of depth and irregular surface elevations of more than 5 mm should not be allowed. The shell should be coated with a curing agent providing a high blocking effect and long durability. To increase adhesion of the coating, surface cleaning with pressurized water is recommended.

Coatings consisting of copolymers in a acrylic–vinyl resin base have been approved for more than 20 years [17]. The curing of the concrete shell generally consists of a primer and two covering coatings of at least 300 g/m^2 each, the latter colored by suitable pigments. Several single-component (acrylate or polyurethane based) or double-component (epoxy resin based) coating systems are approved worldwide and are in a process of continual improvement. Of utmost importance for any coating is the homogeneity of the applied film, between $\geq 200 \mu\text{m}$ for single- and $\geq 300 \mu\text{m}$ for double-component systems, since the durability of the complete coating is determined by the thinnest film spots. An example of a recently built coated cooling tower is shown in Figure 27.55.

If the shell concrete is already severely corroded, all loose particles have to be removed carefully by water jetting. Corroded and open reinforcement then has to be cleaned and covered by a suitable rust preventing coating. Finally, the loss of concrete cover has to be restored, for example, by gunnite concreting.

A second source of damage causing reduced durability of cooling tower shells is cracking, as demonstrated by the resulting crack patterns due to insufficient reinforcement, inadmissible imperfections, soil

FIGURE 27.55 Coated cooling tower shell at Herne Power Station, Germany.

settlements, or even accidents [18]. All these cracks, if exceeding a width of ~ 0.5 mm, should be carefully repaired, preferably by pressurized injection techniques, to maintain sufficient durability.

In order to prevent local reopening of repaired cracks, they can be covered by carbon-fiber bands glued to the concrete with resin. If the shell requires more global stiffening, the application of additional ring stiffeners is an approved measure [11]. This procedure has been discussed in Section 27.7.

Figure 27.56 shows a comparison of the stiffening effect from two different configurations, related to classical stability limits. For the two 165 m high tower variants of identical thickness, the stability limited is increased from $\lambda = 4.029$ (unstiffened except on boundaries) to $\lambda = 6.379$ (two additional stiffeners), both for the load combination $D + 0.6W$. Figure 27.57 shows the cross-section of such a ring stiffener,

FIGURE 27.56 Buckling patterns of 165 m high tower with upper edge member and with/without additional stiffening rings.

FIGURE 27.57 Cross-section of ring stiffeners at Mississippi Tower: 1, original shell wall; 2, *in situ*; and 3, prefabricated.

composed of combined prefabricated and *in situ* cast reinforced concrete parts, which was attached to the Mississippi Tower after it had been hit and damaged by the collapsing central crane during a tornado [3,11].

In the early 1980s, several ring stiffened large cooling towers were erected in Germany and in Belgium [16,19]. Initial use of circumferential ring stiffeners may save concrete in the tower shell, but increases the amount of reinforcement required. Since the ring construction has to be separated from the continuing climbing process of the shell, their erection is the same as for the rehabilitation applications on existing towers. After crane capacities increased, new high towers were again designed without stiffening rings. Reference [20] reports on the ring stiffening of several cooling towers in South Africa that were heavily cracked by soil settlements due to underground mining, starting in 1985.

28.1 Introduction

This chapter deals with structural design and the selection of structural systems for several types of tunnel structure. Methods of construction are important in the selection of structural systems and their details, but space does not permit this chapter to do justice to every complex method of tunnel construction possible in the great variety of geologic environments that exist. The chapter includes methods for seismic analysis of underground structures.

*Deceased.

28.1.1 What is a Tunnel?

Tunnels are located either below ground or below a body of water. Almost all tunnels serve as part of the infrastructure of cities and countries, conveying utilities, water, or sewage, or serving as transportation arteries. Some tunnels serve as storage, and some caverns are used as stadiums, swimming pools, or even for cleaning sewage. In cities, tunnels are often preferred because they can be built without taking up precious surface space. In the open country, tunnels are most likely to be found where it is necessary to traverse obstacles such as mountains, rivers, lakes, and fjords. The depth, cross-section, and alignment of tunnels are determined by the functional requirements of the facility, by geographical and environmental constraints, and by issues of constructibility under the prevailing geotechnical conditions.

The three principal types and methods of tunnel construction are

- *Cut-and-cover tunnels*, built by excavating a trench, constructing the concrete structure in the trench, and covering it up. Methods used include top-down and bottom-up.
- *Bored or mined tunnels*, excavated through rock either by blasting or by tunnel boring machines, or excavated through soil using shields, mechanized to a greater or lesser extent.
- *Immersed or floating tunnels*, made from very large precast concrete or concrete-filled steel elements, floated out, and then either lowered into a prepared trench and covered over (immersed), or anchored or supported below the water surface but not buried (floating).

In this chapter a short section on *tunnel jacking* is included, a procedure used recently in Boston and which is on occasion used in Europe and elsewhere. It is used only for very shallow tunnels when it is vital not to interrupt surface facilities and if other methods are not suitable.

At shallow depth and for short water crossings, the cut-and-cover tunnels are the most economical. Per unit length, immersed or floating tunnels can be more costly than bored or mined tunnels, but because they can often be made shallower and therefore shorter, and because they may serve their function better than other choices, the overall project cost can be less.

28.1.2 Fundamental Approach to Underground Design

Underground design must achieve functionality, stability, and safety of the underground openings during construction and for the lifetime of the structure thereafter. There is no recognized U.S. standard, practice, or code for the design of most underground structures. Designers may apply codes such as ACI Codes and Practices for concrete design, but these were developed for structures above ground, not for underground structures, and only parts of these codes apply to underground structures such as cut-and-cover structures.

There are five basic steps in the design of underground structures:

1. Define functional requirements, including design life and durability requirements.
2. Acquire and analyze geologic, geotechnical, and cultural data relevant to the design and construction of the underground facilities.
3. Determine plausible and possible modes of failure, including construction events, unsatisfactory long-term performance, failure to meet environmental requirements, and flooding; determine means of analyzing these modes of failure and acquire the necessary data.
4. Establish appropriate method(s) of construction considering the geologic and groundwater information, constructibility, and economy.
5. Establish and design appropriate initial and final ground support and lining systems, considering both ground conditions and the method(s) of construction.

28.1.3 Cut-and-Cover Tunnels

28.1.3.1 Introduction

Cut-and-cover tunnels are by far the most common of all the types of tunnel. They are constructed by one of two main methods. With the “bottom-up” approach, a trench is excavated from the surface,

either supporting the sides of the excavation or sloping the sides. The complete structure is then constructed within the excavation; temporary decking may be installed across the top of the excavation to permit early reinstatement of traffic. With “top-down” construction, the walls (in narrow trenches) and the tunnel roof are built first and the surface reinstated; thereafter, the tunnel section is excavated down from the underside of the already constructed roof structure, and the tunnel is completed. For both methods, the tunnel structure is usually either cast-in-place concrete or erected steel structural elements with infill concrete. It is unusual for prefabricated elements to be used for cut-and-cover tunnel structures.

The cut-and-cover method is most attractive for relatively shallow tunnel sections. Cut-and-cover construction, particularly when the bottom-up method is used, can be disruptive to both surface traffic and existing facilities even when temporary decking is used over the cut.

28.1.3.2 Trench Excavation

The tunnel trench may be constructed by

- Sloping back the excavation, with little or no excavation support.
- Using the temporary support of excavation walls, such as soldier piles and lagging or steel sheet piles that do not form part of the permanent structure.
- Using excavation support walls that are designed to be part of the permanent structure.

The first option can be the most economical, but it is often impractical due to adjacent structures and facilities or due to depth. Comparing the second and third options, increased cost and staging difficulties for building permanent excavation support walls must be balanced against the simplicity and ease of building a permanent structure within temporary walls.

28.1.3.3 Top-Down Construction

As a cost-saving measure, this method typically uses the excavation support walls as part of the final structure (for e.g., concrete diaphragm walls cast in slurry-filled trenches, known as slurry walls, or precast wall sections lowered into slurry-filled trenches). After the walls are constructed downward from the surface, excavation proceeds down to the underside of roof level, and the roof is installed. The surface is then restored to its final condition, and excavation proceeds below the finished roof.

Top-down construction requires a different set of analysis assumptions and staging approaches than bottom-up construction, whether or not it has temporary decking. For example, the staging must lay out specific glory hole locations for all stages, being holes that provide access for construction, materials, and removal of excavated soil and rock. This type of staging planning can be more complex than cut-and-cover work with temporary decking or an open cut.

28.1.3.4 Groundwater Impacts

It is important to evaluate groundwater impacts for cut-and-cover construction. The evaluation includes

- Analysis to determine impacts on the water table beyond the zone of excavation.
- Analysis of the stability of the cut during construction.
- Evaluation of buoyancy under final conditions.

In all stages of cut-and-cover excavation and construction, the weight of the structure and backfill will tend to be less than the weight of the soil removed. The staging evaluation can be more complicated in areas with high groundwater levels.

28.1.4 Bored and Mined Tunnels in Soil or Rock

Transportation tunnels in built-up areas are often constructed by tunneling methods such as machine boring or hand mining. Tunneling can cause much less disruption at the surface, especially of local utilities, and is less expensive for deep tunnels. It is common practice to provide at least one diameter of soil or rock cover, though shallower cover is possible.

Depending on functional requirements, bored or mined tunnels come in almost all sizes, ranging from some 2 m in diameter for medium-sized water and sewage conveyance up to about 20 m in diameter for rail stations and some hydropower plant caverns. While rock tunnels excavated by blasting methods can be built to almost any size and shape, tunnels in soil are usually built using a shield, currently to a maximum circular diameter of about 15 m, although larger-diameter machines are being designed. Most rapid transit tunnels are single-track tunnels with a diameter of about 6 m, but a few have been built as double-track tunnels with a diameter of about 10 m. Even smaller tunnels (microtunnels) are used for utilities, but they may be constructed differently.

Functional and environmental requirements determine basic tunnel support and lining requirements such as shape and size, smoothness, water tightness, and durability. Some tunnels through high-quality rock are unlined or only furnished with nominal support consisting of rock bolts, wire mesh, or shotcrete. At the other extreme, transportation tunnels through soft ground below the groundwater table are furnished with durable, watertight linings, generally designed at present as moment resistant reinforced concrete linings with waterproofing membranes. Many sewer tunnels are furnished with corrosion resistant internal linings.

28.1.5 Immersed and Floating Tunnels

28.1.5.1 Immersed Tunnels

Whenever there is a need to cross water, an immersed tunnel should be considered. Besides their use as road and rail tunnels, many have been built for utilities or pedestrian-only use. Immersed tunnels may appear complex to those unfamiliar with the technology because of the operations in and over water that they entail (Figure 28.1). In reality though, the technique is often less risky than bored tunneling, and tunnel element manufacture can be better controlled since it is precast in the dry. As a result, immersed tunnels are nearly always much more watertight and therefore drier than bored tunnels.

Immersed tunnels offer a number of special advantages:

- They do not have to have circular cross-sections unless the external pressure is particularly high. Almost any cross-section can be accommodated, making immersed tunnels particularly attractive for wide highways and combined road or rail tunnels.
- In contrast to a bored tunnel, they can be placed immediately beneath a waterway with a nominal cover of only 1.5 to 2.0 m of backfill to provide protection against dropping anchors or sinking ships. Because they are shallower, this allows immersed tunnel approaches to be shorter and gradients to be flatter, which is an advantage for all tunnels, but especially so for rail tunnels.
- They can be constructed in ground conditions that would make bored tunneling difficult or expensive, such as the soft alluvial deposits characteristic of large river estuaries.

Immersed tunnels have been located in both freshwater and seawater, in hot and cold climates, in busy waterways, and in earthquake zones. Alignments do not need to be straight, so that the tunnels can be designed to suit design speeds, existing land use, topography, and connections to the existing road or rail system. The ideal alignment for an immersed tunnel may not coincide with the ideal alignment for a bridge. Soft ground is ideal for immersed tunnels, but if excavation into rock is required, the high cost of rock excavation under water could make other tunneling methods more cost-effective.

Immersed tunnels are not suitable for every situation. However, if there is water to cross or water can be used to float-in a precast structure, they usually present a feasible alternative to bored tunnels at a comparable or better price. A catalog of existing immersed tunnels is given in Ref. [1].

28.1.5.2 Floating Tunnels

As water depth increases, particularly if the waterway is narrow, tunnels may become excessively long when compared to the width of the crossing. Using shallow alignments, a new option has been developed in which the tunnel is exposed within the water column, resulting in much shorter

FIGURE 28.1 Lowering an immersed tunnel element into the excavated trench (© Parsons Brinckerhoff, Inc. 1967, with permission).

tunnels. Such tunnels are known as *floating* tunnels and appear to be viable using available technology; designs for several locations are well advanced, although none has yet been constructed. While very short *floating* tunnels might not need intermediate supports, longer nonbuoyant tunnels might be supported by columns up from the bed (like an underwater bridge) or suspended from pontoons on the surface. Conversely, anchors might hold down a permanently buoyant tunnel (similar to tension-leg oil platform technology). Further information on floating tunnels can be found in Ref. [1].

Although most immersed tunnels are built for water depths between 5 and 20 m, schemes have been postulated for depths up to 100 m. Such great depths could be avoided by using *floating* tunnel technology, though if submarines ply the waters, the risk of collision might preclude the use of a *floating* tunnel or at the very least will complicate the design.

28.1.6 Jacked Tunnels

Tunnel jacking is a specialized technique for constructing a concrete tunnel, typically rectangular, under surface areas that are being used for facilities considered critical to the degree that interrupting them

would result in serious impacts, not the least of which are significant costs. Examples of such critical surface facilities include operating railway tracks, major roadways, and airport runways. The technique is generally applied in soft ground for relatively short tunnel sections and shallow depth of cover. The method has been employed to construct tunnels of varying uses, including pedestrian passageways, flood control structures, and roadways.

The tunnel jacking method is costly and is not normally considered the preferred technique for constructing an underground crossing. Conventional mined tunneling would be the method of choice if the depth of cover were sufficient to limit the influence of excavation on the surface facilities to acceptable or manageable levels. For shallow tunnels where mined tunneling would be too risky, cut-and-cover methods would be preferred. However, when the costs of shutting down critical surface facilities completely or rerouting or relocating them or providing substitute services for them for the duration of the construction period are taken into account, tunnel jacking may become the most economical method.

28.2 Cut-and-Cover Tunnels

28.2.1 Introduction

For structural evaluation of cut-and-cover tunnel structures, a spectrum can be considered where cut-and-cover tunnels fall between immersed and bored tunnels. Immersed tunnels are largely made of prefabricated structural sections, and their structural analysis resembles the more traditional approach of loads applied to a structure; construction staging must be carefully considered as the tunnel is floated and immersed. Bored tunnels can be thought of as reinforced openings in a competent subgrade material; their structural analysis is usually not a problem of loads applied to a structure, but one of considering how the soil behaves once a gap is constructed and then lined. Analysis of cut-and-cover tunnels will typically consider both of the following features:

- Soil–structure interaction.
- The traditional approach of loads applied to a structural model.

Computer modeling is now able to handle sophisticated soil–structure interaction analysis of cut-and-cover tunnel construction. As the software becomes easier to use and more flexible, more sophisticated analyses of tunnel sections are being performed, as discussed in [Section 28.2.4](#).

An initial distinction can be made between tunnels for which support of excavation (SOE) walls are temporary and those for which cofferdam walls are incorporated into the final structure. In the past, construction walls such as sheet piling and lagging were “throw-away” temporary walls. More recently, however, some engineers have specified that the construction excavation walls be used as part of the final tunnel section. Examples include conventional concrete slurry walls, soldier pile tremie concrete walls, and tangent and secant pile walls. There are important differences in terms of construction issues between incorporating the excavation support or not, with the focus here being on structural analysis and design characteristics. [Figure 28.2](#) shows a schematic of the two different types of section.

When the SOE walls are temporary, the tunnel box is assumed to experience mostly final loading conditions. However, when the SOE walls are included as a part of the final structure, the design loading condition are much more time dependent. The designer will need to consider not just the final loading conditions but also all of the states of stress experienced by the cofferdam walls as they are constructed, braced or tied back, and finally connected to the tunnel as a whole. Many of these stresses are locked-in stresses to be superimposed on later conditions.

The evaluation of impacts on existing facilities is another complication for cut-and-cover tunnel analysis that is not as much of a concern for bored and immersed tunnels. Of the three tunnel types, cut-and-cover tunnels are the most likely to be built adjacent to existing buildings, utilities, and other facilities, so the nature of the tunneling process can lead to significant impacts on existing structures.

FIGURE 28.2 Typical sections for cut-and-cover tunnels.

28.2.2 Structural Analysis

Cut-and-cover tunnel sections are most often modeled as structural frames. In general, however, there are three ways to analyze cut-and-cover tunnel sections:

- *Traditional frame analysis.* A stick figure is drawn to represent the tunnel section. Soil–structure interaction is treated as an applied load to the frame.
- *Frame analysis with a more rigorous soil–structure interaction.* The soil is not just an applied load; its properties are modeled along with the tunnel. An example is treating the subgrade material as a series of springs, the “beam on elastic foundation” (BOEF) approach.
- *Finite element/finite difference analysis.* The continuous soil and the tunnel structural material together are modeled as a continuum.

Table 28.1 describes the attributes, advantages, and disadvantages of the three analysis approaches. Two-dimensional (2D) sectional analysis remains as good practice for most tunnel conditions, even though the most accurate tunnel model is 3D. Structural analysis of tunnels in three dimensions has been performed, but is very complex. A good case can also be made for the fact that a complex computer analysis exceeds the accuracy of its input for this type of design. Given the uncertainty about the way soil behaves, its inherent lack of homogeneity, and difficulties in modeling three-dimensional soil–structure interaction, the 3D structural analysis and design of cut-and-cover tunnels is reserved mostly for special analysis conditions, such as boxes with rigid end diaphragm walls for rail transit stations.

28.2.3 Methods of Framing

A difference between the tunnels with temporary support walls and those with permanent support walls as part of the final tunnel section is related to the framing model for the structure. When SOE walls are temporary, the tunnel section is almost always treated as a box with fixed joints. However, when rigid cofferdam walls become part of the final structure, it can become difficult to construct fixed connections in the field. Therefore, designers may specify partially fixed or shear connections at the roof to wall joints or base slab to wall joints. The number of different ways to model the tunnel frame increases in this case.

Considering the shape of the frame, most cut-and-cover tunnel sections are rectangular, unlike immersed and bored tunnels, which are often round or oval. A rectangular cross-section is the best-fitting shape for most uses of the tunnel, and it is the one requiring the least excavation for the relatively shallow cut-and-cover tunnel and has the simplest formwork. However, the box shape is also a less efficient structural system for carrying compression loading than circular bores. This structural inefficiency is often mitigated by inserting corner haunches (Figure 28.3).

TABLE 28.1 Cut-and-Cover Tunnel Structural Analysis Approches

Type of analysis	Description	Advantages	Disadvantages
“Traditional” analysis	Frame analysis model of tunnel section, with applied loads and assumed uniform support conditions	Used with good results for decades; comparatively easy to formulate	In some cases, can return conservative results, especially for complex tunnel section geometry
Frame analysis with soil–structure interaction	Similar to the traditional method, but the effect of soil is mathematically modeled as a series of springs; base slab springs use the beam on elastic foundation method; lateral springs can also be applied, partly in place of assumed soil loads	Better modeling representation of structure; takes advantage of more realistic base slab soil support to permit smaller slabs in design	Can be more complicated to model than the traditional method; soil springs are difficult to quantify based on soil test data
Finite element analysis	The section soil and structure are modeled as a grid of geometric elements; this category includes many different types of analyses, depending on the mathematical model assumed for the soil type. Structural elements are usually treated as linear elastic	Closest modeling representation to “reality”; better numerical resolution for conditions of difficult tunnel geometry and framing details	Usually complex to set up and run; results require careful interpretation; precision of analysis method can be many times better than the data that form the input, especially for soil model

FIGURE 28.3 Haunched section.

Most cut-and-cover tunnels are constructed from reinforced concrete. When using temporary SOE walls, the tunnel section is formed and cast within them, often with a layer of waterproofing completely enveloping the section. The construction procedure for the tunnel using the SOE walls as part of the structure will involve placement of keys in the cofferdam wall into which the roof and base slab can then frame. Another method is to cast an inside wall against the face of the SOE wall. In this case, the base and roof slabs are supported by the inside wall. The SOE wall may also be structurally connected by a composite design with the inside wall.

Concrete framing is usual, except for very deep or very wide tunnels that require excessively thick concrete slabs. In these cases, one structural type that has been used frequently is steel composite concrete construction. For the roof, a relatively thin concrete slab can be cast with a steel beam, compositely connected using shear studs. Wall members may be designed as steel columns without composite connections to the enveloping concrete, or composite action can be specified. The base slab is the least likely location these days for composite steel–concrete members, although some tunnel

structures are constructed with base, walls, and roof consisting of steel framing with concrete infill. Taking advantage of the comparatively thinner composite beams and columns in the roof and walls, designers raise the tunnel vertical profile and take advantage of its fit in the plan. However, space constraints are typically least severe on the underside where a concrete base slab helps to resist uplift through its additional weight.

28.2.4 Analysis in Section: Typical Frame and BOEF Methods of Analysis

Although there are many types of cut-and-cover tunnel sections, a typical section may have the following features:

- Construction and excavation via temporary, flexible SOE walls like soldier piles and lagging. A mud mat is constructed at the bottom of the excavation to facilitate casting of the base slab. For some types of soil, a geotextile fabric can be placed to help stabilize the excavation.
- Reinforced concrete base slab, roof slab, and walls.
- A layer of waterproofing beneath the base slab, on the outside surfaces of the walls, and above the roof slab. The waterproofing is protected by a layer of lean concrete before backfilling.

A typical structural analysis of this section would use a frame model. Different loadings would be calculated and applied to the model. Analysis would be performed using an indeterminate method like moment distribution or with the assistance of a frame analysis program like STAAD-III or STRUDL.

Based on the results of the analysis, the components of the cut-and-cover tunnel would be sized. Concrete slabs would be designed typically as bending members. There could be some amount of iteration to the process: the engineer, following sizing of the structure, may need to repeat the analysis using the new member sizes.

In the analysis, each member must be assigned initial trial analysis properties such as sectional moment of inertia and cross-sectional area. For a reinforced concrete tunnel, a 1-ft-long length of tunnel is typical for modeling, and the corresponding member properties are calculated based on the assumed structural depth. Similarly, material properties must be calculated and assigned to the members. For example, each member in the frame analysis must be given a modulus of elasticity and its material unit weight.

Assumptions for supports to the frame analysis model are typically handled in one of two ways (Figure 28.4):

- *Traditional frame analysis.* For the simple tunnel box shown, two imaginary support points are placed in the model. An upward distributed vertical pressure, usually uniform, is assumed to act upward below the base slab such that all vertical loads are balanced and the resulting reactions at the imaginary support points are zero.
- *BOEF method.* Spring supports are specified. The value of the spring constant is determined from consideration of the underlying strata and its modulus of subgrade reaction. As shown in Figure 28.4, this method results in a nonuniform base slab pressure, in contrast to the conventional design method of balancing the vertical loads. The resulting soil pressure depends on the width of the tunnel box and the relative stiffness of the soil. If the soil were infinitely stiff, all loads would be transferred to the soil directly beneath the walls of the box. If the soil behaved as a fluid, the load would be uniformly distributed below the base slab.

While much of the current process for cut-and-cover tunnel analysis is a refinement of tried and true methods that have been used for decades, computerized design has brought some new issues to the surface. One such concern is lateral load balancing. In the past, tunnels were analyzed structurally and designed by drawing a frame model, applying some assumed loads, performing frame analysis, and sizing the members. With the increased power of computer frame analysis comes realization of a curious problem: the frames tend to distort laterally.

Unless the assumed lateral loads are perfectly balanced and the frame geometry is perfectly symmetric, the frame models will tend to lean to one side. Studies that use hand calculations would show the same

FIGURE 28.4 Base slab pressure: traditional and beam on elastic foundation (BOEF) analysis.

results were engineers to have the ability to display the deformed shape of the tunnel model in a matter of seconds, as is done using computers.

In reality, the tunnel model would not sway. The “sway” side would be held back by a higher soil pressure than that assumed by the preliminary analysis. For frame models, the issue can be approached in two ways:

- *Add soil springs to wall members.* This is a complex treatment, because of difficulties in calculating properties for lateral springs and in calculating applied loads for the springs to react against.
- *Use lateral load balancing.* Lateral loads are estimated and additional, triangular “balancing” loads are applied to the sway side. The reasoning is that the sway side would be held back via passive pressure from the soil. The amount of passive pressure used in the analysis must be limited to ensure that the structure is not induced to sway in the opposite direction. While it is difficult to specify the resulting stress distribution exactly, a triangular loading approximation is reasonable.

Other conditions in the frame model that need to be considered, which differ from the “typical” section described earlier, include the following:

- *Use of haunches.* For the cast-in-place tunnel section, the designer may place haunches to reduce design spans and bending moments (Figure 28.3). This is an attempt to develop a tunnel shape more in compression, as achieved by a circular bore, and less in bending, which is a disadvantage of the straight, rectangular sections.
- *Integral, rigid SOE walls.* For this condition, a rigid, impervious SOE wall, such as a concrete slurry wall or an SPTC wall, is incorporated into the final structure. For the purpose of structural modeling, the designer has to deal with the added concerns of complex tunnel shapes, loadings on wall segments not directly a part of the box, complicated construction sequence loadings, and others.
- *Different material types and framing methods.* These can include steel composite concrete construction and prestressed concrete elements.

- *Different modeling methods.* All-concrete box tunnels are usually designed with moment connections at the joints. This is not difficult to detail and construct when the box is cast-in-place within temporary cofferdam walls. Other structural models may be more appropriate for some of the other tunnel types and construction methods.
- *Different construction staging approaches (top-down).* The order of construction will influence loading and assumptions. For example, in top-down construction, permanent support of excavation walls used as part of the final structure will be more heavily loaded vertically, because the roof is placed and loaded before the base slab is constructed. The base slab acts as a mat for supporting vertical loads, but it is not available until toward the end of construction of the section.
- *Framing of ducts.* In highway tunnels, ventilation supply ducts may be placed in the base slab, in the roof slab, or as side ducts adjacent to the walls. The ducts introduce additional framing conditions and considerations. For example, ducts formed as part of the base slab can be modeled as a type of Vierendeel truss in a stick frame model.

28.2.5 Loading

Cut-and-cover tunnel loads include the following (note that hydrostatic loads always act normal to the exterior surface of the tunnel):

- *Vertical loads, roof slab.* Soil pressure on the roof slab from backfill, own weight of the roof, a live load surcharge typically uniquely specified for each project, and water below the water table; often, a future air-rights development load.
- *Vertical loads, base slab.* Hydrostatic pressure (acts up), upward soil pressure to balance resultant weight of tunnel and all other imposed loads, own weight of base slab (acts down).
- *Lateral loads.* Hydrostatic pressure, effective soil pressure, lateral soil load due to surcharge loading, special loading conditions due to nearby foundations, and other underground conditions.

Vehicle loading (transit or highway) needs to be considered but may not contribute to the most severe tunnel loading case. The dominant loading direction on a tunnel base slab is up from hydrostatic pressure and soil pressure, so including the downward acting vehicle loads would reduce the overall loads on the base slab. Therefore, the controlling load case is often for an empty tunnel.

In congested urban areas, where many cut-and-cover tunnels are located, the tunnel design may need to consider temporary loads from underpinning existing structures and permanent loads from construction of future structures above the new tunnel. A good example of both concerns is the tunnel design for Boston's Central Artery. The depressed artery is constructed directly beneath the original overhead viaduct, so bridge loads from underpinning of the elevated expressway needed to be included in the tunnel design. In addition, once construction is complete, acres of developable land in downtown Boston will become available, so the tunnel design had to incorporate provisions for future building loads directly on the tunnel boxes.

28.2.6 Finite Element Analysis

The preceding discussion focused on the use of frame models for structural analysis of cut-and-cover tunnel sections. As introduced in [Section 28.2.2](#), frame models with load balancing and frame models with soil–structure interaction assumptions represent the first two of the three analysis methods. These are the traditional approaches for this type of design and have been used since before the advent of computers. However, ways in which frame models form an inaccurate representation of the analysis problem include the following:

- Frame models feature line elements, but in reality, elements of the tunnel section have thickness. For example, base slabs with air vents are thick and massive, and the line elements of the frame are a coarse representation of the structure. Steps can be taken to modify the frame models to account for the mass of the tunnel.

- Frame models treat the surrounding soil as an equivalent applied load. In reality, the soil and structure behave together in a complex soil–structure interaction. Assumed soil loads, used for decades in tunnel design, constitute a conservative but imprecise representation of the analysis problem.

Another concern is the issue of construction staging. Underground structures experience several different states of stress. These are time dependent and depend on the methods of excavation and stabilizing the sides and on the order in which the tunnel components are installed.

For the purposes of this discussion, the finite element method and the finite difference method will be considered the same. Although they differ mathematically, the general approach of the two is similar. They are both used to model cut-and-cover tunnel analysis by modeling the continuous soil as discrete space and having the computer calculate most applied loads by assumptions about staging, soil properties, and boundary conditions.

In general, the finite element method is an analytical tool for solving partial differential equations by first making the equations discrete in the solution domain. The solution domain refers to the physical definition of a problem. For a cut-and-cover tunnel section, the solution domain includes the structural elements of the tunnel, the backfill, the soil behind the walls, and soil beneath the excavation. Transforming the solution domain into discrete elements is done by dividing it into small regions of simple but arbitrary shape — the finite elements. The locations of elements are defined using nodal points (nodes). To solve the equations over the entire domain, the equations for the finite elements are summed, resulting in global matrix equations. The finite element method is usually performed by computer because of the large number of equations and difficulties in incorporating boundary conditions.

A finite element solution can be run for each construction stage. The output from the previous stage — one line of data for each node and element plus loading and material property data — is used as the input for the subsequent stage. Initial conditions are established by applying self-weight. The soil (finite elements) is then excavated (elements removed), and supports are installed for each stage.

The finite element analysis loads the structural model based on the input soil properties and constitutive relationships. Unlike the traditional approach, no assumed applied soil loads are calculated. Although frame models have been used for cut-and-cover tunnel sections traditionally, finite element analysis provides a more rigorous analysis of the problem. A few words of caution are in order, however

- Available information for soil–structure interaction problems will often be less sophisticated than for the analysis model. The finite element study assumes that the soil mass behaves in an elastic or other mathematically quantifiable way. The interpreted soil layer itself, based on investigations that can only approximate actual conditions in place, is taken as a group of homogenous layers. At best, a computer model may need to include certain simplifying assumptions about soil behavior. To complicate matters further, the stress–strain relationship at the soil–structure interface is highly indeterminate, time dependent, and not well understood. Research has focused on ways to extrapolate laboratory conditions to mathematical models, but it is difficult to quantify conditions such as a tunnel wall against several different soil layers.
- In reality, a model with better accuracy would include 3D geometry and loading. However, whatever uncertainties are present for 2D finite element studies are magnified for 3D work.
- Soil–structure finite element analysis is invariably more complicated and time-consuming than frame analysis. Interpretation of results requires much greater care. A highly automated approach can be difficult to run for this type of analysis because the results need to be carefully inspected. Fortunately, software and interpretation methods continue to improve with time.
- While the behavior of the soil mass is very sensitive to the way it is modeled, the ultimate design of the tunnel structure is not. Discounting a few exceptions, the finite element and frame modeling will result in a tunnel design of about the same structural dimensions. Differences that are more significant will be apparent in the calculation of temporary support of excavation structures like struts and tiebacks and the estimation of soil movement in a temporary construction.

Overall, frame analysis of cut-and-cover tunnels is still a viable, appropriate design tool. A suggested approach for structural analysis and design of cut-and-cover tunnels is as follows:

- Prepare sections, taken at a suitable interval, and run frame analysis and design. The frame can be modified to reflect conditions like special structural framing, vents, cofferdam walls incorporated in the final structure, and other features.
- Run a few soil–structure interaction computer analyses for the study of special problems. These can include construction staging, stress analysis of thick, vented members, predictions of soil movement during excavation, estimates of the effects of lateral cross walls (e.g., in subway stations), and other problems where the improved resolution of the finite elements outweighs the increased effort in their application.
- Check the results against frame analysis for a “reality check” of the finite element runs.
- Prepare a few computer frame analyses to study longitudinal conditions. While analysis in section largely governs the tunnel design, special longitudinal conditions should be studied as well. These can include framing of transverse ducts to vent buildings, lateral diaphragm walls at the ends of transit stations, and modeling of changes in foundation material in the longitudinal direction.

28.2.7 Buoyancy

In areas with a high water table, buoyancy will be a concern. The weight of soil taken out for the cut-and-cover tunnel can be less than the weight of the tunnel structure. In addition to the procedures above, buoyancy calculations involve a stability analysis. For the final condition, the weight of the tunnel section must be greater than the upward net hydrostatic pressure. It is conservative not to take advantage of the side friction acting on the tunnel walls, although in certain cases if construction methods and the undisturbed soil are considered, it might be acceptable to use side friction in the calculations. For tunnel sections where the excavation support wall is used as the final structure, the weight of the full wall above and below the tunnel section may be used to resist buoyancy.

Calculations for buoyancy must be done for temporary construction stages as well as for the final condition. The calculations must be consistent with the specified requirements for dewatering for each stage of the excavation and construction.

28.2.8 Evaluation of Construction Impact and Mitigation

An important issue for cut-and-cover tunnel analysis and design is the evaluation and mitigation of construction impacts. By the nature of the methods used, cut-and-cover construction can be more disruptive than bored tunnels. It is important for structural engineers to be familiar with the analytical aspects of evaluating soil movement and the impacts it can have on existing buildings and utilities at the construction site. Soil movement can be due to

- *Inward movement of excavation support walls.* Walls will deflect into cut-and-cover excavation prior to installation of each level of struts or tiebacks supporting the wall. The movement is not recoverable. At each level of excavation support, a certain amount of inward movement will have been recorded, and this is the starting deflection for the next stage of excavation. Therefore, whether using a frame model with assumed applied loads or a finite element analysis, the analysis is nonlinear.
- *Consolidation due to dewatering.* In excavations where the water table is high, it is often necessary to dewater inside to avoid instability. Dewatering inside the cut leads to a drop in the hydrostatic pressure outside the cut. Depending on the soil strata, this can lead to consolidation.

Existing buildings and facilities must be evaluated for estimated soil movement during excavation. This evaluation depends on the type of existing structure, its distance and orientation from the excavation, and other parameters. The analysis is site-specific, and it can be very complex. Empirical

methods and screening tools are available to characterize impacts more generally. These approaches are a good way to get analytically a handle on this complex problem.

Many tools are available to mitigate, measure, and control adverse impacts from soil movement, including

- Design of stiffer and watertight excavation support walls.
- More closely spaced and stiffer excavation support braces and tiebacks.
- Pre-excavation soil improvement.
- Specification of limiting values for allowable movements of excavation support walls, soil profiles, and allowable impacts of depressing the water table during construction.
- Measurement of these impacts by a program of geotechnical and structural instrumentation during excavation.
- Requirement for mitigation plans to react to situations where movement measurements approach allowable limits.

28.3 Tunnel Linings for Bored and Mined Tunnels

This section describes basic principles for the selection and design of lining systems for bored and mined tunnels. For a greater overview of these principles, see Kuesel [3]. For detailed application in the realm of tunnels in hard ground, see U.S. Army Corps of Engineers Manual *Tunnels and Shafts in Rock* [4].

28.3.1 Introduction

The design of bored and mined tunnels differs in principle from the design of most other types of structures. Two important aspects largely govern the design of these tunnels:

- More than for other structures, the design details of the tunnel structure, often even its basic shape, depend on the method and details of construction.
- The principal load-carrying component of the tunnel structure is the soil or the rock mass surrounding the tunnel opening, and the structural lining serves largely to maintain the integrity of the surrounding ground mass.

For these reasons, the method of construction of a bored or mined tunnel must be established before its design can be contemplated, and the design must include analyses or assumptions concerning the interaction between the tunnel lining and the ground.

Principles and details of tunnel linings depend very much on the functional requirements of the finished structure. The lining concept can vary from an unlined and leaky tunnel in rock, supported only by occasional initial ground support such as rock bolts, to a full concrete or steel lining designed to carry the entire rock and groundwater load and to be watertight. The lining concept may be no lining, one-pass lining, or two-pass lining. The lining concept is selected based on the following basic criteria:

- Functional requirements.
- Ground conditions.
- Constructibility.
- Economy.

One of the most important decisions in the development of the lining concept is what to do with the groundwater, both during construction and in the permanent structure.

Highway tunnels and most railway tunnels today are designed to eliminate water inflow through the crown and sidewalls of the tunnels. If the tunnels are above the groundwater table, making the top of the tunnel watertight prevents infiltration of occasional seepage water. If the groundwater is not far above the tunnel, this method will still work, provided adequate drainage is placed outside the waterproofing and through pipes in the tunnel invert. This is a so-called drained tunnel. If the groundwater table is high above the tunnel and the ground is very pervious, then a drained tunnel is not feasible, and

the tunnel must be waterproofed all around, and the lining must be designed for the full groundwater pressure.

Tunnels conveying water for power, irrigation, drainage, or other purposes may be pressurized structures or operated with open-channel flow. These tunnels must be designed for the highest operating and transient internal pressures, compatible with the hydraulic grade-line and the hydraulic controls, in addition to the external loads. Air relief must be provided as required. The tunnel finish must match the roughness (Manning's coefficient) assumed for the hydraulic analyses.

For the design of pressurized tunnels, the external load and the strength of the surrounding rock mass may be considered if the rock is competent, but often the lining must be designed for the full internal pressure. When the internal water pressure is relatively low, less than 100 to 150 psi, it is possible to design steel reinforcement in the concrete lining to accept the hoop tension. With higher pressures, it is usually necessary to use a steel lining. For the design of pressurized tunnels, see the penstock literature or, for example, the U.S. Army Corps of Engineers Manual, *Tunnels and Shafts in Rock* [4].

When the groundwater is aggressive or contains chemicals that cannot be permitted to flow into the potable water in a water supply tunnel, the tunnel should be made watertight. Some groundwater contains chemicals that will clog up drainage facilities. Under those conditions, the drainage paths must be serviceable or the tunnel made watertight. Sewage tunnels with open-channel flow in warm climates will typically require protection against corrosion resulting from generation of hydrogen sulfide. Frequently this protection takes the form of an internal polyvinyl chloride (PVC) or high-density polyethylene (HDPE) membrane cast into the internal tunnel lining.

Another important functional requirement deals with the tolerance of the installation of the tunnel facility. A pressurized-water tunnel can tolerate a wide placement tolerance in all directions without serious impairment of function. A tunnel with gravity flow must satisfy the vertical flow requirement but can tolerate wide horizontal tolerances. The interior of traffic tunnels (rail as well as highway or street) must meet the civil requirements of the guideway and the dynamic envelope of the vehicles.

Setting a concrete form precisely within an excavated tunnel or cavern is usually much easier than producing a precise excavation in the first place. Therefore, a wide tolerance can be applied to the initial excavation and still permit proper placement of the concrete. On the other hand, the one-pass lining is also the final lining and must be built precisely. One-pass linings are often designed with several inches of additional construction tolerance just to make sure the finished structure meets the functional requirements.

28.3.2 Mechanized Tunneling through Soil

Modern tunnel excavation through soil is usually done with a shield, most often a mechanized shield. A shield is usually a circular steel cylinder furnished with a cutting edge. The shield is jacked through the soil as soil is excavated at the face, with the soil being removed through the back. A tunnel lining is erected as the shield advances, against which the propulsion jacks of the shield push. The shield provides the initial ground support. A fully mechanized shield is much like a factory, producing a tunnel in the fashion of an assembly line. Details of the mechanized shield are selected primarily to meet expected ground and groundwater conditions.

28.3.2.1 Dry Soil

In dry ground above the groundwater table, it is usually possible to excavate with an open face or with partial face support. Hand tools or, more commonly, large hydraulic scrapers or hoes are used to loosen the soil and scoop it onto a conveyor belt for loading into muck cars.

If the ground is firm, an initial lining consisting of steel ribs and timber lagging, or unbolted concrete segments, may be expanded against the soil behind the advancing shield tail. On the other hand, a cohesionless sand or silt material will tend to collapse behind the shield tail, and it may be necessary to erect the initial lining inside the shield tail. In this case, the lining will usually be erected and bolted

together to a diameter smaller than the diameter cut by the shield, and the resulting tail void will need to be filled, often with pea gravel and grout.

28.3.2.2 Wet Soil

In soft clay, the ground will tend to be overstressed in the face of an open shield, and ground movements can be unacceptably large. Thus, continuous support is required. This is also the case in most soils below the groundwater table. Without continuous support, the ground will tend to flow uncontrollably into the shield, driven by the seepage forces in the ground. In these cases, a shield with face pressure control is often used today. The front end of the shield is sealed off with a sturdy bulkhead, and sufficient pressure is maintained in the front to keep the soil and the groundwater stable. There are two types of face-pressure shields:

- Slurry tunnel boring machine (slurry TBM).
- Earth-pressure-balance (EPB) TBM.

28.3.2.2.1 Slurry TBM

With a slurry TBM, the sealed front compartment is filled with clay slurry, usually a bentonite slurry, pressurized to balance the groundwater pressure plus at least the active earth pressure acting in front of the face. The pressure is maintained constant either through delicate flow controls or through a compressed-air buffer chamber. The earth is loosened by a rotary cutterhead and kept in suspension in the slurry. The muck-laden slurry is pumped to the ground surface, where the muck is separated and the slurry reconditioned before returning to the tunnel face.

In recent years, the slurry TBM has lost much of its market in favor of the EPB TBM, which does not require an expensive slurry separation and treatment plant. However, the required rotary torque for a large-diameter EPB cutterhead becomes excessive, and all machines over 10 m in diameter to date have been slurry TBMs. The slurry TBM also offers advantages of better face control, in particular in mixed-face and bouldery ground. It also offers the opportunity to place a boulder-crushing unit at the bottom of the face to reduce large boulders to manageable sizes. Figure 28.5 shows a typical slurry TBM.

FIGURE 28.5 Schematic of slurry TBM (courtesy of Parsons Brinckerhoff, Inc.).

28.3.2.2.2 EPB TBM

With the EPB TBM, the front compartment is kept full of soil under sufficient pressure to maintain the stability of the face and minimize ground movement ahead of the face. The soil excavated by the rotary cutterhead is removed from the bottom of the compartment through one or two screw conveyors in series, discharging onto a conveyor belt or directly into muck cars. Groundwater is prevented from flashing through the screw conveyor system by foam, sometimes supplemented by a polymer, or clay slurry added to the soil in the front compartment. The additives must provide sufficient cohesion to counter the groundwater pressure along the length of the screw conveyor. The additives also help lubricate the soil mass, reduce the required torque for turning the cutterhead, and reduce wear on the components.

28.3.3 Linings for Tunnels in Soil

28.3.3.1 One-Pass Lining

Both types of face-pressure TBMs usually require the installation of a bolted, gasketed tunnel lining usually made of concrete segments. In the past, cast iron and fabricated steel segments have been popular but are now much too expensive except in special circumstances. The lining must be installed under the protection of the shield tail, and the tail void must be filled. To prevent excessive movement of soft or loose soil into the tail void, it is usually necessary to fill the tail void as the shield advances and keep the tail void under pressure equal to the ground and groundwater pressure.

After the installation of the segmental lining in the tail of the shield, usually, no additional internal lining is required. This type of lining is usually required when the ground conditions are sufficiently poor to require a face-pressure TBM. The one-pass lining must be fabricated and erected with great precision since once in place, misalignment can be fixed only with great difficulty. The one-pass lining must be designed for all transport and construction loads, including the forces from the shield propulsion jacks. Its adequacy to resist ground loads must also be checked.

28.3.3.2 Two-Pass Lining

When an initial lining can be installed behind the tail of the shield, the advance rate of tunnel excavation is usually much faster and the cost of tunneling cheaper, even if a second lining must be placed inside. The initial lining may be steel ribs with lagging or unbolted concrete segments, just adequate to permit installation of the final lining. The final lining is cast-in-place concrete with one, sometimes two, layer of reinforcement. A waterproofing membrane is usually installed before placing the internal concrete. With a two-pass lining, the initial lining is often considered part of the permanent structure, participating in carrying the loads; however, the inside final lining usually must be designed at least for the groundwater pressure.

28.3.4 Bored Tunnels in Rock

28.3.4.1 Hard-Rock TBM

Long tunnels in rock are now mostly excavated using hard-rock TBMs, which excavate a tunnel of circular cross-section. The rotary cutterhead of a hard-rock TBM is fitted with disk-shaped rock cutters that roll over the face of the tunnel under great thrust, breaking the rock into slivers and advancing the tunnel by a fraction of an inch per rotation, up to tens of feet per hour. In excellent rock with few discontinuities, no immediate ground support is required. More commonly, the rock mass is fractured, and initial ground support in the form of rock bolts or dowels, or even steel sets or lattice girder support, is required.

Propulsion of the advancing TBM, as well as the thrust required for breaking the rock, is usually derived from large pads jacked firmly against the sides of the tunnel. Every 4 to 6 ft or so, the jacks are retracted from the walls, advanced forward toward the face, and re-engaged against the sidewall.

In poor rock, or even in good rock where other parts of the tunnel are advanced through soil-like materials, the TBM may be outfitted with a shield much like a soil TBM. A one-pass or two-pass lining system can be erected in the tail of the shield, as in a soil tunnel. Figure 28.6 shows the cutterhead of a hard-rock TBM, holing through.

28.3.4.2 Roadheader

Another type of rock excavator is the roadheader, which is a smaller excavator or ripper mounted on a slewing and elevating arm. The excavator is equipped with ripper or point-attack teeth that rotate around the axis of the arm or around an axis at right angles with the arm. The roadheader cannot excavate as strong a rock mass as the hard-rock TBM, but it is able to excavate a rectangular or horseshoe-shaped opening. Figure 28.7 shows a typical roadheader.

FIGURE 28.6 Rock TBM holing through (© David Sailors 1988, with permission).

FIGURE 28.7 Roadheader with double rotating cutterhead and gathering apron (© Sandvik 2000, with permission).

28.3.5 Sequential Excavation and Support for Rock Tunnels

Shorter tunnels in rock, and rock tunnels of large cross-sections, are sometimes excavated by roadheader, if the rock is soft enough, but more often by blasting. Blasting is a cyclic operation, which typically includes the following activities in sequence:

- Drilling blast holes in a predesigned pattern and loading them with blasting agents.
- Setting off the blast using millisecond delays so that there is a series of closely timed blasts (reduces vibrations and facilitates the blasting process).
- Removing the loosened rock, loading it into trucks or rail cars, and bringing it out.
- Scaling loosened rock from the crown and the side walls.
- Installing initial ground support, rock bolts, shotcrete, steel ribs, or other components as required.
- Repeating the cycle.

With small cross-sections in good rock, the full face can be blasted at one time. Often a top heading is excavated first, followed by excavation of the bench. In very poor rock, it may be necessary to excavate and support multiple headings.

The final lining is usually made of reinforced concrete cast in place. Below the groundwater table, a waterproofing membrane is placed to cover the initial ground support before placing the cast-in-place lining. As discussed earlier, the tunnel lining may be designed to be undrained, with the final lining accepting the full groundwater pressure. Alternatively, drainage may be provided outside the waterproofing membrane, in which case the final lining may be designed for only a portion of the full groundwater pressure.

28.3.6 Selection of Lining System in a Rock Tunnel

For most transportation tunnels, a substantial final lining is installed. For many tunnels, however, there is a wide selection of tunnel ground support. In some cases, a different ground support system will be selected for different parts of the tunnel depending on geologic conditions and local variations in construction methodology. For example, a steel lining may be required for a portion of a pressure tunnel with high pressure and poor rock, while other parts may require no lining at all. A watertight tunnel may be required through a permeable shattered-rock zone, or through seams of gypsum or anhydrite, which may expand or deteriorate, but it may not be required elsewhere. If a TBM and a substantial initial lining are required in part of the tunnel and if the lining is used to provide part of the reaction for the TBM propulsion, then a contractor may choose to line the entire tunnel even if a lining is not required everywhere for ground support.

28.3.6.1 Unlined Tunnel

In an unlined water tunnel, the water has direct access to the rock, and leakage will occur into and out of the tunnel. Changes in pressure can cause fluctuations and flows in and out of fissures, washing out fines and eventually lead to instability. For an unlined tunnel to be feasible, the rock must be inert to water, free of significant filled joints and faults, able to withstand the internal pressure in the tunnel without hydraulic fracture, and sufficiently tight so that leakage rates are acceptable. Unlined tunnels should be furnished with an invert pavement to provide a suitable surface for vehicles and help to control erosion. Norwegian hydropower tunnels in good crystalline rock are often unlined for most of their length.

28.3.6.2 Shotcrete Lining

A shotcrete lining will provide ground support and may improve leakage and hydraulic characteristics of the tunnel. It also protects the rock against erosion and the deleterious effects of water. To protect water-sensitive ground, the shotcrete should be continuous and crack free and reinforced with wire fabric or fibers. As with unlined tunnels, shotcrete-lined tunnels should be furnished with an invert pavement to provide a suitable surface for vehicles and help control erosion.

28.3.6.3 Unreinforced Concrete Lining

An unreinforced concrete lining is placed to protect the rock and provide a smooth interior surface. Most shafts and tunnels that are not subject to internal pressure are lined with unreinforced concrete. This type of tunnel or shaft lining is acceptable if the rock is in equilibrium before concrete placement, and loads are expected to be uniform and radial. Shrinkage and temperature cracks are expected to occur and can cause leakage. If the groundwater is corrosive to concrete, a tighter lining may be required to prevent corrosion by the seepage water. An unreinforced lining is generally not acceptable through soil overburden or through badly squeezing ground, which can exert nonuniform displacement loads.

The obvious attraction of the unreinforced lining is the substantially lower expense of the lining when no reinforcing steel cage is needed, even if a waterproofing membrane might be set or fibers used to minimize cracks. A considerable amount of information on the use of plain concrete in tunnels is available in the AFTES (French Tunneling Association) *Recommendations in Respect of the Use of Plain Concrete in Tunnels* (AFTES c/o SNCF, 17 Rue d'Amsterdam, F75008 Paris, France) [5].

28.3.6.4 Reinforced Concrete Lining

The reinforcement in linings with only one layer of steel should preferably be placed close to the inside face to resist temperature stresses and shrinkage. Depending on the moment distribution calculated in the lining based on exterior loads, the single steel layer may move from inside to middle to outside around the ring. A lining of this type can remain undamaged at distortions of 0.5% or more, measured as relative diameter change, and can remain functional even at greater distortions.

Multiple layers of reinforcement may be required due to large internal pressures or in a squeezing or swelling ground to resist potential nonuniform distortions. Nonuniform pressures requiring a second layer of steel can also occur through faults and shear zones, near the ground surface, and at connections to adjacent structures.

28.3.6.5 Pipe in Tunnel

This method is often used in water and sewer tunnels up to a size of pipe manageable on the job or on the road, the maximum usually about 14 ft (4.2 m) in diameter. The tunnel is driven and provided with initial ground support, and a steel or concrete pipe is installed. The concrete pipe may be a standard pipe or prestressed pipe with steel core. The pipe may be furnished with interior corrosion protection made of PVC or HDPE to resist sulfuric acids generated by hydrogen sulfide in an anaerobic condition. Plastic pipes as well as glass-reinforced plastic or plastic mortar pipes have also been used.

After placing the pipe, aligning it, and securing it against flotation, the void between the pipe and the rock is filled with flowable mass concrete or, more economically, cellular concrete.

28.3.6.6 Steel Lining

Where the internal pressure in the tunnel exceeds the external (confining) ground and groundwater pressure, a steel lining is usually required to prevent hydro-jacking of the rock mass. With only steel reinforcement (two layers), the ability of the tunnel lining to withstand internal pressure is limited. The guideline concerning confinement is that the weight of the rock mass above the tunnel must exceed the internal operating water pressure, with a suitable safety factor, usually 1.2. This is generally conservative with a level ground surface but not for tunnels running in a valley wall, where the side cover may be smaller. Here, more precise *in situ* stress analyses must be made or *in situ* stress tests performed.

In addition to the interior pressure, the steel lining must also be designed for the exterior pressure. Assuming that pipe leakage occurs over the long-term, the external water pressure is often assumed equal to the interior pressure. The critical design condition is buckling, and external stiffeners are often required. Methods of analyses of both internal and external water pressures for tunnels and shafts are found in the U.S. Army Corps of Engineers Manual, *Tunnels and Shafts in Rock* [4].

28.3.6.7 Concrete Segmental Lining

The one-pass concrete segmental lining is usually used for lining of shield or TBM-driven tunnels through soil. Where portions of a tunnel are in soil and others in rock, it may be convenient to build the entire length of tunnel using concrete segmental lining. Particulars on the design of concrete segmental linings are found in [Section 28.3.8](#).

28.3.7 Structural Design of Permanent Concrete Linings in Rock

28.3.7.1 Rock–Lining Interaction

The most important material for the stability of a tunnel in rock is the rock mass, which accepts most or all of the distress associated with the excavation of the rock opening by redistributing stresses around the opening. The initial ground support and the final lining often serve primarily a confining function, in addition to providing the appropriate interior finish. A lining placed in a rock opening that has reached stability will experience no stresses other than self-weight and internal loads. On the other hand, a lining placed inside an opening that has experienced, say, 70% of its elastic (or elasto-plastic) latent displacement will experience stresses from the release of the remaining 30% of displacement. The actual stresses and distortions will depend on the modulus of the lining and of the rock mass. If the rock modulus or the *in situ* stresses are anisotropic, then the lining will distort as a complex equilibrium is sought.

External loads on a tunnel lining may be following or nonfollowing loads. Typical following loads are the contributions from groundwater pressure, which are independent of the displacement of the lining resulting from the loading. Other types of following loads come from squeezing or swelling ground, where only very large distortions may reduce the load intensity. The typical soil or rock load, however, is to a large measure nonfollowing. As the crown of the tunnel lining yields away from high loads at the top, the loads are relaxed. At the same time, the lining distortion will expand the horizontal diameter of the tunnel, increasing reaction loads on the sides, thus rendering the lining loads more nearly uniform.

28.3.7.2 Cracking of Linings

With nonuniform loads or distortions, moments will occur both in circular and noncircular tunnel linings. Thus, tension cracks can form, the extent of which depends on the combinations of moments and thrusts. Tension cracks in a tunnel lining usually do not form a failure mode. There is usually a compressive component so that a tension crack does not penetrate through the entire section. In fact, separated blocks in compression form a stable arch. Without through-going cracks, water tightness also is not significantly impaired. Calculated extension cracks at the exterior of the lining, facing the rock, may be fictitious because the rock outside the lining is usually in compression and shear bond between lining and rock will prevent a tension crack from actually opening.

As a rule of design, the calculated crack length is usually permitted to reach half the section thickness, whether the lining is reinforced or not. Depending on the end-use requirements of the tunnel, this can be relaxed.

Cracking will also occur in linings due to shrinkage during curing, temperature variations, and the like. Because a blasted rock surface is uneven and the lining thickness, therefore, variable, such cracks can vary in dimension and location and often are concentrated into a few large cracks at the locations of the lesser thicknesses rather than many small cracks. If steel ribs are used for initial ground support, cracks will occur typically at the locations of the ribs. Incorporation of expansion joints is usually not effective in controlling these types of cracks because the concrete is bonded firmly to the irregular face of the rock and initial ground support.

These types of shrinkage cracks may go through the entire cross-section and may be undesirable. To control them, reinforcing steel is often placed close to the interior surface up to a percentage of 0.28 (up to 0.40% in a corrosive environment) of the maximum concrete section thickness. Alternatively, polypropylene, olefin, or steel fibers have been used with success. Construction joints between concrete pours are appropriately furnished with waterstops.

28.3.7.3 Lining Loads for Design

It would be misleading to present an exhaustive treatment of the subject of lining loads for tunnels in rock in this brief treatise. The design loads on the final lining will vary with the rock quality as well as the proportion of the rock load assumed to be carried by the initial ground support (if any). They will also include the external water pressure, if the tunnel is watertight, or at least a part of the external water pressure if the tunnel is drained. Additional nonuniform loads can be derived from squeezing layers of rock and from irregularities in the excavated surfaces. Different assumptions are usually made for circular and noncircular tunnels and for tunnels driven by TBM as opposed to tunnels excavated by blasting, which tends to disturb the rock and add loads.

Guidance to estimate the design rock loads can be found in the rock mechanics literature and in publications such as the U.S. Army Corps of Engineers Manual cited previously. Experienced geologists and rock tunnel engineers should be consulted when establishing these design loads. Conditions in the field should be observed to verify the estimated loads.

28.3.7.4 Methods of Analysis

Closed-form solutions are available for the simple conditions of a circular elastic tunnel lining embedded in a homogenous elastic ground, where the induced stresses are the assumed *in situ* stresses in the ground. The closed-form solution presented in the following is based on the following simplifying assumptions:

- Plain strain, elastic radial lining pressures are equal to *in situ* stresses, or a proportion thereof.
- It includes tangential bond between lining and ground.
- Lining distortion and compression are resisted or relieved by ground reactions.
- Vertical and lateral *in situ* soil or rock stresses are σ_v and $K_0\sigma_v$.
- Modulus and Poisson's ratio of the soil or rock mass are E_r and ν_r , respectively.
- Concrete lining modulus, moment of inertia, and area are E_c , I , and A , respectively, and mean radius is R .

Maximum and minimum bending moments can be determined by the following equation:

$$M = \pm \frac{\sigma_v(1 - K_0)R^2}{4 + (3 - 2\nu_r)/[3(1 + \nu_r)(3 - 4\nu_r)](E_rR^3/E_cI)} \quad (28.1a)$$

Maximum or minimum hoop force can be determined by the following equation:

$$N = \frac{\sigma_v(1 + K_0)R}{2 + (1 - K_0)2(1 - \nu_r)/[(1 - 2\nu_r)(1 + \nu_r)](E_rR/E_cA)} \pm \frac{\sigma_v(1 - K_0)R}{2 + 4\nu_rE_rR^3/[(3 - 4\nu_r)(12(1 + \nu_r)E_cI + E_rR^3)]} \quad (28.1b)$$

Maximum or minimum radial displacement equation:

$$\frac{u}{R} = \frac{\sigma_v(1 + K_0)R^3}{[2/(1 + \nu_r)]E_rR^3 + 2E_cAR^2 + 2E_cI} \pm \frac{\sigma_v(1 - K_0)R^3}{(3 - 2\nu_r)/[(1 + \nu_r)(3 - 4\nu_r)]E_rR^3 + 12E_cI} \quad (28.1c)$$

These simplifying assumptions are hardly ever met in real life and presume essentially the lining "wished in place" into the ground. Nonetheless, the equations are useful in examining the effects of variations of important parameters. The maximum moment is controlled by the flexibility ratio:

$$\alpha = \frac{E_rR^3}{E_cI} \quad (28.2)$$

For a large value of the flexibility ratio (large rock mass modulus), the moment becomes very small. Conversely, for a small value (very rigid lining), the moment is large. If the rock mass modulus

is zero, the rock does not restrain the movement of the lining, and the maximum moment in the lining is

$$M = 0.25 \sigma_v (1 - K_0) R^2 \quad (28.3)$$

With $K_0 = 1$ (uniform stress field) the moment is zero and with $K_0 = 0$ (simple vertical loading of vertical ring) the moment is maximum.

More commonly, structural finite element programs are used for analysis, where the lining ring is modeled as beam elements and the ground as springs representing the modulus of the ground. From these analyses the sectional forces, moment, thrust, and shear are deduced. The structural analysis offers little difficulty, but the loading assumptions and the elastic constants assumed are dependent on both the nature of the ground and the method of construction.

Continuum analyses using finite element or finite difference methods, where the ground is represented by a grid of elements, can analyze more accurately the variations in the ground stratification as well as steps in the construction process. Thrusts and moments in the lining elements can be derived directly.

The concrete cross-section is designed for the moment and thrust using the standard moment thrust or capacity interaction diagram, described in concrete design texts. The typical analyses may be modified to fit just one layer or reinforcement, fiber reinforcement, or none at all. Sometimes a larger theoretical zone of tension in the concrete section may be accepted than strictly according to code.

28.3.8 Design of Segmental Concrete Linings

28.3.8.1 Components of the Lining

The number of segments in a lining ring is decided as a compromise. A small number of segments will give the contractor fewer pieces to handle, for quicker erection, and a smaller number of segment forms. On the other hand, fewer segments are heavier and more difficult to handle. With a wide-open shield, as few as three segments per ring can be handled, but this is rare. More typically, there are five to eight segments per ring, sometimes more for a very large tunnel. The last segment placed is usually wedge-shaped for ease of insertion. Each ring is between 1 and 1.5 m wide, matching the stroke of the shield propulsion jacks, with the narrower rings better suited for tunnels with short-radius curves. Segment rings for curved tunnels are tapered (with ring widths on one side of the tunnel slightly wider than on the other) to allow placement as secants to the curve of the tunnel. Segment joints are usually staggered from ring to ring to provide greater rigidity and redundancy. [Figure 28.8](#) shows the installation of a one-pass liner ring.

The most important parts of the lining are the joints. A one-pass lining must be firmly fixed in a circular form. This usually requires bolts to be installed between rings and between segments in a ring. Sometimes dowels are used between rings. Joints in a one-pass lining must also usually be made watertight, which is usually accomplished by installing a recessed rubber or neoprene gasket around each segment.

The rubber gasket is vulcanized and made to fit the segment precisely. The two opposing gaskets in the joint will be compressed sufficiently so that water leakage through the joint is prevented. The gasket recess and the size and geometry of the gasket are designed to meet the leakage requirements, even if the segments are joined out of tolerance. Laboratory testing of gaskets in adverse installation configuration is often performed.

Another type of gasket is the hydro-swelling gasket, made with rubber and bentonite or similar materials. When exposed to seepage water this gasket will swell three to ten times and fill the available space for a watertight fit. Some important linings are fitted with a hydro-swelling gasket toward the exterior and a rubber gasket toward the interior.

Several types of bolt systems are employed. The most common type consists of straight bolts and nuts with washers and grommets, requiring bolt holes and pockets cast into the segment for their insertion. Curved bolts are easier to install and require smaller bolt pockets. More common today are the straight

FIGURE 28.8 Installation of one-pass liner (© Bernie Martin, with permission).

bolts installed at an angle into an insert cast into the segment. Some designers assume that bolts are for erection only and do not require to be considered for the permanent structure, except at transitions and other critical locations. Some contractors will retrieve most of the bolts after reuse once the lining is in place and the surrounding grout fully cured.

28.3.8.2 Design Conditions

The segments must be analyzed and designed for both the ultimate functional design and the lifetime criteria. They must also withstand all other events during the life of the segments, casting, deforming at low strength, storing, transport, erection, bolting/doweling, shield jacking, forces from out-of-tolerance placement, gasket forces, etc.

Reinforcement is placed not only to help withstand bending moments around the ring but also other forces such as

- Splitting or tension across the section from the force between the segments in a ring.
- Eccentric jacking force tending to break off a corner of the joint.
- Forces from tightening the bolts, in particular when curved bolts are used.
- Torsion across the segment resulting from only partial contact between adjacent ring segments, when segment joints are staggered.

From the point of view of fabrication, it is an advantage if the reinforcing cage is manufactured in part from welded-wire fabric. Recently steel-fiber reinforced concrete without other reinforcing steel has been used successfully for the manufacture of tunnel lining segments.

In the long-term, elements of the lining can corrode if exposed to corrosive environmental agents. For example, sulfates in the soil and groundwater can attack the concrete. Salt in the groundwater will tend to seep through the concrete and concentrate at the inside face as the water evaporates, eventually causing reinforcing steel to corrode. Remedies to improve long-term durability include at least the following:

- Use of high-density, low-permeability concrete with pozzolanic admixtures and microsilica.
- Coating the exterior concrete face with impervious bitumen.
- Epoxy coating of reinforcing steel after fabrication of cages.
- Placement of thick grout or mortar backfill around the lining, designed for water tightness.
- Use of corrosion-resistant bolts and nuts.

28.4 Immersed and Floating Tunnels

28.4.1 Introduction

Although written for immersed tunnels, most concepts in this chapter apply equally to floating tunnels, except for the comments on foundations and backfilling. The primary difference between the design of immersed and floating tunnels is that floating tunnels have to be designed for dynamic loads due to the presence of moving water throughout their life, whereas immersed tunnels need only to consider dynamic loads that occur until finally placed.

28.4.2 Sizing of Tunnel Sections

The needs of the client, the projected traffic volume, the projected vehicle types, and the profiles of the tunnel will dictate the number of traffic lanes required. If uphill grades are long or steep, climbing lanes may be required for heavy vehicles, though it is usual to avoid climbing lanes within the immersed tunnel elements themselves. Due to cost, it is unusual to have full-width emergency lanes or shoulders within tunnels, nominal widths usually sufficing. Very long tunnels may have a short extra lane at intervals to permit emergency stopping.

Unmountable barriers, such as Jersey barriers, are generally used to protect the walls from traffic impact. When the heights of such barriers exceed 600 mm, traffic tends to shy away, making the lane width seem narrower and slowing down motorists.

Walkways within road tunnels should be discouraged, although emergency access through a central wall into an adjacent tunnel should be available. This would require an emergency walkway at least 0.6 m wide on the side adjacent to emergency doors at the level of the top of the barrier and so arranged that vehicle overhangs do not endanger users of the walkway. Such emergency “cross-passages” may need to be provided at intervals of, say, 100 m. Passenger rail tunnels today require an emergency walkway and a place of refuge, often the adjacent tunnel. In immersed rail tunnels, emergency cross-passage doors may be set closer at 50-m intervals, and the emergency walkway may need to be 1.2 m wide to comply with National Fire Protection Association, Inc. (NFPA) 130 escape time limits.

In some cases, it may be desirable to provide an escape duct, usually having an air pressure slightly above that of the highway ducts. Utility ducts may be provided with space in excess of that needed to service the tunnel so that space may be rented out to others. Space above the minimum vertical clearance for road traffic may be needed for lighting and signs. The clearance height for permitted vehicles is usually held as low as possible. Permitted classes of vehicles in any tunnel may be restricted by legislation or owner requirements.

Having thus determined the width and height of internal spaces, preliminary calculations can be made regarding proposed methods of ventilation, jet fan sizes, or duct areas. Although normal ventilation may be designed for stalled traffic conditions, the critical case that defines ventilation may be that of a fuel fire [6]. Space within the tunnel envelope yet outside the traffic envelope may be required to accommodate jet fans, or alternatively, ventilation ducts may be needed.

Air requirements must also be determined. Most immersed tunnel elements are designed only just to float when completed (Figure 28.9), yet be heavy enough to stay submerged by the addition of permanent ballast. A few have been provided with temporary external buoyancy to avoid adding the ballast later. Because of this very delicate balance of being able to float yet later to stay submerged, it is very important that the internal air volume is kept to a minimum, consistent with the demand for internal space. Tolerances to allow for construction variations, fireproofing material on the walls and ceiling, and possible misalignment of elements are additional to other space requirements. In contrast, floating tunnels that rely on buoyancy must have sufficient compartmentalized buoyancy to stay afloat in case of accidental damage, usually considered to be to two adjacent compartments (damaged on the joint).

Once minimum air, traffic, electrical, mechanical, and utility duct requirements have been evaluated, temporary end bulkheads can be sized and calculations made to ensure that tunnel elements float. Initial

FIGURE 28.9 Floating element — airport rail tunnel, Hong Kong (© Christian Ingerslev).

estimates of slab and wall thicknesses, concrete and water densities and steel content (in the form of either structural steel or reinforcement) will be needed to do this. To prevent the incomplete tunnel from floating after removal of the bulkheads, space for additional ballast to be added later (or other means) will need to be provided. If subsequent structural analysis requires any increase in thickness, it may have to be achieved at the expense of adding extra internal space to compensate for the additional weight. Haunches may be necessary to alleviate shear problems at the edges of larger spans. If shear does require reinforcement, it is better to use bent-up bars and avoid shear links in concrete tunnels. Allowance must be made for the addition, if needed, of more concrete or permanent ballast to meet the requirement for an immersed tunnel not to float under final conditions.

28.4.3 Types of Immersed Tunnel

Two main types of tunnel have emerged, known as steel and concrete. Steel tunnels use structural steel, usually in the form of stiffened plate, working compositely with the interior concrete, whereas concrete tunnels do not, relying on steel reinforcing bars or prestressing cables. The number of concrete tunnels is almost twice that of steel tunnels. Steel tunnels can be designed like a ship to have an initial draft of as little as about 2.5 m, as long as the remaining concrete is placed afloat at an outfitting site with greater draft, whereas concrete tunnels have a draft of almost their full depth. Tunnel cross-sections may have flat sides or curved sides.

Historically, the predominant shape of concrete tunnels has been rectangular, which is particularly attractive for wide highways and combined road–rail tunnels, but they have also been circular or curved with a flat bottom. In Europe, Southeast Asia, and Australia, virtually all immersed tunnels are of concrete. In Japan, steel and concrete tunnels are in approximately equal numbers. Most tunnels in North America are steel tunnels.

Steel tunnels have been circular, curved with a flat bottom, and rectangular (particularly in Japan). However, the predominant shape in the past in the United States has been a circular shell within an octagonal shape, with ventilation supply ducts above and exhaust below the roadway. Some of these tunnels consist of a single octagonal tube, while others have a binocular arrangement with two adjacent octagonal tubes forming each tunnel element. This arrangement of ventilation ducts may change, since current techniques permit the use of longitudinal ventilation in much longer tunnels, often obviating the need for separate ventilation ducts. Most or all of the concrete in steel tunnels is placed while the steel

shell is afloat, in direct contrast to concrete tunnels that are virtually complete before being floated out. The order in which concrete is placed for a steel tunnel is tightly controlled to minimize deformations and the resulting locked-in moments. Steel tunnels can be categorized into three subtypes:

- Single shell, where the external structural shell plate works compositely with the interior reinforced concrete and the shell plate requires corrosion protection. The BART tunnel is typical of this type.
- The so-called double-shell tunnel, where the interior structural shell plate works compositely with the reinforced concrete within it and is protected by external concrete placed within nonstructural steel form plates (the second “shell”). This shape has also been used in pairs for several tunnels, the most recent being the Ted Williams in Boston, MA. Double-shell tunnels are found only in the United States. The composite action of the structural steelwork with the concrete infill in this arrangement generally requires a circular tube (Figure 28.10 and Figure 28.11) for the greatest efficiency.
- Sandwich, where internal steel diaphragms connect structural steel plates, both internal and external, and the space between them is subsequently filled with unreinforced nonshrink self-compacting concrete. This type of tunnel is a recent development in Japan. Osaka South Port and Kobe Port tunnels are constructed by this method, the latter being the only steel tunnel so far to carry three lanes per duct.

Concrete can be cast into any shape, so economics can influence whether rectangular or circular sections are used. For the shallowest profiles, rectangular sections (Figure 28.12) may provide the best alternative, side vented if required. Where more than two lanes per tube are needed, concrete rectangular tunnels are usually more economical than steel tunnels. Construction joints in the concrete are areas of weakness in all tunnels and can be vulnerable to leakage, particularly if the external membrane is punctured.

28.4.4 Principles of Design

Elements are designed to resist dead loads, live loads, exceptional loads, and extreme loads [7]. These should be applied in accordance with the relevant codes only where they consider the particular conditions of an immersed tunnel. It is important that in considering the design of any one element, all aspects of the design of that element meet the same code. Because of the requirements during construction to float and later not float, actual loads and densities are important, and incorrect

FIGURE 28.10 Steel immersed tunnel — Ted Williams Tunnel, Boston, MA (© David Sailors 1993, with permission).

FIGURE 28.11 Steel immersed tunnel — Cross Harbour Tunnel, Hong Kong (© Parsons Brinckerhoff, Inc. 1971, with permission).

FIGURE 28.12 Concrete immersed tunnel — Western Harbour Crossing, Hong Kong (© Christian Ingerslev).

assumptions can lead to serious errors. In the absence of relevant codes, the following assumptions may be made:

- Dead load includes all long-term loads and mean water level, that is, the self-weight of the basic structure and secondary elements supported and the pressure due to soil and static water level.
- Live load includes creep, shrinkage, prestress, temperature, backfill, seabed erosion and siltation, traffic, variations in water level, current, storm loads, and earthquakes, each with a return period of 5 years or less. Air pressure transient may apply in high-speed rail tunnels.
- Exceptional loads include loss of support (subsidence) below the tunnel or to one side and storms and extreme water levels with a probability of being exceeded once during the design life.

- Extreme loads include falling anchors, sunken or stranding ships, ship collision, water-filled tunnel, vehicular accidents or derailments with collision, explosion (e.g., vehicular), fire, the design seismic event predicted for the location, and the resulting movement of soils. Some of these loads may be affected by categories of dangerous goods permitted through the tunnel.
- Construction loads.
- Life safety; the tunnel should be checked at ultimate limit state for the safety evaluation earthquake (SEE) using load factors of unity. Life safety is directly linked to the survivability of the structure under the most severe seismic event considered at the location.

Load combinations should be selected with regard to simultaneous probability. For example, extreme seismic events may be assumed to occur without storm loads. Structures should be designed to accommodate expected movements due to deformation of foundations without limiting normal operations. Soil pressures should take account of the soil surface profile as well as the geometry of the structure. Geotechnical considerations should also include effects due to seepage, erosion, a change from drained to undrained conditions, liquefaction, and cuts in soft clays. Differential settlements can be expected at interfaces between types of construction, at locations where immersed tunnels extend into the shoreline, and during construction. Tunnels may require fire protection where spalling and loss of section could cause catastrophic failure and inundation.

At least the following conditions should be considered during analysis and design, with levels of damage and resulting performance levels agreed on with the client:

- Normal operating conditions, with full performance level.
- Abnormal conditions are the conditions immediately after the tunnel has experienced extreme or exceptional loads when no loads except the sunken ship are acting, whereas soil and other conditions may have changed. As a result of applying factored dead, live, and ship loads during abnormal conditions, the tunnel should remain operational under the after-effects of any of the extreme or exceptional loads (but not flooded) and settlement (if applicable). Under the worst possible combination of events, the tunnel should sustain no more than light damage requiring minor repairs, public traffic, perhaps immediately, minor leaks, and effectively full or limited performance level. With operations ceased and closed to traffic, the tunnel should survive some loss of support beneath or to one side.
- As a result of applying factored extreme loads, excluding earthquake, full performance level should result with no more than light damage, minor repairs, brief interruption to public traffic, minor leaks, and effectively no significant loss of service under the most adverse combination of events. For extreme actions, including earthquake, limited or minimum performance level may result.
- Construction conditions, including temporary structures (e.g., sheet piles) and loads due to handling, launching, transporting (including expected wave conditions), and placing, combined with environmental and seismic loads appropriate to the season, duration of use, and location. Abnormal and extreme conditions may be inappropriate.

28.4.5 Analysis

28.4.5.1 General

Methods used for analysis may include the usual frame and finite element methods, but where subsoils are nonuniform or where sudden changes in loading on top of the tunnel occur, such as at the banks of a river, effects may require soil–structure interaction analysis to correctly model soil behavior. Both ultimate and serviceability analysis, as appropriate, should be investigated. Effects to be considered include adequate safety against failure of complete structures and of their components, static equilibrium, buckling, water tightness, fatigue, durability, vibration, cracking, and deformations.

In the absence of other data for immersed tunnels, methods may use the load factors (appropriate load combination multipliers) given in [Table 28.2](#). Where alternate factors are given, the most adverse combinations should be used.

TABLE 28.2 Load Combination Multipliers for Immersed Tunnels

Load case	Normal	Abnormal	Extreme	Construction
Loading				
Dead load and road ballast	1.4/0.9	1.2/0.9	1.05	1.1
Traffic load				
Normal	1.6/0	1.2/0	—	—
Exceptional vehicle	1.4/0	1.2/0	—	—
Centrifugal	1.6/0	1.3/0	—	—
Braking load				
Normal	1.6/0	1.3/0	—	—
Exceptional vehicle	1.4/0	1.2/0	—	—
Wind and waves	—	1.2	1.05	1.2
Current	1.4	1.2	1.05	1.2
Water pressure allowing for tidal variation	1.4/0.9	1.2/0.9	1.05	1.2
Additional water pressure due to surge	—	1.2/0.9	1.05	1.2
Backfill pressure				
Horizontal	0.9/1.6	0.9/1.4	1.05	1.3/0
Vertical	1.6/0.9	1.4/0.9	1.05	1.3/0
Creep and shrinkage	1.3	1.3	1.05	1.1/0.9
Temperature effects and prestressing	1.3	1.3	1.05	1.1
Sunken ship	—	1.2/0	1.05	—
Earthquake	—	1.2	1.05	—
Other extreme loads	—	—	1.05	—
Imposed loads during construction	—	—	—	1.3

28.4.5.2 Analysis of Earthquake Effects

All immersed tunnels should be designed for seismic events appropriate to their location [1, [Chapter 8](#)]. Seismic events during the construction phase should also be considered. Liquefaction of soils around an immersed tunnel should be avoided, perhaps requiring special measures to be taken. An appropriate level of risk should be agreed on with the client because cost implications may be significant.

It may be appropriate to consider three magnitudes of earthquake loading:

- The functional evaluation earthquake (FEE), also known as the design basis earthquake (DBE), should be used first to design the structure for either limited or full performance. A magnitude corresponding to a return period of one to three times the design life is appropriate.
- The SEE should be checked to ensure compliance with minimum performance for life safety and survivability of a design made to FEE. The SEE is the most severe seismic event considered at the location. A performance level agreed on with the client may or may not assume progressive collapse under SEE, but ductility of the structure must be ensured to prevent sudden fracture. A return period of 1000 years or more should be used. As an alternative, however, selecting the maximum credible earthquake (MCE) (i.e., the maximum foreseeable earthquake) or that of large earthquakes that occur at a lesser frequency may sometimes be appropriate.
- A smaller serviceability limit state earthquake, corresponding to a 5- to 10-year return period, may also be included as an ordinary static live load to be combined with other live loads.

For each of these magnitudes, an acceptable structural response to or performance with these loads, including the extent of cracking, movement, damage, formation of plastic hinges, etc., needs to be defined and agreed on with the owner so that the corresponding allowable design stresses and displacements can be determined. (Structural response resulting in collapse or catastrophic inundation is not acceptable.) Typical acceptable performance criteria are

- Minimum performance level
 - Significant damage, repairable or perhaps not.
 - May require full closure or replacement of tunnel.

- Emergency vehicles and slow-moving traffic can still pass any flooding on roadway.
- Limited lighting and ventilation.
- Limited performance level
 - Intermediate damage, repairable over 12 months.
 - Limited emergency and public traffic possible within hours.
 - Limited leakage.
 - Full lighting and ventilation.
- Full performance level
 - Light damage requiring minor repairs.
 - Public traffic immediately.
 - Minor leaks.
 - No significant loss of service.

Not all combinations of earthquake and performance level may be useful to consider. Those that should be used for design would depend on the strategic importance of the tunnel route, the availability of alternative routes, the risks that the owner is prepared to carry, and the cost. Dynamic structural response analysis and assessment of displacements using soil–structure interaction may be necessary and may need to include the effective mass of water. An effective soil drainage system can reduce soil pore pressures.

28.4.6 Methods of Constructing Elements: Concrete and Steel

28.4.6.1 Concrete

An element is a length of tunnel that is floated and immersed as a single rigid unit. The rigidity may be temporary and later released. In other words, elements either may be monolithic or may consist of a number of discrete segments stressed temporarily together longitudinally for ease of transportation and placing. After placing, the stressing may be removed so that each segment may act as a minielement that is free to move at each segment joint. Some Dutch tunnels and the Øresund tunnel between Denmark and Sweden consist of such released segments. The ability to use discrete segments can depend on subsurface conditions, acceptable displacements, and sufficient capacity to resist seismic effects.

28.4.6.1.1 Monolithic Elements

Monolithic elements are cast in bays (equivalent to segments), typically with the floor slab cast first, and followed by the walls and roof in either one or two operations (Figure 28.12). Special efforts to reduce cracking adjacent to previously cast concrete could include low-heat concrete mixes and cooling pipes embedded in the concrete. Reinforcement is continuous across construction joints.

28.4.6.1.2 Discrete Segments

Discrete segments lend themselves to being cast in a single continuous operation, either horizontally (Øresund Tunnel) or vertically and then rotated (Tuas Bay Tunnel). Either way has the advantage of eliminating horizontal construction joints in the walls and the associated thermal cracking. If assembly can be achieved reasonably quickly, a basin or dock sized for a single element can be used. Operations can be tailored to obviate the need to store completed elements before immersion.

External walls and slabs are usually 1 m or more in thickness. These must therefore be considered thick concrete, so special precautions must be taken to avoid cracking during casting. It is particularly important to avoid cracking caused by heat of hydration because such cracks will leak.

28.4.6.2 Steel

A steel tunnel is usually designed to be able to float initially with little or none of the internal concrete having been placed. The bulk or all of the concrete is then placed after launching, either close to the fabrication site or more usually at an outfitting site close to the immersion site. If a graving dock is used (Figure 28.12), a compromise must be reached between the size, the number of reuses, and the schedule.

Testing and repair of any cracks and leaks is needed before submerging the elements. Figure 28.11 shows the Cross Harbour Tunnel on the quayside in Hong Kong almost ready for side launching.

Ease of construction can be achieved by a high degree of mechanization and line fabrication. Prefabricated forms, work shelters (heated in winter), shop welding of any steel plate, and prefabrication of reinforcement cages and prestressing cables can all be used to advantage.

28.4.6.3 Waterproofing

The need for waterproofing concrete tunnels is still a hotly debated issue. A barrier between concrete and salt water, warmer waters, or corrosive waters would appear particularly beneficial. Waterproofing will also reduce the amount of water penetrating the remaining cracks, particularly if the waterproofing adheres to the concrete. In case of fire, concrete that is not saturated with water is less likely to spall since the formation of steam is less likely.

Steel tunnels do not need waterproofing since the structural steel shell serves this purpose well, yielding and not cracking when overloaded, although measures to inhibit corrosion of the steel may be required.

28.4.7 Tunnel Joints

28.4.7.1 Final Joint

Some tunnels are constructed progressively from one end to the other, after which the landside structures are completed. Others may require the last element to be inserted rather than appended to the end of the previous element. To achieve this, a small final gap will have to remain. This closure or final joint corresponds to a short length of tunnel that will need to be cast in place, inserted like a wedge, or jacked out like a piston. Methods used include tremie concrete to seal the joint and dewatering to complete the joint in the dry from the inside.

28.4.7.1.1 Construction Joints

These are horizontal or vertical connections between monolithic parts of a structure. Usually, a waterstop is placed in such a joint. Typically, this would be one of the traditional types of waterstops, although hydrophilic and groutable waterstops are sometimes used. Special moveable watertight joints are required between discrete segments of a tunnel element, where used, designed as expansion joints and perhaps also with shear capacity.

28.4.7.1.2 Immersion Joints

These joints are the ones that are dewatered between tunnel elements subsequent to the immersing and joining operations at the seabed. The joints may remain flexible, or they can be made rigid, as has been common with many steel tunnels. Flexible joints are generally sealed with a temporary immersion gasket or soft-nosed gasket in compression. The use of a secondary independent flexible seal, capable of being replaced from within the tunnel, is common practice (often an omega seal). Each seal should be capable of resisting the external hydrostatic pressure and should allow for expected future movements. Protection should also be provided against damage to seals from within the tunnel, such as impact damage or airborne contaminant damage.

28.4.7.1.3 Seismic Joints

A seismic joint, which can be an immersion joint of special design, may be required to accommodate large differential movements in any direction due to a seismic event. Such a joint would most likely be located at significant changes in cross-section. Figure 28.13 shows a typical seismic joint of BART in San Francisco. Semirigid or flexible joints between elements may also need to be strengthened to carry seismic loads and to prevent catastrophic inundation, typically by using stressed or unstressed prestressing components across the joints or by using bearings and shear keys.

28.4.7.1.4 Terminal Joints (Land Connections)

The terminal joints between the shore ends of an immersed tunnel and the land portions may also be immersion joints. Direct joint connections may be made to land-based structures such as cut-and-cover

FIGURE 28.13 Seismic joint of BART, San Francisco, CA (© Parsons Brinckerhoff, Inc. 1967, with permission).

tunnels or ventilation buildings. These structures may be constructed either before or after placing the immersed tunnel, depending on schedule constraints and local conditions. For a bored or mined tunnel connection, the backfill around the end of the immersed tunnel would first need to be made relatively impermeable, such as by grouting, to allow boring to continue into the end of the immersed tunnel.

Steel immersed tunnels, because of their shallow draft capabilities, may eliminate the need for cut-and-cover tunnel construction in poor ground. After backfilling, the end of the tunnel can be exposed and open depressed highway sections constructed against it. The end of the immersed tunnel was exposed at the Second Downtown Elizabeth River Tunnel in Virginia (Figure 28.14).

Wherever the cross-section changes significantly, seismic actions may generate significant differential movements and the design must accommodate these. Drains, sumps, and pumping stations are required at both portals to remove rainwater that falls within the open sections, and at the tunnel low points to remove wash and leakage water.

Ventilation buildings, if needed, should preferably be sited on land, where they cannot be hit by shipping. The end faces of the buildings may also make suitable interfaces between immersed tunnel elements and on-shore techniques.

28.4.8 Construction Aspects

Dimensional and density checking of the concrete is necessary at all stages of construction to ensure that the design weight is not exceeded, since the tunnel might then not float: it is easier to add more weight than to remove it, and weight can always be added externally.

Temporary bulkheads are needed at the ends of each element, just visible in Figure 28.9 and clearly visible in Figure 28.14. They need to be watertight and yet reasonably simple to remove later. Bulkheads, if made of steel, are often designed for reuse.

Typical foundation layers are 600 mm to 1 m thick above the bottom of the predredged trench. They are mostly formed either by a screeded mattress of stone placed before the tunnel element is immersed or by jetted sand after the element is set on temporary supports, conditions to be allowed for in design. Such supports at the free end of the element are made adjustable, while the other end is first guided and then held by the previously laid element. Other types of design including injection of concrete are sometimes used. Before immersing (Figure 28.1), elements are usually held by temporary lifting hooks while ballast is

FIGURE 28.14 Second Downtown Elizabeth River Tunnel, Virginia (© Parsons Brinckerhoff, Inc. 1983, with permission).

added to provide the necessary negative buoyancy. Survey towers or similar devices are attached to the elements to enable monitoring of position after lowering starts, while bollards and other towing equipment are removed. Calculations to ensure stability at all stages of placement are necessary. Back-filling must be carried out in such a manner that unbalanced lateral forces do not move the element.

28.4.9 Protection against Ship Traffic and Currents

Immersed tunnels should be protected against falling anchors by a layer of either graded material or sacrificial concrete (see [Chapter 6](#) on “Hazard Analysis” in Ref. [1]). The same reference also provides guidance on expected loads from sinking ships, although this is very much dependent on the cargo that the ships would be carrying. Typical results for actual ships passing a particular location, assuming the worst cargo, can be plotted as shown in [Figure 28.15](#). These results may vary further, depending on

- Partially sunken vessels, which may increase these values, particularly if the vessel has a rigid stern post that can produce point loading.
- Critical water depths over which the vessel must pass.
- The water depth at the tunnel location.

If storms cause vessels to drag their anchors, it may be desirable to protect the tunnel further with rock berms over which anchors would be forced. Once clear of the tunnel, the anchors could re-engage.

FIGURE 28.15 Ground pressures from fully sunken ships (courtesy of Christian Ingerslev).

At the proposed site of the tunnel, the depth to the structure below the clearance envelope required for the shipping channel will vary according to the amount of overdredge expected during maintenance and the amount of protective backfill required over the tunnel. Protection may be required to the surface of the bed near the tunnel against scour, not only from currents but also from propellers. At some vessel terminals where propellers are kept turning to maintain position, significant local scour can occur. Overdredge of 1 m is not unusual, depending on the method used for dredging. Anchor loads are usually small compared with structural capacity but may cause local surface damage if insufficient backfill is provided [1]. The type and grading of backfill layers are selected so that they do not damage the tunnel structure and waterproofing, if used, and so that material does not get washed away under anticipated currents.

It may not be necessary to completely bury a tunnel and restore the original bed levels (a *floating* tunnel is an extreme case). In such cases, the effects of hydraulic intrusion of a tunnel into an existing waterway regime may require study since water flow is obstructed. For a floating tunnel, tidal and current effects may also cause dynamic and fatigue effects. In some instances all of these measures have been implemented on a single project.

28.5 Seismic Analysis and Design

28.5.1 Introduction

Tunnels, in general, have performed better during earthquakes than have above ground structures such as bridges and buildings. Tunnel structures are constrained by the surrounding ground and, in general, cannot be excited independent of the ground or be subjected to strong vibratory amplification, such as the inertial response of a bridge structure during earthquakes. Adequate design and construction of seismic resistant tunnel structures, however, should never be overlooked. Their seismic performance could be vital, particularly when they comprise important components of a critical transportation system (e.g., a transit system) in which little redundancy exists.

The general procedure for seismic design and analysis of tunnel structures should be based primarily on the ground deformation approach, that is, the structures should be designed to accommodate the deformations imposed by the ground. The analysis of the structure response can be conducted first by ignoring the stiffness of the structure, leading to a conservative estimate of the ground deformations. This simplified procedure is generally applicable for structures embedded in rock or stiff or dense soil.

In cases where the structure is stiff relative to the surrounding soil, the effects of soil–structure interaction must be taken into consideration.

28.5.2 Performance Record during Earthquakes

Seismic performance data of underground structures, including tunnels, are relatively scarce. Data reported in several studies [2,9–12] show that

- The greatest risk to all types of tunnels (including bored and mined, cut-and-cover, and immersed) occurs when the following conditions exist.
 - An active fault intersects the tunnel.
 - A landslide intersects the tunnel.
 - Soils surrounding the tunnels liquefy.
- Damage potential to tunnels reduces with increasing overburden, due partly to the attenuation of ground-shaking intensity with depth.
- Damage is greater in soils than in competent rock.
- Seismic performance of shallow cut-and-cover rectangular tunnels has been relatively poor in comparison to that of bored tunnels, as evidenced during the 1995 Kobe, Japan, earthquake [13,14]. These rectangular box-type structures are particularly vulnerable at the joints connecting the slabs with the walls or columns when subjected to cyclic racking deformations imposed by the ground.
- Immersed tunnels are susceptible to permanent ground deformations resulting from liquefaction induced settlements, lateral spread, and uplift (flotation), and slope instability (landslides) in soft cohesive soils. Joints connecting tube segments are particularly vulnerable to the relative movements between two adjacent segments during shaking, noting that water tightness is one of the critical performance requirements of immersed tunnels.
- Damage potential to bored tunnels due to ground-shaking effects (excluding permanent displacements due to faulting, landslides, and liquefaction) increases with ground-shaking intensity and decreases with better tunnel lining and support system. Figure 28.16 presents performance data of bored tunnels under the effects of seismic ground shaking alone [10]. The figure suggests that
 - Ground shaking caused little damage in tunnels for peak ground acceleration (PGA) less than about $0.2g$, where g is the gravity of acceleration.
 - Tunnels with ductile lining (reinforced concrete or steel) tend to have performed better, with damage observed only when the PGA exceeds $0.5g$.

28.5.3 Design and Analysis Approach for Ground-Shaking Effects

28.5.3.1 General

Underground tunnel structures undergo three primary modes of deformation during seismic shaking: ovaling or racking, axial, and curvature deformations (see Figure 28.17 and Figure 28.18) [2,12]. The ovaling or racking deformation is caused primarily by seismic waves propagating perpendicular to the tunnel longitudinal axis, causing deformations in the plane of the tunnel cross-section. Vertically propagating shear waves are generally considered the most critical type of waves for this mode of deformation. The axial and curvature deformations are induced by components of seismic waves that propagate along the longitudinal axis.

28.5.3.2 Evaluation of Axial and Curvature Deformations

28.5.3.2.1 Free-Field Deformation Procedure

This procedure assumes that the tunnel lining conforms to the axial and curvature deformations of the ground in the free field (i.e., without the presence of the tunnel). While conservative, this assumption provides a reasonable evaluation because, in most cases, the tunnel lining stiffness is considered relatively

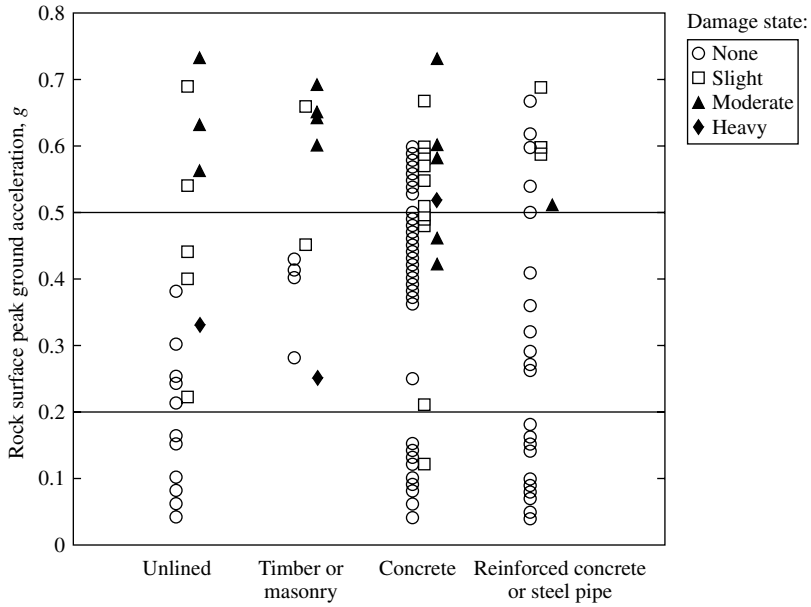

FIGURE 28.16 Rock surface peak ground acceleration for various tunnels (courtesy of M.S. Power, *Summary and Evaluation of Seismic Design of Tunnels*, Draft report submitted to Multidisciplinary Center for Earthquake Engineering Research (MCEER) 1998).

flexible to the ground. This procedure requires minimum input, making it useful as an initial design tool and as a method of design verification.

The lining will develop axial and bending strains to accommodate the axial and curvature deformations imposed by the surrounding ground. St. John and Zahran [15] developed solutions for these strains due to compression P-waves, shear S-waves, and Rayleigh R-waves. Table 28.3 presents the solutions due to the three wave types propagating at an angle, ϕ , in the horizontal plane with respect to the longitudinal axis of the tunnel.

The strains ϵ due to combined axial and curvature deformations can be obtained by combining the longitudinal strains generated by axial and bending strains as follows:

For P-waves

$$\epsilon = \frac{V_p}{C_p} \cos^2 \phi + Y \frac{A_p}{C_p^2} \sin \phi \cos^2 \phi \tag{28.4a}$$

For S-waves

$$\epsilon = \frac{V_s}{C_s} \sin \phi \cos \phi + Y \frac{A_s}{C_s^2} \cos^3 \phi \tag{28.4b}$$

For R-waves

$$\epsilon = \frac{V_R}{C_R} \cos^2 \phi + Y \frac{A_R}{C_R^2} \sin \phi \cos^2 \phi \tag{28.4c}$$

where

V_p = peak particle velocity of P-waves at the tunnel location

V_s = peak particle velocity of S-waves at the tunnel location

V_R = peak particle velocity of R-waves at the tunnel location

A_p = peak particle acceleration of P-waves at the tunnel location

A_s = peak particle acceleration of S-waves at the tunnel location

A_R = peak particle acceleration of R-waves at the tunnel location

C_p = apparent propagation velocity of P-waves

C_s = apparent propagation velocity of S-waves

C_R = apparent propagation velocity of R-waves, and

Y = distance from the neutral axis of the tunnel cross-section to the extreme fiber of the lining

TABLE 28.3 Strain and Curvature Due to Three Wave Types

Wave type	Longitudinal strain	Curvature
P-wave	$\epsilon = \left(\frac{V_p}{C_p}\right) \cos^2 \phi$	$\left(\frac{1}{\rho}\right) = \left(\frac{a_p}{C_p^2}\right) \sin \phi \cos^2 \phi$
	$\epsilon_{\max} = \frac{V_p}{C_p}$ for $\phi = 0^\circ$	$\left(\frac{1}{\rho_{\max}}\right) = 0.385 \left(\frac{a_p}{C_p^2}\right)$ for $\phi = 35.27^\circ$
S-wave	$\epsilon = \left(\frac{V_s}{C_s}\right) \sin \phi \cos \phi$	$\left(\frac{1}{\rho}\right) = \left(\frac{a_s}{C_s^2}\right) \cos^3 \phi$
	$\epsilon_{\max} = \left(\frac{V_s}{2C_s}\right)$ for $\phi = 45^\circ$	$\left(\frac{1}{\rho_{\max}}\right) = \left(\frac{a_s}{C_s^2}\right)$ for $\phi = 0^\circ$
R-wave Compression component	$\epsilon = \left(\frac{V_R}{C_R}\right) \cos^2 \phi$	$\left(\frac{1}{\rho}\right) = \left(\frac{a_R}{C_R^2}\right) \sin \phi \cos^2 \phi$
	$\epsilon_{\max} = \left(\frac{V_R}{C_R}\right)$ for $\phi = 0^\circ$	$\left(\frac{1}{\rho_{\max}}\right) = 0.385 \left(\frac{a_R}{C_R^2}\right)$ for $\phi = 35.27^\circ$
Shear component		$\left(\frac{1}{\rho}\right) = \left(\frac{a_R}{C_R^2}\right) \cos^2 \phi$
		$\left(\frac{1}{\rho_{\max}}\right) = \left(\frac{a_R}{C_R^2}\right)$ for $\phi = 0^\circ$

Note:

- V_p = soil particle velocity caused by P-waves
- a_p = soil particle acceleration caused by P-waves
- C_p = apparent propagation velocity of P-waves
- V_s = soil particle velocity caused by S-waves
- a_s = soil particle acceleration caused by S-waves
- C_s = apparent propagation velocity of S-waves
- V_R = soil particle velocity caused by R-waves
- a_R = soil particle acceleration caused by R-waves
- C_R = propagation velocity of R-waves
- $1/\rho$ = curvature

Source: St. John and Zahrah 1987.

It should be noted that

- S-waves generally cause the largest strains and are the governing wave type.
- The angle of wave propagation, ϕ , should be the one that maximizes the combined axial strains.

The horizontal propagation S-wave velocity, C_s , in general, reflects the seismic shear wave propagation through the deeper rocks rather than that of the shallower soils where the tunnel is located. In general, this velocity value varies from about 2 to 4 km/s. Similarly, the P-wave propagation velocities, C_p , generally vary between 4 and 8 km/s. The designer should consult with experienced geologists and seismologists for determining C_s and C_p .

When the tunnel is located at a site underlain by deep deposits of soil sediments, the induced strains may be governed by the R-waves. In such deposits, detailed geological and seismological analyses should be performed to derive a reliable estimate of the apparent R-wave propagation velocity, C_R .

The combined strains calculated from Equations 28.4a, 28.4b and 28.4c represent the seismic loading effect only. To evaluate the adequacy of the structure under the seismic loading condition, the seismic loading component has to be added to the static loading components using the appropriated loading combination criteria developed for the structures. The resulting combined strains are then compared against the allowable strain limits, which should be developed based on the performance goal established for the structures (e.g., the required service level and acceptable damage level).

28.5.3.2.2 Procedure Accounting for Soil–Structure Interaction Effects

If a very stiff tunnel is embedded in a soft soil deposit, significant soil–structure interaction effects exist, and the free-field deformation procedure presented in the previous subsection may lead to an overly conservative design. In this case, a simplified BOEF procedure should be used to account for the soil–structure interaction effects. According to St. John and Zahran [15], the effects of soil–structure interaction can be accounted for by applying reduction factors to the free-field axial strains and the free-field curvature strains, as follows:

For axial strains

$$R = 1 + \frac{E_l A_l}{K_a} \left(\frac{2\pi}{L} \right)^2 \cos^2 \phi \quad (28.5a)$$

For bending strains

$$R = 1 + \frac{E_l I_l}{K_h} \left(\frac{2\pi}{L} \right)^4 \cos^4 \phi \quad (28.5b)$$

where E_l is Young's modulus of tunnel lining, A_l is the cross-sectional area of the lining, K_h is the transverse soil spring constant, K_a is the longitudinal soil spring constant, L is the wave length of the P-, S-, or R-waves, and I_l is the moment of inertia of the lining cross-section.

It should be noted that the axial strain calculated from Equation 28.5a should not exceed the value that could be developed using the maximum frictional forces, Q_{\max} , between the lining and the surrounding soils. Q_{\max} can be estimated using the following expression:

$$Q_{\max} = \frac{fL}{4} \quad (28.6)$$

where f is the maximum frictional force per unit length of the tunnel.

28.5.3.3 Evaluation of Ovaling Deformations of Bored or Mined Circular Tunnels

The seismic ovaling effect on the lining of bored or mined circular tunnels is best defined in terms of change of tunnel diameter, ΔD_{EQ} . For practical purposes, the ovaling deformations can be assumed to be caused primarily by the vertically propagating shear waves. ΔD_{EQ} can be considered as seismic ovaling deformation demand for the lining. The procedure for determining ΔD_{EQ} and the corresponding lining strains is outlined as follows [12].

28.5.3.3.1 Step 1

Estimate the expected free-field ground strains caused by the vertically propagating shear waves of the design earthquakes. The free-field ground strains can be estimated using the following formula:

$$\gamma_{\max} = \frac{V_S}{C_{SE}} \quad (28.7)$$

where γ_{\max} is the maximum free-field shear strain at the elevation of the tunnel, V_S is the S-wave peak particle velocity at the tunnel elevation, and C_{SE} is the effective shear wave velocity of the medium surrounding the tunnel.

Alternatively, the maximum free-field shear strain can be estimated by a more refined free-field site response analysis (such as in Ref. [16]).

The effective shear wave velocity of the vertically propagating shear wave, C_{SE} , must be compatible with the level of the shear strain that may develop in the ground at the elevation of the tunnel under the design earthquake shaking. A rough estimate of the ratio C_{SE}/C_{SS} (where C_{SS} is the low-strain shear wave velocity of the surrounding medium) can be made as follows:

- For rock, $C_{SE}/C_{SS} \cong 1.0$.
- For stiff to very stiff soil, C_{SE}/C_{SS} may range from 0.7 to 0.9 for low to moderate earthquake shaking and from 0.5 to 0.7 for strong shaking.

Alternatively, site-specific response analyses can be performed for estimating C_{SE} . Site-specific response analyses should be performed on soft soil sites.

The values of the low-strain shear wave velocity, C_{SS} , can be determined using geophysical testing techniques in the field such as P-S logger, cross-hole, and seismic cone penetration methods or estimated from empirical correlation.

28.5.3.3.2 Step 2

By ignoring the stiffness of the tunnel, which is applicable for tunnels in rock or in stiff or dense soils, the lining can be reasonably assumed to conform to the surrounding ground with the presence of a cavity due to the excavation of the tunnel (but without the presence of the lining). The resulting diameter change of the tunnel is

$$\Delta D_{EQ} = \pm 2\gamma_{\max}(1 - \nu_m)D \quad (28.8)$$

where ν_m is Poisson's ratio of the surrounding ground and D is the diameter of the tunnel.

28.5.3.3.3 Step 3

If the structure is stiff relative to the surrounding soil, then the effects of soil-structure interaction should be taken into consideration. The relative stiffness of the lining is measured by the flexibility ratio, F , defined as follows:

$$F = \frac{E_m(1 - \nu_l^2)R_l^3}{6E_l I_{l,1}(1 + \nu_m)} \quad (28.9)$$

where E_m is the strain-compatible elastic modulus of the surrounding ground, R_l is the nominal radius of the tunnel lining, ν_l is Poisson's ratio of the tunnel lining, and $I_{l,1}$ is the moment of inertia of the lining per unit width of tunnel along the tunnel axis.

The strain-compatible elastic modulus of the surrounding ground, E_m , should be derived using the strain-compatible shear modulus, G_m , corresponding to the effective shear wave propagating velocity, C_{SE} .

The moment of inertia of the tunnel lining per unit width, $I_{l,1}$, should be determined based on the expected behavior of the selected lining under the combined seismic and static loads, accounting for cracking and joints between segments and between rings as appropriate.

28.5.3.3.4 Step 4

The diameter change, ΔD_{EQ} , accounting for the soil-structure interaction effects can then be estimated using the following equations:

$$\Delta D_{EQ} = \pm \frac{1}{3}k_1 F \gamma_{\max} D \quad (28.10)$$

$$k_1 = \frac{12(1 - \nu_m)}{2F + 5 - 6\nu_m} \quad (28.11)$$

where k_1 is the Seismic ovaling coefficient.

The seismic ovaling coefficient curves plotted as a function of F and ν_m are presented in [Figure 28.19](#).

The resulting bending moment induced maximum fiber strain, ε_m , and the axial force (i.e., thrust) induced strain, ε_T , in the lining can be derived as follows:

$$\varepsilon_m = \frac{1}{6}k_1 \frac{E_m}{(1 + \nu_m)} R_l^2 \frac{\gamma_{\max} t_1}{2E_l I_{l,1}} \quad (28.12)$$

$$\varepsilon_T = \frac{1}{6}k_1 \frac{E_m}{(1 + \nu_m)} R_l \frac{\gamma_{\max}}{E_l t_1} \quad (28.13)$$

where t_1 is the thickness of the lining.

The solutions presented in Equations 28.10 through 28.13 assume that a full-slippage condition exists along the soil-lining interface, which allows normal stresses (without normal separation) but no tangential shear force. The full-slippage assumption yields slightly more conservative results in estimating

FIGURE 28.19 Seismic ovaling coefficient curves (© Parsons Brinckerhoff, Inc. 1993, with permission).

the diameter change and bending strain but significantly lower values of thrust-induced strain than the no-slippage condition. Therefore, Equation 28.13 should not be used unless a full-slippage mechanism is incorporated in the design. Instead, the no-slippage condition should be assumed in deriving the thrust-induced strain as follows [12]:

$$\epsilon_T = k_2 \frac{E_m}{2(1 + \nu_m)} R_l \frac{\gamma_{\max}}{E_l t} \tag{28.14}$$

$$k_2 = 1 + \frac{F[(3 - 2\nu_m) - (1 - 2\nu_m)C] - \frac{1}{2}(1 - 2\nu_m)^2 + 2}{F[(3 - 2\nu_m) + (1 - 2\nu_m)C] + C[\frac{5}{2} - 8\nu_m + 6\nu_m^2] + 6 - 8\nu_m} \tag{28.15}$$

$$C = \frac{E_m(1 - \nu_l^2)R_l}{E_l t(1 + \nu_m)(1 - 2\nu_m)} \tag{28.16}$$

where C is the compressibility ratio.

The seismically induced strains due to the ovaling effect need to be combined with the strains resulting from nonseismic loading and then checked against the allowable strain limits consistent with the performance goal established for the design of the tunnel lining.

28.5.3.4 Evaluation of Racking Deformations of Rectangular Tunnels

Racking deformations are defined as the differential sideways movements between the top and bottom elevations of the rectangular structures, shown as Δ_s in Figure 28.20. The resulting material strains in the lining associated with the seismic racking deformation, Δ_s , can be derived by imposing the differential deformation on the structure in a structural frame analysis. The procedure for determining, Δ_s taking into account the soil–structure interaction effects, is presented below [12].

28.5.3.4.1 Step 1

Estimate the free-field ground strains γ_{\max} (at the structure elevation) caused by the vertically propagating shear waves of the design earthquakes (see Section 28.5.3.3). Determine $\Delta_{\text{free-field}}$, the differential free-field relative displacements corresponding to the top and the bottom elevations of the rectangular structure (see Figure 28.20), by

$$\Delta_{\text{free-field}} = h\gamma_{\max} \tag{28.17}$$

where h is the height of the structure.

FIGURE 28.20 Racking deformation for a box structure (© Parsons Brinckerhoff, Inc. 1993, with permission).

28.5.3.4.2 Step 2

Determine the racking stiffness, K_s , of the structure from a structural frame analysis. For practical purposes, the racking stiffness can be obtained by applying a unit lateral force at the roof level, while the base of the structure is restrained against translation, but with the joints free to rotate. The structural racking stiffness is defined as the ratio of the applied force to the resulting lateral displacement. In performing the structural frame analysis, it is important to use the appropriate moment of inertia, taking into account the potential development of the cracked section, particularly for the vertical walls.

28.5.3.4.3 Step 3

Determine the flexibility ratio, F_{rec} , of the proposed design of the structure using the following equation:

$$F_{rec} = \frac{G_m w}{K_s h} \tag{28.18}$$

where w is the width of the structure and G_m is the average strain-compatible shear modulus of the surrounding ground.

The flexibility ratio is a measure of the relative racking stiffness of the surrounding ground to the racking stiffness of the structure.

28.5.3.4.4 Step 4

Based on the flexibility ratio obtained from Step 3, determine the racking reduction ratio, R_{rec} , for the structure using Figure 28.21 or the following expression [17]:

$$R_{rec} = \frac{4(1 - \nu_m)}{((3 - 4\nu_m)/F_{rec}) + 1} \tag{28.19}$$

The triangular points in Figure 28.21 correspond to published results [12]. The data in [12] were generated by performing a series of dynamic finite element analyses on a number of cases with varying soil and structural properties, structural configurations, and ground motion characteristics. As indicated in the figure, if $F_{rec} = 1$, the structure is considered to have the same racking stiffness as the surrounding ground, and therefore the racking distortion of the structure is about the same as that of the ground in the free field. When F_{rec} approaches zero, representing a perfectly rigid structure, the structure does not rack regardless of the distortion of the ground in the free field. For $F_{rec} > 1.0$ the structure becomes flexible relative to the ground, and the racking distortion is magnified in comparison to the shear distortion of the ground in

FIGURE 28.21 Racking reduction ratio (© Parsons Brinckerhoff, Inc. 1993, with permission).

FIGURE 28.22 Frame analysis modeling of racking deformations (© Parsons Brinckerhoff, Inc. 1993, with permission).

the free field. This magnification effect is not caused by the effect of dynamic amplification. Rather it is attributed to the fact that the ground has a cavity in it as opposed to the free-field condition.

28.5.3.4.5 Step 5

Determine the racking deformation of the structure, Δ_s , using the following relationship:

$$\Delta_s = R_{rec} \Delta_{\text{free-field}} \tag{28.20}$$

28.5.3.4.6 Step 6

The seismic demand in terms of internal forces as well as material strains can be calculated by imposing Δ_s upon the structure in a frame analysis as depicted in Figure 28.22.

28.5.3.5 Loads Due to Vertical Seismic Motions

The effects of vertical seismic motions can be accounted for by applying a vertical pseudostatic loading, equivalent to the product of the vertical seismic coefficient and the combined dead and design

overburden loads used in static design. The vertical seismic coefficient can be reasonably assumed to be two thirds of the design peak horizontal acceleration divided by gravity. This vertical pseudostatic loading should be applied by considering both up and down directions of motion. Whichever results in a more critical load case should govern.

If there is a potential for a seismically loosened zone to develop above the crown of the tunnel, then the inertial effects of this loosened zone should also be included in the design, unless appropriate stabilization measures are taken to prevent it from occurring.

28.5.4 Tunnel Subjected to Large Displacements

As indicated in [Section 28.5.2](#), the greatest risk to tunnel structures is the potential for large ground movements as a result of unstable ground conditions (e.g., liquefaction and landslides) or fault displacements. In general, it is not feasible to design a tunnel structure to withstand large ground displacements. The proper design measures in dealing with unstable ground conditions may consist of

- Ground stabilization.
- Removal and replacement of the problem soils.
- Rerouting or deep burial to bypass the problem zone.

With regard to the fault displacements, the best strategy is to avoid any potential crossing of active faults. If this is not possible, then the general design philosophy is to accept and accommodate the displacements by either employing an oversized excavation, perhaps backfilled with compressible or collapsible material, or using ductile lining to minimize the instability potential of the lining. In cases where the magnitude of the fault displacement is limited or the width of the sheared fault zone is considerable such that the displacement is dissipated gradually over a distance, design of a strong lining to resist the displacement may be technically feasible. The structures, however, may be subjected to large axial, shear, and bending forces. Many factors need to be considered in the evaluation, including the stiffness of the lining and the ground, the angle of the fault plane intersecting the tunnel, the width of the fault, the magnitude as well as orientation of the fault movement, among others. Analytical procedures are generally used for evaluating the effects of fault displacement on lining response. Some of these procedures were originally developed for buried pipelines [18]. Continuum finite element or finite difference methods have also been used effectively for evaluating the tunnel–ground–faulting interaction effects.

28.5.5 Shaft Structures and Interface Joints

The seismic considerations for the design of vertical shaft structures are similar to those for the lined circular tunnel structures, except that ovaling and axial deformations in general do not govern the design. Considerations should be given to the curvature strains and shear forces of the lining resulting from vertically propagating shear waves. Force and deformation demands may be considerable in cases where shafts are embedded in deep, soft deposits. In addition, potential stress concentrations at the following critical locations along the shaft need to be properly assessed and designed for

- Abrupt change of the stiffness between two adjoining geologic layers.
- Shaft–tunnel or shaft–station interfaces.
- Shaft–surface building interfaces.

Flexible connections to accommodate the potential differential movements are the recommended design strategy between any two structures with drastically different stiffness or mass in poor ground conditions.

28.6 Tunnel Jacking

Tunnel jacking evolved from pipe jacking, retaining many of the same features. Technological advancement from pipe jacking to tunnel jacking occurred in the 1960s, when circular pipe jacked

sections were found to be either too small or inefficient for their intended purpose, so they were replaced by rectangular sections. Over the past four decades, the technique has developed significantly, with tunnel sections ranging from 3 m² to 25 m wide × 12 m high and larger, with lengths exceeding 110 m. The method has been used in many parts of the world, including Europe (particularly in the United Kingdom and Germany), Australia, India, South Africa, Canada, and Japan. In the United States, however, tunnel jacking is a relatively new technique, with only one major application completed to date, consisting of three tunnels constructed under an operating rail network for a major highway extension in Boston, MA. A view of one of the jacking operations for that project is shown in Figure 28.23.

Features of a typical tunnel jacking operation are shown in Figure 28.24. The tunnel box structure is constructed in one or more sections immediately adjacent to the planned alignment, either in a pit for an application that is completely below existing grade or in an open space for the case where the jacking is being performed through an embankment. As with conventional pipe jacking, the frictional resistance that needs to be overcome to jack the complete tunnel length may exceed the total capacity of the jacking system that can be installed in the space available at the rear of the tunnel structure. In that case, the tunnel structure will be divided into sections, with intermediate jacking stations established between them.

The tunnel structure is open at the front end and fitted with a shield, which may be constructed of either steel or reinforced concrete. Depending on the characteristics of the ground through which the

FIGURE 28.23 Tunnel jacking operation in Boston, MA, for a major highway project.

FIGURE 28.24 Cross-section of a typical tunnel jacking operation.

jacking is being done, and on the size of the tunnel cross-section, the shield may be compartmentalized and the individual cells outfitted with breasting doors to minimize the area of unsupported face exposed at the tunnel heading. In some cases, ground improvement techniques such as grouting or even freezing may be implemented in advance of the jacking operation to increase the stand-up time of the ground.

Excavation is typically performed in small increments to avoid creating an unstable unsupported span beyond the leading edge of the shield. Overcutting along the excavation perimeter is carefully controlled to limit the potential for settlement of the ground surface above. Once an excavation cycle is complete, the tunnel structure is jacked ahead either in one step from a rear jacking station or in stages if intermediate jacking stations are being used.

The tunnel structure is advanced with a series of hydraulic jacks, with stroke lengths coordinated with the excavation increments. Depending on the particular system design, the jacks may be situated only along the base of the concrete section or around the entire section perimeter. Required operating capacities and pressures vary with the size of the tunnel being jacked; in larger applications, these parameters can be as much as 500 tons and greater than 40 MPa, respectively. Alignment control can be accomplished by varying the thrust applied in individual or clusters of jacks and through the use of guide walls constructed in the launch area outside the tunnel headwall. Reaction for the jacking force is provided by either a structural frame or thrust blocks at the rear of the tunnel, with spacer blocks or pipe sections or a series of anchorage points used as necessary to maintain continuity of the reaction structure as the tunnel advances into the ground and progressively farther from its starting point.

When the depth of cover is small relative to the width of the tunnel structure, there is a tendency for the overlying soil to be dragged along with the tunnel. To prevent this from occurring, a separation layer is typically introduced between the top surface of the tunnel and the adjacent ground to reduce the frictional resistance. This can be accomplished in a number of ways, with common methods including a series of steel sheets or an array of closely spaced wire ropes. Side friction is controlled by designing a small overcut into the shield structure and if necessary, by the injection of lubricating agents into the interface through multiple ports in the walls of the tunnel structure.

To maintain and protect critical surface facilities during tunnel jacking, tunnel jacking projects nearly always include some form of surface survey program to monitor the impact of the underground excavation, with predetermined corrective action plans already in place, ready to be implemented quickly in the event that ground deformations exceed tolerable thresholds.

Glossary

Advance rate — The amount of progress that a tunnel-boring machine makes — the distance it covers in a day, usually measured in feet or meters; also used for tunneling by other means.

Backfill — Any material such as sand, gravel or crushed stone, grout or concrete, used to fill the remainder of an excavation after a tunnel or other underground structure has been constructed within the excavation.

Ballast — A stabilizing weight (stones or concrete), either temporary or permanent, often added to immersed tunnel elements while floating, being immersed, or in their final position.

Bentonite — A clay mineral that can absorb large amounts of water. When mixed with water, it forms a slurry used to support deep trenches or bore holes against collapse until they can be filled with concrete.

Bottom-up — A method of construction in which a tunnel is built within an excavated trench in a conventional way or sequence: base slab first, then the walls, and finally, the roof. The completed structure is then backfilled and the ground surface reinstated.

Cofferdam — A temporary structure, constructed in water and pumped dry, used to keep water out so that work can be performed in dry conditions.

Controlled blasting — Use of patterned drilling and optimum amounts of explosives and detonating devices to control blasting damage.

Cross-passage — A short passage or tunnel connecting two adjacent tunnels, often used to allow people to escape from one tunnel to another in an emergency.

Crown — The top of a tunnel.

Cut-off wall — An underground wall, either temporary or permanent, used in tunnel excavations to prevent the passage of ground water.

Decking — A plank cover over a work area that serves as a temporary surface for pedestrian and vehicular traffic (including construction equipment), usually made of wood, concrete, or steel.

Dewatering — The removal of ground water from the area to be excavated.

Drill-and-blast — A method of mining in which small-diameter holes are drilled into the rock and then loaded with explosives. The blast from the explosives fragments and breaks the rock away from the face so the rock can be removed. Repeated drilling and blasting advances the underground opening.

Drawdown — A lowering of the normal groundwater level (water table) as the result of dewatering.

Face — The soil being excavated directly in front of the TBM or the surface at the head of a tunnel excavation. A mixed-face is a condition with more than one type of material, such as clay, sand, gravel, cobbles, or rock.

Ground reinforcement — Structural elements installed in the ground by drilling and insertion, including rock dowels or anchors, often grouted in place.

Ground support — Installation of any type of engineering structure around or inside the excavation, such as steel sets, wood cribs, timbers, or lining.

Heading — A smaller tunnel used when a larger tunnel is excavated in several stages. Smaller headings are used when full tunnel excavation at once would not be prudent. Sometimes multiple headings are used simultaneously to increase the number of excavation faces and compensate for slower excavation rates.

Invert — The bottom of a tunnel.

Lining — A temporary or permanent structure, made of concrete or other materials, to secure and finish the tunnel interior or to support an excavation.

Mole — Slang term for a tunnel engineer; also used to describe a TBM.

Open cut — A method of construction in which the excavated trench is left uncovered while the tunnel is constructed.

Overburden — The soil between the ground surface and the roof of a tunnel.

Pilot tunnel — An exploratory tunnel, usually smaller and driven ahead of the main tunnel.

Portal — The entrance to a tunnel.

Sandhog — Slang term for a tunnel worker.

Shaft — A vertical excavation, often used to provide access to a tunnel from the surface.

Shield — A structure used in soft ground to provide support at the face of the tunnel for the soil above the tunnel, to provide space for erecting supports, and to protect the workers excavating and erecting supports.

Shotcrete — Concrete pneumatically projected at high velocity onto a surface; pneumatic method of applying a lining of concrete.

Soft ground — Soils and weak rock that can be easily removed.

TBM — Tunnel boring machine, a machine that excavates a tunnel by drilling out the heading to full size in one operation.

Top-down — A method of construction in which the tunnel walls are built first, using special machinery, within a narrow trench. Next, the roof is built in a shallow excavation, and the ground surface is reinstated. The rest of the tunnel is then excavated and constructed underneath the roof.

Underpinning — The installation of new supports beneath the foundation of a building or other structure to protect it from settlement caused by adjacent tunneling or other construction; sometimes used in place of an old foundation that was removed.

29.1 Introduction

Glass is a brittle material that is weak in tension because of its noncrystalline molecular structure. When glass is stressed beyond its strength limit, breakage occurs immediately without warning, unlike steel and aluminum where plastic mechanism can be formed. Stress or moment redistribution does not occur in glass, and local and then consequential global failure is very common. Testing has shown that glass strength is statistical in nature.

The main constituent of glass is silica sand. Zachariassen and Warren [1] suggested that glass is made up of network formers and modifiers (Figure 29.1). Silicon and oxygen ions bonded together (formers) to form the basic three-dimensional network structure in which ions of sodium, potassium, calcium, and magnesium (modifiers) are bonded in the holes inside the silicon–oxygen former network. Glass is one of the most durable building materials. An extremely important property of glass is its resistance to corrosion attack by water and acid.

There are three basic types of glass: float glass, plate glass, and sheet glass. Float glass is produced by pouring continuously from a furnace onto a large shallow bath of molten tin. In the flow chamber the atmosphere is controlled to prevent oxidation. The second type of glass is plate glass, which is produced by grinding and polishing rough glass. The third type is sheet glass, which is produced by continuously drawing molten glass from a bath through an annealing lehr. A simplified diagrammatic presentation of the production process is illustrated in Figure 29.2. Nowadays, more than 90% of glass is produced by the float process. The float glass is available in a number of modified forms: reflective coated glass, heat-absorbing glass, tempered glass, insulating glass, acoustical glass, etc.

Glass as a building material has been widely used in curtain wall and glass wall systems, which generally provide an esthetic appearance to the complete building. Large glass panels of size in

FIGURE 29.1 Simplified two-dimensional representation of a glass network.

FIGURE 29.2 Manufacturing processes of glass: (a) float glass, (b) plate glass, and (c) sheet glass.

excess of 1.5 m² are commonly used in commercial buildings to date. In practice, they are structurally glazed with structural sealants, on the four sides or on two sides with the other two edges clamped mechanically along the transoms. For shop fronts and entrances of prestigious buildings, an unobstructed view and architectural appearance can normally be provided by using a glass wall system. Generally speaking, their esthetic appearance is more appealing than that of other finishes.

When compared to other building materials such as concrete, steel, or even timber, glass receives relatively less attention from the researcher and the engineer. The probable reason for the lack of research in glass may be the perceptively moderate tendency for collapse when compared with other materials. However, as glass structures have no allowance for plastic deformation, overloading will

not be shed to other parts of a structure, and their breakage normally is without warning due to their brittleness. The breakage will lead to casualties when debris falls onto the street from a high-rise building. In the past two decades or so, it has been noted that glass structures are commonly constructed in areas of high human exposure such as shopping arcades and city malls. The failure of the structure may be catastrophic and cannot therefore be overlooked. Although the uses of laminated and tempered glass can lower the chance of harmful damage, they may not be preferred as they reduce the vision quality of glass.

The major reason for special care in the design of glass is that it has no ductility to allow moment or force redistribution like steel and concrete frames. Further, the overdesign is costly. In Hong Kong, the facade system normally takes a share from 15 to 20% of the total construction cost in a commercial building. Obviously, the resources spent on research in glass are far less than for other materials like concrete and steel. Although glass manufacturers provide design manuals for glass panels, many of these are based on the linear theory [2], which is of inadequate accuracy under high wind pressure. The American [3] and the Canadian [4] design codes of practice for glass require the consideration of nonlinear effect when the glass plate deflection is large and of a magnitude more than three-fourths of its thickness, which is very common in practice. In a general design of glass structures, the glass panel exhibits considerable change in geometry, and an accurate analysis should allow for the geometrically nonlinear effects in accordance with these design codes. Figure 29.3 shows the damage of buildings after a typhoon attack.

Studies have shown that breakage of annealed glass is due to the tensile stress on the hairy cracks on the surface of the panel, resulting in a serious stress concentration. Due to the difficulty in estimating the density and the extent of these hairy cracks in all glass panels, the failure probability instead of direct specification of failure load for a glass panel is usually used as a reference for safety of glass structures. Generally speaking, the probability of failure (POF) of 8/1000 is acceptable for most purposes. In congested areas, the POF should be further reduced.

In recent years, the extensive construction of high-rise buildings with curtain wall envelopes in many cities in China and Hong Kong has further highlighted the importance of conducting more research on

FIGURE 29.3 Damage of buildings after a typhoon attack.

the safety of these structures. In fact, at the time of writing this chapter, use of glass curtain walling is heavily criticized in China as a “hanging bomb.”

29.2 Strength of Glass

In most structural applications of glass it is necessary for the components to sustain mechanical stress. When a material is stressed, it deforms, and strains are created. At a low level of stress, most materials obey Hook’s law, that is, strain is proportional to stress. While the stress level is high, most materials deform plastically. Glass is a brittle material, which cannot accommodate this plastic deformation but breaks without warning. The stress–strain curve in Figure 29.4 shows a perfect linearity from zero strain to failure. The mechanical properties of glass as an engineering material are tabulated in Table 29.1.

Generally speaking, it can be stated that the theoretical strength of a piece of glass is equal to about one tenth of its modulus of elasticity [5]. Glass in compression is extremely strong. The compressive strength can approach 10,000 MPa without breakage. However, glass in tension usually fails at stress levels less than 100 MPa. It has been pointed out that the failure of glass [6] results from a tensile component of stress. Nowadays, it is generally accepted that the failure of glass originates at surface flaws [7] at which stresses are concentrated, as shown in Figure 29.5. Since basically no plastic flow is possible in glass, these flaws lead to high stress concentrations when glass surface is in tension. Because of the random nature of the flaws, a large variability in the strength of individual pieces of glass has been observed and reported [6]. Therefore, the failure strength of glass can only be expressed by means of a statistical analysis. Based on these statistical results, we can only obtain a design value at which the risk of fracture of glass is sufficiently low, but it provides no guarantee that the glass will survive under the design load level.

FIGURE 29.4 Stress–Strain diagram.

TABLE 29.1 Mechanical Properties of Glass

E — Young’s modulus of elasticity	10.4×10^6 psi or 7.2×10^{10} N/m ²
G — Modulus of rigidity	4.3×10^6 psi or 3.0×10^{10} N/m ²
μ — Poisson’s ratio	0.22
α — Coefficient of thermal expansion	$88 \times 10^{-7}/^\circ\text{C}$
ρ — Density	157 lb/ft ³ or 2.5 g/cm ³

An important property of glass is that its strength depends on the duration of load [6] application and on the environmental conditions. This concept is not familiar to engineers and architects. Basically, the relationship between stress and time can be expressed as

$$\sigma^n T = \text{constant} \tag{29.1}$$

where σ is the applied stress, while T is the duration of the stress, and n is a constant with a value between 12 and 20. Figure 29.6 illustrates the strength of glass against time. Since the duration of loading is

FIGURE 29.5 Surface flaw: (a) two-dimensional model of flaw on glass surface, (b) attack of water vapor on the crack, and (c) attack of water vapor on the crack under tensile stress.

FIGURE 29.6 Glass strength and load duration.

important in determining the failure load for a given glass panel, it is necessary to define the loadings in a time-dependent form.

29.2.1 Types of Glass

From a structural point of view, there are several types of glass used in buildings. Their basic properties are discussed as follows.

29.2.1.1 Tempered (Toughened) and Heat-Strengthened Glass

The fracture of glass is initiated from surface flaws. Therefore, the practical strength of glass may be increased by introducing a local high compressive stress near its surfaces. This can be achieved by means of thermal toughening in which the glass plate is heated to approximately 650°C , at which point it begins to soften. Then, its outer surfaces are cooled rapidly by air blasts. The exterior layers are quickly cooled and contracted. This creates a thin layer of high compressive stress at the surfaces, with a region of tensile stress at the center of the glass. As illustrated in Figure 29.7, the stress distribution across the thickness of a plate may be represented by a parabola. This parabolic stress distribution must also be in self-equilibrium. However, the exact shape of this curve depends on the geometric shape of the glass section and the physical properties of the particular glass composition used. The bending strength is usually increased by a factor of 3 to 5 of the strength of annealed glass. Generally speaking, the nominal breaking stress of the glass will be increased by an amount equal to the residual compressive stress

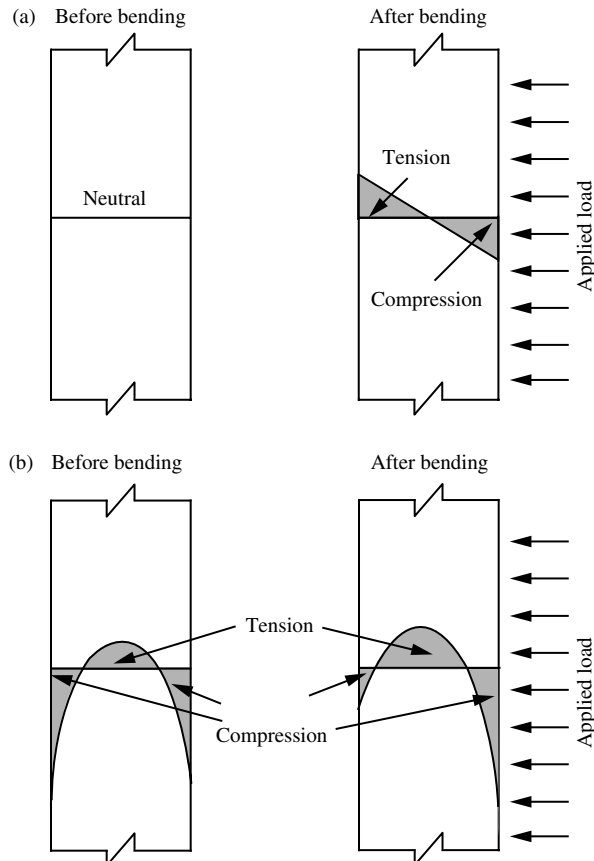

FIGURE 29.7 Stress profiles: (a) annealed glass and (b) toughened glass.

developed at the surface. When the toughened glass is broken, it fractures into small, harmless dice, which result from multiple crack branching due to the release of elastic energy.

29.2.1.2 Annealed Glass

This refers to those glass panels without heat treatment. The permissible stress is taken approximately as 15 N/mm^2 . Sometimes we cannot avoid using annealed glass because of manufacturing difficulties such as the glass panels being too large for heat treatment. Due to its small strength, annealed glass is weak in thermal resistance. Partial shading causes annealed glass to fail by thermal stress. Very often, glass fins are annealed.

29.2.1.3 Tinted Glass

Tinted glass or heat-absorbing glass is made by adding colorant to normal clear glass. Light transmittance varies from 14 to 85%, depending on color and thickness. Because of this, the tinted glass is hot, and heat-strengthened glass is normally used in making tinted glass.

29.2.1.4 Coated Glass

Coated glass is manufactured by placing layers of coating onto the glass surfaces. There are two types, the solar control (reflective) and the low-emissivity (low-e) types. They are more related to energy absorption and light transmission and only indirectly affect the structural strength by changing the thermal stress. Because of this, for colored glass to prevent excessive thermal stress, at least heat-strengthened glass should be used.

29.2.1.5 Wired Glass

Wired glass is made by introducing a steel mesh into molten glass during the rolling process. It is weak in resisting thermal stress and therefore has a high rate of breakage due to sunlight, etc. Polished wired glass is generally used for fire rating since after its breakage, it is stuck to the wire mesh and prevents passage of smoke. However, it is weak in resisting thermal stress. Figure 29.8 shows the damaged wired glass panels under sunlight.

FIGURE 29.8 Broken glass panel due to thermal stress.

FIGURE 29.9 Laminated glass when it is broken.

29.2.1.6 Laminated Glass

This is a very common form of glass formed by bonding two or more glass panes by interlayers like polyvinyl butyral (PVB) or resin. The thickness of this interlayer is normally 0.38, 0.76, 1.52 mm, etc. The major problem for laminated glass is the validity of composite action. Can we assume a composite action, that is, an 8- + 6-mm-thick laminated glass is equivalent to a 14-mm-thick glass? If not, does it behave as two separated panes 8 mm and 6 mm thick?

The actual response for a laminated glass is somewhere between these two extremes. For short-term load, the behavior is closer to composite assumption, while for long-term load, it behaves as separated panes because of creeping effect in the interlayer. However, as the actual response is dependent on the property of the interlayer, it may not be overgeneralized. One method is to use a simple test to measure the deflection of the panel under a specific load and then compare this with the deflection calculated by a finite element program. We can then adjust the equivalent thickness in the program to give the same deflection so that we can determine the equivalent thickness of the laminated glass pane and use it for economical and rational design. ASTM C1172 is a relevant standard for further information and testing. Figure 29.9 shows the property of laminated glass when broken.

29.3 Design of Glass

The linear deflection theory, which assumes that deflections are directly proportional to applied load, is of sufficient accuracy for many engineering applications. However, for a thin glass plate simply supported on four sides, the linear theory is invalidated when the deflection is larger than three fourths of its thickness (Canadian code [4]). The typical load versus central deflection curve for a glass panel is shown in Figure 29.10, and it can be seen that the linear theory is only valid in a small loading range before deflection is significant. The use of the linear theory will result in a deviation from the real solution as shown in Figure 29.10 for deflection and Figure 29.11 for stress. In the linear theory, the location of maximum stress is predicted at the plate center. In fact, the

FIGURE 29.10 Load vs. center deflection of a 4-side simply supported glass pane of 2000 mm × 1000 mm × 5.6 mm.

location of maximum stress changes with the load level and the aspect ratio of glass plate. This change is illustrated in Figure 29.11. From the figure, it can be seen that the maximum principal stresses at the corner and the center are more or less the same for aspect ratio equal to 1 and load level equal to 0.1 kPa in the glass plate under consideration. When the load level is increased to 0.76 kPa, the maximum principal stress at the corner increases more rapidly than the stress at the center. Thus, the maximum stress location is at the corner of the plate. On the other hand, the rate of increase of the maximum principal stress at the center is much faster than the rate of increase of the maximum principal stress at the corner for aspect ratio equal to 5. In this case, the maximum stress is located at the center of the plate. As mentioned above, the failure of glass depends on the stress state and surface flaws. Thus, there is a need to develop a numerical procedure to find out the stresses at various locations of the glass plate under different load levels in order to determine its load capacity in terms of probability of failure.

Glass type	Canadian ^a /U.S. ^b	Australian ^c	U.K. ^d	Chinese ^e
Load duration (s)	60	3	3	60
Load factor	1.5	—	—	1.4
Annealed (N/mm ²)	20–25 (edge/center, following similar)	20	41 for $t \leq 6$, 34.5 for $t \leq 8$, 28 for $t \leq 10$	28 for $5 < t < 12$ 20 for $15 < t < 19$
Heat-strengthened (N/mm ²)	40–50	32	—	—
Tempered (N/mm ²)	80–100	50	59	84 for $5 < t < 12$ 59 for $15 < t < 19$

FIGURE 29.11 Stress against aspect ratio at different load levels.

The design load for glass is time-dependent. It is accepted worldwide that it should be based on the 1-min constant and uniform loads. However, for most applications of glass, load duration has little to no effect on the long-term performance of glass. There are two common methods in the industry for determining glass strength. The first is the empirical glass-to-destruction test method, and the second is the analytical nondestructive computer method.

The empirical glass strength curves were developed from destructive test of glass plates to provide factual data on glass strength. At least 25 glass panes each thickness and area were tested to produce a statistical validity for the average breaking pressure under uniform load conditions. A typical design chart produced from the results of testing glass-to-destruction is included in the appendix of the ASTM Standard E300-84. The effect of aspect ratio of glass plate has not been indicated in this design chart.

Nowadays, the advances in computer technology and the dramatic reductions in computer cost make the computer method for determining glass strength more practical than previously. The finite element method has made it possible to determine glass design data with various supporting systems and loading cases effectively. The finite element method is adopted to calculate the magnitudes and orientations of stress and deflections of the glass plate. The computer outputs are then used with

a statistical or failure prediction model [8] to find out the glass breakage probabilities under the design condition. Glass breaks when the maximum principal tensile stress reaches the critical value determined by the failure prediction model, which is discussed in the subsequent section. Finite element computer analysis indicates that as the aspect ratio of the glass plate changes, the levels and locations of maximum tension stress are also varied. Thus, the method is more realistic in representing the glass strength.

29.4 Failure Criterion

For commercial glass widely used in curtain wall systems, failure and breakage are due to the stress concentrated at the invisible hairy crack on its surfaces. The failure stress of a piece of glass is more dependent on the density of these hairy cracks than the theoretical breakage stress, which can be as high as 10,000 MPa. Thus, a rational design failure stress is expressed in terms of the duration of load (Weibull's theory [9] for failure of brittle material). Treatment of glass to reduce surface tensile stress and the area of the glass panel is being considered by glass manufacturers. As glass plates are usually thin and undergo large displacements, the use of conventional thin plate linear bending theory will yield erroneous results. Indeed, to accurately compute the maximum stress in a panel for checking of stress against failure, the large deflection theory allowing for membrane stress should be used. In the breakage analysis of glass panels, failure is assumed to occur when the maximum tensile stress is equal to the breaking stress of the glass. For ductile material, the yield strength can be accurately measured and, typically, varies over a narrow range. However, as a brittle material, glass has no observable yield strength as other materials such as steel. Thus, the failure of glass can only be represented by breakage stress, which is obtained from a statistical basis. For tempered glass, the breakage stress is usually taken to be four times the failure stress for clear float glass. For heat-strengthened glass, where the tempering process is lighter than for tempered glass, the strength is twice that of annealed glass.

The Canadian Code has adopted the failure prediction model developed by Beason and Morgan [8]. The failure prediction model is based on the simplified formulation, which has been presented by Brown [10] to model the glass strength with load duration. The resistance to failure of a surface flaw can be expressed as follows:

$$K_f = \int_0^{T_f} [\sigma(T)]^n dT \quad (29.2)$$

where T is the load duration and K_f is the resistance to failure of a surface flaw exposed to tensile stress and water vapor. The nominal tensile stress, $\sigma(T)$, at the flaw is expressed as a function of time, and n is a constant of which the value of the best fit, from experimental data, is found to be 16 (Dalglish and Taylor [11]). The duration of the loading causing failure is expressed as T_f . The glass plate fails when K_f reaches some critical values which depend on the flaw's characteristics and stress state at the flaw. With Equation 29.2, we can adjust the strength of glass for different load durations. In a computer analysis, we can compute constant pressure causing glass breakage and relate this to failure pressure with different load durations as follows:

$$P_{60} = P_f \left[\frac{T_f}{60} \right]^{1/n} \quad (29.3)$$

where P_{60} is the constant pressure causing failure of the panel in 60 s and P_f is the constant pressure causing failure at a duration of T_f s.

The use of a design factor of 2.5 has been introduced to control the POF to 0.008. The POF can be expressed in terms of Weibull distribution as follows:

$$\text{POF} = 1 - e^{-B} \quad (29.4)$$

where B is a function that reflects the risk of failure and is given as

$$B = \left(\frac{A}{A_0}\right) \left(\frac{S_{m,p,r}}{S_0}\right)^m \quad (29.5)$$

where e is a natural number, A_0 and S_0 are the area and characteristic strength of the reference glass panel, respectively and A and $S_{m,p,r}$ are the area and characteristic strength of the glass panel, respectively. $S_{m,p,r}$ is a function of the Weibull parameter, m , pressure, p , and aspect ratio, r . Failure data for in-service glass were collected (see Ref. [12]) and fitted to Equation 29.5. The fitted Weibull parameters $m=7$ and $S_0=32.1$ MPa are adopted in Canadian Code, and the reference area, A_0 , is equal to 1 m^2 .

29.5 Stress Evaluation and Common Causes of Breakages

The failure of glass is assumed when the principal tensile stress is equal to or greater than the characteristic strength calculated in Equation 29.5. The bending stress is assumed to vary linearly across the thickness of the plate, and the membrane stress is constant across the thickness of the plate. The total stress is obtained by superimposing the bending and membrane stresses. The stress components at each of the three nodes of the element are then used to calculate the principal stresses within the element. The nodal stresses are averaged at nodes that are attached to more than one element.

29.5.1 Common Causes of Glass Breakage

The causes of breakage for glass can be due to (*not* in order of importance)

- Excessive stress from wind pressure or other loads.
- Thermal stress due to differential temperature on different parts of the pane (for 33°C , the thermal stress is 20.7 N/mm^2).
- Buckling due to large compression (e.g., glass rod and glass fins).
- Surface or edge damage.
- Deep scratches or gouges.
- Severe weld splatter.
- Windborne missiles (i.e., debris impact).
- Direct contact with metal (e.g., window aluminum frame).
- Impurities like nickel sulfide (NiS).
- Excessive deflection bringing glass in contact with other hard objects.

29.5.2 Impurities

One big disadvantage in using tempered glass is the problem of spontaneous breakage due to impurities like NiS. NiS is formed when nickel-rich contaminants like nichrome wire and stainless steel are unavoidably introduced into the glass melting furnace, and when they are mixed with sulfur, NiS is formed. They are harmless in annealed or heat-strengthened glass since the induced stress cannot break the tensile failure stress of glass but causes instantaneous breakage when they are located at the tension zone of tempered glass and expand with temperature and time. For surface stress less than 52 N/mm^2 , NiS is not a problem since its expansion, together with the tensile prestress, cannot generate a breaking stress higher than the failure tension stress of the glass. Therefore, using heat-strengthened glass is a means of solving the problem of NiS. Heat-soaking test is a procedure to break the glass panels

FIGURE 29.12 Glass breakage due to nickel sulfide.

containing NiS in the factory rather than after installation. The time and temperature are important in heat-soaking, and their requirement varies from one country to another. Figure 29.12 shows a picture of glass breakage due to NiS, which is signified by the origin as a pair of butterfly wings.

29.6 Numerical Examples for Breakage Analysis of Glass Structure

Any numerical or analytical method must first be tested and validated before it can be actually used. The limitations and scopes of the method must be clearly investigated and defined. This chapter presents a verification study on the application of the developed finite element method for several nonlinear problems for glass structures. The accuracy of the developed method is then compared with the available solution.

The first example is to compare the results of in-service glass obtained by the Institute for Research in Construction (IRC) [12]. Totally, 47 pieces of in-service glasses obtained from the University of Ottawa's Thompson Residence tested to failure. The second example is the simulation of a curved glass panel under positive and negative wind load. Curved glass panels are frequently used in the construction of observation lift cladding or the exterior staircase of modern prestigious buildings. The third and fourth examples are concerned with glass fin systems that are widely used in shop fronts and entrances of buildings. Two examples of elastic supports are presented that visualize the effects of out-of-plane and in-plane stiffnesses of sealants on the stress distribution within the loaded glass plate. Finally, the results of the simulation of flexible support are compared with a full-scale mock-up test.

29.7 Failure Test of In-Service Glass

The strengths of new glass and in-service glass differ considerably. While the design of glass panels is mostly based on new glass, the actual failure load of in-service glass is of greater interest when one considers safety during the service life of a building.

In this example, the testing results obtained by the IRC of the National Research Council of Canada for 47 in-service window glasses removed from the University of Ottawa's Thompson Residence in 1986 were compared.

The breaking stress of glass is determined by Equations 29.4 and 29.5 with the characteristic strength equal to 32.1 MPa, probability of failure equal to 0.008, reference area, A_0 , equal to 1 m^2 , and the Weibull parameter, m , equal to 7 as recommended by the Canadian Code. It is generally believed that in-service time reduces the breakage stress of a glass panel due to the increased density

TABLE 29.2 Test Results of In-Service Glass (Mean = 2.51, Standard Deviation = 0.62)

of hairy cracks on glass surfaces in the course of resisting wind loads and also when subjected to natural or man-made scratches.

The equivalent 60-s pressure of the testing results and output by NASHell [13] are tabulated in Table 29.2. The average ratio of failure load to the predicted breaking load by NASHell is 2.51. This ratio is considered to be in a reasonable range because the failure stress used in NASHell has included the probability of failure of 8/1000. Not a single sample has a failure load lowered than the predicted load, indicating the reliability of the suggested method in the design of in-service glass panels.

The standard deviation, however, for the failure loads is quite large and is equal to 0.62. This demonstrates the variability of glass strength in practice and also that the nature and behavior of glass strength can only be represented as a probability of failure.

29.8 Curved Glass Panel

In this example, a curved glass panel with base or projected dimension of $1500\text{ mm} \times 1500\text{ mm}$, radius of 1500 mm , Young's modulus of $70,000\text{ MPa}$, Poisson's ratio of 0.22 and thickness of 8 mm , and under uniform lateral load is analyzed (see Figure 29.13). The longitudinal boundaries are hinged and immovable, while the curved edges are restrained in the longitudinal direction. Due to symmetry, only a quarter of the panel is analyzed with mesh size of 10×10 . In Figure 29.14, we can see the load–deflection path at the plate center and the failure loads for annealed glass and tempered glass under positive and negative pressure. Failure is assumed when the maximum principal tensile stress reaches the characteristic strength of 14.25 MPa , which is calculated from Equations 29.4 and 29.5. For tempered glass, the failure stress is assumed to be four times the value for annealed glass [12].

From the figures, it can be seen that the failure pressure ratio for annealed and tempered glasses is the same as the ratio of their stresses where the geometrical change is not significant. However, for compressive load case, the failure pressure ratio for annealed to tempered glasses may not be equal to the ratio of their failure stresses. This is due to the large change in geometry resulting in the nonlinearity between the stress and the load.

29.9 Flexible Support for Full-Scale Mock-Up Test

In this example, the results obtained from a full-scale curtain wall test were compared with the numerical results obtained from the computer program NASHell. In this analysis, the mullions and

FIGURE 29.13 Layout and properties of curved glass panel.

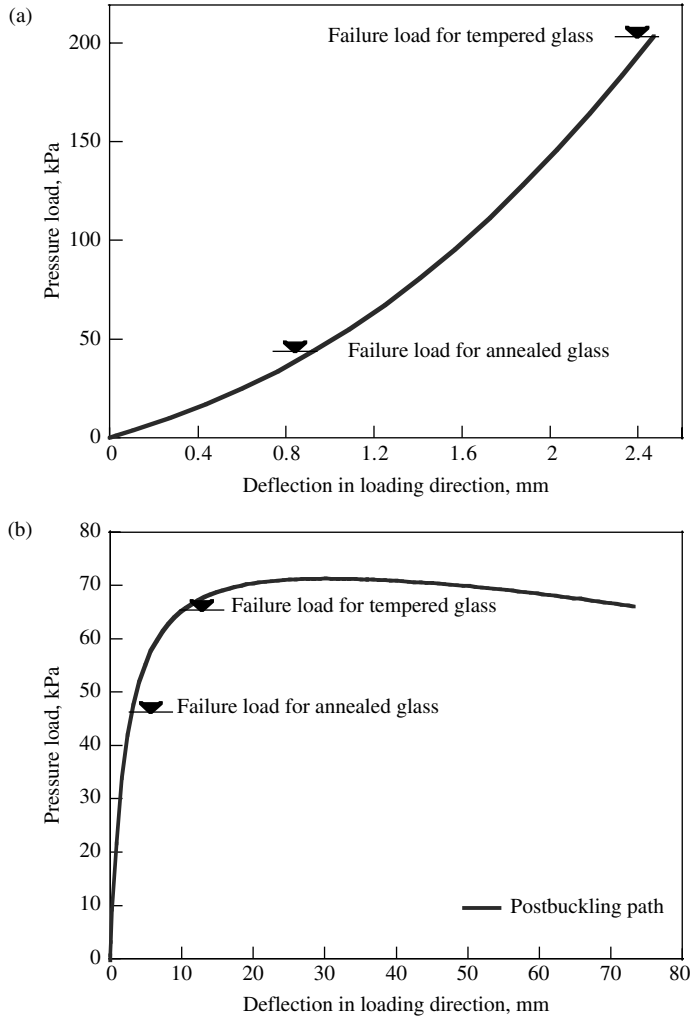

FIGURE 29.14 Load–deflection path of the curved glass at the center: (a) positive pressure and (b) negative pressure.

transoms were modeled by beam element. The size of the glass panel is 1200 mm × 1800 mm × 10 mm (47.25 in. × 70.9 in. × 0.4 in.). The mullions and transoms are aluminum rectangular hollow sections of size 45 mm × 100 mm × 3 mm. The details of the section profile and layout are shown in Figure 29.15. The curtain wall is subjected to a lateral uniform pressure of 3.85 kPa (0.56 psi). Young’s modulus of glass is taken as 71,700 MPa (10.4×10^6 psi) and Poisson’s ratio, as 0.22. Young’s modulus of aluminum is 70,000 MPa.

This problem is aimed to investigate the influence of mullion and transom flexibility to the glass strength. Structural members supporting glass panels are normally supported by brackets to concrete slab or spandrel. Due to the high cost of aluminum and its small Young’s modulus of elasticity of about one third that of steel, the members are generally flexible, so that deflection is commonly a design criterion. In practice, a span of $\frac{1}{175}$ is the tolerance since it is believed that a large deflection in mullion or transom will create a stress pattern on glass that is different from the assumed rigid support case.

This example is aimed to investigate the effect of flexible support due to flexibility in structural members, which, to our knowledge, was not studied previously, though a limiting value of $\frac{1}{175}$ of span is recommended in the Canadian Code of Practice [12].

FIGURE 29.15 Layout of the tested full-scale sample.

TABLE 29.3 Flexible Supports

	Central deflection of glass (mm)	Midpoint deflection of mullion (mm)	Midpoint deflection of transom (mm)
Full-scale mock-up test	12.84	7.45	1.43
NAShell	12.14 (94.55%)	7.36 (98.79%)	1.36 (95.10%)
Built-in fixed support ^a	6.15 (47.90%)	N/A	N/A
Roller simply support ^b	8.99 (70.02%)	N/A	N/A

^a Lateral deflection and rotation are fixed.

^b Lateral deflection is fixed but free to rotate.

Note: Values in parentheses refer to the ratio of the deflections to the measured deflections in the test.

From Table 29.3, we can see that we have underestimated the glass deflection of the glass plate if we consider that the glass plate is fixed support (in rotation and translation) or even simply support (restrained only in translation). The actual deflection of the glass is about double in the case of fixed support and about 1.4 times in the case of simply support. On the other hand, we observe that the deflections obtained by NAShell are close to those in the mock-up test, and the errors in the prediction of deflections are acceptable in engineering practice. The underestimation of deflection would

probably increase the chance of contact with hard objects such as a concrete wall behind the glass and hence increase the failure rate. Deflection limit for serviceability requirement is normally taken as one-sixtyth of shorter span.

29.10 Conclusions

The concept and method for design and analysis of glass panels is described in this chapter. The validity of the finite element formulation has been demonstrated for flat and curved panels with in-plane edge support flexibility. All these problems are related to the practical design of the glass system. Further, a summary of possible causes of breakage for glass panels is presented. It can be seen that, with a proper design and analysis method and methods of installation, glass structures can be designed to meet the safety and serviceability requirements.

30.1 Introduction

Truss connections in circular hollow sections (CHS) present unique design challenges. This chapter discusses the following elements of the subject: Architecture, Characteristics of Tubular Connections, Nomenclature, Failure Modes, Reserve Strength, Empirical Formulations, Design Charts, Application, and Summary and Conclusions.

30.2 Architecture

Architecture is defined as the art and science of designing and successfully executing structures in accordance with aesthetic considerations and the laws of physics, as well as practical and material considerations. Where tubular structures are exposed for dramatic effect, it is often disappointing to see grand concepts fail in execution due to problems in the structural connections of tubes. Such “failures” range from awkward ugly detailing, to learning curve problems during fabrication, to excessive deflections or even collapse. Such failures are unnecessary, as the art and science of welded tubular connections has been codified in the American Welding Society (AWS) *Structural Welding Code* [1]. The AWS design criteria have also been incorporated into the American Institute of Steel Construction (AISC) Specification for the design of steel hollow structural sections [2].

A well-engineered structure requires that a number of factors be in reasonable balance. Factors to be considered in relation to economics and risk in the design of welded tubular structures and their connections include (1) static strength, (2) fatigue resistance, (3) fracture control, and (4) weldability. Static strength considerations are so important that they often dictate the very architecture and layout of the structure; certainly, they dominate the design process and are the focus of this chapter. Many of the other factors also require early attention in design, and it is of benefit to set up quality control/quality assurance programs during construction; these are discussed further in sections of the Code dealing with materials, welding technique, qualification, and inspection.

The designer of record is responsible for structural connections and should not attempt to abdicate his responsibility by placing a “Truss Note” on the drawings such as “All welded truss connections shall develop the full axial capacity of each member at a stress of $0.6F_y$.” The fabricator might simply provide matching weld sizes and let it go at that.

30.3 Characteristics of Tubular Connections

Tubular members benefit from an efficient distribution of their material, particularly in regard to beam bending or column buckling about multiple axes. However, their resistance to concentrated radial load is more problematic. For architecturally exposed applications, the clean lines of a closed section are esthetically pleasing, and they minimize the amount of surface area for dirt, corrosion, or other fouling. Simple welded tubular joints can extend these clean lines to include the structural connections.

Although many different schemes for stiffening tubular connections have been devised [3], the most practical connection is made by simply welding the branch member to the outside surface of the main member (or chord). Where the main member is relatively compact (D/T less than 15 or 20), the branch member thickness is limited to 50 or 60% of the main member thickness, and a prequalified weld detail is used, the connection can develop the full static capacity of the members joined. Where the foregoing conditions are not met, for example, with large-diameter tubes, a short length of heavier material (or joint can) is inserted into the chord to locally reinforce the connection area. Here, the design problem reduces to one of selecting the right combination of thickness, yield strength, and notch toughness for the chord or joint can. Sometimes the entire chord of a truss is sized to satisfy connection requirements. The detailed considerations involved in this design process are the subject of this chapter.

30.4 Nomenclature

Nondimensional parameters for describing the geometry of a tubular connection are given in the following list. Beta, eta, theta, and zeta describes the surface topology. Gamma and tau are two very important thickness parameters. Alpha (not shown) is an ovalizing parameter, depending on load pattern (it was formerly used for span length in beams loaded via tee connections).

β (beta)	d/D , branch diameter/main diameter
η (eta)	branch footprint length/main diameter
θ (theta)	angle between branch and main member axis
ζ (zeta)	g/D , gap/diameter (between balancing branches of a K connection)
γ (gamma)	R/T , main member radius/thickness ratio
τ (tau)	t/T , branch thickness/main thickness

In AWS D1.1 [1], the term “T-, Y-, and K connection” is used generically to describe simple structural connections or nodes, as opposed to coaxial butt and lap joints. A letter of the alphabet (T, Y, K, X) is used to evoke a picture of what the node subassembly looks like.

30.5 Failure Modes

A number of unique failure modes are possible in tubular connections. In addition to the usual checks on weld size, provided for in most design codes, the designer must check for the following failure modes, listed together with the relevant AWS and AISC Code sections.

	AWS	AISC
Local failure (punching shear)	2.24.1.1	9.4 ¶2
General collapse	2.24.1.2	9.4 ¶2.6.3
Unzipping (progressive weld failure)	2.24.1.3	Ref. to AWS
Materials problems	2.26	—
Fracture	C4.12.4.4	—
Delamination	C2.6.3	—
Fatigue	2.36.6	—

30.5.1 Local Failure

AWS design criteria for this failure mode have traditionally been formulated in terms of punching shear. The main member acts as a cylindrical shell in resisting the concentrated radial line loads (force/length, e.g., kip/in.) delivered to it at the branch member footprint. Although the resulting localized shell stresses in the main member are quite complex, a simplified, but still quite useful, representation can be given in terms of punching shear stress, v_p :

$$\text{acting } v_p = f_n \tau \sin \theta \tag{30.1}$$

where f_n is the nominal stress at the end of the branch member, either axial or bending, which is treated separately. Punching shear is the notional stress on the potential failure surface, as illustrated in Figure 30.1. The overriding importance of chord thickness is reflected in tau, while $\sin \theta$ indicates that it is the radial component of load that causes all the mischief.

FIGURE 30.1 Local failure mode and punching shear v_p .

The allowable punching shear stress is given in the AWS Code as

$$\text{allowable } v_p = \frac{F_{y0}}{0.6\gamma} \cdot Q_q \cdot Q_f \quad (30.2)$$

We see that the allowable punching shear stress is primarily a function of main member yield strength (F_{y0}) and gamma ratio (main member radius/thickness), with some trailing terms that tend toward unity. The term Q_q reflects the considerable influence of connection type, geometry, and load pattern, while interactions between branch and chord loads are covered by the reduction factor Q_f . Interactions between brace axial load and bending moments are treated analogous to those for a fully plastic section.

Since 1992, the AWS Code also includes tubular connection design criteria in total load ultimate strength format, compatible with a load and resistance factor design (LRFD) design code formulation. This was derived from and is roughly equivalent to the original punching shear criteria and is the format adopted by AISC.

30.5.2 General Collapse

In addition to local failure of the main member in the vicinity of the branch member, a more widespread mode of collapse may occur, for example, general ovalizing plastic failure in the cylindrical shell of the main member. To a large extent, this is now covered by strength criteria that are specialized by connection type and load pattern, as reflected in the Q_q factor.

For balanced K connections, the inward radial loads from one branch member is compensated by outward loads on the other, ovalizing is minimized, and capacity approaches the local punching shear limit. For T and Y connections, the radial load from the single branch member is reacted by beam shear in the main member or chord, and the resulting ovalizing leads to lower capacity. For cross- or X-connections, the load from one branch is reacted by the opposite branch, and the resulting double dose of ovalizing in the main member leads to still further reductions in capacity. The Q_q term also reflects reduced ovalizing and increased capacity, as the branch member diameter approaches that of the main member.

Thus, for design purposes, tubular connections are classified according to their configuration (T, Y, K, X, etc.). For these “alphabet” connections, different design strength formulae are often applied to each different type. Until recently, the research, testing, and analysis leading to these criteria dealt only with connections having their members in a single plane, as in a roof truss or girder.

Many tubular space frames have bracing in multiple planes. For some loading conditions, these different planes interact. When they do, criteria for the “alphabet” joints are no longer satisfactory. In AWS, an “ovalizing parameter” (alpha, D1.1 Annex L) may be used to estimate the beneficial or deleterious effect of various branch member loading combinations on main member ovalizing. This reproduces the trend of increasingly severe ovalizing in going from K to T/Y to X connections and has been shown to provide useful guidance in a number of more adverse planar (e.g., all-tension double-K [4]) and multiplanar (e.g., hub) situations. However, for similarly loaded members in adjacent planes, for example, paired KK connections in delta trusses, data from Japan indicate that no increase in capacity over the corresponding uniplanar connections should be undertaken [5].

The effect of a short joint can (less than 2.5 diameters) in reducing the ovalizing or crushing capacity of cross-connections is addressed in AWS Section 2.24.1.2(2). Since ovalizing is less severe in K connections, the rule of thumb is that the joint can need only extend 0.25 to 0.4 diameters beyond the branch member footprints to avoid a short-can penalty. Intermediate behavior would apply to T/Y connections.

A more exhaustive discussion would also consider the following modes of general collapse in addition to ovalizing: beam bending of the chord (in T-connection tests), beam shear (in the gap of K connections), transverse crippling of the main member sidewall, and local buckling due to uneven load transfer (either brace or chord). These are illustrated in [Figure 30.2](#).

FIGURE 30.2 Failure modes — general collapse: (a) ovalizing, (b) beam bending, (c) beam shear in the gap, (d) sidewall (web) crippling, and (e) local buckling due to uneven distribution of axial load.

30.5.3 Unzipping or Progressive Failure

The initial elastic distribution of load transfer across the weld in a tubular connection is highly nonuniform, as illustrated in [Figure 30.3](#), with the peak line load often being a factor of 2 higher than that indicated on the basis of nominal sections, geometry, and statics. Some local yielding is required for tubular connections to redistribute this and reach their design capacity. If the weld is a weak link in the system, it may “unzip” before this redistribution can happen. Criteria given in the AWS Code are intended to prevent this unzipping, taking advantage of the higher reserve strength in weld allowable stresses than is the norm elsewhere. For traditional mild steel tubes (not multigrade material of higher actual strength) and overmatched E70 weld metal, a weld effective throat as small as 70% of the branch member thickness has been permitted. Other codes and design situations require effective throats of 100 or 110%.

FIGURE 30.3 Uneven distribution of load across the weld.

30.5.4 Materials Problems

Most fracture control problems in tubular structures occur in the welded tubular connections, or nodes. These require plastic deformation to reach their design capacity. Fatigue and fracture problems for many different node geometries are brought into a common focus by use of the “hot spot” stress, as would be measured by a strain gauge, adjacent to and perpendicular to the toe of the weld joining branch to main member, in the worst region of localized plastic deformation (usually in the chord). Hot spot stress has the advantage of placing many different connection geometries on a common basis with regard to fatigue and fracture.

Charpy impact testing is a method for qualitative assessment of material toughness. The method has been, and continues to be, a reasonable measure of fracture safety when employed with a definitive program of nondestructive testing to eliminate weld area flaws. The AWS recommendations for material selection (C2.26.2.2) and weld metal impact testing (C4.12.4.4) are based on practices that have provided satisfactory fracture experience in offshore structures located in moderate temperature environments, that is, 40°F (+5°C) water and 14°F (−10°C) air exposure. For environments that are either more or less hostile, impact testing temperatures should be reconsidered based on the lowest anticipated service temperature (LAST).

In addition to weld metal toughness, consideration should be given to controlling the properties of the heat affected zone (HAZ). Although the heat cycle of welding sometimes improves hot rolled base metals of low toughness, this region will more often have degraded toughness properties. A number of early failures in welded tubular connections involved fractures that either initiated in or propagated through the HAZ, often obscuring the identification of other design deficiencies, for example, inadequate static strength.

A more rigorous approach to fatigue and fracture problems in welded tubular connections has been taken by using fracture mechanics [6]. The crack tip opening displacement (CTOD) test is used to characterize materials that are tough enough to undergo some plasticity before fracture.

Underneath the branch member footprint, the main member is subjected to stresses in the thru-thickness or short transverse direction. Where these stresses are tensile, due to weld shrinkage or applied loading, delamination may occur — either by opening up preexisting laminations or by laminar tearing in which microscopic inclusions link up to give a fracture having a woody appearance, usually in or near the HAZ. These problems are addressed in API joint can steel specifications 2H, 2W, and 2Y. Preexisting laminations are detected with ultrasonic testing. Microscopic inclusions are prevented by restricting sulfur to very low levels (<60 ppm) and by inclusion of shape control metallurgy in the steel-making ladle. As a practical matter, weldments that survive the weld shrinkage phase usually perform satisfactorily in ordinary service.

Joint can steel specifications also seek to enhance weldability with limitations on carbon and other alloying elements, as expressed by carbon equivalent or P_{cm} formulae. Such controls are increasingly important as residual elements accumulate in steel made from scrap. In AWS Appendix XI [1], the preheat required to avoid HAZ cracking is related to the carbon equivalent, base metal thickness, hydrogen level (from welding consumables), and degree of restraint.

30.5.5 Fatigue

This failure mode has been observed in tubular joints in offshore platforms, dragline booms, drilling derricks, radio masts, crane runways, and bridges. The nominal stress, or detail classification approach, used for nontubular structures fails to recognize the wide range of connection efficiencies and stress concentration factors that can occur in tubular structures. Thus, fatigue design criteria based on either punching shear or hot spot stress appear in the AWS Code. The subject is also summarized in recent papers on tubular offshore structures [7,8].

30.6 Reserve Strength

While the elastic behavior of tubular joints is well predicted by shell theory and finite element analysis, there is considerable reserve strength beyond theoretical yielding due to triaxiality, plasticity, large deflection effects, and load redistribution. Practical design criteria make use of this reserve strength, placing considerable demands on the notch toughness of joint can materials. Through joint classification (API) or an ovalizing parameter (AWS), they incorporate elements of general collapse as well as local failure. The resulting criteria may be compared against the supporting database of test results to ferret out bias and uncertainty as measures of structural reliability. Data for K, T/Y, and X joints in compression show a bias on the safe side of 1.35, beyond the nominal safety factor of 1.8, as shown in [Figure 30.4](#). Tension joints appear to show a larger bias of 2.85; however, this reduces to 2.05 for joints over 0.12 in. thick and 1.22 for joints over 0.5 in., suggesting a thickness effect for tests that end in fracture.

For overload analysis of tubular structures (e.g., earthquake), we need not only ultimate strength but also the load–deflection behavior. Early tests showed ultimate deflections of 0.03 to 0.07 chord diameters, giving a typical ductility of 0.10 diameters for a brace with weak joints at both ends. As more different types of joints were tested, a wider variety of load–deflection behaviors emerged, making such generalizations tenuous.

Cyclic overload raises additional considerations. One issue is whether the joint will experience a ratcheting or progressive collapse failure or will achieve stable behavior with plasticity contained at local hotspots, a process called “shakedown” (as in shakedown cruise). Tubular connections have withstood 60 to several hundred repetitions of plastic strain at loads in excess of their nominal capacity. A conservative analytical treatment is to extend the hot spot S–N design curve into the low-cycle range as strain.

When tubular joints and members are incorporated into a space frame, the question arises as to whether computed bending moments are primary (i.e., necessary for structural stability, as in a sideway portal situation, and must be designed for) or secondary (i.e., an unwanted side effect of deflection, which may be safely ignored or reduced). When proportional loading is imposed, with both axial load and bending moment being maintained regardless of deflection, the joint simply fails when it reaches its failure envelope. However, when moments are due to imposed lateral deflection, and then axial load is imposed, the load path skirts along the failure envelope, shedding the moment and sustaining further increases in axial load.

Another area of interaction between joint behavior and frame action is the influence of brace bending or rotation on the strength of gap K connections. If rotation is prevented, bending moments develop that permit the gap region to transfer additional load. If the loads remain strictly axial, brace end rotation occurs in the absence of restraining moments, and a lower joint capacity is found. These problems arise for circular tubes as well as box connections, and a recent trend has been to conduct joint-in-frame tests to achieve a realistic balance between the two limiting conditions. Loads that maintain their original direction

FIGURE 30.4 Comparison of AWS design criteria with the WRC database.

(as in an inelastic finite element analysis) or, worse yet, follow the deflection (as in testing arrangements with a two-hinge jack) result in a plastic instability of the compression brace stub as a column, which grossly understates the actual joint strength. Existing databases may need to be screened for this problem.

30.7 Empirical Formulations

Because of the foregoing reserve strength issues, AWS design criteria have been derived from a database of ultimate strength tubular joint tests. Comparison with the database (Figure 30.4) indicates a safety index of 3.6 against known static loads for the AWS punching shear criteria.

Safety index is the safety margin, including hidden bias, expressed in standard deviations of total uncertainty. Since these criteria are used to select the main member chord or joint can, the choice of safety index is similar to that used for sizing other structural members, rather than the higher safety margins used for workmanship-sensitive connection items such as welds or bolts.

When the ultimate axial load is used in the context of AISC-LRFD, with a resistance factor of 0.8, AWS ultimate strength is nominally equivalent to punching shear allowable stress design (ASD) for structures having 40% dead load and 60% live load. LRFD falls on the safe side of ASD for structures having a lower

proportion of dead load. AISC criteria for tension and compression members appear to have made the equivalency trade-off at 25% dead load; thus, the LRFD criteria given by AWS would appear to be conservative for a larger part of the population of structures. In Canada, using these resistance factors with slightly different load factors, a 4.2% difference in overall safety factor results — within calibration accuracy [9].

30.8 Design Charts

Research, testing, and applications have progressed to the point where tubular connections are about as reliable as the other structural elements with which designers deal. One of the principal barriers to more widespread use seems to be unfamiliarity. To alleviate this problem, design charts for connections of circular tubes have been presented by Marshall [10]. Packer’s original charts for square and rectangular tubes appear in the AISC Manual.

The capacity of simple, direct, welded, tubular connections are given in terms of punching shear efficiency, E_v , where

$$E_v = \frac{\text{allowable punching shear stress}}{\text{main member allowable tension stress}} \tag{30.3}$$

Charts for punching shear efficiency for axial load, in-plane bending, and out-of-plane bending appear as Figure 30.5 to Figure 30.9. Note that for axial load, separate charts are given for K connections, T/Y connections, and X connections, reflecting their different load patterns and different values of the ovalizing parameter (α). Within each connection or load type, punching shear efficiency is a function of the geometry parameters, diameter ratio (β), and chord radius or thickness (γ), as defined earlier. For K connections, the gap, g , between braces (of diameter d) is also significant, with the behavior reverting to that of T/Y connections for a very large gap. Punching shear efficiency cannot exceed a value of $0.4F_{y0}/0.6F_y = 0.67$, the material limit for shear.

FIGURE 30.5 Values of Q_q for axial load in K connections.

FIGURE 30.6 Values of Q_q for axial load in T and Y connections.

FIGURE 30.7 Values of Q_q for axial load in X connections and other configurations subject to crushing.

30.8.1 Joint Efficiency

The importance of branch/chord thickness ratio tau (t/T) and of angle ($\sin \theta$) becomes apparent in the expression for joint efficiency, E_j , given by

$$E_j = \frac{E_v \cdot Q_f}{(t/T) \sin \theta} \cdot \frac{F_{y0}(\text{chord})}{F_y(\text{branch})} \tag{30.4}$$

where Q_f is the derating factor to account for chord utilization (described in Section 30.8.2), and the ratio of specified minimum yield strengths F_{y0}/F_y drops out if chord and branch are of the same material. In LRFD, joint efficiency is the characteristic ultimate capacity of the tubular connection, as a fraction of the branch member yield capacity. In ASD, joint efficiency is the branch member nominal stress (as a fraction of tension allowable) at which the tubular connection reaches its allowable punching shear. Connections with 100% joint efficiency develop the full yield capacity of the attached branch member, in either design format.

FIGURE 30.8 Values of Q_q for in-plane bending.

FIGURE 30.9 Values of Q_q for out-of-plane bending.

30.8.2 Derating Factor

In most structures, the main member (chord) at tubular connections must do double duty, carrying loads of its own (axial stress f_a and bending f_b) in addition to the localized loadings (punching shear) imposed by the branch members. Interaction between these two causes a reduction in the punching shear capacity, as reflected in the Q_f derating factor, shown in Figure 30.10.

In-plane bending experiences the most severe interaction, as localized shell bending stresses at the tubular intersection are in the same direction and directly additive to the chord's own nominal stresses over a large part of the cross-section. For chords with very high R/T (γ) and high nominal compressive stresses, buckling tendencies further reduce the capacity for localized shell stresses.

Out-of-plane bending is less vulnerable to both these sources of interaction, as high shell stresses only occupy a localized part of the cross-section and are transverse to $P-\Delta$ effects. Axially loaded connections of the types tested thus far exhibit intermediate behavior (although the gap region in K connections might be expected to behave more like in-plane bending).

30.9 Application

What follows is a step-by-step design procedure for simple tubular trusses, applying the charts presented in the foregoing section:

- Step 1.* Lay out the truss and calculate member forces using statically determinate pin-end assumptions. Flexibility of the connections results in secondary bending moments being lower than those given by typical rigid-joint computer frame analyses.
- Step 2.* Select members to carry these axial loads, using the appropriate governing design code, for example, AISC. While doing this, consider the architecture of the connections along the following guidelines:
- A. Keep compact members, with especially low D/T for the main member (chord).
 - B. Keep branch/main thickness ratio (τ) less than unity, preferably about 0.5.
 - C. Select branch members to aim for large beta (branch/main diameter ratio), subject to avoidance of large eccentricity moments.
 - D. In K connections, use a minimum gap of 2 in. between the braces for welding access. For small tubes, this may be reduced to 20% of the branch member diameter. Connection eccentricities up to 25% of the chord diameter may be used to accomplish this. Reconsider truss layout if this gets awkward.
- Step 3.* Calculate and distribute eccentricity moments and moments due to loads applied in-between panel points. These are not secondary moments and must be provided for. They may be allocated entirely to the chord, for connection eccentricities less than 25% of the chord diameter, but should be distributed to both chord and braces for larger eccentricities, portal frames, or Vierendeel-type trusses. Recheck members for these moments and resize as necessary.
- Step 4.* For each branch member, calculate A_y , utilization against member-end yield at the joint. For ASD:

$$A_y = \frac{|f_a|}{0.6F_y} \quad \text{or} \quad \frac{|f_b|}{0.6F_y} \quad (30.5)$$

where f_a is the nominal axial stress and f_b is the bending in the branch. Where used, the $\frac{1}{3}$ increase is applicable to the denominator.

- Step 5.* Also calculate chord utilization, using the formula in [Figure 30.10](#) with chord nominal stresses and specified minimum yield strength. Use the appropriate chart in the figure to determine the derating factor Q_r . At heavily sheared gap K connections and at eccentric bearing shoes, it may (rarely) also be necessary to check beam shear in the main member and its interaction with other chord stresses, for example, using AISC criteria. For circular sections, the effective area for beam shear is half the gross area.
- Step 6.* For each end of each branch member, calculate the joint efficiency, E_j , using Equation 30.4 and the appropriate charts for punching shear efficiency, E_v . Joint efficiencies less than 0.5 are sometimes considered poor practice, rendering the structure vulnerable to incidental loads that the members could resist but not the weaker joints.
- Step 7.* For axial loading alone, or bending alone, the connection is satisfactory if member-end utilization is less than joint efficiency, that is, $A_y/E_j \leq 1.0$. For the general case, with

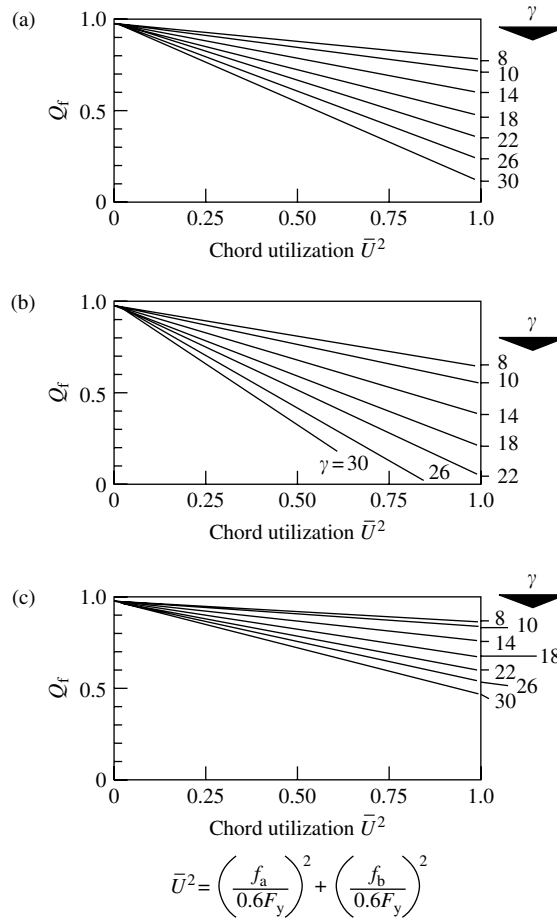

FIGURE 30.10 Derating factor Q_q for (a) axial loads in branch, (b) in-plane bending, and (c) out-of-plane bending.

combinations of axial load and bending, the connection must satisfy the following interaction formula:

$$(A_y/E_j)_{axial}^{1.75} + (A_y/E_j)_{bending} \leq 1.0 \tag{30.6}$$

Step 8. To redesign an unsatisfactory connection, go back to Step 2 and do one of the following:

- A. Increase the chord thickness.
- B. Increase the branch diameter.
- C. Both of the above.

Consider overlapped connections (AWS Section 2.24.1.6) or stiffened connections only as a last resort. Overlapped connections increase the complexity of fabrication but can result in substantial reductions in the required chord wall thickness.

Step 9. When the designer thinks he is done, he should talk to potential fabricators and erectors. Their feedback could be valuable for avoiding unnecessary difficult and expensive construction headaches. Also, make sure they are familiar with and prepared to follow AWS Code requirements for special welder qualifications and that they are capable of coping the brace ends with sufficient accuracy to apply AWS prequalified procedures. Considerable savings can be realized by specifying partial joint penetration welds for tubular T, Y, and K connections

with no root access, where these are appropriate to service requirements. Fabrication and inspection practices for welded tubular connections have been addressed by Post [11].

A more satisfactory version of the “Truss Note” mentioned earlier might read as follows: “The designer has sized the main member (chord) at truss connections to meet the provisions of AWS D1.1-2002 Section 2.24. All welded truss connections (intersecting pipe-to-pipe) with either member less than 0.375 in. thick shall be provided with fillet welds meeting the requirements of AWS D1.1-2002 [Figure 3.2](#). All welded truss connections with both members thicker than 0.375 in. thick shall be provided with partial joint penetration welds meeting the requirements of AWS D1.1-2002 [Figure 3.5](#). Weld strength calculations are generally not required for these prequalified joints, but (if provided) shall be in accordance with AWS D1.1-2002 Sections 2.23 and 2.24.1.3. All bevels and their fit-up shall be inspected before welding commences. Completed welds shall be inspected to verify the full leg lengths as tabulated in AWS. Magnetic particle inspection may be applied at the toes of completed welds, where specified elsewhere in contract documents. Ultrasonic testing is not applicable to welds that are designated to be less than full penetration or to tube thickness less than 0.50 in.”

30.10 Summary and Conclusions

This chapter has served as a brief introduction to the subject of designing welded tubular connections for circular hollow sections. More details on the background and use of AWS, AISC, and international codes in this area can be found in Ref. [12], on the Internet [13,14], and by e-mail to the source 4 of these criteria [15].

31.1 Introduction

The concept of the *effective length factor* has been well established and widely used by practicing engineers and plays an important role in compression member and column design. The essence of the concept is to estimate the interaction effects of the whole frame on an individual compression member. In the development of design interaction equations for beam–columns, much discussion has been focused on the need and validity of using the *effective length factor* K in the equations (Cheong-Siat-Moy 1986; Liew et al. 1991; ASCE 1997; White and Clarke 1997a,b; Schmidt 1999). Although attempts were made to formulate the general interaction equations without K factors, it was found that this was almost impossible if the interaction equations were to be versatile enough for a wide range of slenderness ratios and load combinations (Liew et al. 1991). It is well known that the effective length factor approach introduces inaccuracies into the design process; the simplicity of the approach, however, is likely to still make the approach an important part of compression member design in the foreseeable future (Hellesland and Bjorhovde 1996). The most structural design codes, standards, and specifications worldwide have provisions concerning the effective length factor.

The aim of this chapter is to present a state-of-the-art engineering practice of the effective length factor for the design of compression members and columns. In the first part of this chapter, the basic concept of the effective length factor is discussed. Then, the design implementation for individual columns, framed columns, crossing bracing systems, latticed members, tapered columns, crane columns, gable frames, columns in fire, space frames, truss-type highway sign support structures, precast concrete skeletal frames, and steel moment frames is presented. The determination of whether a frame is braced or unbraced is also addressed. Several detailed examples are given to illustrate the determination of the effective length factor for different cases of engineering applications.

31.2 Basic Concept

Mathematically, the effective length factor or the *elastic K-factor* is defined as

$$K = \sqrt{\frac{P_e}{P_{cr}}} = \sqrt{\frac{\pi^2 EI}{L^2 P_{cr}}} \quad (31.1)$$

where P_e is the Euler load, the elastic buckling load of a pin-ended compression member or column, P_{cr} is the elastic buckling load of an end-restrained compression member or column, E is the modulus of elasticity of the material, I is the moment of inertia in the flexural buckling plane, and L is the unsupported length of the compression member or column.

Physically, the K -factor is a factor that when multiplied by the actual length of the end-restrained column (Figure 31.1a) gives the length of an equivalent pin-ended column (Figure 31.1b) whose buckling load is the same as that of the end-restrained column. It follows that effective length KL of an end-restrained column is the length between the adjacent inflection points of its pure flexural buckling shape.

Practically, the design specifications usually provide the resistance equations for pin-ended columns, while the resistance of framed columns can be estimated through the K -factor to the pin-ended column strength equation. Theoretical K -factor is determined from an elastic eigenvalue analysis of the entire structural system, while practical methods for the K -factor are based on an elastic eigenvalue analysis of selected subassemblages. The effective length concept is the only tool currently available for the design of compression members in engineering structures and it is an essential part of analysis and design procedures.

FIGURE 31.1 Individual column: (a) end-restrained columns and (b) pin-ended column.

31.3 Individual Columns

From an eigenvalue analysis, the general K -factor equation of an individual column as shown in Figure 31.1 is obtained as

$$\det \begin{vmatrix} C + \frac{R_{kA}L}{EI} & S & -(C + S) \\ S & C + \frac{R_{kB}L}{EI} & -(C + S) \\ -(C + S) & -(C + S) & 2(C + S) - \left(\frac{\pi}{K}\right)^2 + \frac{T_k L^3}{EI} \end{vmatrix} = 0 \quad (31.2)$$

where the stability functions C and S are defined as

$$C = \frac{(\pi/K) \sin(\pi/K) - (\pi/K)^2 \cos(\pi/K)}{2 - 2 \cos(\pi/K) - (\pi/K) \sin(\pi/K)} \quad (31.3)$$

$$S = \frac{(\pi/K)^2 - (\pi/K) \sin(\pi/K)}{2 - 2 \cos(\pi/K) - (\pi/K) \sin(\pi/K)} \quad (31.4)$$

The largest value of K that satisfies Equation 31.2 gives the elastic buckling load of an end-restrained column.

Figure 31.2 (AISC 1989, 1999; AASHTO 2004) summarizes the theoretical K -factors for end-restrained columns with some idealized end conditions. The recommended K -factors are also shown in Figure 31.2 for practical design applications. Since actual column conditions seldom comply fully with idealized end conditions used in buckling analysis, the recommended K -factors are always equal or greater than their theoretical counterparts.

31.4 Framed Columns — Alignment Chart Method

In theory, the effective length factor, K , for any columns in a framed structure can be determined from a stability analysis of the entire structural analysis — eigenvalue analysis. Methods available for stability

Buckled shape of column is shown by dashed line	(a)	(b)	(c)	(d)	(e)	(f)
Theoretical <i>K</i> -value	0.5	0.7	1.0	1.0	2.0	2.0
Recommended design value when ideal conditions are approximated	0.65	0.80	1.2	1.0	2.10	2.0
End condition code						
		Rotation fixed and translation fixed Rotation free and translation fixed Rotation fixed and translation free Rotation free and translation free				

FIGURE 31.2 Theoretical and recommended *K*-factors for individual columns with idealized end conditions (AISC 1999).

analysis include the slope deflection method (Winter et al. 1948; Galambos 1968; Chen and Lui 1991), the three-moment equation method (Bleich 1952), and energy methods (Johnson 1960). In practice, however, such an analysis is not practical, and simple models are often used to determine the effective length factors for framed columns (Kavanagh 1962; Lu 1962; Gurfinkel and Robinson 1965; Wood 1974). One such practical procedure that provides an approximate value of the elastic *K*-factor is the alignment chart method (Julian and Lawrence 1959). This procedure has been adopted by the AISC (1989, 1999), ACI (2002), AASHTO (2004), and CSA (1994) *Specifications*, among others. At present, most engineers use the alignment chart method in lieu of an actual stability analysis.

31.4.1 Alignment Chart Method

The structural models employed for determination of *K*-factor for framed columns in the alignment chart method are shown in Figure 31.3. The assumptions used in these models are (Chen and Lui 1991; AISC 1999)

1. All members have constant cross-section and behave elastically.
2. Axial forces in the girders are negligible.
3. All joints are rigid.
4. For braced frames, the rotations at the near and far ends of the girders are equal in magnitude and opposite in direction (i.e., girders are bent in single curvature).
5. For unbraced frames, the rotations at the near and far ends of the girders are equal in magnitude and direction (i.e., girders are bent in double curvature).
6. The stiffness parameters, $L\sqrt{P/EI}$, of all columns are equal.
7. All columns buckle simultaneously.
8. Joint restraint is distributed to the column above and below the joint in proportion to I/L of the two columns.

FIGURE 31.3 Subassemblage models for K -factors of framed columns: (a) braced frames and (b) unbraced frames.

Using the slope deflection equation method and stability functions, the effective length factor equations of framed columns are obtained as

For columns in braced frames:

$$\frac{G_A G_B}{4} (\pi/K)^2 + \left(\frac{G_A + G_B}{2} \right) \left(1 - \frac{\pi/K}{\tan(\pi/K)} \right) + \frac{2 \tan(\pi/2K)}{\pi/K} - 1 = 0 \quad (31.5)$$

For columns in unbraced frames:

$$\frac{G_A G_B (\pi/K)^2 - 36^2}{6(G_A + G_B)} - \frac{\pi/K}{\tan(\pi/K)} = 0 \quad (31.6)$$

where G_A and G_B are stiffness ratios of columns and girders at two end joints A and B of the column section being considered, respectively. They are defined by

$$G_A = \frac{\sum_A (E_c I_c / L_c)}{\sum_A (E_g I_g / L_g)} \quad (31.7)$$

$$G_B = \frac{\sum_B (E_c I_c / L_c)}{\sum_B (E_g I_g / L_g)} \quad (31.8)$$

where \sum indicates the summation of all members rigidly connected to the joint and lying in the plane in which buckling of column is being considered, and subscripts c and g represent columns and girders, respectively.

Equations 31.5 and 31.6 can be expressed in the form of alignment charts as shown in Figure 31.4. It is noted that for columns in braced frames, the range of K is $0.5 \leq K \leq 1.0$; for columns in unbraced frames, the range is $1.0 \leq K \leq \infty$. For column ends supported by, but not rigidly connected to, a footing or foundations, G is theoretically infinity, but unless actually designed as a true friction-free pin, it may be taken as 10 for practical design. If the column end is rigidly attached to a properly designed footing, G may be taken as 1.0 (AISC 1999).

FIGURE 31.4 Alignment charts for effective length factors of framed columns: (a) braced frames and (b) unbraced frames.

EXAMPLE 31.1

Given: A two-story steel frame is shown in Figure 31.5. Using the alignment chart, determine the *K*-factor for the elastic column DE. $E = 29,000$ ksi (200 GPa) and $F_y = 36$ ksi (248 MPa).

Solution

(1) For the given frame, section properties are

Members	Section	I_x (in. ⁴ , mm ⁴ × 10 ⁸)	L (in., mm)	I_x/L (in. ³ , mm ³)
AB and GH	W 10 × 22	118, 0.49	180, 4572	0.656, 10,750
BC and HI	W 10 × 22	118, 0.49	144, 3658	0.819, 13,412
DE	W 10 × 45	248, 1.03	180, 4572	1.378, 22,581
EF	W 10 × 45	248, 1.03	144, 3658	1.722, 28,219
BE	W 18 × 50	800, 3.33	300, 7620	2.667, 43,704
EH	W 18 × 86	1530, 6.37	360, 9144	4.250, 69,645
CF	W 16 × 40	518, 2.16	300, 7620	1.727, 28,300
FI	W 16 × 67	954, 3.97	360, 9144	2.650, 43,426

(2) Calculate *G*-factor for column DE:

$$G_E = \frac{\sum_E (E_c I_c / L_c)}{\sum_E (E_g I_g / L_g)} = \frac{1.378 + 1.722}{2.667 + 4.250} = 0.448$$

$$G_D = 10 \text{ (AISC 1999)}$$

(3) From the alignment chart in Figure 31.4b, $K = 1.8$ is obtained.

FIGURE 31.5 An unbraced two-story frame.

31.4.2 Requirements for Braced Frames

In stability design, one of the major decisions engineers have to make is the determination of whether a frame is braced or unbraced. In actual structures, a completely braced frame seldom exists. But in practice, some structures can be analyzed as braced frames as long as the lateral stiffness provided by bracing systems such as diagonal bracing, shear walls, or equivalent means is large enough. The following brief discussion may provide engineers with the tools to make engineering decisions regarding the basic requirements for a braced frame.

31.4.2.1 Lateral Stiffness Requirement

Galambos (1964) presented a simple conservative procedure to evaluate the minimum lateral stiffness provided by a bracing system so that the frame is considered braced:

$$\text{Required lateral stiffness } T_k = \frac{\sum P_n}{L_c} \tag{31.9}$$

where \sum represents the summation of all columns in one story, P_n is the nominal axial compression strength of the column using the effective length factor $K=1$, and L_c is the unsupported length of the column.

31.4.2.2 Bracing Size Requirement

Galambos (1964) applied Equation 31.9 to a diagonal bracing (Figure 31.6) and obtained the minimum requirements of diagonal bracing for a braced frame as

$$A_b = \frac{[1 + (L_b/L_c)^2]^{3/2} \sum P_n}{(L_b/L_c)^2 E} \tag{31.10}$$

where A_b is the cross-sectional area of diagonal bracing and L_b is the span length of the beam.

A recent study by Aristizabal-Ochoa (1994a) indicates that the size of diagonal bracing required for a totally braced frame is about 4.9 and 5.1% of the column cross-section for “rigid frame” and “simple framing,” respectively, and increases with the moment of inertia of the column, the beam span, and the beam to column span ratio L_b/L_c .

FIGURE 31.6 Diagonal cross bracing system.

31.4.2.3 Threshold Lateral Stiffness of Braces

For a multistory braced frame, Tong and Shi (2001) defined the threshold lateral stiffness as the bracing stiffness at which the critical buckling load in sway buckling mode is equal to the nonsway buckling mode. They found out that most threshold stiffness values are from π^2 to $4\pi^2$ and proposed the following approximate formula (Tong and Shi 2001):

$$T_k = G_{TH} \left(\frac{EI}{L^3} \right) \tag{31.11}$$

$$G_{TH} = \frac{2}{3} \left(\frac{\pi^2}{K_b^2} - \frac{\pi^2}{K_{ub}} \right) \left[\left(\frac{G_A}{G_B} \right)^{0.18} + \left(\frac{G_B}{G_A} \right)^{0.18} \right] \leq 60 \tag{31.12}$$

where K_b and K_{ub} are the effective length factors for braced and unbraced frames, respectively.

31.4.2.4 Stability Index

ACI 318-02 (ACI 2002) permits us to assume a column in a structure is braced if the increase in the lateral load moment due to second-order ($P-\Delta$) effects does not exceed 5% of the first-order moment (MacGregor and Hage 1977). The American Concrete Institute (ACI) also provides an alternative method based on the stability index for a story. The story within a structure can be assumed as braced if the stability index

$$Q = \frac{\sum P_u \Delta_0}{V_u L_c} \leq 0.05 \tag{31.13}$$

where $\sum P_u$ and V_u are the total vertical load and the story shear, respectively, in the story in question; Δ_0 is the first-order relative deflection between the top and bottom of that story due to V_u ; and L_c is the length of the compression member in a frame, measured from center to center of the joints in the frame.

Menon (2001) used the “fuzzy logic” concept and proposed that a frame is “adequately braced” if its stability index Q is less than 0.02, unbraced if Q exceeds 0.06 and “partially braced” if Q lies in the intermediate domain {0.02, 0.06}, and the K -factor can be estimated by the following equations:

$$K = K_{ub} - q_x(K_{ub} - K_b) \tag{31.14}$$

$$q_x = \begin{cases} 1.0 & \text{for } Q \leq 0.02 \\ 1.0 - 0.5(Q/0.02 - 1.0)^2 & \text{for } 0.02 < Q \leq 0.04 \\ 0.5(3.0 - Q/0.02)^2 & \text{for } 0.04 < Q \leq 0.06 \\ 0.0 & \text{for } Q > 0.06 \end{cases} \tag{31.15}$$

where K_{ub} and K_b are the effective length factors for unbraced and braced frames, respectively.

31.4.2.5 AISC Load and Resistance Factor Design Requirements

Based on the concept of dual criterion for bracing design, strength, and stiffness proposed by Winter (1958, 1960), AISC (1999) provides the stability bracing requirements for braced frames, in which the effective length factor K for compression members is taken as unity, unless structural analysis shows that a smaller value may be used.

For frames:

The required story or panel bracing shear force is

$$P_{br} = 0.004 \sum P_u \quad (31.16)$$

The required story or panel shear stiffness is

$$B_{br} = \frac{2 \sum P_u}{\phi L} \quad (31.17)$$

where ϕ is equal to 0.75, $\sum P_u$ is the summation of the factored column axial loads in the story or panel supported by the bracing, and L is the story height or panel spacing.

For individual columns:

1. For relative bracing

The required brace strength is

$$P_{br} = 0.004 P_u \quad (31.18)$$

The required brace stiffness is

$$B_{br} = \frac{2 P_u}{\phi L_b} \quad (31.19)$$

2. For nodal bracing

The required brace strength is

$$P_{br} = 0.01 P_u \quad (31.20)$$

The required brace stiffness is

$$B_{br} = \frac{8 P_u}{\phi L_b} \quad (31.21)$$

where ϕ is equal to 0.75, P_u is the factored column axial load, and L_b is the distance between braces. When the actual spacing of braced points is less than the maximum unbraced length for the required column force with K is equal to 1, then L_b in Equations 31.19 and 31.21 is permitted to be taken equal to L_c . For a more detailed discussion, see Yura (1995).

31.4.3 Simplified Equations to Alignment Charts

A graphical alignment chart determination of the K -factor is easy to perform, while solving the chart Equations 31.5 and 31.6 always involves iteration. With today's personal computer, especially spreadsheet applications in design offices, the following simplified equations may serve as the equivalent of the alignment charts.

31.4.3.1 ACI 318-02 Equations

The ACI Building Code (ACI 318-02) recommends the use of alignment charts as the primary design aid for estimating K -factors, with the following two sets of simplified K -factor equations as an alternative.

For braced frames (Cranston 1972)

$$K = 0.7 + 0.05(G_A + G_B) \leq 1.0 \quad (31.22)$$

$$K = 0.85 + 0.05 G_{\min} \leq 1.0 \quad (31.23)$$

The smaller of the above two expressions provides an upper bound to the effective length factor for braced compression members.

For unbraced frames (Furlong 1971)

$$K = \frac{20 - G_m}{20} \sqrt{1 + G_m} \quad \text{for } G_m < 2 \quad (31.24)$$

$$K = 0.9\sqrt{1 + G_m} \quad \text{for } G_m \geq 2 \quad (31.25)$$

For columns hinged at one end

$$K = 2.0 + 0.3G \quad (31.26)$$

where G_m is the average of the G values at the two ends of columns.

It is found that ACI simplified Equations 31.22 to 31.26 estimate very conservative K -factors when the difference between the relative stiffness ratios at the two ends of an unbraced column becomes larger and when end restraints of a braced column are large. In general, they may not lead to an economical design (Hu et al. 1993).

31.4.3.2 Duan–King–Chen Equations

To achieve both accuracy and simplicity for design purpose, the following alternative K -factor equations were proposed by Duan et al. (1993).

For braced frames

$$K = 1 - \frac{1}{5 + 9G_A} - \frac{1}{5 + 9G_B} - \frac{1}{10 + G_A G_B} \quad (31.27)$$

For unbraced frames

$$K = 4 - \frac{1}{1 + 0.2G_A} - \frac{1}{1 + 0.2G_B} - \frac{1}{1 + 0.01G_A G_B} \quad \text{for } K < 2 \quad (31.28)$$

$$K = \frac{2\pi a}{0.9 + \sqrt{0.81 + 4ab}} \quad \text{for } K \geq 2 \quad (31.29)$$

where

$$a = \frac{G_A G_B}{G_A + G_B} + 3 \quad (31.30)$$

$$b = \frac{36}{G_A + G_B} + 6 \quad (31.31)$$

Equation 31.28 shall be used to first calculate K . If the value of K calculated by Equation 31.28 is greater than 2, Equation 31.29 shall then be used.

31.4.3.3 French Equations

For braced frames

$$K = \frac{3G_A G_B + 1.4(G_A + G_B) + 0.64}{3G_A G_B + 2.0(G_A + G_B) + 1.28} \quad (31.32)$$

For unbraced frames

$$K = \sqrt{\frac{1.6G_A G_B + 4.0(G_A + G_B) + 7.5}{G_A + G_B + 7.5}} \quad (31.33)$$

Equations 31.32 and 31.33 first appeared in the *French Rules for the Design of Steel Structure* in 1966 (CM 1966) and were later incorporated into the *European Recommendation for Steel Construction* in 1978 (ECCS 1978). Neither French CM 66 Rules nor the European Recommendations give the origin of these two formulas. They provide a good approximation to the alignment charts (Dumonteil 1992). For braced frames, Equation 31.32 underestimates K by not more than 0.5% and overestimates it by 1.5%. For unbraced frames, Equation 31.33 approximates K within 2% (Dumonteil 1999).

31.4.3.4 Donnell Equation for Braced Frames

The Donnell equation, developed in 1949 as reported by Rondal (1988), has the following format:

$$K = \sqrt{\frac{G_A G_B + 0.43(G_A + G_B) + 0.17}{G_A G_B + 0.86(G_A + G_B) + 0.68}} \quad (31.34)$$

This is the formula presented by Dumonteil and Valley (1995) in their discussion paper. Its accuracy ranges from 0.4 to 1.3%.

31.4.3.5 Newmark Equation for Braced Frames

Introducing the G -factor, the Newmark (1949) equation has the following form:

$$K = \sqrt{\frac{(G_A + 4/\pi^2)(G_B + 4/\pi^2)}{(G_A + 8/\pi^2)(G_B + 8/\pi^2)}} \quad (31.35)$$

While the accuracy of Equation 31.35 is remarkable, it could still be slightly improved by replacing the term $4/\pi^2$ with 0.41, and the Newmark equation becomes (Dumonteil 1999)

$$K = \sqrt{\frac{(G_A + 0.41)(G_B + 0.41)}{(G_A + 0.82)(G_B + 0.82)}} \quad (31.36)$$

Equation 31.36 underestimates K by no more than 0.1% and overestimates it by less than 1.5%.

31.5 Modifications to Alignment Charts

In using the alignment charts in [Figure 31.4](#) and Equations 31.5 and 31.6, engineers must always be aware of the assumptions used in the development of these charts. When actual structural conditions differ from these assumptions, unrealistic design may result (Johnston 1976; Liew et al. 1991; Hajjar and White 1994; AISC 1999; Dafedar et al. 2001). The Structural Stability Research Council (SSRC) Guide (Johnston 1976) provides methods enabling engineers to make simple modifications of the charts for some special conditions, such as unsymmetrical frames, column base conditions, girder far end conditions, and flexible conditions. Procedures that can be used to account for far ends of restraining columns being hinged or fixed were proposed by Duan and Chen (1988, 1989, 1996) and Essa (1997). Consideration of effects of material inelasticity on the K -factor was developed originally by Yura (1971) and expanded by Disque (1973). LeMessurier (1977) presented an overview of unbraced frames with or without leaning columns. An approximate procedure was also suggested by AISC (1999). Special attention should also be paid to calculation of the proper G -values (Barakat and Chen 1991; Duan 1996; Kishi et al. 1997) when partially restrained (PR) connections are used in frames. Several commonly used modifications are summarized in this section.

31.5.1 Different Restraining Girder End Conditions

When the end conditions of restraining girders are not rigidly joined to columns, the girder stiffness (I_g/L_g) used in the calculation of G_A and G_B in Equations 31.7 and 31.8 should be multiplied by a modification factor α_k as

$$G = \frac{\sum(E_c I_c / L_c)}{\sum \alpha_k (E_g I_g / L_g)} \quad (31.37)$$

where the modification factor α_k developed by Duan (1996) for braced frames and proposed by Kishi et al. (1997) for unbraced frames are given in [Table 31.1](#) and [Table 31.2](#), respectively. In these tables, R_{kN} and R_{kF} are elastic spring constants at the near and far ends of a restraining girder, respectively.

TABLE 31.1 Modification Factor α_k for Braced Frames with Semirigid Connections (Duan 1996)

End conditions of restraining girder		α_k
Near end	Far end	
Rigid	Rigid	1.0
Rigid	Hinged	1.5
Rigid	Semirigid	$\left(1 + \frac{6E_g I_g}{L_g R_{kF}}\right) / \left(1 + \frac{4E_g I_g}{L_g R_{kF}}\right)$
Rigid	Fixed	2.0
Semirigid	Rigid	$1 / \left(1 + \frac{4E_g I_g}{L_g R_{kN}}\right)$
Semirigid	Hinged	$1.5 / \left(1 + \frac{3E_g I_g}{L_g R_{kN}}\right)$
Semirigid	Semirigid	$\left(1 + \frac{6E_g I_g}{L_g R_{kF}}\right) / R^*$
Semirigid	Fixed	$2 / \left(1 + \frac{4E_g I_g}{L_g R_{kN}}\right)$

$$R^* = \left(1 + \frac{4E_g I_g}{L_g R_{kN}}\right) \left(1 + \frac{4E_g I_g}{L_g R_{kF}}\right) - \left(\frac{E_g I_g}{L_g}\right)^2 \frac{4}{R_{kN} R_{kF}}$$

TABLE 31.2 Modification Factor α_k for Unbraced Frames with Semirigid Connections (Kishi, Chen and Goto, 1997)

End conditions of restraining girder		α_k
Near end	Far end	
Rigid	Rigid	1
Rigid	Hinged	0.5
Rigid	Semirigid	$\left(1 + \frac{2E_g I_g}{L_g R_{kF}}\right) / \left(1 + \frac{4E_g I_g}{L_g R_{kF}}\right)$
Rigid	Fixed	2/3
Semirigid	Rigid	$1 / \left(1 + \frac{4E_g I_g}{L_g R_{kN}}\right)$
Semirigid	Hinged	$0.5 / \left(1 + \frac{3E_g I_g}{L_g R_{kN}}\right)$
Semirigid	Semirigid	$\left(1 + \frac{2E_g I_g}{L_g R_{kF}}\right) / R^*$
Semirigid	Fixed	$\left(\frac{2}{3}\right) / \left(1 + \frac{4E_g I_g}{L_g R_{kN}}\right)$

$$R^* = \left(1 + \frac{4E_g I_g}{L_g R_{kN}}\right) \left(1 + \frac{4E_g I_g}{L_g R_{kF}}\right) - \left(\frac{E_g I_g}{L_g}\right)^2 \frac{4}{R_{kN} R_{kF}}$$

R_{kN} and R_{kF} are the tangent stiffnesses of a semirigid connection at buckling. ASCE Task Committee on Effective Length (1997) provides a detailed discussion of frame stability with PR connection.

EXAMPLE 31.2

Given: A steel frame is shown in Figure 31.5. Using the alignment chart with the necessary modifications, determine the K -factor for elastic column EF. $E = 29,000$ ksi (200 GPa) and $F_y = 36$ ksi (248 MPa).

Solution

1. Calculate the G -factor with modification for column EF. Since the far end of the restraining girders is hinged, girder stiffness should be multiplied by 0.5 (see Table 31.2). Using the section properties in Example 31.1, we obtain

$$G_F = \frac{\sum(E_c I_c/L_c)}{\sum \alpha_k (E_g I_g/L_g)} = \frac{1.722}{0.5(1.727) + 0.5(2.650)} = 0.787$$

$$G_E = 0.448$$

2. From the alignment chart in Figure 32.4b, $K = 1.22$ is obtained.

31.5.2 Different Restraining Column End Conditions

To consider different far end conditions of restraining columns, the general effective length factor equations for column C2 (Figure 31.3) were derived by Duan and Chen (1988, 1989, 1996). By assuming that the far ends of columns C1 and C3 are hinged and using the slope deflection equation approach for the subassemblies shown in Figure 31.3, we obtain the following.

31.5.2.1 For a Braced Frame (Duan and Chen 1988)

$$C^2 - S^2 \left[G_{AC1} + G_{BC3} + G_{AC2} G_{BC2} + \frac{(2G_{BC3}/G_A) + (2G_{AC1}/G_B)}{C} - G_{AC1} G_{BC3} \left(\frac{S}{C} \right)^2 \right] + 2C \left(\frac{1}{G_A} + \frac{1}{G_B} \right) + \frac{4}{G_A G_B} = 0 \quad (31.38)$$

where C and S are stability functions as defined by Equations 31.3 and 31.4; G_A and G_B are defined in Equations 31.7 and 31.8; and G_{AC1} , G_{AC2} , G_{BC2} , and G_{BC3} are the stiffness ratios of columns at the A-th and B-th ends of the columns being considered, respectively. They are defined as

$$G_{Ci} = \frac{E_{ci} I_{ci} / L_{ci}}{\sum (E_{ci} I_{ci} / L_{ci})} \quad (31.39)$$

where \sum indicates the summation of all columns rigidly connected to the joint and lying in the plane in which buckling of column is being considered.

Although Equation 31.38 was derived for the special case in which the far ends of both column C1 and column C3 are hinged, this equation is also applicable if adjustment to G_{Ci} is made as follows: (1) if the far end of column Ci (C1 or C3) is fixed, then take $G_{Ci} = 0$ (except for G_{C2}) and (2) if the far end of column Ci (C1 or C3) is rigidly connected, then take $G_{Ci} = 0$ and $G_{C2} = 1.0$. Therefore, Equation 31.38 can be specialized for the following conditions:

1. If the far ends of both column C1 and column C3 are fixed, we have $G_{AC1} = G_{BC3} = 0$ and Equation 31.38 reduces to

$$C^2 - S^2 (G_{AC2} G_{BC2}) + 2C \left(\frac{1}{G_A} + \frac{1}{G_B} \right) + \frac{4}{G_A G_B} = 0 \quad (31.40)$$

2. If the far end of column C1 is rigidly connected and the far end of column C3 is fixed, we have $G_{AC2} = 1.0$ and $G_{AC1} = G_{BC3} = 0$, and Equation 31.38 reduces to

$$C^2 - S^2 + G_{BC2} + 2C \left(\frac{1}{G_A} + \frac{1}{G_B} \right) + \frac{4}{G_A G_B} = 0 \quad (31.41)$$

3. If the far end of column C1 is rigidly connected and the far end of column C3 is hinged, we have $G_{AC1} = 0$ and $G_{AC2} = 1.0$, and Equation 31.38 reduces to

$$C^2 - S^2 \left(G_{BC3} + G_{BC2} + \frac{2G_{BC3}}{G_A C} \right) + 2C \left(\frac{1}{G_A} + \frac{1}{G_B} \right) + \frac{4}{G_A G_B} = 0 \quad (31.42)$$

4. If the far end of column C1 is hinged and the far end of column C3 is fixed, we have $G_{BC3} = 0$, and Equation 31.38 reduces to

$$C^2 - S^2 \left(G_{AC1} + G_{AC2} G_{BC2} + \frac{2G_{AC1}}{G_B C} \right) + 2C \left(\frac{1}{G_A} + \frac{1}{G_B} \right) + \frac{4}{G_A G_B} = 0 \quad (31.43)$$

5. If the far ends of both columns C1 and C3 are rigidly connected (i.e., the assumptions used in developing the alignment chart), we have $G_{C2} = 1.0$ and $G_{Ci} = 0$, and Equation 31.38 reduces to

$$C^2 - S^2 + 2C \left(\frac{1}{G_A} + \frac{1}{G_B} \right) + \frac{4}{G_A G_B} = 0 \quad (31.44)$$

which can be rewritten in the form of Equation 31.5.

31.5.2.2 For an Unbraced Frame (Duan and Chen 1989, 1996)

$$\det \begin{vmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{vmatrix} = 0 \quad (31.45)$$

or

$$a_{11} a_{22} a_{33} + a_{21} a_{32} a_{13} + a_{31} a_{23} a_{12} - a_{31} a_{22} a_{13} - a_{21} a_{12} a_{33} + a_{11} a_{23} a_{32} = 0 \quad (31.46)$$

where

$$a_{11} = C + \frac{6}{G_A} - G_{AC1} \frac{S^2}{C} \quad (31.47)$$

$$a_{22} = C + \frac{6}{G_B} - G_{BC3} \frac{S^2}{C} \quad (31.48)$$

$$a_{33} = -2 \left[C + S - \frac{1}{2} \left(\frac{\pi}{K} \right)^2 \right] \quad (31.49)$$

$$a_{12} = G_{AC2} S \quad (31.50)$$

$$a_{21} = G_{BC2} S \quad (31.51)$$

$$a_{31} = a_{32} = C + S \quad (31.52)$$

$$a_{13} = -(C + S) + G_{AC1} \left(S + \frac{S^2}{C} \right) \quad (31.53)$$

$$a_{23} = -(C + S) + G_{BC3} \left(S + \frac{S^2}{C} \right) \quad (31.54)$$

Although Equation 31.45 was derived for the special case in which the far ends of both column C1 and column C3 are hinged, it can be adjusted to account for the following cases: (1) if the far end of column C_i (C1 or C3) is fixed, then take $G_{Ci} = 0$ (except for G_{C2}) and (2) if the far end of column C_i (C1 or C3)

is rigidly connected, then take $G_{Ci}=0$ and $G_{C2}=1.0$. Therefore, Equation 31.45 can be used for the following conditions:

1. If the far ends of both column C1 and column C3 are fixed, we take $G_{C1}=G_{C3}=0$ and obtain from Equations 31.47, 31.48, 31.53, and 31.54

$$a_{11} = C + \frac{6}{G_A} \quad (31.55)$$

$$a_{22} = C + \frac{6}{G_B} \quad (31.56)$$

$$a_{13} = a_{23} = -(C + S) \quad (31.57)$$

2. If the far end of column C1 is rigidly connected and the far end of column C3 is fixed, we take $G_{AC2}=1.0$ and $G_{AC1}=G_{BC3}=0$ and obtain from Equations 31.47, 31.48, 31.50, 31.53, and 31.54

$$a_{11} = C + \frac{6}{G_A} \quad (31.58)$$

$$a_{22} = C + \frac{6}{G_B} \quad (31.59)$$

$$a_{12} = S \quad (31.60)$$

$$a_{13} = a_{23} = -(C + S) \quad (31.61)$$

3. If the far end of column C1 is rigidly connected and the far end of column C3 is hinged, we take $G_{AC1}=0$ and $G_{AC2}=1.0$ and obtain from Equations 31.47, 31.50, and 31.52

$$a_{11} = C + \frac{6}{G_A} \quad (31.62)$$

$$a_{12} = S \quad (31.63)$$

$$a_{13} = -(C + S) \quad (31.64)$$

4. If the far end of column C1 is hinged and the far end of column C3 is fixed, we have $G_{BC3}=0.0$ and obtain from Equations 31.48 and 31.54

$$a_{22} = C + \frac{6}{G_B} \quad (31.65)$$

$$a_{23} = -(C + S) \quad (31.66)$$

5. If the far ends of both column C1 and column C3 are rigidly connected (i.e., the assumptions used in developing the alignment chart, that is, $\theta_C=\theta_B$ and $\theta_D=\theta_A$), we take $G_{C2}=1.0$ and $G_{Ci}=0$ and obtain from Equations 31.47 to 31.54

$$a_{11} = C + \frac{6}{G_A} \quad (31.67)$$

$$a_{22} = C + \frac{6}{G_B} \quad (31.68)$$

$$a_{12} = a_{21} = S \quad (31.69)$$

$$a_{13} = a_{23} = -(C + S) \quad (31.70)$$

Equation 31.45 is reduced to the form of Equation 31.6.

The procedures to obtain the K -factor directly from the alignment charts without resorting to solve Equations 31.38 and 31.45 were also proposed by Duan and Chen (1988, 1989).

FIGURE 31.7 Tapered rectangular girders: (a) linearly tapered girder and (b) symmetrically tapered girder.

31.5.3 Columns Restrained by Tapered Rectangular Girders

A modification factor α_T was developed by King et al. (1993) for those framed columns restrained by tapered rectangular girders with different far end conditions. The following modified G -factor is introduced in connection with the use of alignment charts:

$$G = \frac{\sum(E_c I_c / L_c)}{\sum \alpha_T (E_g I_g / L_g)} \tag{31.71}$$

where I_g is the moment of inertia of the girder at the near end. Both closed-form and approximate solutions for modification factor α_T were derived. It is found that the following two-parameter power function can describe the closed-form solutions very well:

$$\alpha_T = D(1 - r)^\beta \tag{31.72}$$

where the parameter D is a constant depending on the far end conditions and β is a function of far end conditions and tapering factors a and r as defined in Figure 31.7.

For a braced frame

$$D = \begin{cases} 1.0 & \text{rigid far end} \\ 2.0 & \text{fixed far end} \\ 1.5 & \text{hinged far end} \end{cases} \tag{31.73}$$

For an unbraced frame

$$D = \begin{cases} 1.0 & \text{rigid far end} \\ 2/3 & \text{fixed far end} \\ 0.5 & \text{hinged far end} \end{cases} \tag{31.74}$$

1. For a linearly tapered rectangular girder (Figure 31.7a)

For a braced frame

$$\beta = \begin{cases} 0.02 + 0.4r & \text{rigid far end} \\ 0.75 - 0.1r & \text{fixed far end} \\ 0.75 - 0.1r & \text{hinged far end} \end{cases} \tag{31.75}$$

For an unbraced frame

$$\beta = \begin{cases} 0.95 & \text{rigid far end} \\ 0.70 & \text{fixed far end} \\ 0.70 & \text{hinged far end} \end{cases} \quad (31.76)$$

2. For a symmetrically tapered rectangular girder (Figure 31.7b)

For a braced frame

$$\beta = \begin{cases} 3 - 1.7a^2 - 2a & \text{rigid far end} \\ 3 + 2.5a^2 - 5.55a & \text{fixed far end} \\ 3 - a^2 - 2.7a & \text{hinged far end} \end{cases} \quad (31.77)$$

For an unbraced frame

$$\beta = \begin{cases} 3 + 3.8a^2 - 6.5a & \text{rigid far end} \\ 3 + 2.3a^2 - 5.45a & \text{fixed far end} \\ 3 - 0.3a & \text{hinged far end} \end{cases} \quad (31.78)$$

EXAMPLE 31.3

Given: A one-story frame with a symmetrically tapered rectangular girder is shown in Figure 31.8. Assuming $r=0.5$, $a=0.2$, and $I_g = 2I_c = 2I$, determine the K -factor for column AB.

Solution

1. Using the alignment chart with modification

For joint A, since the far end of the girder is rigid, use Equations 31.78 and 31.72:

$$\begin{aligned} \beta &= 3 + 3.8(0.2)^2 - 6.5(0.2) = 1.852 \\ \alpha_T &= (1 - 0.5)^{1.852} = 0.277 \\ G_A &= \frac{\sum E_c I_c / L_c}{\sum \alpha_T E_g I_g / L_g} = \frac{EI/L}{0.277E(2I)/2L} = 3.61 \\ G_B &= 1.0 \text{ (AISC 1999)} \end{aligned}$$

From the alignment chart in Figure 31.4b, $K=1.59$ is obtained.

FIGURE 31.8 A simple frame with rectangular sections.

2. Using the alignment chart without modification

A direct use of Equations 31.7 and 31.8 with an average section ($0.75h$) results in

$$I_g = 0.75^3(2I) = 0.844I$$

$$G_A = \frac{EI/L}{0.844EI/2L} = 2.37, \quad G_B = 1.0$$

From the alignment chart in Figure 31.4b, $K = 1.49$ or $(1.49 - 1.59)/1.59 = -6\%$ in error on the less conservative side.

31.5.4 Unsymmetrical Frames

When the column sizes or column loads are not identical, adjustments to the alignment charts are necessary to obtain correct K -factors. Figure 31.9 presents a set of curves for a modification factor β developed by Chu and Chow (1969).

$$K_{\text{adjusted}} = \beta K_{\text{alignment chart}} \quad (31.79)$$

If the K -factor of the column under the load λP is desired, further modifications to K are necessary. Denoting K' as the effective length factor of column with $I'_c = \alpha I_c$ subjected to the axial load $P' = \lambda P$ as shown in Figure 31.9, we have

$$K' = K_{\text{adjusted}} \frac{L}{L'} \sqrt{\frac{\alpha}{\lambda}} \quad (31.80)$$

Equation 31.80 can be used to determine K -factors for columns in adjacent stories with different heights L' .

31.5.5 Effects of Axial Forces in Restraining Members

Compressive axial load in a restraining girder reduces its flexural stiffness and then affects adversely the K -factor of the column (AISC 1999). To account for any compression axial load in a girder, the girder stiffness parameter ($E_g I_g / L_g$) in Equations 31.7 and 31.8 should be modified by the factor $[1 - (Q/Q_{cr})]$, where Q is the axial compression load in the girder, and Q_{cr} is the in-plane buckling load of the girder based on $K = 1.0$. Tensile axial load in the girder can be ignored when determining the G -factor.

Bridge and Fraser (1987) observed that K -factors of a column in a braced frame may be greater than unity due to “negative” restraining effects. Figure 31.10 shows the solutions obtained by considering the both “positive” and “negative” values of G -factors. The shaded portion of the graph corresponds to the alignment chart shown in Figure 31.4a when both G_A and G_B are positive.

To account for the effect of axial forces in the restraining members, Bridge and Fraser (1987) proposed a more general expression for G -factor:

$$G = \frac{(I/L)}{\sum_n (I/L)_n \gamma_n m_n} = \frac{\text{stiffness of member } i \text{ under investigation}}{\text{stiffness of all rigidly connected members}} \quad (31.81)$$

where γ is a function of the stability functions S and C (Equations 31.3 and 31.4), m is a factor to account for the end conditions of the restraining member (see Figure 31.11), and subscript n represents the other members rigidly connected to member i . The summation in the denominator is for all members meeting at the joint.

By using Figure 31.10, Figure 31.11, and Equation 31.81, the effective length factor K_i for the i th member can be determined by the following steps:

1. Sketch the buckled shape of the structure under consideration.
2. Assume a value of K_i for the member being investigated.

FIGURE 31.9 Chart for the modification factor β in an unsymmetrical frame.

3. Calculate values of K_n for each of the other members that are rigidly connected to the i th member using the equation

$$K_n = K_i \frac{L_i}{L_n} \sqrt{\left(\frac{P_i}{P_n}\right) \left(\frac{I_n}{I_i}\right)} \tag{31.82}$$

4. Calculate γ and obtain m from Figure 31.11 for each member.
5. Calculate G_i for the i th member using Equation 31.81.
6. Obtain K_i from Figure 31.10 and compare with the assumed K_i at step 2.
7. Repeat the procedure by using the calculated K_i as the assumed K_i until K_i calculated at the end of the cycle is approximately (say, 10%) equal to the K_i at the beginning of the cycle.

FIGURE 31.10 Effective length chart considering both positive and negative effects in braced frame (Bridge and Fraser 1987).

- 8. Repeat steps 2 to 7 for other members of the frame.
- 9. The largest set of K values obtained is then used for design.

The above procedure has been illustrated (Bridge and Fraser 1987) and verified (Koo 1988) to provide a good elastic K -factor of columns in braced frames.

EXAMPLE 31.4

Given: A braced column is shown in Figure 31.12. Consider axial force effects to determine K -factors for columns AB and BC.

Solution

- 1. Sketch buckled shape as shown in Figure 31.12b.
- 2. Assume $K_{AB} = 0.94$.
- 3. Calculate K_{BC} by Equation 31.82:

$$K_{BC} = K_{AB} \frac{L_{AB}}{L_{BC}} \sqrt{\left(\frac{P_{AB}}{P_{BC}}\right) \left(\frac{I_{BC}}{I_{AB}}\right)} = 0.94 \frac{L}{L} \sqrt{\frac{2PI}{P(1.2I)}}$$

$$= 1.22$$

Axial forces	Cases	Exact γ formula	Approximate γ formula	m
Tension		$\frac{C-S}{2}$	$1 + \frac{1}{1.5K_n^2}$	1
		$\frac{C-S^2/C}{3}$		1.5
		$\frac{C}{4}$	$1 + \frac{1}{4K_n^2}$	2
	$\frac{C+S}{6}$	3		
Compression		$\frac{C-S}{2}$	$\begin{cases} 1 - \frac{1}{K_n^2} & \text{for } K_n > 1.0 \\ 2 - \frac{2}{K_n^2} & \text{for } K_n \leq 1.0 \end{cases}$	1
		$\frac{C-S^2/C}{3}$		1.5
		$\frac{C}{4}$	$\begin{cases} 1 - \frac{1}{2K_n^2} & \text{for } K_n > 0.7 \\ 2 - \frac{2}{K_n^2} & \text{for } K_n \leq 0.7 \end{cases}$	2
	$\frac{C+S}{6}$	$1 - \frac{1}{4K_n^2}$		3
Note:	C and S are stability equations			

FIGURE 31.11 Values of γ and m to account for the effect of axial forces in the restraining members.

4. Calculate γ and obtain m from Figure 31.11 for member BC.

Since $K_{BC} > 1.0$

$$\gamma_{BC} = 1 - \frac{1}{K_{BC}^2} = 1 - \frac{1}{1.22^2} = 0.33$$

Far end is pinned, $m_{BC} = 1.5$

5. Calculate G-factor for member AB using Equation 31.81.

$$G_B = \frac{(I/L)}{\sum_n (I/L)_n \gamma_n m_n} = \frac{(1.2I/L)}{(I/L)(0.33)(1.5)} = 2.42$$

$$G_A = \infty$$

6. From Figure 31.10, $K_{AB} = 0.93$. Comparing with the assumed $K_{AB} = 0.94$ it is alright.

FIGURE 31.12 Braced columns: (a) braced columns and (b) buckled shape.

7. Repeat the above procedure for member BC.

Assume $K_{BC} = 1.2$

Calculate K_{AB} by Equation 31.82

$$K_{AB} = K_{BC} \frac{L_{BC}}{L_{AB}} \sqrt{\left(\frac{P_{BC}}{P_{AB}}\right) \left(\frac{I_{AB}}{I_{BC}}\right)} = 1.2 \frac{L}{L} \sqrt{\frac{P(1.2I)}{2PI}} = 0.93$$

Calculate γ and obtain m from Figure 31.11 for member AB

Since $K_{AB} < 1.0$

$$\gamma_{AB} = 2 - \frac{2}{K_{AB}^2} = 2 - \frac{2}{0.93^2} = -0.312$$

Far end is pinned, $m_{AB} = 1.5$

Calculate G -factor for the member BC using Equation 31.81.

$$G_B = \frac{(I/L)}{\sum_n (I/L)_n \gamma_n m_n} = \frac{(I/L)}{(1.2I/L)(-0.312)(1.5)} = -1.78$$

$$G_c = \infty$$

See Figure 31.10, $K_{BC} = 1.18$

Comparing with the assumed $K_{AB} = 1.20$ it is alright.

8. It is seen that the largest set of K -factors is

$$K_{AB} = 1.22 \quad \text{and} \quad K_{BC} = 0.93$$

31.5.6 Consideration of Partial Column Base Fixity

In computing the effective length factor for monolithic connections, it is important to properly evaluate the degree of fixity in foundation. The following two approaches can be used to account for foundation fixity.

31.5.6.1 Fictitious Restraining Beam Approach

Galambos (1960) proposed that the effect of partial base fixity can be modeled as a fictitious beam. The approximate expression for the stiffness of the fictitious beam accounting for rotation of foundation in the soil has the form

$$\frac{I_s}{L_B} = \frac{qBH^3}{72E_{\text{steel}}} \quad (31.83)$$

where q is the modulus of subgrade reaction (varies from 50 to 400 lb/in.³, 0.014 to 0.109 N/mm³), B and H are the width and length (in bending plane) of the foundation, respectively, and E_{steel} is the modulus of elasticity of steel.

Based on the studies of Salmon et al. (1957), the approximate expression for the stiffness of the fictitious beam accounting for the rotations between column ends and footing due to deformation of base plate, anchor bolts, and concrete can be written as:

$$\frac{I_s}{L_B} = \frac{bd^2}{72E_{\text{steel}}/E_{\text{concrete}}} \quad (31.84)$$

where b and d are the width and length of the base plate, respectively and subscripts concrete and steel represent concrete and steel, respectively. Galambos (1960) suggested that the smaller stiffness calculated by Equations 31.83 and 31.84 be used in determining K -factors.

31.5.6.2 AASHTO Load and Resistance Factor Design Approach

The following values are suggested by AASHTO (2004):

- $G = 1.5$ footing anchored on rock
- $G = 3.0$ footing not anchored on rock
- $G = 5.0$ footing on soil
- $G = 1.0$ footing on multiple rows of end bearing piles

31.5.7 Inelastic K -factor

The effect of material inelasticity and end restraint on the K -factors has been studied during the last two decades (Yura 1971; Disque 1973; Jones et al. 1980, 1982; Chapius and Galambos 1982; Sugimoto and Chen 1982; Vinnakota 1982; Lui and Chen 1983; Razzaq 1983; Bjorhovde 1984; Sohal et al. 1995). The inelastic K -factor developed originally by Yura (1971) and expanded by Disque (1973) makes use of alignment charts with simple modifications. It is conservative to design column on the base of elastic K -factors. It is less conservative to design column on the base of inelastic K -factors. To consider the inelasticity of material, the G -values as defined by Equations 31.7 and 31.8 are replaced by G^* (Disque 1973) as follows:

$$G^* = \text{SRF}(G) = \frac{E_t}{E} G \quad (31.85)$$

where E_t is the tangent modulus of the material. For practical application, the stiffness reduction factor (SRF) = (E_t/E) and can be taken as the ratio of the inelastic to elastic buckling stress of the column

$$\text{SRF} = \frac{E_t}{E} \approx \frac{(F_{\text{cr}})_{\text{inelastic}}}{(F_{\text{cr}})_{\text{elastic}}} \approx \frac{(P_u/A_g)}{(F_{\text{cr}})_{\text{elastic}}} \quad (31.86)$$

where P_u is the factored axial load and A_g is the gross section area of member. $(F_{cr})_{inelastic}$ and $(F_{cr})_{elastic}$ can be calculated by AISC (1999) column equations:

$$(F_{cr})_{inelastic} = (0.658)^{\lambda_c^2} F_y \tag{31.87}$$

$$(F_{cr})_{elastic} = \left[\frac{0.877}{\lambda_c^2} \right] F_y \tag{31.88}$$

$$\lambda_c = \frac{KL}{r\pi} \sqrt{\frac{F_y}{E}} \tag{31.89}$$

where K is the elastic effective length factor and r is the radius of gyration about the plane of buckling. Table 31.3 gives the SRF values for different stress levels and slenderness parameters. AISC (1999) provides a direct calculation of SRF as follows:

$$SRF = \begin{cases} 1.0 & \text{for } (P_u/P_y) \leq \frac{1}{3} \\ -7.38 \left(\frac{P_u}{P_y} \right) \log \left(\frac{(P_u/P_y)}{0.85} \right) & \text{for } (P_u/P_y) > \frac{1}{3} \end{cases} \tag{31.90}$$

EXAMPLE 31.5

Given: A two-story steel frame is shown in Figure 31.5. Using the alignment chart to determine the K -factor for inelastic column DE, $E = 29,000$ ksi (200 GPa) and $F_y = 36$ ksi (248 MPa).

Solution

1. Calculate the axial stress ratio

$$\frac{P_u}{A_g F_y} = \frac{300}{13.3(36)} = 0.63$$

2. Obtain $SRF = 0.793$ from Table 31.3

TABLE 31.3 Stiffness Reduction Factor (SRF) for G -values

$P_u/(A_g F_y)$	$(KL/r)_{elastic}$		λ_c	SRF (Equation 31.86)
	36 ksi (248 MPa)	50 ksi (345 MPa)		
1.00	0.0	0.0	0.155	0.000
0.95	31.2	26.5	0.350	0.133
0.90	44.7	38.0	0.502	0.258
0.85	55.6	47.1	0.623	0.376
0.80	65.1	55.2	0.730	0.486
0.75	73.9	62.7	0.829	0.588
0.70	82.3	69.8	0.923	0.680
0.65	90.5	76.8	1.015	0.763
0.60	98.5	83.6	1.105	0.835
0.55	106.6	90.4	1.195	0.896
0.50	114.7	97.4	1.287	0.944
0.45	123.2	104.5	1.381	0.979
0.40	131.9	111.9	1.480	0.998
0.39	133.7	113.5	1.500	1.000

From Equation 31.83b

$$\text{SRF} = -7.38 \left(\frac{P_u}{P_y} \right) \log \left(\frac{(P_u/P_y)}{0.85} \right) = -7.38(0.63) \log \left(\frac{0.63}{0.85} \right) = 0.605$$

3. Calculate the modified G -factor

$$G_E = 0.448 \text{ (Example 31.1)}$$

$$G_E^* = \text{SRF}(G_E) = 0.794(0.448) = 0.355$$

$$G_D = 10 \text{ (AISC 1999)}$$

4. From the alignment chart in [Figure 31.4b](#), we have

$$(K_{DE})_{\text{inelastic}} = 1.75$$

31.6 Framed Columns — Alternative Methods

31.6.1 LeMessurier Method

Considering that all columns in a story buckle simultaneously and strong columns will brace weak columns (Figure 31.13), a more accurate approach to calculate K -factors for columns in a sidesway frame was developed by LeMessurier (1977). The K_i value for the i th column in a story can be obtained by the following expression:

$$K_i = \sqrt{\frac{\pi^2 EI_i}{L_i^2 P_i} \left(\frac{\sum P + \sum C_L P}{\sum P_L} \right)} \quad (31.91)$$

where P_i is the axial compressive force for member i , subscript i represents the i th column, and $\sum P$ is the sum of axial force of all columns in a story.

$$P_L = \frac{\beta EI}{L^2} \quad (31.92)$$

$$\beta = \frac{6(G_A + G_B) + 36}{2(G_A + G_B) + G_A G_B + 3} \quad (31.93)$$

$$C_L = \left(\beta \frac{K_0^2}{\pi^2} - 1 \right) \quad (31.94)$$

where K_0 is the effective length factor obtained by the alignment chart for unbraced frames and P_L is

FIGURE 31.13 Subassembly of LeMessurier method.

only for *rigid columns*, which provide sidesway stiffness. For a cantilever column, $C_L = 0.216$. In multi-story structures, C_L may be expediently approximated by 0.2 for all columns except for pin-ended columns, for which $C_L = 0$.

EXAMPLE 31.6

Given: A sway frame with unequal height columns is shown in Figure 31.14a. Determine the elastic K -factors for columns by using the LeMessurier method. Member properties are

Member	A (in. ² , mm ²)	I (in. ⁴ , mm ⁴ , $\times 10^8$)	L (in., mm)
AB	21.5, 13,871	620, 2.58	240, 6096
BD	21.5, 13,871	620, 2.58	240, 6096
CD	7.65, 4,935	310, 1.29	120, 3048

Solution

The detailed calculations are listed in Table 31.4.

By using Equation 31.91, we obtain

$$\begin{aligned}
 K_{AB} &= \sqrt{\frac{\pi^2 EI_{AB}}{L_{AB}^2 P_{AB}} \left(\frac{\sum P + \sum C_L P}{\sum P_L} \right)} \\
 &= \sqrt{\frac{\pi^2 E(620)}{(240)^2 (2P)} \left(\frac{3P + 0.495P}{0.271E} \right)} = 0.83 \\
 K_{CD} &= \sqrt{\frac{\pi^2 EI_{CD}}{L_{CD}^2 P_{CD}} \left(\frac{\sum P + \sum C_L P}{\sum P_L} \right)} \\
 &= \sqrt{\frac{\pi^2 E(310)}{(120)^2 (P)} \left(\frac{3P + 0.495P}{0.271E} \right)} = 1.66
 \end{aligned}$$

31.6.2 Lui Method

A simple and straightforward approach for determining the effective length factors for framed columns without the use of alignment charts and other charts was proposed by Lui (1992). The formula takes into

FIGURE 31.14 A frame with unequal columns: (a) frame dimensions and loads and (b) frame subjected to fictitious lateral loads.

TABLE 31.4 Example 31.6 — Detailed Calculation by LeMessurier Method

Members	AB	CD	Sum	Notes

$C_L P$	0.33P	0.165P	0.495P	

account both the member instability and the frame instability effects explicitly. The K -factor for the i th column in a story was obtained in a simple form:

$$K_i = \sqrt{\left(\frac{\pi^2 EI_i}{P_i L_i^2}\right) \left[\left(\sum \frac{P}{L}\right) \left(\frac{1}{5 \sum \eta} + \frac{\Delta_1}{\sum H}\right) \right]} \tag{31.95}$$

where $\sum(P/L)$ represents the sum of axial force to length ratio of all members in a story, $\sum H$ is the story lateral load producing Δ_1 , Δ_1 is the first-order interstory deflection, and η is the member stiffness index and can be calculated by

$$\eta = \frac{(3 + 4.8m + 4.2m^2)EI}{L^3} \tag{31.96}$$

where m is ratio of the smaller to larger end moments of the member, it is taken as positive if the member bends in reverse curvature, and negative for single curvature.

It is important to note that the term $\sum H$ used in Equation 31.95 is not the actual applied lateral load. Rather, it is a small disturbing or fictitious force (taken as a fraction of the story gravity loads) to be applied to each story of the frame. This fictitious force is applied in a direction such that the deformed configuration of the frame will resemble its buckled shape.

EXAMPLE 31.7

Given: Determine K -factors by using the Lui method for the frame shown in [Figure 31.14a](#). $E = 29,000$ ksi (200 GPa).

Solution

Apply fictitious lateral forces at B and D (Figure 31.14b) and perform a first-order analysis. Detailed calculation is shown in [Table 31.5](#).

By using Equation 31.95, we obtain

$$\begin{aligned} K_{AB} &= \sqrt{\left(\frac{\pi EI_{AB}}{P_{AB} L_{AB}^2}\right) \left[\left(\sum \frac{P}{L}\right) \left(\frac{1}{5 \sum \eta} + \frac{\Delta_1}{\sum H}\right) \right]} \\ &= \sqrt{\left(\frac{\pi^2 (29,000)(620)}{(2P)(240)^2}\right) \left[\left(\frac{P}{60}\right) \left(\frac{1}{5(56.24)} + 0.019\right) \right]} = 0.76 \end{aligned}$$

 &= \sqrt{\left(\frac{\pi^2 (29,000)(310)}{P(120)^2}\right) \left[\left(\frac{P}{60}\right) \left(\frac{1}{5(56.24)} + 0.019\right)\right]} = 1.52
 \end{aligned}$$

31.6.3 Essa Method

Considering different story drafts, different stiffness parameters, $L\sqrt{P/EI}$, for columns, and different girder connections for the structural models shown in Figure 31.3, Essa (1998) presented a general effective length factor equation for column C_2 by solving five equations. Those five equations are obtained by considering the equilibrium of joints A and B and story shear for columns $C_1, C_2,$ and C_3 .

31.6.4 Cheong-Siat-Moy Method

Considering an individual end-restrained column as shown in Figure 31.1a, Equation 31.2 was presented in detail by Cheong-Siat-Moy (1999). When the beams bend in exact double curvature, R_{kA} and R_{kB} are directly related to G_A and G_B , respectively ($R_k = 6/G$). Equation 31.2 will become Equation 31.5 for braced frames when $T_k = \infty$ and Equation 31.6 for unbraced frames when $T_k = 0$.

T_k is the difference between the final lateral stiffness (T_{kf}) and the initial lateral stiffness (T_{ki}) of a column as follows:

$$T_k = T_{kf} - T_{ki} = \frac{P_i}{\sum P} T_{story} - T_{0i} \tag{31.97}$$

where T_{story} is the first-order lateral story stiffness and T_{0i} is the first-order lateral stiffness of column i .

An improved lateral stiffness T_k associated with $\gamma, P,$ and h and the first-order stiffness property was proposed by Helleland (2000) as follows:

$$T_k = T_{kf} - T_{ki} = \frac{(\gamma P/h)_i}{\sum \gamma P/h} T_{story} - T_{0i} \tag{31.98}$$

The term γ is the flexibility parameter and can be expressed as $\gamma = 1 + C_L$. A rather simple, yet fairly accurate expression was developed by Helleland (1998):

$$\gamma = 1 + 0.11 \frac{1 + [1 - (0.5G_{max})^p]^3}{(1 + 0.5G_{min})^2} \tag{31.99}$$

TABLE 31.6 Comparison of K -factors for Frame in Figure 31.14a

Columns	Theoretical	Alignment chart	Lui, Equation (31.80)	LeMessurier, Equation (31.76)
AB	0.70	1.17	0.76	0.83
CD	1.40	1.17	1.52	1.67

where $p = 1$ for $G_{\max} \leq 2$ and $p = -1$ for $G_{\max} > 2$. G_{\max} is the larger and G_{\min} is the smaller of the G -factors at the column ends.

31.6.5 Remarks

For a comparison, Table 31.6 summarizes K -factors for the frames shown in Figure 31.14a obtained from the alignment chart, the LeMessurier and Lui methods, as well as an eigenvalue analysis. The methods of both LeMessurier and Lui are based on the story-buckling concept. It is seen that errors in alignment chart results are rather significant in this case. Although the K -factors predicted by Lui's and LeMessurier's formulas are identical in most cases, the simplicity and independence of any chart in the case of Lui's formula make it more desirable for design office use (Shanmugam and Chen 1995). Essa's (1998) method overcomes some of the limitations imposed on the development of alignment chart and incorporates effects of inelastic behavior, different column stiffness parameters, and different restraining girder conditions. The Cheong-Siat-Moy (1999) method is dependent on the nondimensionalized lateral stiffness parameter of the column and can be used for partially braced frames. A comprehensive parametric study encouraged engineers to use the story-based K -factors for stability assessment (Roddis et al. 1998). Xu and Liu (2002) developed a story-based approach for both unbraced partially and fully restrained frames.

31.7 Unbraced Frames with Leaning Columns

A column framed with simple connections is often called a *leaning column*. It has no lateral stiffness or sidesway resistance. A column framed with the rigid moment-resisting connection is called a *rigid column*. It provides the lateral stiffness or sidesway resistance to the frame. When a frame system (Figure 31.15a) includes leaning columns, the effective length factors of rigid columns must be modified. Several approaches to account for the effect of leaning columns were reported in the literature (Yura 1971; Lim and McNamara 1972; LeMessurier 1977; Cheong-Siat-Moy 1986; Aristizabal-Ochoa 1994). A detailed discussion about leaning columns for practical applications was presented by Geschwindner (1995, 2002).

31.7.1 Rigid Columns

31.7.1.1 Yura Method

Yura (1971) discussed frames with leaning columns and noted the behavior of stronger columns assisting weaker ones in resisting sidesway. He concluded that the alignment chart gives valid sidesway buckling solutions if the columns are in the elastic range, and all columns in a story reach their individual buckling loads simultaneously. For columns that do not satisfy these two conditions, the alignment charts is generally overly conservative. The Yura approach states that

1. The maximum load-carrying capacity of an individual column is limited to the load permitted on that column for the braced case $K = 1.0$.
2. The total gravity loads that produce sidesway are distributed among the columns, which provides lateral stiffness in a story.

FIGURE 31.15 A frame with leaning columns: (a) a leaning column frame and (b) model for a leaning column.

31.7.1.2 Lim and McNamara Method

Based on the story-buckling concept and using the stability functions, Lim and McNamara (1972) presented the following formula to account for the leaning column effect:

$$K_n = K_0 \sqrt{1 + \frac{\sum Q}{\sum P} \left(\frac{F_0}{F_n} \right)} \tag{31.100}$$

where K_n is the effective length factor accounting for leaning columns; K_0 is the effective length factor determined by the alignment chart (Figure 31.3b) not accounting for the leaning columns; $\sum P$ and $\sum Q$ are the loads on the restraining columns and on the leaning columns in a story, respectively; and F_0 and F_n are the eigenvalue solutions for a frame without and with leaning columns, respectively. For normal column end conditions that fall somewhere between fixed and pinned, $F_0/F_n = 1$ provides a K -factor on the conservative side by less than 2% (Geschwindner 1995). Using $F_0/F_n = 1$, Equation 31.100 becomes

$$K_n = K_0 \sqrt{1 + \frac{\sum Q}{\sum P}} \tag{31.101}$$

Equation 31.93 gives the same K -factor as the modified Yura approach (Geschwindner 1995).

31.7.1.3 LeMessurier and Lui Methods

Equation 31.91 developed by LeMessurier and Equation 31.95 proposed by Lui (1992) can be used for frames both with and without leaning columns. Since the K -factor expressions (Equations 31.91 and 31.95) were derived for an entire story of the frame, they are applicable to frames with and without leaning columns.

31.7.1.4 AISC Load and Resistance Factor Design Method

The current AISC (1999) Commentary adopts the following two modified effective length factors K' for rigidly connected columns.

For story stiffness method

$$K' = \sqrt{\frac{P_e}{0.822 P_u} \sum P_u \left(\frac{\Delta_{0h}}{\sum HL} \right)} \tag{31.102}$$

where

$$P_e = \frac{\pi^2 EI}{L^2} \tag{31.103}$$

P_u is the required axial compressive strength of the column under consideration, $\sum P_u$ is the required axial compressive strength of all columns in a story, Δ_{0h} is the lateral interstory deflection, $\sum H$ is the sum of all story horizontal forces producing Δ_{0h} , and L is the story height. The 0.822 factor is the ratio of the lateral column shear force per radian of drift to the buckling load of a sway permitted column with large end restraint, $G=0$. This factor will approach 1.0 for more flexible systems with a large percentage of leaner columns.

For the story buckling method

$$K' = \sqrt{\frac{P_c}{P_u} \left(\frac{\sum P_u}{\sum P_{e2}} \right)} \tag{31.104}$$

where $\sum P_{e2}$ is the sum of Euler loads of all columns in a story providing lateral stiffness for the frame based on the effective length factor obtained from the alignment chart for an unbraced frame, P_u is the required axial compressive strength for rigid column, and $\sum P_u$ is the required axial compressive strength of all columns in a story.

EXAMPLE 31.8

Given: A frame with a leaning column is shown in [Figure 31.16a](#) (Lui and Sun 1995). Evaluate the K -factor for column AB using various methods. The bottom of column AB is assumed to be ideally pin-ended for comparison purposes. $E=29,000$ ksi (200 GPa).

Solution

Alignment Chart Method

$$G_A = \infty$$

$$G_B = \frac{\sum E_c I_c / L_c}{\sum \alpha_k E_g I_g / L_g} = \frac{EI/L}{0.5EI/L} = 2.0$$

From [Figure 31.3b](#), we have $K_{AB} = 2.6$.

Lima and McNamara Method

For this frame, $\sum P = \sum Q = P$ and $K_0 = 2.6$. From Equation 31.100, we have

$$K_{AB} = K_0 \sqrt{1 + \frac{\sum Q}{\sum P}} = 2.6 \sqrt{1 + 1} = 3.68$$

LeMessurier Method

For column AB, $G_A = \infty$ and $G_B = 2.0$; from the alignment chart, $K_0 = 2.6$.

According to Equations 31.91 to 31.94, we have

$$\beta|_{G_A=\infty} = \frac{6(G_A + G_B) + 36}{2(G_A + G_B) + G_A G_B + 3} \Big|_{G_A=\infty} = \frac{6}{2 + G_B} = \frac{6}{2 + 2} = 1.5$$

$$\sum P_L = (P_L)_{AB} = \frac{\beta EI}{L^2} = 1.5 \frac{EI}{L^2}$$

$$C_L = \left(\beta \frac{K_0^2}{\pi^2} - 1 \right) = (1.5) \frac{2.6^2}{\pi^2} - 1 = 0.0274$$

$$K_{AB} = \sqrt{\frac{\pi^2 EI_{AB}}{L_{AB}^2 P_{AB}} \left(\frac{\sum P + \sum C_L P}{\sum P_L} \right)} = \sqrt{\frac{\pi^2 EI}{L^2 P} \left(\frac{2P + 0.0274P}{1.5EI/L^2} \right)}$$

$$= \sqrt{13.34} = 3.65$$

FIGURE 31.16 A leaning column frame: (a) frame dimension and loads and (b) frame subjected to fictitious lateral loads.

AISC Load and Resistance Factor Design Method

Using Equation 31.102 for column AB

$$K_{AB} = \sqrt{\frac{\sum P_u}{P_{AB}} \times \left(\frac{I_{AB}}{\sum (I/K_{i0}^2)} \right)} = K_{i0} \sqrt{2} = 3.68$$

Lui Method

1. Apply a small lateral force $H = 1$ kip as shown in Figure 31.16b.
2. Perform a first-order analysis and find $\Delta_1 = 0.687$ in. (17.45 mm).
3. Calculate η factors from Equation 31.96.

Since column CD buckles in a single curvature, $m = -1$,

$$\eta_{CD} = \frac{(3 + 4.8m + 4.2m^2)EI}{L^3} = \frac{(3 - 4.8 + 4.2)EI}{L^3} = \frac{2.4EI}{L^3}$$

For column AB, $m = 0$,

$$\eta_{AB} = \frac{(3 + 4.8m + 4.2m^2)EI}{L^3} = \frac{3EI}{L^3}$$

$$\sum \eta = \frac{3EI}{L^3} + \frac{2.4EI}{L^3} = \frac{5.4(29,000)(100)}{(144)^3}$$

$$= 5.245 \text{ kip/in. (0.918 kN/mm)}$$

4. Calculate the K -factor from Equation 31.95

$$K_{AB} = \sqrt{\left(\frac{\pi^2 EI_{AB}}{P_{AB} L_{AB}^2}\right) \left[\left(\sum \frac{P}{L}\right) \left(\frac{1}{5 \sum \eta} + \frac{\Delta_1}{\sum H}\right) \right]}$$

$$= \sqrt{\left(\frac{\pi^2 (29,000)(100)}{P(144)^2}\right) \left[\left(\frac{2P}{144}\right) \left(\frac{1}{5(5.245)} + \frac{0.687}{1}\right) \right]} = 3.73$$

From an eigenvalue analysis, $K_{AB} = 3.69$ is obtained. It is seen that a direct use of the alignment chart leads to a significant error for this frame, and other approaches give good results. However, the LeMessurier approach requires the use of the alignment chart, and the Lui approach requires a first-order analysis subjected to a fictitious lateral loading.

31.7.2 Leaning Columns

Recognizing that a leaning column is being braced by rigid columns, a model for the leaning column as shown in [Figure 31.15b](#) was proposed by Lui (1992). Rigid columns provide lateral stability to the whole structure and are represented by a translation spring with a spring stiffness S_K . The K -factor for a leaning column can be obtained as

$$K = \text{larger of } \begin{cases} 1 \\ \sqrt{\frac{\pi^2 EI}{S_K L^3}} \end{cases} \quad (31.105)$$

For most commonly framed structures, the term $(\pi^2 EI/S_K L^3)$ normally does not exceed unity, and so $K = 1$ often governs. AISC (1999) suggests that leaning columns with $K = 1$ may be used in unbraced frames provided that the lack of lateral stiffness from simple connections to the frame ($K = \infty$) is included in the design of moment frame columns. Aristizabal-Ochoa (1994b) recommended that (1) the K -factors of leaning columns are identical to the K -factors of the rigid columns when they are subjected to the same magnitude axial loads and are made of the same section and (2) the K -factors of leaning columns must be greater than 1.0 or the K -factor corresponding to the fully braced column with the same supports or boundary conditions.

31.7.3 Remarks

Numerical studies by Geschwindner (1995, 2002) found that the Yura approach gives overly conservative results for some conditions, the Lim and McNamara approach provides sufficiently accurate results for design, and the LeMessurier approach is the most accurate, among the three. The Lim and McNamara approach could be appropriate for preliminary design, while the LeMessurier and Lui approaches would be appropriate for final design.

31.8 Crossing Bracing Systems

Diagonal bracing or X-bracing is commonly used in steel structures to resist horizontal loads. In current practice, the design of these types of bracing system is based on the assumptions that the compression diagonal has negligible capacity and the tension diagonal resists the total load. The assumption that the compression diagonal has a negligible capacity usually results in an overdesign (Picard and Beaulieu 1987, 1988).

Picard and Beaulieu (1987, 1988) reported theoretical and experimental studies on double-diagonal cross bracings (Figure 31.6) and found that

1. A general effective length factor equation (Figure 31.17) is given as

$$K = \sqrt{0.523 - \frac{0.428}{C/T}} \geq 0.50 \tag{31.106}$$

where C and T represent the compression and tension forces obtained from an elastic analysis, respectively.

2. When the double diagonals are continuous and attached at the intersection point, the effective length of the compression diagonal is 0.5 times the diagonal length, that is, $K=0.5$, because the C/T ratio is usually smaller than 1.6.

EL-Tayem and Goel (1986) reported a theoretical and experimental study about the X-bracing system made from single equal-leg angles. They concluded that

1. Design of X-bracing system should be based on an exclusive consideration of one half-diagonal only.
2. For X-bracing systems made from single equal-leg angles, an effective length of 0.85 times the half-diagonal length is reasonable, that is, $K=0.425$.

FIGURE 31.17 Effective length factor of compression diagonal (Picard and Beaulieu 1987).

Sabelli and Hohbach (1999) studied the relationship between axial load and end rotational stiffness for cross-braced frames. For in-plane buckling, the lower bound values of K -factor equal 0.422 for pinned-end and 0.245 for fixed-end; the upper bound values of K -factor equal 0.4 for pinned-end and 0.272 for fixed-end. For out-of-plan buckling, the lower bound values of K -factor equal 0.5 for pinned-end and 0.35 for fixed-end.

31.9 Latticed and Built-Up Members

The main difference of behavior between solid-webbed members and latticed members and built-up members is the effect of shear deformation on their buckling strength. For solid-webbed members, shear deformation has a negligible effect on their buckling strength, while for latticed structural members using lacing bars and batten plates, shear deformation has a significant effect on their buckling strength. It is common practice that when the buckling model involves relative deformation produced by shear forces in the connectors, such as lacing bars and batten plates, between individual components, a modified effective length factor K_m is defined as follows:

$$K_m = \alpha_v K \tag{31.107}$$

where K is the usual effective length factor of a latticed member acting as a unit obtained from a structural analysis and α_v is the shear factor to account for shear deformation on the buckling strength, or the modified effective slenderness ratio $(KL/r)_m$ should be used in the determination of the compressive strength. Details of the development of the shear factor α_v can be found in textbooks by Bleich (1952) and Timoshenko and Gere (1961). The following section briefly summarizes α_v formulas for various latticed members.

31.9.1 Laced Columns

For laced members as shown in Figure 31.18, by considering shear deformation due to the lengthening of diagonal lacing bars in each panel and assuming hinges at joints, the shear factor α_v has the form

$$\alpha_v = \sqrt{1 + \frac{\pi^2 EI}{(KL)^2 A_d E_d \sin \phi \cos^2 \phi}} \tag{31.108}$$

FIGURE 31.18 Typical configurations of laced members: (a) single lacing and (b) double lacing.

where E_d is the modulus of elasticity of materials for lacing bars, A_d is the cross-sectional area of all diagonals in one panel, and ϕ is the angle between the lacing diagonal and the axis that is perpendicular to the member axis.

If the lengths of the lacing bars are given (Figure 31.18), Equation 31.108 can be rewritten as

$$\alpha_v = \sqrt{1 + \frac{\pi^2 EI}{(KL)^2} \frac{d^3}{A_d E_d a b^2}} \quad (31.109)$$

where a , b , and d are height of the panel, depth of the member, and length of the diagonal, respectively.

The SSRC (Galambos 1988) suggested that a conservative estimate of the influence of 60 or 45° lacing, as generally specified in bridge design practice, can be made by modifying the overall effective length factor K by multiplying a factor α_v , originally developed by Bleich (1952) as follows:

$$\alpha_v = \sqrt{1 + 300/(KL/r)^2} \quad \text{for } \frac{KL}{r} > 40 \quad (31.110)$$

$$\alpha_v = 1.1 \quad \text{for } \frac{KL}{r} \leq 40 \quad (31.111)$$

EXAMPLE 31.9

Given: A laced column with angles and cover plates is shown in Figure 31.19. As usual, $K_y = 1.25$, $L = 30$ ft (9144 mm). Determine the modified effective length factor $(K_y)_m$ by considering the shear deformation effect.

Section properties

$$I_y = 2259 \text{ in.}^4 \quad (9.4 \times 10^8 \text{ mm}^4)$$

$$E = E_d$$

$$A_d = 1.69 \text{ in.}^2 \quad (1090 \text{ mm}^2)$$

$$a = 6 \text{ in.} \quad (152 \text{ mm})$$

$$b = 11 \text{ in.} \quad (279 \text{ mm})$$

$$d = 12.53 \text{ in.} \quad (318 \text{ mm})$$

Solution

1. Calculate the shear factor α_v by Equation 31.110

$$\begin{aligned} \alpha_v &= \sqrt{1 + \frac{\pi^2 EI}{(KL)^2} \frac{d^3}{A_d E_d a b^2}} \\ &= \sqrt{1 + \frac{\pi^2 E(2259)}{(1.25 \times 30 \times 12)^2} \frac{12.53^3}{1.69E(6)(11)^2}} = 1.09 \end{aligned}$$

2. Calculate $(K_y)_m$ by Equation 31.107

$$(K_y)_m = \alpha_v K_y = 1.09(1.25) = 1.36$$

31.9.2 Columns with Battens

The battened column has a greater shear flexibility than either the laced column or the column with perforated cover plates, hence the effect of shear distortion must be taken into account in calculating the effective length of a column (Johnston 1976). For the battened members shown in Figure 31.20a, assuming that the points of inflection in the battens are at the batten midpoints and that the points

FIGURE 31.19 A laced column.

of inflection in the longitudinal element occur midway between the battens, the shear factor α_v is obtained as

$$\alpha_v = \sqrt{1 + \frac{\pi^2 EI}{(KL)^2} \left(\frac{ab}{12E_b I_b} + \frac{a^2}{24EI_f} \right)} \quad (31.112)$$

where E_b is the modulus of elasticity of materials for batten plates, I_b is the moment inertia of all battens in one panel in the buckling plane, and I_f is the moment inertia of one side of the main components taken about the centroid axis of the flange in the buckling plane.

EXAMPLE 31.10

Given: A battened column is shown in Figure 31.21. As usual, $K_y = 0.8$, $L = 30$ ft (9144 mm). Determine the modified effective length factor $(K_y)_m$ by considering the shear deformation effect.

Section properties

$$I_y = 144 \text{ in.}^4 \quad (6.0 \times 10^7 \text{ mm}^4)$$

$$E = E_b$$

FIGURE 31.20 Typical configurations of members with battens and with perforated cover plates: (a) battens, (b) lacing-battens, and (c) perforated cover plates.

$$I_f = 1.98 \text{ in.}^4 \quad (8.24 \times 10^5 \text{ mm}^4)$$

$$a = 15 \text{ in.} \quad (381 \text{ mm})$$

$$b = 9 \text{ in.} \quad (229 \text{ mm})$$

$$I_b = 9 \text{ in.}^4 \quad (3.75 \times 10^6 \text{ mm}^4)$$

Solution

1. Calculate the shear factor α_v by Equation 31.112

$$\alpha_v = \sqrt{1 + \frac{\pi^2 EI}{(KL)^2} \left(\frac{ab}{12E_b} + \frac{a^2}{24E_f} \right)}$$

$$= \sqrt{1 + \frac{\pi^2 E(144)}{(0.8 \times 30 \times 12)^2} \left(\frac{15(9)}{12E(9)} + \frac{15^2}{24E(1.98)} \right)} = 1.05$$

2. Calculate $(K_y)_m$ by Equation 31.107

$$(K_y)_m = \alpha_v K_y = 1.05(0.8) = 0.84$$

31.9.3 Laced-Battened Columns

For the laced-battened columns as shown in Figure 31.20b, considering the shortening of the battens and the lengthening of the diagonal lacing bars in each panel, the shear factor α_v can be expressed as

$$\alpha_v = \sqrt{1 + \frac{\pi^2 EI}{(KL)^2} \left(\frac{d^3}{A_d E_d a b^2} + \frac{b}{a A_b E_b} \right)} \tag{31.113}$$

where E_b is the modulus of elasticity of materials for battens and A_b is the cross-sectional area of all battens in one panel.

FIGURE 31.21 A batten column.

31.9.4 Columns with Perforated Cover Plates

For members with perforated cover plates shown in Figure 31.20c, considering the horizontal cross-member as infinitely rigid, the shear factor α_v has the form

$$\alpha_v = \sqrt{1 + \frac{\pi^2 EI}{(KL)^2} \left(\frac{9c^3}{64aEI_f} \right)} \tag{31.114}$$

where c is the length of a perforation.

It should be pointed out that the usual K -factor based on a solid member analysis is included in Equations 31.108 to 31.114. However, since the latticed members studied previously have pin-ended conditions, the K -factor of the member in the frame was not included in the second terms

of the square root of the above equations in their original derivations (Bleich 1952; Timoshenko and Gere 1961).

EXAMPLE 31.11

Given: A column with perforated cover plates is shown in Figure 31.22. As usual, $K_y = 1.3$, $L = 25$ ft (7620 mm). Determine the modified effective length factor $(K_y)_m$ by considering the shear deformation effect.

Section properties

$$I_y = 2467 \text{ in.}^4 \quad (1.03 \times 10^8 \text{ mm}^4)$$

$$I_f = 35.5 \text{ in.}^4 \quad (1.48 \times 10^6 \text{ mm}^4)$$

$$a = 30 \text{ in.} \quad (762 \text{ mm})$$

$$c = 14 \text{ in.} \quad (356 \text{ mm})$$

FIGURE 31.22 A column with perforated cover plates.

Solution

1. Calculate the shear factor α_v by Equation 31.114

$$\begin{aligned} \alpha_v &= \sqrt{1 + \frac{\pi^2 EI}{(KL)^2} \left(\frac{9c^3}{64aEI_f} \right)} \\ &= \sqrt{1 + \frac{\pi^2 E(2467)}{(1.3 \times 25 \times 12)^2} \left(\frac{9(14)^3}{64(30)E(35.5)} \right)} = 1.03 \end{aligned}$$

2. Calculate $(K_y)_m$ by Equation 31.107

$$(K_y)_m = \alpha_v K_y = 1.03(1.3) = 1.34$$

31.9.5 Built-Up Members with Bolted and Welded Connectors

AISC (1999) specifies that if the buckling of a built-up member produces shear forces in the connectors between individual component members, the usual slenderness ratio KL/r for compression members must be replaced by the modified slenderness ratio $(KL/r)_m$ in determining the compressive strength:

1. For snug-tight bolted connectors

$$\left(\frac{KL}{r} \right)_m = \sqrt{\left(\frac{KL}{r} \right)_0^2 + \left(\frac{a}{r_i} \right)^2} \tag{31.115}$$

2. For welded connectors and for fully tightened bolted connectors

$$\left(\frac{KL}{r} \right)_m = \sqrt{\left(\frac{KL}{r} \right)_0^2 + 0.82 \frac{\alpha^2}{(1 + \alpha^2)} \left(\frac{a}{r_{ib}} \right)^2} \tag{31.116}$$

where $(KL/r)_0$ is the slenderness ratio of the built-up member acting as a unit, $(KL/r)_m$ is the modified slenderness ratio of the built-up member, a/r_i is the largest slenderness ratio of the individual components, a/r_{ib} is the slenderness ratio of the individual components relative to its centroidal axis parallel to the axis of buckling, a is the distance between connectors, r_i is the minimum radius of gyration of individual components, r_{ib} is the radius of gyration of individual components relative to its centroidal axis parallel to the member axis of buckling, α is the separation ratio $= h/2r_{ib}$, and h is the distance between centroids of individual components perpendicular to the member axis of buckling

Equation 31.115 is the same as that used in the current Italian code as well as in other European specifications, based on test results (Zandonini 1985). In the equation, the bending effect is considered in the first term in square root, and shear force effect is taken into account in the second term. Equation 31.116 was derived from elastic stability theory and was verified by test data (Aslani and Goel 1991). In both cases the end connectors must be welded or slip-critical bolted (Aslani and Goel 1991).

EXAMPLE 31.12

Given: A built-up member with two back-to-back angles is shown in [Figure 31.23](#). Determine the modified slenderness ratio $(KL/r)_m$ in accordance with AISC (1999), Equation 31.108:

$$\begin{aligned} r_{ib} &= 0.735 \text{ in. (19 mm)} \\ a &= 48 \text{ in. (1219 mm)} \\ h &= 1.603 \text{ in. (41 mm)} \\ (KL/r)_0 &= 70 \end{aligned}$$

FIGURE 31.23 A built-up member with back-to-back angles.

Solution

1. Calculate the separation factor α

$$\alpha = \frac{h}{2r_{ib}} = \frac{1.603}{2(0.735)} = 1.09$$

2. Calculate the modified slenderness ratio $(KL/r)_m$ by Equation 31.116

$$\begin{aligned} \left(\frac{KL}{r}\right)_m &= \sqrt{\left(\frac{KL}{r}\right)_0^2 + 0.82 \frac{\alpha^2}{(1 + \alpha^2)} \left(\frac{a}{r_{ib}}\right)^2} \\ &= \sqrt{(70)^2 + 0.82 \frac{1.09^2}{(1 + 1.09^2)} \left(\frac{48}{0.735}\right)^2} \\ &= 82.5 \end{aligned}$$

31.10 Tapered Columns

The state-of-the-art design for tapered structural members was provided in the SSRC guide (Galambos 1988). The charts as shown in Figure 31.24 and Figure 31.25 can be used to evaluate the effective length factors for tapered column restrained by prismatic beams (Galambos 1988). In these figures, I_T and I_B are the moments of inertia of top and bottom beams, respectively; b and L are lengths of beam and column, respectively; and γ is the tapering factor as defined by

$$\gamma = \frac{d_1 - d_0}{d_0} \tag{31.117}$$

where d_0 and d_1 are the section depths of column at the smaller and larger ends, respectively.

FIGURE 31.24 Effective length factor for tapered columns in braced frames (Galambos 1988).

Effects of shear deformation on the effective length factors of tapered I-section columns in a portal frame Figure 31.26 were studied by Li and Li (2000).

$$n = \frac{I_{c1}}{I_{c0}} \tag{31.118}$$

$$\lambda_c = \frac{L_c}{\sqrt{I_{c0}/A_{c0}}} = \frac{L_c}{r_{c0}} \tag{31.119}$$

When $\lambda_c \geq 36\sqrt{0.02n} + 26$, shear effect can be ignored.

The following shear factor was proposed to account for the tapered columns (Li and Li 2000):

$$\alpha_v = 1.0 + f_1(n)e^{-(\lambda_c - 17.75)/4} + f_2(n)e^{-(\lambda_c - 17.75)/22} \tag{31.120}$$

$$f_1(n) = 0.029031 + 0.0088n - 0.0003416n^2 + 0.000004155n^3 \tag{31.121}$$

$$f_2(n) = 0.06523 + 0.0112n - 0.0001056n^2 \tag{31.122}$$

31.11 Crane Columns

The columns in mill buildings and warehouses are designed to support overhead crane loads. The cross-section of a crane column may be uniform or stepped (see Figure 31.27). Over the past two decades, a number of simplified procedures have been developed for evaluating the K -factors for crane columns (Huang 1968; Anderson and Woodward 1972; Lay 1973; Agarwal and Stafiej 1980; Moore 1986;

FIGURE 31.25 Effective length factor for tapered columns in unbraced frames (Galambos 1988).

FIGURE 31.26 A tapered portal frame.

Fraser 1989, 1990; AISE 1991; Bendapudi 1994). Those procedures have limitation in terms of column geometry, loading, and boundary conditions. Most importantly, most of these studies ignored the interaction effect between the left and right columns of frames and were based on isolated member analyses (Lui and Sun 1995). Recently, a simple, yet reasonably accurate, procedure for calculating the K -factors for crane columns with any value of relative shaft length, moment of inertia, loading, and

FIGURE 31.27 Typical crane columns.

boundary conditions was developed by Lui and Sun (1995). On the basis of the story stiffness concept and accounting for both member and frame instability effects in the formulation, Lui and Sun (1995) proposed the following procedure (see Figure 31.28):

1. Apply the fictitious lateral loads αP (α is an arbitrary factor, 0.001 may be used) in such a direction as to create a deflected geometry for the frame that closely approximates its actual buckled configuration.
2. Perform a first-order elastic analysis on the frame subjected to the fictitious lateral loads (Figure 31.28b). Calculate $\Delta_i / \sum H$, where Δ_i is the average lateral deflection at the intermediate load points (i.e., points B and F) of columns and $\sum H$ is the sum of all fictitious lateral loads that act at and above the intermediate load points.
3. Calculate η using the results obtained from a first-order elastic analysis for lower shafts (i.e., segments AB and FG), according to Equation 31.89.
4. Calculate the K -factor for the lower shafts using Equation 31.88.
5. Calculate the K -factor for upper shafts using the following formula:

$$K_U = K_L \left(\frac{L_L}{L_U} \right) \sqrt{\left(\frac{P_L + P_U}{P_U} \right) \left(\frac{I_U}{I_L} \right)} \quad (31.123)$$

where P is the applied load and subscripts U and L represent the upper and lower shafts, respectively.

EXAMPLE 31.13

Given: A stepped crane column is shown in Figure 31.29a. The example is the same frame as that used by Fraser (1990) and Lui and Sun (1995). Determine the effective length factors for all columns using the Lui approach. $E = 29,000$ ksi (200 GPa).

$$I_{AB} = I_{FG} = I_L = 30,000 \text{ in.}^4 \quad (1.25 \times 10^{10} \text{ mm}^4)$$

$$A_{AB} = A_{FG} = A_L = 75 \text{ in.}^2 \quad (48,387 \text{ mm}^2)$$

FIGURE 31.28 Crane column model for effective length factor computation: (a) frame subjected to gravity loads and (b) frame subjected to fictitious lateral loads (Lui and San 1995).

FIGURE 31.29 Pin-based stepped crane columns: (a) frame subjected to gravity loads and (b) frame subjected to fictitious lateral loads.

$$I_{BC} = I_{EF} = I_{CE} = I_U = 5420 \text{ in.}^4 \quad (2.26 \times 10^9 \text{ mm}^4)$$

$$A_{BC} = A_{EF} = A_{CE} = A_U = 34.14 \text{ in.}^2 \quad (22,026 \text{ mm}^2)$$

Solution

1. Apply a set of fictitious lateral forces with $\alpha = 0.001$ as shown in Figure 31.29b
2. Perform a first-order analysis and find

$$(\Delta_1)_B = 0.1086 \text{ in. (2.76 mm)} \quad \text{and} \quad (\Delta_1)_F = 0.1077 \text{ in. (2.74 mm)}$$

so,

$$\frac{\Delta_1}{\sum H} = \frac{(0.1086 + 0.1077)/2}{0.053 + 0.3 + 0.053 + 0.14} = 0.198 \text{ in./kip} \quad (1.131 \text{ mm/kN})$$

3. Calculate η factors from Equation 31.89

Since the bottom of columns AB and FG is pin-based, $m=0$,

$$\begin{aligned}\eta_{AB} &= \eta_{FG} = \frac{(3 + 4.8m + 4.2m^2)EI}{L^3} = \frac{3EI}{L^3} \\ &= \frac{(3)(29,000)(30,000)}{(396)^3} = 42.03 \text{ kip/in. (7.36 mm/kN)}\end{aligned}$$

$$\sum \eta = 42.03 + 42.03 = 84.06 \text{ kip/in. (14.72 mm/kN)}$$

4. Calculate the K -factors for columns AB and FG using Equation 31.88

$$\begin{aligned}K_{AB} &= \sqrt{\left(\frac{\pi^2(29,000)(30,000)}{(353)(396)^2}\right) \left[\left(\frac{353 + 193}{396}\right) \left(\frac{1}{5(84.06)} + 0.198\right)\right]} \\ &= 6.55\end{aligned}$$

$$\begin{aligned}K_{FG} &= \sqrt{\left(\frac{\pi^2(29,000)(30,000)}{(193)(396)^2}\right) \left[\left(\frac{353 + 193}{396}\right) \left(\frac{1}{5(84.06)} + 0.198\right)\right]} \\ &= 8.85\end{aligned}$$

5. Calculate the K -factors for columns BC and EF using Equation 31.123

$$\begin{aligned}K_{BC} &= K_{AB} \left(\frac{L_{AB}}{L_{BC}}\right) \sqrt{\left(\frac{P_{AB} + P_{BC}}{P_{BC}}\right) \left(\frac{I_{BC}}{I_{AB}}\right)} \\ &= 6.55 \left(\frac{396}{156}\right) \sqrt{\left(\frac{353}{53}\right) \left(\frac{5,420}{30,000}\right)} = 18.2\end{aligned}$$

$$\begin{aligned}K_{EF} &= K_{FG} \left(\frac{L_{FG}}{L_{EF}}\right) \sqrt{\left(\frac{P_{FG} + P_{EF}}{P_{EF}}\right) \left(\frac{I_{EF}}{I_{FG}}\right)} \\ &= 8.85 \left(\frac{396}{156}\right) \sqrt{\left(\frac{193}{53}\right) \left(\frac{5,420}{30,000}\right)} = 18.2\end{aligned}$$

The K -factors calculated above are in good agreement with the theoretical values reported by Lui and Sun (1995).

31.12 Columns in Gable Frames

For a pin-based gable frame subjected to a uniformly distributed load on the rafter as shown in Figure 31.30a, Lu (1965) presented a graph (Figure 31.30b) to determine the effective length factors of columns. For frames having different member sizes for rafter and columns having (L/h) of (f/h) ratios not covered in Figure 31.30, an approximate method is available for determining K -factors of columns (Hansell 1964). The method is to find an equivalent portal frame whose span length is equal to twice the rafter length L_r (see Figure 31.30a). The K -factors can be determined from the alignment charts using $G_{\text{top}} = (I_c/h)/(I_r/2L_r)$ and the corresponding G_{bottom} .

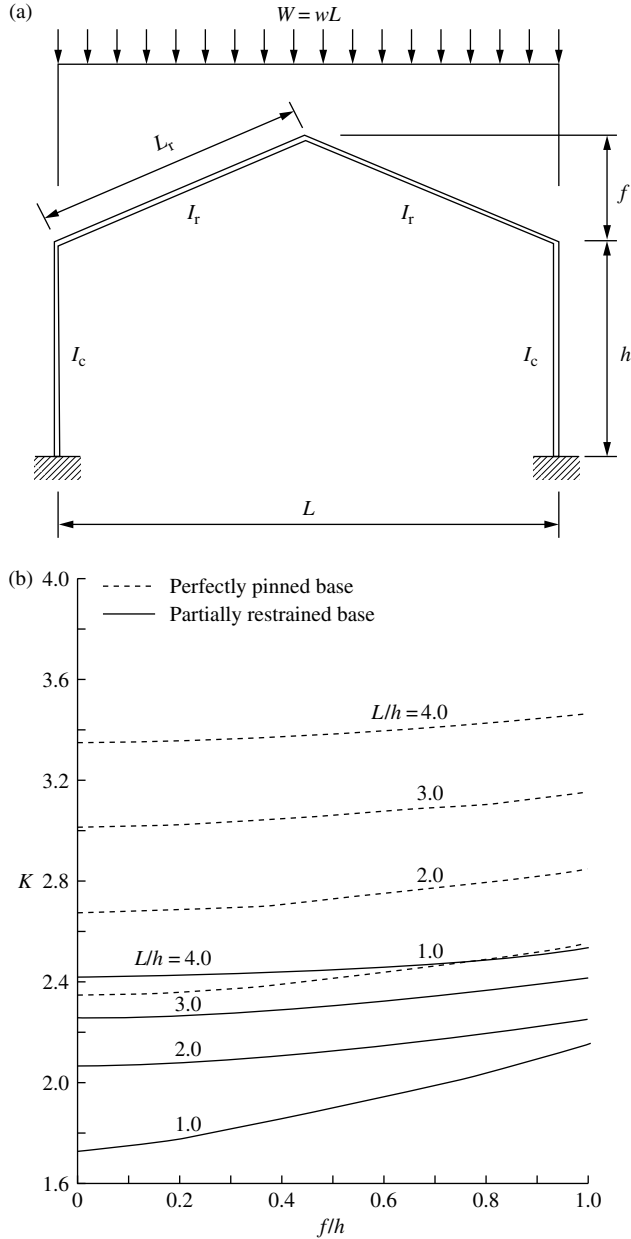

FIGURE 31.30 Effective length factor for columns in pinned-base gable frames: (a) a pinned-base gable frame and (b) effective length factors (Lu 1965).

31.13 Columns in Fire

The effects of structural continuity on fire exposed columns have been investigated over the last two decades. In the fire limit state, unexposed relative cool parts impose restraint on the structure's elements under fire. The Eurocode 4 Part 1.2 (ECS 1994) recommends that the K -factor for braced frames for a column continuous at both ends may be taken as 0.5 and that for a column continuous at one end may be taken as 0.7.

Experimental studies on fixed-ended steel columns in fire performed by Ali (2000) and Ali and O'Connor (2001) gave an average value of 0.56 for highly restrained columns and 0.61 for a low rotational restraint.

Theoretical studies on concrete-filled columns (Wang 1999) found that Eurocode recommendations give very accurate results of fire resistance for unreinforced subframe columns. The fire resistance of reinforced subframe columns were slightly overestimated, but the difference was small. An extensive parametric study on concrete-filled steel square hollow sections (Bailey 2000) concluded that for braced columns continuous at both ends, $K=0.55$ without considering local buckling at the top of the heated column, and $K=0.75$ when considering the effects of possible local buckling; for braced columns continuous at one end, $K=0.8$; for an idealized pinned foundation, $K=1.0$.

31.14 Members in Space Frames

Space frames with various nodal connection systems are widely used all over the world. The current design method is based on the assumption that the joints are pin-ended. Experimental and theoretical investigations on Oktalok space frame as shown in Figure 31.31 provided the following formula to estimate effective length factor of members in Oktalok space frames (Zhao et al. 2000):

$$K = 1.25 - \frac{L/r}{246} \quad (31.124)$$

where $98 \leq L/r \leq 140$.

31.15 Truss-Type Highway Sign Support Structures

For a typical truss-type highway sign support structure as shown in Figure 31.32, the main vertical support columns are usually assumed as fixed at the base and pinned to the top truss box. $K=1.0$ is

FIGURE 31.31 Oktalok nodal system.

FIGURE 31.32 A Typical truss-type sign support structure.

often conservatively assumed for the main vertical support columns in design. Some engineers may take a more conservative approach and use $K = 2.0$, assuming the frame to be unbraced against sidesway in the perpendicular direction. $K = 0.85$ is assumed for diagonal members. The current overly simplified procedure does not provide a true presentation of actual behavior (DeWolf and Yang 2000) and may lead to excessively conservative design. A structural system stability analysis indicated that a significant reduction in the effective length factors can be achieved for both columns and diagonals. DeWolf and Yang (2000) recommended that

- Changing the sizes of the diagonals has a significant influence on the overall in-plane buckling strength of columns but does not affect the out-of-plane buckling strength.
- Increasing the restraints of the connections between the top of the columns and the sign box structures can increase the out-of-plane buckling strength. If the connection between top box and column is pinned, $K = 1.37$. If it is fully restricted against rotation, $K = 0.82$.

31.16 Precast Concrete Skeletal Frames

Precast skeletal structures are usually designed either as unbraced structures, up to three or four stories, or as fully braced structures, up to 15 to 20 stories in height. The design and analysis of precast skeletal structures is greatly influenced by the behavior of beam-to-column connections. Eillott et al. (1998) conducted a series of experimental studies of precast concrete beam–column connections and proposed an approach to calculate the *K*-factors.

Precast concrete frames (Figure 31.33) are analyzed either as fully unbraced structures (upper frame) or as partially braced structures (lower frame) where shear walls or cores provide lateral bracing up to a certain level and the frame is unbraced above this point. The following equations were proposed to evaluate the *K*-factors for the subframes, F1, F2, and F3 (Figure 31.33):

For frame F1

$$K = \begin{cases} 1 + \frac{1}{0.2 + 10G_s} + \frac{G}{0.3 + 1.8G_s - 0.45G_s^2} & \text{for } 0.1 < G_s \leq 2 \\ 1.1 + \frac{1}{7.4 + 7.4G_s - 0.4G_s^2} + \frac{G}{1.6 + 0.3G_s} & \text{for } 2 \leq G_s \leq 10 \end{cases} \quad (31.125)$$

For frame F2

$$K = \begin{cases} 1 + \frac{1}{2.0 + 2G_s + 4G_s^2} + \frac{G}{4 + 0.5G_s} & \text{for } 0.1 < G_s \leq 2 \\ 1 + \frac{1}{8.6 + 8.4G_s - 0.4G_s^2} + \frac{G}{3.9 + 0.9G_s} & \text{for } 2 \leq G_s \leq 10 \end{cases} \quad (31.126)$$

For frame F3

$$K = \begin{cases} 1 + \frac{1}{1.25 + 2.5G_s + 2.5G_s^2} + \frac{G}{2.25 + 0.5G_s} & \text{for } 0.1 < G_s \leq 2 \\ 1 + \frac{1}{6.5 + 5.6G_s - 0.3G_s^2} + \frac{G}{2.7 + 0.3G_s} & \text{for } 2 \leq G_s \leq 10 \end{cases} \quad (31.127)$$

where *G* is the column end stiffness ratio as defined in Equation 31.7 and *G_s* is the relative semirigidity of the beam-to-column connection and is defined as joint stiffness *J*/beam flexural stiffness *4EI/L*.

31.17 Steel Moment Frame

In the proposed American Institute of Steel Construction (AISC) 2005 Specification, attempts are made to use *K*=1.0 for nominal column strengths, *P_n*, in the interaction equations, when the required

FIGURE 31.33 Types of precast frames.

strengths for members, connections, and other structural elements are obtained from the second-order elastic analysis under load and resistance factor design (LRFD) combinations. Its appendix provides the direct second-order analysis method for steel moment frames.

31.17.1 Second-Order Elastic Analysis

The second-order analysis required for using $K=1.0$ in the interaction equations should capture both the $P-\delta$ and the $P-\Delta$ effects. The analysis may be performed either using a direct second-order analysis or by modifying the results of a first-order analysis using the B_1 and B_2 amplification factors (AISC 1999), provided that the B_1 and B_2 factors are based on the reduced flexural stiffness. Approximate $P-\Delta$ methods should be permitted when the factored axial loads in all columns are less than 15% of their respective Euler buckling loads. When the second-order displacement based on 20% reduced elastic stiffness is greater than six times the first-order displacement, it is recommended to increase the frame stiffness to limit the amplification to 6. Otherwise, the high nonlinearity would be such that small changes in gravity load or member stiffness will result in large changes in the calculated second-order effects.

31.17.2 Direct Second-Order Analysis

The direct second-order analysis uses the notional load concept and the reduced flexural stiffness principle.

31.17.2.1 Notional Load Concept

Notional loads are lateral loads that are applied at each floor level and are specified in terms of the gravity loads applied at that floor level to account for the effects of geometric imperfections, inelasticity, or both. A notional load applied at floor i , $N_i=0.002Y_i$, should be added to the factored lateral load in all LRFD load combinations. Y_i is the gravity load from the load combination acting on floor i and should be equal to or greater than the gravity load associated with the load combination being evaluated. The notional load should be applied in the direction that adds to the destabilizing effects under the specified load combination.

31.17.2.2 Reduced Stiffness Principle

A reduced flexural stiffness, $(EI)^*$, should be used for all members.

$$(EI)^* = \begin{cases} 0.8\tau EI & \text{for columns} \\ 0.8EI & \text{for other members} \end{cases}$$

$$\tau = \begin{cases} 1.0 & \text{for } P_u/P_y \leq 0.5 \\ 4 \left[\frac{P_u}{P_y} \left(1 - \frac{P_u}{P_y} \right) \right] & \text{for } P_u/P_y > 0.5 \end{cases} \quad (31.128)$$

Alternatively, where $P_u > 0.5P_y$ for any column in the moment frame, an additive notional load of $N_i=0.001Y_i$ should be added to the required notional load discussed in [Section 31.17.2.1](#).

31.18 Summary

This chapter summarizes the state-of-the-art use of effective length factors for individual columns, framed columns, diagonal bracing systems, latticed and built-up members, tapered columns, crane columns, gable frames, columns in fire, space frames, truss-type highway sign support structures, precast concrete skeletal frames, and steel moment frames. Design implementation with formulas, charts, tables, various modification factors adopted in current codes and specifications, as well as those used in engineering practice are described. Several examples are given to illustrate the steps of practical applications of various methods.

Glossary

- Alignment chart** — A nomograph for determining the effective length factor K for some types of compression members.
- Braced frame** — A frame in which the resistance to lateral load or frame instability is primarily provided by diagonal bracing, shear walls, or equivalent means.
- Built-up member** — A member made of structural metal elements that are welded, bolted, and riveted together.
- Column** — A vertical structural member whose primary function is to carry loads parallel to its longitudinal axis.
- Compression member** — A structural member whose primary function is to carry compression loads parallel to its longitudinal axis.
- Crane column** — A column that is designed to support overhead crane loads.
- Effective length factor K** — A factor that when multiplied by actual length of the end-restrained column gives the length of an equivalent pin-ended column whose elastic buckling load is the same as that of the end-restrained column.
- Framed column** — A column in a framed structure.
- Gable frame** — A frame with a gabled roof.
- Latticed member** — A member made of two or more rolled shapes that are connected to one another by means of lacing bars, batten plates, or perforated plates.
- Leaning column** — A column that is connected to a frame with simple connections and does not provide lateral stiffness or sidesway resistance.
- LRFD (load and resistance factor design)** — A method of proportioning structural components (members, connectors, connecting elements, and assemblages) such that no applicable limit state is exceeded when the structure is subjected to all appropriate load combinations.
- Tapered column** — A column that has a continuous reduction in section from top to bottom.
- Unbraced frame** — A frame in which the resistance to lateral loads is provided by the bending stiffness of frame members and their connections.

32.1 Introduction

This chapter presents an overview of aspects related to the design of structural bracing used in beams, columns, and frame structures and is intended for practicing civil and structural engineers. Many of the design guidelines presented were incorporated into the 2002 *Load and Resistance Factor Design Manual* published by the American Institute of Steel Construction (AISC). The intended focus is on simplicity and ease of implementation over exact formulations. The basis for the design formulations along with a classification system for bracing systems is first presented. Design formulations are presented with illustrative numerical examples. Finally, common faulty bracing details are presented.

32.2 Types of Bracing

Bracing used in structural systems generally serve two primary functions. They resist secondary loads on structures (e.g., wind bracing) and increase the strength of individual members by resisting deformation in the weakest direction [1]. For the latter case, structural bracing forces higher modes of deformation by providing resistance to lateral and/or rotational displacement. This is achieved through axial, shear, and/or flexural deformations of the bracing member. Diaphragms, for instance, provide restraint through their shear stiffness while diagonal cross-bracing relies on axial stiffness.

Bracing systems used to control instability fall into four general classifications: relative, nodal, continuous, or lean-on. Common configurations of each type are shown in [Figure 32.1](#). Relative bracing

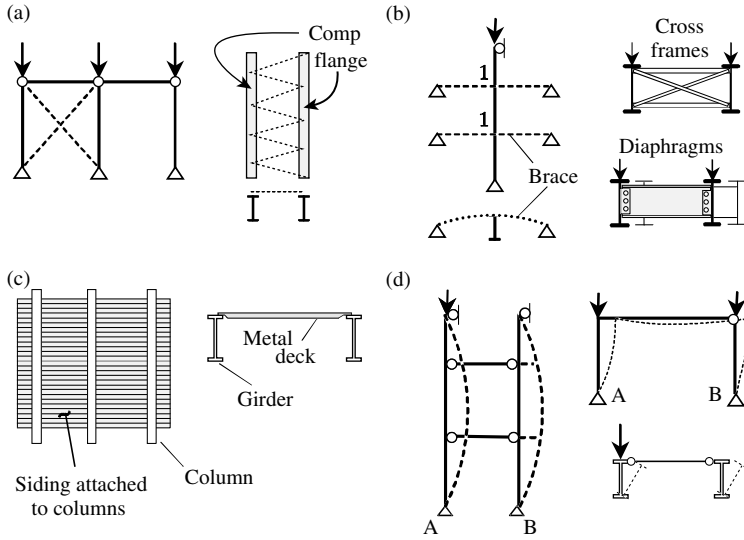

FIGURE 32.1 Types of bracing: (a) relative; (b) nodal; (c) continuous; and (d) lean-on.

systems, such as diagonal bracing or shear walls, prevent the relative lateral movement of adjacent stories or of adjacent points along the length of a member. Relative systems can be readily identified if a cut at any location along the length of a braced member passes through the brace member itself. Nodal systems control the movement only where they attach to the braced member and do not directly interact with adjacent brace points. Cross-frames or diaphragms between two adjacent beams are considered nodal braces. Continuous systems provide uninterrupted support along the entire length of a member, leaving no unbraced length. Shear walls and roof or floor deck are examples of continuous bracing systems. Lean-on systems rely on adjacent structural members to provide support. Lean-on bracing links together adjacent structural members such that buckling of one member requires all members in the system to buckle with the same lateral displacement.

32.3 Background

Structural bracing used to increase the strength of members must possess both sufficient *strength* and *stiffness* [2]. Simple bracing design rules such as designing a brace to resist 2% of the member compressive force address only the strength criterion. The stiffness of the brace along with the out-of-straightness of the member has a direct effect on the magnitude of the brace force [1]. Design recommendations based on perfectly straight members should not be used directly in design since extremely large brace forces and displacements may result [3].

32.3.1 Member Out-of-Straightness and Brace Stiffness

Winter [1,2] developed the concept of a dual *strength* and *stiffness* criterion for the design of bracing used to control instability. The required brace strength cannot be uniquely determined, but depends on both the magnitude of the brace stiffness and member initial out-of-straightness. The relationship between these parameters is illustrated for the relative column brace in Figure 32.2 and can be extended to other types of bracing systems. In order to reach the Euler buckling load, P_e , the brace must possess a minimum stiffness known as the *ideal stiffness*, β_i . Figure 32.3 shows the relationship between the brace stiffness and force. When the ideal stiffness is used ($\beta = \beta_i$), as the column load approaches P_e the sway deflections become very large. Unfortunately, this results in very large brace forces since $P_{br} = \beta \Delta$. At twice the ideal stiffness ($\beta = 2\beta_i$), the brace force equals 0.4% of the column load when $P = P_e$. For practical designs, the

FIGURE 32.2 Relative brace.

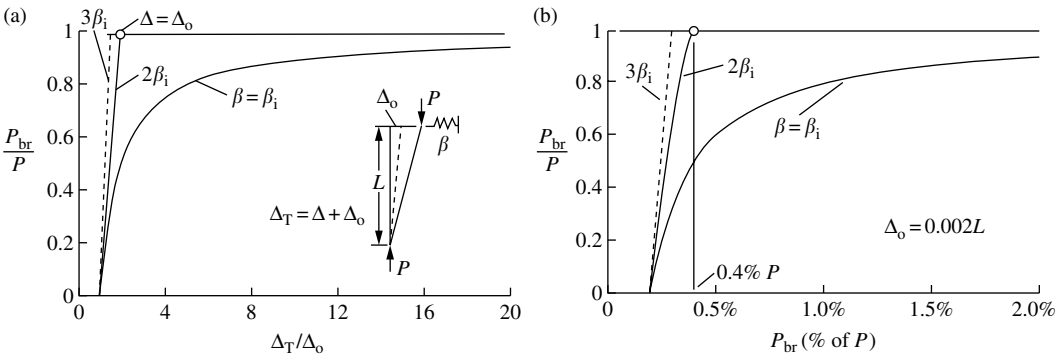

FIGURE 32.3 Effect of initial out-of-plumbness.

deflections and corresponding brace forces are kept small by using brace stiffnesses greater than the ideal stiffness. The plots developed in Figure 32.3 were based on an assumed initial out-of-straightness equal to $0.002L$. Larger out-of-straightness values linearly increase the magnitude of the brace forces.

32.3.2 Member Shortening

Compression elements such as columns or the compression flanges of beams shorten under externally applied compressive forces. For relative tension braces, shortening increases the brace force requirements by causing an apparent increase in the member out-of-straightness, as shown in Figure 32.4. As the member being braced shortens, slack is introduced into the bracing. Lateral movement at the brace points is necessary in order to return the tension brace to its original length prior to member shortening. The increases in brace force due to shortening can be accounted for by adding the out-of-straightness due to shortening to the initial out-of-straightness (see Example 32.1).

32.3.3 Member Inelasticity

The bracing requirements for relative braces are a function of the load on the member and the distance between adjacent brace points and not the elasticity or inelasticity of the member. For a nodal bracing system, there has been some debate about the effects of inelasticity on the bracing requirements. Research, however, has indicated that inelasticity of the main members does not affect the bracing requirements [3]. For continuous and lean-on bracing systems, the bracing requirements, which will be presented later, are based on the elastic and inelastic stiffnesses of the braced members. For these bracing systems, the influence of inelasticity on the buckling solution can be reasonably approximated using the tangent modulus $E_T = \tau E$, where E is the elastic modulus and τ is the inelastic stiffness reduction factor.

FIGURE 32.4 Effect of member shortening for relative bracing.

In the AISC load and resistance factor design (LRFD) specification, when the axial stress is less than one third the yield stress, F_y , the column is classified as elastic ($\tau = 1.0$). At greater stress levels, the stiffness reduction factor is given by

$$\tau = -7.38 \left(\frac{P_u}{P_y} \right) \log \left[\frac{(P_u/P_y)}{0.85} \right] \quad (32.1)$$

where P_u is the required column strength and P_y is the column squash load.

32.3.4 Brace Connection Stiffness

The connections details used to attach structural bracing members can be of great importance when designing or evaluating the overall performance of a bracing system. If the connections are flexible, the stiffness of the overall bracing system can be significantly less than the stiffness of the bracing member alone. The stiffness of a bracing system can be evaluated as springs in series using

$$\frac{1}{\beta_{\text{sys}}} = \frac{1}{\beta_{\text{br}}} + \sum \frac{1}{\beta_{\text{conn}}} \quad (32.2)$$

The system stiffness, β_{sys} , will always be less than the smaller of the brace member stiffness, β_{br} , and any of the connection stiffnesses, β_{conn} .

32.4 Safety Factors

The bracing design recommendations that will follow are based on ultimate strength. The loads on the members being braces are assumed to be factored. Since both strength and stiffness are essential requirements for adequate bracing, resistance factors for each are necessary. When using an LRFD approach, the required stiffness is divided by a resistance factor of $\phi = 0.75$ to obtain a conservative requirement. The design brace force is based on factored loads and compared to the factored design strength of the brace and its connections.

32.5 Column or Frame Bracing

Column or frame bracing systems can be relative, nodal, continuous, or lean-on. The design recommendations for relative and nodal column bracing are based on an initial out-of-straightness $\Delta_o = 0.002L$, where L is the column length and a brace stiffness equal to twice the ideal stiffness. The initial displacement, Δ_o , is defined as the lateral offset between two adjacent brace points caused by sources other than brace elongations from gravity loads or compressive forces. For example, Δ_o may be a displacement due to wind or other lateral forces, erection tolerances, or column shortening. If Δ_o differs from $0.002L$, the brace force, P_{br} , will change in direct proportion to the actual Δ_o . In frame

systems where a story may contain n_0 columns, each having a random out-of-plumbness, an average value for Δ_o can be used [4]

$$\Delta_o = 0.002L\sqrt{n_0} \quad (32.3)$$

32.5.1 Column Buckling and Design Philosophy

For no-sway columns, the effective length factor, K , will be less than 1.0. Most designs conservatively use $K=1.0$ and in most situations achieving $K < 1.0$ is not economical. For sway permitted columns, the effective length $K \geq 1.0$. Bracing used to prevent sway can reduce the effective length to $K=1.0$ and achieve significant economic savings.

The bracing design criterion for columns is based on providing sufficient strength and stiffness to allow a sway column to achieve the Euler buckling load corresponding to $K=1.0$. For columns that possess nonzero end restraint, this *does not* correspond to the no-sway buckling load since for these cases K is theoretically less than unity.

For flexural buckling modes, brace points attached in-line with the centroid of the structural member are most effective. For torsional buckling modes, bracing must prevent twist of the cross-section to be effective.

32.5.2 Relative Systems

AISC LRFD brace requirements for *relative* column bracing are

$$\beta_{br} = \frac{2P_u}{\phi L_b} \quad (32.4)$$

$$P_{br} = 0.004P_u \quad (32.5)$$

where $\phi = 0.75$, P_u is the required compressive strength of the column, and L_b is the required brace spacing.

When the actual brace stiffness provided, β_{act} , differs from the required value given in Equation 32.4, the brace strength requirement can be modified using

$$P_{br} = 0.004 \sum P_u \frac{1}{2 - (\beta_{br}/\beta_{act})} \quad (32.6)$$

EXAMPLE 32.1

Relative Column Brace Design

A typical tension-only X-brace must stabilize three bents. Each bent carries a total factored load of 600 kip (125 + 300 + 175). Assume the floor acts as a rigid diaphragm and all $\Delta_o = 0.002L$ and all columns are $W14 \times 53$ ($A_g = 15.6 \text{ in.}^2$).

$$\sum P_u = (3 \text{ bents})(125 + 300 + 175) = 1800 \text{ kip}$$

Bracing shear force:

$$P_{br} = 0.004(1800) = 7.2 \text{ kip}$$

Bracing shear stiffness:

$$\beta_{br} = \frac{2(1800)}{0.75(12)} = 400 \text{ kip/ft}$$

Design recommendations assume brace shear force and stiffness are perpendicular to column. Therefore, for an inclined threaded rod (A36 steel):

Strength:

$$P_{br} = \frac{7.2 \text{ kip}}{\cos \theta} = 8.64 \text{ kip} = 0.9(36)A_g \quad (A_g)_{req'd} = 0.27 \text{ in.}^2$$

Stiffness:

$$\frac{A_g E}{21.6 \text{ ft}} \cos^2 \theta = 400 \text{ k/ft}$$

$$(A_g)_{req'd} = 0.43 \text{ in.}^2 \leftarrow \text{Controls}$$

$$\text{Use } \frac{3}{4} \text{ in. dia. rod } (A_g = 0.44 \text{ in.}^2)$$

Consider effects of shortening

$$\Delta_{os} = \text{sway due to shortening} = \Delta_{sh} \tan \theta$$

$$\Delta_{sh} = \frac{300(12 \times 12)}{(15.6)(29,000)} = 0.095 \text{ in.}$$

$$\Delta_{os} = 0.095 \left(\frac{12}{18} \right) = 0.063 \text{ in.}$$

$$\frac{\Delta_{os}}{L} = \frac{0.063}{(12 \times 12)} = 0.00044$$

$$P_{br} = 8.64 \text{ kip} \left(\frac{0.002 + 0.0004}{0.002} \right) = 10.5 \text{ kip}$$

$$(A_g)_{req'd} = 0.32 \text{ in.}^2 < 0.43 \text{ in.}^2 \text{ stiffness still controls}$$

32.5.3 Nodal Systems

Figure 32.5 shows the relationship between brace stiffness and buckling load for a column with three equally spaced nodal braces. The exact solution taken from Timoshenko and Gere [5] illustrates the increase in buckling load and changes in mode shapes as the brace stiffness increases.

FIGURE 32.5 Discrete bracing.

For nodal column bracing, the ideal brace stiffness is a function of the number of intermediate braces [1,2]. For a single brace at midheight $\beta_i = 2P/L$. For many closely spaced braces the ideal stiffness approaches $\beta_i = 4P/L$. Twice the ideal stiffness for the most severe case was adopted by the AISC LRFD for many braces.

AISC LRFD brace requirements for *nodal* column bracing are

$$\beta_{br} = \frac{8P_u}{\phi L_b} \tag{32.7}$$

$$P_{br} = 0.01P_u \tag{32.8}$$

where $\phi = 0.75$, P_u is the required compressive strength of the column, and L_b is the required brace spacing.

For n equally spaced braces, the ideal stiffness can be approximated as

$$\beta_i = N_i \frac{P_u}{L_b} \tag{32.9}$$

where $N_i \approx 4 - 2/n$. Using the recommended stiffness equal to twice the ideal stiffness and applying the resistance factor gives

$$\beta_{br} = N_i \frac{2P_u}{\phi L_b} \tag{32.10}$$

Equation 32.10 is based on equally spaced braces and is unconservative for unequal spacings. The required stiffness for unequal brace spacings can be obtained using Winter’s rigid bar model [6]. In this model, the column is represented using rigid links with fictitious hinges at brace locations and the braces are represented using simple springs. Under the applied load, displacements are imposed at brace locations and equilibrium is enforced to obtain N_i . This technique is illustrated in Example 32.2. For a single nodal brace at any location along the length of a column, with the longest segment defined as L and the shorter segment as αL , N_i can be conservatively determined using

$$N_i = 1 + \frac{1}{\alpha} \tag{32.11}$$

EXAMPLE 32.2

Nodal Column Brace — Unequal Spacing

1. Introduce hinge at **B** and displace arbitrary distance Δ .
2. Sum forces and moments to obtain reactions at **A** and **C**.
3. Cut and sum moments at **B** on **AB** to obtain

$$P\Delta = 0.6\beta\Delta(0.4L)$$

$$\beta_i = 4.16 \frac{P}{L}$$

$$N_i = 4.16$$

Conservative approximation

$$N_i = 1 + \frac{1}{0.4/0.6} = 2.5$$

The brace stiffness requirements for nodal bracing are inversely proportional to the unbraced length, L_b . Closer-spaced braces require more stiffness because the derivations are based upon allowing the column to reach a load that corresponds to buckling of the most critical unbraced length

with a K -factor equal to 1.0. In many instances, there are more potential brace points than necessary to support the member forces required. Using the actual unbraced length may result in excessively conservative stiffness requirements. Therefore, the maximum unbraced length that enables the column to reach the required loading, L_q , can be used. For example, say the column shown in Figure 32.5 is supported against weak-axis buckling at three locations giving an unbraced length of L . If a single brace at midheight giving an unbraced length of $1.5L$ would be sufficient to carry the load on the column, then the required stiffness for the three braces could be conservatively estimated using the permissible unbraced length of $1.5L$ in Equation 32.10 in place of the actual unbraced length of L (see Example 32.3).

EXAMPLE 32.3

Nodal Column Brace Design

Two 8 ft cross-members brace a 30 ft WT5 × 19.5 compression member. Buckling about x - x axis controls since brace flexural stiffness is much lower than axial stiffness. $F_y = 36$ ksi. Find the required brace strength and stiffness.

$$n = 2, N_i = 4 - \frac{2}{2} = 3$$

$$\beta_{br} = 3 \frac{2(200)}{0.75(10 \times 12)} = 13.33 \text{ k/in.} = \frac{F}{\Delta} = \frac{48EI}{(8 \times 12)^3}$$

$$I_{req'd} = \frac{13.33(96)^3}{48(29,000)} = 8.5 \text{ in.}^4$$

$$P_{br} = 0.01(200) = 2 \text{ kip}$$

$$M_{br} = \frac{2(96)}{4} = 48 \text{ kip in.}$$

32.5.4 Continuous Systems

Figure 32.6 shows the relationship between brace stiffness and buckling load for a continuously braced column. The exact solution can be approximated using the following equation [3]:

$$P_{cr} = P_e + \frac{2L}{\pi} \sqrt{\bar{\beta}P_e} \tag{32.12}$$

where P_e is the Euler buckling load, L is the column length, and $\bar{\beta}$ is the brace stiffness per unit length.

The continuous brace formulation given in Equation 32.12 can also be applied for equally spaced discrete braces by determining an equivalent brace stiffness per unit length, $\bar{\beta}$, using

$$\bar{\beta} = \beta \cdot \frac{n}{L} \tag{32.13}$$

where n is the number of braces within the column length, L . This method is accurate for two or more discrete braces and is illustrated in Example 32.4.

Corrugated metal deck is a common type of continuous lateral bracing and acts like a shear diaphragm with the properties of a relative brace. The stiffness and strength properties of the metal

FIGURE 32.6 Continuous bracing.

FIGURE 32.7 Continuous metal-deck bracing.

deck are generally defined in a per unit width basis (e.g., shear stiffness = G' kip/rad per ft width). The bracing requirements for the shear diaphragm can be determined from the relative brace requirements presented in Section 32.5.2, as shown in Figure 32.7. Properties for corrugated deck can be obtained from the Steel Deck Institute *Diaphragm Design Manual* [7]. The required shear diaphragm stiffness per unit width is

$$G'_{req'd} = \frac{2P_u}{\phi b} \tag{32.14}$$

Dividing the perpendicular brace force requirement by the diaphragm width gives the required shear strength per unit width, S_u

$$S_u = \frac{0.004P_u}{b} \tag{32.15}$$

It should be noted that the brace force requirements given in Equation 32.13 are in addition to other load demands placed on the diaphragm.

EXAMPLE 32.4

Nodal Column Braces as Effective Continuous Braces

Consider a column of length $3L_b$ with two equally spaced nodal braces giving an unbraced length of L_b . Estimate the critical load of an ideally-braced column by approximating the nodal braces as an equivalent continuous brace.

Ideal nodal brace stiffness required to buckle between brace points

$$N_i \approx 4 - \left(\frac{2}{n}\right) = 3 \quad \beta_i = N_i \frac{P_{cr}}{L} = \frac{3P_{cr}}{L_b}$$

Equivalent continuous stiffness using Equation 32.13

$$\bar{\beta} = \left(\frac{3P_{cr}}{L_b}\right) \left(\frac{2 \text{ braces}}{3L_b}\right) = \frac{2P_{cr}}{L_b^2}$$

Critical load using Equation 32.12

$$P_{cr} = \frac{P_{cr}}{9} + \frac{2(3L_b)}{\pi} \sqrt{\left(\frac{2P_{cr}}{L_b^2}\right) \left(\frac{P_{cr}}{9}\right)} = 1.011P_{cr}$$

32.5.5 Lean-On Systems

Lean-on bracing systems provide a means for some members in a structural system to rely on other members for stability. One of the most commonly encountered examples of lean-on systems are frames with “leaning” pin-ended columns connected to columns with nonzero end restraint. For these systems, the $\sum P$ concept [8] can be used to design the members. This concept states that a system remains stable so long as the sum of the applied loads, $\sum P$, is less than the sum of the buckling strength of each individual member, $\sum P_{cr}$, and the load in any individual member is less than the load corresponding to buckling between braces (no sway) for that member. This concept is illustrated in Example 32.5.

EXAMPLE 32.5

Lean-On Column Brace

Is the W10 × 33 capable of bracing the W12 × 58?

A36 steel, factored loads shown, fully braced out of plane

W10 × 33

$$A_g = 9.71 \text{ in.}^2$$

$$I_x = 171 \text{ in.}^4$$

W12 × 58

$$A_g = 17.0 \text{ in.}^2$$

$$I_y = 107 \text{ in.}^4$$

No sway capacity — From AISC Manual ($KL_y = 8 \text{ ft}$)
 W12 × 58: ($\phi P_n = 482 \text{ k}$) > ($P_u = 450 \text{ k}$) OK

Sway capacity — Using $\sum P$ concept

Column A (W12 × 58)

$$\frac{P_u}{F_y A_g} = \frac{450}{(36)(17.0)} = 0.735 > \frac{1}{3} \quad \therefore \text{inelastic}$$

$$\tau = -7.38(0.735) \log\left(\frac{0.735}{0.85}\right) = 0.342$$

$$\phi P_n = 0.85(0.342)(0.877) \frac{\pi^2(29,000)(107)}{(288)^2} = 94 \text{ k}$$

Column B (W10 × 33)

$$\frac{P_u}{F_y A_g} = \frac{50}{(36)(9.71)} = 0.143 < \frac{1}{3} \quad \therefore \text{elastic } \tau = 1.0$$

$$\phi P_n = 0.85(1.0)(0.877) \frac{\pi^2(29,000)(171)}{(288)^2} = 440 \text{ k}$$

Using $\sum P$ concept

$$\left(\sum \phi P_n = 94 + 440 = 534 \text{ k}\right) > \left(\sum P_u = 50 + 450 = 500 \text{ k}\right) \text{ OK}$$

32.5.6 Torsional Bracing

In order for a brace to effectively increase the load-carrying capacity of a member, it must restrain the movement of the lowest buckling mode. Depending on the cross-section, the lowest buckling mode of a compression member may be flexural (lateral), torsional, or a combined flexural–torsional. Bracing against flexural modes must prevent the lateral translation of the member cross-section. Bracing against torsional modes must restrain the twist of the cross-section. Bracing details such as a rod framing into a wide-flange column web (Figure 32.8) resist lateral buckling about the weak axis but do not prevent twist and are ineffective torsional braces.

For doubly symmetric sections such as wide-flange columns, weak-axis flexural buckling controls for an unbraced member. Providing sufficient weak-axis lateral bracing, in some instances, will result in the section being controlled by the torsional buckling mode. If bracing is provided that prevents both translation and twist of a doubly symmetric cross-section, weak-axis buckling will always control.

The torsional buckling load, P_T , for a column restrained about an axis modified by τ is given by the following (see Figure 32.9) [5]:

Axis of restraint along weak axis of column:

$$P_T = \frac{\tau P_{ey} [(d^2/4) + y_{br}^2] + GJ}{y_{br}^2 + r_x^2 + r_y^2} \quad (32.16)$$

Axis of restraint along strong axis of column:

$$P_T = \frac{\tau P_{ey} [(d^2/4) + (I_x/I_y)x_{br}^2] + GJ}{x_{br}^2 + r_x^2 + r_y^2} \quad (32.17)$$

where x_{br} , y_{br} are the coordinates of axis of restraint with respect to column centroid, d is the column depth, and P_{ey} is the Euler load based on a column length between points of zero twist.

To compensate for the assumption in the derivation of Equations 32.16 and 32.17 that the brace is infinitely stiff, the maximum factored column load should be limited to $0.90P_T$ [3].

FIGURE 32.8 Ineffective torsional column brace.

FIGURE 32.9 Buckling of a column about a restrained axis: (a) lateral brace at flange and (b) buckled shape.

FIGURE 32.10 Typical torsional brace details: (a) control twist with struts and (b) moment connection with stiffener.

If column loads greater than P_T are required, torsional bracing must be provided. Two typical bracing schemes are shown in Figure 32.10. For continuous girders with moment connections, twisting restraint is provided. However, partial depth stiffeners should be used to control web distortion. The design requirements for torsional bracing are based on the nodal requirements presented in Section 32.5.3 and are obtained by introducing equal and opposite brace forces on each flange. The magnitude of these forces is based on the assumption that each flange carries one-half of the total column load. The resulting brace moment, $M_T = 0.5P_{br}d$. Using the angle of twist $\theta = \Delta/d$ as shown in Figure 32.9b, the stiffness requirement $\beta_T = M_T/\theta = 0.5P_{br}d^2/\Delta$ reduces to

$$\beta_T = 0.5\beta_{br}d^2 \tag{32.18}$$

where β_{br} is the nodal brace stiffness requirement from Section 32.5.3.

32.6 Beam Bracing

Structural bracing for beams can be generally classified as either a *lateral* or a *torsional* system. Lateral beam bracing, like column bracing, can be relative, nodal, continuous, or lean-on while torsional systems can be nodal or continuous. Cross-frames or diaphragms connecting adjacent girders control twist of the cross-section and represent purely torsional systems. Similarly, joists attached to the compression flange of a simply supported beam control twist by preventing the lateral movement of the compression flange relative to the tension flange and represent a purely lateral system. Some bracing systems, such as a composite slab attached to the top flanges of a beam using shear connectors, simultaneously provide both lateral and torsional restraints. Combined lateral and torsional systems have been shown to be more effective braces than either lateral or torsional systems alone for beams with uniform moment [9,10].

In order to be an effective brace, both lateral and torsional systems must prevent the relative displacement of the top and bottom of a beam (i.e., twist of the cross-section). Properly designed cross-frames interconnecting adjacent beams are considered brace points when evaluating the buckling strength of the beams. Even though the beams can move laterally, the cross frames are still effective braces because they prevent *twist* of the cross-section. Both tests and theory have confirmed this fact [11,12].

32.6.1 Inflection Points as Brace Points

Inflection points are sometimes mistakenly identified as brace points in restrained beams. This often occurs when the top flange of a beam is laterally braced by a slab or joists all along the span while the bottom flange remains unbraced. Even in these instances, the inflection point *cannot* be considered a brace point. The justification for this can be illustrated by comparing the two beams shown in Figure 32.11. Beam A has a moment on one end with an unbraced length $L_b = L$ while Beam B has equal and opposite end moments resulting in an inflection point at midspan and an unbraced length $L_b = 2L$. The buckling moment for Beam B is 68% of Beam A. If the inflection point were a brace point, the critical moment for both beams would be identical. A plan view of the buckled shape of Beam B illustrates how the top and bottom flanges move in opposite directions at midspan. Even an actual brace on one flange at the inflection point does not provide effective bracing at midspan because twist is not restrained [12].

32.6.2 Lateral Bracing

The primary factors influencing the effectiveness of *lateral* beam bracing are

- Number or spacing of braces
- Vertical position of the braces on the cross-section
- Vertical position of the loads on the cross-section
- Moment gradient on the beam

Increasing the number of braces along the length of a beam can increase the load-carrying capacity by reducing the unbraced length. Like column bracing, however, the brace stiffness requirements increase with the number of braces. This is because the design recommendations assume the beam must reach a load corresponding to buckling between brace points. Similarly, if more brace points are provided than necessary to support the required loads, the maximum permissible unbraced length, L_q , may be used in place of the actual unbraced length, L_b .

The vertical position of a lateral brace along the height of a beam significantly affects the effectiveness of lateral bracing. Lateral bracing is most effective when positioned at the compression flange of

FIGURE 32.11 Beam with inflection point.

FIGURE 32.12 Lateral buckling of cantilever and simple beams: (a) max moment at max twist and (b) zero moment at max twist.

FIGURE 32.13 Effect of load and brace positions.

a beam. In most configurations, this places the brace the furthest distance from the center of twist of the buckled cross-section as shown in Figure 32.12a. The exception to this rule is for cantilever beams (Figure 32.12b) where the position of the buckled cross-section reveals that a brace located at the tension flange is most beneficial.

When a beam is bent in reverse curvature, the compression and tension flanges switch at the point of inflection. Beams such as these, in which both the top and bottom flanges encounter compression along the span, have more severe bracing requirements than beams where compression resides only in one flange [3]. In these situations, lateral bracing is required on *both* flanges to prevent twist of the cross-section.

The vertical position of transverse loads on beams has significant influence on the effectiveness of lateral bracing. Loads applied higher on the cross-section, such as at the top flange, have more pronounced destabilizing effects while loads applied lower on the cross-section tend to provide added stability when compared to centroidal loading. The effect of top-flange loading is even greater when lateral bracing is located near the centroid of the section. In these situations, the center of twist shifts to a position closer to mid-depth and the centroidal brace becomes almost totally ineffective as shown in Figure 32.13. Therefore, centroidal lateral beam braces are not recommended due to the effects of both cross-section distortion and load position.

The load position effect described above is based on the assumption that the load remains vertical and passes through the original point of contact on the member as it buckles. For many structural systems,

FIGURE 32.14 Tipping effect and cross-section distortion.

the load transferred to beams is applied through secondary members or a floor slab. When loading is through a slab, for example, a restoring torque is created by a tipping effect during buckling as illustrated in Figure 32.14. This tipping effect has been shown to significantly increase the lateral buckling capacity even if the slab is only resting (not positively attached) on the top flange [12]. Unfortunately, the benefits of tipping are severely limited by distortion of the cross-section and are difficult to quantify. As a result, the beneficial effects of tipping are generally neglected.

The AISC LRFD lateral beam brace requirements were based on the following design recommendations developed by Yura [3]:

The brace stiffness requirement for both *relative* and *nodal* beam bracings is

$$\beta_{br} = \frac{2N_i(C_b P_f) C_t C_d}{\phi L_b} \tag{32.19}$$

The brace strength requirement for *relative* bracing is

$$P_{br} = 0.004 \frac{M_u C_t C_d}{h_{oh}} \tag{32.20}$$

and for *nodal* bracing it is

$$P_{br} = 0.01 \frac{M_u C_t C_d}{h_{oh}} \tag{32.21}$$

where

- N_i = 1.0 for relative bracing
 = $(4 - 2/n)$ for nodal bracing
n = number of intermediate braces
- P_f = beam compressive flange force
 = $\pi^2 EI_{yc} / L_b^2$
I_{yc} = out-of-plane moment of inertia of the compression flange
- C_t = top-flange loading factor
 = 1.0 for centroidal loading
 = $1 + (1.2/n)$ for top-flange loading
- C_d = $1 + (M_S/M_L)^2$ for reverse-curvature bending
 = 1.0 for single-curvature bending
M_S = smallest moment causing compression in each flange
M_L = largest moment causing compression in each flange
- C_b = nonuniform moment modification factor
 = $\frac{12.5M_{max}}{2.5M_{max} + 3M_A + 4M_B + 3M_C}$
M_{max} = absolute value of maximum moment in unbraced segment
M_A = absolute value of moment at quarter point of unbraced segment
M_B = absolute value of moment at midspan of unbraced segment
M_C = absolute value of moment at three-quarter point of unbraced segment

The brace force requirements were developed assuming an initial lateral displacement of the compression flange equal to $0.002L_b$ and vary in direct proportion to the actual out-of-straightness.

The term $2N_i C_i$ can be conservatively approximated as 10 for any number of nodal braces and 4 for any number of relative braces. The term $C_b P_f$ can also be conservatively approximated as M_u/h_{oh} . Using the worst-case top-flange loading ($C_i = 2.0$) and the previous assumptions yields the AISC LRFD brace requirements for lateral beam bracing (Example 32.6):

AISC LRFD brace requirements for *relative* lateral beam bracing:

$$\beta_{br} = \frac{4M_u C_d}{\phi L_b h_{oh}} \tag{32.22}$$

$$P_{br} = 0.008 \frac{M_u C_d}{h_{oh}} \tag{32.23}$$

AISC LRFD brace requirements for *nodal* lateral beam bracing:

$$\beta_{br} = \frac{10M_u C_d}{\phi L_b h_{oh}} \tag{32.24}$$

$$P_{br} = 0.02 \frac{M_u C_d}{h_{oh}} \tag{32.25}$$

where

$$\phi = 0.75$$

M_u = required flexural strength

h_o = distance between flange centroids

$C_d = 1 + (M_s/M_L)^2$ for reverse-curvature bending
 = 1.0 for single-curvature bending

L_b = distance between braces

EXAMPLE 32.6

Relative Lateral Beam Brace

Design the diagonals of the top flange horizontal truss to stabilize the five simply-supported 90 ft girders. The factored moment at midspan $M_u = 1200$ k ft and $F_y = 36$ ksi for bracing.

Stiffness

$$\beta_{br} = \frac{4.0(1200 \times 12)(1.0)}{0.75(18 \times 12)(49)} (2.5 \text{ girders}) = 18.1 \text{ k/in.}$$

$$\left(\frac{AE}{L}\right)_{br} \cos^2 \theta = \left(\frac{A_{br}(29,000)}{9 \times 12 \times \sqrt{5}}\right) \left(\frac{1}{\sqrt{5}}\right)^2 = 18.1$$

$$A_{br} = 0.75 \text{ in.}^2 \leftarrow \text{Controls}$$

Strength

$$P_{br} = 0.008 \frac{(1200 \times 12)(1.0)}{49} (2.5 \text{ girders}) = 5.88 \text{ k}$$

$$A_{br} = \frac{5.88\sqrt{5}}{(0.9 \times 36)} = 0.41 \text{ in.}^2$$

$$\text{Use } L2 \times 2 \times \frac{1}{4} \quad (A_g = 0.944 \text{ in.}^2)$$

32.6.3 Torsional Bracing

The primary factors influencing the effectiveness of *lateral* beam bracing have relatively little influence on the design of *torsional* beam bracing. Unlike lateral beam bracing, the number of braces, brace location on the cross-section, and load position are relatively unimportant when sizing a torsional brace. Not only is a torsional brace equally effective if attached to the top or bottom flange, but beams in reverse curvature do not alter the torsional brace requirements. The effectiveness of a torsional brace, however, is greatly affected by distortion of the cross-section as illustrated in Figure 32.15. Although the torsional brace prevents twist at the top flange, distortion of the web permits a relative displacement between the two flanges. A web stiffener located at the brace location is often used to control the distortion.

AISC LRFD brace requirements for torsional beam bracing:

$$\beta_{Tb} = \frac{\beta_T}{(1 - (\beta_T/\beta_{sec}))} \quad (32.26)$$

$$M_{br} = \frac{0.024M_u L}{nC_b L_b} \quad (32.27)$$

where

$$\beta_{sec} = \frac{3.3E}{h_{oh}} \left(\frac{1.5h_{oh}t_w^3}{12} + \frac{t_s b_s^3}{12} \right) \quad (32.28)$$

$$\beta_T = \frac{2.4LM_u^2}{\phi nEI_y C_b^2} \quad (32.29)$$

where

$$\phi = 0.75$$

L = span length

n = number of nodal braced points within span

E = modulus of elasticity

I_y = out-of-plane moment of inertia of beam

C_b = nonuniform moment modification factor

t_w = thickness of beam web

FIGURE 32.15 Cross-section distortion.

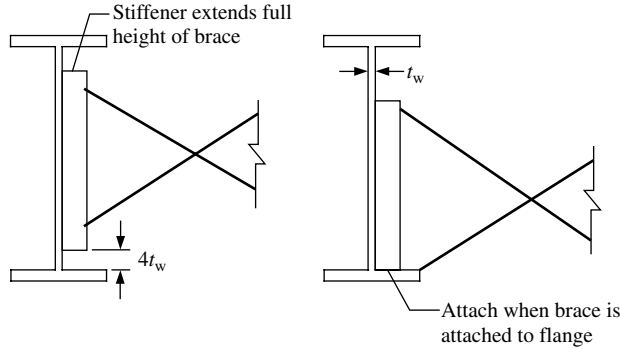

FIGURE 32.16 Web stiffener details for torsional beam bracing.

t_s = thickness of web stiffener(s)

b_s = stiffener width for one-sided stiffeners, which is twice the individual stiffener width for pairs of stiffeners

β_T represents the torsional stiffness of the brace member itself. For flexible connections, Equation 32.2 should be used. β_{sec} is the torsional stiffness associated with the beam web and any transverse web stiffeners that may be present (web distortional stiffness). The required torsional brace stiffness, β_{Tb} , will be negative if $\beta_{sec} < \beta_T$, which indicates the brace will not be effective due to insufficient web distortional stiffness. The coefficient 2.4 in Equation 32.29 comes from using twice the ideal stiffness with a 20% increase to account for top-flange loading. The required strength, M_{br} , assumes an initial twist of 1° (0.0175 rad).

When web stiffeners are required, the AISC LRFD specification requires they extend the full depth of the brace as shown in Figure 32.16. When the brace is attached to the beam flange the stiffeners must also be attached to the flange. When the brace is not attached to the beam flange, the stiffener may be terminated at a distance equal to $4t_w$ from the flange.

The continuous torsional beam bracing requirements use the same formulations as the nodal bracing requirements. For continuous bracing, the term L/n in Equations 32.27 and 32.29 is taken equal to 1.0 and the unbraced length, L_b , in Equation 32.27 is taken equal to L_q , the maximum unbraced beam length necessary to carry the required factored loads.

For singly symmetric cross-sections, an effective moment of inertia, I_{eff} , is used in place of I_y as given by

$$I_{eff} = I_{yc} + \frac{y_t}{y_c} I_{yt} \tag{32.30}$$

where I_{yc} is the compression flange out-of-plane moment of inertia, I_{yt} is the tension flange out-of-plane moment of inertia, y_c is the distance from centroid to extreme compression fiber, and y_t is the distance from centroid to extreme tension fiber.

The torsional stiffness of typical beam-type braces is shown in Figure 32.17. Adjacent girders connected on the top flanges with decking, for example, will buckle in the same direction and develop the reverse-curvature stiffness of the brace. The stiffnesses of typical truss-type diaphragm systems are shown in Figure 32.18 and are based on elastic truss analyses. For X-systems designed for tension only, the horizontal members in the truss are not required. For K-brace systems, only one horizontal member is necessary.

32.7 Faulty Details

Numerous structural failures have occurred because of the structural arrangement shown in Figure 32.19. The beam (or truss) is continuous over the top of the column. The critical components are: column in compression, compression in the bottom flange of the beam or chord of the truss, and no bottom flange bracing at point *a* and possibly point *b*. The sway at the top of the column shown in Sect B–B can result in a *K*-factor much greater than 2.0. The bottom flange of the beam can possibly provide bracing to the

FIGURE 32.17 Stiffness formulas for diaphragms.

FIGURE 32.18 Stiffness formulas for cross-frames.

FIGURE 32.19 Structural detail with probable instability.

FIGURE 32.20 Inadequate torsional bracing detail.

top of the column if there are braces at point *b* and consideration is given to the compression in the flange when evaluating its stiffness. In general, a brace, such as a bottom chord extension from the joist, should be used at point *a*. Beam web stiffeners at the column location will also be effective unless bottom flange lateral buckling is critical.

Another common faulty bracing detail is shown in Figure 32.20. The girts that frame into the column flange prevent weak-axis translation at the braced flange. Since the girts are discontinuous, they will not prevent twist of the cross-section and will force the column to buckle about a restrained axis (see also Figure 32.9b). For this column, there are three possible buckling modes: strong-axis flexural buckling ($L_b = KL_C$), weak-axis flexural buckling ($L_b = KL_G$), and torsional buckling about a restrained axis ($L_b = KL_C, \gamma_{br} = a$ assuming no twist at column ends).

Nomenclature

A	cross-sectional area of primary member	M_S	smallest moment causing compression in each flange along beam length
A_{br}	cross-sectional area of brace member	M_T	torsional brace moment
A_d	area of diagonal member in cross-frame	M_u	required bending strength
A_h	area of horizontal member in cross-frame	N_i	brace stiffness coefficient for nodal braces
A_g	gross cross-sectional area	P_{br}	brace force
C_b	bending coefficient dependent on moment gradient	P_{cr}	member buckling load
C_d	reverse-curvature bending factor	P_e	Euler column buckling load
C_t	top-flange loading factor	P_{ey}	Euler buckling load based on distance between points of zero twist
E	modulus of elasticity	P_f	beam compressive flange force
E_T	tangent modulus of elasticity	P_T	torsional buckling load
F_y	specified minimum yield stress	P_u	required compressive strength of column
G	shear modulus of elasticity	P_y	column squash load
G'	diaphragm shear stiffness per unit width	S	cross-frame or diaphragm length
I	moment of inertia	S_x	strong-axis section modulus
I_{eff}	effective moment of inertia for singly symmetric beam sections	S_u	required diaphragm shear strength per unit width
$I_{req'd}$	required moment of inertia	V	shear force
I_x, I_y	moment of inertia about strong and weak axes, respectively	b	orthogonal distance between point of restraint and weak axis of member
I_{yc}, I_{yt}	out-of-plane moment of inertia of compression and tension flanges, respectively	b_s	stiffener width for one-sided stiffeners
J	torsion constant for section	d	member depth
K	column effective length factor	f_b	bending stress
L	member length	h_{br}	depth of cross frame
L_b	required brace spacing or laterally unbraced length; length between points that are either braced against lateral displacement of the compression flange or braced against twist of the cross-section		torsional brace
L_q	maximum unbraced length for required forces	h_{oh}	distance between flange centroids
M_A	absolute value of moment at quarter point of unbraced beam segment	n	number of braces within span
M_B	absolute value of moment at midspan of unbraced beam segment	n_0	number of columns in a story
M_C	absolute value of moment at three-quarter point of unbraced beam segment	r_x, r_y	radius of gyration about strong and weak axes, respectively
M_L	largest moment causing compression in each flange along beam length	t_w	thickness of beam web
M_{max}	absolute value of max moment in unbraced beam segment	t_s	thickness of web stiffener
		x_{br}, y_{br}	coordinates of axis of restraint with respect to column centroid
		y_c, y_t	coordinates with respect to centroid of extreme compression and tension fibers, respectively
		$\bar{\beta}$	continuous brace stiffness per unit length
		β_{act}	stiffness provided by brace member
		β_{br}	required lateral brace stiffness
		β_{conn}	stiffness of brace connection
		β_{sec}	web distortional stiffness including any transverse web stiffeners if present
		β_{sys}	stiffness of brace system
		β_T	nodal torsional brace stiffness

β_{Tb}	required nodal torsional brace stiffness including web distortion	Δ_T	total column sway deflection
Δ	translational displacement	ϕ	resistance factor
Δ_o	column initial out-of-straightness	θ	complementary angle between diagonal brace and axial member or twist of member cross-section
Δ_{os}	column out-of-straightness due to shortening	τ	inelastic stiffness reduction factor
Δ_{sh}	shortening or compression element

33.1 Introduction

The stub girder system was developed in response to a need for new and innovative construction techniques that could be applied to certain parts of multistory steel-framed buildings. Originated in the early 1970s, the system aimed at providing construction economies through the integration of the electrical and mechanical service ducts into the part of the building volume that is occupied by the floor framing system of the building [1,2]. Since the overall height of the floor system at times could become large, increases in the overall height of the structure and hence the steel tonnage for the project could be significant. At other times the height could be reduced, but only at the expense of having sizeable web penetrations for the ductwork to pass through. This solution often entailed reinforced web openings, further increasing the construction cost.

The composite stub girder floor system was developed subsequently. Making extensive use of relatively simple shop fabrication techniques, basic elements with limited fabrication needs, simple connections between the main floor system elements and the structural columns, and composite action between the concrete floor slab and the steel load-carrying members, a floor system of significant strength, stiffness, and ductility was devised. This led to a reduction in the amount of structural steel that traditionally had been needed for the floor framing. When coupled with the use of continuous, composite transverse floor beams and the shorter erection time that was needed for the stub girder system, this yielded attractive cost savings.

Since its introduction, the stub girder floor system has been used for a variety of steel-framed buildings in the United States, Canada, Mexico, and Europe, ranging in height from 2 to 72 stories. Despite this relatively widespread usage, the analysis techniques and the design criteria remain unknown to many designers. This chapter will offer examples of practical uses of the system, together with recommendations for suitable design and performance criteria.

33.2 Description of the Stub Girder Floor System

The main element of the system is a special girder, fabricated from standard hot-rolled wide-flange shapes, that serves as the primary framing element of the floor. Hot-rolled wide-flange shapes are also used as transverse floor beams, running in a direction perpendicular to the main girder. The girder and the beams are usually designed for composite action, although the system does not rely on having composite floor beams, and the latter are normally analyzed as continuous beams. The transverse floor beams normally use a smaller size member as a drop-in span within the positive moment region.

Load and resistance factor design (LRFD) is preferred for stub girders, since it gives lower steel weights and simple connections. The costs of an LRFD-designed stub girder are therefore lower than those associated with allowable stress design (ASD).

Figure 33.1 shows the elevation of a typical stub girder. The girder that is shown uses four stubs, oriented symmetrically with respect to the midspan of the member. The locations of the transverse floor beams are assumed to be the quarter points of the span, and the supports are simple. In practice many variations of this layout are used, to the extent that the girders may utilize any number of stubs. However, three to five stubs is the most common choice. The locations of the stubs may differ significantly from the symmetrical case and the exterior stubs may have been placed at the very ends of the bottom chord. However, this is not difficult to address in the modeling of the girder, and the essential requirements are that the forces that develop as a result of the choice of girder geometry be accounted for in the design of the girder components and the adjacent structure. These actual forces are used in the design of the various elements, as distinguished from the simplified models that are currently used for many structural components.

The choices of elements, etc., are at the discretion of the designer and depend on the service requirements of the building as seen from the architectural, structural, mechanical, and electrical viewpoints. Unique design considerations must be made by the structural engineer, for example, if it is decided to eliminate the exterior openings and connect the stubs to the columns in addition to the chord and the slab.

Figure 33.1 shows the main components of the stub girder, as follows:

1. Bottom chord.
2. Exterior and interior stubs.

FIGURE 33.1 Elevation of a typical stub girder.

3. Transverse floor beams.
4. Formed steel deck.
5. Concrete slab with longitudinal and transverse reinforcement.
6. Stud shear connectors.
7. Stub stiffeners.
8. Beam-to-column connection.
9. The bottom chord should preferably be a hot-rolled wide-flange shape of column-type proportions, most often in the W12 to W14 series of wide-flange shapes. Other chord cross-sections have been considered; for example, tee shapes and rectangular tubes have certain advantages as far as welded attachments and fire protection are concerned, respectively. However, these other shapes also have significant drawbacks. The rolled tube, for example, cannot accommodate the shear stresses that develop in certain regions of the bottom chord. Rather than using a tee or a tube, therefore, a smaller W-shape (in the W10 series, for example) is most likely the better choice under these conditions.

The steel grade for the bottom chord, in particular, is important, since several of the governing regions of the girder are located within this member, and tension is the primary stress resultant. It is therefore possible to take advantage of higher strength steels, and 50 ksi yield stress steel has typically been the choice.

The floor beams and the stubs are mostly of the same size W-shape and are normally selected from the W16 and W18 series of shapes. This is directly influenced by the size(s) of the heating, ventilating, and air conditioning (HVAC) ducts that are to be used. Although it is not strictly necessary that the floor beams and the stubs use identical shapes, it avoids a number of problems if such a choice is made. These two components of the floor system at least should have the same height.

The concrete slab and the steel deck constitute the top chord of the stub girder. It is either made from lightweight or normal weight concrete, although if the former is available, even at a modest cost premium, it is preferred. The reason is the lower dead load of the floor, especially since the shores that will be used are strongly influenced by the concrete weight. Further, the shores must support several stories before they can be removed. In other words, the stub girders must be designed for shored construction, since the girder requires the slab to complete the system. In addition, the bending rigidity of the girder is substantial and a major fraction is contributed by the bottom chord. The reduction in slab stiffness that is prompted by the lower value of the modulus of elasticity for the lightweight concrete is therefore not as important as it may be for other types of composite bending members.

Concrete strengths of 3000 to 4000 psi are most common, although the choice also depends on the limit state of the stud shear connectors. The concrete does not control the strength of the stub girder, apart from in certain long-span girders, some local regions in the slab, and the desired mode of behavior of the slab-to-stub connection (which limits the maximum f'_c -value that can be used). Consequently, there is little to gain by using high-strength concrete.

The steel deck should be of the composite type, and a number of manufacturers produce suitable types. Normal deck heights are 2 and 3 in., but most floors are designed for the 3 in. deck. The deck ribs are run parallel to the longitudinal axis of the girder, since this gives better deck support on the transverse floor beams. It also increases the top chord area, which lends additional stiffness to a member that can span substantial distances. Finally, the parallel orientation provides a continuous rib trough directly above the girder centerline, improving the composite interaction of the slab and the girder.

Due to fire protection requirements, the thickness of the concrete cover over the top of the deck ribs is either $4\frac{3}{16}$ in. (normal weight concrete) or $3\frac{1}{4}$ in. (lightweight concrete). This eliminates the need for applying fire protective material to the underside of the steel deck.

Stud shear connectors are distributed uniformly along the length of the exterior and interior stubs, as well as on the floor beams. The number of connectors is determined on the basis of the computed shear forces that are developed between the slab and the stubs. This is in contrast to the current design practice for simple composite beams, which is based on the smaller of the ultimate axial load-carrying capacity of

the slab and the steel beam [3]. However, the simplified approach of current specifications is not applicable to members where the cross-section varies significantly along the length (nonprismatic beams). The computed shear force design approach also promotes connector economy, in the sense that a much smaller number of shear connectors is required in the interior shear transfer regions of the girder [4–6].

The stubs are welded to the top flange of the bottom chord with fillet welds. In the original uses of the system, the design called for all-around welds [1,2]; subsequent studies demonstrated that the forces that are developed between the stubs and the bottom chord are concentrated toward the end of the stubs [4,5,7]. The welds should therefore be located in these regions.

The type and locations of the stub stiffeners that are indicated for the exterior stubs in Figure 33.1, as well as the lack of stiffeners for the interior stubs, represent one of the major improvements that were made to the original stub girder designs. Based on extensive research [4,5], it was found that simple end-plate stiffeners were as efficient as the traditional fitted ones, and in many cases the stiffeners could be eliminated at no loss in strength and stiffness to the overall girder.

Figure 33.1 shows that a simple (shear) connection is used to attach the bottom chord of the stub girder to the adjacent structure (column, concrete building core, etc.). This is the most common solution, especially when a duct opening needs to be located at the exterior end of the girder. If the support is an exterior column, the slab will rest on an edge member; if it is an interior column, the slab will be continuous past the column and into the adjacent bay. This may or may not present problems in the form of slab cracking, depending on the reinforcing steel placement around the column.

The stub girder has sometimes been used as part of the lateral load-resisting system of steel-framed buildings [8,9]. Although this has certain disadvantages insofar as column moments and the concrete slab reinforcement are concerned, the girder does provide significant lateral stiffness and ductility for the frame. As an example, the maintenance facility for Mexicana Airlines at the Mexico City International Airport, a structure utilizing stub girders in this fashion, survived the 1985 Mexico City Earthquake with no structural damage [9].

Expanding on the details that are shown in Figure 33.1, Figure 33.2 illustrates two cross-sections of a typical stub girder and Figure 33.3 shows a complete girder assembly with lights, ducts, and suspended

FIGURE 33.2 Cross-sections of a typical stub girder.

FIGURE 33.3 Stub girder with suspended ceiling, lights, and ducts.

ceiling. Of particular note are the longitudinal reinforcing bars. They add flexural strength as well as ductility and stiffness to the girder. These bars are commonly placed in two layers, with the top one just below the heads of the stud shear connectors. The lower rebars must be raised above the deck proper, using high chairs or other means.

The transverse rebars are important for adding shear strength to the slab, and they also help in the shear transfer from the connectors to the slab. The transverse bars also increase the overall ductility of the stub girder, and placing the bars in a herringbone pattern leads to a small improvement in the effective width of the slab.

Thirty-six or 50 ksi yield stress steel has been the common choice for stub girder floor systems, with a preference for the latter, because of the smaller bottom chord size that can be used. However, all detail materials (stiffeners, connection angles, etc.) are made from 36 ksi steel. Welding is usually done with 70-grade low hydrogen electrodes, using either the Shielded Metal Arc Welding (SMAW), Flux Cored Arc Welding (FCAW), or Gas Metal Arc Welding (GMAW) process, and the stud shear connectors are welded in the normal fashion. All of the work is done in the fabricating shop, except for the shear connectors, which are applied in the field where they are welded directly through the steel deck.

33.3 Methods of Analysis and Modeling

33.3.1 General Observations

In general, any number of methods of analysis may be used to determine the bending moments, shear forces, and axial forces in the components of the stub girder. However, it is essential to bear in mind that the modeling of the girder, or, in other words, how the actual girder is transformed into an idealized structural system, should reflect the relative stiffness of the elements. This means that it is important to establish realistic trial sizes of the components, through an appropriate preliminary design procedure. The subsequent modeling will then lead to stress resultants that are close to the magnitudes that can be expected in actual stub girders. Based on this approach, the design that follows is likely to require few changes, and those that are needed are often so small that they have no practical impact on the overall stiffness distribution and the final member forces. The preliminary design procedure is therefore a very important step in the overall design.

33.3.2 Preliminary Design Procedure

It is not necessary to make any assumptions about the stress distribution over the depth of the girder, other than to adhere to the strength model that was developed for normal composite beams [3,10]. The stress distribution will vary anyway along the span because of the openings. The strength model of Hansell et al. [10] assumes that when the ultimate moment is reached, all or a portion of the slab is failing in compression, with a uniformly distributed stress of $0.85f'_c$. The steel shape is simultaneously yielding in tension. Equilibrium is therefore maintained and the internal stress resultants are determined using first principles. Tests have demonstrated excellent agreement with theoretical analyses that utilize this approach [4–6,10].

FIGURE 33.4 Stub girder for design example.

The design procedure follows the criteria of the AISC LRFD Specification [3]. The applicable resistance factor is given for the case of gross cross-section yielding. This is because the preliminary design is primarily needed to find the bottom chord size and this component is primarily loaded in tension [4–6,11]. The load factors are given by the ASCE 7 load standard [12] for the combination of dead plus live load.

The load computations follow the choice of the layout of the floor framing plan, whereby girder and floor beam spans are determined. This gives the tributary areas that are needed to calculate the dead and live loads. The load intensities are governed by local building code requirements or by the American Society of Civil Engineers (ASCE) recommendations, in the absence of a local code.

Reduced live loads should be used wherever possible. This is especially advantageous for stub girder floor systems, since spans and tributary areas tend to be large. ASCE 7 [12] makes use of a live load reduction factor, RF , which is significantly simpler to use and also less conservative than that of earlier codes. The standard places some restrictions on the value of RF , to the effect that the reduced live load cannot be less than 50% of the nominal value for structural members that support only one floor. Similarly, it cannot be less than 40% of the nominal live load if two or more floors are involved.

Proceeding with the preliminary design, the stub girder and its floor beam locations determine the magnitudes of the concentrated loads that are to be applied at each of the latter locations. The following illustrative example demonstrates the steps of the solution.

Figure 33.4 shows the layout of the stub girder for which the preliminary sizes are needed. Other computations have already given the sizes of the floor beam, the slab, and the steel deck. The span of the girder is 40 ft, the distance between adjacent girders is 30 ft, and the floor beams are located at the quarter points. The steel grade remains to be chosen; the concrete is lightweight, with $w_c = 120$ pcf and a compressive strength of $f'_c = 4000$ psi.

Loads:

Estimated dead load: 74 psf

Nominal live load: 50 psf

Live load reduction factor:

$$RF = 0.25 + 15/\sqrt{[2 \times (30 \times 30)]} = 0.60$$

Reduced live load:

$$RLL = 0.60 \times 50 = 30 \text{ psf}$$

Load factors (for $D + L$ combination):

For dead load: 1.2

For live load: 1.6

Factored distributed loads:

Dead load, $DL = 74 \times 1.2 = 88.8$ psf

Live load, $LL = 30 \times 1.6 = 48.0$ psf

Total = 136.8 psf

Concentrated factored load at each floor beam location: Due to the locations of the floor beams and the spacing of the stub girders, the magnitude of each load, P , is

$$P = 136.8 \times 30 \times 10 = 41.0 \text{ kip}$$

Maximum factored midspan moment: The girder is symmetric about midspan and the maximum moment therefore occurs at this location

$$M_{\max} = 1.5 \times P \times 20 - P \times 10 = 820 \text{ k ft}$$

Estimated interior moment arm for full stub-girder cross-section at midspan (refer to Figure 33.2 for typical details): The interior moment arm, that is, the distance between the compressive stress resultant in the concrete slab and the tensile stress resultant in the bottom chord is set equal to the distance between the slab centroid and the bottom chord (wide flange shape) centroid. This is simplified and conservative. In the example, the distance is estimated as

$$\text{Interior moment arm, } d = 27.5 \text{ in.}$$

This is based on having a 14-series W-shape for the bottom chord, W16 floor beams and stubs, a 3 in. high steel deck, and $3\frac{1}{4}$ in. of lightweight concrete over the top of the steel deck ribs (this allows the deck to be used without having sprayed-on fire protective material to the underside). These are common sizes for the stub-girder system.

In general, the interior moment arm varies between 24.5 and 29.5 in., depending on the heights of the bottom chord, floor beams/stubs, steel deck, and concrete slab.

Slab and bottom chord axial forces, F (these are the compressive and tensile stress resultants)

$$F = M_{\max}/d = (820 \times 12)/27.5 = 357.9 \text{ kip}$$

Required cross-sectional area of bottom chord, A_s : The required cross-sectional area of the bottom chord can now be found. Since the chord is loaded in tension, the ϕ -value is 0.9.

It is also important to note that in the Vierendeel analysis that is commonly used in the final evaluation of the stub girder, the member forces will be somewhat larger than those determined through the simplified preliminary procedure. It is therefore recommended that an allowance of some magnitude be given for the Vierendeel action. This is done most easily by increasing the area A_s by a certain percentage. Based on experience [6,11], an increase of one third is suitable, and such has been done in the computations that follow.

On the basis of the data that have been developed, the required area of the bottom chord is

$$A_s = \frac{(M_{\max}/d)}{\phi \times F_y} \times \frac{4}{3} = \frac{F}{0.9 \times F_y} \times \frac{4}{3}$$

which gives A_s -values for 36 and 50 ksi steel of

$$A_s = \frac{357.9}{0.9 \times 36} \times \frac{4}{3} = 14.73 \text{ in.}^2 \quad (F_y = 36 \text{ ksi})$$

$$A_s = \frac{357.9}{0.9 \times 50} \times \frac{4}{3} = 10.60 \text{ in.}^2 \quad (F_y = 50 \text{ ksi})$$

Conclusions: If 36 ksi steel is chosen for the bottom chord of the stub girder, the wide-flange shapes W12 \times 50 and W14 \times 53 will be suitable. If 50 ksi steel is the choice, the sections may be W12 \times 40 or W14 \times 38.

The final decision is made by the structural engineer. However, since W12-series shapes will save approximately 2 in. in net floor system height, per story of the building, this would mean significant savings if the overall structure is 10 to 15 stories or more. The differences in stub girder strength and stiffness are not likely to play a role [7,12].

33.3.3 Choice of Stub Girder Component Sizes

Some examples were given in the earlier sections for the choices of chord and floor beam sizes, deck height, and slab configuration. These were made primarily on the basis of acceptable geometries, deck size, and fire protection requirements, to mention some examples. However, construction economy is critical and the following guidelines will assist the user. The data that are given are based on actual construction projects.

Economical span lengths for the stub girder range from 30 to 50 ft, although the preferable spans are 35 to 45 ft. Fifty-foot span girders are erectable, but these are close to the limit where the dead load becomes excessive, which has the effect of making the slab govern the overall design. This is usually not an economical solution. Spans shorter than 30 ft are known to have been used successfully; however, this depends on the load level and the type of structure, to mention the key considerations.

Depending on the type and configuration of steel deck that has been selected, the floor beam spacing should generally be maintained between 8 and 12 ft, although larger values have been used. The decisive factor is the ability of the deck to span the distance between the floor beams.

The performance of the stub girder is not particularly sensitive to the stub lengths that are used, as long as these are kept within reasonable limits. In this context, it is important to observe that it is usually the exterior stub that controls the behavior of the stub girder. As a practical guideline, the exterior stubs are normally 5 to 7 ft long; the interior stubs are considerably shorter, normally around 3 ft, but components up to 5 ft long are known to have been used. When the stub lengths are chosen, it is necessary to bear in mind the actual purpose of the stubs and how they carry the loads on the stub girder. That is, the stubs are loaded primarily in shear, which explains why the interior stubs can be kept so much shorter than the exterior ones.

The shear connectors that are welded to the top flange of the stub, the stub web stiffeners, and the welds between the bottom flange of the stub and the top flange of the bottom chord are crucial to the function of the stub girder system. For example, the first application of stub girders utilized fitted stiffeners at the ends and sometimes at midlength of all of the stubs. Subsequent research demonstrated that the midlength stiffener did not perform any useful function and that only the exterior stubs needed stiffeners in order to provide the requisite web stability and shear capacity [5,6]. Regardless of the span of the girder, it was found that the interior stubs could be left unstiffened, even when they were made as short as 3 ft [6].

Similar savings were realized for the welds and the shear connectors. In particular, in lieu of all-around fillet welds for the connection between the stub and the bottom chord, the studies showed that a significantly smaller amount of welding was needed, and often only in the vicinity of the stub ends. However, specific weld details must be based on appropriate analyses of the stub, considering overturning, weld capacity at the tension end of the stub, and adequate ability to transfer shear from the slab to the bottom chord.

33.3.4 Modeling of the Stub Girder

The original work of Colaco [1,2] utilized a Vierendeel modeling scheme for the stub girder to arrive at a set of stress resultants, which in turn were used to size the various components. Elastic finite element analyses were performed for some of the girders that had been tested, mostly to examine local stress distributions and the correlation between test and theory. However, the finite element solution is not a practical design tool.

Other studies have examined approaches such as nonprismatic beam analysis and variations of the finite element method [5]. The nonprismatic beam solution is relatively simple to apply. On the other hand, it is not as accurate as the Vierendeel approach, since it tends to overlook some important local effects and overstates the service load deflections [4,5].

On the whole, therefore, the Vierendeel modeling of the stub girder has been found to give the most accurate and consistent results, and the correlation with test results is good [1,4,5,7]. Finally, it offers the best physical similarity with actual girders; many designers have found this to be an important advantage.

There are no “simple” methods of analysis that can be used to find the bending moments, shear forces, and axial forces in Vierendeel girders. Once the preliminary sizing has been accomplished, a computer solution is required for the girder. In general, all that is required for the Vierendeel evaluation is a two-dimensional plane frame program for elastic structural analysis. This gives moments, shears, and axial forces, as well as deflections, joint rotations, and other displacement characteristics. The stress resultants are used to size the girder and its elements and connections; the displacements reflect the serviceability of the stub girder.

Once the stress resultants are known, the detailed design of the stub girder can proceed. A final run-through of the girder model should then be done, using the components that were chosen, to ascertain that the performance and strength are sufficient in all respects. Under normal circumstances no alterations are necessary at this stage.

As an illustration of the Vierendeel modeling of a stub girder, the girder itself is shown in Figure 33.5a and the Vierendeel model in Figure 33.5b. The girder is the same as the one used for the preliminary design example. It has four stubs and is symmetrical about midspan; therefore, only one half is illustrated. The boundary conditions are shown in Figure 33.5b.

The bottom chord of the model is assigned a moment of inertia equal to the major axis I_x -value, $I_{x\infty}$ of the wide-flange shape that was chosen in the preliminary design. However, some analysts believe that

FIGURE 33.5 Vierendeel modeling of a stub girder: (a) stub girder and (b) its Vierendeel model.

since the stub is welded to the bottom chord, a portion of its flexural stiffness should be added to that of the moment of inertia of the wide-flange shape [4,5,7]. This approach is identical to treating the bottom chord W-shape as if it has a cover plate on its top flange. The area of this “cover plate” is the same as the area of the bottom flange of the stub. This should be done only in the areas where the stubs are placed. In the regions of the interior and exterior stubs it is therefore realistic to increase the moment of inertia of the bottom chord by the parallel-axis value of $A_f \times d_f^2$ where A_f designates the area of the bottom flange of the stub and d_f is the distance between the centroids of the flange plate and the W-shape.

The bending stiffness of the top Vierendeel chord equals that of the effective width portion of the slab. This should include the contributions of the steel deck as well as the reinforcing steel bars that are located within this width. In particular, the influence of the deck is important. The effective width is determined from the criteria in the AISC LRFD Specification [3]. These were originally developed on the basis of analyses and tests of prismatic composite beams. The approach has been found to give conservative results [4,5], but should continue to be used until more accurate criteria are available.

In the computations for the slab, the cross-section is conveniently subdivided into simple geometric shapes. The individual areas and moments of inertia are determined on the basis of the usual transformation from concrete to steel, using the modular ratio $n = E/E_c$, where E is the modulus of elasticity of the steel and E_c is that of concrete. The latter must reflect the density of the concrete that is used, and can be computed from [13]

$$E_c = 33 \times w_c^{1.5} \times \sqrt{f'_c} \quad (33.1)$$

The shear connectors used for the stub are required to develop 100% interaction, since the design is based on the computed shear forces, rather than the axial capacity of the steel beam or the concrete slab, as is used for prismatic beams in the AISC Specification [3]. However, it is neither common nor proper to add the moment of inertia contribution of the top flange of the stub to that of the slab, contrary to what is done for the bottom chord. The reason for this is that dissimilar materials are joined and some local concrete cracking and/or crushing can be expected to take place around the shear connectors.

The discretization of the stubs into vertical Vierendeel girder components is relatively straightforward. Considering the web of the stub and any stiffeners, if applicable (for exterior stubs, most commonly, since interior stubs usually can be left unstiffened), the moment of inertia about an axis that is perpendicular to the plane of the web is calculated. As an example, Figure 33.6 shows the stub and stiffener configuration for a typical case. The stub is a 5 ft long W16 \times 26 with $5\frac{1}{2} \times \frac{1}{2}$ in. end-plate stiffeners. The computations give

Moment of inertia about the z - z axis:

$$\begin{aligned} I_{zz} &= [0.25 \times (60)^3]/12 + 2 \times 5.5 \times 0.5 \times (30)^2 \\ &= 9450 \text{ in.}^4 \end{aligned}$$

Depending on the number of Vierendeel truss members that will represent the stub in the model, the bending stiffness of each is taken as a fraction of the value of I_z . For the girder shown in Figure 33.5, where the stub is discretized as three vertical members, the magnitude of I_{vert} is found as

Moment of inertia of vertical member:

$$I_{\text{vert}} = I_{zz}/(\text{no. of verticals}) = 9450/3 = 3150 \text{ in.}^4$$

The cross-sectional area of the stub, including the stiffeners, is similarly divided between the verticals

Area of vertical member:

$$\begin{aligned} A_{\text{vert}} &= [A_{\text{web}} + 2 \times A_{\text{st}}]/(\text{no. of verticals}) \\ &= [0.25 \times (60 - 2 \times 0.5) + 2 \times 5.5 \times 0.5]/3 \\ &= 6.75 \text{ in.}^2 \end{aligned}$$

FIGURE 33.6 Plan view of stub with end plate stiffeners.

Several studies have aimed at finding the optimum number of vertical members to use for each stub. However, the strength and stiffness of the stub girder are insignificantly affected by this choice and a number between 3 and 7 is usually chosen. As a rule of thumb, it is advisable to have one vertical per foot length of stub, but this is only a guideline.

The verticals are placed at uniform intervals along the length of the stub, usually with the outside members close to the stub ends. Figure 33.5 illustrates the approach. As for end conditions, these vertical members are assumed to be rigidly connected to the top and bottom chords of the Vierendeel girder.

One vertical member is placed at each of the locations of the floor beams. This member is assumed to be pinned to the top and bottom chords, as shown in Figure 33.5, and its stiffness is conservatively set equal to the moment of inertia of a plate with a thickness equal to that of the web of the floor beam and a length equal to the beam depth. In the example, $t_w = 0.25$ in.; the beam depth is 15.69 in. This gives a moment of inertia of

$$([15.69 \times 0.25^3]/12) = 0.02 \text{ in.}^4$$

and the cross-sectional area is

$$(15.69 \times 0.25) = 3.92 \text{ in.}^2$$

The Vierendeel model shown in Figure 33.5b indicates that the portion of the slab that spans across the opening between the exterior end of the exterior stub and the support for the slab (a column, or a corbel of the core of the structural frame) has been neglected. This is a realistic simplification, considering the low rigidity of the slab in negative bending.

Figure 33.5b also shows the support conditions that are used as input data for the computer analysis. In the example, the symmetrical layout of the girder and its loads make it necessary only to analyze one half of the span. This cannot be done if there is any kind of asymmetry and the entire girder must then be analyzed. For the girder that is shown, it is known that only vertical displacements can take place at midspan; horizontal displacements and end rotations are prevented at this location. At the far ends of the bottom chord only horizontal displacements are permitted and end rotations are free to occur. The reactions that are found are used to size the support elements, including the bottom chord connections and the column.

The structural analysis results are shown in Figure 33.7, in terms of the overall bending moment, shear force and axial force distributions of the Vierendeel model given in Figure 33.5b. Figure 33.7d repeats the layout details of the stub girder, to help identify the locations of the key stress resultant magnitudes with the corresponding regions of the girder.

The design of the stub girder and its various components can now be done. This must also include deflection checks, even though research has demonstrated that the overall design will not be governed by deflection criteria [6]. However, since the girder has to be built in the shored condition, the girder is often fabricated with a camber, approximately equal to the dead load deflection [6,11].

FIGURE 33.7 Bending moment, shear force, and axial force distributions for stub girder and critical points for strength checks.

33.4 Design Criteria for Stub Girders

33.4.1 General Observations

In general, the design of the stub girder and its components must consider overall member strength criteria as well as local checks. For most of these, the AISC Specification [3] gives requirements that address the needs.

In several important areas there are no standardized rules that can be used in the design of the stub girder, and the designer must rely on rational engineering judgment to arrive at satisfactory solutions. This applies to the parts of the girder that have to be designed on the basis of computed forces, such as shear connectors, stiffeners, stub-to-chord welds, and slab reinforcement. The modeling and evaluation of the capacity of the central portion of the concrete slab are also subject to interpretation. However, the design recommendations that are given in the following are based on a wide variety of practical and successful applications.

It is again emphasized that the design throughout is based on the stress resultants that have been determined in the Vierendeel or other analysis, rather than on idealized code criteria. However, the capacities of materials and fasteners, as well as the requirements for the stability and strength of tension and compression members, adhere strictly to the AISC design requirements. Any interpretations that have been made are conservative.

33.4.2 Governing Sections of the Stub Girder

Figure 33.5 and Figure 33.7 show certain circled numbers at various locations throughout the span of the stub girder. These reflect the sections of the girder that are the most important for one reason or another and are the ones that must be examined to determine the required member size, etc. These are the *governing sections of the stub girder* and are itemized as follows:

1. Points 1, 2, and 3 indicate the critical sections for the bottom chord.
2. Points 4, 5, and 6 indicate the critical sections for the concrete slab.
3. Point 7, which is a region rather than a specific point, indicates the critical shear transfer region between the slab and the exterior stub.

The design checks that must be made for each of these areas are discussed in the following.

33.4.3 Design Checks for the Bottom Chord

The size of the bottom chord is almost always governed by the stress resultants at midspan or Point 3 in Figure 33.5 and Figure 33.7. This is also why the preliminary design procedure focused almost entirely on determining the required chord cross-section at this location. As the stress resultant distributions in Figure 33.7 show, the bottom chord is subjected to combined positive bending moment and tensile force at Point 3, and the design check must consider the beam-tension member behavior in this area.

Combined bending and tension must also be evaluated at Point 2, the exterior end of the interior stub. The local bending moment in the chord is generally larger here than at midspan, but the axial force is smaller. Only a computation can confirm whether Point 2 will govern in lieu of Point 3. Further, although the location at the interior end of the exterior stub (Point 2a) is rarely critical, the combination of negative moment and tensile force should be evaluated.

At Point 1 of the bottom chord, which is located at the exterior end of the exterior stub, the axial force is equal to zero. At this location the bottom chord must therefore be checked for pure bending as well as shear.

The preceding applies only to a girder with simple end supports. When it is part of the lateral load-resisting system, axial forces will exist in all parts of the chord. These must be resisted by the adjacent structural members.

33.4.4 Design Checks for the Concrete Slab

The top chord carries varying amounts of bending moment and axial force, as illustrated in Figure 33.7, but the most important areas are indicated as Points 4 to 6. The axial forces are always compressive in the concrete slab; the bending moments are positive at Points 5 and 6 but negative at Point 4. As a result, this location is normally the one that governs the performance of the slab, not the least because the reinforcement in the positive moment region includes the cross-sectional area of the steel deck.

The full effective width of the slab must be analyzed for combined bending and axial force at all of Points 4 through 6. Either the composite beam-column criteria of the AISC LRFD Specification [3] or the criteria of the reinforced concrete structures code of American Concrete Institute (ACI) [13] may be used for this purpose.

33.4.5 Design Checks for the Shear Transfer Regions

Region 7 is the shear transfer region between the concrete slab and the exterior stub, and the combined shear and longitudinal compressive capacity of the slab in this area must be determined. The shear transfer region between the slab and the interior stub always has a smaller shear force.

Region 7 is critical and several studies have shown that the slab in this area will fail in a combination of concrete crushing and shear [4–7]. The shear failure zone usually extends from corner to corner of the steel deck, over the top of the shear connectors, as illustrated in Figure 33.8. This also emphasizes why the placement of the longitudinal reinforcing steel bars in the central flute of the steel deck is important,

FIGURE 33.8 Shear failure zone in concrete slab above stub.

as well as the location of the transverse bars: both groups should be placed just below the level of the top of the shear connectors (see Figure 33.2). The welded wire mesh reinforcement that is used as a matter of course, mostly to control shrinkage cracking in the slab, also assists in improving the strength and ductility of the slab in this region.

33.4.6 Design of Stubs for Shear and Axial Load

The shear and axial force distributions indicate the governing stress resultants for the stub members. It is important to note that since the Vierendeel members are idealized from the real (i.e., continuous) stubs, bending is not a governing condition. Given the sizes and locations of the individual vertical members that make up the stubs, the design checks are made for axial load and shear. For example, referring to Figure 33.7, it is seen that the shear and axial forces in the exterior and interior stubs, and the axial forces in the verticals that represent the floor beams, are the following:

Exterior stub verticals:

Shear forces: 103 kip 63 kip 99 kip
 Axial forces: -18 kip 0.4 kip 3 kip

Interior stub verticals:

Shear forces: 38 kip 19 kip 20 kip
 Axial forces: -5 kip 0.8 kip 4 kip

Floor beam verticals:

Exterior: Axial force = -39 kip
 Interior: Axial force = -12 kip

Shear forces are zero in these members.

The areas and moments of inertia of the verticals are known from the modeling of the stub girder. Figure 33.7 also shows the shear and axial forces in the bottom and top chords, but the design for these elements has been addressed earlier in this chapter.

The design checks that are made for the stub verticals will also indicate whether there is a need for stiffeners for the stubs, since the evaluations for axial load capacity should always first be made on the assumption that there are no stiffeners. However, experience has shown that the exterior stubs always must be stiffened; the interior stubs, on the other hand, will almost always be satisfactory without stiffeners, although exceptions can occur.

The axial forces that are shown for the stub verticals in the preceding are small but typical, and in all probability only the exterior end of the exterior stub really requires a stiffener. This was examined in one of the stub girder research studies, where it was found that a single stiffener would suffice, although the resulting lack of structural symmetry gave rise to a tensile failure in the unstiffened area of the stub [5].

Although this occurred at a very late stage in the test, the type of failure represents an undesirable mode of behavior, and the use of single stiffeners therefore was discarded. Further, by reason of ease of fabrication and erection, stiffeners should always be provided at both stub ends.

It is essential to bear in mind that if stiffeners are required, the purpose of such elements is to add to the area and moment of inertia of the web, to resist the axial load that is applied. There is no need to provide *bearing* stiffeners, since the load is not transmitted in this fashion. The most economical solution is to make use of end-plate stiffeners of the kind that is shown in Figure 33.1; extensive research evaluations showed that this was the most efficient and economical choice [4,5,7].

The vertical stub members are designed as columns, using the criteria of the AISC Specification [3]. For a conservative solution, an effective length factor of 1.0 may be used. However, it is more realistic to utilize a K -value of 0.8 for the verticals of the stubs, recognizing the end restraint that is provided by the connections between the chords and the stubs. The K -factor for the floor beam verticals must be 1.0, due to the pinned ends that are assumed in the modeling of these components, as well as the flexibility of the floor beam itself for buckling of the vertical member.

33.4.7 Design of Stud Shear Connectors

The Vierendeel girder shear force diagram gives the shear forces that must be transferred between the slab and the stubs. These are the factored shear force values that are to be resisted by the connectors. The example shown in Figure 33.7 indicates the individual shear forces for the stub verticals, as listed in the preceding section. However, in the design of the overall shear connection, the total shear force that is to be transmitted to the stub is used, and the stud connectors are then distributed uniformly along the stub. The design strength of each connector is determined in accordance with the LRFD Specification [3], including any deck profile reduction factor.

Analyzing the girder whose data are given in Figure 33.7, the following is known:

Exterior stub:

$$\text{Total shear force} = V_{es} = 103 + 63 + 99 = 265 \text{ kip}$$

Interior stub:

$$\text{Total shear force} = V_{is} = 38 + 19 + 20 = 77 \text{ kip}$$

The nominal strength, Q_n , of the stud shear connectors is given by the LRFD Specification; thus

$$Q_n = 0.5 \times A_{sc} \sqrt{f'_c \times E_c} \leq A_{sc} \times F_u \quad (33.2)$$

where A_{sc} is the cross-sectional area of the stud shear connector, f'_c and E_c are the compressive strength and modulus of elasticity of the concrete, respectively, and F_u is the specified minimum tensile strength of the stud shear connector steel (60 ksi) (ASTM A108).

In the equation for Q_n , the left-hand side reflects the ultimate limit state of shear yield failure of the connector; the right-hand side gives the ultimate limit state of tension fracture of the stud. Although shear almost always governs, and is the desirable mode of behavior, a check has to be made to ensure that tension fracture will not take place. This is achieved by the appropriate value of E_c , setting $F_u = 60$ ksi, and solving for f'_c from the Equation 33.2. The requirement that must be satisfied in order for the stud shear limit state to govern is given by Equation 33.3:

$$f'_c \leq \frac{57,000}{w_c} \quad (33.3)$$

This gives the limiting values for concrete strength as related to the density (Table 33.1).

For concrete with $w_c = 120$ pcf and $f'_c = 4000$ psi, as used in the design example, $E_c = 2,629,000$ psi. Using $\frac{3}{4}$ -in. diameter studs, the nominal shear capacity is

$$Q_n = 0.5[\Pi(0.75)^2/4]\sqrt{(4.2, 629)} \leq [\Pi(0.75)^2/4]60$$

TABLE 33.1 Concrete Strength Limitations for Ductile Shear Connector Failure

Concrete density w_c (pcf)	Maximum concrete strength, f'_c (psi)
145 (= NW)	4000
120	4800
110	5200
100	5700
90	6400

which gives

$$Q_n = 22.7 \text{ kip} < 26.5 \text{ kip}$$

The LRFD Specification [3] does not give a resistance factor for shear connectors, on the premise that the ϕ -value of 0.85 for the overall design of the composite member incorporates the stud strength variability. This is not satisfactory for composite members such as stub girders and composite trusses. However, a study was carried out to determine the resistance factors for the two ultimate limit states for stud shear connectors [14]. Briefly, on the basis of extensive analyses of test data from a variety of sources, and using the Q_n -equation as the nominal strength expression, the values of the resistance factors that apply to the shear yield and tension fracture limit states, respectively, are

Stud shear connector resistance factors:

$$\text{Limit state of shear yielding: } \phi_{\text{conn}} = 0.90$$

$$\text{Limit state of tension fracture: } \phi_{\text{conn}} = 0.75$$

The required number of shear connectors can now be found as follows, using the total stub shear forces, V_{es} and V_{is} , computed earlier in this section:

Exterior stub:

$$\begin{aligned} n_{es} &= V_{es} / (0.9 \times Q_n) = V_{es} / (\phi_{\text{conn}} Q_n) \\ &= 265 / (0.9 \times 22.7) = 13.0 \end{aligned}$$

That is, use $14\frac{3}{4}$ -in. diameter stud shear connectors, placed in pairs and distributed uniformly along the length of the top flange of each of the exterior stubs.

Interior stub:

$$\begin{aligned} n_{is} &= V_{is} / (0.9 \times Q_n) = V_{is} / (\phi_{\text{conn}} Q_n) \\ &= 77 / (0.9 \times 22.7) = 3.8 \end{aligned}$$

That is, use $4\frac{3}{4}$ -in. diameter stud shear connectors, placed singly and distributed uniformly along the length of the top flange of each of the interior stubs.

Considering the shear forces for the stub girder of [Figure 33.5](#) and [Figure 33.7](#), the number of connectors for the exterior stub is approximately three times that for the interior one. Depending on span, loading, etc., there are instances when it will be difficult to fit the required number of studs on the exterior stub, since typical usage entails a double row, spaced as closely as permitted. Several avenues may be followed to remedy such a problem; the easiest one is most likely to use a higher strength concrete, as long as the limit state requirements for Q_n and Table 33.1 are satisfied. This entails only minor reanalysis of the girder.

33.4.8 Design of Welds Between Stub and Bottom Chord

The welds that are needed to fasten the stubs to the top flange of the bottom chord are primarily governed by the shear forces that are transferred between these components of the stub girder. The shear

force distribution gives these stress resultants, which are equal to those that must be transferred between the slab and the stubs. Thus, the factored forces V_{es} and V_{is} that were developed in Section 33.4.7 are used to size the welds.

Axial loads also act between the stubs and the chord; these may be compressive or tensile. In Figure 33.7, it is seen that the only axial force of note occurs in the exterior vertical of the exterior stub (load = 18 kip); the other loads are very small compressive or tensile forces. Unless a significant tensile force is found in the analysis, it will be a safe simplification to ignore the presence of the axial forces insofar as the weld design is concerned.

The primary shear forces that have to be taken by the welds are developed in the outer regions of the stubs, although it is noted that in the case of Figure 33.5, the central vertical element in both stubs carry forces of some magnitude (63 and 19 kip, respectively). However, this distribution is a result of the modeling of the stubs; analyses of girders where many more verticals were used have confirmed that the major part of the shear is transferred at the ends [5,6,11]. The reason is that the stub is a full shear *panel*, where the internal moment is developed through stress resultants that act at points toward the ends, in a form of bending action. Tests have also verified this characteristic of the girder behavior [5,7]. Finally, concentrating the welds at the stub ends will have significant economic impact [4–6].

In view of these observations, the most effective placement of the welds between the stubs and the bottom chord is to concentrate them across the ends of the stubs and along a short distance of both sides of the stub flanges. For ease of fabrication and structural symmetry, the same amount of welding should be placed at both ends, although the forces are always smaller at the interior ends of the stubs. Such U-shaped welds were used for a number of the full-size girders that were tested [4,5,7], with only highly localized yielding occurring in the welds. A typical detail is shown in Figure 33.9; this reflects what is recommended for use in practice.

Prior to the research that led to the change of the welded joint design, the stubs were welded with all-around fillet welds for the exterior as well as the interior elements. The improved, U-shaped detail provided for weld metal savings of approximately 75% for interior stubs and around 50% for exterior stubs.

For the sample stub girder, W16 × 26 shapes are used for the stubs. The total forces to be taken by the welds are

$$\text{Exterior stub: } V_{es} = 265 \text{ kip}$$

$$\text{Interior stub: } V_{is} = 77 \text{ kip}$$

Using E70XX electrodes and $\frac{5}{16}$ -in. fillet welds (the fillet weld size must be smaller than the thickness of the stub flange, which is $\frac{3}{8}$ in. for the W16 × 26), the total weld length for each stub is L_w , given by (refer to Figure 33.9)

$$L_w = 2(b_{fs} + 21)$$

since U-shaped welds of length $(b_{fs} + 21)$ are placed at each stub end. The total weld lengths required for the stub girder in question are therefore

Exterior stub:

$$\begin{aligned} (L_w)_{es} &= V_{es} / (0.707 a \phi_w F_w) \\ &= 265 / \left[0.707 \left(\frac{5}{16} \right) \cdot 0.75 (0.6 \cdot 70) \right] = 38.1 \text{ in.} \end{aligned}$$

Interior stub:

$$\begin{aligned} (L_w)_{is} &= V_{is} / (0.707 a \phi_w F_w) \\ &= 77 / \left[0.707 \left(\frac{5}{16} \right) \cdot 0.75 (0.6 \cdot 70) \right] = 11.1 \text{ in.} \end{aligned}$$

FIGURE 33.9 Welding details for end of stub to bottom chord of stub girder.

In the above expressions, $a = \frac{5}{16}$ in. = fillet weld size, $\phi_w = 0.75$, and $F_w = 0.6F_{EXX} = 0.6 \times 70 = 42$ ksi for E70XX electrodes. The total U-weld lengths at each stub end are therefore

- Exterior stub: $L_{Ues} = 19.1$ in.
- Interior stub: $L_{Uis} = 5.6$ in.

With a flange width for the W16 \times 26 of 5.50 in., the above lengths can be simplified as

$$L_{Ues} = 5.50 + 7.0 + 7.0$$

where L_{es} is chosen as 7.0 in. For the interior stub

$$L_{Uis} = 5.50 + 2.0 + 2.0$$

where L_{is} is chosen as 2.0 in.

The details chosen are a matter of judgment. In the example, the interior stub for all practical purposes requires no weld other than the one across the flange, although at least a minimum weld return of $\frac{1}{2}$ in. should be used.

33.4.9 Floor Beam Connections to Slab and Bottom Chord

In the Vierendeel model, the floor beam is represented as a pinned-end compression member. It is designed using a K -factor of 1.0, and the floor beam web by itself is almost always sufficient to take the axial load. However, the floor beam must be checked for web crippling and web buckling under shoring conditions.

No shear is transferred from the beam to the slab or the bottom chord. In theory, therefore, any attachment device between the floor beam and the other components should not be needed. However, due to construction stability requirements, as well as the fact that the floor beam usually is designed for composite action normal to the girder, fasteners are needed. In practice, these are not actually designed; rather, one or two stud shear connectors are placed on the top flange of the beam and two high strength bolts attach the lower flange to the bottom chord.

33.4.10 Connection of Bottom Chord to Supports

In the traditional use of stub girders, the girder is supported as a simple beam and the bottom chord end connections need to be able to transfer vertical reactions to the supports. The supports may be columns or the girder may rest on corbels or other types of supports that are part of the concrete core of the building. For both of these cases the reactions that are to be carried to the adjacent structure are given by the analysis.

Any shear-type beam connections may be used to connect the bottom chord to a column or a corbel or similar bracket. It is important to ascertain that the chord web shear capacity is sufficient, including block shear.

Some designers prefer to use slotted holes for the connections and to delay the final tightening of the bolts until after the shoring has been removed. This is done on the premise that the procedure will leave the slab essentially stress free from the construction loads, leading to less cracking in the slab during service. Other designers specify additional slab reinforcement to take care of any cracking problem. Experience has shown that both methods are suitable.

The slab may be supported on an edge beam or similar element at the exterior side of the floor system. There is no force transfer ability required of this support. In the interior of the building the slab will be continuously cast across other girders and around columns; this will almost always lead to some cracking, both in the vicinity of the columns as well as along beams and girders. With suitable placement of floor slab joints, this can be minimized, and appropriate transverse reinforcement for the slab will reduce, if not eliminate, the longitudinal cracks.

Data on the effects of various types of cracks in composite floor systems are scarce. Current opinion appears to be that the strength is not significantly influenced. In any case, the mechanics of the short- and long-term service response of composite beams is not well understood. Studies have developed models for the cracking mechanism and the crack propagation [15]; the correlation with a wide variety of laboratory tests is good. However, a comprehensive study of concrete cracking and its implications for structural service and strength needs to be undertaken.

33.4.11 Use of Stub Girder for Lateral Load System

The stub girder was originally conceived only as being part of the vertical load-carrying system of structural frames, and the use of simple connections, as discussed in [Section 33.4.9](#), came from this development. However, recognizing that a deep, long-span member can be very effective as a part of the lateral load-resisting system for a structure, several attempts have been made to incorporate the stub girder into moment frames and similar systems. The projects of Colaco in Houston [8] and Martinez-Romero [9] in Mexico City were successful, although the designers noted that the cost premium could be substantial.

For the Colaco structure, his applications reduced drift, as expected, but gave much more complex beam-to-column connections and reinforcement details in the slab around the columns. Thus, the exterior stubs were moved to the far ends of the girders and moment connections were designed for the full depth. For the Mexico City building, the added ductility was a prime factor in the survival of the structure during the 1985 earthquake.

The advantages of using the stub girders in moment frames are obvious. Some of the disadvantages have been outlined; in addition, it must be recognized that the lack of room for perimeter HVAC ducts may be undesirable. This can only be addressed by the mechanical engineering consultant. As a general rule, a designer who wishes to use stub girders as part of the lateral load-resisting system should examine all structural effects and also incorporate nonstructural considerations such as those prompted by HVAC and electronic communication needs.

33.4.12 Deflection Checks

The service load deflections of the stub girder are needed for several purposes. First, the overall dead load deflection is used to assess the camber requirements. Due to the long spans of typical stub girders, as well

as the flexibility of the framing members and the connections during construction, it is important to end up with a floor system that is as level as possible by the time the structure is ready to be occupied. Thus, the girders must be built in the shored condition and the camber should be approximately equal to 75% of the dead load deflection.

Second, it is essential to bear in mind that each girder will be shored against a similar member at the level below the current construction floor. This member, in turn, is similarly shored, albeit against a girder whose stiffness is greater, due to the additional time of curing of the concrete slab. This has a cumulative effect for the structure as a whole and the dead load deflection computations must take this response into account.

In other words, the support for the shores is a flexible one and deflections therefore will occur in the girder as a result of floor system movements of the structure at levels in addition to the one under consideration. Although this is not unique to the stub girder system, the span lengths and the interaction with the frame accentuate the influence on the girder design.

Depending on the structural system, it is also likely that the flexibility of the columns and the connections will add to the vertical displacements of the stub girders. The deflection calculations should incorporate these effects, preferably by utilizing realistic modified E_c -values, and determining displacements as they occur in the frame. Thus, the curing process for the concrete might be considered, since the strength development as a function of time is directly related to the value of E_c [13]. This is a subject that is open for study, although similar criteria have been incorporated in studies of the strength and behavior of composite frames [16,17]. However, detailed evaluations of the influence of time-dependent stiffness still need to be made for a wide variety of floor systems and frames. The cumulative deflection effects can be significant for the construction of the building and consequently also must enter into the contractor's planning. This subject is addressed briefly in [Section 33.5](#).

Third, the live load deflections must be determined to assess the serviceability of the floor system under normal operating conditions. Several studies have demonstrated that such displacements will be significantly smaller than the $L/360$ requirement that is normally associated with live load deflections [5–7,11]. It is therefore rarely possible to design a girder that meets the strength and the deflection criteria simultaneously. In other words, strength governs the overall design.

Finally, although they rarely play a role in the overall response of the stub girder, the deflections and end rotations of the slab across the openings of the girder should also be checked. This is primarily done to assess the potential for local cracking, especially at the stub ends and at the floor beams. However, proper placement of the longitudinal girder reinforcement is usually sufficient to prevent problems of this kind, since the deformations tend to be small.

33.5 Influence of Method of Construction

A number of construction-related considerations have already been addressed in various sections of this chapter. The most important ones relate to the fact that the stub girders must be built in the shored condition. The placement and removal of the shores may have a significant impact on the performance of the member and the structure as a whole. In particular, too early shore removal may lead to excessive deflections in the girders at levels above the one where the shores were located. This is a direct result of the low stiffness of “green” concrete. It can also lead to “ponding” of the concrete slab, producing larger dead loads than accounted for in the original design. Finally, larger girder deflections can be translated into an “inward pulling” effect on the columns of the frame. However, this is clearly a function of the framing system.

On the other hand, the use of high early strength cement and similar products can reduce this effect significantly. Further, since the concrete usually is able to reach about 75% of the 28-day strength after 7 to 10 days, the problem is less severe than originally thought [4,6,11]. In any case, it is important for the structural engineer to interact with the general contractor, in order that the influence of the method of construction on the girders as well as the frame can be quantified, however simplistic the analysis procedure may be.

Due to the larger loads that can be expected for the shores, the latter must either be designed as structural members or at least be evaluated by the structural engineer. The size of the shores is also influenced by the number of floors that are to have these supports left in place. As a general rule, when stub girders are used for multistory frames, the shores should be left in place for at least three floor levels. Some designers prefer a larger number; however, any choices of this kind should be based on computations for sizes and effects. Naturally, the more floors that are specified, the larger the shores will have to be.

34.1 Introduction

Fatigue and fracture are two important limit states that need to be checked in the design and evaluation of structures. Fatigue is the formation of a crack due to cyclic loading. The fatigue limit state is defined as the development of a through-thickness crack. This is a serviceability limit state and does not necessarily mean that the structure is in danger of fracture or collapse. Fracture is the rupture in tension or rapid extension of a crack leading to gross deformation, loss of function or serviceability, or complete separation of the component.

This section of the handbook presents an overview of information useful to structural engineers in evaluating the fatigue and fracture limit states of steel, aluminum, and concrete structural components. Topics include materials selection, design, and detailing for new structures, as well as assessment of existing structures. The emphasis of this chapter is on structural steel components, since aluminum and other metal components are not common in the primary load-carrying systems of most civil structures. Fatigue of concrete components is covered only briefly since it is rarely a significant problem. As a practical matter, fracture of concrete is checked by usual strength design calculations and therefore is not covered here. The fracture mechanics of concrete is covered elsewhere [1].

Although most of the examples involve buildings or bridges, the information is equally applicable to similar details in cranes, ships, offshore structures, heavy vehicle frames, etc. The primary difference between various structure types is in the applied loading, whereas the type of structure does not affect the resistance of the details to fatigue or fracture.

Since the scope of this section is limited to practical information, there are many interesting aspects of fatigue and fracture that are not discussed. There are several good texts that can serve as a starting point for more in-depth studies [2–4].

34.2 Fatigue

Fatigue resistance for a particular detail is the allowable constant-amplitude stress range (S) for a specified number of cycles of loading (N), typically expressed in an S – N curve. S – N curves are based on fatigue tests of full-scale members with welded or bolted details. The assignment of various details to specific categories for S – N curve analysis is discussed below, including bolts, anchor rods, hollow structural sections, concrete members, and cables.

When information about a specific crack is available, a fracture mechanics crack growth rate analysis should be used to calculate the remaining life [3,4]. However, in the design stage, without specific initial crack size data, the fracture mechanics approach is not any more accurate than the S – N curve approach [5]. Therefore, the fracture mechanics crack growth analysis will not be discussed further.

34.2.1 Fatigue Resistance

The approach to designing and assessing structures for fatigue is empirical and is based on tests of full-scale members with welded or bolted details. Such tests indicate that

- The strength and type of steel have only a negligible effect on the fatigue resistance expected for a particular detail [6–10].
- The welding process also does not typically have an effect on the fatigue resistance [11,12].
- The primary effect of constant-amplitude fatigue loading can be accounted for in the live-load stress range [6–9], that is, the mean stress is not significant.

The independence of fatigue resistance from the type of steel greatly simplifies the development of design rules for fatigue since it eliminates the need to generate fatigue data for every type of structural steel. Testing that has been performed on welded details in stainless steel show that the fatigue strength of stainless steel details is comparable to that of ferritic structural steel details [13].

The reason that the dead load has little effect is that, locally, there are very high residual stresses. In details that are not welded, such as anchor rods, there is a mean stress effect [14]. A worst-case conservative assumption, that is, a high tensile mean stress, is made in the testing and in the design of these nonwelded details.

34.2.1.1 Standard S – N Curves

The nominal stress approach is the established approach for fatigue design and assessment of steel and aluminum structures. The nominal stress approach is based on S – N curves, where S is the nominal stress range and N is the number of cycles until the appearance of a visible crack. Details are designed based on the nominal stress range in the connecting members rather than the local “concentrated” stress at the detail. The nominal stress is usually obtained from standard design equations for bending and axial stress and does not include the effect of stress concentrations of welds and attachments. Usually, the nominal stress in the members can be easily calculated without excessive error. However, the proper definition of the nominal stresses may become a problem in regions of high stress gradients.

Figure 34.1 shows the S – N curves for steel that are used throughout North America for a variety of welded structures, including the American Association of State Highway and Transportation Officials (AASHTO) bridge design specifications [15], the American Institute for Steel Construction (AISC) *Manual of Steel Construction* [16], the American Railway Engineering and Maintenance-of-Way Association (AREMA) *Manual for Railway Engineering* [17], the American Welding Society (AWS D1.1) *Structural Welding Code* [18], and the Canadian Standards Association (CSA S16–2001) *Limit States Design of Steel Structures* [19].

AASHTO has seven S – N curves for seven categories (A through E') of weld details. The fatigue design procedure is based on associating the weld detail under consideration with a specific category. The effects of the welds and other stress concentrations, including the typical defects and residual stresses, are reflected in the ordinate of the S – N curves for the various detail categories.

FIGURE 34.1 *S*–*N* curves for the seven primary fatigue categories from the AASHTO, AREMA, AWS, and AISC specifications; the dotted lines are the constant-amplitude fatigue limits (CAFLs) and indicate the detail category.

TABLE 34.1 Parameters for *S*–*N* Curves

AASHTO, AISC, and AWS category	Coefficient A for steel (MPa ³)	CAFL ^a for steel (MPa)	Equivalent Eurocode 3 category	Nearest BS 7608 category	Coefficient A for aluminum (MPa ³)	Exponent for aluminum	CAFL for aluminum (MPa)
A	$.81.9 \times 10^{11}$	165	160	B	2.18×10^{19}	6.85	70

E'	$.1.28 \times 10^{11}$	18	40	W	N/A	N/A	N/A

^a CAFL, constant-amplitude fatigue limit.

The inverse slope of the regression line fit to the test data for welded details is typically in the range 2.9 to 3.1 [8]. In the AISC, AASHTO, AREMA, and CSA codes as well as in Eurocode 3 (EU3) [20], the slopes have been standardized at 3.0. Therefore, the *S*–*N* curves can be represented by the following power–law relationship:

$$N = \frac{A}{S^3} \tag{34.1}$$

where *N* is the number of stress cycles, *S* is the nominal stress range, and *A* is a constant particular to the detail category, as given in Table 34.1.

AISC and AWS also have a Category F with a slope greater than 3 for checking the shear stress in the throat of welds. AASHTO and CSA S16 require checking the shear stress in the throat of welds according to Category E rather than Category F. However, the minimum weld size requirements and the weld strength requirements generally will ensure sufficient weld throat to avoid fatigue. There are few, if any, documented fatigue cracking cases associated with shear stress through the throat of fillet welds, therefore it is unnecessary to check the shear stress range in the throat of welds for fatigue and this will not be discussed further.

Eurocode 3 (EC3)' [20] and the British Standard 7608 [21] also use a nominal stress approach, but they each have unique sets of *S*–*N* curves with different category labels. However, the end result of

checking the stress range will be approximately the same regardless of which of these sets of $S-N$ curves is used, since all of these design specifications are empirical and are calibrated with the same database of full-scale test results. None of these sets of $S-N$ curves has any inherent advantages or will estimate the fatigue life of a detail more accurately than any other set of $S-N$ curves. Seven of the fourteen Eurocode curves are the same as the seven AASHTO curves, as indicated in Table 34.1. The American Bureau of Shipping (ABS) guidelines [22], the U.K. Health and Safety Executive [23], and other groups in the marine industry use $S-N$ curves from the British Standards (BS 7608) [21]. The BS 7608 $S-N$ curves can be associated approximately with the AASHTO $S-N$ curves so that knowledge of the fatigue strength of details in this specification can be translated to an equivalent AASHTO category. Table 34.1 cross-references the BS 7608 $S-N$ curves with the nearest AASHTO $S-N$ curves.

In the nominal stress range approach, each detail category has a constant-amplitude fatigue limit (CAFL), which is also given in Table 34.1. The CAFL is a stress range below which no fatigue cracks occurred in tests conducted with constant-amplitude loading. These limits are shown as the horizontal lines on the right side of the $S-N$ curves in Figure 34.1. The Eurocode and BS $S-N$ curves define the fatigue limits differently.

34.2.1.2 The Effect of Corrosion of Fatigue Resistance

The full-scale fatigue experiments on which the fatigue rules are based were carried out in moist air and therefore reflect some degree of environmental effect or corrosion fatigue. Therefore, the lower-bound $S-N$ curves in Figure 34.1 can be used for the design of details with a mildly corrosive environment (such as the environment for bridges, even if salt or other corrosive chemicals are used for deicing) or provided with suitable corrosion protection (galvanizing, other coating, or cathodic protection). Some design codes for offshore structures have reduced fatigue life (by approximately a factor of 2) when details are exposed to seawater [21,23].

At relatively high stress ranges at which most accelerated tests are conducted, the effect of seawater is clearly detrimental. However, there is evidence that the effect of corrosion in seawater is not so severe for long-life variable-amplitude fatigue of welded details. Full-scale fatigue experiments in seawater at realistic service stress ranges do not show significantly lower fatigue lives [24], provided that corrosion is not so severe that it causes pitting or significant section loss. At relatively low stress ranges near the CAFL, typical of service loading, it appears that build-up of corrosion product in the crack may increase crack closure and retard crack growth, at least enough to offset the increase that would otherwise occur due to the environmental effect. The fatigue lives seem to be more significantly affected by the stress concentration at the toe of welds than by the corrosive environment.

Severely corroded members may be evaluated as Category E details [25], regardless of their original category (unless of course they were Category E' or worse to start with). However, pitting or significant section loss from severe corrosion can lower that fatigue strength [25,26].

34.2.1.3 $S-N$ Curves for Aluminum

$S-N$ curves have been proposed by the Aluminum Association for welded aluminum structures [27,28]. The categories for details are similar to those for steel, although the fatigue strength of a detail is approximately 38% of the fatigue strength of the same detail in steel. For aluminum, the exponent in Equation 34.1 is variable and is given in Table 34.1 with the coefficient A and CAFL. The design procedures are similar and the classification of details into categories is approximately the same.

34.2.2 Fatigue Loading

Since fatigue is typically only a serviceability problem, members and connections are designed for fatigue using service loads. Most structures experience what is known as long-life variable-amplitude loading, that is, very large numbers of random-amplitude cycles greater than the number of cycles associated with the CAFL [29]. For example, a structure loaded continuously at an average rate of once per minute (0.016 Hz), would accumulate 10 million cycles in 19 years. With long-life variable-amplitude loading,

structures are usually designed so that only a small fraction of cycles, on the order of 0.01%, exceed the CAFL [29,30].

If the percentage of stress ranges exceeding the CAFL is greater than 0.01%, the history of N variable stress ranges can be converted to N cycles of an effective stress range that can then be used just like the constant-amplitude stress range in S - N curve analysis. Typically, Miner's Rule [31] is used to calculate an effective stress range from a histogram of variable stress ranges. Theoretically, this effective constant-amplitude stress range results in approximately the same fatigue damage for a given number of cycles as that for the same number of cycles of the variable-amplitude service history. If the stress ranges are counted in discrete "bins," as in a histogram, the effective stress range, S_{Re} [29] can be calculated as

$$S_{Re} = \left(\sum_i (\alpha_i S_{ri}^3) \right)^{1/3} \quad (34.2)$$

where α_i is the number of stress cycles with stress range in the bin with average value S_{ri} divided by the total number of stress cycles (N).

Variable-amplitude fatigue tests conducted with various sequences in the variable-amplitude loading history have shown that Miner's Rule is reasonably accurate in most cases but can be unconservative with some load histories with unusual sequences. For this reason, some fatigue design specifications for offshore structures put a safety factor of 2.0 on life if Miner's Rule is used [23].

In the AASHTO specifications [15], the stress range from the fatigue design truck represents the effective stress range. No additional safety factor is used for Miner's Rule since it is relatively accurate for truck loading on bridges. For large numbers of cycles, the AASHTO specification has another check that involves comparing the stress range from the fatigue design truck to half of the CAFL. The rationale for this check is that if the effective stress range is less than half the CAFL, most of the stress ranges should be below the CAFL, but occasionally (about once a day) the stress range can exceed the CAFL with no significant effect.

Misalignment at a welded joint is a primary factor in susceptibility to cracking. The misalignment causes eccentric loading, local bending, and stress concentration. The stress concentration factor (SCF) associated with misalignment is

$$SCF = 1.0 + 6e/t \quad (34.3)$$

where e is the eccentricity and t is the smaller of the thicknesses of two opposing loaded members. The nominal stress times the SCF should then be compared to the appropriate category. Generally, such misalignment should be avoided at fatigue critical locations. Equation 34.3 can also be used where e is the distance that the weld is displaced out of plane due to angular distortion. A thorough guide to the SCF for various types of misalignment and distortion, including plates of unequal thickness, can be found in British Standard BS 7910 [32].

34.2.3 Categorization of Details

The following is a brief simplified overview of the categorization of fatigue details. In all cases, the applicable specifications should also be checked. Several reports have been published that show a large number of illustrations of details and their categories in addition to those in AISC and AASHTO specifications [33,34]. Also, the EC3 [20] and the British Standard BS 7608 [21] have more detailed illustrations for their categorization than AISC or AASHTO specifications. A book by Maddox [9] discusses categorization of many details in accordance with BS 7608, from which roughly equivalent AASHTO categories can be inferred (using Table 34.1). In most cases, the fatigue strength recommended in these European standards is similar to the fatigue strength in the AISC and AASHTO specifications. However, there are several cases where the fatigue strength is significantly different; usually, the European specifications are more conservative.

There have been very few, if any, failures that have been attributed to details with fatigue strength greater than Category C. Most structures have many Category C or even more severe details, and these

will generally govern the fatigue design. Therefore, only Category C and more severe details will be discussed in depth.

34.2.3.1 Welded Joints

Welded joints are considered transverse if the axis of the weld is perpendicular to the primary stress range. Unless there is a stress concentration from the configuration of the detail, transverse welds are typically Category C details. For example, the transverse welds connecting stiffeners to the web and flange of girders are Category C details.

Full-penetration groove welded butt joints subjected to nondestructive evaluation (NDE) such as ultrasonic testing or radiographic testing are also Category C details. If the reinforcement of these full-penetration butt joints is ground smooth, they are Category B details. Tests show that groove welds that contain large internal discontinuities that were not screened out by NDE had fatigue strength comparable to Category E [5]. BS 7608 [21] and BS 7910 [32] have reduced fatigue strength curves for groove welds with defects that are generally in agreement with these experimental data. Transverse groove welds with a permanent backing bar are reduced to Category D [35,36]. One-sided welds with melt through (without backing bars) are also classified as Category D [35,36].

Continuous longitudinal welds are Category B or B' details. However, the termination of a longitudinal fillet weld is more severe (Category E). The termination of full-penetration groove longitudinal welds requires a ground transition radius but gives greater fatigue strength, depending on the radius. If longitudinal welds must be terminated, it is better to extend the welds to a location along the structural member where the stress ranges are small or entirely in compression.

Cope holes, cutouts, and snipes should be used for weld access and to avoid intersecting welds. If the thermally cut surfaces have edges conforming to the ANSI smoothness of 1000, these may be considered Category D details, even if welds terminate at these details [35,36]. A rougher cope hole may be treated as a Category E detail. If the steel at the thermally cut edge transforms to martensite, in some cases small cracks may occur that will propagate at even lower stress ranges.

Attachments normal to flanges or plates that do not carry significant load are rated Category C if less than 51 mm long in the direction of the primary stress range, D if between 51 and 101 mm long, and E if greater than 101 mm long. If there is not at least a 10-mm edge distance, then Category E applies for an attachment of any length. Category E', slightly worse than Category E, applies if the attachment plates or the flanges exceed 25 mm in thickness.

The cruciform joint where the load-carrying member is discontinuous is considered a Category C detail because it is assumed that the plate transverse to the load-carrying member does not have any stress range. A special reduction factor for the fatigue strength is provided when the load-carrying plate exceeds 13 mm in thickness. This factor accounts for the possible crack initiation from the unfused area at the root of the fillet welds (as opposed to the typical crack initiation at the weld toe for thinner plates) [37].

In most other types of load-carrying attachments, there is interaction between the stress range in the transverse load-carrying attachment and the stress range in the main member. In practice, each of these stress ranges is checked separately. The attachment is evaluated with respect to the stress range in the main member, and then it is separately evaluated with respect to the transverse stress range. The combined multiaxial effect of the two stress ranges is taken into account by a relative decrease in the fatigue strength, that is, most load-carrying attachments are considered Category E details.

34.2.3.2 Bolted Joints and Anchor Rods

Small holes are considered Category D details. Therefore, rivetted and mechanically fastened joints (other than high-strength bolted joints) loaded in shear are evaluated as Category D in terms of the net-section nominal stress. High-strength A325 and A490 bolted joints that are properly pretensioned and loaded in shear are Category B details in terms of the net-section nominal stress. Pin plates and eyebars are designed as Category E details in terms of the net-section nominal stress.

Bolted joints loaded in direct tension are more complicated. Typically, these provisions are applied to hanger-type or bolted flange connections where the bolts are pretensioned against the plies. In this case, the total fluctuating load is resisted by the area of the precompressed plies, so that the bolts are subjected to only a fraction of the total load [38]. However, the analysis to determine this fraction is difficult. In the AISC Specifications [16] and in BS7608 [21], the designer may assume the load range in the bolts is 20% of the total applied service load (dead plus live load). The total applied service load must include any prying load. Prying is very detrimental to fatigue, so it is best to minimize prying forces by using sufficiently thick plates [16].

In the AISC Specifications [16], the stress range in the bolts is calculated on the tensile stress area, A_t , given by

$$A_t = \frac{\pi}{4} \left(d_b - \frac{0.9743}{n} \right)^2 \tag{34.4}$$

where d_b is the nominal diameter (the body or shank diameter) and n is threads per inch. (Note that the constant would be different if metric threads are used.)

Test data on bolts in direct tension (with the stress range computed on the tensile stress area) are shown in Figure 34.2 [39,40]. The M20 bolts and B7 rods are similar in strength to A325 high-strength bolts (862-MPa tensile strength). Different size diameters of the B7 bolts were also tested, with the results showing that size did not have an impact on the fatigue limit. Category E seems to be the lower bound for bolts in direct tension.

Anchor rods in concrete cannot be adequately pretensioned and therefore do not behave like hanger-type or bolted flange connections. In the double-nut configuration, they are pretensioned between nuts on either side of the base plate, but the part below the bottom nut is still exposed to the full load range. Fatigue test data are available for anchor rods [14,41,42]. The data for anchor rods with a double-nut configuration tightened one third of a turn past snug tight are shown in Figure 34.3. These data agree well with the bolt data shown in Figure 34.2, that is, the lower-bound fatigue strength is Category E.

These test data were obtained at low enough stress ranges to allow for definition of the CAFL. There was one failure at 69 MPa but below this stress range there were all runouts. Therefore, the CAFL is much greater than the CAFL for other Category E details, which is 31 MPa. Choosing from among the CAFLs for the other categories, the CAFL was taken as that for Category D or 48 MPa.

FIGURE 34.2 S-N curves for B7 and M20 snug-tight bolts in tension.

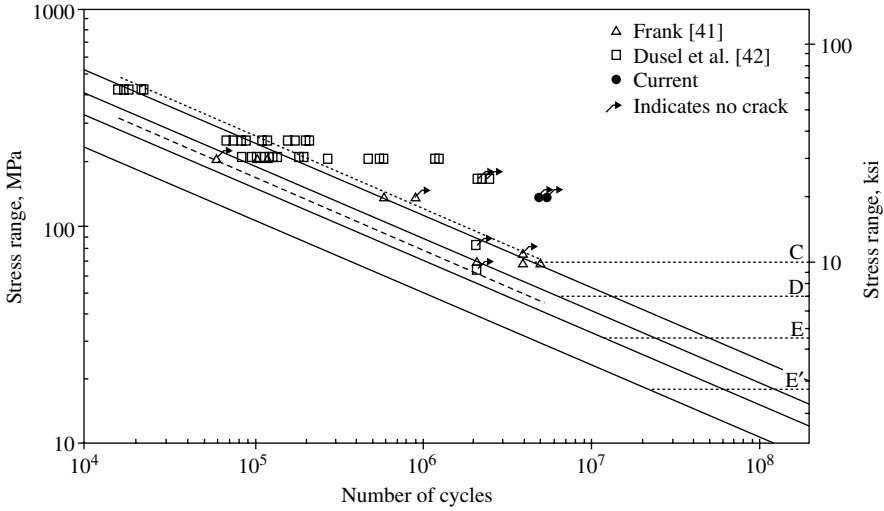

FIGURE 34.3 S–N curves for double-nut anchor rods tightened one third of a turn past snug tight.

FIGURE 34.4 S–N curves for snug-tight anchor rods.

Figure 34.4 shows fatigue test data for anchor rods that were only snug tight. Specimens with a 1:40 misalignment are also included. Under these conditions, the lower-bound fatigue strength corresponds to Category E'. Since no failures occurred below a stress range of 62 MPa in this case, the CAFL at 48 MPa applies regardless of tightening or alignment.

Based on these data, in the AISC Specifications [16] the fatigue resistance of bolts or anchor rods in direct tension, on the tensile stress area, is taken as Category E' in the finite-life range with a CAFL of 48 MPa.

34.2.3.3 Hollow Structural Sections

There have been numerous publications regarding the fatigue strength of rectangular and circular hollow structural sections (HSS), as summarized in Van Wingerde et al. [43]. The majority of recent work has taken place in Europe under the advisement of the European Coal and Steel Community (ECCS), the British Department of Energy (DEn), now called the Health and Safety Executive, and the Comité

International pour le Développement et l'Étude de la Construction Tubulaire (CIDECT) [44]. The research has resulted in design recommendations that have been adopted by the International Institute of Welding (IIW Document XIII-1804-99 and XV-1035-99) [45] and CIDECT *Design Guide* #8 [46] and have been proposed for inclusion into AWS D1.1 [18] and EC3 [20]. The CIDECT fatigue design guidelines include both the nominal-stress approach and the hot-spot stress approach. AWS D1.1 [18] also has nominal-stress and hot-spot stress $S-N$ curves for HSS, although these are not considered as accurate as the CIDECT guidelines. Unlike AWS, the CIDECT guidelines distinguish between circular hollow sections (CHS) and rectangular hollow sections (RHS).

Many sign, signal, and light supports are fabricated from HSS. AASHTO has published a new specification for these types of structures [47] that includes fatigue design using the nominal-stress approach and classification of the common details with respect to the AWS $S-N$ curves, based on research in NCHRP Report 412 [14]. In addition, this specification has fatigue design loads for natural wind gusts, galloping, and vortex shedding. Many aspects of this specification could also be applied to wind turbines, communication towers, and other flexible structures exposed to wind.

The hot-spot stress approach is similar to the nominal-stress approach and is also based on full-scale tests, except that the $S-N$ curves in this approach are based on the hot-spot stress range [48]. The hot-spot stress is the stress normal to the weld axis, originally defined at some small distance (about 6 mm) from the weld toe. The hot-spot stress can be measured, calculated using finite-element analysis, or determined from parametric formulas derived from the finite-element analyses and measurements.

A distinction is made between the geometric stress concentration, that is, that associated with the arrangement of the members, and the local stress concentration, that is, that associated with the weld toe. In the hot-spot approach, the effect of the geometric stress concentration, expressed as the SCF, is taken out of the fatigue resistance and instead is included in the analysis. This has the advantage of collapsing all the $S-N$ curves for different categories into a single baseline $S-N$ curve, but it has the disadvantage of increasing the complexity of the analysis. A simple structural analysis is usually performed to obtain the axial and bending forces entering a joint, from which nominal stresses are calculated. The hot-spot stress at a weld is determined by multiplying the appropriate nominal stress by the SCF. The test data and the baseline $S-N$ curve still include the effect of the local stress concentration, which is impossible to calculate accurately and therefore must still be treated empirically.

A simple approach that works well is to define the hot-spot stress as the stress measured with a 3-mm strain gage placed as close as practically possible to the weld toe, that is, centered about 6 mm from the weld toe [49]. This is essentially the definition originally used by AWS [48]. The baseline $S-N$ curve used with the hot-spot stress defined this way is essentially the same as the nominal-stress $S-N$ curve (Category C) for a transverse butt or fillet weld in a nominal membrane stress field, that is, a stress field without any geometric stress concentration [49]. This makes sense since the stress at the weld toe of this detail would include the local stress concentration but would not be affected by geometric stress concentration. In other words, the SCF is equal to 1.0, and the hot-spot stress is equal to the nominal stress in this detail.

The CIDECT research updated parametric equations used for SCF calculations and unified the definition of hot-spot stress. The definition of hot-spot stress is more complex than the simple AWS definition and involves extrapolating the stress from multiple strain gage measurements or analysis points [46]. However, the CIDECT design guidelines contain parametric equations that can be used to calculate SCF based on nondimensional parameters (brace to chord diameter ratio, brace diameter to thickness ratio, brace to chord thickness ratio, and chord length to diameter ratio) for different types of loading. A minimum SCF of 2.0 is recommended.

Obviously, the SCF and the baseline curve are dependent on the definition of the hot-spot stress [50]. The CIDECT baseline hot-spot $S-N$ curve is the T' curve from BS 7608 (equivalent to the Eurocode class 114 curve) for use with 16-mm-thick sections (see Figure 34.5). This is about 25% higher than the baseline $S-N$ curve used with the AWS-defined hot-spot stress (6 mm from the weld toe). In hollow structural joints, there is a pronounced thickness effect, with thinner sections having higher fatigue lives. CIDECT included the thickness effect in the definition of the hot-spot $S-N$ curves, as shown in Figure 34.5.

FIGURE 34.5 Hot-spot $S-N$ curves for CHS joints ($4\text{ mm} \leq t \leq 50\text{ mm}$) and RHS joints ($4\text{ mm} \leq t \leq 16\text{ mm}$).

34.2.3.4 Reinforced and Prestressed Concrete, Strands, and Cables

Because of the relatively low stresses, concrete structures are typically less sensitive to fatigue than welded steel and aluminum structures. However, fatigue may govern the design when impact loading is involved, such as pavement, bridge decks, and rail ties. Also, in high-strength concrete the applied stress ranges increase, and so should the concern for fatigue.

According to ACI Committee Report 215R-74 in the *Manual of Standard Practice* [51], the fatigue strength of plain concrete at 10 million cycles is approximately 55% of the ultimate strength. However, even if failure does not occur, repeated loading may contribute to premature cracking of the concrete, such as inclined cracking in prestressed beams. This cracking could then lead to localized corrosion and fatigue of the reinforcement [52].

The fatigue strength of straight, unwelded reinforcing bars and prestressing strand can be described (in terms of the categories for steel details described earlier) with the Category B $S-N$ curve. The lowest stress range that has been known to cause a fatigue crack in a straight reinforcing bar was 145 MPa, which occurred after more than a million cycles. Mean stress level, yield strength, bar size, geometry, and deformations had minimal effect. ACI Committee 215 suggests that members be designed to limit the stress range in the reinforcing bar to 138 MPa for high levels of mean stress (increases up to 160 MPa as mean stress is reduced).

Fatigue tests show that previously bent bars had only about half the fatigue strength of straight bars and failures have occurred down to 113 MPa [53]. Committee 215 recommends that half of the stress range for straight bars be used, that is, 69 MPa for the worst-case mean stress. Equating this recommendation to the $S-N$ curves for steel details, bent reinforcement may be treated as a Category D detail.

Provided the quality is good, butt welds in straight reinforcing bars do not significantly lower the fatigue strength. However, tack welds reduce the fatigue strength of straight bars about 33%, with failures occurring as low as 138 MPa. Fatigue failures have been reported in welded wire fabric and bar mats [54].

Batchelor et al. [55] tested deck panels with a single stationary concentrated load applied at the center. The contact area represented the assumed contact area of the pneumatic tires of large trucks. The only fatigue tests that did not result in failure at the end of 2.5 and 3 million cycles were performed with a loading of less than the 50% of the estimated ultimate punching strength of the deck (P_u). Other research also supports a fatigue limit of $0.5P_u$ at 2 to 3 million cycles for a stationary pulsating load [56,57].

However, the behavior and the fatigue limit are different in the case of rolling loads, as on a bridge. Flexural cracking along the reflection of the longitudinal and transverse reinforcement on the bottom surface was detected in bridges in service, and this is different from cracking patterns in tests with stationary pulsating loads [58]. Tests with moving or rolling loads indicate that the fatigue limit was as low as $0.21P_u$ at 2 to 3 million cycles, comparable to the average flexural cracking load level of about $0.26P_u$ [58–60]. In some of the tests [56,58,59] it was demonstrated that the transverse cracks from the constructional period and the water penetration during service life decreased the ultimate punching shear and fatigue strengths of the reinforced concrete deck. However, these studies have not established any quantitative interaction between the deterioration from the environmental factors and the repetitive axle load.

Test data show that measured stress ranges in the reinforcement at the location of cracks in a highly deteriorated deck under high axle loads are less than 35 MPa, well below the 138-MPa threshold discussed earlier [61]. Therefore, under service load, fatigue does not appear to be a problem for deck reinforcement. This is consistent with the fact that fatigue of reinforced concrete decks is governed by punching failure of the concrete part of the structure.

If prestressed members are designed with sufficient precompression so that the section remains uncracked, there is not likely to be any problem with fatigue. This is because the entire section is resisting the load ranges, and the stress range in the prestressing strand is minimal. Similarly, for unbonded prestressed members, the stress ranges will be very small. However, there is reason to be concerned about bonded prestressing at cracked sections because the stress range increases locally. The concern for cracked sections is even greater if corrosion is involved. The pitting from corrosive attack can dramatically lower the fatigue strength of the reinforcement [52].

Although the fatigue strength of the prestressing strand in air is about equal to Category B, when the anchorages are tested as well, the fatigue strength of the system is as low as half the fatigue strength of the wire alone (i.e., about Category E). When actual beams are tested, the situation is very complex, but it is clear that much lower fatigue strength can be obtained [62,63]. Committee 215 has recommended the following for prestressed beams:

1. The stress range in prestressed reinforcement, determined from an analysis considering the section to be cracked, shall not exceed 6% of the tensile strength of the reinforcement. (Author's note: this is approximately equivalent to Category C.)
2. Without specific experimental data, the fatigue strength of unbonded reinforcement and its anchorages shall be taken as half of the fatigue strength of the prestressing steel. (Author's note: this is approximately equivalent to Category E.) Lesser values shall be used at anchorages with multiple elements.

The Post-Tensioning Institute (PTI) has issued *Recommendations for Stay Cable Design, Testing, and Installation* [64]. The PTI recommends that uncoupled bar stay cables are Category B details, while coupled (glued) bar stay cables are Category D. The fatigue strengths of stay cables are verified through fatigue testing. Two types of tests are performed: (1) fatigue testing of the strand and (2) testing of relatively short lengths of the assembled cable with anchorages. The recommended test of the system is 2 million cycles at a stress range (158 MPa) that is 35 MPa greater than the fatigue allowable for Category B at 2 million cycles. This test should pass with less than 2% wire breaks. A subsequent proof test must achieve 95% of the guaranteed ultimate tensile strength of the tendons.

34.2.4 Low-Cycle Fatigue and Seismic Frame Details

Steel braced frames and moment-resisting frames are expected to withstand cyclic plastic deformation without cracking in a large earthquake. If brittle fracture of these moment frame connections is suppressed by good detailing and minimum notch toughness levels, as discussed in the next section, the connections can be cyclically deformed into the plastic range and will eventually fail by tearing at a location of strain concentration [65]. This limit state is referred to as low-cycle fatigue. Some examples of low-cycle fatigue cracks are shown in [Figure 34.6](#), [Figure 34.7](#), [Figure 34.8](#), and [Figure 34.9](#) from full-scale beam-to-column

FIGURE 34.6 Low-cycle fatigue crack developing at the toe of the beam flange weld in a moment-frame connection after (a) 11 cycles and (b) 17 cycles of 4% drift.

FIGURE 34.7 Cross-section of beam flange weld showing low-cycle fatigue crack developing at the weld toe.

connection tests of the welded-unreinforced flange, welded web (WUF-W) connection, which is one of the FEMA 350 prequalified connections for special moment frames in high seismic regions [66]. Figure 34.6 and Figure 34.7 show low-cycle fatigue cracks forming at the beam flange weld. Figure 34.8 shows a low-cycle fatigue crack forming at the weld of the beam web to the column flange, and Figure 34.9 shows a low-cycle fatigue crack forming at the weld access hole. The detailing in these connections is well balanced since the low-cycle fatigue failure at all of these details occurred between 12 and 16 cycles of the maximum required drift angle in each case.

Most past research on low-cycle fatigue has involved pressure vessels and some other types of mechanical engineering structures. Since low-cycle fatigue is an inelastic phenomenon, the strain range is the key parameter rather than the stress range. The Coffin–Manson rule [67] has been used to relate the strain range in smooth tensile specimens to life. Manson suggested a conservative lower-bound simplification, called Manson’s universal slopes equation [68]:

$$\Delta\varepsilon = 3.5 \frac{\sigma_u}{E} N^{-0.12} + \varepsilon_f^{0.6} N^{-0.6} \tag{34.5}$$

where $\Delta\varepsilon$ is the total strain range, σ_u is the tensile strength, and ε_f is the elongation at fracture.

FIGURE 34.8 Low-cycle fatigue crack developing at the end of the beam web to column flange weld in a moment-frame connection.

FIGURE 34.9 Low-cycle fatigue crack developing at the weld access hole in a moment-frame connection.

Note that the first term in Equation 34.5 is the elastic part of the total strain range (which is relatively insignificant when there are fewer than 100 cycles), and the second term is the plastic part of the total strain range. Figure 34.10 shows a plot of Manson’s universal slopes equation where σ_u is 450 MPa and ϵ_f is 25%, typical minimum properties for Grade 50 structural steel. Many studies have shown that Manson’s universal slopes equation is conservative compared to experimental data from smooth specimens [68,69]. However, because of buckling at greater strain ranges, most of the experimental data are for strain ranges less than 1%, that is, for cycles greater than 1000. Limited data exist at higher strain ranges — some are shown in Figure 34.10 for A36 steel smooth specimens machined from the flanges of wide-flange sections [69].

At present, very little is understood about low-cycle fatigue in welded or bolted structural details. For example, it is a very difficult task just to predict accurately the local strain range at a location of cyclic local flange buckling. However, Krawinkler and Zohrei [70] and Ballio and Castiglioni [71,72] showed that the number of cycles to failure by low-cycle fatigue of welded connections could be predicted by the local strain range in a power law that is analogous to an $S-N$ curve. Ballio and Castiglioni [71,72] showed that the power law would have an exponent of 3, just like the elastic $S-N$ curves. Krawinkler and Zohrei [70] also showed that Miner's rule could be used to predict the number of variable-amplitude cycles to failure based on constant-amplitude test data.

Therefore, it may be possible to predict and design against low-cycle fatigue using strain-range versus number-of-cycles curves that are extrapolated from the high-cycle fatigue design $S-N$ curves. Figure 34.10 shows the AASHTO/AISC $S-N$ curves for Categories A and C, converted from stress range to strain range by dividing the stress ranges by the elastic modulus and extrapolated up to one cycle.

There are only limited data to support this approach. Figure 34.10 shows some data from the same full-scale WUF-W beam-to-column connection tests for which the low-cycle fatigue cracks were shown in Figure 34.6, Figure 34.7, Figure 34.8, and Figure 34.9. These tests are subjected to a standard series of cycles of increasing ranges of total drift as shown in Figure 34.11. They are cycled at 4% drift until they

FIGURE 34.10 Comparison of standard $S-N$ curves presented in terms of strain range and Manson's universal slopes equation for Grade 50 (350-MPa yield strength) steel to low-cycle fatigue test data.

FIGURE 34.11 Standard drift-cycle history for testing moment-frame subassemblies.

fail by low-cycle fatigue. The measured flange strain ranges in these tests varied from 3.7 to 4.8% during the 4% drift cycles. The number of cycles plotted in Figure 34.10 is the equivalent number of cycles at 4% drift, which is the actual number of cycles at 4% plus one additional cycle which, according to Miner’s rule, is equivalent in damage to all of the cycles at 3% and less. Since maximum flange strains were used rather than nominal values, this is analogous to a hot-spot approach for high-cycle fatigue. As discussed previously in Section 34.2.3.3, the Category C *S-N* curve is a suitable baseline *S-N* curve for the hot-spot approach. It appears that the Category C *S-N* curve is also a good lower bound to these low-cycle fatigue data. The scatter in the data is substantial, as is also true in high-cycle fatigue.

Also shown in Figure 34.10 are data for smaller coupon-type specimens with transverse butt welds, which would be expected to be Category C details. These are some of the only available data with fewer than 5000 cycles. These coupon data are also in reasonable agreement with the extrapolated Category C curve as a lower bound.

34.3 Fracture

34.3.1 Fracture Resistance

Unlike fatigue, fracture behavior depends strongly on the type and strength level of the steel or filler metal. In fact, the fracture resistance of each type of steel or weld metal varies significantly from heat to heat, or from lot to lot. In fact, in rolled shapes, the fracture resistance may vary significantly within the cross-section. Therefore, design or assessment for fracture resistance will usually involve a measurement of the material’s fracture resistance, or fracture toughness. Although fracture toughness can be measured directly in fracture mechanics tests, the usual practice is to characterize the toughness of steel in terms of the impact energy absorbed by a Charpy V-notch (CVN) specimen. Because the Charpy test is relatively easy to perform, it will likely continue to be the measure of toughness used in steel specifications.

Since it is not directly related to the fracture toughness, CVN energy is often referred to as notch toughness. The notch toughness is still very useful, however, since it can often be correlated to the fracture toughness and then used in a fracture mechanics assessment [3,32,73,74]. Figure 34.12 shows a plot of the CVN energy of A588 Grade 50 (350-MPa yield strength) structural steel at varying temperature. These results are typical for ordinary hot-rolled structural steel.

The fracture limit state includes phenomena ranging from brittle fracture of low-toughness materials at service load levels to ductile tensile rupture of a component. The transition between these phenomena

FIGURE 34.12 Charpy transition curve for A588 Grade 50 (350-MPa yield strength) structural steel.

depends on temperature, as reflected by the variation of CVN with temperature as shown in [Figure 34.12](#). The transition is a result of changes in the underlying microstructural fracture mode.

Brittle fracture on the so-called lower shelf in [Figure 34.12](#) is associated with cleavage of individual grains on select crystallographic planes. Brittle fracture may be analyzed with linear-elastic fracture mechanics theory because the plastic zone at the crack tip is very small.

At the high end of the temperature range, the so-called upper shelf, ductile fracture is associated with the initiation, growth, and coalescence of microstructural voids, a process requiring much energy. The net section of plates or shapes fully yields and then ruptures with large slanted shear lips on the fracture surface.

Transition-range fracture occurs at temperatures between the lower and upper shelves and is associated with a mixture of cleavage and shear fracture. Large variability in toughness at constant temperature and large changes with temperature are typical of transition-range fractures.

Brittle fracture can be thought of as an interruption of what would otherwise be ductile plastic deformation in tension, much like buckling can interrupt ductile plastic deformation in compression. For the purposes of structural engineering, it is usually only necessary to make sure that brittle fracture does not occur, so that is the emphasis in this chapter. As long as the behavior is in the transition range or upper shelf, the resulting ductility is generally sufficient. For example, as discussed in the previous section, moment-frame connections will tolerate a certain minimum number of cycles of large rotations governed by the low-cycle fatigue limit state, as long as specific details are used and minimum CVN requirements are assured. If low-toughness weld metal that does not meet minimum requirements is used, brittle fracture may occur before the expected number of cycles [65].

34.3.2 Material Specification and Detailing to Avoid Fracture

Details that have good fatigue resistance, Category C and better, are usually also optimized for resistance to fracture. Detailing rules to avoid fracture are very similar to the common-sense rules to avoid fatigue. For example, intersecting welds should always be avoided due to the probability of defects and excessive constraint. Intersecting welds, or even welds of too close proximity, have caused brittle fractures. For example, in December 2000, fractures occurred in large plate girders of the Hoan Bridge in Milwaukee [75]. These fractures occurred at a shelf plate detail for attachment of the lateral wind bracing to the girders where the shelf plate fit around, and intersected the welds of, a vertical stiffener, as shown in [Figure 34.13](#).

Fractures have also occurred at poorly executed weld access holes, as shown in [Figure 34.14](#). AWS D1.1 [18] has detailing rules for base metal and welds that are good practice for bolted joints as well as welded joints. Additional requirements are provided in the AISC Specifications [16,76] or other applicable specifications. For example, AWS and AISC have specific rules for the size of weld access holes and the radii and smoothness of all thermally cut edges.

The detailing rules of the AWS D1.1 and the AISC load and resistance factor design (LRFD) specification are sufficient for most statically loaded structures. More stringent detailing rules are also provided in AWS D1.5 [77] for bridges due to fatigue concerns. For example, weld backing bars must usually be removed. AASHTO Construction Specifications [78] have some additional requirements, for example, holes in primary load-carrying members must be drilled and not punched. This is because punching may strain-harden the material (reducing toughness and ductility) and introduce microcracks.

Also, more stringent detailing rules are provided in the AISC Seismic Specification [76] and in FEMA 350 [66] due to concerns about brittle fracture and low-cycle fatigue. For example, the connections for special moment frames must be prequalified with specific details, such as the access hole visible in [Figure 34.8](#) and [Figure 34.9](#).

In these and other applications requiring substantial ductility, stress concentrations such as re-entrant corners should be avoided and instead transition radii that are ground smooth should be provided, as shown in [Figure 34.8](#) and [Figure 34.9](#). The ends of butt welds are always a potential location of defects.

FIGURE 34.13 Fractured girder of the Hoan Bridge in Milwaukee and view of critical shelf plate detail featuring intersecting welds.

If possible, it is better to locate butt welds away from such stress concentrations. If not, it is important to use runout tabs and to later grind the ends of the weld to a radius. Fillet weld terminations should not be ground, for this will expose a very thin ligament near the weld root that will tear easily.

The enhanced detailing required by the bridge [77,78] or seismic [66,76] specifications are expensive to implement relative to what would be required by AWS D1.1 [18] and AISC LRFD Specification [16]. Therefore, they should not be specified if extraordinary ductility is not required in a structural component, which is the case for most statically loaded structures.

AASHTO specifications for bridge steel and weld filler metal and ASTM specifications for ship steel (A131) require minimum CVN values at specific temperatures. However, since fatigue is not expected in conventional buildings and therefore the risk of fracture is much lower, CVN is often not explicitly specified for the steel or weld metal for buildings. Rather, the strategy is to allow only specific American Society for Testing and Materials (ASTM) specifications for steel and AWS classifications for weld filler metal that are known to function well in buildings. However, if there is special concern about brittle fracture and (1) high-ductility demand (as in seismic frames), (2) low-temperature exposure,

FIGURE 34.14 Fracture emanating from a poorly executed weld access hole.

or (3) fatigue or impact loading, then a supplemental requirement for a minimum CVN at a specific temperature should be considered, along with enhanced detailing. Since there is usually a premium cost, a supplemental CVN requirement should only be specified when necessary.

As shown in Figure 34.12, the typical lower-shelf CVN is about 10 J. Therefore, when a minimum CVN of 20 J or more is specified at some temperature, the most important result of such a specification is that the lower shelf of the Charpy curve will start at a temperature lower than the specified temperature. In fact, this indicates that the lower shelf of a structure loaded statically or at intermediate strain rates such as traffic loading on a bridge is even lower, a phenomenon known as the temperature shift [3]. Because of the temperature shift, the temperature at which the CVN requirement is specified may be greater than the lowest anticipated service temperature.

As long as the material is not on the lower shelf at service temperature, brittle fracture will not occur as long as large cracks do not develop. It almost does not matter what the specified CVN value is as long as it is at least 20 J. Usually, an average from three tests of 34 J (25 ft lbs) or 27 J (20 ft lbs) is specified at a particular temperature. The greater the value of the average CVN requirement, the more certain it is that the material is well above the lower shelf, but there may be a greater premium to be paid with diminishing increases in certainty.

In addition to brittle fracture, there is occasionally a problem with steel or weld metal that has low upper-shelf toughness. Such a material can give a ductile failure mode but without sufficient ductility. To guard against this type of material, a CVN requirement of 54 J (40 ft lbs) is often specified at 21°C (room temperature).

34.3.2.1 Steel Plates and Shapes

AASHTO specifications for Grade 50 (minimum 350-MPa yield strength) bridge steel up to 38-mm thick require a CVN at a temperature that is 38°C *greater* than the minimum service temperature. The temperature shift accounts for the effect of strain rates, which are lower in the service loading of bridges (on the order of 10^{-3}) than in the Charpy test (greater than 10^1). The temperature shift means that when a CVN is specified at some temperature, it ensures that the transition temperature for the structure is at least 38°C less than the specified temperature. For bridge steel, the specified minimum CVN is 20 J for nonfracture critical members and 34 J for fracture critical members. Fracture critical members are defined as those that if fractured would result in collapse of the bridge.

Most of the United States (except Alaska and a small part of the northern tier states) has a lowest anticipated service temperature greater than -34°C , the limit for AASHTO Zone II. In Zone II, bridge steel is required to have a minimum of 20 J at 4°C .

ASTM A673 has specifications for the frequency of Charpy testing. The H frequency requires a set of three CVN specimens to be tested from one location for each heat or about 50 tons. These CVN test specimens can be taken from a plate with thickness up to 9 mm different from the product thickness if it is rolled from the same heat. The P frequency requires a set of three specimens to be tested from one end of every plate, or from one shape in every 15 tons of that shape. For bridge steel, the AASHTO code requires CVN tests at the H frequency as a minimum. For fracture critical members, CVN testing at the P frequency is required.

For buildings, A36, A572, A588, or A992 do not have a specified minimum CVN, unless supplemental specifications (CVN testing in accordance with ASTM A6/A6M, Supplementary Requirement S5) should be cited.

One exception is shapes meeting A913, which are produced using a special quenched and self-tempering process that results in good toughness. A913 shapes have a specified minimum CVN (average of three tests) of 54 J at 21°C .

In most cases, ordinary structural steel has sufficient toughness for the required performance in buildings, even under these demanding conditions. For example, Figure 34.15 shows a histogram of CVN data at 4°C from the flanges of shapes for more than 2200 heats of A992 steel from five producers in 1998 [79]. The CVN values were widely dispersed, and the mean values were typically very high, on the order of 160 J or more. Table 34.2 shows some summary statistics for the A992 steel CVN. These data show that 99.9% of the A992 steel meets Zone II, bridge steel requirement of 20 J at 4°C . Therefore, as stated previously, it may not be worth paying the premium for specifying the supplemental CVN requirement since the requirement is almost always met by all structural steel, at least that from the major suppliers (U.S. and European) of the North American market.

Although the toughness of the flanges is generally quite good, the toughness of shapes is usually not homogenous. For example, in rotary straightened W-shapes there is often an area of reduced notch toughness in a limited region of the web immediately adjacent to the flange, referred to as the “k-area,” as illustrated in Figure 34.16 [80]. Following the 1994 Northridge earthquake, there was a tendency to specify thicker continuity plates that were groove welded to the web and flange and thicker doubler plates that were often groove welded in the gap between the doubler plate and the flanges. These welds were highly restrained and may have caused cracking during fabrication in some cases [81].

FIGURE 34.15 CVN histogram for A992 steel at 4°C .

TABLE 34.2 Summary of Statistics for CVN for A992 Structural Steel

Temperature	% less than 29 Joules (15 ft-lbs)	First quartile (75% exceedence) Joules (ft-lbs)	Mean Joules (ft-lbs)	Samples
0°C (32°F)	0.25	54 (40)	143 (106)	395
4°C (40°F)	0.13	88 (65)	163 (121)	2280
21°C (70°F)	0.09	104 (77)	175 (160)	1058

**FIGURE 34.16** Location of the k-area affected by rotary straightening.

AISC issued an Advisory in 1997 [82] that recommended that the welds for continuity plates should terminate well away from the k-area. The Advisory defined the k-area as the “region extending from approximately the midpoint of the radius of the fillet into the web approximately 1 to 1.5 in beyond the point of tangency between the fillet and web.”

Recent pull-plate tests [83–86] and full-scale beam–column joint tests [65,86,87] have shown that this problem can be avoided if the continuity plates are fillet welded to both the web and the flange, the cutout or snipe at the corners of the continuity plates is at least 38 mm, and the fillet welds are stopped short by a weld leg length from the edges of the cutout, as shown in Figure 34.17. These tests also show that groove welding these continuity plates to the flanges or the web is unnecessary.

Tests have also shown the viability of fillet welding doubler plates to the flanges in lieu of groove welds [65,84–86]. In most applications, if groove welds are not absolutely needed, fillet welds are almost always preferred due to the lower restraint, lower residual stress, fewer defects, and associated reduced risk of fracture.

Another relatively rare type of cracking in structural steel is galvanized cope cracking, which is thought to be due to a phenomenon called liquid metal embrittlement. It has occurred at the edges of thermally cut copes or rolled beams. The thermal cutting is believed to cause microcracking, allowing the molten zinc and other metals to penetrate the microcracks and causing them to propagate into larger visible cracks [88].

In the early 1980s, there were several fractures that occurred when jumbo sections with welded splices were used as tension chords in long-span trusses [89]. Figure 34.18 shows an example of such a fracture that originated at poorly cut access holes at the welded splices where they intersected the web/flange core region of jumbo shapes [89]. This web/flange core region (not the same as the k-area) often had course

grain regions with very low toughness. Plates greater than 50 mm thick may also have regions of low toughness at midthickness.

Therefore, AISC specifications now have special detailing requirements for weld access holes and a supplemental Charpy requirement for shapes with flange thickness greater than 38 mm and plates thicker than 51 mm, when these are welded and subject to primary tensile stress from axial load or bending. These jumbo shapes and thick plates must exhibit an average of 27 J at 21°C. In the shapes, the central longitudinal axis of the specimens must be located on a line in a plane one fourth of the way through the thickness from the inside flange surface at the intersection with the web midthickness. The test specimens are taken from the top of each ingot used to produce the product.

FIGURE 34.17 Recommended placement of continuity plate fillet welds to avoid contact of welds with k-area.

FIGURE 34.18 Jumbo section used as tension chord in a roof truss and fracture in web originating from weld access holes at welded splice.

34.3.2.2 Weld Filler Metal

Prior to the 1994 Northridge Earthquake, the welds in the welded special moment frame (WSMF) connections were commonly made with the self-shielded flux-cored arc welding (FCAW-S) process using an E70T-4 weld wire. Figure 34.19 shows a plot of CVN versus temperature for deposited weld metal using E70T-4, E70TG-K2 (another FCAW-S filler metal), and ordinary E7018 shielded metal arc welding (SMAW) electrodes. The CVN for E70T-4 is less than 20 J for temperatures up to 40°C [74].

Many of these low-toughness WSMF connections fractured in the earthquake [90]. Figure 34.20 shows a fractured beam flange end and a cross-section. Figure 34.21 shows the crack-like notch created by the backing bar. The fracture surfaces, such as those shown in Figure 34.20, indicate that the fractures originate in the root of the weld, typically at a lack-of-fusion defect adjacent to the backing bar notch

FIGURE 34.19 Typical Charpy impact energy from E70T-4 FCAW-S weld metal from Northridge WSMF connections compared to another FCAWS-S (E70TG-K2) and SMAW (E7018) weld metal.

FIGURE 34.20 Fracture surface and weld cross-section from moment-frame connection that fractured in the Northridge Earthquake showing a typical crack that originated at the backing bar notch.

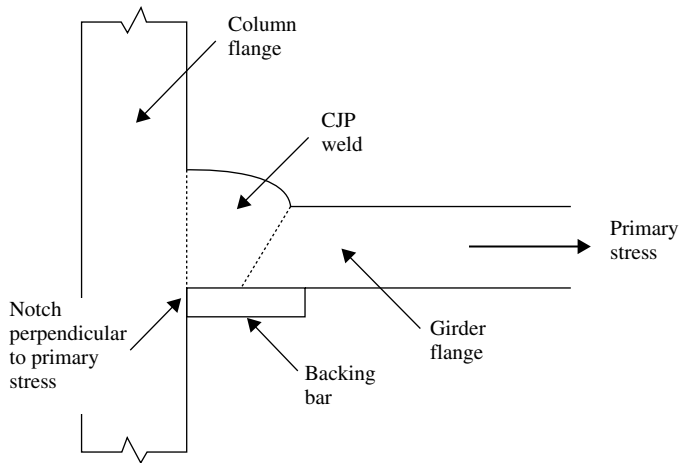

FIGURE 34.21 Schematic cross-section of pre-Northridge groove weld detail with backing bar.

[91,92]. This lack-of-fusion defect is difficult to avoid when the weld must be stopped on one side of the web and started on the other side.

A fracture mechanics assessment shows that the low-toughness E70T-4 weld metal would be predicted to fracture in the presence of the crack-like notch at stress levels well below the yield point [73,74]. In addition to the low toughness and the crack-like notch and defect, there were many other important factors in these fractures. The overall lack of redundancy, that is, the reliance on only one or two massive WSMFs to resist lateral load in each direction, contributes to large forces, increase in the thickness of the members, and the high constraint of the connections.

FEMA 350 has proposed improved connections, such as the WUF-W connection [66]. In addition to specifying notch-tough filler metals, the detailing of the WUF-W connection is also improved relative to the pre-Northridge connection. On the bottom flange weld, the backing bar must be removed, the weld back gouged, and a reinforcing fillet placed underside. On the top flange, the backing bar may be left in place, but the notch is sealed with a fillet weld as shown in Figure 34.7, reducing the adverse effect of the notch.

The FEMA guidelines [66,93] recommend that weld metal be used that meets two CVN test requirements: (1) 54 J at 21°C (to avoid low upper-shelf weld metal) and (2) 27 J at -18°C (to ensure that the service temperature is above the lower shelf). Testing done as part of the FEMA program suggests that another FCAW-S filler metal, E70T-6, can meet these requirements. The AWS classification [94] requires E70T-6 to have 27 J at -29°C. The AISC seismic specifications [76] also require the weld metal for these welds to have a minimum CVN of 27 J at -29°C. However, weld deposits with CVN far less than required have been obtained under some conditions with E70T-6, despite certifications indicating that the filler metal met the AWS classification requirements, leading to brittle fractures in full-scale tests [65].

The FEMA requirements for minimum toughness are adequate, provided they can be consistently met. Toughness is an inherently variable material property, particularly in a nonhomogenous material such as a weld. For this reason, the toughness requirements should be treated as a lower-bound value and not as an average. This can be accomplished either through strict quality assurance or specification of welding consumables that have lower-bound toughness consistently above the FEMA minimum.

The former is the approach required by the FEMA *Recommended Specifications and Quality Assurance Guidelines* [93]. These Recommended Specifications require toughness testing on each

production lot of the specified filler metal. However, upon approval of the engineer, this requirement may be waived and the consumable manufacturer's certification testing may be used to verify the material's suitability [93].

The manufacturer's testing may not be sufficient to preclude brittle weld deposits, since the testing need only be conducted once a year on a single production lot of the particular electrode [94]. Alternatively, specification of higher toughness consumables (e.g., E71T-8) that consistently meet minimum requirements may be a more reliable means of insuring welds of sufficient toughness.

34.4 Summary

1. Structural elements where the live load is a large percentage of the total load are potentially susceptible to fatigue. Many factors in fabrication can increase the potential for fatigue, including notches, misalignment and other geometrical discontinuities, thermal cutting, weld joint design (particularly backing bars), residual stress, nondestructive evaluation and weld defects, intersecting welds, and inadequate weld access holes.
2. The fatigue design procedures in the AASHTO and AISC specifications are based on control of the stress range and knowledge of the fatigue strength of the various details. Using these specifications, it is possible to identify and avoid details expected to have low fatigue strength.
3. Low-cycle fatigue is a limit state for members and connections repeatedly cycled in the inelastic range, such as for seismic loading. Low-cycle fatigue can be predicted using strain-range versus cycles curves derived from the stress-based $S-N$ curves for high-cycle fatigue.
4. Welded connections and thermal-cut holes, copes, blocks, or cuts are potentially susceptible to brittle fracture. Many interrelated design variables can increase the potential for brittle fracture, including lack of redundancy, large forces and moments with dynamic loading rates, thick members, geometrical discontinuities, and high constraint of the connections. Low temperature can be a factor for exposed structures. The factors mentioned above, which influence the potential for fatigue, have a similar effect on the potential for fracture. In addition, cold work (e.g., from rotary straightening or punching holes), flame straightening, weld heat input, and weld sequence can also affect the potential for fracture.
5. The AASHTO specifications require a minimum CVN notch toughness at a specified temperature for the base metal and the weld metal of members loaded in tension or tension due to bending. Almost two decades of experience with these bridge specifications have proved that they are successful in significantly reducing the number of brittle fractures.
6. Surveys of CVN for wide-flange shapes sold in North America show that 99.9% of this steel meets the AASHTO bridge steel requirements for service down to -34°C . Therefore, under most circumstances, there is no need to specify CVN for shapes used in buildings.
7. Achieving the required minimum CVN toughness in the girder flange-to-column flange groove welds is critical for good performance in the prequalified steel moment connections. Lot testing should be considered, or it may be necessary to specify electrodes that typically far exceed the minimum toughness levels. Either step would assure that minimum CVN requirements represent a realistic lower-bound of weld toughness deposited in the field.

35.1 Introduction

In recent years, innovative means of enhancing structural functionality and safety against natural and man-made hazards have been in various stages of research and development. By and large, these approaches can be grouped into three broad areas as shown in [Table 35.1](#): (1) base isolation; (2) passive energy dissipation; and (3) active control. Of the three, base isolation can be considered a more mature technology (e.g., ATC 1993; Skinner et al. 1993) with wider applications as compared with the other two.

Passive energy dissipation systems encompass a range of materials and devices for enhancing damping, stiffness, and strength, and can be used both for natural hazard mitigation and for rehabilitation of aging or deficient structures (e.g., Soong and Dargush 1997; Constantinou et al. 1998; Hanson and Soong 2001). In recent years, serious efforts have been undertaken to develop the concept of energy dissipation, or supplemental damping, into a workable technology, and a number of these devices have been installed in structures throughout the world. In general, such systems are characterized by a capability to enhance energy dissipation in the structural systems in which they are installed. This effect may be achieved either by conversion of kinetic energy to heat or by transferring of energy among vibrating modes. The first method includes devices that operate on principles such as yielding of metals, phase transformation in metals, frictional sliding, deformation of viscoelastic solids or fluids, and fluid orificing. The latter method includes supplemental oscillators that act as dynamic absorbers. A list of such devices, which have found applications, is given in [Table 35.1](#).

TABLE 35.1 Structural Protective Systems

Base isolation	Passive energy dissipation	Active control
Elastomeric bearings	Metallic dampers Friction dampers	Active bracing systems Active mass dampers
Lead rubber bearings	Viscoelastic dampers Viscous fluid dampers	Variable stiffness or damping systems
Sliding friction pendulum	Tuned mass dampers Tuned liquid dampers	

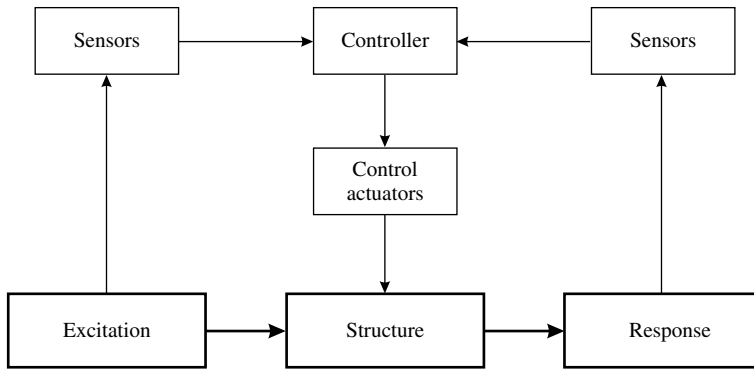

FIGURE 35.1 Block diagram of active structural control.

Among the current passive energy dissipation systems, those based on fluid orificing and on deformation of viscoelastic polymers represent technologies in which the U.S. industry has a worldwide lead. Originally developed for industrial and military applications, these technologies have found recent applications in natural hazard mitigation in the form of either energy dissipation within the primary structural system or as elements of base isolation systems.

The possible use of active control systems and some combinations of passive and active systems, so-called hybrid systems, as a means of structural protection against wind and seismic loads has also received considerable attention in recent years. Active/hybrid control systems are force delivery devices integrated with real-time processing evaluators/controllers and sensors within the structure. These systems must react simultaneously with the hazardous excitation to provide enhanced structural behavior for improved service and safety. Figure 35.1 is a block diagram of the active structural control problem. The basic task is to find a control strategy that uses the measured structural responses to calculate the control signal that is appropriate to send to the actuator. Structural control for civil engineering applications has a number of distinctive features, largely due to implementability issues, that set it apart from the general field of feedback control. First of all, when addressing civil structures, there is considerable uncertainty, including nonlinearity, associated with both physical properties and disturbances such as earthquake and wind. Additionally, the scale of the forces involved is quite large, there are a limited number of sensors and actuators, the dynamics of the actuators can be quite complex, and the systems must be fail-safe (e.g., Soong 1990; Dyke et al. 1994, 1995; Housner et al. 1994; Kobori 1994).

Nonetheless, remarkable progress has been made over the last 25 years in research on using active and hybrid systems as a means of structural protection against wind, earthquakes, and other hazards (e.g., Soong 1990; Soong and Reinhorn 1993; Soong and Constantinou 1994). A number of semiactive systems have also been developed, in which a control algorithm is used to adjust device properties with only

minimal power input (e.g., Kobori et al. 1993; Patten et al. 1996; Soong and Spencer 2002). Research to date has reached the stage where active systems, such as those listed in Table 35.1, and semiactive systems have been installed in full-scale structures. Some active systems are also used temporarily in construction of bridges or large span structures (e.g., lifelines, roofs) where no other means can provide adequate protection. Additionally, most of the full-scale systems have been subjected to actual wind forces and ground motions, and their observed performances provide invaluable information in terms of (1) validating analytical and simulation procedures used to predict system performance, (2) verifying complex electronic–digital–servohydraulic systems under actual loading conditions, and (3) verifying the capability of these systems to operate or shutdown under prescribed conditions.

The focus of this section is on passive energy dissipation and active control systems. Their basic operating principles and methods of analysis are given in Section 35.2, followed by a review in Section 35.3 of recent development and applications. Code development is summarized in Section 35.4, and some comments on possible future directions in this emerging technological area are advanced in Section 35.5. In the following sections, we shall use the term *structural protective systems* to represent either passive energy dissipation systems or active control systems.

35.2 Basic Principles and Methods of Analysis

With recent development and implementation of modern structural protective systems, the entire structural engineering discipline is now undergoing a major change. The traditional idealization of a building or bridge as a static entity is no longer adequate. Instead, structures must be analyzed and designed by considering their dynamic behavior. It is with this in mind that we present some basic concepts related to topics that are of primary importance in understanding, analyzing, and designing structures that incorporate structural protective systems.

In what follows, a simple single-degree-of-freedom (SDOF) structural model is discussed. This represents the prototype for dynamic behavior. Particular emphasis is given to the effect of damping. As we shall see, increased damping can significantly reduce system response to time-varying disturbances. While this model is useful for developing an understanding of dynamic behavior, it is not sufficient for representing real structures. We must include more detail. Consequently, a multi-degree-of-freedom (MDOF) model is then introduced and several numerical procedures are outlined for general dynamic analysis. A discussion comparing typical damping characteristics in traditional and control-augmented structures is also included. Finally, a treatment of energy formulations is provided. Essentially, one can envision an environmental disturbance as an injection of energy into a structure. Design then focuses on the management of that energy. As we shall see, these energy concepts are particularly relevant in the discussion of passively or actively damped structures.

35.2.1 Single-Degree-of-Freedom Structural Systems

Consider the lateral motion of the basic SDOF model, shown in Figure 35.2, consisting of a mass m , supported by springs with total linear elastic stiffness k , and a damper with linear viscosity c . This SDOF system is then subjected to an external disturbance characterized by $f(t)$. The excited model responds with a lateral displacement $x(t)$ relative to the ground that satisfies the equation of motion:

$$m\ddot{x} + c\dot{x} + kx = f(t) \quad (35.1)$$

in which a superposed dot represents differentiation with respect to time. For a specified input, $f(t)$, and with known structural parameters, the solution of this equation can be readily obtained.

In the above, $f(t)$ represents an arbitrary environmental disturbance such as wind or an earthquake. In the case of an earthquake load

$$f(t) = -m\ddot{x}_g(t) \quad (35.2)$$

where $\ddot{x}_g(t)$ is ground acceleration.

FIGURE 35.2 SDOF structure model.

FIGURE 35.3 SDOF structure model with passive damper element.

Consider now the addition of a generic passive or active control element into the SDOF model, as indicated in Figure 35.3. The response of the system is now influenced by this additional element. The symbol Γ in Figure 35.3 represents a generic integrodifferential operator, such that the force corresponding to the control device is written simply as Γx . This permits quite general response characteristics, including displacement-, velocity-, or acceleration-dependent contributions, as well as hereditary effects. The equation of motion for the extended SDOF model then becomes, in the case of an earthquake load,

$$m\ddot{x} + c\dot{x} + kx + \Gamma x = -(m + \bar{m})\ddot{x}_g \tag{35.3}$$

with \bar{m} representing the mass of the control element.

The specific form of Γx needs to be specified before Equation 35.3 can be analyzed, which is necessarily highly dependent on the device type. For passive energy dissipation systems, it can be represented by a

force–displacement relationship such as the one shown in Figure 35.4, representing a rate-independent elastic–perfectly plastic element. For an active control system, the form of Γx is governed by the control law chosen for a given application. Let us first note that, denoting the control force applied to the structure in Figure 35.1 by $u(t)$, the resulting dynamical behavior of the structure is governed by Equation 35.3 with

$$\Gamma x = -u(t) \tag{35.4}$$

Suppose that a feedback configuration is used in which the control force $u(t)$ is designed to be a linear function of measured displacement $x(t)$ and measured velocity $\dot{x}(t)$. The control force $u(t)$ takes the form

$$u(t) = g_1 x(t) + g_2 \dot{x}(t) \tag{35.5}$$

In view of Equation 35.4, we have

$$\Gamma x = -[g_1 + g_2 d/dt]x \tag{35.6}$$

The control law is, of course, not necessarily linear in $x(t)$ and $\dot{x}(t)$ as given by Equation 35.5. In fact, nonlinear control laws may be more desirable for civil engineering applications (Wu and Soong 1995). Thus, for both passive and active control cases, the resulting Equation 35.3 can be highly nonlinear.

Assume for illustrative purposes that the base structure has a viscous damping ratio $\zeta = 0.05$ and that a simple massless yielding device is added to serve as a passive element. The force–displacement relationship for this element, depicted in Figure 35.4, is defined in terms of an initial stiffness \bar{k} and a yield force \bar{f}_y . Consider the case where the passively damped SDOF model is subjected to the 1940 El Centro S00E ground motion as shown in Figure 35.5. The initial stiffness of the elastoplastic passive device is specified as $\bar{k} = k$, while the yield force \bar{f}_y is equal to 20% of the maximum applied ground force. That is,

$$\bar{f}_y = 0.20 \text{Max}\{m|\ddot{x}_g|\} \tag{35.7}$$

The resulting relative displacement and total acceleration time histories are presented in Figure 35.6. There is significant reduction in response compared to that of the base structure without the control element, as shown in Figure 35.7. Force–displacement loops for the viscous and passive

FIGURE 35.4 Force–displacement model for elastic–perfectly plastic passive element.

FIGURE 35.5 1940 El Centro S00E accelerogram.

FIGURE 35.6 1940 El Centro time history response for SDOF structure with passive element: (a) displacement and (b) acceleration.

FIGURE 35.7 1940 El Centro time history response for SDOF structure without passive element: (a) displacement and (b) acceleration.

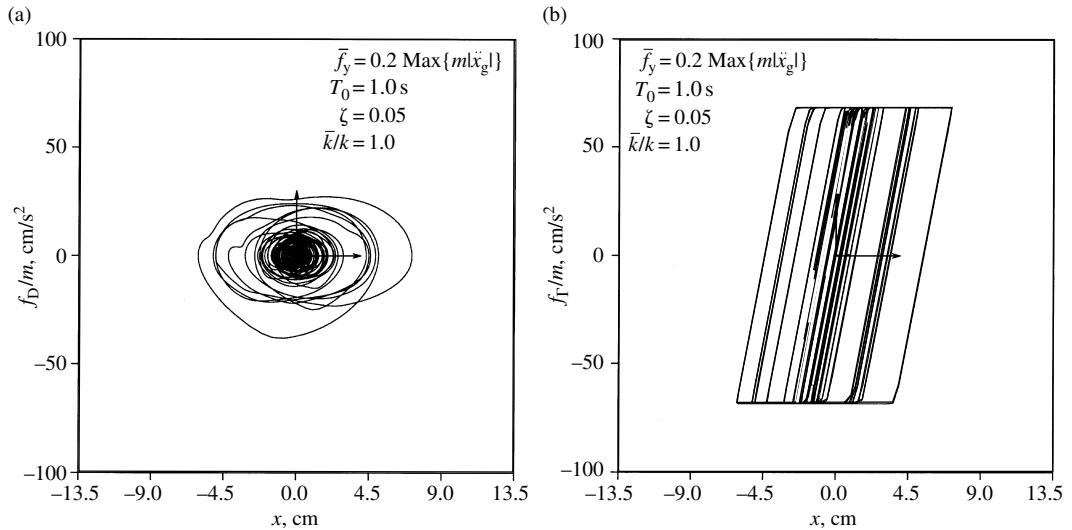

FIGURE 35.8 1940 El Centro force–displacement response for SDOF structure with passive element: (a) viscous element and (b) passive element.

elements are displayed in Figure 35.8. In this case, the size of these loops indicates that a significant portion of the energy is dissipated in the control device. This tends to reduce the forces and displacements in the primary structural elements, which of course is the purpose of adding the control device.

35.2.2 Multi-Degree-of-Freedom Structural Systems

In light of the preceding arguments, it becomes imperative to accurately characterize the behavior of any control device by constructing a suitable model under time-dependent loading. Multiaxial representations may be required. Once that model is established for a device, it must be properly incorporated into a mathematical idealization of the overall structure. Seldom is it sufficient to employ an SDOF idealization for an actual structure. Thus, in the present subsection, the formulation for dynamic analysis is extended to a MDOF representation.

The finite element method (FEM) (e.g., Zienkiewicz and Taylor 1989) currently provides the most suitable basis for this formulation. From a purely physical viewpoint, each individual structural member is represented mathematically by one or more finite elements having the same mass, stiffness, and damping characteristics as the original member. Beams and columns are represented by one-dimensional elements, while shear walls and floor slabs are idealized by employing two-dimensional finite elements. For more complicated or critical structural components, complete three-dimensional models can be developed, and incorporated into the overall structural model in a straightforward manner via substructuring techniques.

The FEM actually was developed largely by civil engineers in the 1960s from this physical perspective. However, during the ensuing decades the method has also been given a rigorous mathematical foundation, thus permitting the calculation of error estimates and the utilization of adaptive solution strategies (e.g., Szabo and Babuska 1991). Additionally, FEM formulations can now be derived from variational principles or Galerkin weighted residual procedures. Details of these formulations is beyond our scope. However, it should be noted that numerous general-purpose finite element software packages currently exist to solve the structural dynamics problem, including ABAQUS, ADINA, ANSYS, and NASTRAN. While none of these programs specifically addresses the special formulations needed to

characterize structural protective systems, most permit generic user-defined elements. Alternatively, one can utilize packages geared exclusively toward civil engineering structures, such as SAP 2000, ETABS, DRAIN, and IDARC, which in some cases can already accommodate typical passive elements.

Via any of the above-mentioned methods and programs, the displacement response of the structure is ultimately represented by a discrete set of variables, which can be considered the components of a generalized relative displacement vector $\mathbf{x}(t)$ of dimension N . Then, in analogy with Equation 35.3, the N equations of motion for the discretized structural system, subjected to uniform base excitation and time varying forces, can be written as

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{C}\dot{\mathbf{x}} + \mathbf{K}\mathbf{x} + \mathbf{\Gamma}\mathbf{x} = -(\mathbf{M} + \bar{\mathbf{M}})\ddot{\mathbf{x}}_g \quad (35.8)$$

where \mathbf{M} , \mathbf{C} , and \mathbf{K} represent the mass, damping, and stiffness matrices, respectively, while $\mathbf{\Gamma}$ symbolizes a matrix of operators that model the protective system present in the structure. Meanwhile, the vector $\ddot{\mathbf{x}}_g$ contains the rigid body contribution of the seismic ground displacement to each degree-of-freedom. The matrix $\bar{\mathbf{M}}$ represents the mass of the protective system.

There are several approaches that can be taken to solve Equation 35.8. The preferred approach, in terms of accuracy and efficiency, depends upon the form of the various terms in that equation. Let us first suppose that the protective device can be modeled as direct linear functions of the acceleration, velocity, and displacement vectors. That is,

$$\mathbf{\Gamma}\mathbf{x} = \bar{\mathbf{M}}\ddot{\mathbf{x}} + \bar{\mathbf{C}}\dot{\mathbf{x}} + \bar{\mathbf{K}}\mathbf{x} \quad (35.9)$$

Then, Equation 35.8 can be rewritten as

$$\hat{\mathbf{M}}\ddot{\mathbf{x}} + \hat{\mathbf{C}}\dot{\mathbf{x}} + \hat{\mathbf{K}}\mathbf{x} = -\hat{\mathbf{M}}\ddot{\mathbf{x}}_g \quad (35.10)$$

in which

$$\hat{\mathbf{M}} = \mathbf{M} + \bar{\mathbf{M}} \quad (35.11a)$$

$$\hat{\mathbf{C}} = \mathbf{C} + \bar{\mathbf{C}} \quad (35.11b)$$

$$\hat{\mathbf{K}} = \mathbf{K} + \bar{\mathbf{K}} \quad (35.11c)$$

Equation 35.10 is now in the form of the classical matrix structural dynamic analysis problem. In the simplest case, which we will now assume, all of the matrix coefficients associated with the primary structure and the passive elements are constant. As a result, Equation 35.10 represents a set of N linear second-order ordinary differential equations with constant coefficients. These equations are, in general, coupled. Thus, depending upon N , the solution of Equation 35.10 throughout the time range of interest could become computationally demanding. This required effort can be reduced considerably if the equation can be uncoupled via a transformation; that is, if $\hat{\mathbf{M}}$, $\hat{\mathbf{C}}$, and $\hat{\mathbf{K}}$ can be diagonalized. Unfortunately, this is not possible for arbitrary matrices $\hat{\mathbf{M}}$, $\hat{\mathbf{C}}$, and $\hat{\mathbf{K}}$. However, with certain restrictions on the damping matrix $\hat{\mathbf{C}}$, the transformation to modal coordinates accomplishes the objective via the modal superposition method (see, e.g., Clough and Penzien 1975).

As mentioned earlier, it is more common having $\mathbf{\Gamma}\mathbf{x}$ in Equation 35.9 nonlinear in \mathbf{x} for a variety of passive and active control elements. Consequently, it is important to develop alternative numerical approaches and design methodologies applicable to more generic passively or actively damped structural systems governed by Equation 35.8. Direct time-domain numerical integration algorithms are most useful in that regard. The Newmark beta algorithm, for example, is one of these algorithms and is used extensively in structural dynamics.

35.2.3 Energy Formulations

In Section 35.2.1 and Section 35.2.2, we have considered SDOF and MDOF structural systems. The primary thrust of our analysis procedures has been the determination of displacements, velocities,

accelerations, and forces. These are the quantities that, historically, have been of most interest. However, with the advent of innovative concepts for structural design, including structural protective systems, it is important to rethink current analysis and design methodologies. In particular, a focus on energy as a design criterion is conceptually very appealing. With this approach, the engineer is concerned, not so much with the resistance to lateral loads but rather, with the need to dissipate the energy input into the structure from environmental disturbances. Actually, this energy concept is not new. Housner (1956) suggested an energy-based design approach even for more traditional structures several decades ago. The resulting formulation is quite appropriate for a general discussion of energy dissipation in structures equipped with structural protective systems.

In what follows, an energy formulation is developed for an idealized structural system, which may include one or more control devices. The energy concept is ideally suited for application to nontraditional structures employing control elements, since for these systems proper energy management is a key to successful design. To conserve space, only SDOF structural systems are considered. However, these ideas can be easily generalized to MDOF systems.

Consider once again the SDOF oscillator shown in Figure 35.2 and governed by the equation of motion defined in Equation 35.1. An energy representation can be formed by integrating the individual force terms in Equation 35.1 over the entire relative displacement history. The result becomes

$$E_K + E_D + E_S = E_I \quad (35.12)$$

where

$$E_K = \int m\dot{x} \, dx = \frac{m\dot{x}^2}{2} \quad (35.13a)$$

$$E_D = \int c\dot{x} \, dx = \int c\dot{x}^2 \, dt \quad (35.13b)$$

$$E_S = \int kx \, dx = \frac{kx^2}{2} \quad (35.13c)$$

$$E_I = \int f \, dx \quad (35.13d)$$

The individual contributions included on the left-hand side of Equation 35.12 represent the relative kinetic energy of the mass (E_K), the dissipative energy caused by inherent damping within the structure (E_D), and the elastic strain energy (E_S). The summation of these energies must balance the input energy (E_I) imposed on the structure by the external disturbance. Note that each of the energy terms is actually a function of time and that the energy balance is required at each instant throughout the duration of the loading.

Consider aseismic design as a more representative case. It is unrealistic to expect that a traditionally designed structure will remain entirely elastic during a major seismic disturbance. Instead, inherent ductility of structures is relied upon to prevent catastrophic failure, while accepting the fact that some damage may occur. In such a case, the energy input (E_I) from the earthquake simply exceeds the capacity of the structure to store and dissipate energy by the mechanisms specified in Equations 35.13a–c. Once this capacity is surpassed, portions of the structure typically yield or crack. The stiffness is then no longer a constant and the spring force in Equation 35.1 must be replaced by a more general functional relation $g_S(x)$, which will commonly incorporate hysteretic effects. In general, Equation 35.13c is redefined as follows for inelastic response:

$$E_S = \int g_S(x) \, dx = E_{S_e} + E_{S_p} \quad (35.14)$$

in which E_S is assumed separable into additive contributions E_{S_e} and E_{S_p} , representing the fully recoverable elastic strain energy and the dissipative plastic strain energy, respectively.

FIGURE 35.9 Energy response of traditional structure: (a) damageability limit state and (b) collapse limit state (Uang and Bertero 1986).

Figure 35.9a provides the energy response of a 0.3-scale, six-story concentrically braced steel structure as measured by Uang and Bertero (1986). The seismic input consisted of the 1978 Miyagi-Ken-Oki Earthquake signal scaled to produce a peak shaking table acceleration of 0.33g, which was deemed to represent the damageability limit state of the model. At this level of loading, a significant portion of the energy input to the structure is dissipated, with both viscous damping and inelastic hysteretic mechanisms having substantial contributions. If the intensity of the signal is elevated, an even greater share of the energy is dissipated via inelastic deformation. Finally, for the collapse limit state of this model structure at 0.65g peak table acceleration, approximately 90% of the energy is consumed by hysteretic phenomena, as shown in Figure 35.9b. Evidently, the consumption of this quantity of energy has destroyed the structure.

From an energy perspective, then, for proper aseismic design, one must attempt to minimize the amount of hysteretic energy dissipated by the structure. There are basically two viable approaches available. The first involves designs that result in a reduction in the amount of energy input to the structure. Base isolation systems and some active control systems, for example, fall into that category. The second approach, as in the passive and semiactive control system cases, focuses on the introduction of additional energy dissipating mechanisms into the structure. These devices are designed to consume a portion of the input energy, thereby reducing damage to the main structure caused by hysteretic dissipation. Naturally, for a large earthquake, the devices must dissipate enormous amounts of energy.

The SDOF system with a control element is displayed in Figure 35.3, while the governing integro-differential equation is provided in Equation 35.3. After integrating with respect to x , an energy balance equation can be written

$$E_K + E_D + E_{S_c} + E_{S_p} + E_C = E_I \tag{35.15}$$

where the energy associated with the control element is

$$E_C = \int \Gamma x dx \tag{35.16}$$

and the other terms are as previously defined.

As an example of the effects of control devices on the energy response of a structure, consider the tests of a one-third scale three-story lightly reinforced concrete framed building conducted by Lobo et al. (1993). Figure 35.10a displays the measured response of the structure due to the scaled 1952 Taft

FIGURE 35.10 Energy response of test structure: (a) without passive devices and (b) with passive devices (Lobo et al. 1993).

N21E earthquake signal normalized for peak ground accelerations of 0.20g. A considerable portion of the input energy is dissipated via hysteretic mechanisms, which tend to damage the primary structure through cracking and the formation of plastic hinges. On the other hand, damage is minimal with the addition of a set of viscoelastic braced dampers. The energy response of the braced structure, due to the same seismic signal, is shown in Figure 35.10b. Notice that although the input energy has increased slightly, the dampers consume a significant portion of the total, thus protecting the primary structure.

35.2.4 Energy-Based Design

While the energy concept, as outlined briefly above, does not currently provide the basis for aseismic design codes, there is a considerable body of knowledge that has been developed from its application to traditional structures. Housner (1956, 1959) was the first to propose an energy-based philosophy for earthquake resistant design. In particular, he was concerned with limit-design methods aimed toward preventing collapse of structures in seismically active regions. Housner assumed that the energy input calculated for an undamped, elastic idealization of a structure provided a reasonable upper bound to that for the actual inelastic structure.

Berg and Thomaidis (1960) examined the energy consumption in SDOF elastoplastic structures via numerical computation and developed energy input spectra for several strong-motion earthquakes. These spectra indicate that the amount of energy E_I imparted to a structure from a given seismic event is quite dependent upon the structure itself. The mass, the natural period of vibration, the critical damping ratio, and yield force level were all found to be important characteristics.

On the other hand, their results did suggest that the establishment of upper bounds for E_I might be possible and thus provided support for the approach introduced by Housner. However, the energy approach was largely ignored for a number of years. Instead, limit-state design methodologies were developed that utilized the concept of displacement ductility to construct inelastic response spectra as proposed initially by Veletsos and Newmark (1960).

More recently, there has been a resurgence of interest in energy-based concepts. For example, Zahrah and Hall (1982) developed a MDOF energy formulation and conducted an extensive parametric study of energy absorption in simple structural frames. Their numerical work included a comparison between energy-based and displacement ductility-based assessments of damage, but the authors stopped short of issuing a general recommendation.

A critical assessment of the energy concept as a basis for design was provided by Uang and Bertero (1988). The authors initially contrast two alternative definitions of the seismic input energy. The quantity specified in Equation 35.13d is labeled the relative input energy, while the absolute input energy (E_{I_a}) is defined by

$$E_{I_a} = \int m \ddot{x}_r dx_g \quad (35.17a)$$

In conjunction with this latter quantity, an absolute kinetic energy (E_{K_a}) is also required, where

$$E_{K_a} = \frac{m \dot{x}_I^2}{2} \quad (35.17b)$$

The absolute energy equation corresponding to Equation 35.15 then becomes

$$E_{K_a} + E_D + E_{S_e} + E_{S_p} + E_C = E_{I_a} \quad (35.18)$$

Based upon the development of input energy spectra for an SDOF system, the authors conclude that, while both measures produce approximately equivalent spectra in the intermediate period range, E_{I_a} should be used as a damage index for short period structures and E_I is more suitable for long period structures. Furthermore, an investigation revealed that the assumption of Housner to employ the idealized elastic strain energy, as an estimate of the actual input energy, is not necessarily conservative. Uang and Bertero also studied a MDOF structure and concluded that the input energy spectra for an SDOF can be used to predict the input energy demand for that type of building. In a second portion of the report, an investigation was conducted on the validity of the assumption that energy dissipation capacity can be used as a measure of damage. In testing cantilever steel beams, reinforced concrete shear walls, and composite beams the authors found that damage depends upon the load path.

The last observation should come as no surprise to anyone familiar with classical failure criteria. However, it does highlight a serious shortcoming for the use of the energy concept for limit design of traditional structures. As was noted above, in these structures, a major portion of the input energy must be dissipated via inelastic deformation, but damage to the structure is not determined simply by the magnitude of the dissipated energy. On the other hand, in nontraditional structures incorporating passive damping mechanisms, the energy concept is much more appropriate. The emphasis in design is directly on energy dissipation. Furthermore, since an attempt is made to minimize the damage to the primary structure, the selection of a proper failure criterion is less important.

35.3 Recent Development and Applications

As a result of serious efforts that have been undertaken in recent years to develop and implement the concept of passive energy dissipation and active control, a number of these devices have been installed in structures throughout the world, including Japan, New Zealand, Italy, Mexico, Canada, and the United States. In what follows, advances in terms of their development and applications are summarized.

35.3.1 Passive Energy Dissipation

As alluded to in [Section 35.1](#) and [Table 35.1](#), a number of passive energy dissipation devices have been developed and installed in structures for performance enhancement under wind or earthquake loads. Discussions presented below are centered around some of the more common devices that have found applications in these areas.

35.3.1.1 Metallic Yield Dampers

One of the effective mechanisms available for the dissipation of energy input to a structure from an earthquake is through inelastic deformation of metals. The idea of utilizing added metallic energy dissipators within a structure to absorb a large portion of the seismic energy began with the conceptual

and experimental work of Kelly et al. (1972) and Skinner et al. (1975). Several of the devices considered included torsional beams, flexural beams, and U-strip energy dissipators. During the ensuing years, a wide variety of such devices have been studied or tested (Tyler 1985; Bergman and Goel 1987; Whittaker et al. 1991; Tsai et al. 1993). Many of these devices use mild steel plates with triangular or X shapes so that yielding is spread almost uniformly throughout the material. A typical X-shaped plate damper or added damping and stiffness (ADAS) device is shown in Figure 35.11. Other materials, such as lead and shape-memory alloys, have also been evaluated (Aiken and Kelly 1992). Some particularly desirable features of these devices are their stable hysteretic behavior, low-cycle fatigue property, long-term reliability, and relative insensitivity to environmental temperature. Hence, numerous analytical and experimental investigations have been conducted to determine these characteristics of individual devices.

After gaining confidence in their performance based primarily on experimental evidence, implementation of metallic devices in full-scale structures has taken place. The earliest implementations of metallic dampers in structural systems occurred in New Zealand and Japan. A number of these interesting applications are reported in Skinner et al. (1980) and Fujita (1991). More recent applications include the use of ADAS dampers in seismic upgrades of existing buildings in Mexico (Martinez-Romero 1993) and in the United States (Perry et al. 1993). The seismic upgrade project discussed in Perry et al. (1993) involves the retrofit of the Wells Fargo Bank building in San Francisco, CA. The building is a two-story nonductile concrete frame structure originally constructed in 1967 and subsequently damaged in the 1989 Loma Prieta earthquake. The voluntary upgrade by Wells Fargo utilized chevron braces and ADAS damping elements. More conventional retrofit schemes were rejected due to an inability to meet the performance objectives while avoiding foundation work. A plan view of the second floor including upgrade details is provided in Figure 35.12. A total of seven ADAS devices were employed, each with a yield force of 150 kps. Both linear and nonlinear analyses were used in the retrofit design process. Further three-dimensional response spectrum analyses, using an approximate equivalent linear representation for the ADAS elements, furnished a basis for the redesign effort. The final design was verified with DRAIN-2D nonlinear time history analyses. A comparison of computed response before and after the upgrade is contained in Figure 35.13. The numerical results indicated that the revised design was

FIGURE 35.11 ADAS device (Whittaker et al. 1991).

FIGURE 35.12 Wells Fargo Bank building retrofit details (Perry et al. 1993).

FIGURE 35.13 Comparison of computed results for Wells Fargo Bank Building — envelope of response values in X direction (Perry et al. 1993).

stable and that all criteria were met. In addition to the introduction of the bracing and ADAS dampers, several interior columns and a shear wall were strengthened.

An alternative passive damper utilizing the principles of metallic yielding is the unbonded brace (Shiba et al. 1998; Wada et al. 2000). These braces consist of a central steel core that provides energy dissipation in both tension and compression. In order to prevent buckling, the brace is encased in a concrete-filled steel tube or a fiber-reinforced concrete sheathing. Special coatings are used to reduce friction between the steel core and surrounding concrete. Despite its recent development, a number of applications of the unbonded brace have already appeared in Japan and the United States.

35.3.1.2 Friction Dampers

Friction dampers utilize the mechanism of solid friction that develops between two solid bodies sliding relative to one another to provide the desired energy dissipation. Several types of friction dampers have been developed for the purpose of improving seismic response of structures. In some cases, additional research on the long-term behavior of frictional systems may be appropriate.

A simple brake lining frictional system was studied by Pall et al. (1980); however, a special damper mechanism, devised by Pall and Marsh (1982), and depicted in Figure 35.14, permits much more effective operation. During cyclic loading, the mechanism tends to straighten buckled braces and also enforces slippage in both tensile and compressive directions.

Several alternate friction damper designs have also been proposed in the literature. For example, Roik et al. (1988) discuss the use of three-stage friction-grip elements. A simple conceptual design, the slotted bolted connection (SBC), was investigated by FitzGerald et al. (1989) and Grigorian et al. (1993). Another design of a friction damper is the energy dissipating restraint (EDR) manufactured by Fluor Daniel, Inc. There are several novel aspects of the EDR that combine to produce very different response characteristics. A detailed presentation of the design and its performance is provided in Nims et al. (1993).

In the last decade, there have been several commercial applications of friction dampers aimed at providing enhanced seismic protection of new and retrofitted structures. This activity in North America is primarily associated with the use of Pall friction devices in Canada. For example, the applications of friction dampers to the McConnel Library of the Concordia University in Montreal, Canada, is discussed in Pall and Pall (1993). A total of 143 dampers were employed in this case. Interestingly, the architects chose to expose 60 of the dampers to view due to their esthetic appeal. A series of nonlinear DRAIN-TABS (Guendeman-Israel and Powell 1977) analyses were utilized to establish the optimum slip load for the devices, which ranges from 600 to 700 kN depending upon the location within the structure. For the three-dimensional time-history analyses, artificial aseismic signals were generated with a wide range of frequency contents and a peak ground acceleration scaled to 0.18g to represent expected ground motion in Montreal. Under this level of excitation, an estimate of the equivalent damping ratio for the structure with frictional devices is approximately 50%. In addition, for this library complex, the use of the friction dampers resulted in a net savings of 1.5% of the total building cost.

FIGURE 35.14 X braced friction damper (Pall and Marsh 1982).

35.3.1.3 Viscoelastic Dampers

Viscoelastic (VE) materials used in structural applications are usually copolymers or glassy substances that dissipate energy through shear deformation. A typical VE damper, which consists of VE layers bonded with steel plates, is shown in Figure 35.15. When mounted in a structure, shear deformation and hence energy dissipation takes place when structural vibration induces relative motion between the outer steel flanges and the center plates. Significant advances in research and development of VE dampers, particularly for seismic applications, have been made in recent years through analyses and experimental tests (e.g., Chang et al. 1994; Lai et al. 1995; Shen et al. 1995).

The first applications of VE dampers to structures were for reducing acceleration levels, or increasing human comfort, due to wind. In 1969, VE dampers were installed in the twin towers of the World Trade Center in New York, NY, as an integral part of the structural system. There were about 10,000 VE dampers in each tower, evenly distributed throughout the structure from the 10th to the 110th floor. Prior to their collapse, the towers experienced a number of moderate to severe wind storms and the observed performance of the VE dampers has been found to agree well with theoretical values. In 1982, VE dampers were incorporated into the 76-story Columbia SeaFirst Building in Seattle against wind-induced vibrations (Keel and Mahmoodi 1986). To reduce the wind-induced vibration, the design called for 260 dampers to be located alongside the main diagonal members in the building core. The addition of VE dampers to this building was calculated to increase its damping ratio in the fundamental mode from 0.8 to 6.4% for frequent storms and to 3.2% at design wind. Similar applications of VE dampers were made to the Two Union Square Building in Seattle in 1988. In this case, 16 large VE dampers were installed parallel to four columns in one floor.

Seismic applications of VE dampers to structures began more recently. A seismic retrofit project using VE dampers began in 1993 for the 13-story Santa Clara County building in San Jose, CA (Crosby et al. 1994). Situated in a high seismic risk region, the building was built in 1976. It is approximately 64 m in height and nearly square in plan, with 51×51 m on typical upper floors. The exterior cladding consists of full-height glazing on two sides and metal siding on the other two sides. The exterior cladding, however, provides little resistance to structural drift. The equivalent viscous damping in the fundamental mode is less than 1% of critical.

The building has been extensively instrumented, providing invaluable response data obtained during a number of past earthquakes. A plan for seismic upgrade of the building was developed, in part, when the response data indicated large and long-duration response, including torsional coupling, to even moderate earthquakes. The final design called for installation of two dampers per building face per floor

FIGURE 35.15 Typical VE damper configuration.

FIGURE 35.16 Location of VE dampers in Santa Clara County building.

FIGURE 35.17 Santa Clara County building VE damper configuration.

level as shown in Figure 35.16, which would increase the equivalent damping in the fundamental mode of the building to about 17% of critical, providing substantial reductions to building response under all levels of ground shaking. A typical damper configuration is shown in Figure 35.17.

35.3.1.4 Viscous Fluid Dampers

Damping devices based on the operating principle of high-velocity fluid flow through orifices have found numerous applications in shock and vibration isolation of aerospace and defense systems. In the past decade, research and development of viscous fluid dampers for seismic applications to civil

engineering structures have been performed to accomplish three major objectives. The first was to demonstrate by analysis and experiment that viscous fluid dampers can improve seismic capacity of a structure by reducing damage and displacements and without increasing stresses. The second was to develop mathematical models for these devices and demonstrate how these models can be incorporated into existing structural engineering software codes. Finally, the third was to evaluate reliability and environmental stability of the dampers for structural engineering applications.

As a result, viscous fluid (VF) dampers have in recent years been incorporated into many civil engineering structures. For example, early applications of VF dampers include the Pacific Bell North Area Operations Center and the Woodland Hotel in California and a 35-story building in downtown Boston (Constantinou et al. 1998).

As with most of the passive systems considered above, the VF dampers are incorporated into the structural system through the use of either diagonal or chevron bracing. With this configuration, the magnitude of the displacement across the passive device is at most equal to the interstory drift. Consequently, large dampers may be required, particularly for stiff structures.

One remedy is to introduce a damping amplification, such as in the toggle-brace damper system (Constantinou et al. 2001). Furthermore, in order to reduce the impact of bracing on the architectural aspects of design, alternative configurations can be utilized. An example is the scissor-jack-damper energy dissipation system (Sigaher and Constantinou 2003), which can provide relatively open bays and damping magnification factors between two and five.

In several other applications, VF dampers were used in combination with seismic isolation systems. For example, VF dampers were incorporated into base isolation systems for five buildings of the new San Bernardino County Medical Center, located close to two major fault lines, in 1995. The five buildings required a total of 233 dampers, each having an output force of 320,000 lbs and generating an energy dissipation level of 3,000 horsepower at a speed of 60 in./s. A layout of the damper-isolation system assembly is shown in Figure 35.18 and Figure 35.19 gives the dimensions of the viscous dampers employed.

FIGURE 35.19 Dimensions of viscous fluid damper for San Bernardino County Medical Center.

FIGURE 35.20 Undamped absorber and main mass subject to harmonic excitation (Frahm's absorber).

35.3.1.5 Tuned Mass Dampers

The modern concept of tuned mass dampers (TMDs) for structural applications has its roots in dynamic vibration absorbers studied as early as 1909 by Frahm (Den Hartog 1956). A schematic representation of Frahm's absorber is shown in Figure 35.20, which consists of a small mass m and a spring with spring stiffness k attached to the main mass M with spring stiffness K . Under a simple harmonic load, one can show that the main mass M can be kept completely stationary when the natural frequency ($\sqrt{k/m}$) of the attached absorber is chosen to be (or tuned to) the excitation frequency.

As in the case of VE dampers, early applications of TMDs have been directed toward mitigation of wind-induced excitations. It appears that the first structure in which a TMD was installed is the Centerpoint Tower in Sydney, Australia (ENR 1971; Kwok and MacDonald 1987). One of only two buildings in the United States equipped with a TMD is the 960-ft Citicorp Center in New York, NY, in which the TMD is situated on the 63rd floor. At this elevation, the building can be represented by a simple modal mass of approximately 20,000 tons, to which the TMD is attached to form a two-degrees-of-freedom system. Tests and actual observations have shown that the TMD produces an approximate effective damping of 4% as compared to the 1% original structural damping, which can reduce the building acceleration level by about 50% (Petersen 1980, 1981). The same design principles were followed in the development of the TMD for installation in the John Hancock Tower, Boston, MA (ENR 1975). In this case, however, the TMD consists of two 300-ton mass blocks. They move in phase to provide lateral response control and out-of-phase for torsional control.

Numerical and experimental studies have been carried out to examine the effectiveness of TMDs in reducing seismic response of structures. It is noted that a passive TMD can only be tuned to a single structural frequency. While the first-mode response of an MDOF structure with TMD can be substantially reduced, the higher-mode response may in fact increase as the number of stories increases. For earthquake-type excitations, it has been demonstrated that, for shear structures up to 12 floors, the first-mode response contributes more than 80% to the total motion (Wirsching and Yao 1970). However, for a taller building on a firm ground, higher modal response may be a problem that needs further study. In Villaverde (1994), three different structures were studied; the first is a two-dimensional ten-story shear building, the second a three-dimensional one-story frame building, and the third a three-dimensional cable-stayed bridge, by using nine different kinds of real earthquake records. Numerical and experimental results show that the effectiveness of TMDs on reducing the response of the same structure under different earthquakes or of different structures under the same earthquake is significantly different; some cases give good performance and some have little or even no effect. It implies that there is a dependency of the attained reduction in response on the characteristics of the ground motion that excites the structure. This response reduction is large for resonant ground motions and diminishes as the dominant

frequency of the ground motion gets further away from the structure's natural frequency to which the TMD is tuned.

It is also noted that the interest in using TMDs for vibration control of structures under earthquake loads has resulted in some innovative developments. An interesting approach is the use of a TMD with active capability, the so-called AMD or active tuned mass damper. Systems of this type have been implemented in a number of tall buildings in Japan (Soong et al. 1994). Some examples of such systems will be discussed in [Section 35.3.2](#).

35.3.1.6 Tuned Liquid Dampers

The basic principles involved in applying a tuned liquid damper (TLD) to reduce the dynamic response of structures is quite similar to that discussed above for the TMD. In effect, a secondary mass in the form of a body of liquid is introduced into the structural system and tuned to act as a dynamic vibration absorber. However, in the case of TLDs, the response of the secondary system is highly nonlinear due either to liquid sloshing or the presence of orifices. TLDs have also been used for suppressing wind-induced vibrations of tall structures. In comparison with TMDs, the advantages associated with TLDs include low initial cost, virtually free maintenance, and ease of frequency tuning.

It appears that TLD applications have taken place primarily in Japan. Examples of TLD-controlled structures include the Nagasaki Airport Tower, installed in 1987, the Yokohama Marine Tower, also installed in 1987, the Shin-Yokohama Prince Hotel, installed in 1992, and the Tokyo International Airport Tower, installed in 1993 (Tamura et al. 1994, 1995). The TLD installed in the 77.6 m Tokyo Airport Tower, for example, consists of about 1400 vessels containing water, floating particles, and a small amount of preservatives. The vessels, shallow circular cylinders 0.6 m in diameter and 0.125 m in height, are stacked in six layers on steel-framed shelves. The total mass of the TLD is approximately 3.5% of the first-mode generalized mass of the tower and its sloshing frequency is optimized at 0.743 Hz. Floating hollow cylindrical polyethylene particles were added in order to optimize energy dissipation through an increase in surface area together with collisions between particles.

The performance of the TLD has been observed during several storm episodes. In one of such episodes with a maximum instantaneous wind speed of 25 m/s, the observed results show that the TLD reduced the acceleration response in the cross-wind direction to about 60% of its value without the TLD.

35.3.2 Active Control

As mentioned in [Section 35.1](#), the development of active, hybrid, and semiactive control systems has reached the stage of full-scale applications to actual structures. Since 1989, over 40 active or hybrid systems have been installed in building structures, primarily in Japan. In addition, a number of bridge towers have employed active systems during erection (Fujino 1994).

In recent years, significant effort has also been directed toward the development of semiactive control devices and systems. These systems permit the variation of device properties (e.g., stiffness, damping) based upon structural response. Often very little power is required to operate these devices and fail-safe passive modes are provided. Examples of semiactive devices include variable stiffness systems (Kobori et al. 1993; Liang et al. 1999a,b), variable fluid dampers (Patten et al. 1996; Symans and Constantinou 1997; Kurata et al. 1999), electrorheological dampers (Gavin et al. 1996a,b; Makris et al. 1996), and magnetorheological dampers (Spencer et al. 1997; Yang et al. 2002).

A complete review of active, hybrid, and semiactive systems will not be attempted here. Instead, described briefly below are two active control applications and their observed performances. The performances of these systems under recent wind and earthquake episodes are summarized in this section. More details of these applications can be found in Soong et al. (1994).

35.3.2.1 Sendagaya INTES Building

An AMD system was installed in the Sendagaya INTES building in Tokyo in 1991. As shown in [Figure 35.21](#), the AMD was installed atop the 11th floor and consists of two masses to control transverse

FIGURE 35.21 Sendagaya INTES building.

FIGURE 35.22 Top view of AMD in Sendagaya building.

and torsional motions of the structure while hydraulic actuators provide the active control capabilities. The top view of the control system is shown in Figure 35.22 where ice thermal storage tanks are used as mass blocks so that no extra mass is introduced. The masses are supported by multistage rubber bearings intended for reducing the control energy consumed in the AMD and for insuring smooth mass movements (Higashino and Aizawa 1993).

Sufficient data were obtained for evaluation of the AMD performance when the building was subjected to strong wind on March 29, 1993, with peak instantaneous wind speed of 30.6 m/s. An example of the response Fourier spectra using samples of 30-s durations are shown in Figure 35.23, showing good performance in the low-frequency range. The response of the fundamental mode was reduced by 18 and 28% for translation and torsion, respectively. Similar performance characteristics were observed during a series of earthquakes recorded between May 1992 and February 1993.

FIGURE 35.23 Sendagaya building — response Fourier spectra (March 29, 1993).

FIGURE 35.24 Hankyu Chayamachi building.

35.3.2.2 Hankyu Chayamachi Building

The 160-m 34-story Hankyu Chayamachi building, as shown in Figure 35.24, is located in Osaka, Japan, where an AMD system was installed in 1992 for the primary purpose of occupant comfort control. In this case, the heliport at the roof top is utilized as the moving mass of the AMD, which weighs 480 tons and is about 3.5% of the weight of the tower portion. The heliport is supported by six multistage rubber bearings. The natural period of rubber and heliport system was set to 3.6 s, slightly lower than that of the building (3.8 s). The AMD mechanism used here has the same architecture as that of Sendagaya INTES, namely, scheme of the digital controller, servomechanism, and the hydraulic design, except that two

FIGURE 35.25 Hankyu Chayamachi building — acceleration Fourier spectra.

actuators of 5-ton thrusts are attached in horizontal orthogonal directions. Torsional control is not considered here.

Acceleration Fourier spectra during a recent typhoon are shown in Figure 35.25. Since the building in this case oscillated primarily in its fundamental mode, significant reductions in acceleration levels were observed.

An observation to be made in the performance of control systems such as those described above is that efficient active control systems can be implemented with existing technology under practical constraints such as power requirements and stringent demand of reliability. Thus, significant strides have been made considering that serious implementational efforts began less than 10 years prior to construction. On the other hand, the active dampers developed for Sendagaya INTES and Hankyu Chayamachi buildings were designed primarily for response control due to wind and moderate earthquakes. In order to reach the next level in active/hybrid control technology, an outstanding issue that needs to be addressed is whether such systems, with limited control resources and practical constraints such as mass excursions, can be made effective under strong earthquakes.

35.4 Code Development

Extensive efforts in the field of passive energy dissipation and the increased interest of the engineering profession in this area over the past decade has resulted in the development of guidelines and recommended provisions for the design and implementation of passive energy dissipation devices. A brief review of that development in the United States is provided in this section.

Initially, the Energy Dissipation Working Group (EDWG) of the Base Isolation Subcommittee of the Structural Engineers Association of Northern California (SEAONC) developed a document that provided design guidelines applicable to a wide range of system hardware (Whittaker et al. 1993). The scope included metallic, friction, viscoelastic, and viscous devices. On the other hand, TMDs and TLDs were not addressed. The general philosophy of that document was to confine inelastic deformation primarily to the energy dissipators, while the main structure was to remain elastic for the design basis earthquake. Furthermore, since passive energy dissipation technology was still relatively new, a conservative approach was taken on many issues. For example, an experienced independent engineering review panel was required to conduct a review of the energy dissipation system and testing programs.

The 1994 edition of the National Earthquake Hazard Reduction Program (NEHRP) Recommended Provisions for Seismic Regulations for New Buildings (FEMA 1995) then introduced an appendix on passive energy dissipation systems, which is similar to the SEAONC document in both scope and philosophy. Again, a conservative approach was adopted. However, the primary intention was to introduce passive energy dissipation technology to potential users, rather than to provide design requirements.

More recently, NEHRP Guidelines for the Seismic Rehabilitation of Buildings (FEMA 1997a,b) have been developed to include sections on seismic protective systems. This entire document uses a performance-based design approach in which displacements (or damage) control the design. Chapter 9 of these guidelines, and the associated commentary, specifically addresses seismic isolation and passive energy dissipation systems. The passive systems may involve displacement-dependent (e.g., metallic yielding, friction), velocity-dependent (e.g., fluid viscous, viscoelastic solid, viscoelastic fluid), or other (e.g., shape memory, friction-spring re-centering) devices. Very limited guidance is also provided for dynamic vibration absorbers and active control systems. Four distinct analysis procedures are defined, including linear static, linear dynamic, nonlinear static, and nonlinear dynamic approaches. However, the linear procedures are only applicable under certain restrictive conditions. As with the earlier documents, a comprehensive testing program must be conducted and the design must be reviewed by an independent engineering review panel.

For new construction, the FEMA (1995) document mentioned above has now been superseded by FEMA (2001), which includes an appendix to Chapter 13 on structures with damping systems. As stated in the preface to that appendix, it is intended for trial use by design professionals and other interested parties. Both displacement-dependent and velocity-dependent passive devices are considered. Along with nonlinear static and dynamic analysis procedures, this appendix includes an equivalent lateral force analysis procedure and a response spectrum analysis procedure. (Further details on the theoretical basis for these two new linear methods can be found in Ramirez et al. 2000.) A prototype test program, quality control plan, and independent review panel are again required elements in these recommended provisions.

35.5 Concluding Remarks

An attempt is made in this section to introduce the basic concepts of passive energy dissipation and active control, and to review current development, structural applications, and code-related activities in this exciting and fast expanding field. While significant strides have been made in terms of implementation of these concepts to structural design and retrofit, it should be emphasized that this entire technology is still evolving. Significant improvements in both hardware and design procedures will certainly continue for a number of years to come.

The acceptance of innovative systems in structural engineering is based on a combination of performance enhancement versus construction costs and long-term effects. Continuing efforts are needed in order to facilitate wider and more timely implementation. These include effective system integration and further development of analytical and experimental techniques by which performances of these systems can be realistically assessed. Structural systems are complex combinations of individual structural components. New innovative devices need to be integrated into these complex systems, with realistic evaluation of their performance and impact on the structural system, as well as verification of their ability of long-term operation. Additionally, innovative ideas for new devices require exploration through experimentation and adequate basic modeling. A series of standardized benchmark structural models, representing large buildings, bridges, towers, lifelines, etc., with standardized realistically scaled-down excitations, representing natural hazards, can be of significant value in helping to provide an experimental and analytical testbed for proof-of-concept of existing and new devices. In the United States, the Network for Earthquake Engineering Simulation also can be expected to have a significant impact on the further development of structural protective systems.

36.1 Introduction

Society relies on its engineers to design structures that are safe and perform as intended. The public wants to cross bridges, enter buildings, and live downstream of dams without having to give conscious thought as to whether there is any danger of collapse. The nation's civil engineers have a distinguished history of performing this service. As research has progressed, experience has developed and been codified, and computers have increased computational speed and ability, design methods have become increasingly sophisticated. Traditional design approaches that rely on allowable stress and factor of safety

analysis have expanded to incorporate reliability and system-based performance methods. Design optimization methods are beginning to examine the entire life cycle performance of a structure. While this is a new and evolving (and therefore incomplete) field, this chapter explains many of the principles, concepts, and issues involved in examining the performance of a structure over its entire useful life.

Design optimization research often attempts to produce the lowest cost structure that meets specific design criteria. During the 1960s through the 1990s, the objective often involved minimizing the weight of a structure and considered only the costs of design and construction (labor, equipment, materials, etc.). Over the past 15 years, research efforts have increasingly demonstrated that these initial costs are often dwarfed by the costs of repairing, inspecting, and maintaining a structure over its useful life. A truly optimum and efficient solution needs to account for these costs. In its simplest form, the difference is illustrated in the following two examples.

EXAMPLE 36.1

The local highway department advertised for bids for a concrete highway bridge. The requirements specified that the concrete must exceed 25 MPa in compressive strength and must have a factor of safety of at least 2.0 with respect to a standard HS-20 truck crossing the bridge at all locations. Company A submitted a bid for \$70,000, and Company B submitted a bid for \$100,000. Both designs met the specifications, and both bidders were qualified to do the work. Which company should get the job?

Answer

Company A, based on the lower cost.

EXAMPLE 36.2

The local highway department expects the useful life of the highway bridge to be 60 years. The highway department engineer investigates the two proposals in Example 36.1 further and determines that the design submitted by Company A is less expensive because the concrete is not as durable. This engineer estimates that the Company A bridge will require a major rehabilitation every 20 years for a cost of \$30,000 and will require a major inspection every 5 years at a cost of \$5,000 each time. The Company B bridge will require a major rehabilitation every 30 years for a cost of only \$20,000. The inspection of this bridge will also cost \$5,000, but it only needs to be done every 10 years. The engineer uses a discount rate of money (which accounts for inflation) of 3% and determines that the preventive maintenance and failure costs of both designs are about equal and, therefore, irrelevant to the decision. Both options require a major rehabilitation at year 60, so there is no difference in salvage value. Which company should get the job?

Answer

The analysis requires that the costs associated with both projects be converted to present value for a valid comparison. Even though the Company A bid appears to now cost \$185,000 (i.e., undiscounted total cumulative cost = \$70,000 + 2 × \$30,000 + 11 × \$5,000), over the life of the structure compared to \$145,000 (i.e., undiscounted total cumulative cost = \$100,000 + \$20,000 + 5 × \$5,000) for Company B, the timing of the payments is important.

The equation for converting a future value (FV) to a present value (PV) is

$$PV = \frac{FV}{(1+r)^n}$$

where r is the discount rate and n is the number of years.

Company A

$$\begin{aligned} \text{Total cost} &= \$70,000 + \frac{\$30,000}{(1+0.03)^{20}} + \frac{\$30,000}{(1+0.03)^{40}} + \frac{\$5,000}{(1+0.03)^5} + \frac{\$5,000}{(1+0.03)^{10}} + \cdots + \frac{\$5,000}{(1+0.03)^{55}} \\ &= \$70,000 + \$16,610 + \$9,197 + \$4,313 + \$3,720 + \cdots + \$1,141 + \$984 = \$121,022 \end{aligned}$$

Company B

$$\begin{aligned} \text{Total cost} &= \$100,000 + \frac{\$20,000}{(1 + 0.03)^{30}} + \frac{\$5,000}{(1 + 0.03)^{10}} + \frac{\$5,000}{(1 + 0.03)^{20}} + \frac{\$5,000}{(1 + 0.03)^{30}} \\ &\quad + \frac{\$5,000}{(1 + 0.03)^{40}} + \frac{\$5,000}{(1 + 0.03)^{50}} \\ &= \$100,000 + \$8,240 + \$3,720 + \$2,768 + \$2,060 + \$1,533 + \$1,141 = \$119,462 \end{aligned}$$

The two options are quite similar, but it now looks like Company B bid would provide the lower life cycle cost and would be the better choice. The result is highly sensitive to the discount rate. If the discount rate had been 4% instead of 3%, Company A would have been a better choice with a life cycle cost of \$110,350 versus a cost to Company B of \$115,113. Note that (a) the total present value costs decrease as the discount rate rises and (b) the present value costs of expenses late in the life of the structure can become negligible. For this problem the crossover discount rate is about 3.2%, where for any discount rate above that value, Company A will be the preferred alternative. Company B is the best choice for any rate below 3.2% as shown in Figure 36.1a. However, if the service life is reduced to 40 years, Company A is the better choice for any value of the discount rate different from 0% (i.e., at 0% Companies A and B have the same lifetime cost of \$135,000, as shown in Figure 36.1b).

FIGURE 36.1 Present value of total cumulative cost for two competing bids associated with various discount rates for a structure with (a) 60-year service life and (b) 40-year service life.

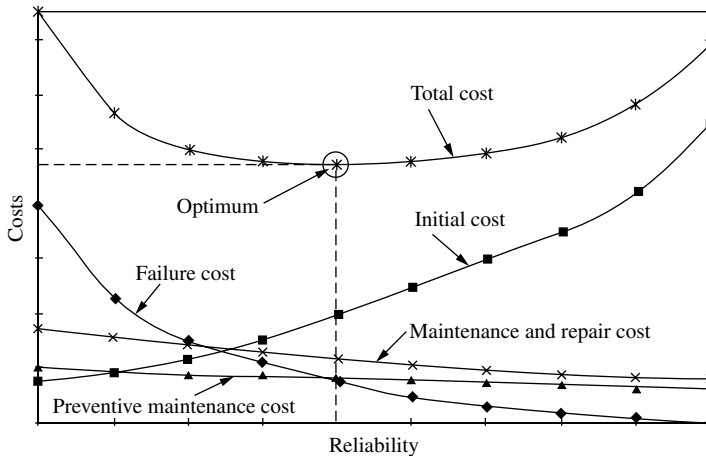

FIGURE 36.2 Optimum reliability of a structure based on total life cycle cost.

These two simple examples illustrate the difference between a traditional design approach, which relies only on the initial cost of the structure, and the life cycle cost approach, which includes all costs over the useful life of the structure. These total life cycle costs are the sum of the initial cost, maintenance costs, inspection and repair costs, and cost of failure. The failure cost typically comprises those costs associated with structural failure multiplied by their probability of occurrence. Incorporating the failure cost requires a probabilistic assessment of the structure, which by necessity requires a reliability-based approach to the problem. Once the costs have been computed and included, an optimum solution, as shown in Figure 36.2, produces the lowest total life cycle cost.

While the life cycle cost is a better measure on which to make a decision, the approach is more complex and introduces many additional issues and considerations over the traditional approach. The discount rate is only one consideration. Others include the following: what costs are included in the failure cost, what is the effect of maintenance on the reliability of a structure, how is a structure expected to deteriorate over time, how far can a structure be allowed to deteriorate before public safety requires a repair, how often should a structure be inspected and how reliable is the information provided by each inspection? The answers to these questions are the subject of frequent debate and the focus of considerable research. The approaches are still being developed. This chapter will address many of these issues, show some relevant examples, and provide some initial solutions to this evolving field.

36.2 Safety and Risk Assessment

Society expects its infrastructure to be safe and depends on its engineers to make it so. The American Society of Civil Engineers (ASCE) canon of ethics requires that the safety of the public is paramount. Sadly, there is no absolute guarantee of safety, and if there was, it would be prohibitively expensive. Risk is usually defined as the product of the failure probability and the consequences (i.e., measured in monetary terms) of failure. The responsibility of civil engineers is to find an acceptable level of risk that society can tolerate and then design and maintain structures to ensure that risk is not exceeded. Engineers are expected to do this within a reasonable cost, which becomes both a balancing act and an optimization problem. Even a deterministic approach to structural analysis attempts to define safety, usually in the form of a factor of safety. Reliability methods offer a more detailed accounting of risk that involves quantifying the uncertainty associated with every variable, the correlation between the variables, the system relationship between structural components, and the consequences of failure. Reliability methods are complex and require significant input data to execute. An elementary example is illustrated as follows.

EXAMPLE 36.3

Two structures are designed to withstand a load with an expected value of 100 kN. The load can vary slightly; in fact, it is estimated to be a normally distributed variable with a standard deviation of 10 kN. Structure A is made of a highly tested material that produces consistent and repeatable results. Its strength is normally distributed with a mean strength of 150 kN and a standard deviation of only 5 kN. Structure B is composed of a stronger material but one that shows greater variability in its characteristics. Its strength is also normally distributed and has a mean of 200 kN but a standard deviation of 30 kN. The load and the strength in both structures are independent — and therefore uncorrelated. Quantify the safety using both a deterministic and a probabilistic approach and decide which structure is safer.

Answer

Using the deterministic approach, the factor of safety (FS) is defined as the ratio of the capacity of the structure to the demand placed on it.

Structure A

$$\text{FS} = \frac{\text{Capacity}}{\text{Demand}} = \frac{150}{100} = 1.5$$

Structure B

$$\text{FS} = \frac{200}{100} = 2.0$$

Structure B has the larger factor of safety and is, therefore, safer.

Taking a probabilistic approach for two statistically independent, normally distributed random variables, the safety is expressed in terms of a reliability index (β).

Structure A

$$\beta = \frac{\mu_{\text{Capacity}} - \mu_{\text{Demand}}}{\sqrt{\sigma_{\text{Capacity}}^2 + \sigma_{\text{Demand}}^2}} = \frac{150 - 100}{\sqrt{10^2 + 5^2}} = 4.47$$

Structure B

$$\beta = \frac{200 - 100}{\sqrt{10^2 + 30^2}} = 3.16$$

where μ_x and σ_x are the mean and standard deviation of the random variable X . The random variables in this problem are capacity and demand.

Under these conditions, the reliability index is translated to a probability of failure as follows: $p_f = \Phi(-\beta)$, where Φ is the distribution function of the standard normal variate. From a Table of Standard Normal Probability, one observes that the probability of failure for Structure A is approximately $p_f = 0.0000038$ and for Structure B, $p_f = 0.00079$. By this analysis, Structure A is the safer structure by a considerable margin. Figure 36.3 illustrates the demand and capacities for the two structures. Failure occurs when demand exceeds capacity. The reliability analysis becomes more complex, as illustrated in Section II, Chapter 12 of the *Handbook*, when the types of probability density distributions vary, the number of random variables increases, and correlation is considered.

While the safety of both structures has been quantified, the question remains as to whether either structure is safe enough to meet societal expectations. Acceptable risk, especially when considering the value of a human life and injuries is difficult to quantify. People die on the highways every day; bridges occasionally collapse; and hurricanes, wildfires, and earthquakes seem to destroy homes and lives every year. For each of these events, there is some level at which the public will demand improvement from their government. The issue of a threshold level of safety is not trivial. Menzies (1996) contends after considerable analysis that society will accept a risk to life of 1 in 1,000,000 per year for the specific example of short-span bridges in the United Kingdom. He further states that acceptable risk levels depend on value judgments and societal norms and cannot be found solely by analysis.

FIGURE 36.3 The capacity and demand for Structures A and B. Failure occurs when demand exceeds capacity.

Fortunately, every engineer does not have to examine societal values and make this determination; those engineers who write the building codes provide that service. As the United States has transitioned to probability-based codes in steel, concrete, and wood, the code committees have wisely calibrated these new codes to those design requirements that have been successful in the past. The American Association of State Highway and Transportation Officials (AASHTO) load and resistance factor design (LRFD) code (AASHTO 1998) calibrates the design of elements of a new bridge in the reliability index range $\beta = 3.0$ to $\beta = 4.0$. The exact value is determined by a load factor modifier η , which accounts for ductility, redundancy, and importance of the structure. If the modifiers, for example, dictated a reliability requirement of $\beta = 3.5$ for Structures A and B in the previous example, it would appear that Structure B ($\beta = 3.16$) was inadequate and Structure A ($\beta = 4.47$) was substantially overdesigned.

While the codes provide a great means to compare different designs, they do not necessarily yet measure society's preferences and risk tolerances. Since there will always be a scarcity of resources to fund everything the public desires, every decision to improve the safety of a bridge or building is a trade-off and a consent to accept additional risk in some other area such as disease prevention or police protection. Risk assessment ultimately needs to be viewed in this broader context. People face risks every day and most of these risks are quantifiable. *Technology Review* (1979) lists smoking 1.4 cigarettes, drinking 0.5l of wine, traveling 300 miles by car, and flying 1000 miles by airplane as activities that increase the chance of death by one in a million. Even with these statistics, people will not make rational preferences such as the family who drives for three days rather than fly to a location because they perceive it to be safer. Corotis (2003a,b) contends that people's perceptions of risk are affected by whether the risk is objective or subjective, aleatoric or epistemic, familiar or unfamiliar, and voluntary or involuntary. Real world decisions are based on that perception of risk which can include dread, familiarity, number of people exposed, trust, and technological stigma. Corotis further suggests that the public uses several standards to assess risk (cost-benefit analysis, revealed preferences, expressed preferences, and calibrated values) and that future building codes should take all of these into account if society's preferences are to be effectively addressed. This remains a fruitful area for future research.

Even if one concedes that the current building codes provide a reasonable assessment of society's tolerance for risk acceptance, there are additional issues with life cycle cost analysis. Any structure will start deteriorating from the day it is placed in service and, if not maintained, will continually worsen over time. In a design situation, the optimization of a life cycle cost must consider the level to which a structure should be designed and to what level it will be allowed to deteriorate before a repair or replacement is needed. Should the reliability specified in the codes be an average reliability over the lifetime of the structure (β_{lifetime}), the reliability to which a structure is designed (β_{design}),

FIGURE 36.4 Alternate life cycle Plans A and B for a designated structure.

or the threshold reliability below which a structure is not allowed to fall ($\beta_{\text{threshold}}$), or do multiple reliabilities need to be specified? The answer to this question has not yet been adequately addressed and remains a promising area of research.

EXAMPLE 36.4

A designer proposes two alternate life cycle plans (Plan A and Plan B) for a structure, as illustrated in Figure 36.4. Which plan should the client accept?

Answer

There is not enough information available to decide. If the plans are to be evaluated on the average reliability over the lifetime of the structure, the plans are equivalent since β_{lifetime} (i.e., $0.5(\beta_{\text{min}} + \beta_{\text{max}})$) is the same for both. Plan A initially designs the structure to a higher level of safety, which incurs greater initial costs of construction and allows the structure to deteriorate to a lower level of safety, which increases the likelihood of failure and thus incurs greater failure costs. Plan B, on the other hand, has a narrower band of acceptable reliability and requires more frequent (and probably more costly) maintenance actions throughout the structural life. All estimated costs and the discount rate would be needed to determine the better plan. In addition, the analysis needs to include societal standards to determine a minimum acceptable value of $\beta_{\text{threshold}}$. A single value for reliability does not completely define the problem.

36.3 Failure Cost

In most life cycle cost analyses, the failure cost represents the costs incurred by a structural failure multiplied by the probability of failure. What appears to be a straight-forward concept can become quite complex. Costs of failure may be expressed in terms of a point-in-time, annual, or lifetime cost depending on the type of problem. The costs of failure can vary by orders of magnitude over the life of the structure depending on the reliability range the structure is allowed to pass through.

EXAMPLE 36.5

Referring to the life cycle plans in Example 36.4 (see Figure 36.4), assume that for Plan A, $\beta_{\text{design}} = 4.0$ and $\beta_{\text{threshold}} = 2.0$ and for Plan B, $\beta_{\text{design}} = 3.5$ and $\beta_{\text{threshold}} = 2.5$. The cost if the structure fails is

expected to be \$2 million. Compute the range of point-in-time failure costs for the two plans assuming that the reliability index was computed using the standard normal variate:

Plan A

$$\begin{aligned}\beta_{\text{design}} &= 4.0 \longrightarrow p_f = 0.0000317 & \text{Cost}_{\text{failure}} &= \$63 \\ \beta_{\text{threshold}} &= 2.0 \longrightarrow p_f = 0.0233 & \text{Cost}_{\text{failure}} &= \$46,000\end{aligned}$$

Plan B

$$\begin{aligned}\beta_{\text{design}} &= 3.5 \longrightarrow p_f = 0.000233 & \text{Cost}_{\text{failure}} &= \$466 \\ \beta_{\text{threshold}} &= 2.5 \longrightarrow p_f = 0.00621 & \text{Cost}_{\text{failure}} &= \$12,420\end{aligned}$$

A lifetime cost of failure would need to account for how this cost changes over time. The more controversial issue is what costs are included when computing the cost of failure.

EXAMPLE 36.6

The Highway Department commissioned a study to determine the costs associated with the failure of a highway bridge that crosses the river going through the center of town. The study reported a failure cost of \$67 million broken down as follows:

Cost of clean-up. \$1.2 million

Design cost of new bridge. \$2.2 million

Cost of constructing a new bridge. \$13.5 million

Expected cost of human injuries. \$2.5 million (based on the estimated ten people injured and relying on insurance actuaries to estimate a cost)

Expected cost of additional lawsuits. \$5 million

Cost of accident investigation. \$0.9 million

Cost of legislation and oversight to prevent similar occurrence. \$2.7 million

User costs. \$37.0 million (based on the 10,000 people using the bridge every day, who will lose 1 hour on alternate crossing means for 180 days, plus the additional commercial costs associated with transporting goods on alternate routes)

Loss of goodwill and public trust. \$2.0 million (almost impossible to evaluate)

What is a realistic cost of failure to use for a life cycle analysis?

Answer

There is no correct answer, which is why this cost is so controversial. The most rigid approach is for the Highway Department to only count those costs that come out of its own budget and that have to be paid directly. In that case, the failure cost would be the \$16.9 million associated with the costs of clean-up, establishing an alternate crossing, and providing a new bridge (i.e., \$1.2 million + \$2.2 million + \$13.5 million). In the extreme, a private owner might only consider the amount that insurance premiums would rise as a result of a failure.

A more reasonable approach is to include those costs where money will change hands in some form. The failure cost might then be \$28 million, which includes everything except the goodwill and user costs. It is typical for user costs to dwarf all other costs in a life cycle analysis, so a decision on whether or not to use them is critical. Finally, there are others who would include additional costs that are not listed here, and the failure cost might be higher than \$67 million.

In most life cycle analyses, the failure cost, however it is computed, is treated as a deterministic quantity. In reality, it is more uncertain and probabilistic than most other quantities in the analysis. Every cost listed above has some uncertainty associated with it. Attempting to put a cost on a human life or injury is a highly emotional, social, and political issue. Predicting the number of accident victims is highly dependent on the circumstances associated with the structural failure. The cost of repercussions will also depend on the details of the failure and whether the failure is an explainable isolated phenomenon

or follows on the heels of other structural failures and generates public pressure for greater action. The collapse of the Silver Bridge in 1967 resulted in the monumental bridge inspection and reporting program in place today. If that cost was included in the failure cost of the Silver Bridge, it would add substantially to the amount. If it was, it would also have to be offset by the benefit derived from a mandated biennial bridge inspection program. Again, the point is that failure costs are hotly debated, highly uncertain, and tremendously difficult to compute — another area ripe for future research.

Ayyub and Popescu (2003) have developed software that includes the probability of failure and consequence assessment in deciding among competing projects. Reliability and failure consequences can be considered along with cost, project criticality, use level, and societal preference in making a risk-informed decision on an expenditure. An analytical hierarchy is established, and pairwise comparisons of the various alternatives are made with respect to the relevant criteria. The results are comparison matrices and priority vectors that provide a weighted summation that is used to prioritize the choices. This represents just one attempt to incorporate the failure cost with other relevant criteria to make an optimal life cycle decision.

36.4 Condition Assessment and System Performance

Life cycle cost requires that the condition of a structure be assessed throughout its useful life. While it would be possible to track the factor of safety as a structure deteriorates and experiences different loads over time, reliability methods are much more reasonable — especially if a probability of failure is needed to compute the failure cost. Since the fundamentals of a reliability analysis are covered in [Section II, Chapter 12](#) of the *Handbook*, they are not repeated here. To summarize, if the capacity, R , and the demand, L , are random and the uncertainties can be quantified, then the reliability or probability of safe performance, p_s , can be expressed as

$$p_s = P(R - L > 0) = \iint_{R > L} f_{R,L}(r, l) \, dr \, dl$$

where $f_R(r)$ and $f_L(l)$ are the probability density functions (PDFs) of R and L , respectively and $f_{R,L}(r, l)$ is their joint PDF. A limit state function, $g(\mathbf{X}) = 0$, describes the performance of the system in terms of the vector of basic random variables, \mathbf{X} , and defines the failure surface, which separates the survival region from the failure region.

While current design codes focus on designing for specific components and failure modes, structural systems may have multiple components or failure modes. There are many advantages in quantifying the interrelationship between these components and analyzing a structure as an entire system. For example, a system analysis can reveal that some repairs are more important than others. It may also indicate that while each individual component of a structure may have adequate safety, the structure as a whole may still be unsafe.

36.4.1 Series Systems

A series system, also called a weakest-link system, fails when any individual member in the system fails. A chain is only as strong as its weakest link — and that is only true if the failure events are perfectly correlated. If a series system is treated as a series of z elements, the probability of failure of the system p_f is written as the probability of a union of events:

$$p_f = p\left(\bigcup_{a=1}^z \{g_a(\mathbf{X}) \leq 0\}\right)$$

where $\bigcup_{a=1}^z \{g_a(\mathbf{X}) \leq 0\}$ is the union of all z failure mode events. Depending on the correlation between the failure modes, the possible range of values for p_f are (Cornell 1967)

$$\max[p_f(a)] \leq p_f \leq 1 - \prod_{a=1}^z (1 - p_f(a))$$

The lower bound occurs when the failure modes are perfectly correlated ($\rho = 1.0$) and the upper bound when they are statistically independent ($\rho = 0.0$), where ρ is the correlation coefficient between the safety margins of any pair of failure modes. Ditlevsen (1979) developed tighter bounds using joint-event probabilities, which accounted for failure mode correlation.

EXAMPLE 36.7

A series system consists of three components, where the probability of failure of each individual component is $p_f = 0.01$. What is the probability of failure of the system if the failure modes are independent? If they are perfectly correlated?

Answer

If the three failure modes are independent, so the correlation is $\rho = 0.0$, the failure probability of the system is

$$p_{f,\text{series}} = 1.0 - (1.0 - 0.01)(1.0 - 0.01)(1.0 - 0.01) = 0.0297$$

If the three failure modes are perfectly correlated, so the correlation is $\rho = 1.0$, the failure probability of the system is $p_{f,\text{series}} = 0.01$.

36.4.2 Parallel Systems

A parallel system, also called a redundant or fail-safe system, requires every individual member to fail for the system to fail. A parallel system is at least as safe as its most reliable member. The probability of failure of a parallel system is the probability of an intersection of failure events:

$$p_f = p\left(\bigcap_{a=1}^z \{g_a(\mathbf{X}) \leq 0\}\right)$$

where $\bigcap_{a=1}^z \{g_a(\mathbf{X}) \leq 0\}$ is the intersection of all z failure mode events.

The possible range of values for this system failure probability are (Ang and Tang 1984)

$$\prod_{a=1}^z (1 - p_f(a)) \leq p_f \leq \min[p_f(a)]$$

where the lower bound results from mutual independence and the upper bound from perfect correlation. These bounds are often too wide to provide a useful solution. An alternative approach is to reduce all random variables to their equivalent normal distributions and solve the n -dimensional joint standardized distribution integral (Thoft-Christensen and Murotsu 1986):

$$p_f = \int_{\beta_1}^{\infty} \int_{\beta_2}^{\infty} \cdots \int_{\beta_z}^{\infty} \frac{1}{(2\pi)^{z/2} \sqrt{\det[\rho_{\text{sys}}]}} e^{-1/2\{\beta\}[\rho_{\text{sys}}]^{-1}\{\beta\}^T} d\{\beta\}$$

where $\{\beta\} = \{\beta_a, \beta_b, \dots, \beta_z\}$, ρ_{sys} is the system correlation matrix, and z is the number of members in the parallel system.

EXAMPLE 36.8

A parallel system consists of three components where the probability of failure of each individual component is $p_f = 0.01$. What is the probability of failure of the system if the failure modes are independent? If they are perfectly correlated?

Answer

For a parallel system consisting of three components whose individual probabilities of failure are $p_f = 0.01$, the system failure probability is upper bounded (first-order) by $p_{f,\text{parallel}} = \min(p_{f1}, p_{f2}, p_{f3}) = 0.01$ if

the three failure modes are perfectly correlated, and it is lower bounded (first-order) by $p_{f,parallel} = (0.01)(0.01)(0.01) = 0.000001$ if the three failure modes are independent. As indicated in this simplified example, there can be huge errors if correlation is neglected.

36.4.3 General Systems

Many general engineering systems can be modeled as a combination of series and parallel systems. For example, a series of y parallel systems where each parallel system a has z_a components would have a probability of failure expressed as

$$p_f = P\left(\bigcup_{a=1}^y \bigcap_{b=1}^{z_a} \{g_{ab}(\mathbf{X}) \leq 0\}\right)$$

where $g_{ab}(\mathbf{X})$ identifies the limit state equation for a specific component in the system model. Most complex systems can be sequentially broken down into simpler equivalent subsystems. The reliabilities of a series subsystem and parallel subsystem are solved individually as described above using the reliabilities and direction cosines at the points of failure of individual components. An example of how a series-parallel system is reduced is shown in Figure 36.5. The system shown contains six components (1–6). Initially, the two parallel subsystems are reduced to equivalent components (7 and 8) that formed part of a series system. The series system is then reduced to a single equivalent component (9). The correlation of the equivalent components is computed using equivalent alpha vectors that are a function of the equivalent direction cosines as described in Estes and Frangopol (1998). Any structural system that can be modeled as a combination of series and parallel components can be analyzed.

EXAMPLE 36.9

The three-bar indeterminate truss shown in Figure 36.6 (Estes 1997; Estes and Frangopol 2001b) is modeled as a series-parallel system where the failure of any two bars will cause failure of the system. Let the event “Bar 2 | 1” indicate failure of bar 2 given that bar 1 has already failed, and let “Bar 1” indicate failure of bar 1. The resistances of the three perfectly ductile bars are assumed random variables as follows:

$$R_{\text{bar1}} \longrightarrow N[15, 1.5], \quad R_{\text{bar2}} \longrightarrow N[15, 1.5], \quad R_{\text{bar3}} \longrightarrow N[10, 1.0]$$

where $N[10, 1.0]$ indicates that the variable is normally distributed with a mean value of 10 kN and a standard deviation of 1.0 kN. The load on the truss P is also a random variable with parameters

FIGURE 36.5 Reduction of a series-parallel system to a single equivalent component. (Estes and Frangopol 2001b. Reprinted with permission from the Computational Structural Engineering Institute.)

FIGURE 36.6 Three-bar indeterminate truss modeled as a series-parallel system. (Estes and Frangopol 2001b. Reprinted with permission from the Computational Structural Engineering Institute.)

$N[20, 4.0]$, where 20 and 4.0 are the mean and standard deviation (in kN), respectively. The resistances are independent. The limit state equations that describe the components in the series-parallel model are (Estes and Frangopol 2001b)

1. Prior to any bars failing (Bar 1, Bar 2, Bar 3)

$$g(1) = R_1(2.0A_1A_3 + \sqrt{2}(A_1A_2 + A_3A_2)) - \sqrt{2}PA_1(\cos \theta + \sin \theta) - 2.0PA_2 \cos \theta = 0$$

$$g(2) = R_2(2.0A_1A_2 + \sqrt{2}(A_1A_2 + A_3A_2)) - \sqrt{2}P((A_1 - A_3) \cos \theta + (A_1 + A_3) \sin \theta) = 0$$

$$g(3) = R_3(\sqrt{2}A_1A_3 + A_1A_2 + A_3A_2) + P(A_3 \sin \theta - A_3 \cos \theta - \sqrt{2}A_2 \cos \theta)$$

2. Given failure of bar 1 (Bar 2 | 1, Bar 3 | 1)

$$g(4) = R_2A_2 - P(\sin \theta + \cos \theta) + \sqrt{2}R_1A_1 = 0$$

$$g(5) = R_3A_3 - P\sqrt{2} \cos \theta + R_1A_1 = 0$$

3. Given failure of bar 2 (Bar 1 | 2, Bar 3 | 2)

$$g(6) = R_1A_1 - \sqrt{2}/2(P(\sin \theta + \cos \theta)) + R_2A_2 = 0$$

$$g(7) = R_3A_3 - \sqrt{2}/2(P(\cos \theta - \sin \theta)) + R_2A_2 = 0$$

4. Given failure of bar 3 (Bar 1 | 3, Bar 2 | 3)

$$g(8) = R_1A_1 - P\sqrt{2} \cos \theta + R_3A_3 = 0$$

$$g(9) = R_2A_2 - P(\sin \theta + \cos \theta) + \sqrt{2}R_3A_3 = 0$$

Answer

Using first-order reliability methods the reliability indices for the three individual bars are found to be $\beta_{\text{bar1}} = 3.48$, $\beta_{\text{bar2}} = 7.42$, and $\beta_{\text{bar3}} = 3.90$. The reliability of the series-parallel system $\beta_{\text{system}} = 4.19$. These reductions and computations were performed using RELSYS (RELIability of SYStems) (Estes and Frangopol 1998), a computer program developed at the University of Colorado. Due to the parallel nature of the model, the reliability of the system was greater than the reliability of two of the bars. The most critical link in the simplified series system was the one involving bars 1 and 3 in parallel, which is why the system reliability was so much lower than the reliability of bar 2. Correlation between failure

modes improves the reliability of a series system and decreases the reliability of a parallel system. Although the resistances are independent, the failure modes are correlated because the same load source P was common to all three bars. Estes and Frangopol (2001b) examine the performance and maintenance of this truss system over time.

In a life cycle cost analysis, the system reliability index accounts for the degree of redundancy and extra safety in a structure. As seen in AASHTO (1998), the importance, ductility, and redundancy of a structure all affect the allowable safety level of a structure. For system performance purposes, Frangopol et al. (1992) classified structural redundancy based on a system redundancy measure (α_{system}) and a redundancy range (γ_{system}), where

$$\alpha_{\text{system}} = \beta_{\text{system}} - \beta_{\text{weakest member}}$$

$$\gamma_{\text{system}} = \beta_{\text{strongest member}} - \beta_{\text{weakest member}}$$

Based on these probabilistic measures, structural systems are classified as follows:

Very redundant systems

$$\alpha_{\text{system}} > \gamma_{\text{system}} \geq 0$$

Redundant systems

$$\gamma_{\text{system}} \geq \alpha_{\text{system}} > 0$$

Nonredundant systems

$$\alpha_{\text{system}} \leq 0$$

EXAMPLE 36.10

Based on the classification system above, categorize the redundancy of the truss shown in Example 36.9.

Answer

$$\alpha_{\text{system}} = 4.19 - 3.48 = 0.71$$

$$\gamma_{\text{system}} = 7.42 - 3.48 = 3.94$$

Since $\gamma_{\text{system}} \geq \alpha_{\text{system}} > 0$, the truss structure is classified as redundant.

36.5 Damage and Deterioration

A life cycle cost analysis for a structure requires a number of assumptions about the loading, resistance, and deterioration. In general, a structure will begin to deteriorate and experience reliability reduction from the day it is placed in service. A predictive model is needed to estimate how the loads and resistances will change over time. The deterioration model is usually derived theoretically, obtained from laboratory data, or extrapolated from the behavior of similar structures under similar conditions. These models predict future performance over several decades and are the basis for optimum life cycle inspection and repair planning. Common deterioration mechanisms include corrosion, fatigue, rotting, and spalling, among others.

EXAMPLE 36.11

A structural engineer is designing a retaining wall where the main structural members are exposed, unpainted steel I-beams located in the downtown area. In performing a life cycle cost analysis of the structure, the designer needs to predict the degree of section loss in the beams over time due to corrosion. Corrosion is a common deterioration mechanism that is difficult to predict since it is dependent on the type of steel, the local environment, the presence of moisture, and even the location of the steel member

in the structure. Ideally, the designer would prefer to allow samples of the same type of steel that is used in the project to corrode over time under the same conditions as the proposed structure and use those data to develop a deterioration model. However, it is costly and time consuming to obtain this information. A literature search reveals that Albrecht and Naeemi (1984) developed a commonly referenced corrosion propagation model that predicts the average corrosion penetration $C(t)$ (μm) at any time t (years) as follows:

$$C(t) = At^B$$

where A and B are regression parameters based on the environment and type of steel. For carbon steel in an urban environment, A has a mean value of $\mu_A = 80.2$ and a standard deviation of $\sigma_A = 33.68$, while $\mu_B = 0.593$ and $\sigma_B = 0.24$. The correlation coefficient between A and B is $\rho_{A,B} = 0.68$. What is the estimated section loss after 10 years? After 20 years?

Answer

A probabilistic analysis using Monte Carlo simulation with @RISK software (Palisade 2003) (100,000 simulations) reveals a distribution for $C(t)$ that looks lognormal in shape and has the parameters shown in Table 36.1. In all cases, the uncertainty in the result, as indicated by the extremely large standard deviation, is quite high and increases with time. Column (1) represents the values if the correlation between A and B is not included in the analysis. Column (2) includes the correlation, and Column (3) truncates the distribution for A at 0.0 on the lower end to prevent any results that show a thickness increase due to corrosion. Such results can be quite different depending on the tools that the analyst chooses to use. The information derived from these tools is not exact, and there is no guarantee that the model from the literature matches how the retaining wall will actually behave. Still, the model provides a reasonable predictive tool to make an estimate, but in each case, the analyst needs to understand its limitations.

EXAMPLE 36.12

The support beams in the retaining wall in Example 36.11 are European wide-flange beams HE 180 M having a yield strength of 355 MPa. The initial dimensions of the beam as shown in Figure 36.7 are $b = 186$ mm, $h = 200$ mm, $t_w = 14.5$ mm, and $t_f = 24$ mm. Apply the thickness loss from Example 36.11 to reflect the loss in moment capacity in the I-beam after 10 years. After 20 years.

Answer

The plastic moment capacity of the beam is the product of the yield strength and the plastic section modulus. Because the beam and the assumed corrosion pattern as shown in Figure 36.7 are symmetrical, the neutral axis is located at the centroid of the beam and does not shift. The plastic section modulus (Z) is the first moment of area about the neutral axis:

$$Z = 2(y_1A_1 + y_2A_2)$$

TABLE 36.1 Thickness Loss on Retaining Wall Support Beam Due to Corrosion, Based on Albrecht and Naeemi (1984) Model

t (years)	Thickness loss $C(t)$					
	$\rho = 0.0$		$\rho = 0.68$		$\rho = 0.68^a$	
	(1)		(2)		(3)	
	μ (μm)	σ (μm)	μ (μm)	σ (μm)	μ (μm)	σ (μm)
10	366	283	423	409	426	408
20	614	603	739	908	743	904

^a Distribution of A is truncated.

FIGURE 36.7 Dimensions necessary for computing the plastic section modulus (Z) on a corroding wide-flange beam.

TABLE 36.2 The Plastic Moment Capacity at Various Points in Time of a Retaining Wall Support Beam that is Deteriorating Due to Corrosion

Time (years)	Plastic section modulus, Z (cm ³)		Yield strength, F_y (MPa)		Plastic moment capacity, M_{capacity} (kN m)	
	μ	σ	μ	σ	μ	σ
0	869	0	394	47.2	342	41.0
10	830	37.2	394	47.2	327	41.9
20	802	78.6	394	47.2	316	49.0
40	754	159	394	47.2	297	72.7

where

$$A_1 = (0.5h - t_f + d_{\text{corr}})(t_w - 2d_{\text{corr}})$$

$$y_1 = 0.5(0.5h - t_f + d_{\text{corr}})$$

$$A_2 = (b - 2d_{\text{corr}})(t_f - 2d_{\text{corr}})$$

$$y_2 = 0.5h - d_{\text{corr}} - 0.5t_f$$

$$d_{\text{corr}} = C(t)/1000$$

Applying a bias factor of 1.11 and the coefficient of variation of 0.12 for the yield strength of steel (Nowak and Collins 1995), the yield strength of steel is a normally distributed variable with a mean of 394 MPa and a standard deviation of 47.2 MPa. Simulation using these parameters provides a moment capacity for the beam shown in Table 36.2.

EXAMPLE 36.13

Assuming that the load effect (i.e., maximum moment caused by the load on the member) on the retaining wall beam is normally distributed with a mean value of 250 kN m and a standard deviation of 25 kN m, assess the condition of the support beam from Example 36.12 in terms of probability of failure at years 10, 20, and 40.

Answer

The probability of failure (p_f) is the probability that the demand will exceed the capacity. In this case, the relevant failure mode is bending, so $p_f = p(M_{\text{demand}} \geq M_{\text{capacity}})$. The limit state equation that defines the failure surface is $g(\mathbf{X}) = X_1 - X_2 = 0$, where $X_1 = M_{\text{capacity}}$ and $X_2 = M_{\text{demand}}$. Because both are assumed to be normally distributed, the results are as follows:

Year 0

$$\beta = \frac{\mu_{\text{Capacity}} - \mu_{\text{Demand}}}{\sqrt{\sigma_{\text{Capacity}}^2 + \sigma_{\text{Demand}}^2}} = \frac{342 - 200}{\sqrt{41.1^2 + 20^2}} = 3.107 \rightarrow p_f = 0.000946$$

Year 10

$$\beta = \frac{327 - 200}{\sqrt{41.9^2 + 20^2}} = 2.735 \rightarrow p_f = 0.003115$$

Year 20

$$\beta = \frac{316 - 200}{\sqrt{49^2 + 20^2}} = 2.192 \rightarrow p_f = 0.014197$$

Year 40

$$\beta = \frac{297 - 200}{\sqrt{72.7^2 + 20^2}} = 1.286 \rightarrow p_f = 0.099142$$

While the loss in plastic section modulus may not appear extreme, the probability of failure has increased dramatically with time.

This example shows how reliability can be computed at points in time for a deteriorating structure. The example was greatly simplified as it assumed that all distributions were normal and that the load did not change over time. It ignored extreme loading events and other failure modes, all of which must be accounted for in a real world problem.

36.6 Time-Dependent Reliability

The methods described above apply to computing the reliability of a structure at a specific point in time. When attempting to make decisions about a structure over its useful life, time becomes an important variable. If the future load and resistance of the structure can be predicted, the simplest approach is a point-in-time method where the reliability is computed at various specific times in the future. A trend is established, and the structure is planned for a repair when the reliability falls below an acceptable target reliability level. Loads tend to increase over time, and the resistance tends to decrease as the structure deteriorates, so the overall reliability can generally be expected to decrease over time. A weakness of this approach is that it fails to account for previous structural performance.

A more accepted, yet increasingly complex, approach to time-dependent reliability is to compute the probability that a structure will perform safely for a specified period of time (Enright and Frangopol 1998a,b). Whereas reliability is defined as the probability that an element is safe at one particular time, the survivor function $S(t)$ defines the probability that an element is safe at any time t :

$$S(t) = P(T \geq t) = p_s(t)$$

where the random variable T represents time and $t \geq 0$. The probability that a failure, $p_f(t)$, takes place over a time interval Δt is expressed as

$$f(t)\Delta t = P[t_1 < T \leq t_1 + \Delta t]$$

where the PDF $f(t) = -S'(t)$. It is assumed that the derivative $S'(t)$ exists. The probability of failure between times t_a and t_b is

$$P(t_a \leq T \leq t_b) = \int_{t_a}^{t_b} f(t) dt$$

The reliability is often expressed in terms of a hazard function, $H(t)$, also called the instantaneous failure rate, the hazard rate, or simply the failure rate. The hazard function expresses the likelihood of failure in the time interval t_1 to $t_1 + dt$ given that the failure has not already occurred prior to t_1 and can be expressed as

$$H(t) = \frac{f(t)}{p_s(t)} = -\frac{-S'(t)}{S(t)} = -\frac{1}{p_s(t)} \frac{dp_s(t)}{dt}$$

Thus, the hazard function is the ratio of $f(t)$ to the survivor function $S(t)$. All hazard functions must satisfy the nonnegativity requirement. Their units are typically given in failures per unit time. Large and small values of $H(t)$ indicate great and small risks, respectively (Leemis 1995).

EXAMPLE 36.14

For the deteriorating retaining wall beam in Example 36.13, use the hazard function to determine the probability that the retaining wall will fail in its 20th year if it has not failed earlier. Table 36.3 shows the hazard functions in 2-year increments based on the following computations:

$$p_s(t) = p_s(0) = 1.0 - p_f(0) = 1.0 - 0.000946 = 0.999054$$

$$\frac{dp_s(t)}{dt} = \frac{dp_s(2)}{dt} = \frac{(0.998844 - 0.999054)}{2 - 0} = -0.00011$$

$$H(t) = H(2) = \frac{-1}{p_s(2)} \frac{dp_s(2)}{dt} = \frac{-1(-0.00011)}{0.998844} = 0.000105$$

The graph of the hazard function is shown in Figure 36.8 Because the numerical differentiation causes uneven jumps in the curve, a best fit line through the points, often by fitting a Weibull distribution to the points, provides a smooth curve. Therefore, as shown in Table 36.3, the hazard rate at year 20, provided by best fit, is $H(20) = 0.001951$.

EXAMPLE 36.15

The retaining wall in the previous example has survived and performed well without maintenance for 19 years. In developing his annual budget, the owner is trying to decide whether this is a cost-effective time to replace the support beams in the structure. The replacement cost for new supporting beams is \$67,000. The new support beams are expected to have a service life of 20 years before they would need replacing again. The discount rate r is 6%. If the wall fails, there are several possible consequences as follows: (a) There is a 30% chance that the wall will simply bow excessively and there will be long-term

TABLE 36.3 The Hazard Function $H(t)$ for the Support Beams in a Retaining Wall That Is Deteriorating Due to Corrosion

Year	Reliability index (β)	Probability of failure (p_f)	Probability of survival (p_s)	Derivative (dp_s/dt)	Hazard function ($H(t)$)	Best fit $H(t)$
0	3.107	0.000946	0.999054	—	—	—
2	3.047	0.001156	0.998844	-0.00011	0.000105	0.000098

8	2.834	0.002297	0.997703	-0.00025	0.000250	0.000266
10	2.735	0.003115	0.996885	-0.00041	0.000410	0.000371
12	2.646	0.004073	0.995927	-0.00048	0.000481	0.000517
14	2.550	0.005381	0.994619	-0.00065	0.000657	0.000721
16	2.422	0.007717	0.992283	-0.00117	0.001177	0.001004
18	2.312	0.010399	0.989601	-0.00134	0.001355	0.001400
20	2.192	0.014197	0.985803	-0.0019	0.001926	0.001951

FIGURE 36.8 The hazard function for a retaining wall beam over a 20-year period.

warning that something is wrong. The entire wall would need to be replaced, control measures would be installed, and an accelerated schedule would result for an estimated cost of \$200,000. (b) There is a 50% chance that the wall will fail catastrophically, slide down the hill, but not spill onto the roadway below. The cost associated with a clean-up, immediate repair, and delaying of traffic while the project is under way is \$450,000. (c) There is a 15% chance that the wall would fail catastrophically, extend onto the highway below, and cause accidents. The estimated cost for this scenario is \$1.2 million. (d) There is a 5% chance of resulting injuries and fatalities, which raises the estimated cost to \$3.6 million. From a purely financial perspective, should the owner replace the wall this year?

Answer

The probability that the wall will fail this year given that it has not failed already is provided by the hazard function in Table 36.3 as $H(t) = H(20) = 0.001951$. The expected cost of failure is illustrated in the event tree in Figure 36.9 and calculated as

$$E(\text{Cost}_{\text{failure}}) = 0.30(\$200,000) + 0.50(\$450,000) + 0.15(\$1,200,000) + 0.05(\$3,600,000) = \$645,000$$

$$E(\text{Cost}_{\text{year 20}}) = \$645,000(0.001951) + \$0(1 - 0.001951) = \$1,242$$

This value represents the annual cost of keeping the retaining wall in service in its present state. In this example, no maintenance is assumed, and thus there is no cost associated with the wall performing as intended.

The annual cost of the support beam replacement is obtained by converting the present value of the \$67,000 replacement cost (C_{pv}) to an annual cost (C_{annual}) over the expected 20-year life.

$$C_{\text{annual}} = \frac{C_{pv}r(1+r)^n}{(1+r)^n - 1} = \frac{\$67,000(0.06)(1+0.06)^{20}}{(1+0.06)^{20} - 1} = \$5,841$$

The beam replacement is not justified at this time based on the comparative annual costs of the alternatives (i.e., \$5841 > \$1242). This methodology is used by the Army Corps of Engineers to justify major rehabilitation projects on structures (USACE 1996).

EXAMPLE 36.16

Based on the information in Example 36.15, what is the annual probability of failure that would justify a replacement of the retaining wall support beams? When is this expected to occur?

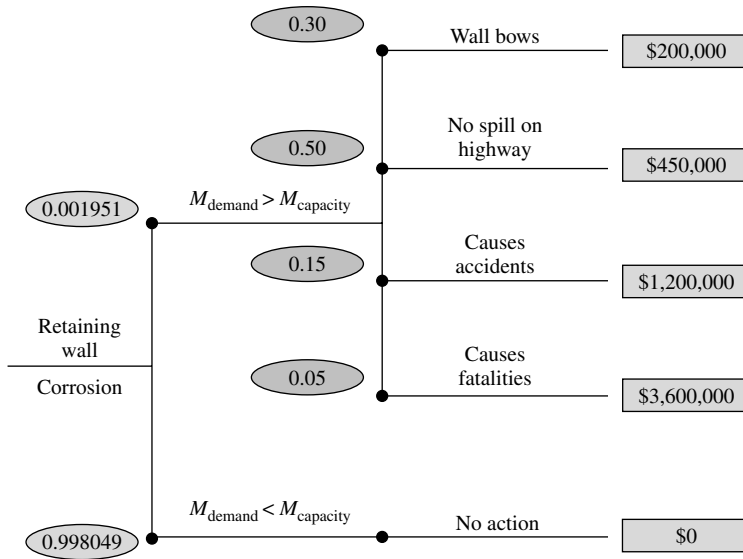

FIGURE 36.9 Event tree that describes the failure consequences and costs associated with the failure of a retaining wall.

The annual probability of failure that would justify the support beam replacement is $\$5,841 / \$645,000 = 0.0091$. By continuing the analysis in Table 36.3, the best-fit values for $H(28) = 0.0074$ and $H(30) = 0.0103$ indicate that the replacement should be justified by the 30th year of service.

36.7 Inspection

The reliability of a structure that is forecasted over several decades is only as valid as the input data and models that support it. Despite the best intentions, a deterioration model taken from the literature or from the behavior of a similar structure under similar conditions could be grossly inaccurate. A systematic inspection program is needed to verify that the structure is behaving as predicted and to provide new data to modify the prediction models if it is not. Inspections can be expensive, so it becomes important to schedule them to optimize the benefit of the information gathered through inspections.

36.7.1 Nondestructive Evaluation Inspection

A nondestructive evaluation (NDE) inspection that is targeted for specific information and does not damage the structure is usually the preferred type of inspection. The information obtained from these inspections is not readily observable and often correlates with a specific defect such as fatigue cracks in members, corrosion of girders, or deterioration of concrete. These techniques (AASHTO 1994) can include radiography, acoustics travel tomography (Bond et al. 2000; Kepler et al. 2000), ultrasonics, thermography, or electric potential, among others. In some cases, such as the thickness of corrosion on exposed steel, a direct measurement is made. In other cases where a defect is hidden, such as scaling of concrete, acoustics travel tomography, thermography, or radar are useful to infer damage. Special methods are used when there is a high degree of correlation between a test result such as electric potential or an acoustical sounding and the defect being sought such as the presence of corrosion in the steel reinforcement of a concrete structure. Sometimes several techniques may be used in combination to improve the confidence in the structural condition. For example, magnetic particle tests, dye penetrants, and ultrasonics are all useful methods to detect fatigue cracks, and if similar conclusions are reached by all three methods, the credibility of the results is enhanced.

Future trends include adaptive computer networks, innovative sensors and wireless technology that will be able to offer continuous monitoring and automated diagnostics on critical structures. In all cases, a probabilistic analysis must account for the ability of the equipment to detect a specific level of damage or distress. Similarly, false positives, where the equipment indicates damage where none exists, must be considered.

EXAMPLE 36.17

A local Department of Transportation (DOT) management policy is to replace its concrete bridge decks when there is active corrosion in 50% of the deck. A serviceability failure in concrete decks is often determined by the amount of active corrosion in the steel reinforcing. The expansion due to corrosion causes concrete to spall, which reduces driving speeds, increases accident hazards, and eventually requires replacement of the deck. The half-cell potential test is used to detect active corrosion in concrete slab reinforcement by measuring the electric potential difference between a standard portable copper–copper sulfate half-cell placed on the surface of the concrete and the embedded reinforcing steel. According to ASTM (1987), if the potential difference reading is more positive than -200 mV, there is a greater than 90% probability that corrosion activity is not taking place in that area. Similarly, if the potentials of an area are more negative than -350 mV, there is a greater than 90% probability that corrosion activity is taking place. For electric potential readings that fall in between those ranges, corrosion activity is more uncertain.

In an effort to better quantify the uncertainty, Marshall (1996) compiled the half-cell potential data from 89 different bridges. The PDF of half-cell potentials in areas where the deck was known to be undamaged (i.e., there was no reinforcement corrosion) was a normal distribution with a mean value of -207 mV and a standard deviation of 80.4 mV. Similarly, the PDF for half-cell readings in damaged areas of deck was found to be $N[-354$ mV, 69.7 mV] as shown in Figure 36.10. The overlap of the two PDFs indicates a significant risk of misinterpretation of actual readings based on half-cell potential mapping.

FIGURE 36.10 Probability density functions (PDFs) of half-cell potentials in areas where the deck is known to be damaged and undamaged.

In a half-cell potential test for a bridge deck, readings were taken at eight locations evenly spread throughout the deck. The potential difference readings in (mV) were $-200, -225, -297, -300, -305, -310, -197,$ and -330 . What is the probability of active corrosion at each of these locations? Estimate the percentage of damage to the deck. Does it need to be replaced at this time?

Answer

The probability of damage (p_{dam}) at one of the readings can be determined as

$$P_{dam} = \frac{\text{pdf}_{\text{bad-}x}}{\text{pdf}_{\text{bad-}x} + \text{pdf}_{\text{good-}x}}$$

where $\text{pdf}_{\text{bad-}x}$ and $\text{pdf}_{\text{good-}x}$ are the values of the density distributions in Figure 36.10 for the damaged and undamaged decks for a half-cell reading of x , respectively. Because the distributions in Figure 36.10 are both normal, the probability of damage when the half-cell reading is -200 mV is obtained as follows:

$$\text{pdf}_{\text{good-}(-200 \text{ mV})} = \frac{1}{\sigma\sqrt{2\pi}} e^{-(1/2)((x-\mu)/\sigma)^2} = \frac{1}{80.4\sqrt{2\pi}} e^{-(1/2)((200-207)/80.4)^2} = 0.004943$$

$$\text{pdf}_{\text{bad-}(-200 \text{ mV})} = \frac{1}{69.7\sqrt{2\pi}} e^{-(1/2)((200-354)/69.7)^2} = 0.000432$$

$$P_{dam} = \frac{0.000432}{(0.000432 + 0.004943)} = 0.080$$

The results for the other seven readings are computed in a similar manner and are shown in Table 36.4. The assessed percentage of damage over the deck ($p_{dam \text{ deck}}$) would be the weighted average of the probabilities of damage:

$$p_{dam \text{ deck}} = \frac{\sum_{i=1}^n P_{dam i}}{n} = \frac{(0.080 + 0.156 + 0.573 + 0.591 + 0.621 + 0.651 + 0.074 + 0.752)}{8} = 43.7\%$$

where i is an individual half-cell reading and n is the total number of readings taken. According to the repair policy, the deck does need to be replaced until $p_{dam \text{ deck}} = 0.50$, but at $p_{dam \text{ deck}} = 0.437$, it is getting close.

There are three main sources of uncertainty that need to be quantified with an NDE inspection: (a) the quality of the inspection equipment and its ability to accurately read whatever measurement is being taken, (b) the correlation between whatever the equipment is measuring and the presence of an actual defect, and (c) the ability to assess the condition of an entire structure based on a finite number of readings. In Example 36.17, the accuracy of the equipment and whether eight evenly spaced readings were sufficient to assess the condition of the entire deck were not addressed. For a probabilistic analysis and an update of a structure's reliability, these uncertainties should all be quantified and considered. Such data are not readily available for most NDE techniques, are often difficult to obtain, and remain a bountiful area for continued research. Estes and Frangopol (2001c) used these half-cell results to optimize maintenance planning for an existing concrete deck.

TABLE 36.4 Probability of Damage for Various Half-Cell Potential Readings on a Reinforced Concrete Deck

Half-cell reading (-mV)	Probability density distribution for undamaged deck, $\text{pdf}_{\text{good-}x}$	Probability density distribution for damaged deck, $\text{pdf}_{\text{bad-}x}$	Probability of damage, P_{dam}

36.7.2 Visual Inspection — Condition Ratings

Many structures undergo periodic, formalized visual inspections that assess the overall condition of a structure. The Federal Highway Administration (FHWA 2002), for example, requires that every bridge in the National Bridge Inventory be inspected every 2 years and is given a numerical rating ranging from 9 (best) to 1 (worst). Similarly, the Army Corps of Engineers uses a 100-point condition index system to classify lock and dam structures based on a visual inspection (Stecker et al. 1997).

The inspection results come from inspector observations rather than a series of specific tests. The advantages of visual inspections are that they are easy to conduct, require minimal equipment, are not overly time consuming, and are economical. The primary disadvantage is that a visual inspection only discovers surface effects and the minimum detectable flaws are often a function of lighting, visual acuity, viewing angle, and inspector accessibility to the defect (FHWA 1986). Furthermore, the numerical rating is often based on a vague word description. Without making some assumptions, it would be impossible to translate those condition ratings into useful information for a reliability analysis. In the absence of any other information, these visual inspections can be useful.

EXAMPLE 36.18

A bridge engineer is attempting to update the life cycle maintenance plans for the managed highway bridges. When the bridges were designed, the girders were scheduled for replacement based on the reliability after a specific degree of corrosion deterioration. There is neither time nor money to perform a specific inspection on every bridge, but the records of the mandated biennial visual inspections are available. The State DOT has implemented the PONTIS Bridge Management System (PONTIS 1995), which assigns specialized condition ratings to virtually all bridge components. One of the components is Element 107 (Painted Open Steel Girders) which is classified into one of five condition states as shown in Table 36.5 (CDOT 1995; Estes and Frangopol 2003). The word description is a bit vague, so the bridge manager interviews the expert inspectors and further quantifies the definitions of the condition states (CSs) as shown in the last two columns of Table 36.5.

TABLE 36.5 CDOT (1995) Suggested Condition State (CS) Ratings for Element 107: Painted Open Steel Girders (First Three Columns) plus Necessary Revisions (Last Two Columns) to Update Reliability

CS	Description	Rust code	Section loss ^a (%)	Density distribution ^a
1	No evidence of active corrosion; paint system sound and protecting the girder	—	0–2	Lognormal
2	Slight peeling of the paint, pitting, or surface rust, etc.	Light R1	0–5	Normal ^b
3	Peeling of the paint, pitting, surface rust, etc.	R1	0–10	Normal ^b
4	Flaking, minor section loss (<10% of the original thickness)	R2	10–30	Normal ^b
4	Flaking, swelling, moderate section loss (>10% but <30% of the original thickness); structural analysis not warranted	R3		
5	Flaking, swelling, moderate section loss (>10% but <30% of the original thickness); structural analysis not warranted due to location of corrosion on member	R3	>30	Lognormal
5	Heavy section loss (>30% of original thickness); may have holes through base metal	R4		

^a Not part of the PONTIS definition — created to quantify the observed corrosion.

^b The normal distributions are truncated at zero.

Source: Estes and Frangopol 2003. Reprinted with permission from the American Society of Civil Engineers.

For example, the bridge manager discovers that when an inspector classifies a girder as CS 2, there will be somewhere between 0 and 5% section loss. Due to the training that the inspectors receive, they can be expected to classify the bridge correctly 98% of the time. The bridge manager observes the inspection results for three different girders. The first girder is given a rating of CS = 2. It was rated as CS = 1 during the last inspection and has just made the transition to CS = 2. The second girder has been classified as CS = 2 for the fourth consecutive inspection. The third girder has been classified as CS = 2 for the past eight inspections. The bridge manager uses historical data on many similar bridges to determine that a bridge typically remains in CS = 2 for 10.8 years before transitioning to CS = 3. What values for thickness loss might the bridge manager use to conduct the reliability analysis and update the maintenance plan for this bridge?

Answer

It is assumed that a girder enters a CS for the first time at the mean value of section loss associated with this CS. CS 2 is assumed to be normally distributed and is correctly classified 98% of the time. The girder enters this CS at mean section loss value $\mu = 2.5\%$. Assuming that the incorrect inspector classifications (2%) are evenly divided between 1% too low and 1% too high, the standard deviation of section loss is computed using the cumulative distribution function of the standard normal variate $\Phi(s)$. Therefore, if the girder is classified as CS = 2, the probability that all values of section loss are less than 5% is 0.99. Therefore,

$$p(\text{loss} < 5\%) = 0.99 = \Phi\left(\frac{\text{loss} - \mu}{\sigma}\right) = \Phi\left(\frac{5.0\% - 2.5\%}{\sigma}\right)$$

The standard deviation is therefore

$$\sigma = \frac{5.0\% - 2.5\%}{\Phi^{-1}(0.99)} = \frac{2.5\%}{2.33} = 1.074\%$$

The standard deviation would have been higher if the quality of the inspectors had been lower and vice versa. For the first girder that has just entered the CS, the percent section loss parameters are $N[2.5, 1.074]$. As the girder remains longer in a given CS, it is assumed to deteriorate. Assuming linear transition through the CS, the mean value of the distribution is expected to shift progressively higher until it reaches 5% section loss as follows:

$$\frac{(5.0 - 2.5)\%}{10.8 \text{ years}} = 0.23\% \text{ per year}$$

Girder 2 has been at CS = 2 for 6 years (i.e., four consecutive inspections that represent three inspection intervals, each lasting 2 years). The mean value for the Girder 2 section loss is

$$\mu = 2.5\% + 0.23\% \text{ per year} (6 \text{ years}) = 3.89\%$$

Assuming the same rate of mean section loss for all girders and a constant standard deviation of the loss, the percent section loss distribution for Girder 2 is therefore $N[3.89, 1.074]$. Finally, Girder 3 has remained at CS = 2 for 14 years (seven inspection intervals), which exceeds the expected 10.8-year transition period. It would be unreasonable to assume a mean value of section loss greater than 5% because an inspector would have logically classified such a girder as CS = 3. The percent section loss distribution for Girder 3 is therefore $N[5.0, 1.074]$ and will remain at that rating until an inspector rates the girder into a higher CS.

This example illustrates just one approach to the problem. The bridge manager could have assumed a constant coefficient of variation rather than a constant standard deviation throughout the CS. The object is to make conservative assumptions and determine how a structure is actually behaving in relation to the deterioration model that may have been postulated several decades earlier. While this approach is not a substitute for a specified NDE inspection, it is better than no additional information. At least, it will identify those structures where a more detailed inspection is needed. This approach has been used on an actual highway bridge (Estes and Frangopol 2003) and on the miter gate for a navigational structure (Estes et al. 2002, 2004).

36.7.3 Inspection Optimization

Because targeted NDE inspections are time consuming and expensive, they should be planned and timed for when they will produce the most benefit. Such an inspection will typically trigger a decision on whether or not to make a repair. The timing of the inspection should coincide with when the information is most needed.

EXAMPLE 36.19

A highway bridge is expected to have a service life of 45 years. The concrete bridge deck is not expected to last that long and will potentially have to be replaced several times during the life of the bridge. The reinforcing in the bridge deck is expected to corrode as chlorides from the deicing salts penetrate the deck and reach a critical concentration at the reinforcing steel. The tensile forces resulting from the corrosion expansion cause the bridge deck to spall. Based on the deterioration model provided in Estes and Frangopol (2001c), the corrosion initiation time is a normally distributed variable with a mean value of 19.6 years and a standard deviation of 7.51 years. The bridge deck will be replaced when there is active corrosion over 50% of the bridge deck (see Example 36.17). The bridge manager plans for three lifetime inspections using the half-cell potential test. The present value cost of replacing the bridge deck is \$225,600, and the cost of conducting the half-cell test is \$1,072. Using a discount rate of 2% along with the assumptions provided in Estes and Frangopol (2001c), what are the optimal inspection times for the half-cell tests? What is the expected total cost of the inspections and deck replacements?

Answer

Every time an inspection is made, there will be a decision to replace the deck or not replace the deck. With three lifetime inspections, there are eight possible repair/no repair paths available as shown in Figure 36.11. The inspection times are determined by optimizing the minimum expected total lifetime cost $E(C_{\text{tot}})$. The constraints are that the expected damage at each inspection time (t_1 , t_2 , and t_3) and at the end of service life ($t_4 = 45$ years) will be less than the maximum allowable damage of 50% active corrosion. Additional constraints were added so that inspections must be at least 2 years apart, but not more than 20 years apart. Using the optimization program ADS (Vanderplaats 1986), Figure 36.12 shows that the optimum inspection times were at $t_1 = 10.05$ years, $t_2 = 19.76$ years, and $t_3 = 35.45$ years (Estes 1997; Frangopol and Estes 1999; Estes and Frangopol 2001c). The expected percentage of damage, which is a weighted average of the eight possible paths in Figure 36.11, is shown for each time, t . The probability of taking any given path is a function of the probability of failure at the time of inspection, as shown in Figure 36.11. The most likely path, for example, was Branch 6, where the likelihood was 58.9%. The path involves a single repair after the second inspection and no repair after the first and third inspections. This reflects that the deck was 10.2% damaged at t_1 , 50.9% damaged at t_2 , and 30.1% damaged at t_3 . Conversely, the least likely paths (0.1%) were Branch 1 and Branch 8, which are associated with repair after every inspection and after none of the inspections, respectively. The expected damage at any point in time $E(\text{Damage})(t)$ is equal to the sum over all possible branches of the event tree given that the particular branch is taken as $E[\text{Damage}(t) | \text{Branch}_i]$ multiplied by the probability of taking that branch P_{b_i} .

$$E(\text{Damage})(t) = \sum_{i=1}^{2^m} E[\text{Damage}(t) | \text{Branch}_i] \times P_{b_i}$$

where m is the number of inspections.

The minimized expected total cost $E(C_{\text{tot}})$ is the sum of the expected repair costs $E(C_{\text{rep}})$ and the inspection costs C_{insp} . The inspection costs are the discounted actual costs of inspection:

$$C_{\text{insp}} = \sum_{k=1}^m \frac{C_{\text{insp}_k}}{(1+r)^{t_k}} = \frac{\$1,072}{(1+0.02)^{10.06}} + \frac{\$1,072}{(1.02)^{19.76}} + \frac{\$1,072}{(1.02)^{35.45}} = \$2,045$$

FIGURE 36.12 Optimum inspection strategy and expected damage for a bridge deck with 45 years of service life, three lifetime inspections, and 2% discount rate. (Estes and Frangopol 2001c. Reprinted with permission from Elsevier.)

TABLE 36.6 Expected Cost of Repair for Concrete Bridge Deck with 45 Years of Service Life, Three Lifetime Inspections, and 2% Discount Rate

Event tree	Discounted cost of repair				Probability of taking branch	Expected cost of repair
	Repair 1, $t_1 = 10.05$	Repair 2, $t_2 = 19.76$	Repair 3, $t_3 = 35.45$	Total		
Branch 1	\$184,887	\$152,455	\$111,805	\$449,147	0.001	\$449
Branch 2	\$184,887	\$152,455	0	\$337,342	0.003	\$1,012
Branch 3	\$184,887	0	\$111,805	\$296,692	0.058	\$17,208
Branch 4	\$184,887	0	0	\$184,887	0.005	\$924
Branch 5	0	\$152,455	\$111,805	\$264,260	0.160	\$42,281
Branch 6	0	\$152,455	0	\$152,455	0.589	\$89,796
Branch 7	0	0	\$111,805	\$111,805	0.183	\$20,460
Branch 8	0	0	0	0	0.001	0
Total expected cost of repair						\$172,130

Source: Estes and Frangopol 2001c. Reprinted with permission from Elsevier.

The expected cost of repair $E(C_{rep})$ is the sum over all branches of the discounted replacement costs associated with an individual branch $C_{rep|Branch_i}$, multiplied by the probability of taking that branch P_{b_i} ,

$$E(C_{rep}) = \sum_{i=1}^{2^m} C_{rep|Branch_i} P_{b_i}$$

$$C_{rep|Branch_i} = \sum_{j=1}^{nr} \frac{C_{rep_j}}{(1+r)^{t_j}} = \sum_{j=1}^{nr} \frac{\$225,600}{(1+r)^{t_j}}$$

where nr is the total number of repairs. Table 36.6 shows the repair costs associated with each inspection and the expected cost associated with each path. The total expected cost of repair is \$172,130. The total expected cost is therefore

$$E(C_{tot}) = \$172,130 + \$2,045 = \$174,175$$

None of the eight paths as shown will actually be taken. After the first inspection, a decision to repair or not repair will be made. Half of the branches on the tree will be eliminated, and the optimization will be run again using the updated information. Frangopol and Estes (1999) and Estes and Frangopol (2001c) provide more detail on this bridge deck example and methodology.

36.7.4 Updating

Once an inspection has been completed (whether it is NDE or visual), the information should be used to update the assessment of structural condition, the load and deterioration models, and the future repair and maintenance strategies. Bayesian updating techniques are very useful when faced with two sets of uncertain information and a planner needs to know which to believe. Bayesian updating uses both the prior information and the new inspection information to account for the relative uncertainty associated with each (Enright and Frangopol 1999a).

Assume that prior to an inspection, a random variable Θ was believed to have a density function $f'(\Theta)$, where Θ is the parameter of that distribution (i.e., the deterioration model). During an inspection, a set of values x_1, x_2, \dots, x_n representing a random sample from a population X with underlying density function $f(x)$ are observed and are fit to a new density function $f(x_i)$ (i.e., the inspection results). The updated or posterior density function $f''(\Theta)$, which uses both sets of information and provides the best use of both, can be expressed as (Ang and Tang 1975)

$$f''(\Theta) = kL(\Theta)f'(\Theta)$$

where $L(\Theta)$ is a likelihood function and k is a normalizing constant. For the case where both $f'(\Theta)$ and $f(x)$ are normally distributed, the posterior function $f''(\Theta)$ is also normally distributed and has the mean value and standard deviation, respectively, as

$$\mu'' = \frac{\mu(\sigma')^2 + \mu'(\sigma)^2}{(\sigma')^2 + (\sigma)^2} \quad \text{and} \quad \sigma'' = \sqrt{\frac{(\sigma')^2(\sigma)^2}{(\sigma')^2 + (\sigma)^2}}$$

where μ , μ' , and μ'' represent the mean values of the inspection results, the prior distribution, and the posterior distribution, respectively. The values σ , σ' , and σ'' represent the standard deviations of those same distributions.

EXAMPLE 36.20

An engineer is attempting to update the reliability analysis of a miter gate on a navigation lock to justify a major rehabilitation. The miter gate is supported by vertically framed steel beams that are corroding over time. Separate deterioration models were used for the atmospheric zone of the gate, which is only exposed to the air, and the splash zone, which is exposed to raising and lowering of the water in the lock chamber. The predicted values for the mean and standard deviation of the thickness loss (in μm) after 50 years based on the deterioration models for the atmospheric zone are $\mu = 298$ and $\sigma = 197$, respectively. The splash zone is expected to corrode much faster, and its 50-year predicted loss is $\mu = 5,085$ and $\sigma = 1,301$. The miter gate undergoes a periodic visual inspection. With some conservative assumptions, these visual inspections are converted to probabilistic quantities (Estes et al. 2004). The inspection results reveal that the actual section loss is $\mu = 285$ and $\sigma = 151$ and was about the same in both the splash zone and the atmospheric zone. What updated values for section loss will be used in the updated reliability analysis?

Answer

For the atmospheric zone, the posterior distribution is characterized by

$$\mu'' = \frac{285(197)^2 + 298(151)^2}{(197)^2 + (151)^2} = 290$$

$$\sigma'' = \sqrt{\frac{(197)^2(151)^2}{(197)^2 + (151)^2}} = 120$$

For the splash zone, the posterior distribution is characterized by

$$\mu'' = \frac{285(1,301)^2 + 5,085(151)^2}{(1,301)^2 + (151)^2} = 348$$

$$\sigma'' = \sqrt{\frac{(1,301)^2(151)^2}{(1,301)^2 + (151)^2}} = 150$$

Figure 36.13 (Estes et al. 2004) shows the prior, inspection, and posterior distributions for the corrosion loss in both the splash zone and the atmospheric zone. Because of the high degree of corrosion expected in the splash zone and its associated uncertainty, the inspection results dominated the posterior distribution. The projected deterioration and its uncertainty were much less in the atmospheric zone. The deterioration model and the inspection results received about equal weight in computing the posterior distribution. Estes et al. (2002, 2004) provide a complete description of this example.

FIGURE 36.13 Bayesian updating based on inspection results for the atmospheric and splash zones on a corroding miter gate. (Estes et al. 2004. Reprinted with permission from Elsevier.)

36.8 Maintenance and Repair

Maintenance and repair are actions taken to slow a structure’s rate of deterioration, improve its performance, and lengthen its useful life. The options range from preventive maintenance to partial repairs to replacement of major components. For each option, the analyst needs to know the cost of the remediation and its positive effect on the safety of the structure. Based on the answer, the analyst needs to optimize the timing of the maintenance action and compare its benefits to other available options. The situation will be different for every type of structure and deterioration.

The problem is illustrated conceptually in [Figure 36.14](#) (Frangopol et al. 2001c), where under ideal conditions, a structure would perform as intended without maintenance throughout its useful life.

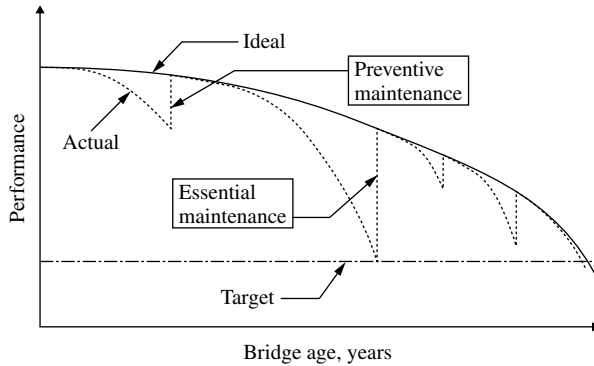

FIGURE 36.14 The effect of various types of maintenance on a typical structure. (Frangopol et al. 2001c. Reprinted with permission from the International Association for Bridge and Structural Engineering.)

TABLE 36.7 Description of the Random Variables Incorporated into an Analysis of the Effects of Preventive Maintenance

Variable	Description
β_0	Initial reliability index
t_i	Time of damage initiation
α	Performance deterioration rate without maintenance
γ	Immediate improvement in reliability index after the application of preventive maintenance
t_R	Rehabilitation time (i.e., time at which the minimum acceptable reliability level is reached without maintenance)
t_{PI}	Time of first application of preventive maintenance
t_P	Time of reapplication of preventive maintenance
t_{PD}	Duration of preventive maintenance effect on bridge reliability
θ	Reliability index deterioration rate during preventive maintenance effect
t_{RP}	Rehabilitation time associated with a preventive maintenance program (i.e., time at which the minimum acceptable reliability level is reached considering preventive maintenance)

Its reliability would decline over time due to a natural aging process, fair wear and tear on the structure, or a gradual increase in the load on the structure and would not fall below an acceptable level during the life of the structure. In reality, structures deteriorate, and various maintenance or repair actions can improve the reliability. It may be preventive maintenance long before a deterioration becomes serious or some form of essential maintenance to prevent the structure from falling below a critical performance level (see Figure 36.14).

36.8.1 Preventive Maintenance

Preventive maintenance may delay the onset of deterioration. A fresh coat of paint will often prevent a steel beam from corroding or a wooden support from rotting. This type of maintenance may also relieve additional stresses on the structure by cleaning an expansion joint or lubricating a bearing. It is often a continuous program with a predictable cost, but the benefits can be difficult to quantify.

Frangopol (1998) and Frangopol et al. (2001b) defined the eight random variable models associated with every aspect of the preventive and essential maintenance processes. This model was successfully applied to individual and groups of bridges in the United Kingdom and the United States (Frangopol et al. 2001b; Frangopol 2003; Frangopol and Neves 2003; Neves and Frangopol 2004; Petcherdchoo et al. 2004). One example of application consisted of maintenance of 713 existing steel/concrete bridges constructed between 1955 and 1998 in the United Kingdom (Frangopol et al. 2001b). Table 36.7 describes all the random variables considered in this example, and Table 36.8 lists their values with

TABLE 36.8 Random Variable Parameters for Preventive Maintenance Based on Database of Existing Bridges

Random variable	Distribution type	Failure mode					
		Shear parameters			Bending parameters		
		(1)	(2)	(3)	(1)	(2)	(3)
β_0	Lognormal	8.5	1.5	—	7.5	1.2	—
t_I (years)	Lognormal	15	5	—	15	5	—
α (years ⁻¹)	Uniform	0.005	0.20	—	0.002	0.10	—
t_{PI} (years)	Lognormal	20	5	—	20	5	—
t_P (years)	Triangular	10	15	20	10	15	20
t_{PD} (years)	Lognormal	10	2	—	10	2	—
θ (years ⁻¹)	Uniform	0.00	0.05	—	0.000	0.025	—
γ	Lognormal	0.2	0.04	—	0.2	0.04	—

Note: Distribution parameters — lognormal: (1) mean value and (2) standard deviation; uniform: (1) minimum value and (2) maximum value; triangular: (1) minimum value, (2) mode value, and (3) maximum value.

FIGURE 36.15 Random variables affecting the reliability of a group of bridges based on a preventive maintenance program. (Frangopol et al. 2001b. Reprinted with permission from the American Society of Civil Engineers.)

respect to shear and moment failure modes of this group of bridges (Frangopol et al. 2001b). Figure 36.15 illustrates the distributions associated with these random values and a sample life cycle plan that shows three applications of preventive maintenance (Frangopol et al. 2001b). Given these variables, Monte Carlo simulation was used to obtain the distributions of the times when essential maintenance is required (i.e., the so called rehabilitation time) with and without previous preventive maintenance actions. The analysis provides the basis for planning the number and timing of preventive maintenance activities to extend the service life of the group of bridges by the desired time period.

EXAMPLE 36.21

Using the mean values for the parameters in Table 36.8, devise a deterministic preventive maintenance plan for a bridge with respect to shear that will extend its useful life by 10 years. Assume that the minimum acceptable reliability index is $\beta_{target} = 3.0$. If each application of preventive maintenance costs \$3,000, what is the present value preventive maintenance cost using a discount rate of 4%?

Answer

For these values, the current life of the bridge structure is

$$t_R = t_1 + \frac{\beta_0 - \beta_{\text{target}}}{\alpha} = 15 + \frac{8.5 - 3.0}{0.1025} = 15 + 53.6 = 68.6 \approx 69 \text{ years}$$

If the bridge life is to be extended 10 years, then a preventive maintenance program will be designed such that $t_{RP} = 79$ years. The preventive maintenance cycle, t_p , lasts 15 years and the change in reliability index during that time is

$$\Delta\beta_{\text{maint}} = t_{PD}\theta + (t_p - t_{PD})\alpha - \gamma = 10(0.025) + (15 - 10)(0.1025) - 0.12 = 0.5625$$

For the equivalent 15-year time period without maintenance, the change in reliability index is

$$\Delta\beta_{\text{no-maint}} = t_p\alpha = 15(0.1025) = 1.5375$$

The benefit of a preventive maintenance application in terms of increment in reliability index is

$$\Delta\beta = \Delta\beta_{\text{no-maint}} - \Delta\beta_{\text{maint}} = 1.5375 - 0.5625 = 0.975$$

To extend the life of the bridge 10 years, $\Delta\beta_{\text{reqd}}$ needs to be

$$\Delta\beta_{\text{reqd}} = 10\alpha = 10(0.1025) = 1.025$$

The number of maintenance applications (n) to achieve this is

$$n = \frac{\Delta\beta_{\text{reqd}}}{\Delta\beta} = \frac{1.025}{0.975} = 1.05$$

Therefore, two preventive maintenance actions must be applied ($n = 2$). One cost-effective strategy is to schedule the maintenance as late in the life of the structure as possible. One approach is to gain as much as possible from the positive effect of the final preventive maintenance action which lasts $t_{PD} = 10$ years. That would suggest applying the second maintenance action at year 69 and the first maintenance action 15 years earlier, at year 54. [Figure 36.16](#) illustrates this strategy, which combines scheduled maintenance late in the life of the structure and maintains the reliability at a high level. The present value of preventive maintenance cost (C_{PM}), discounted at year 0 (i.e., time of construction), is

$$C_{PM} = \frac{\$3,000}{(1 + 0.04)^{54}} + \frac{\$3,000}{(1.04)^{69}} = \$360 + \$200 = \$560$$

The plan should also be checked with respect to the moment failure mode.

In many real world examples, it would not make sense to move preventive maintenance until the end of the life of the structure, but the strategy makes sense in the limited context of the problem. If failure costs were included in the analysis, there may be advantages to keeping the lifetime reliability of the structure higher and thus maintaining the structure sooner.

36.8.2 Repairs

The strategy for making repairs is similar to that for preventive maintenance as different options and their effects must be evaluated. The costs of some structural repairs are functions of the level of deterioration. Automobile body work is an example, where the amount of filling, sanding, and addition of extra material is proportional to the amount of deterioration. The costs of other structural repairs are independent of the level of structural deterioration, as, for example, adding a reinforcing plate or replacing a member, where the cost is the same regardless of the degree of deterioration. Choosing the proper mix of repairs and preventive maintenance and then timing their application in an efficient manner can be a difficult challenge.

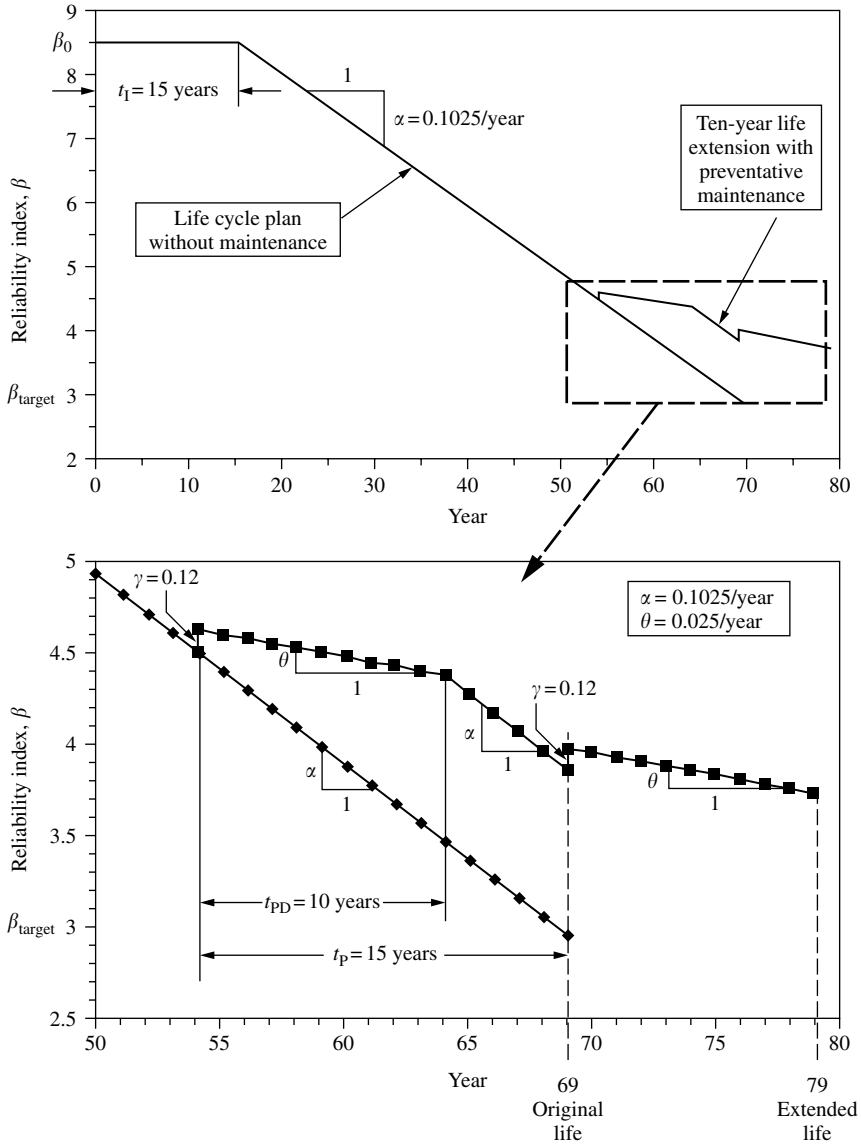

FIGURE 36.16 Preventive maintenance plan to extend the life of a bridge deck by 10 years.

EXAMPLE 36.22

How can one determine the best combination of repair and maintenance options for a given structure or category of structures?

Answer

Kong and Frangopol (2003b) looked at eight different maintenance scenarios and used a program LCADS (Life-Cycle Analysis of Deteriorating Structures) to predict the reliability profiles for an individual bridge associated with each maintenance strategy. The eight scenarios shown in Figure 36.17 include both preventive and essential maintenance. Sample combinations include no maintenance (E0), three applications of essential maintenance (E3), and two applications of essential maintenance with periodic preventive maintenance (E2,P). Figure 36.18 shows the mean system reliability index

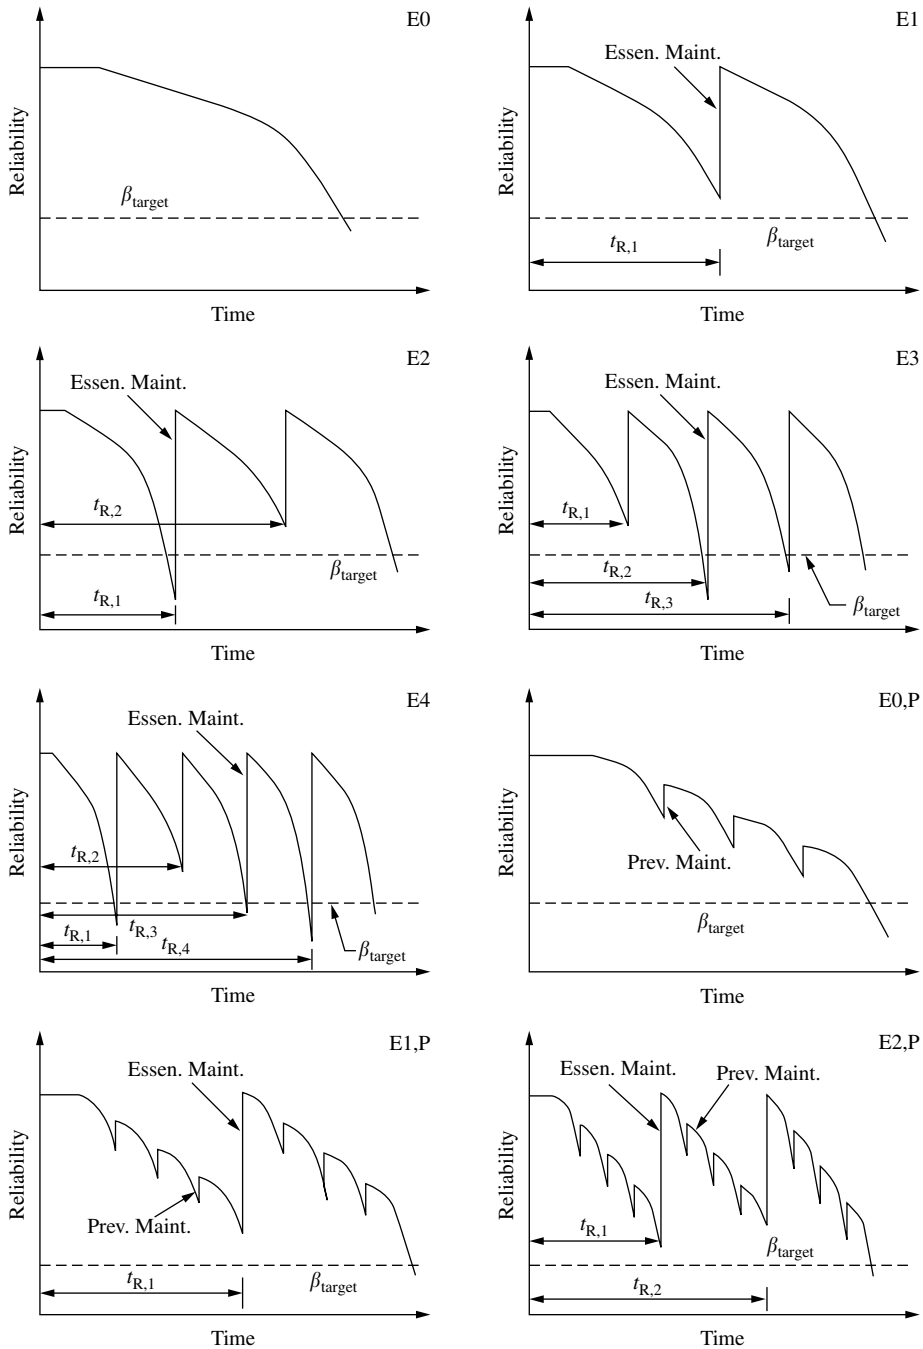

FIGURE 36.17 Eight different maintenance scenarios for a steel/concrete bridge involving various combinations of preventive and essential maintenance. (Kong and Frangopol 2003b. Reprinted with permission from the American Society of Civil Engineers.)

FIGURE 36.18 Mean reliability profile associated with different maintenance scenarios. (Kong and Frangopol 2003b. Reprinted with permission from the American Society of Civil Engineers.)

profiles associated with the different scenarios over time. Data from groups of existing steel and concrete bridges were the basis for determining deterioration rates, repair effects, and associated costs.

36.8.3 Expected Life Cycle Maintenance Cost

Frangopol and Kong (2001) and Kong and Frangopol (2003a) provided a computational procedure for the evaluation of the expected life cycle maintenance cost of deteriorating structures by considering the uncertainties associated with the application of subsequent maintenance actions. The methodology can be used to determine the expected number of maintenance interventions on a deteriorating structure, or a group of deteriorating structures, during a specified time horizon and the associated expected maintenance costs. The method is suitable for application to both new and existing civil infrastructures under various maintenance strategies. The ultimate objective is to evaluate the costs of alternative maintenance strategies and determine the optimum maintenance regime over a specified time horizon. In its present format, the first line of application of the method is for highway bridges. However, the method can be used for any structure, or group of structures, requiring maintenance in the foreseeable future. The proposed method can be programmed and incorporated into an existing software package for life cycle costing of civil infrastructures.

36.9 Discount Rate

As shown in several earlier examples, the choice of repair and the timing of both inspection and repair can be highly dependent on the discount rate of money. With a higher discount rate, expenditures and investments made later in the life of a structure become more attractive. There is considerable debate as to what the correct discount rate should be. Some governments mandate a rate (such as 6%) that must be used on all public civil infrastructure projects, which at least ensures consistency between these

FIGURE 36.19 Histogram showing the historical discount rates from the years 1962 to 2002; the discount rate was defined as the interest rate on 1-year U.S. Treasury bills minus the inflation rate (from Federal Reserve 2003; McMahon 2003).

projects. A more rational approach is to use the difference between the rate of return on a risk-free investment and the inflation rate as the appropriate discount rate, which is about 2 to 3%. Since these rates are well publicized over time, the discount rate could easily become a random variable based on years of past experience. Using this approach, Figure 36.19 shows a histogram reflecting the discount rate in the United States from 1962 to 2002, which reflects the difference between the short-term interest rate offered on 1-year U.S. Treasury bills (Federal Reserve 2003) and the annual inflation rate (McMahon 2003). With these data, the discount rate has a mean value of 2.07% and a standard deviation of 2.11%. The results would change somewhat depending on the years included in the study, the type of investment classified as risk free, and the commodity prices used to determine the inflation rate.

36.10 Condition and Reliability Indices as Joint Performance Indicators

The use of visual inspections and the resulting condition index has been, in the past three decades, the primary source of information on deteriorating bridge structures. As was previously discussed, the reliability index is a consistent measure of structural safety. Therefore, structure management systems should be based on reliability (Frangopol et al. 2000). Frangopol (2002) and Frangopol and Neves (2003) and Neves and Frangopol (2004) proposed a model incorporating condition and reliability indices as joint measures of performance. The condition and reliability indices are considered constant during a period after construction denoted as time of initiation of damage, t_{ic} and t_i , respectively. After this period, the deterioration rates of condition and reliability indices, α_c and α , are considered constant.

Each maintenance action can lead to one, several, or all of the following effects: (a) increase in the condition index or reliability index immediately after application, (b) suppression of the deterioration in condition index or reliability index during a time interval after application, and (c) reduction of the deterioration rate of condition index or reliability index during a time interval after application.

FIGURE 36.20 Condition index profile without or with maintenance. (Neves and Frangopol 2004. Reprinted with permission from Elsevier.)

These effects are modeled through several random variables such as (a) increase in condition index and reliability index immediately after application, γ_c and γ , respectively; (b) time during which the deterioration processes of condition index and reliability index are suppressed, t_{dc} and t_d , respectively; and (c) time during which the deterioration rates in condition index and reliability index are suppressed or reduced, t_{pdc} and t_{pd} , respectively. All variables characterizing the condition profile without or with preventive maintenance are indicated in Figure 36.20. The variables defining the reliability index profiles with or without maintenance are defined in a similar manner (Frangopol and Neves 2003; Neves and Frangopol 2004).

EXAMPLE 36.23

A bridge manager is responsible for maintaining a group of highway bridges. One of these bridges is currently 15 years old and is deteriorating fast. The manager feels that the bridge might become unsafe ($\beta < 3.0$) before reaching its prescribed service life (i.e., 75 years). Analyzing the existing records on the performance of the bridge during the past 15 years the manager realizes that there were no visual defects in the first 3 years of service, after which small cracks were visible. The first signs of corrosion appeared when the bridge was 10 years old. Measuring the loss of reinforcement at the present time (at year 15) the manager estimated that a loss of bending resistance of 4% had occurred. The most economical maintenance action available is the replacement of the concrete cover. This will correct visual defects and delay deterioration. The bending load effect and the bending resistance (both in kN m) at the beginning of service life are characterized by normal distributions $N[85, 12]$ and $N[180, 9]$, respectively.

It is assumed that the replacement of concrete cover improves the condition index C to its initial value (at time $t=0$). After this concrete replacement, the condition index does not deteriorate for a period of 3 years, as is the case of a new structure. The replacement of the concrete cover does not improve the reliability index but delays any further deterioration until the condition index reaches the level corresponding to initiation of corrosion. Using the above assumptions, estimate the effect of concrete cover replacement on condition and reliability and find the time of application of maintenance such that the target reliability index is not violated during the entire service life.

Answer

The visual deterioration of a bridge can be assessed by the condition index. This index is defined in discrete terms as 0 — no chloride contamination; 1 — onset of corrosion; 2 — onset of cracking; and 3 — loose concrete/significant delamination. According to existing records, the initiation time of condition deterioration is 3 years. Assuming that the coefficient of variation of the resistance is constant over time, the mean resistance reduction of 4% results in a bending resistance after 15 years that is characterized by a normal distribution with a mean and standard deviation as follows:

$$\mu_{15 \text{ years}}^R = 180 \times 0.96 = 172.8 \text{ kN m} \quad \text{and} \quad \sigma_{15 \text{ years}}^R = 9 \times 0.96 = 8.64 \text{ kN m}$$

The initial (at time $t=0$) reliability index and the reliability index at 15 years are

$$\beta(t=0) = \frac{180 - 85}{\sqrt{12^2 + 9^2}} = 6.333$$

$$\beta(t=15) = \frac{172.8 - 85}{\sqrt{12^2 + 8.64^2}} = 5.938$$

The time of initiation of deterioration of reliability is equal to the time for corrosion to start (i.e., 10 years). The deterioration rate of the reliability index is given by

$$\alpha = \frac{\beta(t=10) - \beta(t=15)}{15 - 10} = \frac{6.333 - 5.938}{5} = 0.079 \text{ per year}$$

The condition index deterioration rate, in absolute value, is

$$\alpha_c = \frac{C(t=10) - C(t=3)}{10 - 3} = \frac{1 - 0}{7} = 0.143 \text{ per year}$$

The effect of concrete cover replacement is analyzed at different points in time. To ensure a reliability index above the minimum target during the entire lifetime, maintenance should be applied when the condition index reaches the value 3.0. Figure 36.21 shows the effect of this maintenance action on the condition and reliability indices. Therefore, the times of application of maintenance action such that the target reliability index is not violated during the entire service life are when the bridge is 24, 48, and 72 years old.

EXAMPLE 36.24

Consider the previous example, but assume that uncertainties are associated with the parameters defining the condition and reliability indices as shown in Table 36.9. Compute the mean and standard deviation profiles of the performance indicators of the bridge considering that maintenance is applied when the condition index reaches $C=3.0$.

Answer

The mean and standard deviation of condition and reliability can be computed using Monte-Carlo simulation. The mean and standard deviation profiles for this scenario obtained by using 50,000 simulations are shown in Figure 36.22. These probabilistic results, which consider the uncertainties associated with both bridge deterioration and the effect of maintenance actions, show that the resulting performance profiles are considerably smoother than those obtained deterministically. Furthermore, the standard deviation profile shows that the uncertainty in performance varies over time. The mean reliability index at $t=75$ years is close to the value obtained in the previous analysis. However, due to uncertainty in the variables that define the reliability index profile, there exists a probability that the reliability index is less than 3.0.

These results illustrate the importance of probabilistic analysis. The uncertainties associated with the deterioration and effects of maintenance actions can lead to performance much different from that predicted from a deterministic analysis.

FIGURE 36.21 Condition and reliability index profiles for bridge considering cyclic replacement of concrete cover.

TABLE 36.9 Parameters Defining the Profiles under no Maintenance and Effects of Replacing Concrete Cover

	Variables	Values
Profiles under no maintenance	Initial condition index	0
	Deterioration rate of condition index (year ⁻¹)	$T(0.09; 0.14; 0.19)^a$
	Time of initiation of deterioration of condition index (years)	3
	Initial reliability index	6.33
	Deterioration of reliability index (year ⁻¹)	$T(0.03; 0.079; 0.13)^a$
Effects of replacement of concrete cover	Time of initiation of deterioration of reliability index (years)	10
	Improvement in condition index	To $C = 0$
	Delay in condition index deterioration (years)	$T(2; 3; 4)^a$
	Improvement in reliability index	0
	Delay in reliability index deterioration	Until $C = 1$

^a $T(a, b, c)$ represents a triangular distributed random variable with a = minimum, b = mode, and c = maximum.

36.11 Life Cycle Cost Examples

Since life cycle cost analysis and reliability methods are still relatively new, the methodology and procedures are still being developed. The research is admittedly incomplete. There are many researchers who are suggesting approaches, developing techniques, and applying them to real structures. It is from these studies that standardized procedures and prescribed codes will eventually emerge. This final section briefly examines three such case studies that have attempted to apply many of the concepts discussed in this chapter to actual structures.

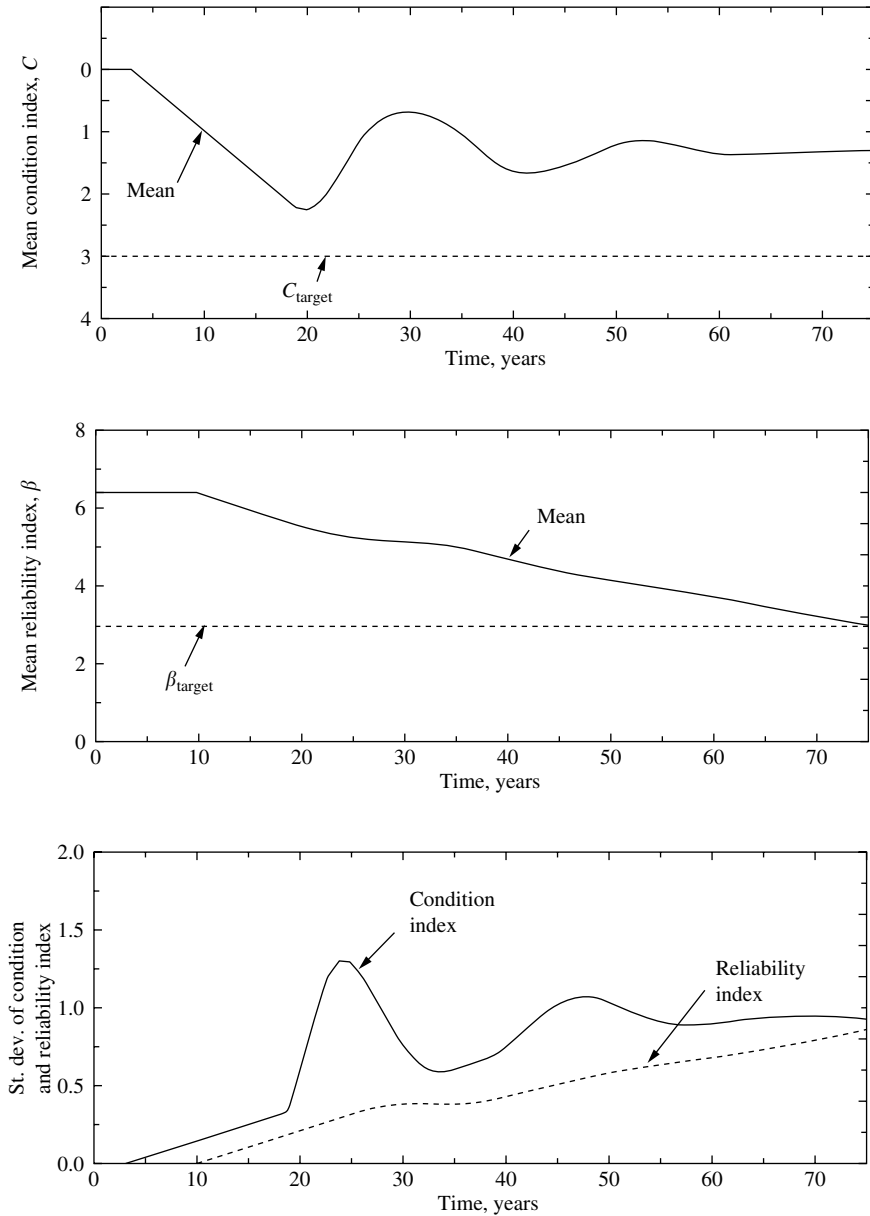

FIGURE 36.22 Mean and standard deviation of bridge condition and reliability index profiles considering cyclic replacement of concrete cover.

Case 36.1

Frangopol et al. (1997a,b) examined the life cycle cost design of reinforced concrete T-girders on highway bridges. The deterioration mechanism was corrosion of the reinforcing steel after sufficient chloride penetration into the concrete. The AASHTO (1992) bridge specification equations for both moment and shear capacities were used to optimize the T-girder for various life spans without the need for maintenance. Corrosion rates v of 0.0064, 0.0089, and 0.0114 cm/year (0.0025, 0.0035, and

FIGURE 36.23 Optimized concrete T-girder designed for a 25-year service life and a minimum acceptable reliability index of 3.0 while sustaining a deterioration rate of 0.0089 cm/year (0.0035 in./year) on corroding reinforcing steel (beam dimensions are in centimeters). (Frangopol et al. 1997a. Reprinted with permission from the American Society of Civil Engineers.)

0.0045 in./year) were considered for the steel reinforcement once corrosion was initiated. The Reliability Based Structural Optimization (RBSO) included 21 design variables such as flange width, number of stirrups, reinforcement ratio, and height of the web. In Frangopol et al. (1997a), the objective of the optimization process was to minimize the total cost of steel, concrete, and failure. Figure 36.23 shows the optimized concrete T-girder that sustains a corrosion deterioration rate of 0.0089 cm/year (0.0035 in./year). The minimum area of steel is 93.54 cm^2 (14.5 in.^2) and the dimensions of the beam are designed to ensure a minimum acceptable reliability of $\beta = 3.0$ throughout its expected 25-year service life. The analysis was completed for different deterioration rates, service lives, and acceptable reliabilities. Figure 36.24 shows that the optimum reliability index is $\beta^* = 2.5$ for a T-girder with an expected 75-year life and a deterioration rate of 0.0064 cm/year (0.0025 in./year) based on the minimum total life cycle cost. The cost of the steel was assumed to be 50 times as great as the cost of the concrete, and the failure cost was 10,000 times the cost of the concrete.

Next, Frangopol et al. (1997b) included preventive maintenance costs, which increased linearly over time. Inspection costs were included, and four inspection methods with varying costs and capabilities were available. The cost of repair was a function of the degree of damage, and an applied aging factor dictated the effect of the postrepair reliability. With multiple lifetime inspections, an event tree accounted for the repair/no repair decisions made after the inspection. The total expected life cycle cost was based on the consequences and probability associated with each branch on the event tree (Frangopol et al. 1997b). Figure 36.25 shows the reliability of a concrete T-girder over a 75-year life using a life cycle strategy that applies four inspections ($m=4$) and three repairs ($n=3$). The corrosion rate is

FIGURE 36.24 Optimum design of a concrete T-girder based on minimum total life cycle cost. The corrosion rate is 0.0064 cm/year (0.0025 in./year) due to corrosion of the reinforcement, and the expected service life is 75 years. (Frangopol et al. 1997a. Reprinted with permission from the American Society of Civil Engineers.)

$v = 0.0064 \text{ cm/year}$ (0.0025 in./year), and the inspection technique has a 50% probability of detection when there is 10% damage ($\eta_{0.5} = 0.10$). The number of inspections, inspection technique, and number of repairs were varied until an optimal life cycle cost solution was obtained. The study included both uniform and nonuniform inspection intervals. While a lot of the information was hypothetical, the study was one of the first to incorporate so many key aspects of life cycle analysis and design.

Case 36.2

Estes and Frangopol (1999) treated an existing Colorado highway bridge as a structural system and developed an optimal repair strategy based on minimum life cycle cost. The bridge in Figure 36.26 consisted of three simple spans where each span contained nine girders. The girders were classified as interior, exterior, and interior-exterior based on their load and exposure condition. Using 13 failure modes and 24 random variables, the bridge was modeled as a series-parallel system. After eliminating the nonrelevant failure modes and taking advantage of symmetry and assumed failure mode correlation, the simplified series-parallel model shown in Figure 36.26 was developed assuming that any three adjacent girders must fail for the bridge superstructure to fail. Both shear and moment failure modes were considered for the girders. The girders were corroding over time, and both the concrete slab and the pier cap were deteriorating due to exposure to chlorides from road salts. Meanwhile the live load was increasing over time.

FIGURE 36.25 The reliability of a concrete T-girder over its 75-year life under a life cycle plan that implements four inspections ($m=4$) and three repairs ($n=3$). The corrosion rate of the reinforcement is 0.0064 cm/year (0.0025 in./year), and the capability of the inspection technique is a 50% probability of detection when there is 10% damage. (Frangopol et al. 1997b. Reprinted with permission from the American Society of Civil Engineers.)

A repair was required any time the reliability of the bridge system fell below $\beta_{\text{system}} = 2.0$. Five repair options that included replacing the deck, replacing exterior girders, replacing exterior girders and deck, replacing superstructure, and replacing the entire bridge were considered along with their associated costs using a discount rate of 2%. Figure 36.27 shows the lifetime reliability of the relevant individual failure modes and the bridge system when the repair strategy is to continually replace the slab. The slab gets replaced at year 50 and year 94 when the system reliability falls below acceptable levels. At year 106, replacement of the slab is no longer sufficient to raise the system reliability above the minimum requirement, and some other repair option is necessary. The optimal solution was obtained by applying various combinations of the discrete repair alternatives.

Figure 36.27 indicates that some failure modes (shear in the exterior and interior–exterior girders) were allowed to fall below the minimum threshold $\beta = 2.0$ due to the parallel nature of the structural model. Due to different deterioration rates of various bridge components and effects of repair on reliability of these components, the most relevant failure mode in the beginning of the life of the structure was not necessarily the most critical mode later on. Different repair strategies were developed for different series–parallel models, different deterioration rates, and different correlations among girder resistances.

FIGURE 36.26 Colorado highway bridge modeled as a series-parallel system of failure modes. (Estes and Frangopol 1999. Reprinted with permission from the American Society of Civil Engineers.)

FIGURE 36.27 System reliability over time for deteriorating Colorado highway bridge where deck is replaced when system reliability falls below $\beta_{System} = 2.0$. (Estes and Frangopol 1999. Reprinted with permission from the American Society of Civil Engineers.)

This is one of the first studies to use real cost data for an existing structure and apply a system approach to life cycle analysis. The study only considered strength-based failure modes and chose an arbitrary value for the minimum acceptable system reliability. Ordinarily, a formal evaluation of failure costs and societal expectations would be needed to establish this value. The study above relied on point-in-time reliabilities as opposed to reliability over a specific time interval. Enright and Frangopol (1996, 1998a, 1999a,b) offer a cumulative time failure probability approach example for deteriorating concrete bridges. Estes and Frangopol (2003) illustrate how the reliability of this bridge can be updated over time using the results of biennial visual inspections. Estes and Frangopol (2001), Stewart and Val (2003), and Stewart et al. (2004) examined replacement strategies for deteriorating concrete bridges, considering both strength and serviceability limit states.

Case 36.3

Akgül and Frangopol (2003, 2004) examined a network of 14 Colorado highway bridges as shown in Figure 36.28. Seven bridges were prestressed concrete, three were steel I-beam, and four were steel plate girder. The year of construction ranges from 1951 to 1994, and the average daily truck traffic ranges from 5 to 2955 trucks per day. Each bridge was modeled as a system of failure modes. The prestressed bridges, for example, included flexure failure of the girders at the center and over the piers and flexure failure of the slab. Using a deterioration model that accounted for chloride penetration of the concrete, the system reliability was computed over time for each bridge in the network. The computational platform used in

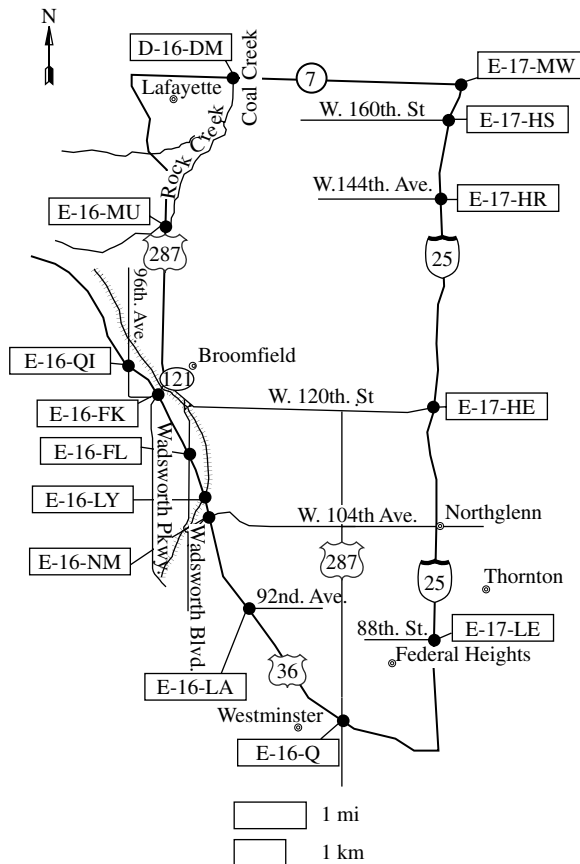

FIGURE 36.28 Bridge network consisting of 14 highway bridges in the Denver–Boulder corridor of Colorado. (Akgül and Frangopol 2003. Reprinted with permission from the American Society of Civil Engineers.)

this study is described in Akgül and Frangopol (2004). A study of networks of bridges (Frangopol et al. 2000a) offers new opportunities for life cycle cost. Akgül and Frangopol (2003) relate the system reliability of the bridges to the load rating for which there are existing data on all bridges. Bridges can be prioritized based on their importance to the overall network and historical inspection data become more useful for maintenance planning of a large category of bridges.

While all three examples in this section involve highway bridges, the concepts are applicable for any structures. Highway bridges are common examples because bridges are critical structures; there exist over 600,000 in the national database, and the Federal Highway Administration and the State DOTs have invested greatly in bridge management systems that provide much of the supporting data needed to support life cycle analyses.

36.12 Conclusions

A life cycle analysis of a structure introduces a number of issues that are not considered in deterministic or probabilistic time invariant solutions. Factors such as deterioration rates, inspection capabilities, repair effects, failure costs, discount rates, and threshold reliabilities present a number of challenges — many of which have not yet been solved. Life cycle analyses are necessarily more complex and require additional input data than those used in conventional time-invariant analyses. It is important to dismiss any misconception that very extensive data are required to perform probabilistic life cycle structural analysis. In fact, probabilistic methods allow the analysis of incomplete data in a much more reliable and consistent manner than conventional deterministic methods. Such analyses also reveal that the costs of maintenance, repair, and inspection may greatly exceed the original cost of construction. In times of scarce and competing resources for an aging infrastructure, these costs cannot be ignored. This chapter has used examples to illustrate the issues involved in condition assessment and life cycle cost analysis and design of deteriorating structures and highlighted some studies that have attempted to address these challenges. There is an urgent need for civil engineers to (a) acquire a good understanding of financial management under uncertainty, (b) have a stronger grasp of reliability-based optimal decision making, and (c) increase their role in the ultimate decisions on life cycle management of our decaying civil infrastructure systems.

Acknowledgments

The partial financial support of the U.S. National Science Foundation through grants CMS-9506435, CMS-9912525, and CMS-0217290, of the U.S. Army Corps of Engineers Construction, Engineering Research Laboratory, of the U.K. Highways Agency and of the Civil Engineering Division of the Netherlands Ministry of Transport, Public Works, and Water Management is gratefully acknowledged. Glossary

Bias factor — A factor that relates the nominal deterministic value of a quantity to the mean value of that quantity when it is considered a random variable.

Coefficient of variation — Ratio of the mean value to the standard deviation of a random variable; it is a convenient nondimensional measure of variability (Ang and Tang 1975).

Component (with one failure mode) — A portion of a system represented by a single failure mode and thus a single limit state equation.

- Condition rating** — A rating assigned by an inspector to identify the structural condition, usually by matching the visual condition of a structure to the most appropriate written description of distress.
- Correlation (linear)** — A measure of the (linear) relationship between two random variables, usually indicated by a correlation coefficient that ranges from $\rho = 1$ (perfect positive correlation) to $\rho = -1$ (perfect negative correlation), where $\rho = 0$ indicates no correlation.
- Deterioration model** — A mathematical relationship that describes how a structure is expected to deteriorate over time, usually obtained from laboratory data, theory, or other studies.
- Deterministic** — No (aleatory and epistemic) uncertainties are present; everything is certain.
- Discount rate** — The interest rate to be used to convert future monetary sums to present value to allow alternatives to be compared over time.
- Ductility** — A measure of the ability of a structural member to elongate prior to rupture; a ductile member is still able to carry a load after yielding and allows warning prior to failure, which normally produces a safer structure.
- Expected cost** — A mean value of the cost; expected cost is used when there is uncertainty associated with the cost and is often a weighted average of the costs associated with various alternatives and their probability of occurrence.
- Factor of safety** — The ratio of the capacity of a structure (resistance) to the demand placed upon it (load or load effect).
- Failure** — When a structure no longer performs as intended; using the performance function, failure is defined as $g(\mathbf{X}) < 0$.
- Failure cost** — Costs incurred by a structural failure multiplied by the probability of failure.
- Hazard function** — Provides the instantaneous rate of failure; expresses the likelihood of failure in a specific time interval given that the structure has not already failed.
- Importance** — A measure of the criticality of a structure, usually determined by the degree of consequence if the structure fails.
- Independent (statistically)** — Two events are independent if the occurrence or (nonoccurrence) of one event does not affect the probability of the other event (Ang and Tang 1975); if two variables are independent, their correlation coefficient is zero.
- Initial cost** — Those costs associated with the design and construction of a structure (e.g., permits, architect fees, materials, equipment, labor); typically, those costs associated with placing a structure into service.
- Life cycle cost** — Total costs associated with a structure throughout its entire life; typically includes initial, maintenance, inspection, repair, and failure costs.
- Limit state** — The boundary between the desired and undesired performance of a structure; the boundary is typically represented by a limit state equation $g(\mathbf{X}) = 0$.
- Mean value** — The central tendency of a random variable; in the discrete case, the mean value is the average value of the data, in the continuous case where $f_X(X)$ is the density function of a random variable, the mean value is $\mu = \int_{-\infty}^{\infty} xf_x(x) dx$ (Rao 1992).
- Nondestructive evaluation** — The assessment or inspection of a structure conducted without damaging the structure; the evaluation can be visual or involve testing equipment.
- Parallel system** — A system where all members must fail for the system to fail.
- Preventive maintenance** — Precautionary maintenance actions, design to forestall damage and deterioration of a structure.
- Probability density function** — For a continuous random variable, $f_X(X)$ is a function that defines the probability of detecting X in the infinitesimal interval $(x, x + dx)$; therefore, $f_X(X) dx = P(x \leq X \leq x + dx)$.
- Random variable** — A function that maps events from the sample space into the axis of real numbers; it can be continuous, discrete, or mixed.
- Redundancy** — Measure of reserve capacity; failure of a single member will not cause failure of a redundant structure.
- Reliability** — Probability of safe performance of a structure.

Reliability index — A measure of reliability, denoted as β ; the shortest distance from the origin to the failure surface in standard normal space; when both load and resistance are normally distributed, $p_f = \Phi(-\beta)$, where Φ is the distribution function of the standard normal variate.

Risk — A function of the probability of occurrence of an adverse event and the consequence of the event; often risk is defined by the probability of failure of the adverse event and its consequence (Ang and De Leon 2005).

Safe — A structure performing as intended.

Series system — A system that fails if any member of the system fails.

Survivor function — Defines the probability that a structure is safe at any particular time.

Visual inspection — A periodic inspection where an inspector observes a structure and classifies its condition in terms of predefined condition ratings.

Notation

A	= cross-sectional area; regression parameter in corrosion model	k	= normalizing constant
B	= regression parameter in corrosion model	L	= load or load effect
b	= length of flange	$L(\Theta)$	= likelihood function
C	= cost; condition index value	M	= bending moment
CS	= condition state	m	= number of inspections
$C(t)$	= average corrosion penetration at time t (μm)	$N[7, 1.5]$	= normally distributed variable with a mean value of 7 and standard deviation of 1.5
d_{corr}	= depth of corrosion penetration	n	= number of time intervals; number of maintenance applications; number of repairs
$E(C)$	= expected value of cost	nr	= number of repairs
$E[\text{Damage}(t) $ Branch $_i]$	= expected damage at time t given that branch i was taken	p_f	= probability of failure
$f_L(I)$	= probability density function of load	p_s	= probability of safe performance
FS	= factor of safety	$\text{pdf}_{\text{bad-x}}$	= value of probability density function for damaged deck
$f_R(r)$	= probability density function of resistance	PV	= present value of cost
$f_{R,L}(r, I)$	= joint probability density function of resistance and load	R	= resistance
$f(t)$	= probability density function	R1	= rust code 1
$f(x_i)$	= probability density function of inspection results	r	= discount rate of money
FV	= future value	$S(t)$	= survival function
F_y	= yield strength	$T(a, b, c)$	= triangular distribution where minimum value is a , mode is b , and maximum value is c
$f'(\Theta)$	= prior density function	t	= time
$f''(\Theta)$	= posterior density function	t_1	= damage initiation time
$g(\mathbf{X})$	= performance function	t_f	= thickness of flange
$H(t)$	= hazard function	t_w	= thickness of web
h	= depth of column cross-section	X	= random variable
		y	= number of parallel systems in the series system; distance from neutral axis to centroid of shape in composite cross-section
		Z	= plastic section modulus
		z	= number of members in the parallel system

α	= system redundancy measure; reliability index deterioration rate without maintenance	$\eta_{0.5}$	= amount of damage when there is a 50% probability of detection
α_c	= condition index deterioration rate	μ	= mean value
β	= reliability index	v	= corrosion rate
Φ	= the distribution function of the standard normal variate	θ	= angle; reliability index deterioration rate during preventive maintenance effect
γ	= redundancy range; immediate improvement in reliability index after application of preventive maintenance	Θ	= random variable
		ρ	= correlation coefficient
		σ	= standard deviation

37.1 Introduction

Structural fire safety is one of the three requirements that have to be fulfilled by a fire resistant construction, whose function is to ensure that a fire in a building is contained within the compartment of origin so that occupants in other parts of the building can escape to safety and fire damages do not become excessive. To achieve this, the load bearing structure of a fire resistant construction should not collapse in fire. The other two fire resistance requirements are

- *Insulation.* The unexposed surface of a fire resistant construction should not be heated excessively and cause further ignition. Clearly, whether any material will be ignited or not will not only depend on the temperature of the unexposed surface, but also on its nature and its relative position to the unexposed surface. Nevertheless, at present, regulations worldwide limit the average temperature rise on the unexposed surface to 140°C and the maximum local temperature rise to 180°C.
- *Integrity.* Gaps should not develop in fire resistant construction to spread fire.

The practice of dividing a building into a number of compartments bounded by fire resistant construction is called fire resistant compartmentation. It should be pointed out that fulfillment of the

above three fire resistance requirements only applies to those elements of construction that are necessary for the fire resistant compartment to contain fire. Other elements, whose failure to fulfill these requirements does not lead to a failure of the fire resistant compartment, do not require any fire safety design consideration. Before the designer commences detailed structural fire safety design calculations, he should work with the client and the fire service authority to determine the size of the fire resistant construction. This will depend on factors such as fire regulations on the maximum size of fire resistant compartmentation, insurance premium, and fire brigade access and is beyond the scope of this chapter.

Until recently, assessment of fire resistance of a construction is performed experimentally in standard fire resistance test furnaces and under the standard fire condition. Each country has its own fire resistance test standard [e.g., ASTM E-119 (ASTM 1985) in the United States, BS 476 (BSI 1987) in the United Kingdom, and ISO 834 (ISO 1975)], but they are largely similar. The standard fire resistance test has many shortcomings, for example, high cost, time consuming, limitation of specimen size, idealized loading condition, idealized support condition, lack of repeatability, and unrealistic fire exposure. It is now possible to perform some fire resistant design by calculations and the objective of this chapter is to introduce the reader to structural design calculations to ensure stability of load bearing members in the event of a fire.

It should be pointed out that the behavior of a complete structure in fire and that of isolated elements can be different because a complete structure will have characteristics, such as load redistribution, structural interactions, that will not exist in isolated elements. Also, it is worth noting that current calculation methods are based on flexural behavior at small deflections. The behavior of structural elements at large deflections can be vastly different and such a different behavior may be explored to improve structural fire safety design. Behaviors of elements at large deflections and complete structures in fire are beyond the scope of this chapter. Interested readers may consult the book by Wang (2002).

In general, design calculations to check structural safety in fire involves three parts:

1. Assessment of the fire severity to which a structural member is exposed. For structural fire safety design, a fire is usually quantified by a temperature–time relationship of the fire.
2. Evaluation of the temperature field in the structural member under the above fire condition.
3. Calculation of the remaining load carrying capacity of the structural member at elevated temperatures and comparison with the applied load.

This chapter will introduce the reader to all three aspects of structural fire safety design, while emphasizing on the third.

It is understandable that the September 11 tragedy has initiated the interest of many engineers in structural fire safety design. However, it must be mentioned that there had already been great progresses on this topic well before the September 11 event in many parts of the world, particularly in Europe and the United Kingdom. At present, there is a systematic and comprehensive coverage of structural fire safety design methods in Europe, through developments of the so-called Eurocodes. Thus, this chapter will adopt Eurocodes as the basis of its design guidance. However, it is hoped that there will be sufficient explanations of the fundamental engineering principles so that the basis of Eurocode design rules can be similarly adopted in different design environments.

37.2 Fire Severity

Fire severity to structural fire safety design is akin to applied mechanical loads on a structure to structural design at ambient temperature. Fires can occur anywhere; however, for structural fire safety design, they are often assumed to take place in a building enclosure. In such a situation, starting from ignition, a fire can go through a number of stages. In the early stages, combustion is restricted to local areas near the ignition source and temperatures of the combustion gases are low, the safety of a structure exposed to fire attack is very rarely threatened. Later, under certain circumstances, a localized fire can

transform very quickly to involve all the combustible materials in the fire enclosure. The transition from a localized fire to a fire engulfing the entire enclosure is called flashover and the fire at this stage is called a postflashover fire. At this stage, the combustion gas temperatures are very high and stability of the building structure may be threatened, the consequence of which can lead to rapid fire spread and loss of life and property. It is this stage of the fire behavior that will be described below. Interested readers should consult some excellent textbooks, such as Drysdale (1999) and Karlsson and Quinterie (2000), to obtain a deep understanding of enclosure fire behavior.

37.2.1 Standard Fire Exposure

There are two ways of dealing with postflashover fires for structural fire safety design. First, the standard fire temperature–time relationship may be adopted. The standard fire equation is similar in different countries of the world. In the European standard (CEN 2000a), the standard fire temperature–time relationship is given by

$$T_{\bar{h}} = T_a + 345 \log(8t + 1) \quad (37.1)$$

where the standard fire exposure time (t) is in minutes and the fire temperature $T_{\bar{h}}$ and ambient temperature T_a are in degrees celsius.

Equation 37.1 is used for wood based, or cellulosic, fires. For fire resistant design of offshore structures, the standard hydrocarbon fire curve should be used. This fire has a much faster rate of initial increase in temperature. The standard hydrocarbon fire temperature–time relationship is given by (CEN 2000a)

$$T_{\bar{h}} = 1080(1 - 0.325e^{-0.167t} - 0.675e^{-2.5t}) + T_a \quad (37.2)$$

Figure 37.1 plots the two standard fire curves. It is obvious that the standard cellulosic fire curve gives a monotonically increasing temperature–time relationship that cannot be sustained in any real fire. In order to reflect some reality in the standard fire exposure, a limiting time of fire exposure is specified. This is the familiar standard fire resistance rating. In standard fire resistance design calculations, specifications for the required standard fire resistance rating are based on very broad criteria such as the occupancy type and height of a building. Whilst these criteria give a broad indication of fire load and consequence of fire exposure, they do not consider other important factors that affect the behavior of an enclosure fire such as ventilation condition and construction materials.

37.2.2 Natural Fire Exposure

As a regulatory control tool, the standard fire exposure is simple to use. However, fires cannot be expected to behave according to the standard temperature–time relationship. For more realistic

FIGURE 37.1 A comparison of standard cellulosic and hydrocarbon fire temperature–time relationships.

assessment of performance of structures in fire, it is necessary to quantify realistic fire behavior. Assuming that a fire enclosure is at the same temperature during the postflashover phase, the fire temperature–time relationship may be determined by carrying out an energy balance analysis for the fire enclosure; that is

heat input into the fire (heat released from combustion) = heat losses from the fire

Figure 37.2 depicts a postflashover enclosure fire situation. Heat losses from the fire include

1. Heat lost to the outside by hot gases flowing out of the fire compartment through openings (\dot{Q}_{lc}).
2. Heat lost to the enclosure lining (\dot{Q}_{lw}).
3. Heat lost to the outside environment by radiation through the opening (\dot{Q}_{lr}).
4. Heat required to increase the combustion gas temperature (\dot{Q}_{lg}).

The rate of heat release is the most important factor. At present, due to the difficulty of numerically modeling fire spread and random distribution of combustible materials in a fire enclosure, it is not possible to accurately calculate the rate of heat release of a fire. Nevertheless, from considerations of the main governing factors of burning, a number of empirical equations have been derived. From basic hydrodynamics, it can be shown that the amount of hot gases flowing out of a fire compartment is related to $A_v\sqrt{h_v}$, the so-called ventilation factor, where A_v is the opening area and h_v is the opening height. In order to sustain burning, cold air should be supplied into the fire compartment to replenish the lost hot gases. Thus, the amount of cold air entering the fire compartment is also related to $A_v\sqrt{h_v}$. It follows that the amount of fresh oxygen supply to the fire is related to $A_v\sqrt{h_v}$. If burning is ventilation controlled, that is, the rate of burning is governed by the amount of fresh oxygen available, the rate of heat release of a fire is a function of $A_v\sqrt{h_v}$. On the other hand, if the opening is large but the burning area is small, a fire can become fuel controlled, that is, the rate of burning is governed by the available surface area of the fuel bed or combustible materials. Also, the amount of available combustible materials, that is, the fuel load, will determine the duration of burning.

Fire development inside a fire enclosure will also be affected by thermal properties of the fire enclosure lining materials, that is, the bounding walls and floors. A material that has a low thermal conductivity, that is, heat is difficult to penetrate the material, will lose a small amount of heat through the material. A material that has a high thermal capacitance, that is, a large amount of heat is required to raise its temperature, will absorb a large amount of heat of the burning fire and vice versa. Combining these two factors, the quantity that is used to describe the thermal properties of fire enclosure lining materials is $k\rho C$ where k and ρC are the thermal conductivity and thermal capacitance of the lining materials, respectively.

Using the three quantities mentioned above, that is, the ventilation factor, the fire enclosure lining material property, and the fuel load, a number of approximate temperature–time relationships of

FIGURE 37.2 Fully developed enclosure fire, showing various heat losses.

postflashover enclosure fires have been developed. Among them, the so-called parametric temperature–time curves of Eurocode 1 Part 1.2 (CEN 2000a), based on the results of Pettersson et al. (1976), are widely accepted. As shown in Figure 37.3, a parametric fire curve has an ascending branch and a descending branch. The ascending branch is used to describe the temperature–time relationship of a fire during its growth and steady burning stages, when it is ventilation controlled. The descending branch describes the decay period of the fire. The ascending branch is expressed by

$$T_{fi} = 1325(1 - 0.324e^{-0.2t^*} - 0.204e^{-1.7t^*} - 0.472e^{-19t^*}) \tag{37.3}$$

where the modified time t^* (in hours) is related to the real time t (in hours) by

$$t^* = t\Gamma \tag{37.4}$$

in which Γ is a dimensionless parameter, given by

$$\Gamma = \left(\frac{O}{0.04}\right)^2 \left(\frac{1160}{b}\right)^2 \tag{37.5}$$

In Equation 37.5, O is the ventilation factor defined as

$$O = \frac{A_v\sqrt{h_v}}{A_t} \tag{37.6}$$

in which A_t is the total enclosure (including openings) area.

In Equation 37.5, $b = \sqrt{k\rho C}$ [in $J/(m^2 s^{1/2} K)$] is the overall thermal property of the fire enclosure lining material. For a fire enclosure constructed of a combination of different lining materials, complicated equations have recently been introduced in Eurocode 1 Part 1.2 (CEN 2000a) to find an equivalent value of b .

The ascending branch of the fire temperature–time relationship terminates at time (t_d^*) when the maximum fire temperature is obtained. This time is a function of the fire load in the fire enclosure and is given by

$$t_d^* = 0.00013 \frac{q_{t,d}\Gamma}{O} \text{ (in hours)} \tag{37.7}$$

In Equation 37.7, $q_{t,d}$ is the fire load density (in MJ/m^2) related to the total surface area of the fire enclosure A_t . Since fire load density is usually specified with regard to the floor area A_f , the fire load per enclosure area $q_{t,d}$ is related to the fire load per floor area ($q_{f,d}$) using

$$q_{t,d} = q_{f,d}A_f/A_t \tag{37.8}$$

It can be seen that the ascending branch of the fire temperature–time curve is not dependent on the fire load. This is because a fire is assumed to be ventilation controlled and the rate of heat release is the

FIGURE 37.3 Parametric time–temperature curve of Eurocode 1 Part 1.2.

same, depending only on the ventilation condition. The effect of fire load is to change the duration of burning t_d^* according to Equation 37.7.

For simplicity, the descending branch is given by a straight line. Since structural behavior is only slightly affected by the descending branch of the fire temperature–time relationship, more complicated equations for the descending branch are not justified. The rate of the descending branch depends on the fire duration. The fire temperature during cooling is given by

$$\begin{aligned} T_{fi} &= T_{fi,max} - 625(t^* - t_d^*) && \text{for } t_d^* \leq 0.5 \\ T_{fi} &= T_{fi,max} - 250(3 - t_d^*)(t^* - t_d^*) && \text{for } 0.5 < t_d^* < 2.0 \\ T_{fi} &= T_{fi,max} - 250(t^* - t_d^*) && \text{for } t_d^* \geq 2.0 \end{aligned} \quad (37.9)$$

In Equation 37.9, $T_{fi,max}$ is the maximum fire temperature, obtained by substituting the time in Equation 37.7 into Equation 37.3.

In Eurocode 1 Part 1.2 (CEN 2000a), the limit of application of the above fire temperature–time relationship is for fire compartments up to 100 m² in floor area with the maximum compartment height at 4 m. For larger or taller compartments, the effect of nonuniform temperature distribution in the fire enclosure cannot be ignored. Unfortunately, simple methods are not available yet.

From previous discussions, it is clear that the fire temperature–time relationship depends on the amount of combustible materials (or fuel load) in a fire enclosure, the ventilation condition, and thermal properties of the fire enclosure lining material. During a design, the ventilation condition and thermal properties of the fire enclosure lining material may be estimated from construction details, that is, the window size and construction materials. Thermal properties of some enclosure lining materials may be found in Table 37.1.

The design fire load is building specific. However, since the exact type and amount of combustible materials will not be known during the design stage, it is unlikely that the design fire load can be known with any certainty. In fire engineering design calculations, it is common to specify a generic fire load for a type of building, depending on its proposed use. This is similar to specifying a general structural load for structural design at ambient temperature. Values in Table 37.2 may be used as a guide. More detailed information on fire load may be obtained from a Conseil International du Batiment (CIB) report (CIB 1986). It is important to point out that there are many uncertainties about the design fire load. When conducting a fire engineering design, the designer should perform a sensitivity study to investigate the consequence of adopting a range of possible fire loads.

EXAMPLE 37.1

Natural fire exposure

Figure 37.4 shows the dimensions and other design data of a fire enclosure. Evaluate the postflashover fire temperature–time curve inside the enclosure.

TABLE 37.1 Thermal Properties of Generic Fire Protection Materials

Generic material	Density, kg/m ³	Thermal conductivity, W/(m K)	Specific heat, J/(kg K)	Moisture content, (% by wt.)
Sprayed mineral fiber	250–350	0.1	1050	1.0
Vermiculite slabs	300	0.15	1200	7.0
Vermiculite/gypsum slabs	800	0.15	1200	15.0
Gypsum plaster	800	0.2	1700	20.0
Mineral fiber sheets	500	0.25	1500	2.0
Aerated concrete	600	0.3	1200	2.5
Lightweight concrete	600	0.8	1200	2.5
Normal weight concrete	2200	1.7	1200	1.5

FIGURE 37.4 Enclosure information for Example 37.1.

Calculation results

Floor area: $A_f = 54 \text{ m}^2$

Total enclosure area: $A_t = 228 \text{ m}^2$

Design fire load density per m² enclosure area: $q_{t,d} = 720 * 54/228 = 170.5 \text{ MJ/m}^2$

Window area: $A_v = 9 \text{ m}^2$

Opening factor: $O = \frac{9 \times \sqrt{1.5}}{228} = 0.04835 \text{ m}^{1/2}$

Lining property: $b = \sqrt{1600 \times 0.8 \times 1200} = 1239.4 \text{ J}/(\text{m}^2 \text{ s}^{1/2} \text{ K})$

Equation 37.5 gives $\Gamma = \left(\frac{0.04835}{0.04}\right)^2 \times \left(\frac{1160}{1239.4}\right)^2 = 1.28$

Equation 37.7 gives $t_d^* = 0.00013 \times \frac{170.5 \times 1.28}{0.04835} = 0.587 \text{ h}$

Equation 37.3 gives $T_{f_i,max} = 844 + 20 = 864^\circ\text{C}$

The real time at the maximum fire temperature $t_d = 0.587/1.28 = 0.458 \text{ h}$

For the cooling part, Equation 37.9 will be used, giving the time t^* necessary to reach the ambient temperature as $t^* = 1.937 \text{ h}$. The real time is $1.937/1.28 = 1.5136 \text{ h}$.

Figure 37.5 plots the complete fire temperature–time relationship.

FIGURE 37.5 Temperature–time relationships.

37.3 Introduction to Heat Transfer

Having determined the temperature–time relationship of a fire to which a structural member is exposed, the next step is to calculate the temperatures in the structural member. Building structures are usually treated as either one-dimensional, such as beams and columns, or two-dimensional, such as slabs and walls. For a one-dimensional member, it is common to assume that there is no temperature variation along its length. For a two-dimensional member, temperatures are assumed to change only through its thickness. Calculating temperatures in a structural member exposed to fire involves using heat transfer analysis. Only a brief introduction to heat transfer theory will be given in this chapter, with particular emphasis on applications under fire conditions.

There are three basic mechanisms of heat transfer: conduction, convection, and radiation. In conduction, energy or heat is exchanged in solids on a molecular scale without any movement of macroscopic portions of matter relative to one another. Convection refers to heat transfer at the interface between a fluid and a solid surface. Here, the exchange of heat is due to fluid motion. This motion may be the result of an external force, causing the fluid to flow over the solid surface at speed. This is called forced convection. Convection can also occur due to buoyancy-induced flow when there is a temperature gradient in the fluid, causing a density gradient. This is called natural convection. Radiation is the exchange of energy by electromagnetic waves that, like visible light, can be absorbed, transmitted or reflected at a surface. Unlike conduction and convection, heat transfer by radiation does not require any intervening medium between the heat source and the receiver. Thus, in the context of structural fire safety design, heat conduction describes the heat transfer process inside a structural member and heat convection and radiation describe the thermal boundary condition of the structural member.

37.3.1 Conduction

The basic equation for one-dimensional heat conduction is Fourier's law of heat conduction. It is expressed as

$$\dot{Q} = -k \frac{dT}{dx} \quad (37.10)$$

where, referring to Figure 37.6, dT is the temperature difference across an infinitesimal thickness dx . \dot{Q} is the rate of heat transfer (heat flux) across the material thickness. The minus sign in Equation 37.10 indicates that heat flows from the higher temperature side to the lower temperature side.

FIGURE 37.6 Heat conduction in one dimension.

FIGURE 37.7 Temperature distribution with constant thermal conductivity.

The constant of proportionality k is the thermal conductivity of the material. In many practical applications of fire safety engineering, the material thermal conductivity within the relevant temperature range may be approximated as a constant. Thus, Equation 37.10 may be replaced by its finite difference equivalent

$$\dot{Q} = -k \frac{T_2 - T_1}{\Delta x} \quad \text{or} \quad T_1 - T_2 = \dot{Q} \frac{\Delta x}{k} \tag{37.11}$$

where, referring to Figure 37.7, T_1 and T_2 are temperatures at the two sides of a material and Δx is the material thickness. $\Delta x/k$ expresses the thermal resistance of the material.

37.3.2 Convection

Heat convection and radiation are considered at the interface between a structural member and the fire or the ambient temperature air. When applying thermal boundary conditions, it is often assumed that

the heat exchange between the fluid and the structural surface is related to the temperature difference at the interface. Therefore, on the fire side from fire to structural surface

$$\dot{Q} = h_{fi}(T_{fi} - T_s) \quad (37.12)$$

On the ambient temperature air side from structural surface to the ambient temperature air

$$\dot{Q} = h_a(T_s - T_a) \quad (37.13)$$

where T_{fi} and T_a are the fire and air temperatures, respectively and T_s is the structural surface temperature.

Quantities h_{fi} and h_a are the overall heat exchange coefficients on the fire and air side, respectively. Depending on the relationship between the fire/air and the structural surface, the heat exchange coefficients (h_{fi} and h_a) may only contain the convective component (h_c), the radiant component (h_r), or both.

The convective heat transfer coefficient depends on many factors. However, for structural fire applications, the structural temperatures are relatively insensitive to its exact values. Eurocode 1 Part 1.2 (CEN 2000a) recommends constant convective heat transfer coefficients as follows: on the fire side, $h_c = 25 \text{ W/m}^2$ and on the air side, $h_c = 10 \text{ W/m}^2$.

37.3.3 Radiation

If a structural surface is in direct contact with fire/air, radiant heat transfer between the structural surface and the fire/air may be assumed to occur between two very large parallel plates of area A , whose distance apart is small compared with the size of the plates so that radiation at their edges is negligible. Under this circumstance and assuming graybody radiant heat transfer, the radiant heat exchange coefficient is

$$h_r = \varepsilon_r \sigma (T_2^2 + T_1^2)(T_2 + T_1) \quad (37.14)$$

where σ is the Stefan–Boltzmann coefficient ($= 5.876 \times 10^{-8} \text{ W/(m K}^4\text{)}$) and ε_r is often referred to as the resultant emissivity given by

$$\varepsilon_r = \frac{1}{1/\varepsilon_1 + 1/\varepsilon_2 - 1} = \frac{\varepsilon_1 \varepsilon_2}{\varepsilon_1 + \varepsilon_2 - \varepsilon_1 \varepsilon_2} \quad (37.15)$$

in which ε_1 and ε_2 are the graybody emissivities of the two surfaces, that is, that of the structural surface and fire/air, respectively.

37.3.4 Some Simplified Solutions of Heat Transfer

General heat transfer problems are difficult to solve and will usually require the use of numerical heat transfer procedures. However, for two common cases of unprotected and protected steelworks exposed to fire attack, simple analytical solutions have been derived to enable their temperatures to be calculated quickly. These simple analytical solutions have been derived by using the “lumped mass method,” that is, the entire steel mass is given the same temperature. For unprotected steelwork

$$\Delta T_s = \frac{h}{\rho_s C_s} \frac{A_s}{V} (T_{fi} - T_s) \Delta t \quad (37.16)$$

where V and A_s are the volume and exposed surface area of the steel element, respectively, ρ_s is the density of steel, and C_s is the specific heat of steel. The ratio A_s/V in Equation 37.16 is often referred to as the section factor of the steel element. T_{fi} and T_s are the fire and steel temperatures, respectively. h is the total heat transfer coefficient between the fire and the steel surface, including both the convective and radiant components. When using Equation 37.16, a step-by-step approach is necessary and the time increment should be small ($\Delta t < 5 \text{ s}$).

For protected steelwork

$$\Delta T_s = \frac{(T_{fi} - T_s)A_s/V}{(t_p/k_p)C_p\rho_s(1 + (1/3)\phi)}\Delta t - (e^{\phi/10} - 1)\Delta T_{fi}, \quad \text{where } \phi = \frac{C_p\rho_p}{C_s\rho_s}t_p\frac{A_s}{V} \quad (37.17)$$

Additional symbols in Equation 37.17 include t_p , the fire protection thickness; k_p , thermal conductivity of the fire protection; C_p , specific heat of the fire protection; ρ_p , density of the fire protection; and ΔT_{fi} , the increment in fire temperature during the time interval Δt . The time increment should not be too large. When using Equation 37.17, the time increment (Δt) should not exceed 30 s.

Because of the second term in Equation 37.17, it is possible that at the early stage of increasing fire temperature, the increase in steel temperature (ΔT_s) may be negative. In this case, the steel temperature increase should be taken as zero.

37.3.5 Section Factors

Equations 37.16 and 37.17 clearly indicate that the temperature rise in a steel element is directly related to the section factor A_s/V , that is, the ratio of the heated surface area to the volume of the steel element. Consider a unit length of a steel element where the end effects are ignored, the section factor may alternatively be expressed as H_p/A , where H_p is the fire exposed perimeter length of the steel cross-section and A is the cross-sectional area of the steel element. Section factors for a few common types of steel sections exposed to fire are given in Table 37.3.

EXAMPLE 37.2

Section factor

Calculate the section factor (H_p/A) for the two cases shown in Figure 37.8.

Calculation results

Case 1, Figure 37.8a

$$\begin{aligned} H_p &= 2 \times 400 + 150 \times 3 - 2 \times 10 = 1230 \text{ mm}, \\ A &= 2 \times 15 \times 150 + (400 - 15 \times 2) \times 10 = 8200 \text{ mm}^2 \\ H_p/A &= 0.15 \text{ mm}^{-1} = 150 \text{ m}^{-1} \end{aligned}$$

Case 2, Figure 37.8b

$$\begin{aligned} H_p &= 2\pi R_o = 300\pi, \quad A = \pi(R_o^2 - R_i^2) = 2900\pi \\ H_p/A &= 0.1034 \text{ mm}^{-1} = 103.4 \text{ m}^{-1} \end{aligned}$$

37.3.6 Thermal Properties of Materials

In order to use Equations 37.16 and 37.17, it is necessary to have available information on the thermal properties (thermal conductivity k , density ρ , and specific heat C) of steel and insulation materials.

37.3.6.1 Steel

The thermal properties of steel are known with reasonable accuracy and the following values are given in Eurocode 3 Part 1.2 (CEN 2000b):

Density

$$\rho_s = 7850 \text{ kg/m}^3$$

Thermal conductivity [W/(m K)]

$$\begin{aligned} k_s &= 54 - \frac{T_s}{300} \quad \text{for } 20^\circ\text{C} \leq T_s \leq 800^\circ\text{C} \\ k_s &= 27.3 \quad \text{for } T_s > 800^\circ\text{C} \end{aligned}$$

TABLE 37.3 Section Factors of a Steel Element

Fire exposure situation	A_p/V
Unprotected steel section exposed to fire exposure around all sides	$\frac{2(2B - t_w + D)}{A_s}$
	
Fire exposure on all sides of board protection	$\frac{2(B + D)}{A_s}$
	
Fire protection on three sides: profile protection	$\frac{2(B - t_w) + B + 2D}{A_s}$
	
Fire protection on three sides: board protection	$\frac{2D + B}{A_s}$
	

Note: B = section width, D = steel depth, A_s = cross-sectional area, t_w = web thickness.

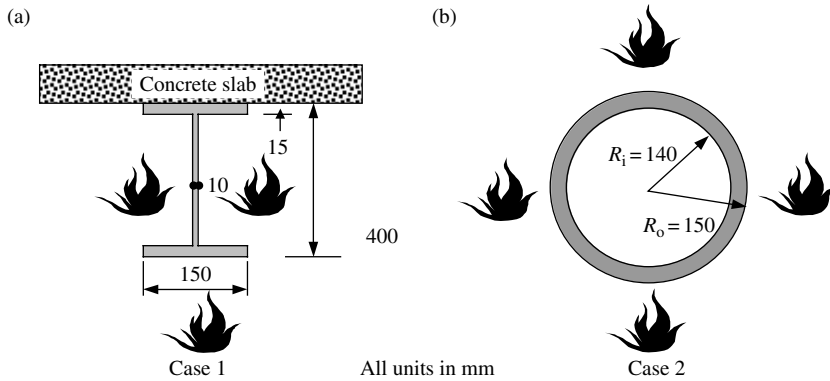

FIGURE 37.8 Dimensions of steel cross-sections.

Specific heat [J/(kg K)]

$$C_s = 425 + 0.773T_s - 0.00169T_s^2 + 2.22 \times 10^{-6}T_s^3 \quad \text{for } 20^\circ\text{C} \leq T_s \leq 600^\circ\text{C}$$

$$C_s = 666 - \frac{13,002}{T_s - 738} \quad \text{for } 600^\circ\text{C} < T_s \leq 735^\circ\text{C}$$

$$C_s = 545 - \frac{17,820}{T_s - 731} \quad \text{for } 735^\circ\text{C} < T_s \leq 900^\circ\text{C}$$

$$C_s = 650 \quad \text{for } T_s > 900^\circ\text{C}$$

37.3.6.2 Insulation Materials

It is much more difficult to obtain information on the thermal properties of fire protection materials. This is partly due to the specific nature of fire protection materials, which have complicated and variable chemical reactions at high temperatures. An important factor contributing to this lack of information is that most fire protection materials are proprietary systems from different manufacturers and commercial sensitivity prevents publication of this type of information.

Information in Table 37.1 should only be used as a general guide for a few generic types of fire protection material.

Intumescent coatings offer a number of advantages, for example, architectural appearance and the possibility of offsite applications and are increasingly being used as fire protection materials to steel structures. At present, there are no suitable simplified design equations for steel structures protected with intumescent coatings. The designer has to rely on information provided by the intumescent coating manufacturer from standard fire resistance tests.

EXAMPLE 37.3

Temperatures in unprotected steelwork

For the cross-section in Example 37.2, case 1, calculate the unprotected steel temperature under the natural fire condition evaluated in Example 37.1. For steel, assume a constant density of 7850 kg/m^3 and a constant specific heat of 650 J/(kg K) . Also, assume a constant resultant emissivity of 0.5 and a convective heat transfer coefficient of $25 \text{ W/(m}^2 \text{ K)}$.

Calculation results

The calculations are performed for intervals of 5 s and results of only the first time increment are shown.

Equation 37.15 gives $h_r = 2.95 \text{ W/(m}^2 \text{ K)}$. The total heat transfer coefficient is $27.95 \text{ W/(m}^2 \text{ K)}$.

After a time increment of $\Delta t = 5$ s, Equation 37.3 in Example 37.1 gives a fire temperature of 41.74°C . The steel temperature is 20°C . The section factor from case 1 of Example 37.2 is 150 m^{-1} . Equation 37.17 gives $\Delta T_s = 0.0616^\circ\text{C}$. Thus, the steel temperature after 5 s is 20.0616°C .

Figure 37.5 plots the unprotected steel temperature development. The maximum steel temperature is 829.25°C , reached just after 30 min.

EXAMPLE 37.4

Temperatures in protected steelwork

For the cross-section in case 2 of Example 37.2, calculate the protected steel temperature under the natural fire condition obtained in Example 37.1. Fire protection is by sprayed lightweight concrete whose thermal properties are given in Table 37.1. Assume the same steel thermal properties as in Example 37.3.

Calculation results

The calculations are performed for intervals of 5 s and results of only the first time increment are shown.

Equation 37.17 gives $\phi = 1.129$ and $\Delta T_s = -2.54^\circ\text{C}$. As pointed out in Section 37.3.4, this negative number should be changed to 0.

Figure 37.5 plots the protected steel temperature development. The maximum steel temperature is 602.58°C , reached at 51.25 min.

37.4 Design of Structural Elements at Elevated Temperatures

37.4.1 General

The remaining sections of this chapter will introduce the reader to design calculations to assess structural stability at elevated temperatures. In Europe, the structural fire safety design of steel elements is covered in ENV 1993-1-2 (CEN 2000b), commonly known as Eurocode 3 Part 1.2 (to be referred to as Eurocode 3 hereafter), composite steel/concrete elements in ENV 1994-1-2 (CEN 2001) or Eurocode 4 Part 1.2 (Eurocode 4), reinforced concrete structures in ENV 1992-1-2 (CEN 1996), or Eurocode 2 Part 1.2, timber structures in ENV 1995-1-2 (CEN 2000c) or Eurocode 5 Part 1.2 and masonry structures in ENV 1996-1-2 (CEN 1997) or Eurocode 6 Part 1.2. At present, design calculations for steel and composite steel/concrete structures are advanced. Design calculations for concrete and timber structures are relatively brief and there is a significant lack of information for fire safety design of masonry structures. Also, there is very little information available to enable fire safety design calculations for structures made of more “specialist” construction materials such as glass, fiber reinforced plastics, aluminum. This chapter will present detailed information to enable fire safety design calculations of steel and composite steel/concrete structural elements. Structures using other materials will not be dealt with in this chapter due to a significant lack of information.

It should be borne in mind that fire is an accidental event and its coincidence with extreme structural loading is rare. Fire attack is more likely to occur during normal use of a building. Therefore, for structural fire safety design, the design structural loads should be those present during normal service of a building, and further reduced to allow for occupant escape and combustible materials burning off.

Investigations into the collapse of the World Trade Center (FEMA 2002) have raised concern over the reliability of fire protection materials. It is assumed in this chapter that a fire protection material is able to fulfill its intended functions during the life of the protected structure and also during a fire exposure. This may be ensured by making sure that the fire protection material can stick to the protected structure or by limiting deflections of the structure. Also, fire protection materials may get damaged. At present, there are very few studies of this problem and there is insufficient information to help develop a sensible simple

design guide to assess the acceptable extent of damage to fire protection materials. In the light of this, the designer has to ensure that any damage to the fire protection material is repaired.

The structural fire safety design criterion is the same as at ambient temperature, that is, the residual load carrying capacity of a structural member should not be lower than the applied load under the fire condition.

37.4.2 Mechanical Properties of Steel and Concrete at Elevated Temperatures

37.4.2.1 Steel

The stress–strain relationships of steel at elevated temperatures depend on whether steady state or transient state testing is employed. In steady state testing, the material temperature is held at a constant value and stress is changed. In transient state testing, stress is applied and the material temperature is then changed. Transient state testing is preferred since it reflects the realistic situation of a structure in fire, where structural loads are applied before fire exposure. In transient state testing, the rate of heating has some influence due to creep strain. But since the steel creep strain is small, mechanical testing of steel at elevated temperatures is usually carried out by using a typical heating rate of about 10°C/min as found in realistic steel structures exposed to fire conditions.

In Eurocode 3, the stress–strain curve of steel consists of a straight line for the initial response, followed by an elliptical relationship and then a plateau. Table 37.4 gives the mathematical descriptions used in Eurocode 3 and Figure 37.9 provides an illustration of this model and shows various parameters to be used in the mathematical model. In order to use this model, the reduced strength and stiffness of steel at elevated temperatures are required as input data and Table 37.5 gives their values, expressed as ratios of the values at elevated temperatures to that at ambient temperature. These ratios are often referred to as retention factors.

The thermal expansion strain (ϵ_{th}) of steel is given by

$$\begin{aligned} \epsilon_{th} &= -2.416 \times 10^{-4} + 1.2 \times 10^{-5} T + 0.4 \times 10^{-8} T^2 & \text{for } T \leq 750^\circ\text{C} \\ \epsilon_{th} &= 0.011 & \text{for } 750 < T \leq 860^\circ\text{C} \\ \epsilon_{th} &= -0.0062 + 2 \times 10^{-5} T & \text{for } T > 860^\circ\text{C} \end{aligned}$$

TABLE 37.4 Mathematical Model of the Stress–Strain Relationship of Steel at Elevated Temperatures

Strain range	Stress σ
$\epsilon \leq \epsilon_{p,T}$	ϵE_T
$\epsilon_{p,T} < \epsilon < \epsilon_{y,T}$	$f_{p,T} - c + \frac{b}{a} \sqrt{[a^2 - (\epsilon_{y,T} - \epsilon)^2]}$
$\epsilon_{y,T} \leq \epsilon \leq \epsilon_{t,T}$	$f_{y,T}$
Parameters	$\epsilon_{p,T} = \frac{f_{p,T}}{E_T}$, $\epsilon_{y,T} = 0.02$, $\epsilon_{t,T} = 0.15$
Functions	$a^2 = (\epsilon_{y,T} - \epsilon_{p,T}) \left(\epsilon_{y,T} - \epsilon_{p,T} + \frac{c}{E_T} \right)$ $b^2 = c(\epsilon_{y,T} - \epsilon_{p,T}) E_T + c^2$ $c = \frac{(f_{y,T} - f_{p,T})^2}{(\epsilon_{y,T} - \epsilon_{p,T}) E_T - 2(f_{y,T} - f_{p,T})}$

Source: European Committee for Standardisation (CEN), 2000b, *Draft prEN 1993-1-2, Eurocode 3: Design of Steel Structures, Part 1.2: General Rules, Structural Fire Design* (London: British Standards Institution).

In simple calculations, the coefficient of thermal expansion of steel may be assumed to be a constant so that the incremental thermal expansion strain is given by

$$\epsilon_{th} = 14 \times 10^{-5} \Delta T$$

37.4.2.2 Concrete

37.4.2.2.1 Thermal Strains

The thermal strain of concrete is complex and is influenced by a number of factors. According to Anderberg and Thelandersson (1976) and Khoury and coworkers (Khoury 1983; Khoury et al. 1986), the thermal strain of concrete may be divided into thermal expansion strain, creep strain, and a stress induced transient thermal strain. Interested readers should refer to the above references for more

FIGURE 37.10 Stress–strain relationship of concrete at elevated temperatures.

detailed information on how to evaluate these different strain components. Eurocode 4 (CEN 2001) takes a simple approach and gives the coefficient of thermal expansion of concrete as

$$\begin{aligned} \epsilon_{th} &= -1.8 \times 10^{-4} + 9 \times 10^{-6} T + 2.3 \times 10^{-11} T^3 & \text{for } 20^\circ\text{C} \leq T \leq 700^\circ\text{C}; \\ \epsilon_{th} &= 0.0014 & \text{for } T > 700^\circ\text{C}. \end{aligned}$$

37.4.2.2.2 Stress–Strain Relationships

The mechanical properties of concrete are more variable than those of steel. Phan and Carino (1998, 2000) recently carried out a survey of mechanical properties of concrete (including high strength concrete) at elevated temperatures. Khoury (1992) provided an explanation of the variability in concrete mechanical properties at elevated temperatures. Values in Eurocode 4 (CEN 2001) may be regarded as the lower bound values of different test results for normal strength concrete.

Figure 37.10 shows the Eurocode 4 model for the stress–strain relationship of concrete and definitions of various parameters. The stress–strain relationship is divided into two parts: the ascending part and the descending part.

The Eurocode 4 equation for the ascending part is

$$\sigma_{c,T} = f_{c,T} \left\{ 3 \left(\frac{\epsilon_{c,T}}{\epsilon_{cu,T}} \right) / \left[2 + \left(\frac{\epsilon_{c,T}}{\epsilon_{cu,T}} \right)^3 \right] \right\} \tag{37.18}$$

where $\sigma_{c,T}$, $\epsilon_{c,T}$, $f_{c,T}$, $\epsilon_{cu,T}$ are, respectively, the stress, strain, peak stress, and strain at peak stress for concrete at elevated temperature T .

From Equation 37.18, the initial Young’s modulus of concrete may be obtained from

$$E_{c,T} = \frac{3 f_{c,T}}{2 \epsilon_{cu,T}} \tag{37.19}$$

The descending part is a straight line, joining the peak point (A) with the point of concrete crush (B) in Figure 37.10.

Values of $f_{c,T}$, $\epsilon_{cu,T}$ and $\epsilon_{crush,T}$ are required to determine the complete stress–strain relationship of concrete at elevated temperatures. Table 37.6 gives their values recommended by Eurocode 4 (CEN 2001). This table also gives the retention factors for modulus of elasticity.

37.4.3 Design of Steel Elements

37.4.3.1 Steel Beams

In general, the load carrying capacity of a steel beam depends on the bending moment capacity of its cross-section and its slenderness if lateral torsional buckling occurs. Unlike structural design at ambient

temperature, lateral torsional buckling of a steel beam is usually not a problem in fire. This is because steel beams that are required to have fire resistance are floor beams whose compression flanges are restrained by the floor slabs. Steel beams that should be checked for lateral torsional buckling at ambient temperature, for example, roof beams, do not require fire resistance. Therefore, the following design method will only consider the cross-sectional bending resistance of a beam.

Eurocode 3 gives two methods to calculate the plastic bending moment capacity of a steel beam. The first method is the bending moment capacity method that is generally applicable to cross-sections with nonuniform temperature distributions. In this method, the steel cross-section is divided into a number of thin slices of approximately the same temperature. The plastic bending moment capacity of the cross-section is calculated according to the reduced strengths of steel at the temperatures of these slices.

EXAMPLE 37.5

Plastic bending moment capacity of a nonuniformly heated steel beam

An example is given in [Table 37.7](#) to illustrate this method. Input information for this example are shown in [Figure 37.11](#).

As can be seen, the plastic bending moment capacity method requires many calculations. Hence, the only benefit of using this more elaborate method is to explore possible benefits of nonuniform temperature distribution in the cross-section of a beam, particularly to justify the use of unprotected steelwork.

Instead of using the plastic bending moment method, Eurocode 3 also gives an alternative method that is much simpler to use. In this simple method, the plastic bending moment capacity of a beam is given by

$$M_{p,fi} = k_{y,T} M_p / \kappa_1 \tag{37.20}$$

where M_p is the plastic bending moment capacity of the cross-section at ambient temperature; $k_{y,T}$ is the retention factor for the effective yield strength of steel at the maximum temperature in the lower flange. Thus, $k_{y,T} M_p$ gives the reduced plastic bending moment capacity of the cross-section at a uniform temperature T . The modification factor κ_1 is used to account for nonuniform temperature distribution in the cross-section and $\kappa_1 = 0.7$. For the above example, $k_{y,T} M_p = 137.5$ kN m. Using Equation 37.20 gives a value of 196.5 kN m, which is close to that obtained using the more time-consuming plastic bending moment capacity method.

37.4.3.2 Steel Columns

It is commonly assumed that a steel column is surrounded by fire on all sides so that the steel temperature is uniform. Because the stress–strain relationships of steel at elevated temperatures are non-linear and cannot be assumed to be elastic–perfectly plastic, calculations of the column resistance in fire are slightly different from those at ambient temperature. In Eurocode 3, the column axial compressive resistance is calculated from

$$P_{c,fi} = \chi_{fi} P_{u,fi} \tag{37.21}$$

where $P_{u,fi}$ is the column squash load at elevated temperature T and is calculated from

$$P_{u,fi} = A_s k_{y,T} f_y \tag{37.22}$$

χ_{fi} is the column strength reduction factor to account for the column slenderness effect and is given by

$$\chi_{fi} = \frac{1}{\phi_{fi} + \sqrt{\phi_{fi}^2 - \bar{\lambda}_{fi}^2}}, \quad \text{with } \phi_{fi} = \frac{1}{2} (1 + \alpha \bar{\lambda}_{fi} + \bar{\lambda}_{fi}^2) \tag{37.23}$$

where α is an imperfection factor, $\alpha = 0.65 \sqrt{f_y/235}$.

The column slenderness in fire $\bar{\lambda}_{fi}$ is calculated using

$$\bar{\lambda}_{fi} = \bar{\lambda} \sqrt{\frac{k_{y,T}}{k_{E,T}}} \tag{37.24}$$

where $\bar{\lambda}$ is the column slenderness at ambient temperature. $\bar{\lambda}$ is defined as

$$\bar{\lambda} = \lambda \sqrt{\frac{f_y}{\pi^2 E}}, \quad \text{with } \lambda = \frac{L_e}{r_y} \quad (37.25)$$

where L_e and r_y are the column buckling length and radius of gyration of the column cross-section about the relevant axis of buckling.

37.4.3.3 Steel Connections

The behavior of steel connections in fire is complicated due to complex temperature distributions in connections and connection interactions with the adjacent structure. Fortunately, since a connection is much “bulkier” than the connected members, its temperatures are much lower, and, if designed properly, it is rarely the weak link in the structure. Current design methods require that when fire protection materials are applied to a structure, the thickness of protection applied to a connection should be based on the thickness required for whichever of the members joined by the connection that has the highest section factor H_p/A .

However, it should be pointed out that the above comments are related to steel structures in flexural bending under fire conditions, where a connection does not have to resist any tensile force. High tensile forces can develop in the connected steel beams to fracture connections, which was observed during the Cardington fire research on the steel framed building (Newman et al. 2000) when the connections were cooling, or found from investigations of the World Trade Center collapse (FEMA 2002) due to possible development of catenary action in the floor trusses at very large deflections. If the designer anticipates tensile forces to develop in the connected beams, it is important that their values are quantified accurately and connections are designed to resist such tensile forces.

37.4.3.4 Other Types of Steel Structures

37.4.3.4.1 Stainless Steel Structures

Due to architectural demand and superior corrosion resistance, stainless steels are becoming more widely used. Although their fire resistance is only a minor factor in determining whether to use stainless steel or not, stainless steel does have superior fire resistance to conventional carbon steels.

Baddoo (1999) gives some information on the strength retention factors of stainless steels at different elevated temperatures. Whilst conventional carbon steel loses about 50% of its strength at a temperature of around 600°C, the temperature that gives the same loss in the strength of stainless steel is much higher, at about 800°C. Also, the surface of stainless steel has a much higher reflectivity, hence the emissivity ($1 - \text{reflectivity}$) of stainless steel is much lower. Typically, the emissivity of stainless steel is about 0.3 to 0.4, compared to about 0.8 for carbon steel. This gives a much lower temperature in a stainless steel structure in fire. For realistic loading conditions, it is almost certain that stainless steel structures will be able to be engineered to provide sufficient fire resistance without the need for fire protection.

With suitable modifications to take into consideration the reduced strength and stiffness of stainless steel at elevated temperatures, the same design method for carbon steel may be extended to stainless steel structures (Baddoo and Burgen 1998).

37.4.3.4.2 Portal Frames

Portal frames are usually single storey buildings with a small density of occupants. Escape in the case of fire attack is relatively easy. Therefore, fire safety of a portal frame only becomes a requirement when the portal frame is adjacent to another building and it is necessary to prevent fire spread from the portal frame building to the adjacent building. Fire spread from a portal frame building is usually through collapsed walls; consequently, the structural safety requirement for a portal frame under fire attack is to ensure that the portal frame columns in the walls remain upright so that the walls are stable. The portal frame girders may be allowed to collapse.

The Steel Construction Institute in the United Kingdom has developed a design guide (Newman 1990) for portal frames in fire. Using this guide, portal frames are usually designed without fire protection.

37.4.3.4.3 Water Cooled Structures

The design of water cooled structures (Bond 1975) relies on the principle that boiling water has a very high value of convective heat transfer coefficient, some 3 or 4 orders higher than the convective heat transfer coefficient of air. If boiling water is replenished, heat on a water cooled steel structure is taken away and steel temperatures remain low. Typically, steel temperatures in a water cooled structure do not exceed 150°C. Therefore, structural stability of a water cooled structure is rarely a design issue. Design is mainly concerned with hydraulic calculations to ensure sufficient water supply and circulation in case of fire.

Water cooling a steel structure to achieve fire protection is expensive and because of this it is rarely used solely for the purpose of fire protection. It is usually combined with other functions. An excellent example (Bressington 1997) of recent application of this technique is in the roof truss of the cargo handling facility of Hong Kong Air Cargo Terminals Ltd. The steel structural roof truss is made of circular hollow sections and is used as the water distribution pipe for sprinklers. On operation of the sprinklers in the event of a fire, internal water flow through the steelwork members also provides sufficient cooling.

37.4.3.4.4 External Steelwork

In the case of a building enclosure fire, fire exposure on the external steelwork differs from that on the interior steelwork in two ways:

- The fire temperature to the external steelwork is much lower than that to the interior steelwork.
- The external steelwork may not be directly engulfed in fire.

These two differences ensure that temperatures in the external steelwork are kept lower than their failure temperatures so that fire protection is not necessary.

Law and O'Brien (1989) developed a design method for external steelwork and the design method in Eurocode 3 is based on their work.

37.4.4 Composite Steel/Concrete Members

37.4.4.1 Composite Slabs

Composite slabs are constructed from reinforced concrete slabs in composite action with steel decking underneath. The steel decking acts as support to the concrete during construction and is generally profiled to maximize structural efficiency. Composite slabs usually form the floor of a fire resistant compartment. Hence, they should meet all the requirements of fire resistant construction; that is, in addition to sufficient load bearing resistance, they should also have adequate insulation and maintain their integrity during fire attack.

Composite floor slabs are noncombustible and will not suffer integrity failure by burning through. However, the problem of integrity failure may occur at the junctions between a composite slab and other construction elements. Particular attention should be paid to the slab edges where large cracks may occur due to large rotations. It is important that reinforcement bars should be made continuous over the supports.

To check whether a slab can fulfill the insulation requirement, it is necessary to carry out a heat transfer analysis to determine temperatures on the unexposed surface of the slab. Results of this temperature analysis can then be used to determine the minimum slab thickness above which the unexposed surface temperature is unlikely to exceed the allowed values. For most applications where the required standard fire resistance rating does not exceed 90 min, the required minimum slab thickness will almost certainly be less than that required by other functions such as control of deflections. Hence, the insulation requirement for composite slabs is very rarely a problem in fire resistant design.

FIGURE 37.12 A continuous slab exposed to fire.

37.4.4.1.1 Load Bearing Capacity of One-Way Spanning Composite Slabs

When calculating the load bearing resistance of a composite slab in fire, it is often assumed that it is one-way spanning, being effective only in the direction of the concrete rib. For a continuous composite slab, the plastic design method may be used, in which plastic hinges are assumed to form at the supports and locations of the maximum bending moment in the span of the slab. For example, for the interior span of a continuous slab under uniformly distributed load, as shown in Figure 37.12,

$$M_{+,fi} + M_{-,fi} \geq M_{fi,max}, \quad \text{i.e., } M_{+,fi} + M_{-,fi} \geq \frac{1}{8}wL^2 \tag{37.26}$$

where $M_{+,fi}$ and $M_{-,fi}$ are the sagging and hogging bending moment resistance of the slab, respectively, and $M_{fi,max}$ is the maximum free bending moment in the slab under fire conditions.

For the end span of a continuous slab with uniformly distributed load, as shown in Figure 37.12,

$$M_{+,fi} + \frac{1}{2}M_{-,fi} = \frac{1}{8}wL^2 + \frac{M_{-,fi}^2}{2L^2w} \tag{37.27}$$

or approximately

$$M_{+,fi} + 0.45M_{-,fi} \geq \frac{1}{8}wL^2 \tag{37.28}$$

In order to determine the slab load carrying capacity in fire, the sagging bending moment capacity $M_{+,fi}$ and hogging bending moment capacity $M_{-,fi}$ should be evaluated.

When calculating the sagging bending moment capacity of a slab, the reinforcement near the fire side is in tension and the compressive concrete is on the unexposed side of the slab. Since the temperature rise on the unexposed side of the slab is required to be below 140°C to fulfill the insulation requirement, the concrete in compression can be assumed to be cold and its cold strength may be used when calculating the sagging bending moment capacity of the slab. Contributions from the steel decking are usually ignored because the decking will be unprotected and may debond because it is under direct fire attack. Figure 37.13 shows the calculation procedure. In Figure 37.13, f_c is the design strength of concrete in bending at ambient temperature, A_r , $p_{y,r}$, and $k_{y,r}(T)$ are the area, design strength at ambient temperature, and strength retention factor of the reinforcement at temperature T , and $k_{y,r}(T)$ may be obtained from Figure 37.14.

Under a hogging bending moment, the compression face of a composite slab is exposed to fire where there is a very steep temperature gradient. When calculating the hogging bending moment capacity, the composite slab, including the concrete in the ribs, should be divided into a number of layers each of approximately constant temperature. The contribution of each layer should be evaluated separately and then integrated to give the total slab resistance.

FIGURE 37.13 Calculation method for sagging bending moment capacity.

FIGURE 37.14 Retention factors of cold worked reinforcing steel (from European Committee for Standardisation (CEN), 2001, *prEN 1994-1-2, Eurocode 4: Design of Composite steel and Concrete Structures, Part 1.2: Structural Fire Design* (London: British Standards Institution)).

37.4.4.1.2 Load Bearing Capacity of Two-Way Spanning Slabs

The load carrying capacity of a composite slab in one-way spanning is usually sufficient under fire conditions. However, in some cases, it may be necessary to utilize the slab strength in two-way spanning. This is particularly the case when it is necessary to justify the elimination of fire protection from some of the slab-supporting steel beams. The yield line analysis (Johansen 1962) for reinforced concrete slabs may be used to give a safe estimate of the slab load carrying capacity in two-way spanning.

The real benefit of utilizing the strength of a slab in two-way spanning is the possibility of using tensile membrane action in the slab, under which the strength of the slab can be many times higher than that given by yield line analysis. Recently, a design method has been developed to use tensile membrane action in steel framed buildings to eliminate fire protection to some steel beams. For detailed design equations and examples, reference should be made to the two papers by Bailey and Moore (2000a, 2000b) and a publication by the United Kingdom’s Steel Construction Institute (Newman et al. 2000).

37.4.4.2 Composite Beams

For a conventional composite beam with concrete slabs on top of the steel section, the sagging bending moment capacity of the composite cross-section may be calculated by the bending moment capacity method, similar to steel beams (Section 37.4.3.1). The concrete in compression may be assumed to be cold and the steel temperatures may be calculated using Equations 37.16 or 37.17. If the steel section is protected, it may be assumed to have a uniform temperature distribution and its section factor A_p/V is that of the entire section, calculated according to Table 37.3. If the steel section

is unprotected, the steel section will have a nonuniform temperature distribution. For temperature calculations, the steel section may approximately be divided into two parts: the upper flange and the lower flange plus the web.

EXAMPLE 37.6

Plastic bending moment capacity of a composite cross-section

Figure 37.15 shows a composite cross-section exposed to fire underneath the slab. The steel section is unprotected and fire exposure is according to the temperature–time relationship in Example 37.1. At ambient temperature, the design strength of steel is 275 N/mm² and the design compression strength of concrete is 20 N/mm². Calculate the minimum sagging bending moment capacity of the composite cross-section in fire.

Calculation results

According to the dimensions in Figure 37.15, the section factor of the top flange is 80 m⁻¹ and that of the web/bottom flange is 147 m⁻¹.

Following calculations in Example 37.2, the maximum top flange temperature is 802.8°C reached at 32.25 min and the maximum lower flange/web temperature is 847.2°C reached at 28.75 min. It is interesting to notice that under natural fire exposure, different parts of a structural member will reach their maximum temperatures at different times. Therefore, in theory, calculations of the plastic bending moment capacity of the cross-section should be performed as a function of time. For simplicity, in this example, the maximum temperatures of the top flange and bottom flange/web, attained at different times, are used.

From Table 37.5, the residual steel strengths and tensile capacity of the steel cross-section are

Top flange: $f_y = 0.1086 \times 275 = 29.9 \text{ N/mm}^2$, $A_s = 2250 \text{ mm}^2$, $N_{uf} = 67.3 \text{ kN}$

Bottom flange/web: $f_y = 0.08639 \times 275 = 23.76 \text{ N/mm}^2$

The lower flange tension resistance: $N_{lf} = 53.5 \text{ kN}$

The web area is 3700 mm², giving the web tension resistance: $N_{wf} = 87.9 \text{ kN}$

The total tensile resistance of the steel cross-section: $N_s = N_{uf} + N_{wf} + N_{lf} = 208.7$

Assume the top of the concrete slab is cold. The depth of concrete in compression is $208.7 \times 1000 / (20 \times 2000) = 5.22 \text{ mm}$.

FIGURE 37.15 Composite cross-section dimensions for Example 37.6.

Taking moment about the top surface of the slab, the residual sagging bending moment capacity of the composite cross-section is

$$\begin{aligned} M_f &= [-208.7 \times 5.22/2 + 67.3 \times (130 + 15/2) + 87.9 \times (130 + 400/2) \\ &\quad + 53.5 \times (130 + 400 - 15/2)]/1000 \\ &= 65.7 \text{ kNm} \end{aligned}$$

37.4.4.3 Composite Columns

37.4.4.3.1 Resistance to Axial Load According to Eurocode 4

The general equation for calculating the squash load of a composite column is

$$P_{u,fi} = \sum (A_i f_i)_c + \sum (A_i f_i)_s + \sum (A_i f_i)_r \quad (37.29)$$

where f_i is the design strength of the i th layer and subscripts “c,” “s,” and “r” represent concrete, steel, and reinforcement, respectively. Due to nonuniform temperature distribution, each component of the composite cross-section is divided into a number of layers of approximately the same temperature.

Similarly, the rigidity (EI) of the composite cross-section is calculated using the following equation:

$$(EI)_{fi} = \sum (EI)_{i,s} + \sum 0.8(EI)_{i,c} + \sum (EI)_{i,r} \quad (37.30)$$

where symbols E and I are the initial modulus of elasticity and second moment of area of the appropriate component material about the relevant axis of buckling of the entire composite cross-section, respectively.

The composite column compression resistance in fire is given by

$$P_{c,fi} = \frac{\chi_{fi}}{1.2} P_{u,fi} \quad (37.31)$$

where the compression strength reduction factor in fire is calculated by

$$\chi_{fi} = \frac{1}{\phi_{fi} + \sqrt{\phi_{fi}^2 - \bar{\lambda}_{fi}^2}} \quad \text{with } \phi_{fi} = 0.5 \left[1 + \alpha(\bar{\lambda}_{fi} - 0.2) + \bar{\lambda}_{fi}^2 \right] \quad (37.32)$$

in which the initial imperfection factor α has a value of 0.49.

The column slenderness factor $\bar{\lambda}_{fi}$ in fire is defined by

$$\bar{\lambda}_{fi} = \sqrt{\frac{P_{u,fi}}{P_{cr,fi}}} \quad (37.33)$$

where the Euler buckling load in fire is calculated using

$$P_{cr,fi} = \frac{\pi^2 (EI)_{fi}}{L_e^2} \quad (37.34)$$

in which L_e is the column effective length.

37.4.4.3.2 Simplified Temperature Calculation Method for Unprotected Concrete Filled Columns

The temperature calculation method is based on the method of Lawson and Newman (1996) with modification by Wang (2000). This method assumes that the composite column is unprotected.

In this method, the steel shell temperature is calculated by

$$T_s = C_2 T_{fi} \quad (37.35)$$

where T_{fi} is the standard fire temperature and C_2 is a multiplication factor depending on the fire resistance time. C_2 is given by

$$C_2 = 1 - 0.02t \times \frac{120 - FR}{120}, \quad \text{but } C_2 \leq 1.0 \quad (37.36)$$

FIGURE 37.16 Temperatures of a concrete slab exposed to the standard fire from underneath (from European Committee for Standardisation (CEN), 2001, *prEN 1994-1-2, Eurocode 4: Design of Composite steel and Concrete Structures, Part 1.2: Structural Fire Design* (London: British Standards Institution)).

TABLE 37.8 Multiplication Factor C_1

Diameter or size of square section (mm)	Distance of center of layer from out surface (mm)				
	10	30	50	70	>70
200	1.08	1.22	1.41	1.60	1.80
300	1.05	1.14	1.22	1.36	1.50
400	1.03	1.09	1.18	1.25	1.35
500	1.02	1.07	1.12	1.18	1.25

Source: Lawson, R.M. and Newman, G.M., 1996, *Structural fire design to EC3 & EC4, and comparison with BS 5950*, Technical Report, SCI Publication 159, The Steel Construction Institute.

where FR is the fire resistance rating in minutes and t is the thickness of the steel shell in mm. The concrete temperature is calculated by

$$T_c = C_1 C_2 T_{slab} \tag{37.37}$$

where C_1 is a multiplication factor depending on the composite section size and location of the concrete (and is independent of the standard fire resistance time) and T_{slab} is the temperature in an infinitely wide concrete slab exposed to fire on one side (given in Figure 37.16). Values of C_1 are given in Table 37.8.

If reinforcement is used, the reinforcement temperature should be taken as that of the concrete at the same location. Furthermore, for reinforcement in the corners of a square section, due to heating from two sides of the composite section, the reinforcement temperature should be calculated from an equivalent depth of half the concrete cover depth.

EXAMPLE 37.7

Compression resistance of a composite column

Figure 37.17 shows the dimensions of a concrete filled circular steel section. The effective length of the column is 4 m. Calculate the column compression resistance for a standard fire resistance period of 60 min. At ambient temperature, steel has a design strength of 275 N/mm² and Young’s modulus of 205,000 N/mm². Concrete has a design compression strength of 40 N/mm² and modulus of elasticity of 20,000 N/mm².

FIGURE 37.17 Column cross-section size for Example 37.7.

TABLE 37.9 Calculation Results for Example 37.7

Zone	Radius (mm)	T_{slab} (°C)	T_{zone} (°C)	A (mm ²)	I (cm ⁴)	f_i (N/mm ²)	E_i (N/mm ²)	$(fA)_i$ (kN)	$(EI)_i$ (kN m ²)
Steel	130–150	—	756	17,593	17,329	44.77	22,058	787.6	3322.4
Con.	110–130	421	480	15,080	10,933	25.2	7,875	380	861
Con.	90–110	250	305	12,566	6,346	33.84	12,250	425	777.4
Con.	70–90	150	204	10,053	3,267	35.92	14,310	361	467.5
Con.	0–70	130	195	15,394	1,886	36.1	14,512	556	273.7

Calculation results

Divide the composite cross-section into steel tube, three concrete rings of equal thickness of 20 mm, and a concrete core of 70 mm radius. Table 37.9 gives, for each zone of the composite cross-section, temperature (in °C, calculated using Equations 37.35–37.37), area (mm²), second moment of area about a principle axis of the entire cross-section (cm⁴), reduced design strength (in N/mm²), and Young's modulus (in N/mm², from Table 37.5 for steel and Table 37.6 for concrete) at elevated temperatures, compression resistance (in kN) and rigidity (EI , in kN m²).

Equation 37.29 gives $P_{u,fi} = 2509.6$ kN. Equation 37.34 gives the Euler buckling load in fire $P_{cr,fi} = 5226.1$ kN, giving a column slenderness in fire $\bar{\lambda}_{fi} = 0.7885$. Equation 37.32 gives $\chi_{fi} = 0.563$ and Equation 37.31 gives the column compression resistance in fire $P_{c,fi} = 1413$ kN.

37.4.4.3.3 High Strength Concrete Filled Columns

With the introduction of high strength concrete, the load carrying capacity of a concrete filled column can be further enhanced. However, the increase in fire resistance is relatively small because high strength concrete loses its strength at a much lower temperature than normal strength concrete. By adding a small amount of steel fibre to the concrete, the elevated temperature performance of high strength concrete can be much improved and the performance of fibre reinforced high strength concrete filled steel columns is similar to that with normal strength concrete filling (Kodur and Wang 2001). Provided the strength and stiffness retention factors are available, Equations 37.29 and 37.30 can also be used.

37.5 Design for Unprotected Steelwork

The quest for knowledge is one of the main drivers of research to investigate the behavior of steel and composite structures under fire conditions. However, it should be recognized that the desire to reduce or

eliminate fire protection to steelwork is an equally strong incentive to carry out these studies. Fire protection to steelwork can represent a significant part of the total steel structural cost and the elimination of fire protection to steelwork represents a significant saving in construction cost to the client. But more importantly, by reducing the use of fire protection, steel becomes more competitive and the steel industry can benefit from an increased market share. After the September 11 event, it is also appropriate to consider using unprotected steelwork in fire situations for safety. Without fire protection, there would be no problem related to possible unreliable use of fire protection materials.

There are a number of ways of designing for unprotected steelwork, including risk assessment to reduce the requirement of fire resistance, using the so-called fire resistant steel (Sakumoto 1998) to increase the strength of steel at elevated temperatures, over-design steel elements at ambient temperature so as to increase their reserve of strength in fire, integrating the functions of fire protection and structural load bearing of concrete, and utilizing advanced structural behavior. Wang and Kodur (2000) provide a summary of these techniques. This section will give a brief introduction to the last two methods because they can be readily implemented in practice.

37.5.1 Integration of Structural Load Bearing and Fire Protection Functions of Concrete

It should be appreciated that it is very rare for steelwork to be used alone. Steel is usually used in combination with other materials, in particular with concrete. Concrete is not only a structural material, it also has good thermal insulation properties. Therefore, by combining these two functions of concrete, composite structures may be constructed to give inherently high fire resistance. The systems that will be described below have made special considerations of fire resistance in their design and construction. The following paragraphs will give a short description of their main features and the inherent standard fire resistance that they can achieve. This should enable the designer to determine quickly a possible structural load bearing system where the main design concern is to use unprotected steelwork. More detailed information may be found in Bailey and Newman (1998).

37.5.1.1 Beams

Three types of construction may be used:

1. Slim floor/asymmetric beam, shown in Figures 37.18a and b. In the slim floor construction, a wide plate is welded to the bottom flange of a universal column section and composite floor slabs are supported on the wide plate. In an asymmetric steel beam, the bottom flange is rolled wider than the top flange. Both systems use the same principle to achieve unprotected steelwork: the

FIGURE 37.18 Steel/composite beams of high fire resistance: (a) slim floor beam, (b) asymmetrical beam, (c) shelf angle beam, and (d) partially encased steel beam.

web of the steel section is protected by the concrete and provides the majority of the bending resistance of the steel beam at elevated temperatures. Only the steel section is assumed to have load carrying capacity, but lateral torsional buckling is prevented by the concrete slabs.

2. Shelf angle beams, shown in Figure 37.18c. In this system, steel angles are welded to the web of a steel beam and these angles are used to support precast concrete floor units. This system is mainly used to reduce the structural depth of the floor. Since the angles, the upper flange, and the upper portion of the web of the steel section are shielded from fire exposure, 60 min of fire resistance can be achieved using this system without fire protection.
3. Partially encased beams, shown in Figure 37.18d. By casting concrete in between the flanges of a regular universal beam section, only the downward side of the lower flange will be exposed to fire. Both the web and the upper flange are shielded from fire exposure and can provide high structural resistance. Composite floor slabs may be connected to the top of the partially encased steel beam via shear connectors to obtain composite action. Since concrete is cast between flanges of the steel section, no temporary formwork is necessary. By using reinforcement, standard fire resistance of up to 3 h can be obtained without fire protection to the steelwork.

Table 37.10 summarizes the standard fire resistance rating that can be achieved by different types of unprotected steel beams.

37.5.1.2 Columns

Three types of unprotected columns may be used:

1. Columns with blocked-in webs as shown in Figure 37.19a. In this construction, lightweight aerated concrete blocks are placed between the flanges of a universal steel section. The aerated concrete blocks not only provide good insulation to the column web, they also reduce the average column flange temperature compared to a bare steel column. A standard fire resistance rating of 30 min can be achieved without additional fire protection.
2. Partially encased steel columns with unreinforced and reinforced concrete as shown in Figure 37.19b. In a column with blocked-in web, the lightweight aerated concrete only provides insulation to the steel section and the system cannot provide 60 min fire resistance. If normal

TABLE 37.10 Standard Fire Resistance Rating of Unprotected Steel Beams

Type of construction	Standard fire resistance time (min)
Bare universal beams	15
Slim floor/asymmetrical beams	60
Shelf angle beams	60
Partially encased beams	>60

TABLE 37.11 Standard Fire Resistance Rating of Unprotected Steel Columns

Type of column	Standard fire resistance time (min)
Universal column	15
Blocked-in column	30
Partially encased with unreinforced concrete	60
Partially encased with reinforced concrete	>60
Concrete filled hollow section without reinforcement	60
Concrete filled hollow section with reinforcement	>60

Source: Bailey, C.G. and Newman, G.N., 1998, The design of steel framed building without applied fire protection, *The Structural Engineer*, 76(5), 77–81.

strength concrete is used to provide composite action, much higher fire resistance can be obtained. If unreinforced concrete is used, 60 min of fire resistance can be obtained. Reinforcement may be used to give much higher fire resistance.

- Concrete filled hollow steel sections as shown in [Figure 37.19c](#). Concrete filling of hollow steel sections is a very practical solution to form composite columns. Either unreinforced or reinforced concrete may be used. This type of column has been described in some detail in [Section 37.4.4.3](#). To summarize, unreinforced concrete filled columns can achieve 60 min of fire resistance. If reinforcement is used, much higher fire resistance may be obtained.

To summarize, Table 37.11 gives the standard fire resistance time that can be achieved by different types of unprotected columns.

The usefulness of [Table 37.10](#) and Table 37.11 is to enable readers to reach a decision quickly on the form of construction to achieve the required standard fire resistance without fire protection.

37.5.2 Utilizing Whole Building Performance in Fire

It has long been recognized that the behavior of a whole building in fire is much better than that of its individual members. By achieving a better understanding of whole building behavior, it is possible to achieve the objective of eliminating fire protection in conventionally designed and constructed steel framed buildings. Two methods based on the whole building behavior may be considered.

37.5.2.1 Utilization of Structural Redundancy

Up to now, the design of steel structures for fire safety has generally been based on the assessment of individual structural members, that is, each structural member should achieve the required fire resistance. However, it should be realized that for a building to remain stable under fire conditions, serving the principal need of containing a fire and preventing its spread, it is not absolutely necessary for every individual structural member to remain stable. Fire protection may be eliminated for some steel members if, in the absence of these members, an alternative load path due to structural redundancy can be developed to retain structural stability.

For example, in a multistory steel framed structure, floor loads are transferred by floor slabs to the supporting steel beams and the beam reactions are then transmitted to the supporting steel columns and thence to the foundations. For fire design, it is usually assumed that the load path selected for the ambient temperature design remains unchanged under fire conditions and that each member in this load path has to have sufficient fire resistance.

It is now appreciated that the load transmission path in a structure is not a fixed one. If one load path breaks down, other alternative load paths may exist and safely transfer the applied loads to the foundation. For example, [Figure 37.20a](#) shows part of a steel framed structure and the usual load carrying path adopted in the ambient temperature design. However, if the floor slabs are designed to have higher load bearing resistance than required at ambient temperature, it is quite possible for the alternative load carrying sequence in [Figure 37.20b](#) to develop in fire.

FIGURE 37.20 An example of alternative load paths in a structure: (a) load path of ambient temperature and (b) possible load path in fire.

At ambient temperature (Figure 37.20a), the secondary beams are needed to control excessive slab deflections. Under fire conditions, applied floor loads are reduced and large slab deflections are permissible. Thus, failure of some secondary beams is permissible provided a sufficient network of beams remain available to keep transfer the slab load to the columns. A possible system of this type is shown in Figure 37.20b. In Figure 37.20b, fire protection for the dotted secondary beams is not required. Of course, the design load carrying capacity of the slab can be further increased even to bypass some main steel beams.

37.5.2.2 Developing Better Understanding of Structural Behavior in Fire

Structural fire safety design has been developed based on extending current structural design methods at ambient temperature to elevated temperatures. At ambient temperature, due to the need to avoid large deflections, design methods are based on flexural behavior at small deflections. These current design methods can be very conservative and structural members may have much higher strength if large deflections are allowed. By exploiting this enhanced load bearing capacity, fire protection may be eliminated. An example is the utilization of tensile membrane action in reinforced composite slabs in steel framed buildings (Newman et al. 2000).

37.6 Concluding Remarks

This chapter has given an introduction to different aspects of structural fire safety design, including evaluation of the severity of fire exposure, calculations of temperatures in structures exposed to fire, and assessment of load carrying capacities of structures at elevated temperatures. An important emphasis of this chapter is structural fire safety design from first principles, rather than following the prescriptive route. Materials presented in this chapter are based on developments in Europe. However, the fundamental knowledge should be equally applicable in other situations. A number of examples have been

provided to illustrate the applications of various specific recommendations. There have been tremendous advances in fire safety design of steel and composite steel/concrete structures such that these types of structures are now increasingly being fire engineered to improve design. However, there are still large scopes for research and development in structural fire safety, especially with regard to other types of structures, such as concrete, timber, masonry. It is hoped that this chapter will arouse the interest of the reader in this subject. Structural fire safety design is a relatively new and evolving subject. It is expected that future editions of this chapter will provide more comprehensive coverage of this important topic of structural engineering.

WWW Sites

Nowadays the internet can provide a rich source of information on everything. There are many web sites that give information on fire related topics. The following web sites are well-known organizations that have a interest in the topic of this chapter, structural fire engineering. They are divided into three groups: government and research organizations whose main functions are legislation, research, and dissemination; academic institutions whose main functions are research and education; and industrial companies that are involved in research and development to some extent, but whose main interest is in the application of fire engineering in practical projects. It is inevitable that this list is biased toward U.K. organizations.
