

8th Edition

PRINCIPLES OF MODERN  
CHEMISTRY

Oxtoby Gillis Butler

# PERIODIC TABLE OF THE ELEMENTS

**KEY**

- Main group metals
- Transition metals
- Metalloids
- Nonmetals, noble gases

Atomic number  
Symbol  
Name  
Atomic mass

An element

Example: Au (Gold) with atomic number 79 and atomic mass 196.9665.

1  
**H**  
Hydrogen  
1.0079

Period number  
Group number, U.S. system  
Group number, IUPAC system

1A (1)  
2A (2)

81	82	83	84	85	86	87	88	89	90
113	114	115	116	117	118	119	120	121	122

66	67	68	69	70	71
66	67	68	69	70	71
100	101	102	103	104	105
100	101	102	103	104	105
106	107	108	109	110	111
106	107	108	109	110	111
112	113	114	115	116	117
112	113	114	115	116	117
118	119	120	121	122	123
118	119	120	121	122	123

Numbers in parentheses are mass numbers of radioactive isotopes.

Atomic masses shown here are March 2013 IUPAC values. Elements for which the International Union of Pure and Applied Chemistry (IUPAC) has officially sanctioned the discovery and approved a name are indicated by their chemical symbols in this table. Elements that have been reported in the literature but not yet officially sanctioned and named are indicated by atomic number.

Standard Atomic Masses  
of the Elements 2013, IUPAC

Based on Relative Atomic Mass of  $^{12}\text{C} = 12$ , where  $^{12}\text{C}$  is a neutral atom  
in its nuclear and electronic ground state.<sup>1</sup>

Name	Symbol	Atomic Number	Atomic Weight	Name	Symbol	Atomic Number	Atomic Weight
Actinium <sup>2</sup>	Ac	89	(227)	Neodymium	Nd	60	144.242(3)
Aluminum	Al	13	26.981 5386(8)	Neon	Ne	10	20.1797(6)
Americium <sup>2</sup>	Am	95	(243)	Neptunium <sup>2</sup>	Np	93	(237)
Antimony	Sb	51	121.760(1)	Nickel	Ni	28	58.6934(4)
Argon	Ar	18	39.948(1)	Niobium	Nb	41	92.906 38(2)
Arsenic	As	33	74.921 60(2)	Nitrogen	N	7	14.0067(2)
Astatine <sup>2</sup>	At	85	(210)	Nobelium <sup>2</sup>	No	102	(259)
Barium	Ba	56	137.327(7)	Osmium	Os	76	190.23(3)
Berkelium <sup>2</sup>	Bk	97	(247)	Oxygen	O	8	15.9994(3)
Beryllium	Be	4	9.012 182(3)	Palladium	Pd	46	106.42(1)
Bismuth	Bi	83	208.980 40(1)	Phosphorus	P	15	30.973 762(2)
Bohrium <sup>2</sup>	Bh	107	(270)	Platinum	Pt	78	195.084(9)
Boron	B	5	10.811(7)	Plutonium <sup>2</sup>	Pu	94	(244)
Bromine	Br	35	79.904(1)	Polonium <sup>2</sup>	Po	84	(209)
Cadmium	Cd	48	112.411(8)	Potassium	K	19	39.0983(1)
Calcium	Ca	20	40.078(4)	Praseodymium	Pr	59	140.907 65(2)
Californium <sup>2</sup>	Cf	98	(251)	Promethium <sup>2</sup>	Pm	61	(145)
Carbon	C	6	12.0107(8)	Protactinium <sup>2</sup>	Pa	91	231.035 88(2)
Cerium	Ce	58	140.116(1)	Radium <sup>2</sup>	Ra	88	(226)
Cesium	Cs	55	132.905 4519(2)	Radon <sup>2</sup>	Rn	86	(222)
Chlorine	Cl	17	35.453(2)	Rhenium	Re	75	186.207(1)
Chromium	Cr	24	51.9961(6)	Rhodium	Rh	45	102.905 50(2)
Cobalt	Co	27	58.933 195(5)	Roentgenium <sup>2</sup>	Rg	111	(280)
Copper	Cu	29	63.546(3)	Rubidium	Rb	37	85.4678(3)
Curium <sup>2</sup>	Cm	96	(247)	Ruthenium	Ru	44	101.07(2)
Darmstadtium <sup>2</sup>	Ds	110	(281)	Rutherfordium <sup>2</sup>	Rf	104	(265)
Dubnium <sup>2</sup>	Db	105	(268)	Samarium	Sm	62	150.36(2)
Dysprosium	Dy	66	162.500(1)	Scandium	Sc	21	44.955 912(6)
Einsteinium <sup>2</sup>	Es	99	(252)	Seaborgium <sup>2</sup>	Sg	106	(271)
Erbium	Er	68	167.259(3)	Selenium	Se	34	78.96(3)
Europium	Eu	63	151.964(1)	Silicon	Si	14	28.0855(3)
Fermium <sup>2</sup>	Fm	100	(257)	Silver	Ag	47	107.8682(2)
Fluorine	F	9	18.998 4032(5)	Sodium	Na	11	22.989 769 28(2)
Francium <sup>2</sup>	Fr	87	(223)	Strontium	Sr	38	87.62(1)
Gadolinium	Gd	64	157.25(3)	Sulfur	S	16	32.065(5)
Gallium	Ga	31	69.723(1)	Tantalum	Ta	73	180.947 88(2)
Germanium	Ge	32	72.64(1)	Technetium <sup>2</sup>	Tc	43	(98)
Gold	Au	79	196.966 569(4)	Tellurium	Te	52	127.60(3)
Hafnium	Hf	72	178.49(2)	Terbium	Tb	65	158.925 35(2)
Hassium <sup>2</sup>	Hs	108	(277)	Thallium	Tl	81	204.3833(2)
Helium	He	2	4.002 602(2)	Thorium <sup>2</sup>	Th	90	232.038 06(2)
Holmium	Ho	67	164.930 32(2)	Thulium	Tm	69	168.934 21(2)
Hydrogen	H	1	1.00794(7)	Tin	Sn	50	118.710(7)
Indium	In	49	114.818(3)	Titanium	Ti	22	47.867(1)
Iodine	I	53	126.904 47(3)	Tungsten	W	74	183.84(1)
Iridium	Ir	77	192.217(3)	Uranium <sup>2</sup>	U	92	238.028 91(3)
Iron	Fe	26	55.845(2)	Vanadium	V	23	50.9415(1)
Krypton	Kr	36	83.798(2)	Xenon	Xe	54	131.293(6)
Lanthanum	La	57	138.905 47(7)	Ytterbium	Yb	70	173.054(5)
Lawrencium <sup>2</sup>	Lr	103	(262)	Yttrium	Y	39	88.905 85(2)
Lead	Pb	82	207.2(1)	Zinc	Zn	30	65.38(2)
Lithium	Li	3	6.941	Zirconium	Zr	40	91.224(2)
Lutetium	Lu	71	174.9668(1)	Copernicium <sup>2</sup>	Cn	112	(285)
Magnesium	Mg	12	24.3050(6)	— <sup>2,3</sup>		113	(284)
Manganese	Mn	25	54.938 045(5)	Flerovium <sup>2</sup>	Fl	114	(289)
Meitnerium <sup>2</sup>	Mt	109	(276)	— <sup>2,3</sup>		115	(288)
Mendelevium <sup>2</sup>	Md	101	(258)	Livermorium <sup>2</sup>	Lv	116	(293)
Mercury	Hg	80	200.59(2)	— <sup>2,3</sup>		117	(294)
Molybdenum	Mo	42	95.96(2)	— <sup>2,3</sup>		118	(294)

1. The atomic masses of many elements vary depending on the origin and treatment of the sample. This is particularly true for Li; commercially available lithium-containing materials have Li atomic masses in the range of 6.939 and 6.996. Uncertainties are given in parentheses following the last significant figure to which they are attributed.

2. Elements with no stable nuclide; the value given in parentheses is the atomic mass number of the isotope of longest known half-life. However, three such elements (Th, Pa, and U) have a characteristic terrestrial isotopic composition, and the atomic weight is tabulated for these.

3. Not yet named.

# 5 REASONS

to buy your textbooks  
and course materials at

# CENGAGE **brain**.com

- 1 SAVINGS:**  
Prices up to 75% off, daily coupons, and free shipping on orders over \$25
- 2 CHOICE:**  
Multiple format options including textbook, eBook and eChapter rentals
- 3 CONVENIENCE:**  
Anytime, anywhere access of eBooks or eChapters via mobile devices
- 4 SERVICE:**  
Free eBook access while your text ships, and instant access to online homework products
- 5 STUDY TOOLS:**  
Study tools\* for your text, plus writing, research, career and job search resources

*William M. Gelbart*

*Yuan T. Lee*

*our Ph.D. advisers*

*for their distinguished careers in scientific research and education*

*The search for truth is in one way hard and in another easy, for it is evident that no one can master it fully or miss it completely.*

*But each adds a little to our knowledge of nature, and from all the facts assembled there arises a certain grandeur.*

(Greek inscription, taken from Aristotle, on the facade of the National Academy of Sciences building in Washington, D.C.)

# BRIEF CONTENTS

## UNIT I

### Introduction to the Study of Modern Chemistry xxviii

- 1 The Atom in Modern Chemistry 2
- 2 Chemical Formulas, Equations, and Reaction Yields 35

## UNIT II

### Chemical Bonding and Molecular Structure 50

- 3 Atomic Shells and Classical Models of Chemical Bonding 52
- 4 Introduction to Quantum Mechanics 124
- 5 Quantum Mechanics and Atomic Structure 177
- 6 Quantum Mechanics and Molecular Structure 219
- 7 Bonding in Organic Molecules 289
- 8 Bonding in Transition Metal Compounds and Coordination Complexes 325

## UNIT III

### Kinetic Molecular Description of the States of Matter 368

- 9 The Gaseous State 370
- 10 Solids, Liquids, and Phase Transitions 414
- 11 Solutions 441

## UNIT IV

### Equilibrium in Chemical Reactions 478

- 12 Thermodynamic Processes and Thermochemistry 480

- 13 Spontaneous Processes and Thermodynamic Equilibrium 526
- 14 Chemical Equilibrium 563
- 15 Acid–Base Equilibria 611
- 16 Solubility and Precipitation Equilibria 667
- 17 Electrochemistry 693

## UNIT V

### Rates of Chemical and Physical Processes 752

- 18 Chemical Kinetics 754
- 19 Nuclear Chemistry 807
- 20 Molecular Spectroscopy and Photochemistry 839

## UNIT VI

### Materials 902

- 21 Structure and Bonding in Solids 904
- 22 Inorganic Materials 935
- 23 Polymeric Materials and Soft Condensed Matter 967

## APPENDICES

- A Scientific Notation and Experimental Error A.2
  - B SI Units, Unit Conversions, and Physics for General Chemistry A.8
  - C Mathematics for General Chemistry A.21
  - D Standard Chemical Thermodynamic Properties A.37
  - E Standard Reaction Potentials at 25°C A.45
  - F Physical Properties of the Elements A.47
  - G Answers to the Odd-Numbered Problems A.56
- Index/Glossary I.1

## UNIT I Introduction to the Study of Modern Chemistry xxviii

### 1 The Atom in Modern Chemistry 2

- 1.1 The Nature of Modern Chemistry 2
- 1.2 Elements: The Building Blocks of Matter 5
- 1.3 Indirect Evidence for the Existence of Atoms: Laws of Chemical Combination 8
- 1.4 The Physical Structure of Atoms 15
- 1.5 Mass Spectrometry, Isotopes, and the Measurement of Relative Mass 23
- 1.6 The Mole: Counting Molecules by Weighing 26

### 2 Chemical Formulas, Equations, and Reaction Yields 35

- 2.1 Empirical and Molecular Formulas 36
- 2.2 Chemical Formula and Percentage Composition 37
- 2.3 Writing Balanced Chemical Equations 39
- 2.4 Mass Relationships in Chemical Reactions 43
- 2.5 Limiting Reactant and Percentage Yield 45

## UNIT II Chemical Bonding and Molecular Structure 50

### 3 Atomic Shells and Classical Models of Chemical Bonding 52

- 3.1 Representations of Molecules 54
- 3.2 The Periodic Table 59
- 3.3 Forces and Potential Energy in Atoms 62
- 3.4 Ionization Energies, the Shell Model of the Atom, and Shielding 70
- 3.5 Electron Affinity 77
- 3.6 Electronegativity: The Tendency of Atoms to Attract Electrons in Molecules 79
- 3.7 Forces and Potential Energy in Molecules: Formation of Chemical Bonds 83
- 3.8 Ionic Bonding 85
- 3.9 Covalent and Polar Covalent Bonding 90
- 3.10 Electron Pair Bonds and Lewis Diagrams for Molecules 99
- 3.11 The Shapes of Molecules: Valence Shell Electron-Pair Repulsion Theory 106
- 3.12 Oxidation Numbers 112
- 3.13 Inorganic Nomenclature 114

## 4 Introduction to Quantum Mechanics 124

- 4.1 Preliminaries: Wave Motion and Light 126
- 4.2 Evidence for Energy Quantization in Atoms 130
- 4.3 The Bohr Model: Predicting Discrete Energy Levels in Atoms 139
- 4.4 Evidence for Wave–Particle Duality 142
- 4.5 The Schrödinger Equation 154
- 4.6 Quantum Mechanics of Particle-in-a-Box Models 158
- 4.7 **A DEEPER LOOK** Wave Functions for Particles in Two- and Three-Dimensional Boxes 166

## 5 Quantum Mechanics and Atomic Structure 177

- 5.1 The Hydrogen Atom 178
- 5.2 Shell Model for Many-Electron Atoms 196
- 5.3 Aufbau Principle and Electron Configurations 201
- 5.4 Shells and the Periodic Table: Photoelectron Spectroscopy 206
- 5.5 Periodic Properties and Electronic Structure 209

## 6 Quantum Mechanics and Molecular Structure 219

- 6.1 Quantum Picture of the Chemical Bond 221
- 6.2 Exact Molecular Orbitals for the Simplest Molecule:  $H_2^+$  225
- 6.3 Molecular Orbital Theory and the Linear Combination of Atomic Orbitals Approximation for  $H_2^+$  231
- 6.4 Homonuclear Diatomic Molecules: First-Period Atoms 235
- 6.5 Homonuclear Diatomic Molecules: Second-Period Atoms 237
- 6.6 Heteronuclear Diatomic Molecules 246

- 6.7 Summary Comments for the LCAO Method and Diatomic Molecules 252
- 6.8 Valence Bond Theory and the Electron Pair Bond 253
- 6.9 Orbital Hybridization for Polyatomic Molecules 259
- 6.10 Predicting Molecular Structures and Shapes 266
- 6.11 Using the LCAO and Valence Bond Methods Together 270
- 6.12 Summary and Comparison of the LCAO and Valence Bond Methods 275
- 6.13 **A DEEPER LOOK** Properties of the Exact Molecular Orbitals for  $H_2^+$  278

## 7 Bonding in Organic Molecules 289

- 7.1 Petroleum Refining and the Hydrocarbons 290
- 7.2 The Alkanes 291
- 7.3 The Alkenes and Alkynes 297
- 7.4 Aromatic Hydrocarbons 300
- 7.5 Fullerenes 303
- 7.6 Functional Groups and Organic Reactions 304
- 7.7 Pesticides and Pharmaceuticals 316

## 8 Bonding in Transition Metal Compounds and Coordination Complexes 325

- 8.1 Chemistry of the Transition Metals 326
- 8.2 Introduction to Coordination Chemistry 333
- 8.3 Structures of Coordination Complexes 339
- 8.4 Crystal Field Theory: Optical and Magnetic Properties 345
- 8.5 Optical Properties and the Spectrochemical Series 352
- 8.6 Bonding in Coordination Complexes 355

## UNIT III Kinetic Molecular Description of the States of Matter 368

### 9 The Gaseous State 370

- 9.1 The Chemistry of Gases 371
- 9.2 Pressure and Temperature of Gases 373
- 9.3 The Ideal Gas Law 380
- 9.4 Mixtures of Gases 383
- 9.5 The Kinetic Theory of Gases 385
- 9.6 Real Gases: Intermolecular Forces 394
- 9.7 **A DEEPER LOOK** Molecular Collisions and Rate Processes 399

### 10 Solids, Liquids, and Phase Transitions 414

- 10.1 Bulk Properties of Gases, Liquids, and Solids: Molecular Interpretation 415
- 10.2 Intermolecular Forces: Origins in Molecular Structure 421
- 10.3 Intermolecular Forces in Liquids 426

10.4 Phase Equilibrium 430

10.5 Phase Transitions 432

10.6 Phase Diagrams 434

### 11 Solutions 441

- 11.1 Composition of Solutions 442
- 11.2 Nature of Dissolved Species 445
- 11.3 Reaction Stoichiometry in Solutions: Acid–Base Titrations 448
- 11.4 Reaction Stoichiometry in Solutions: Oxidation–Reduction Titrations 452
- 11.5 Phase Equilibrium in Solutions: Nonvolatile Solutes 459
- 11.6 Phase Equilibrium in Solutions: Volatile Solutes 467
- 11.7 Colloidal Suspensions 472

## UNIT IV Equilibrium in Chemical Reactions 478

### 12 Thermodynamic Processes and Thermochemistry 480

- 12.1 Systems, States, and Processes 482
- 12.2 The First Law of Thermodynamics: Internal Energy, Work, and Heat 485
- 12.3 Heat Capacity, Calorimetry, and Enthalpy 492
- 12.4 The First Law and Ideal Gas Processes 495
- 12.5 Molecular Contributions to Internal Energy and Heat Capacity 498
- 12.6 Thermochemistry 504
- 12.7 Reversible Processes in Ideal Gases 512
- 12.8 **A DEEPER LOOK** Distribution of Energy among Molecules 517

### 13 Spontaneous Processes and Thermodynamic Equilibrium 526

- 13.1 The Nature of Spontaneous Processes 527
- 13.2 Entropy and Spontaneity: A Molecular Statistical Interpretation 530
- 13.3 Entropy and Heat: Macroscopic Basis of the Second Law of Thermodynamics 535
- 13.4 Entropy Changes in Reversible Processes 537
- 13.5 Entropy Changes and Spontaneity 541
- 13.6 The Third Law of Thermodynamics 544
- 13.7 The Gibbs Free Energy 547
- 13.8 **A DEEPER LOOK** Carnot Cycles, Efficiency, and Entropy 552

**14 Chemical Equilibrium 563**

- 14.1** The Nature of Chemical Equilibrium 564
- 14.2** The Empirical Law of Mass Action 568
- 14.3** Thermodynamic Description of the Equilibrium State 574
- 14.4** The Law of Mass Action for Related and Simultaneous Equilibria 581
- 14.5** Equilibrium Calculations for Gas-Phase and Heterogeneous Reactions 583
- 14.6** The Direction of Change in Chemical Reactions: Empirical Description 589
- 14.7** The Direction of Change in Chemical Reactions: Thermodynamic Explanation 598
- 14.8** Distribution of a Single Species between Immiscible Phases: Extraction and Separation Processes 602

**15 Acid–Base Equilibria 611**

- 15.1** Classifications of Acids and Bases 612
- 15.2** Properties of Acids and Bases in Aqueous Solutions: The Brønsted–Lowry Scheme 619
- 15.3** Acid and Base Strength 622
- 15.4** Equilibria Involving Weak Acids and Bases 630
- 15.5** Buffer Solutions 635
- 15.6** Acid–Base Titration Curves 640
- 15.7** Polyprotic Acids 645

- 15.8** Organic Acids and Bases: Structure and Reactivity 649

- 15.9** **A DEEPER LOOK** Exact Treatment of Acid–Base Equilibria 655

**16 Solubility and Precipitation Equilibria 667**

- 16.1** The Nature of Solubility Equilibria 668
- 16.2** Ionic Equilibria between Solids and Solutions 671
- 16.3** Precipitation and the Solubility Product 674
- 16.4** The Effects of pH on Solubility 678
- 16.5** Complex Ions and Solubility 680
- 16.6** **A DEEPER LOOK** Selective Precipitation of Ions 685

**17 Electrochemistry 693**

- 17.1** Electrochemical Cells 694
- 17.2** Cell Potentials and the Gibbs Free Energy 700
- 17.3** Concentration Effects and the Nernst Equation 708

The eighth edition of *Principles of Modern Chemistry* is written for students in honors and upper-mainstream general chemistry courses who seek to understand and interpret chemical events at the molecular level. The relation of molecular structure to function and properties requires the introduction of molecular structure early in the course and the use of structural arguments in presenting the remaining topics. Moreover, students will soon be introduced to the predictive power of chemical computations and simulations, for which a solid background in the description of molecular structure is essential.

The organization of the eighth edition is fundamentally the same as that of the seventh edition, and presents the material from a unified, molecular point of view that continues to emphasize the central role of structure, but with greater focus on the electronic structure of molecules as a unifying theme. This edition also deepens and broadens the introduction of chemical principles in several chapters. Recognizing that in the top colleges and universities that use this text, over 90% of students taking introductory chemistry have taken a single-variable calculus course in high school, or are taking calculus as a co-requisite for the course, we have improved several portions of the text. These revisions include a more quantitative treatment of the forces and potential energy in molecules (Chapter 3), dipole moments (Chapter 3), molecular collisions (Chapters 9 and 18), and the Maxwell-Boltzmann distribution of molecular speeds (Chapter 9). The eighth edition also includes major revisions in the chapters on quantum mechanics and molecular structure (Chapter 6), electrochemistry (Chapter 17), nuclear chemistry (Chapter 19), and molecular spectroscopy and photochemistry (Chapter 20).

## Significant Changes in This Edition

- **OWLv2 for General Chemistry**—Our online learning solution OWLv2 has been revised to offer more flexible student and instructor functionality, new personalized study tools, enhanced integration with learning management systems, and improved analytics. OWLv2 includes Quick Prep, new iPad-compatible visualizations, tutorials, and simulations, and new Adaptive Study Plans. Tutors, Visualizations, and Simulations have been converted from Flash to HTML, allowing for easier navigation and streamlined grading.
- **Revised Writing Style without Loss of Rigor**—The language is more modern and less formal. We have introduced a more conversational writing style, designed to engage our students as active participants in developing the presentation. We have examined every sentence in the book to simplify and lighten the language without compromising intellectual integrity.

- **Greater Flexibility in Topic Coverage**—In response to comments by students, faculty, and reviewers, greater modularity and flexibility have been built into the text to make it compatible with alternative sequences of topics. While keeping the discussion of bonding and structure at the beginning of the book, we have been careful to maintain the option to follow the “macro-to-micro” approach used in previous editions. Selecting alternative approaches is facilitated by the unit structure of the book; we offer several suggestions in the **Teaching Options** section.
- **Streamlined Topic Coverage**—In response to suggestions by both users and reviewers of the text, we have taken care in this revision to retain only those topics that were felt to be critical for students. Chapters 19 and 20, especially, were shortened after extensive surveying of professors who teach the course; what remains (we think) are chapters that are more readily covered within the framework of a conventional two-semester course.
- **New Problems**—We’ve added approximately 30 new and revised problems throughout the book. These follow the unique tradition established in previous editions that all problems are based on actual experimental data measured on real chemical systems. We intend the problems to guide our students in developing intuition for chemical results and the magnitudes of chemical quantities, as well as facility in numerical calculations.

## Organizational Approach for Selected Chapters and Major Changes to Content for Eighth Edition

### Chapter 1: The Atom in Modern Chemistry

This chapter describes the physical structure of the atom, as determined from the classic experiments of Thomson, Millikan, and Rutherford. For this edition, we added an introduction of the electrostatic force on negatively and positively charged particles (see Section 1.4.3), improved the coverage of the J.J. Thompson experiment measuring the charge-to-mass ratio of the electron (see Section 1.4.3), and incorporated coverage of the mole, counting molecules by weighing (which was Section 2.1 in the seventh edition; it is Section 1.6 here in the eighth edition).

### Chapter 3: Atomic Shells and Classical Models of Chemical Bonding

This chapter provides a substantial introduction to molecular structure by coupling experimental observation with interpretation through simple classical models. Today, the tools of classical bonding theory—covalent bonds, ionic bonds, polar covalent bonds, electronegativity, Lewis electron dot diagrams, and VSEPR theory—have all been explained by quantum mechanics. It is a matter of preference whether to present the classical theory first and then gain deeper insight from the quantum explanations, or to cover the quantum theory first and then see the classical theory as a limiting case. Our experience has been that presenting the classical description first enables our students to bring considerably greater sophistication to their first encounter with quantum mechanics and therefore to develop a deeper appreciation for that subject. We have seen that this approach offers definitive pedagogical advantages by enabling students to

- learn the language and vocabulary of the chemical bond starting from familiar physical concepts.

- become familiar with the properties of a broad array of real molecules *before* attempting to explain these results using quantum mechanics.
- develop experience in using physical concepts and equations to describe the behavior of atoms and molecules.

We have organized this chapter to meet these goals. Changes for the eighth edition include the following:

- The chapter now presents attractive and repulsive forces between nuclei and electrons, and between atoms in a diatomic molecule, using simple vectors in two dimensions, so that students may correctly calculate the direction of attractive and repulsive forces between particles (see Section 3.3). We emphasize the physical insight gained from the new quantitative treatment.
- We have streamlined and improved the discussion of polar covalent bonding, removing the application of the virial theorem but retaining the basic description of Coulomb forces between electrons and nuclei (see Sections 3.7 and 3.9).
- We introduce the direction of a molecular dipole moment, in addition to its magnitude (see Section 3.9.4).

## Chapter 4: Introduction to Quantum Mechanics

This chapter presents a significant introduction to the concepts and vocabulary of quantum mechanics through very careful choice of language, illustrations with experimental data, interpretation with aid of simple models, and extensive use of graphical presentations.

For the eighth edition we improved the treatment of the particle-in-a-box with examples (Example 4.7 and the solution to Problem 37) that show students how to use the mathematical solutions to answer questions about the probability of the electron being found in different regions of space. We chose the chemical system of 1,3-butadiene for the example. The added material (mainly in Section 4.6) is appropriate both for students who have had integration in their single-variable calculus course and for students who would simply estimate the area under a curve graphically.

## Chapter 5: Quantum Mechanics and Atomic Structure

This chapter provides a comprehensive introduction to the hydrogen atomic orbitals, the Hartree orbitals, the shell model of the atom as explained by the Hartree orbitals, and the relation of the shell model to experimental measurements such as photoelectron spectroscopy and the periodic properties of atoms. In this edition, recognizing that students' quantitative understanding of electron density in molecular systems begins with their introduction to atomic wave functions, we added graphical and analytical examples (Examples 5.2 and 5.3) to help students navigate the three-dimensional coordinate system in atoms (see Sections 5.1.2 and 5.1.3). Equation 5.7 reduces the integration over three dimensions to an integral that students may solve using single-variable calculus (or estimate graphically) to aid their understanding of the graphs of  $r^2\psi^2$  and  $r^2R^2$  presented in the chapter.

## Chapter 6: Quantum Mechanics and Molecular Structure

This chapter provides a gentle ramp-up, starting from a qualitative overview of the quantum picture of the chemical bond and its relation to the potential energy curve for a molecule. The discussion proceeds through molecular orbital theory (MO), then valence bond theory (VB), then the combined use of MO and VB, and ends with a comparison of MO with VB. Changes for this edition include:

- The pedagogy in the introductory section titled Quantum Picture of the Chemical Bond (Section 6.1) has been shortened and improved.
- The graphics and equations presented in the treatment of LCAO-MO theory (see Sections 6.5 and 6.6) have been revised to represent constructive and destructive interference using the same wave functions that are presented in Chapter 5. The linear combinations of atomic orbitals used to construct hybrid atomic orbitals (Section 6.9) have been revised and the pedagogy is shortened and improved.
- The treatment of polyatomic molecules has been improved, including delocalized  $\pi$  bonding in  $\text{NO}_2$ , 1,3-butadiene, and benzene.
- The summary and comparison of LCAO-MO theory and the valence bond model was shortened and improved (Section 6.12).

## Chapter 7: Bonding in Organic Molecules

The purpose of this chapter is to describe the bonding and nomenclature in alkanes, alkenes, alkynes, aromatics, and conjugated hydrocarbons and in the major functional groups. Our main goal is to illustrate the bonding theories from Chapter 6 with examples from organic chemistry that can be used in conjunction with Chapter 6. For the new edition we updated the nomenclature to give IUPAC names (retaining the common names where advisable) and moved the graphics related to delocalized  $\pi$  molecular orbitals in 1,3-butadiene and benzene to Chapter 6.

## Chapter 8: Bonding in Transition Metal Compounds and Coordination Complexes

We present a comprehensive introduction to bonding in transition metal compounds and coordination complexes using MO and VB theory as developed in Chapter 6. Our goal is to demonstrate that MO theory is not limited to the first- and second-period diatomic molecules and that it provides the most satisfactory method for describing bonding in coordination complexes. The material covered in this chapter now provides a self-contained introduction to structure and bonding in inorganic chemistry that should provide sound preparation for an advanced inorganic chemistry course. For the new edition, we have revised and improved the figures related to chiral molecules (see Section 8.3.3) and crystal field theory (see Section 8.4.2).

## Chapter 9: The Gaseous State

In this chapter we improved the treatment of the Maxwell-Boltzmann distribution of molecular speeds (see Section 9.5.2) to help students estimate the fraction of molecules with speed in a given range and to understand why the rate of a chemical reaction might increase with temperature. We also introduced the concept of relative velocity in the treatment of molecular collisions (see Section 9.7.2) so that students have a basis for deriving (in Chapter 18) the expression

for the rate of an elementary bimolecular reaction in terms of the product of the concentrations of the two reacting species.

## Chapter 10: Solids, Liquids, and Phase Transitions

For the eighth edition, we have introduced calculus to the treatment of compressibility and thermal expansion (see Sections 10.1.2 and 10.1.3).

## Chapter 12: Thermodynamic Processes and Thermochemistry

The treatment in this and prior editions gives the instructor flexibility on how to cover traditional thermochemistry in conjunction with direct applications of the laws of thermodynamics. Stronger students may be encouraged to solve problems starting from the axioms and deriving the needed formulas from first principles.

## Chapter 13: Spontaneous Processes and Thermodynamic Equilibria

The chapter presents a molecular statistical interpretation of entropy alongside the traditional macroscopic description involving the reversible transfer of heat. It carefully develops the conditions under which one may use the change in Gibbs free energy to assess the spontaneity of a reaction.

## Chapter 14: Chemical Equilibrium

To provide flexibility for instructors, this chapter is written to allow thermodynamics to be taught either before or after equilibrium. Each topic is introduced first from the empirical point of view, and then followed immediately with the thermodynamic treatment of the same topic. Instructors who prefer to treat thermodynamics first can use the chapter as written, whereas those who prefer the empirical approach can skip appropriate sections, and then come back and pick up the thermo-based equilibrium sections after they cover basic thermodynamics. “Signposts” are provided in each section to guide these two groups of readers; the options are clearly marked. Specific examples of this flexible approach are:

- Section 14.2 provides a thorough discussion of procedures for writing the empirical law of mass action for gas-phase, solution, and heterogeneous reactions, with specific examples for each.
- Section 14.3 follows with the thermodynamic prescription for calculating equilibrium constants from tabulated Gibbs free energy values for gas-phase, solution, and heterogeneous reactions, with specific examples for each. For students who have covered Chapters 12 and 13, it gives a succinct derivation of  $\Delta G = \Delta G^\circ + RT \ln Q$  and the relationship between  $Q$  and  $K$ .
- Sections 14.4 and 14.5 present a variety of equilibrium calculations based on the empirical law of mass action.
- Section 14.6 discusses direction of change in terms of the empirical reaction quotient  $Q$ , with illustrations in gas-phase, solution, and heterogeneous reactions.
- Section 14.7 discusses direction of change from the point of view of thermodynamics, relating  $Q$  to the Gibbs free energy change and the equilibrium constant.

## Chapter 15: Acid–Base Equilibria

The examples establishing the molecular-level interpretation of acid-base equilibria (see Section 15.8) have been carefully vetted and improved.

## Chapter 17: Electrochemistry

This chapter provides a molecular level interpretation of electrochemical processes unique in an undergraduate textbook, as far as we are aware, to complement the standard thermodynamic treatment of the subject. We introduce the idea that a redox potential (a free energy) can be associated with an orbital energy level, which allows us to use energy-level diagrams to help students visualize electron transfer processes pictorially. This approach also allows us to introduce an electrostatic driving force for electrochemical processes and connect it to the thermodynamic driving force. We explicitly identify the conditions under which this approximation is valid (outer sphere electron transfer processes, negligible entropic contribution to the Gibbs free energy) so that our students can use this description with confidence.

For the eighth edition we streamlined and improved the introductory material on electric potential versus potential energy (see Section 17.1), moved the essential material on the molecular interpretation of electrochemical processes to later sections in the chapter to better integrate the pedagogy and applications, and deleted the long subsection on alternative reference electrodes in Section 17.2, moving the essential material to earlier in Section 17.2. We revised the applications in the molecular electrochemistry section (which was Section 17.5 in the seventh edition and is now Section 17.4 in the eighth edition) to shorten the presentation and improve clarity, including the discussion of using semiconductors in solar cells for generating  $H_2$  as an alternative fuel.

## Chapter 18: Chemical Kinetics

For the eighth edition we revised and improved the treatment of collision theory (see Section 18.6.1) to allow students to solve problems of importance in atmospheric chemistry, such as the reaction of Cl with methane. The concepts of relative velocity and impact parameter are developed with new graphics and simple examples (Examples 18.9, 18.10, and 18.11) and the connection with molecular collisions (as introduced in Chapter 9) are firmly established. We also expanded the material on molecular beam experiments (see Section 18.6.4). The seventh edition subsection on mechanisms of enzyme-catalyzed reactions is now presented as a *Connection to Biology*.

## Chapter 19: Nuclear Chemistry

Chapter 19 has been extensively reorganized and streamlined, with the focus now on balancing nuclear reactions, mass–energy relationships, and predicting the spontaneity of nuclear reactions (with improved notation in the eighth edition), and the kinetics of radioactive decay. This material is followed by a detailed description of selected key applications. The first set of applications, covered under the heading, Radiation in Biology and Medicine (see Section 19.4), retains the *Connection to Medicine* presented in the seventh edition. The chapter ends with applications in nuclear fission, including nuclear power reactors (see Section 19.5.1), and fusion (in the sun and other stars and in proposed energy applications).

## Chapter 20: Molecular Spectroscopy and Photochemistry

Chapter 20 has been reorganized in the eighth edition to provide an introduction to molecular energy levels first, including a discussion of how one might probe them using traditional absorption spectroscopy or more modern laser spectroscopy (specifically laser-induced fluorescence). Other changes include:

- A streamlined discussion of direct absorption methods and Raman spectroscopy (see Section 20.2), which included removing the detailed description of Fourier transform methods that was in the middle of the vibrational spectroscopy section in the last edition.
- A reorganized order of topics, so that rotational spectroscopy in diatomic molecules is now treated first, followed by vibrations in diatomics and then infrared spectroscopy of diatomic molecules involving a change in both the vibrational and the rotational quantum number (see consecutive subsections in Section 20.3.1). Rotations and vibrations in polyatomic molecules follow (see Section 20.3.2), ending with material from the seventh edition on characteristic vibrational frequencies of organic functional groups.
- A simplified treatment of nuclear magnetic resonance (NMR) spectroscopy, making it more physically intuitive (see Section 20.4), while retaining material on Fourier-transform NMR from the seventh edition.
- The revision of several figures in the chapter with a focus on scientific accuracy.
- A shortened, streamlined section titled Introduction to Atmospheric Chemistry (see Section 20.6) that retains the discussion of the chemistry of ozone but removes, in response to reviewer feedback, much of the last edition's coverage of climate change. (The full treatment that was found in the seventh edition will be made available on the instructors' website.)
- A shortened, streamlined *A Deeper Look* section (Section 20.8), that retains the coverage on lasers but omits the coverage of the Einstein radiation relations.

## Chapter 21: Structure and Bonding in Solids

For the eighth edition we improved the discussion regarding symmetries of the cube primitive (see Section 21.1) and improved the accuracy of several figures.

## Chapter 22: Inorganic Materials

For the eighth edition we improved graphics in the section on silicates (see Section 22.1.1).

## Appendices

For the eighth edition we added to the appendix on mathematical background for general chemistry a subsection that introduces vectors (see Section C.7). We also improved the notation and pedagogy in portions of the appendix on physics background for general chemistry (see Section B.2).

## Teaching Options

The text is structured and written to give instructors significant flexibility in choosing the order in which topics are presented. We suggest several such possibilities here. In all cases we recommend starting with Chapter 1 to provide a contemporary introduction to the structure and properties of the atom, as well as to help our students understand how we came to acquire this understanding. Our own students report that this early introduction to the scientific method, following these historical examples, has been helpful to them in subsequent courses. We then recommend working through the material in Chapter 2 to establish a secure foundation in “chemical accounting methods” that is necessary for studying all the remaining chapters. Particularly well-prepared students can skip Chapter 2, especially if diagnostics are available to ascertain satisfactory background.

### Classical Bonding before Introduction to Quantum Theory

*Chapters 1–6; selections from Chapters 7 and 8; Chapters 9–23*

This is the sequence we have found most effective overall all for two reasons: (1) introducing the classical description before tackling quantum mechanics helps our students see the need to understand the latter approach, and (2) it enables our students to bring substantially greater maturity to their first exposure to quantum theory. This leads to deeper and quicker mastery of quantum theory and its applications to atomic and molecular structure. Instructors who wish to introduce molecular spectroscopy earlier can easily cover Sections 20.1 through 20.4 immediately after Chapter 6.

### Introduction to Quantum Theory before Bonding

*Chapters 1, 2, 4, 5, 3, 6; selections from Chapters 7 and 8; Chapters 9–23*

These sequences are appropriate for instructors who prefer to establish a background in quantum theory before discussing ionic and covalent bonding, Lewis diagrams, and VSEPR theory. Instructors who prefer to cover these classical bonding topics after quantum mechanics but before MO and VB theory would cover Chapter 3 before Chapter 6. Those who want to present the full quantum story first and then present the classical description as the limiting case would cover Chapter 3 after Chapter 6. We recommend that both of these sequences cover Section 3.3 (force and potential energy in atoms) before Chapter 4 to give students a good physical feeling for Rutherford’s planetary model of the atom in preparation for the quantum theory. Instructors who wish to introduce molecular spectroscopy earlier can easily cover Sections 20.1 through 20.4 immediately after Chapter 6.

### Traditional “Macro-to-Micro” Approach

*Chapters 1, 2, 9–19, 3–8, 20–23*

This sequence covers fully the macroscopic descriptions of chemical phenomena and then begins to interpret them in terms of molecular structure. Instructors could choose either of the two bonding approaches suggested earlier for the specific order of Chapters 3 through 6 late in this course. This sequence repre-

sents a rather pure form of the “macro-to-micro” approach that was followed in the first three editions. Alternatively, they could cover Chapter 3 between Chapter 2 and Chapter 9, as was done in the fourth and fifth editions. This approach has the advantage of building a substantial foundation in structure—and a complete discussion of chemical nomenclature—as the basis for the macroscopic descriptions, while leaving the quantum theory of bonding to come later in the course.

## Thermodynamics before Chemical Equilibrium

### *Chapters 12–17*

This is the sequence we have found to be the most effective. If students first have a good understanding for the physical basis of equilibrium, then the facts and trends of chemical equilibrium quickly begin to form patterns around molecular structure. The equilibrium state is determined by the changes in entropy and bond energies associated with each chemical reaction.

## Empirical Chemical Equilibrium before Thermodynamics

### *Chapter 14 (omit Sections 14.3, 14.7); Chapters 15, 16, 12, 13; Sections 14.3, 14.7; Chapter 17*

Perhaps to provide background for quantitative laboratory work, others may wish to present chemical equilibrium earlier in the course in a more empirical fashion, before the presentation of thermodynamics. Chapter 14 is clearly marked with “signposts” to facilitate this sequence.

## Modified “Macro-to-Micro” Approach

### *Chapters 1–3, 9, 10, 12–14, 11, 15, 4–7, 20, 16–19, 8, and 21; selections from Chapters 22 and 23*

The syllabus currently in use at The University of Chicago follows the approach of thermodynamics before chemical equilibrium, and covers most of quantum mechanics in the winter months (so students co-enrolled in calculus are up to speed by then). Molecular spectroscopy (Chapter 20) and applications to organic chemistry (selected from Chapter 7) immediately follow, or are interleaved with, the coverage of quantum mechanics and molecular structure during the winter. Chapters 16 to 19 and Chapter 21 follow in the spring with Chapter 8 immediately following Chapter 19 in our regular course and Chapter 7 in our honors course. This allows students to switch between our honors and regular course in the winter if they desire. For an honors course populated primarily by students who have scored a 4 or 5 in AP chemistry, we retain the student’s interest by covering only selected sections of Chapters 1, 3, 9 (focusing on the material in Section 9.5 and later), 10, and 11, and we skip Chapter 2. We then focus on a first-principles development of thermodynamics and chemical equilibrium in Chapters 12 to 14, immediately followed by chemical applications in Chapter 15 and selected portions of Chapter 16. This is followed by the comprehensive treatment of quantum mechanics, Chapters 4 to 6, the last with added material on molecular orbitals for a variety of polyatomics covered in Chapter 7 along with some radical species such as the allyl radical. Chapters 8 and 20 are typically covered then, followed by Chapters 16 through 21 in the spring and special topics selected by the instructor.

## General Aspects of Flexibility

Certain topics may be omitted without loss of continuity. For example, a principles-oriented course might cover the first 20 chapters thoroughly and then select one or two specific topics in the last chapters for close attention. A course with a more descriptive orientation might omit the sections entitled *A Deeper Look . . .*, which are more advanced conceptually and mathematically than the sections in the main part of the book, and cover the last three chapters more systematically. Additional suggestions are given in the *Instructor's Manual* that accompanies the book.

## Features

### Mathematical Level

This book presupposes a solid high school background in algebra and coordinate geometry. The concepts of slope and area are introduced in the physical and chemical contexts in which they arise, and differential and integral notation is used in parallel with these concepts. Thus, students with a single-variable calculus background are engaged fully, while students without that background will not be at a disadvantage. Simple vectors are introduced to aid in discussing force and velocity, with an elementary section in Appendix C covering vectors in Cartesian coordinates. The book is fully self-contained in its use of mathematical methods. Methods are introduced at “point of use,” and Appendix C provides a more comprehensive introduction (or review) of the material as needed.

Key equations in the text are highlighted in color and numbered on the right side of the text column. Students should practice using them for chemical calculations. The steps to derive each of these equations are presented in the text, so students do not conclude they must simply memorize these equations. Rather they are taught how to develop these relationships from first principles.

### Updated Design and New Illustrations and Photographs

This eighth edition features a modern design, whose elements have been carefully arranged for maximum clarity and whose aesthetics should engage today's visually oriented students. We have selected photographs and illustrations to amplify and illuminate concepts in the narrative text. All illustrations of atomic and molecular orbitals, charge density, and electrostatic potential energy maps were generated expressly for this textbook. Most orbitals and charge densities were calculated by Mr. Hatem Helal (Cambridge University, UK) in the Materials Simulation Center at the California Institute of Technology, directed by Professor William A. Goddard III. Dr. Kelly Gaither (Director, Visualization and Data Analysis group, Texas Advanced Computing Center) plotted the images using state-of-the-art software at the Scientific Visualization Laboratory at The University of Texas at Austin. The colors, lighting effects, and viewing angles were chosen to display three-dimensional objects with maximum clarity and to provide chemical insight. In many cases quantitative contour plots accompany the three-dimensional isosurfaces representing orbitals to help our students understand how the appearances of isosurfaces depend on choices made by scientists and that these isosurfaces are not unique.

## Molecular Art

The sixth edition introduced an art program in which molecular shapes are rendered with quantitative accuracy and in modern graphical style. Most of the illustrations of atomic and molecular orbitals, charge density, and electrostatic potential energy maps were generated from accurate quantum chemistry calculations carried out at the California Institute of Technology. Orbitals were plotted using state-of-the-art visualization software at the Texas Advanced Computing Center, University of Texas at Austin. The colors, lighting effects, and viewing angles were chosen to display three-dimensional objects with maximum clarity and to provide chemical insight.

## Worked Examples

This textbook includes worked examples that demonstrate the methods of reasoning applied in solving chemical problems. The examples are inserted immediately after the presentation of the corresponding principles, and cross-references are made to related problems appearing at the end of the chapter.

## A Deeper Look

Sections entitled *A Deeper Look . . .* provide students with a discussion of the physical origins of chemical behavior. The material that they present is sometimes more advanced mathematically than that in the main parts of the book. The material provided in these sections allows instructors to more easily tailor the breadth and depth of their courses to meet their specific objectives.

## Key Terms

Key terms appear in boldface where they are first introduced. Definitions for all key terms are also included in the Index/Glossary for ready reference.

## “Connections to...”

A number of essays provide “Connections to...” other branches of science, engineering, and medicine. Coupled with the interdisciplinary Cumulative Exercises that have long been a hallmark of *Principles of Modern Chemistry*, these “Connections” give a substantial sampling of applications of the principles of chemistry.

## Chapter Summary

Immediately at the end of each chapter is a summary that ties together the main themes of the chapter in a retrospective narrative. This complements the introductory passage at the beginning of the chapter in a manner that conveys the importance of the chapter. The summary is the first in a set of four end-of-chapter features that constitute a comprehensive set of tools for organizing, studying, and evaluating mastery of the chapter.

## Cumulative Exercise

At the end of each of Chapters 2 through 21 is a cumulative exercise, a unique feature of *Principles* since its inception that focuses on a problem of chemical interest and draws on material from the entire chapter for its solution. Working through a chapter's cumulative exercise provides a useful review of material in the chapter, helps our students put principles into practice, and prepares them to solve the problems that follow.

## Concepts and Skills

Each chapter concludes with a list of concepts and skills (task-oriented) for each section in the chapter for review by our students. Included in this list are cross-references to the section in which the topic was covered, a concise review of material essential to that topic, the key equations for each topic, and cross-references to end-of-chapter problems that help test mastery of the particular skill involved. Our own students report that this feature has been very helpful to them for self-testing and review of material.

## Problems

Problems are grouped into three categories. Answers to odd-numbered “paired problems” (which have red problem numbers) are provided in Appendix G; they enable students to check the answer to the first problem in a pair before tackling the second problem. *Additional Problems*, which are unpaired, illustrate further applications of the principles developed in the chapter. *Cumulative Problems* integrate material from the chapter with topics presented earlier in the book. We integrate more challenging problems throughout the problems sets and identify them with asterisks.

## Appendices

Appendices A, B, and C are important pedagogically. Appendix A discusses experimental error and scientific notation. Appendix B introduces the SI system of units used throughout the book and describes the methods used for converting units. Appendix B also provides a brief review of some fundamental principles in physics, which may be particularly helpful to students in understanding topics covered in Chapters 3, 4, 5, 6, 9, 10, 12, 13, 17, 18, 19, and 20. Appendix C provides a review of mathematics for general chemistry. Appendices D, E, and F are compilations of thermodynamic, electrochemical, and physical data, respectively.

## Index/Glossary

The Index/Glossary at the back of the book provides brief definitions of all bold-faced key terms, as well as cross-references to the pages on which the terms appear.

## Acknowledgments

In preparing the eighth edition, we have benefited greatly from the comments of students who used the first seven editions over the years. We would also like to acknowledge the many helpful suggestions of colleagues at Pomona College, The University of Chicago, the University of California–Los Angeles, and other colleges and universities who have taught from this book. We are particularly grateful to Professors Robin Garrell, Ken Houk, Herb Kaesz, and Thomas Mason of UCLA, Professor Greg Engel of The University of Chicago, Professor Michael Topp of the University of Pennsylvania, Professor Gina Frey of Washington University, and Professors Eric Anslyn, Al Bard, Ray Davis, Brad Holliday, Simon Humphrey, Brent Iverson, Richard Jones, Peter Rossky, Jason Shear, John Stanton, Keith Stevenson, David Vanden Bout, Grant Willson, and Robert Wyatt of The University of Texas–Austin, Professor Samir Anz of California Polytechnic State University–Pomona, and Professor Andrew J. Pounds of Mercer University for their helpful comments and advice.

We extend special thanks to the following professors who offered comments on the seventh edition or reviewed manuscript for the eighth edition:

Joseph BelBruno, Dartmouth College  
Kenneth Brown, Georgia Institute of Technology  
Lynne M. Butler, Haverford College  
Justin Ferman, University of Massachusetts–Amherst  
Regina F. Frey, Washington University of St. Louis  
Henry C. Griffin, University of Michigan  
Philippe Guyot-Sionnest, The University of Chicago  
Paul J. Karol, Carnegie Mellon University  
Walter Loveland, Oregon State University  
Doug Loy, University of Arizona  
Tom Mason, University of California–Los Angeles  
Donald R. Neu, St. Cloud State University  
Andrew J. Pounds, Mercer University  
Robert C. Scarrow, Haverford College  
George Schatz, Northwestern University  
Michael L. Stein, The University of Chicago  
Bozhi Tian, The University of Chicago  
Michael R. Topp, University of Pennsylvania  
Lauren Webb, University of Texas at Austin  
Steven W. Yates, University of Kentucky

We are grateful to Dr. Melita Morton Balch for her critical corrections to the manuscript, and to Dr. Justin Fermann for his very careful attention to detail as accuracy reviewer of the eighth edition.

We are much indebted to our longtime friend Professor Eric J. Heller of Harvard University for the beautiful and striking images that grace the covers

of the sixth, seventh, and eighth editions of our book. Professor Heller's work demonstrates that images of great beauty can arise from scientific research and that artistic renderings effectively convey the meaning of scientific results. We are certain this image will entice readers to peek between the covers of our book, and we hope they find scientific beauty on the inside as well as on the cover!

We are particularly grateful to friends and colleagues who provided original scientific illustrations for the book. They are Professor Wilson Ho (University of California–Irvine), Dr. Gilberto Medeiros-Ribeiro and Dr. R. Stanley Williams (Hewlett-Packard Research Laboratories), Professor Leonard Fine (Columbia University), Professor Andrew J. Pounds (Mercer University) and Dr. Mark Iken (Scientific Visualization Laboratory, Georgia Institute of Technology), Dr. Stuart Watson and Professor Emily Carter (Princeton University), Professor Nathan Lewis (California Institute of Technology), Dr. Don Eigler (IBM Almaden Research Center), Dr. Gerard Parkinsen and Mr. William Gerace (OMICRON Vakuumphysik), Dr. Richard P. Muller and Professor W.A. Goddard III (California Institute of Technology), Professor Mounji Bawendi and Ms. Felice Frankel (Massachusetts Institute of Technology), Professor Graham Fleming (University of California–Berkeley), Professors Donald Levy, Philippe Guyot-Sionnest, and David Mazziotti (The University of Chicago), Professor W.E. Moerner (Stanford University), Dr. Jane Strouse (University of California–Los Angeles), Professor James Speck and Professor Stephen Den Baars (University of California–Santa Barbara), Professor John Baldeschwieler (California Institute of Technology), and Dr. Thomas Koop (Bielefeld University).

We are especially grateful to Mr. Hatem H. Helal (California Institute of Technology and Cambridge University, UK), who carried out the quantum chemistry calculations for most of the orbital illustrations in Chapters 4, 5, 6, and 8, and to Dr. Kelly P. Gaither (Texas Advanced Computing Center, The University of Texas at Austin), who generated these illustrations from the results of the calculations. Our longtime friend and colleague Professor William A. Goddard III (California Institute of Technology) very generously made his computational facilities available for these calculations and provided much good advice as we selected and prepared these illustrations. Sarah Chandler (The University of Texas at Austin) was very helpful in generating a number of graphs and two-dimensional surfaces.

We are also indebted to Professor Charles M. Knobler of the University of California–Los Angeles; Professor Jurg Waser, formerly of the California Institute of Technology; and Mrs. Jean T. Trueblood (widow of the late Professor Kenneth N. Trueblood of the University of California–Los Angeles) for permission to incorporate selected problems from their distinguished textbook *ChemOne*, Second Edition, McGraw-Hill, New York (1980).

On a personal note, it gives us genuine pleasure to dedicate this eighth edition of our textbook to our own Ph.D. research advisers Professors Bill Gelbart (Oxtoby), Karl Freed (Gillis), and Yuan T. Lee (Butler). They showed us the excitement of doing scientific research and the joy of transmitting scientific knowledge to the next generation. Their legacy inspires our work with our own students in the laboratory, in the classroom, and in the pages of this textbook.

The staff members at Cengage Learning have been most helpful in preparing this eighth edition. In particular, we gratefully acknowledge the superb work of content developer Ed Dodd, who made sure all the changes to the text and graphics for the eighth edition were done perfectly. We also acknowledge the role of our associate product manager, chemistry, Krista M. Mastroianni. Content developer Elizabeth Woods coordinated production of the ancillary materials. Senior content developer Lisa Weber handled the media products. Senior content project manager, Teresa L. Trego, at Cengage, and Cassie Carey, senior production editor at Graphic World Publishing Services, kept the schedule mov-

ing smoothly. We acknowledge the contributions of art director Maria Epes, and John Sarantakis, project manager, intellectual property acquisition. We are grateful to marketing director Nicole Hamm for helping us obtain valuable comments from users and reviewers. We gratefully acknowledge the continuing support of product director Mary Finch.

Laurie J. Butler  
*The University of Chicago*

November 2014

### David W. Oxtoby

David W. Oxtoby became the ninth president of Pomona College on July 1, 2003. An internationally noted chemist, he previously served as dean of physical sciences at The University of Chicago. At Pomona, he holds a coterminous appointment as president and professor of chemistry. Before coming to Pomona, he was associated with the University of Chicago for nearly three decades, with brief interludes to serve as a visiting professor at such places as the University of Paris; the University of Bristol in Great Britain; and the University of Sydney in Australia. Oxtoby is a fellow of the American Physical Society and a member of the American Chemical Society and the American Association for the Advancement of Science. After earning his bachelor's degree, summa cum laude, from Harvard University, he went on to earn his Ph.D. at the University of California, Berkeley. As a research chemist, he is author or co-author of more than 165 scientific articles on such subjects as light scattering, chemical reaction dynamics, and phase transitions. In addition to co-authoring *Principles of Modern Chemistry* and *Chemistry: Science of Change*, he has received fellowships from the Guggenheim, von Humboldt, Dreyfus, Sloan, Danforth, and National Science foundations.

### H.P. Gillis

H.P. Gillis conducts experimental research in the physical chemistry of electronic materials, emphasizing phenomena at solid surfaces and interfaces. Dr. Gillis received his B.S. (Chemistry and Physics) at Louisiana State University and his Ph.D. (Chemical Physics) at The University of Chicago. After postdoctoral research at the University of California–Los Angeles and 10 years with the technical staff at Hughes Research Laboratories in Malibu, California, Dr. Gillis joined the faculty of Georgia Institute of Technology. Dr. Gillis moved to University of California–Los Angeles, where he currently serves as adjunct professor of materials science and engineering. He has taught courses in general chemistry, physical chemistry, quantum mechanics, surface science, and materials science at UCLA and at Georgia Institute of Technology.

### Laurie J. Butler

Laurie J. Butler uses molecular beam and laser spectroscopic techniques, along with associated computational modeling, to study the chemical reaction dynamics of radical intermediates and of electronically excited molecules. She received her B.S. (Chemistry) at the Massachusetts Institute of Technology and her Ph.D. (Physical Chemistry) at the University of California, Berkeley (the latter under the direction of Nobel Laureate Y.T. Lee). After a short postdoctoral position at University of Wisconsin–Madison, she accepted a faculty position at The University of Chicago. Fellow of the AAAS, the American Chemical Society, and the American Physical Society, she has co-authored over a hundred scientific papers. She teaches introductory and physical chemistry to the brilliant undergraduates at Chicago, for which she received the University's Quantrell teaching award, as well as graduate-level courses in quantum mechanics and in chemical reaction dynamics.

# Introduction to the Study of Modern Chemistry

The surface of a silicon crystal imaged using a scanning tunneling microscope. Individual silicon atoms appear as purple protrusions above the background. The surface was cleaned in an ultrahigh vacuum to remove all impurity atoms and the image was taken at very low temperatures ( $-220^{\circ}\text{C}$ ) to obtain the high resolution shown here. There are two kinds of surface silicon atoms shown in this image: "corner" silicon atoms that form hexagonal rings around a hole in the surface layer and "center" silicon atoms that appear as pairs arranged around the hexagonal rings.

**M**odern chemistry explores the world of atoms and molecules, seeking to explain not only their bonding, structures, and properties, but also how these very structures are transformed in chemical reactions. The search for atoms and molecules began with the speculations of ancient philosophers and—stimulated by the classic experiments of the 18th and 19th centuries—led to John Dalton’s famous atomic hypothesis in 1808. The quest continues. The invention of the scanning tunneling microscope (STM) in the 1980s, along with other microscopic and spectroscopic techniques, has enabled contemporary scientists to detect and manipulate individual atoms and molecules.

## Unit Chapters

### CHAPTER 1

The Atom in Modern Chemistry

### CHAPTER 2

Chemical Formulas, Equations, and Reaction Yields

## Unit Goals

- To describe the key experiments and the underlying physical models that justify the central role of the atom in modern chemistry
  - Chemical evidence for the existence and properties of atoms and molecules
  - Physical evidence for the existence and properties of atoms and molecules
  - The modern, planetary model of the atom
- To introduce the established quantitative procedures that describe chemical reactions as rearrangements of atoms, forming products from reactants
  - The mole concept that relates weighing and counting of molecules and atoms
  - Balanced chemical equations that relate moles of reactants to moles of products

## 1

## CHAPTER

# The Atom in Modern Chemistry

- 1.1 The Nature of Modern Chemistry
  - 1.2 Elements: The Building Blocks of Matter
  - 1.3 Indirect Evidence for the Existence of Atoms: Laws of Chemical Combination
  - 1.4 The Physical Structure of Atoms
  - 1.5 Mass Spectrometry, Isotopes, and the Measurement of Relative Mass
  - 1.6 The Mole: Counting Molecules by Weighing
- Connection to Nanotechnology:*  
Imaging Atoms, Molecules, and Chemical Reactions by Scanning Tunneling Microscopy

Reversible single atom transfer using the scanning tunneling microscope. This image was taken under the same conditions as the one shown opposite page 1. One of the “center” silicon atoms (imaged in red) has been transferred halfway to another center atom site by the scanning tunneling microscope tip. The atom is stable in this position at low temperatures but returns to its home site as the temperature is raised above  $-100^{\circ}\text{C}$ .

## 1.1 The Nature of Modern Chemistry

Chemists study the properties of substances and the reactions that transform substances into other substances. Chemists are particularly interested in understanding how and why specific chemical reactions occur, in order to tailor the properties of existing substances to meet particular needs—and to create entirely new substances designed to have specific properties. Chemistry has improved agricultural production, helped prevent and cure many diseases, increased the efficiency of energy production, and reduced environmental pollution, to cite just a few advances. A particularly exciting challenge for modern chemical research is to understand the dynamics of these chemical transformations, because they govern phenomena as diverse as the evolution of small carbon-containing molecules in interstellar space, changes in terrestrial atmospheric and climatic patterns caused by pollutants, and the unfolding of life processes in living organisms.

**FIGURE 1.1** Alchemists searched in vain for procedures that would turn base metals into gold. Their apparatus foreshadowed equipment in modern chemical laboratories.

Chemistry influences almost every area of science and technology; advances in chemistry inform disciplines as different as solid-state physics and molecular biology, and the synthetic methods and analytical techniques developed by chemists support research and manufacturing in important areas like medicine and microelectronics. Perhaps no other science covers as broad a range of topics as does chemistry. Within a single modern chemistry department, you're likely to find chemists creating new materials and developing strategies for sustainable energy, devising synthetic routes that conserve all of the atoms in starting materials, detecting and identifying single molecules, designing new molecules for therapeutic purposes and translating those developments into clinical trials, and developing highly selective integrated sensors for a variety of applications in science and technology. Despite the diversity of these areas of scientific inquiry, they are all unified by a single set of fundamental scientific principles, which we will introduce in this textbook.

Chemistry is a relatively young science, and its foundations weren't established until the last quarter of the 18th century. Before that, most chemists were known as *alchemists*—early entrepreneurs who sought to transform the properties of materials for economic gain (Fig. 1.1). For centuries their obsession was to transform “base” metals, such as lead, into gold. They boldly assumed that the properties of one material could somehow be extracted and transferred to another. If the essential properties—such as yellow color, softness, and ductility—could be assembled from various inexpensive sources, then gold could be created at great profit.

The alchemists persisted in their efforts for more than a thousand years. Although they collected many useful, empirical results that have since been incorporated into modern chemistry, they never transformed base metals into gold. Many scientists had begun to challenge the basic assumptions of the alchemists by the middle of the 17th century. These doubts culminated with the publication of *The Sceptical Chymist* by Robert Boyle in England in the 1660s, one of the pivotal events that marked the beginning of modern chemistry. Another century was required to establish the conceptual foundations of modern chemistry, a field that flourished throughout the 19th and 20th centuries and remains vibrant today.

The error of the alchemists is obvious to modern observers: they did not follow the scientific method. A new idea is accepted only temporarily in the scientific method, in the form of a **hypothesis**. It is then subjected to rigorous testing, in carefully controlled experiments. A hypothesis is elevated to a **scientific law** only after it has survived many such tests. Concepts or ideas that have earned the status of scientific laws by direct and repeated testing then can be applied with confidence in new situations. A scientific law must be predictive, in addition to being explanatory; failure to accurately predict the results of a new experiment is sufficient to invalidate a scientific law. Had a proper set of tests been made in separate, independent experiments, the alchemists would have recognized that the properties of a material are, in fact, intrinsic, inherent characteristics of that material and cannot be extracted from it.

The history of the alchemists shows the origin of a certain duality in the nature of modern chemistry, which persists to the present. Because chemistry contributes to the foundations of numerous professions and industries, we see the urge to apply established chemical knowledge for profit. But we also see the urge to create new chemical knowledge, driven by both intellectual curiosity and by the desire to have reliable information for applications. Many scientists and engineers from different disciplines contribute to both basic and applied chemical research and development. Irrespective of the specific context, conducting chemical research requires scrupulous adherence to the scientific method, in which the new knowledge generated is subjected to rigorous scrutiny before it earns the confidence of the scientific community.

Most students who study chemistry will apply what they have learned during the course of their professional careers rather than conduct research in chemistry. Still, a useful strategy for learning to think like an experienced chemist is to assume that you are personally responsible for establishing the scientific foundations of chemistry for the very first time. Upon encountering a new topic, try this: imagine that you are the first person ever to see the laboratory results on which it is based. Imagine that you must construct the new concepts and explanations to interpret these results, and that you will present and defend your conclusions before the scientific community. Be suspicious. Cross-check everything. Demand independent confirmations. Always remain, with Boyle, the “skeptical chemist.” Follow the scientific method in your acquisition of knowledge, even from textbooks. In this way, you will make the science of chemistry your own, and you will experience the intellectual joys of discovery and interpretation. Most important, you will recognize that chemistry is hardly a closed set of facts and formulas. Quite the contrary, it is a living, growing method for investigating all aspects of human experience that depend on changes in the composition of substances. Finally, learning to examine critically what we call “the nature of the evidence” will help you make better decisions as consumers and citizens in a world where science and technology continue to become increasingly important parts of modern life.

### 1.1.1 Conservation of Matter and Energy

The science of chemistry rests on two well-established principles: the conservation of matter and the conservation of energy. The total amount of matter involved in chemical reactions is conserved—that is, it remains constant during the course of every chemical reaction. Matter is neither created nor destroyed in chemical reactions; the components of the reactants are simply rearranged to form products.

These rearrangements are inevitably accompanied by changes in energy, which brings us to the second principle. The total amount of chemical energy stored in the reactants is almost always different than that stored in the products; this difference manifests itself in the form of thermal, electrical, or mechanical energy required for, or produced by, chemical reactions. But energy is neither created nor destroyed during chemical reactions; it has always been found to be conserved.

These two core principles must be modified slightly for nuclear reactions, which occur at energies so high that matter and energy can be converted into one another through Einstein’s relation,  $E = mc^2$ . The *sum* of mass and energy is conserved in nuclear reactions.

### 1.1.2 Macroscopic Methods and Nanoscopic Models

Chemical reasoning, as used both in applications and in basic research, resembles a detective story in which tangible clues lead to a mental picture of events never directly witnessed by the detective. Chemical experiments are conducted in laboratories equipped with beakers, flasks, analytical balances, pipettes, optical and infrared spectrometers, lasers, vacuum pumps, pressure gauges, mass spectrometers, centrifuges, and other apparatus. Each of these devices exists on the *macroscopic* scale—that is, it is perceptible by ordinary human senses. Macroscopic objects range in size from about 1 meter (m) down to about 1 millimeter (mm), which is  $1 \times 10^{-3}$  m. But the actual chemical transformation events occur in the *nanoscopic* world of atoms and molecules—objects far too small to be detected by the naked eye, even with the aid of a first-class microscope. One nanometer (nm) is  $1 \times 10^{-9}$  m. So our modern laboratory instruments are the bridge between these worlds, giving us the means not only to influence the actions of

**FIGURE 1.2** Hydrogen and oxygen gas are produced in the ratio 2:1 when an electrical current is passed through water that contains dissolved sulfuric acid. The insert illustrates how chemists view this macroscopic chemical reaction as arising from the rearrangement of atoms on the nanoscale.

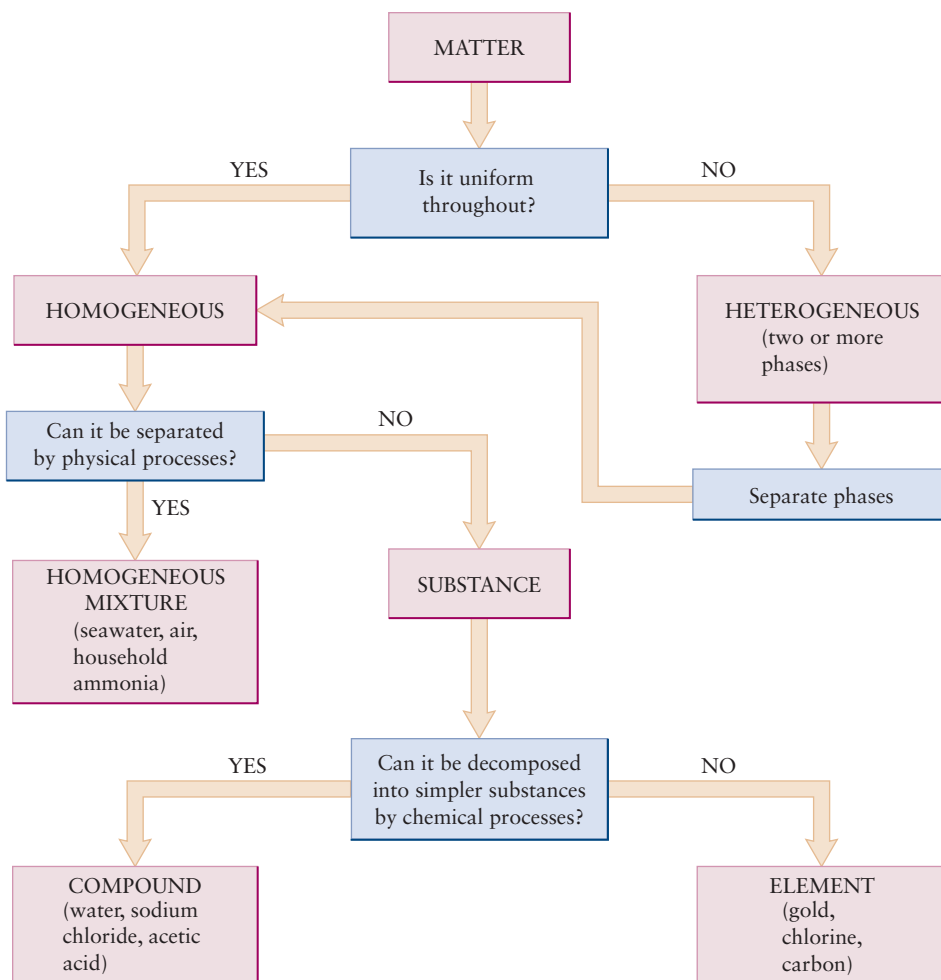

the atoms and molecules but also to measure their response. Figure 1.2 shows views of both worlds simultaneously. In illustrating the chemical decomposition of water into gaseous hydrogen and oxygen by electrolysis, the figure shows the relationship between events on the macroscale and on the nanoscale. Chemists *think* in the highly visual nanoscopic world of atoms and molecules, but they *work* in the tangible world of macroscopic laboratory apparatus. These two approaches to the chemical sciences cannot be divorced, and we emphasize their interplay throughout this textbook. Students of chemistry must master not only the fascinating concepts of chemistry, which describe the nanoscopic world of atoms and molecules, but also the macroscopic procedures of chemistry on which those concepts are founded.

## 1.2 Elements: The Building Blocks of Matter

Chemists study how sets of pure substances transform into other sets of pure substances in chemical reactions. These investigations apply two modes of reasoning and physical procedures—analysis (taking things apart) and synthesis (putting things together)—that go back to early Greek philosophers, who sought to identify the constituents of all matter as four elements: air, earth, fire, and water. Contemporary chemists classify matter using a very different set of fundamental building blocks, but the analysis and synthesis steps are basically unchanged.

### 1.2.1 Substances and Mixtures

Investigating chemical reactions can be greatly complicated and often obscured by the presence of extraneous materials. The first step is to learn how to analyze and classify materials to ensure that you are working with *pure* substances before initiating any reactions (Fig. 1.3). Suppose you take a sample of a

**FIGURE 1.3** Process flowchart for analyzing matter.

material—a gas, liquid, or solid—and examine its various properties or distinguishing characteristics, such as its color, odor, or density. How uniform are those properties throughout the sample? Different regions of a piece of wood, for example, have different properties, such as variations in color and texture. Wood, then, is said to be **heterogeneous**. Other materials, such as air or mixtures of salt and water, are classified as **homogeneous** materials because their properties are the same throughout a given sample. But these mixtures, although homogeneous, cannot be called pure substances. Thus, call a substance a **mixture** when it is possible to separate it into components by ordinary physical means such as melting, freezing, boiling, or dissolving in solvents (Fig. 1.4). These operations provide

**FIGURE 1.4** (a) A solid mixture of blue  $\text{Cu}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$  and yellow  $\text{CdS}$  is added to water. (b) Although the  $\text{Cu}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$  dissolves readily and passes through the filter, the  $\text{CdS}$  remains largely undissolved and is retained by the filter. (c) Evaporation of the solution leaves nearly pure crystals of  $\text{Cu}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ .

© Cengage Learning/Leon Levandowski

ways of separating materials from one another by their properties: freezing points, boiling points, and solubilities. Air, for example, is a mixture of several components—oxygen, nitrogen, argon, and various other gases. If air is liquefied and then warmed slowly, the gases with the lowest boiling points evaporate first, leaving behind in the liquid those with higher boiling points. Such a separation would not be perfect, but the processes of liquefaction and evaporation could be repeated to improve the purity of the component gases to any required degree.

If all these physical procedures (and many others) fail to separate matter into portions that have different properties, the material is said to be a **pure substance**. What about the common material sodium chloride, which we call table salt? Is it a substance? The answer is yes if we use the term *sodium chloride* (NaCl), but no if we use the term *table salt*. Table salt is a mixture of mostly sodium chloride but also small amounts of sodium iodide (needed by the thyroid gland) and magnesium carbonate (needed to prevent the salt from caking). Even if these two components were not added, table salt contains other impurities that had not been removed in its preparation, so to that extent, table salt is a mixture. In contrast, when we refer to sodium chloride, we imply that it is a pure substance that contains only NaCl. The pure substance sodium chloride is a compound, not an element.

Nothing is absolutely pure in practice, so the word **substance** is an idealization. Among the purest materials ever prepared are silicon (Fig. 1.5) and germanium. These elements are used in electronic devices and solar cells, and their electronic properties require either high purity or else precisely controlled concentrations of deliberately added impurities. Meticulous chemical and physical methods have enabled scientists to prepare germanium and silicon with concentrations of impurities that are less than one part per billion. Any higher concentrations of certain impurities would alter the electrical properties of these materials.

### 1.2.2 Elements

Literally millions of substances have so far been either discovered or synthesized and formally identified. Are these the fundamental building blocks of matter? Happily not, for their classification alone would pose an insurmountable task. In fact, all of these substances are merely combinations of much smaller numbers of building blocks called **elements**. Elements are substances that cannot be decomposed into two or more simpler substances by ordinary physical or chemical means. The word *ordinary* excludes the processes of radioactive decay, whether natural or artificial, and high-energy nuclear reactions that *do* transform elements into one another. When a substance contains two or more chemical elements, we call it a **compound**. For example, hydrogen and oxygen are elements because no further chemical separation is possible, whereas water is a

**FIGURE 1.5** Nearly pure elemental silicon is produced by pulling a 10-inch-long solid cylinder (called a boule) out of the melt, leaving most of the impurities behind.

compound because it can be separated into hydrogen and oxygen by passing an electric current through it (see Fig. 1.2). *Binary* compounds are substances, such as water, that contain two elements, *ternary* compounds contain three elements, *quaternary* compounds contain four elements, and so on.

At present, scientists have identified some 118 chemical elements. A few have been known since before recorded history, principally because they occur in nature as elements rather than in combination with one another in compounds. Gold, silver, lead, copper, and sulfur are the most common of these. Gold is found in streams in the form of little granules (placer gold) or nuggets in loosely consolidated rock. Sulfur is associated with volcanoes, and copper often can be found in its native state in shallow mines. Iron occurs (only rarely) in its elemental state (in meteorites); it usually is combined with oxygen or other elements. Ancient metallurgists, in the second millennium B.C., somehow learned to reduce iron oxide to metallic iron using charcoal in forced-draft fires, and the Iron Age was born.

The names of the chemical elements and the symbols that designate them have a fascinating history. The symbols for many elements come from their Latin names, such as gold (aurum, symbol Au), copper (cuprum, Cu), and iron (ferrum, Fe). Some elements have names that describe their characteristic reactions or source; hydrogen (H), for example, means “water former” and potassium (kalium, K) takes its common name from potash (potassium carbonate), a useful chemical obtained in early times by leaching the ashes of wood fires with water. Many elements take their names from Greek and Roman mythology: cerium (Ce) from Ceres, goddess of plenty; tantalum (Ta) from Tantalus, who was condemned in the afterlife to an eternity of hunger and thirst while close to water and fruit that were always tantalizingly just out of reach; niobium (Nb) from Niobe, daughter of Tantalus; and mercury (hydrargyrum, Hg), which means silver water, named after the quickly moving god. Some elements are named for continents: europium (Eu) and americium (Am). Other elements are named after countries: germanium (Ge), francium (Fr), and polonium (Po). Cities provided the names of other elements: holmium (Stockholm, Ho), ytterbium (Ytterby, Yb), and berkelium (Berkeley, Bk). Some are named for the planets: uranium (U), plutonium (Pu), and neptunium (Np). Other elements take their names from colors: praseodymium (green, Pr), rubidium (red, Rb), and cesium (sky blue, Cs). Still others honor great scientists: curium (Marie Curie, Cm), mendelevium (Dmitri Mendeleev, Md), fermium (Enrico Fermi, Fm), einsteinium (Albert Einstein, Es), and seaborgium (Glenn Seaborg, Sg).

### 1.3 Indirect Evidence for the Existence of Atoms: Laws of Chemical Combination

How did we acquire the chemical evidence for the existence of atoms and the scale of relative atomic masses? It is an instructive story, both in its own right and as an illustration of how science progresses.

We may know the elements to be the most fundamental substances, and we may know that they can be combined chemically to form compound substances, but that knowledge provides us no information about the nanoscopic structure of matter or how that nanoscopic structure controls and is revealed by chemical reactions. Ancient philosophers dealt with these fascinating questions by proposing assumptions, or *postulates*, about the structure of matter. The Greek philosopher Democritus (c. 460–370 B.C.) postulated the existence of unchangeable *atoms* of the elements, which he imagined to undergo continuous random motion in the vacuum, a remarkably modern point of view. It follows from this postulate that matter is not divisible without limit; there is a lower limit to

which a compound can be divided before it becomes separated into atoms of the elements from which it is made. Lacking both experimental capabilities and the essentially modern scientific view that theories must be tested and refined by experiment, the Greek philosophers were content to leave their views in the form of assertions.

Experimental measurements showed that the ratios of the masses of compounds that react to form other compounds is also fixed. These results could be interpreted only by inferring that the smallest indivisible units of the elements (atoms) combined to form the smallest indivisible units of the compounds (molecules). The definite mass ratios involved in reactions suggested a convenient method for counting the number of atoms of each element participating in the reaction. These results, summarized as the **laws of chemical combination**, provided overwhelming, if indirect, evidence for the existence of atoms and molecules.

For more than a century, we have become so accustomed to speaking of atoms that we rarely stop to consider the experimental evidence for their existence that was collected in the 18th and 19th centuries. Twentieth-century science developed a number of sophisticated techniques to measure the properties of single atoms and powerful microscopes to observe them (see *Connection to Nanotechnology*). But long before single atoms were detected, chemists could speak with confidence about their existence and the ways in which they combine to form molecules. Moreover, although the absolute masses of single atoms of oxygen and hydrogen were not measured until the early 20th century, chemists could assert (correctly) some 50 years earlier that the *ratio* of their masses was close to 16:1.

### 1.3.1 Law of Conservation of Mass

The first steps toward formulating the laws of chemical composition were taken during the 18th century in the course of studies of heat and combustion. It had been observed that an organic material, such as wood, left a solid residue of ash when burned; similarly, a metal heated in air was transformed into a “calx,” which we now call an oxide. The popular explanation for these phenomena in the early 18th century was that a property called *phlogiston* was driven out of wood or metal by the heat of a fire. From the modern perspective, this seems absurd, because the ash weighed less than the original wood, whereas the calx weighed more than the metal. The principle of conservation of mass had not yet been established at that time, and people saw no reason why the mass of a material should not change when heated.

Further progress could be made only by carefully measuring the changes in mass<sup>1</sup> that occur in chemical reactions. The balance had been known since antiquity, but it had been used principally as an assayer’s tool and for verifying the masses of coins or commodities in commerce. The analytical balance developed in the 18th century was accurate to perhaps 1 part in 10,000, enabling much more accurate measurements of mass changes accompanying chemical reactions than had been possible previously. French chemist Antoine Lavoisier used the analytical balance (see the photo on page 35) to demonstrate that the sum of the masses of the products of a chemical reaction equals the sum of the masses of the reactants to the high degree of accuracy provided by the instrument. Lavoisier heated mercury in a sealed flask that contained air. After several

<sup>1</sup>Chemists sometimes use the term *weight* in place of *mass*. Strictly speaking, weight and mass are not the same. The mass of a body is an invariant quantity, but its weight is the force exerted on it by gravitational attraction (usually by the Earth). Newton’s second law relates the two ( $weight = m \times g$ , where  $g$  is the acceleration due to gravity). As  $g$  varies from place to place on the Earth’s surface, so does the weight of a body. In chemistry, we deal mostly with ratios, which are the same for masses and weights. In this textbook we use the term *mass* exclusively, but *weight* is still in colloquial chemical use.

**FIGURE 1.6** The red solid, mercury oxide, decomposes into liquid mercury and oxygen gas, when heated. Note the drops of liquid mercury condensing on the side of the test tube.

days, a red substance, an oxide of mercury, was produced. The gas remaining in the flask was reduced in mass and could no longer support life or combustion; a candle was extinguished by it, and animals suffocated when forced to breathe it. We now know that this residual gas was nitrogen, and that the oxygen in the air had reacted with the mercury. Lavoisier then took a carefully weighed amount of the red oxide of mercury and heated it to a very high temperature (Fig. 1.6). He weighed both the mercury and the gas that were produced and showed that their combined mass was the same as that of the mercury oxide with which he had started. After further experiments, Lavoisier was able to state the **law of conservation of mass**:

*Mass is neither created nor destroyed in chemical reactions; it is conserved.*

Lavoisier was the first to observe that a chemical reaction is analogous to an algebraic equation. We would write his second reaction as

although during Lavoisier's lifetime, the identity of the gas (oxygen) was only just being discovered by Joseph Priestley.

### 1.3.2 Law of Definite Proportions

Rapid progress ensued as chemists began to make accurate determinations of the masses of reactants and products. A controversy arose between two schools of thought, led by a pair of French chemists, Claude Berthollet and Joseph Proust. Berthollet believed that the proportions (by mass) of the elements in a particular compound were not fixed, but could actually vary over a certain range. Water, for example, might contain more or less than 11.1% hydrogen by mass, the generally accepted value. Proust disagreed, arguing that any apparent variation was due to impurities and experimental errors. He also stressed the difference between homogeneous mixtures and chemical compounds. In 1794, Proust published the fundamental **law of definite proportions**:

*In a given chemical compound, the proportions by mass of the elements that compose it are fixed, independent of the origin of the compound or its mode of preparation.*

Pure sodium chloride contains 60.66% chlorine by mass, whether we obtain it from salt mines, crystallize it from waters of the oceans or inland salt seas, or synthesize it from its elements, sodium and chlorine.<sup>2</sup>

The law of definite proportions was a crucial step in the development of modern chemistry, and Proust's conclusions had become widely accepted by the time Dalton published his atomic theory. We now recognize that this law is not strictly true in all cases. Although all gaseous compounds obey Proust's law, certain solids have compositions that vary over small ranges; such a solid is called a **nonstoichiometric compound**. An example is wüstite, which has the nominal chemical formula FeO (with 77.73% iron by mass), but the composition of which, in fact, ranges continuously from Fe<sub>0.95</sub>O (with 76.8% iron) down to Fe<sub>0.85</sub>O (74.8% iron), depending on the method of preparation. Such compounds are called **berthollides**, in honor of Berthollet. We now know, on the atomic level, why they are nonstoichiometric (see discussion in Section 21.4).

The development of the law of definite proportions provides an excellent example of how science progresses. Measurements of the compositions of a large number of compounds supported the law of definite proportions, but later,

<sup>2</sup>This statement needs some qualification. As explained in the next section, many elements have several *isotopes*, which are species whose atoms have almost identical chemical properties but different masses. Natural variation in isotope abundance leads to small variations in the mass proportions of elements in a compound, and larger variations can be induced by artificial isotopic enrichment.

more precise measurements uncovered exceptions to the general principle that had been established. The following explanation of the exceptions leads to a deeper understanding.

### 1.3.3 Dalton's Atomic Theory

English scientist John Dalton was by no means the first person to propose the existence of atoms; as we have seen, speculations about them date back to ancient Greek times (the word *atom* is derived from Greek *a-* [“not”] plus *tomos* [“cut”], meaning “not divisible”). Dalton's major contribution to chemistry was to marshal the evidence for the existence of atoms. He showed that the mass relationships found by Lavoisier and Proust could be interpreted most simply by postulating the existence of atoms of the various elements.

In 1808, Dalton published *A New System of Chemical Philosophy*, in which the following five postulates comprise the **atomic theory of matter**:

1. Matter consists of indivisible atoms.
2. All the atoms of a given chemical element are identical in mass and in all other properties.
3. Different chemical elements have different kinds of atoms; in particular, their atoms have different masses.
4. Atoms are indestructible and retain their identities in chemical reactions.
5. Atoms of the elements combine with each other in small integer ratios to form compounds.

Dalton's fourth postulate clearly is related to the law of conservation of mass. The fifth aims to explain the law of definite proportions. Perhaps Dalton's reasoning went something like this: Suppose you reject the atomic theory and believe instead that compounds are subdivisible without limit. What, then, ensures the constancy of composition of a substance such as sodium chloride? Nothing! But if each sodium atom in sodium chloride is matched by one chlorine atom, then the constancy of composition can be understood. So in this argument for the law of definite proportions, it does not matter how small the atoms of sodium and chlorine are. It is important merely that there be some lower bound to the subdivisibility of matter, because the moment we put in such a lower bound, arithmetic steps in. Matter becomes countable, and the units of counting are simply atoms. Believing in the law of definite proportions as an established experimental fact, Dalton *postulated* the existence of the atom.

### 1.3.4 Law of Multiple Proportions

The composition of a compound is shown by its **chemical formula**. The symbol  $\text{H}_2\text{O}$  for water specifies that there are two atoms of hydrogen for each atom of oxygen in one unit of water. We now know that the two hydrogen atoms are strongly bound to the oxygen atom in a discrete unit called a **molecule** and that the atoms in one water molecule are not strongly bound to the atoms of any other water molecule. Many solid substances do not exist as molecules but as infinite arrays of ions or atoms bonded to each other in ways that do not allow us to identify a particular molecule uniquely; they are called ionic and covalent solids. The chemical formula for these pure substances gives the relative ratios of the numbers of their constituent atoms. How do we know that these are the true proportions? The determination of chemical formulas (and the accompanying determination of relative atomic masses), building on the atomic hypothesis of Dalton, was a major accomplishment of 19th-century chemistry.

The simplest compounds made from two different elements is a **diatomic molecule** that contains one atom of each element. Eighteenth- and nineteenth-century chemists knew, however, that two elements often combine in different proportions, suggesting the existence of multiple compounds that are more complicated than diatomic molecules.

Carbon (C) and oxygen (O), for example, combine under different conditions to form two different compounds, which we will call A and B. Analysis shows that A contains 1.333 grams (g) of oxygen per 1.000 g of carbon, and B contains 2.667 g of oxygen per 1.000 g of carbon. Although at this point we know nothing about the chemical formulas of the two oxides of carbon, we can say immediately that molecules of compound A contain half as many oxygen atoms per carbon atom as do molecules of compound B. The evidence for this is that the ratio of the masses of oxygen in A and B, for a fixed mass of carbon in each compound, is 1.333:2.667, or 1:2. If the formula of compound A were CO, then the formula of compound B would have to be CO<sub>2</sub>, C<sub>2</sub>O<sub>4</sub>, C<sub>3</sub>O<sub>6</sub>, or some other multiple of CO<sub>2</sub>. We cannot say from these data which of these (or an infinite number of other possibilities) are the true formulas of the molecules of compounds A and B, but we do know this: The number of oxygen atoms per carbon atom in the two compounds is the *quotient of integers*.

Let's consider another example. Arsenic (As) and sulfur (S) combine to form two sulfides, A and B, in which the masses of sulfur per 1.000 g of arsenic are 0.428 and 0.642 g, respectively. The ratio of these masses is 0.428:0.642 = 2:3. We conclude that *if* the formula of compound A is a multiple of AsS, then the formula of compound B must be a multiple of As<sub>2</sub>S<sub>3</sub>.

These two examples illustrate the **law of multiple proportions**:

*When two elements form a series of compounds, the masses of one element that combine with a fixed mass of the other element are in the ratio of small integers to each other.*

In the first example, the ratio of the masses of oxygen in the two compounds, for a given mass of carbon, was 1:2. In the second example, the ratio of the masses of sulfur in the two compounds, for a given mass of arsenic, was 2:3. Today, we know that the carbon oxides are CO (carbon monoxide) and CO<sub>2</sub> (carbon dioxide), and the arsenic sulfides are As<sub>4</sub>S<sub>4</sub> and As<sub>2</sub>S<sub>3</sub>. Dalton could not have known this, however, because he had no information from which to decide how many atoms of carbon and oxygen are in one molecule of the carbon-oxygen compounds or how many atoms of arsenic and sulfur are in the arsenic-sulfur compounds.

### EXAMPLE 1.1

Chlorine (Cl) and oxygen form four different binary compounds. Analysis gives the following results:

Compound	Mass of O Combined with 1.0000 g Cl
A	0.22564 g
B	0.90255 g
C	1.3539 g
D	1.5795 g

- (a) Show that the law of multiple proportions holds for these compounds.
- (b) If the formula of compound A is a multiple of Cl<sub>2</sub>O, then determine the formulas of compounds B, C, and D.

#### Solution

- (a) Form ratios by dividing each mass of oxygen by the smallest, which is 0.22564 g:

$$0.22564 \text{ g} : 0.22564 \text{ g} = 1.0000 \text{ for compound A}$$

$$0.90255 \text{ g} : 0.22564 \text{ g} = 4.0000 \text{ for compound B}$$

$$1.3539 \text{ g} : 0.22564 \text{ g} = 6.0003 \text{ for compound C}$$

$$1.5795 \text{ g} : 0.22564 \text{ g} = 7.0001 \text{ for compound D}$$

The ratios are whole numbers to a high degree of precision, and the law of multiple proportions is satisfied.

(Continued)

(b) If compound A has a formula that is some multiple of  $\text{Cl}_2\text{O}$ , then compound B is  $\text{Cl}_2\text{O}_4$  (or  $\text{ClO}_2$ , or  $\text{Cl}_3\text{O}_6$ , and so forth) because it is four times richer in oxygen than is compound A. Similarly, compound C, which is six times richer in oxygen than compound A, is  $\text{Cl}_2\text{O}_6$  (or  $\text{ClO}_3$ , or

$\text{Cl}_3\text{O}_9$ , and so forth), and compound D, which is seven times richer in oxygen than compound A, is  $\text{Cl}_2\text{O}_7$  (or a multiple thereof).

**Related Problems: 7, 8, 9, 10**

Dalton made a sixth assumption, which was incorrect, to resolve the dilemma of the absolute number of atoms present in a molecule; he called it the “rule of greatest simplicity.” If two elements A and B form only one compound then the chemical formula for that compound will be the simplest possible: AB. Thus, he assumed that when hydrogen and oxygen combine to form water, the reaction is

Dalton was wrong, however, as we now know, and the correct reaction is

### 1.3.5 Law of Combining Volumes

French chemist Joseph Gay-Lussac conducted some important experiments, at about the same time as Dalton, on the relative volumes of gases that react completely with one another to form new gases. He discovered the **law of combining volumes**:

*The ratio of the volumes of any pair of gases in a gas phase chemical reaction (at the same temperature and pressure) is the ratio of simple integers.*

Here are three examples:

2 volumes of hydrogen + 1 volume of oxygen  $\longrightarrow$  2 volumes of water vapor

1 volume of nitrogen + 1 volume of oxygen  $\longrightarrow$  2 volumes of nitrogen oxide

3 volumes of hydrogen + 1 volume of nitrogen  $\longrightarrow$  2 volumes of ammonia

### 1.3.6 Avogadro's Hypothesis

Gay-Lussac did not interpret his experimental findings theoretically but, shortly after their publication in 1811, the Italian chemist Amedeo Avogadro used them to formulate an important postulate that became known as Avogadro's hypothesis:

*Equal volumes of different gases at the same temperature and pressure contain equal numbers of particles.*

The question immediately arose: Are “particles” of the elements the same as Dalton's atoms? Avogadro believed that they were not; rather, he proposed that elements could exist as diatomic molecules. Avogadro's hypothesis could explain Gay-Lussac's law of combining volumes (Fig. 1.7). Thus, the reactions we wrote out in words become

The coefficients in the above reactions are proportional to the volumes of the reactant and product gases in Gay-Lussac's experiments, and the chemical

**FIGURE 1.7** The cubes shown contain equal volumes of different gases at the same temperature and pressure. The combining volumes that Gay-Lussac observed for the two reactions can be understood if each cube contains the same number of molecules (Avogadro's hypothesis), and if hydrogen, oxygen, and nitrogen exist as diatomic molecules, as shown.

formulas of the reactions agree with modern results. Dalton, on the other hand, would have written those reactions as

The combining volumes predicted by Avogadro's hypothesis for all three of these reactions as written would be

which did not agree with the results of Gay-Lussac's experiments.

Avogadro's hypothesis not only predicted the correct molecular formulas but also the correct relative atomic masses of the elements. Chemical analysis during the 18th century had demonstrated that 1 g of hydrogen gas reacts completely with 8 g of oxygen gas to produce 9 g of water. If Dalton's formula for water, HO, were correct, then an atom of oxygen would weigh 8 times as much as an atom of hydrogen; that is, Dalton's assumption requires the **relative atomic mass** of oxygen to be 8 on a scale where the relative atomic mass of hydrogen had been chosen to be 1. Avogadro's hypothesis predicted, however, that each water molecule has twice as many atoms of hydrogen as oxygen; therefore, to explain the observed experimental mass relation, the relative mass for oxygen must be 16, a result consistent with modern measurements.

We might expect that Dalton would have welcomed Avogadro's brilliant hypothesis, but he did not. Dalton and others insisted that elements could not exist as diatomic molecules. One reason for their belief was the then-popular idea that a force called *affinity* held molecules together. Affinity expressed the attraction of opposites, just as we think of the attraction between positive and negative electric charges. Why should two atoms of the same type be held together in a molecule if the affinity theory were true? Moreover, if atoms of the same element did bond together somehow in pairs, why shouldn't they aggregate further to form molecules with three, four, or six atoms, and so forth? Avogadro's reasoning did not attract the attention it deserved because so many chemists continued to believe in the affinity theory, resulting in great confusion due to the adoption of different chemical formulas for the same molecule. A textbook

published in 1861 by the German chemist August Kekulé titled *Lehrbuch der Organischen Chemie* gave 19 different chemical formulas for acetic acid!

In 1860, 50 years after Avogadro's work, Italian chemist Stanislao Cannizzaro presented a paper at the First International Chemical Congress in Karlsruhe, Germany, that convinced others to accept Avogadro's approach. Cannizzaro had analyzed many gaseous compounds and was able to show that their chemical formulas could be established with a consistent scheme that used Avogadro's hypothesis and avoided any extra assumptions about molecular formulas. Gaseous hydrogen, oxygen, and nitrogen (as well as fluorine, chlorine, bromine, and iodine), did indeed turn out to be diatomic molecules under ordinary conditions, thus vindicating Avogadro and his hypothesis.

## 1.4 The Physical Structure of Atoms

The laws of chemical combination that culminated in Dalton's atomic theory and Avogadro's hypothesis reinforced the original Greek concept that the atom was the ultimate and indivisible building block of matter. By the end of the 19th century, new experimental results forced scientists to abandon this view and to conclude that atoms themselves were composed of a number of smaller, *elementary* particles. It took about 40 years to identify and measure the properties of these sub-atomic particles. This was a fascinating period in the development of modern science. Physicists built upon the advances of chemists to develop a deeper understanding of the fundamental structure of matter. Knowledge of the components of the atom and of the forces that hold them together stimulated entirely new fields of basic science and technology that continue to the present. Three themes characterize the research in this period: (1) how electric and magnetic fields (at that time only recently understood and described by the empirical laws of electricity and magnetism) became the dominant probes of the structure of matter, (2) the importance of clearly formulated hypotheses that could be tested experimentally, and (3) how the results we describe for several key experiments led to the general conclusions and insights that were drawn.

We suggest that you review the relevant sections of Appendix B before continuing because interpreting the results of experiments described in the following paragraphs requires an elementary understanding of electricity and magnetism.

### 1.4.1 Electrolysis and the Existence of Ions

The story begins around the last quarter of the 19th century, by which time Faraday's laws of electrolysis had been generally accepted. Faraday had studied electrochemical reactions extensively; reactions in which the passage of an electric charge produces chemical changes (see Section 17.1). The electrolysis of water, shown in Figure 1.2, is an example of an electrochemical reaction—the electric current passing through the water decomposes it into the elements hydrogen and oxygen. Faraday discovered that the amount of water decomposed, and the amount of hydrogen and oxygen produced at the electrodes, were directly proportional to the quantity of charge passed. He observed the same result for many different electrochemical reactions, which led him to suggest that there must exist a fixed unit of electricity that is transferred in all these reactions. This conclusion was perhaps the first suggestion that all matter is composed of some electrical component that can be stripped away and transferred from reactants to products. Faraday named the electrically charged entities **ions**, the Greek word for “wanderer.” He measured the amount of charge necessary to produce 1 g of hydrogen from the electrolysis of water and thus calculated the **charge-to-mass ratio** for the hydrogen ion, which was about  $10^8 \text{ C kg}^{-1}$  in modern units.

Faraday's measurement was important, for nothing was known about the detailed structure or even the mass of the hydrogen ion at the time. Knowing the charge-to-mass ratio made it possible to investigate the properties of ions through their response to electric and magnetic fields. These studies would have to be carried out in gases at reduced pressure, where the charged particles could travel long distances without collisions, and their deflections by electric and magnetic fields could be measured. Also, Faraday's measurement established the order of magnitude for this quantity against which the charge-to-mass ratios of other particles would later be compared.

## 1.4.2 Glow Discharges and Cathode Rays

The electrical components of gaseous substances were discovered in studies of the *glow discharge*, a process in which soft and beautiful light is emitted when electricity is forced to pass through a gas at low pressure. This phenomenon created great excitement among physicists and stimulated intense research projects to explain the nature of the discharge and the origin of the light. An early example of a glow discharge tube is the *Crookes tube*, an apparatus (Figure 1.8) invented by William Crookes to study the principles of electric discharges. Modern neon signs are examples of glow discharge tubes. The color of the glow depends upon the gas; neon produces a red emission, argon is purple, and mercury is blue, as shown in Figure 1.8. The glass tube has inside two conducting plates separated from each other, and when a large electrical potential difference is applied (imagine hooking up the negative terminal of a battery to the plate called the “cathode” and the positive terminal to the plate called the “anode”), current passes through the gas and the gas glows. The glass on the right end of the tube is coated with a phosphor that glows when illuminated by radiation. Figure 1.8b shows a faint blue glow discharge that becomes weak as the gas pressure is reduced and eventually disappears at very low pressures. The phosphor at the end of the tube continues to glow, however, even when all of the gas has been evacuated. It appeared to be illuminated by some mysterious rays being emitted from the cathode and these rays were observed to travel in straight lines. Because these mysterious rays persist even when there is no gas in the tube, they must be emitted from the cathode and so were named **cathode rays**. Several decades of research revealed that these cathode rays could be deflected by both magnetic and electric fields and could heat a piece of metal foil in the tube until it glowed. Influenced by Maxwell's recent electromagnetic theory of light, one school of physicists believed the cathode rays to be a strange form of invisible light, whereas another group considered them a stream of negatively charged particles. The latter group was right, as demonstrated by the definitive experiments of J. J. Thomson described in the next section.

(a)

(b)

**FIGURE 1.8** A Crookes tube. (a) The Crookes tube is a glass cylinder that is evacuated and then filled with different gases to study the properties of glow discharges. A discharge is established when voltages are applied between the cathode (the electrode on the left) and the anode (the electrode in the arm below the main side of the tube). The glass face on the right side of the tube is coated with a phosphor that glows when irradiated. (b) A weak blue glow discharge that disappears at low pressure is shown. The phosphorescence from the end of the tube persists even when no gas is present, providing evidence for the existence of cathode rays.

## 1.4.3 Negative Charge in the Atom: Electrons

In 1897, British physicist J. J. Thomson conducted a set of experiments that established that the cathode rays are negatively charged particles, now called **electrons**. His experiments showed that these negatively charged particles were deflected by an electric field and that the direction of the displacement was consistent with their negative charge.

Figure 1.9 shows the force exerted on a positively charged particle (+) and on a negatively charged particle (−), when the particles are in a uniform electric field  $\vec{E}$ . The upper metal plate has an excess negative charge on it, while the lower plate has an excess positive charge on it; this establishes an electric field  $\vec{E}$  between the plates that points upward, in the +y direction, as shown by the blue **vector** (arrow) in the figure. This electric field exerts a force  $\vec{F}$  on a charged

**FIGURE 1.9** The direction of the electric field between two charged metal plates, and the resulting direction of the electrostatic force exerted on a negatively charged particle and on a positively charged particle.

particle given by  $\vec{F} = q\vec{E}$ , where  $q$  is the charge of the particle. Thus, when  $q$  is positive the force  $\vec{F}$  points in the same direction as  $\vec{E}$  (upward, in the  $+y$  direction), as shown by the red vector  $\vec{F}$  in the figure, but when  $q$  is negative the force  $\vec{F}$  points downward (in the  $-y$  direction), as shown by the green arrow in Figure 1.9. In the key experiment by J. J. Thomson described in the next paragraph, the negatively charged particles are moving in the  $+x$  direction when they experience this downward force, in the  $-y$  direction, so the component of the force in the  $y$  direction,  $F_y$ , is a negative number (downward), while the component of the force in the  $x$  direction,  $F_x$ , is zero.

### Charge-to-Mass Ratio of the Electron

The cathode ray tube used to measure the charge-to-mass ratio of the electron is shown schematically in Figure 1.10. The glass tube is evacuated to very low pressures so that electrons can travel the length of the tube without being scattered by residual gases. The glass face on the right side of the tube is coated with a phosphor that emits light when irradiated. Electrons emitted from the cathode are accelerated toward the anode, and those that pass through the hole in the anode form a collimated beam that lights up the phosphor where it hits. The electrical deflection plates bend the beam down, and the displacement is measured directly from the positions of the phosphorescent spots on the screen. The magnetic field is then turned on, and the field strength required to restore the beam to its original position is recorded. The charge-to-mass ratio of the electron can be calculated by measuring the displacement and knowing the strengths of the electric and magnetic fields applied.

The voltage applied to the deflection plates establishes a uniform electric field between them that exerts a constant downward force on electrons in the region that is given by

$$F_y = -eE = m_e a_y \quad [1.1]$$

where  $-e$  is the charge on the electron and  $E$  is the strength of the electric field. The constant acceleration that results from this force is calculated using Newton's second law,

$$a_y = \frac{-eE}{m_e} \quad [1.2]$$

**FIGURE 1.10** Thomson's apparatus, used to measure the charge-to-mass ratio,  $e/m_e$ , of the electron. Electrons emitted from the cathode (cathode rays) travel across the tube from left to right. An electric field deflects the beam down and a magnetic field deflects the beam up. The deflection  $S$ , due to the electric field alone, was measured. The beam was then restored to its original position by applying the magnetic field. The charge-to-mass ratio for the electron was determined from these two measurements, as discussed in the text. ( $\ell$  is the length of the electric deflection plates.)

which results in a displacement in the downward direction with magnitude given by

$$D = \frac{1}{2} |a_y| t^2 \quad [1.3]$$

where  $t$  is the time required to travel the distance  $\ell$ , the length of the plates. Substituting  $t = \ell/|v_x|$ , for electrons traveling through the plates at constant speed  $v_x = dx/dt$ , and  $|a_y|$  (the magnitude of the downward acceleration due to the electric field) from Equation 1.2 into Equation 1.3 gives:

$$D = \frac{1}{2} |a_y| t^2 = \frac{1}{2} \left( \frac{e}{m_e} \right) \left( \frac{\ell}{|v_x|} \right)^2 E \quad [1.4]$$

the magnitude of the downward displacement. The deflected electrons travel in straight lines after they leave the region between the plates, because there are no additional forces acting on them, and they strike the fluorescent screen at distance  $S$  below the position of the undeflected beam. This extra path length “magnifies” the displacement by the factor  $2L/\ell$ , where  $L$  is the distance from the center of the plates (a distance of  $\ell/2$  from the left edge) to the screen, as shown in Figure 1.11.

Electrons arriving at the screen have been displaced by

$$S = \left( \frac{2L}{\ell} \right) D = \left( \frac{e}{m_e} \right) \left( \frac{\ell}{|v_x|} \right)^2 \left( \frac{L}{\ell} \right) E \quad [1.5]$$

**FIGURE 1.11** Path followed by an electron beam subject to a force in the downward direction between two electrostatic plates. No force is exerted in the horizontal direction, so the component of velocity in the  $+x$  direction,  $v_x$ , is constant, but between the plates of length  $\ell$  the force is in the downward direction, so  $v_y$ , the  $y$  component of the velocity, is negative (downward) and increases in magnitude until the electron reaches the right edge of the plates. After that the electrons travel with constant  $v_x$  and  $v_y$ , so the path is straight. The average  $v_y$  between the plates is half of the final value of  $v_y$  at the right edge of the plates, so if one extrapolates the trajectory backwards from the straight portion of the deflected beam, it intersects the undeflected path at  $x = \ell/2$ . This gives the magnification ratio  $S/D = L/(\ell/2) = 2L/\ell$ .

Equation 1.5 could be solved for the charge-to-mass ratio, if the velocity of the electrons could be determined, because all of the other quantities could be measured directly in this experiment.

Thomson made an ingenious modification to his experiment to measure the velocity of the electrons directly and thereby determine  $e/m_e$ . He established a magnetic field in the same region as the electric field by passing an electric current through a pair of coils, as shown in Figure 1.10. The magnetic field was oriented perpendicular to both the electric field and to the flight path of the electrons, and it exerted an upward force on them. Thomson could return the deflected beam to its original position by varying the strengths of the two fields so that the net force on the electrons was zero. The force due to the electric field  $E$  was

$$F_{y \text{ (due to electric field)}} = -eE \quad [1.6]$$

and the force due to the magnetic field  $B$  was

$$F_{y \text{ (due to magnetic field)}} = e|v_x|B \quad [1.7]$$

so the velocity can be calculated by noting that when the two fields are adjusted so the beam is not deflected, the sum of the two forces must be zero. Thus,  $-eE + e|v_x|B = 0$  gives:

$$|v_x| = \frac{E}{B} \quad [1.8]$$

Substituting this result for the absolute value of  $v_x$  into Equation 1.5 gives the deflection observed under the influence of the electric field alone as

$$S = \left(\frac{e}{m_e}\right) \left(\frac{\ell B}{E}\right)^2 \left(\frac{L}{\ell}\right) E \quad [1.9]$$

which can be solved to find the magnitude of the charge-to-mass ratio of the electron.

$$\frac{e}{m_e} = \frac{SE}{\ell LB^2} \quad [1.10]$$

Each of the quantities on the right-hand side of Equation 1.10 was measured directly in Thomson's experiment, allowing him to determine the magnitude of the charge-to-mass ratio for the electron for the first time. The currently accepted value is  $e/m_e = 1.758820 \times 10^{11} \text{ C kg}^{-1}$ , with the charge and mass measured in the SI units coulombs and kilograms, respectively. (See Appendix B for a full discussion of units of measure.)

### Charge of the Electron

Thomson was able to measure only the charge-to-mass *ratio* of the electron in his experiment, and so an independent measurement of either the charge or the mass was required to determine the values of both of these fundamental physical quantities. The American physicist Robert Millikan and his student H. A. Fletcher measured the charge of the electron in 1906, in an elegant experiment that is illustrated schematically in Figure 1.12. An atomizer, like one used to spray perfume, injects very small (about  $1 \mu\text{m}$ ) droplets of oil into a chamber above a pair of electrically charged plates that are separated by an insulator. From time to time a drop falls through a hole in the upper plate and enters the region between the plates; the droplets pick up a charge during the spraying process or by collisions with ions in the chamber air. The voltage applied to the plates establishes a constant electric field in this region that pushes negatively charged particles up, countering the downward pull of gravity. Millikan and his student observed hundreds to thousands of single droplets for extended periods

**FIGURE 1.12** Millikan's apparatus, used to measure the charge of the electron,  $-e$ . Individual drops are suspended by adjusting the electric field to provide an electrostatic force that opposes the gravitational force; the charge on the electron was determined by equating these two forces as discussed in the text.

of time (as long as many hours), and they were able to control the motions of individual droplets by controlling the applied voltage. Individual droplets could be suspended for long periods of time by balancing the gravitational force by an opposing electrical force. Once suspended, individual droplets were sometimes observed to suddenly jump either upward or downward as they acquired negative or positive charges from ions in the air; they could be returned to their stable positions by adjusting the voltages on the plates.

The net force on stationary droplets is zero; balancing the electrical and gravitational forces gives  $Mg = QE$ , where  $M$  is the mass of the droplet,  $g$  is the acceleration due to gravity,  $Q$  is the magnitude of the charge on the droplet, and  $E$  is the electric field strength. The masses of individual droplets were calculated by multiplying their densities by their volumes (determined by measuring their diameters using the microscope). The gravitational acceleration  $g$  is a known constant, and the electric field strength was controlled and measured in each experiment, allowing Millikan to calculate the  $Q$  for each individual drop. The charges observed varied significantly from droplet to droplet but they were always an integral multiple of the one smallest unit of charge. Millikan pointed out for the first time that the magnitude of the fundamental unit of positive charge was exactly the same as the magnitude of the fundamental unit of negative charge. The value that Millikan reported for the magnitude of the charge of the electron was  $1.59 \times 10^{-19}$  C. The currently accepted value is  $e = 1.602176565 \times 10^{-19}$  C which, along with the currently accepted value for the  $e/m_e$  ratio gives  $m_e = 9.10938291 \times 10^{-31}$  kg for the electron mass.

**FIGURE 1.13** Modified Crookes tube.

#### 1.4.4 Positive Charge in the Atom: The Nucleus

Careful observation of the discharges in Crookes tubes showed that there was a glow that extended behind the cathode; a special version of the Crookes tube, shown in Figure 1.13 (based upon an original sketch by Thomson), was used to study the origin of this glow. The holes in the cathode (called canals) allowed part of the discharge to pass through and create pencils of light that were called **canal rays**. The German physicist Wilhelm Wien proceeded to study their

properties by measuring their deflections in both electric and magnetic fields. He drew the following conclusions from these measurements:

1. The canal rays passing through the cathode were deflected by magnetic fields in a direction that established them as positively charged particles.
2. The electric and magnetic fields required to deflect these particles were much larger than those used in Thomson's experiments, proving that the particles were much more massive than the electron, at least as massive as the hydrogen atom.
3. The electric and magnetic fields required to deflect particles from different gases by the same amount were different, proving that the positively charged particles associated with different gases had different masses.

Thomson, J.J. Elements of the mathematical theory of electricity and magnetism. Cambridge University Press, 1921

**FIGURE 1.14** Traces of parabolic paths produced by positive ions in Thomson's experiments on the "positive rays." The ions giving rise to particular trajectories in the lower right quadrant of the figure are identified.

Thomson took up the further study of these "rays of positive electricity," as he called them, using a variation of his cathode ray tube apparatus. Imagine a version of the apparatus shown in Figure 1.10 with three modifications: (1) the voltages on the anode (the plate with the hole) and cathode are reversed so that positively charged particles pass through the hole and strike the front of the tube; (2) the magnetic field coils are rotated by  $90^\circ$  so that the electric and magnetic fields are now parallel to one another; and (3) the front of the tube is fitted with a photographic plate. The magnetic field deflects the particles horizontally while the electric field deflects them vertically, as before, and the film shows parabolic traces that depend upon the charge-to-mass ratio of the ions and on their velocities. Figure 1.14 shows one such set of traces, the identity of the particles being established by calculating the trajectories expected from their charge-to-mass ratios and the known field strengths. The particles are recognized as positively charged *ions* formed by removal of one or more electrons from an atom or molecule, usually by collisions with high-energy electrons. Mercury ions (from the vacuum pump) are clearly identified, a set with one unit of positive charge and a second set with two units of positive charge.  $\text{CO}^+$  and neon ions with two different masses were identified (see later). Other experiments (not shown) established the utility of the method for identifying the individual components of complex mixtures of gases. Thomson did not fail to point out the importance of this new method for chemical analysis, which forms the basis for mass spectrometry, one of our most important methods for determining molecular weights and structures.

Thomson and Wien had discovered two new, and quite different, types of electrically charged particles that comprise matter: a light particle with a negative charge that appeared to be a common constituent of all atoms, and a number of much heavier, positively charged particles whose relative masses depended on the elements from which they were produced. Although it was generally then agreed that these particles were the building blocks of atoms, it was not at all clear how they were assembled. That piece of the puzzle remained unsolved until a stunning discovery was made in the laboratory of Ernest Rutherford in 1911, which relied upon results in earlier studies of radioactivity.

### Discovery of the Atomic Nucleus

Radioactivity from natural sources was discovered in 1889 by the French physicists Henri Becquerel and Marie and Pierre Curie. Becquerel showed that rays emitted from uranium salts and uranium metal darkened nearby photographic plates that had been shielded from light by black paper. The Curies discovered the radioactive elements thorium, polonium, and radium. They demonstrated that while emitting radiation these elements were transformed into other elements by *radioactive decay*. This apparent violation of one of the key postulates of Dalton's atomic theory stimulated intense interest in discovering

**FIGURE 1.15** Schematic of Rutherford's experiment on the scattering of particles by thin (600 nm) gold foils. (a) Flashes of light mark the arrival of alpha particles at the fluorescent screen. More than 100,000 alpha particles per minute were weakly deflected, and only about 20 alpha particles per minute were deflected backwards, under typical conditions. (b) Interpretation of the Rutherford experiment: Most of the alpha particles pass through the space between nuclei and are deflected only slightly (A). A few pass close to a nucleus and are more strongly deflected (B). Some are even scattered backward (C). The size of the nucleus, relative to the size of a gold atom, is much smaller than the diagram suggests.

the mechanism of radioactive decay. Chapter 19 describes this very important process from a modern point of view, and reassures us that elements are not transmuted one into another by ordinary chemical reactions. Radioactive decay is not a revival of medieval alchemy! Our interest here is to use the emitted radiation as another probe of atomic structure.

By 1911, New Zealander Ernest Rutherford and his students at the University of Manchester had been investigating radioactive decay for a number of years. They had determined that the emitted radiation has at least two components, which they labeled  $\alpha$  and  $\beta$  on the basis of their relative ability to penetrate solid materials. They had shown that  $\alpha$  particles are doubly charged He atoms, by measuring their charge-to-mass ratios and by physically trapping and identifying the He gas produced. Now they wanted to study their interactions with matter to see if they could serve as probes of atomic structure. Rutherford chose to work with very thin gold foils (600 nm or about 2000 gold atoms thick) so the  $\alpha$  particles could pass through the sample and their properties be measured after they exited the foil. Deflections of a collimated beam of alpha particles by a gold foil were measured by observing the scintillations they produced on a fluorescent ZnS screen (Fig. 1.15). Almost all of the alpha particles passed straight through the foil, but a few were deflected through large angles. Some particles even scattered backwards, in a few rare events! Rutherford was astounded, because the alpha particles were relatively massive and fast moving. In his words, "It was almost as incredible as if you fired a 15-inch shell at a piece of tissue paper and it came back and hit you." He and his students studied the frequency with which such large deflections occurred. They concluded that most of the mass in the gold foil was concentrated in dense, extremely small, positively charged particles that they called nuclei. By analyzing the trajectories of the particles scattered by the foil, they estimated the radius of the gold nucleus to be less than  $10^{-14}$  m and the positive charge on each nucleus to be approximately  $+100e$  (the actual value is  $+79e$ ).

### 1.4.5 Rutherford's Planetary Model of the Atom

Based on these experimental results, Rutherford proposed a model of the atom in which the charge on the nucleus is  $+Ze$ , with  $Z$  electrons surrounding the nucleus out to a distance of about  $10^{-10}$  m (0.1 nm). This integer  $Z$  is called the

atomic number of the element. Atomic numbers are given on the inside front cover of this book. The Rutherford model for a gold atom has 79 electrons (each with charge  $-1e$ ) arranged about a nucleus of charge  $+79e$ . The electrons occupy nearly the entire volume of the atom, whereas nearly all its mass is concentrated in the nucleus.

The model of the atom Rutherford proposed is often called the “planetary model” of the atom because he envisioned the electrons occupying most of the atomic volume (like the planets in a solar system), centered on the small, dense nucleus (like the sun). The Rutherford model has become the universally accepted picture of the structure of the atom. The properties of a given chemical element arise from the charge  $+Ze$  on its nucleus and the presence of  $Z$  electrons around the nucleus. Although the planetary model has been extremely successful in explaining many of the properties of atoms, it has an inherent flaw that was recognized later: it couldn’t possibly exist according to the laws of classical physics! We discuss this and other failures of classical physics to explain the properties of atoms in Chapter 4.

## 1.5 Mass Spectrometry, Isotopes, and the Measurement of Relative Mass

**Mass spectrometry** developed rather quickly after Thomson had shown how relative atomic and molecular masses could be measured directly by observing the deflections of ions in electric and magnetic fields. The most startling new result of his studies was the appearance of a new ion with a relative mass of 22 (see Fig. 1.14) that did not correspond to any known element; the doubly charged ion appeared at mass 11, leaving little doubt that this was a new species. This result was obtained with every sample of neon gas studied, including those of exceptional purity, and led Thomson to propose that neon was in fact not a simple gas but a mixture of two gases, the more abundant component having a relative mass of 20 and the less abundant component a relative mass of 22. It appeared, therefore, that the atomic mass of neon, determined by chemical means to be 20.2, was somehow an average of the masses of the two kinds of neon atoms. This was an astonishing result that seemed inconsistent with what was known about the elements at the time. The sample was chemically pure, and there was no room in the periodic table for a new element of mass 22 whose chemical properties were identical to those of neon. This interpretation was later confirmed using more advanced mass spectrometric methods, and this experiment provided one of the earliest clues for the existence of what became known as an **isotope** from the Greek *isos-* [“equal”] plus *topos* [“place”].

Refinements of Thomson’s technique made it possible to measure relative masses extremely accurately and led to the discovery of the isotopes of many elements. A simple mass spectrometer, like the one shown schematically in Figure 1.16, consists of three elements: a region in which atoms or molecules are ionized and accelerated, one in which their flight paths are bent by magnetic forces, and a detector that measures the ion current. Positive ions are created by electron impact, the electrons being emitted from a heated filament and accelerated by an applied voltage as shown. The ions are then accelerated by an electric field created by a voltage applied to the plates shown, and enter the magnetic field region where they experience a magnetic force with magnitude given by

$$F_B = qvB$$

where  $q$  is the positive charge of the ion and  $v$  is its speed.

The deflection due to this force can be calculated using the same approach we described for Thomson’s experiments, but for the present purpose it is

**FIGURE 1.16** A simplified representation of a modern mass spectrometer. A gas mixture containing the isotopes  $^{20}\text{Ne}$  and  $^{22}\text{Ne}$  is introduced through the gas inlet. Atoms are ionized by electron impact and then accelerated by the electric field established between the accelerating plates. The ion beam passes into a magnetic field, where it is separated into components on the basis of the ions' charge-to-mass ratios. The conditions chosen for this illustration allow the heavier  $^{22}\text{Ne}^+$  ions to pass through the slit in the plate (A) and reach the detector while the lighter  $^{20}\text{Ne}^+$  ions strike the plate at position B and are not detected. Different conditions would move the  $^{22}\text{Ne}^+$  beam to position C and allow the  $^{20}\text{Ne}^+$  ions to pass through the slit and reach the detector.

**FIGURE 1.17** A sketch of the mass spectrum of Ne, showing only the two isotopes  $^{20}\text{Ne}$  and  $^{22}\text{Ne}$ .

sufficient to note that the lighter ions are deflected more than the heavier ions for a given magnetic field strength. The figure shows, for example, that  $^{20}\text{Ne}$  has been deflected more than  $^{22}\text{Ne}$ , which is passing through the slit and being detected under this set of conditions. A mass spectrum is acquired by scanning the magnetic field and measuring the ion current as a function of the magnetic field strength. The mass spectrum of neon, for example, consists of two peaks, as shown schematically in Figure 1.17; the more intense peak is  $^{20}\text{Ne}$  and the less intense peak is  $^{22}\text{Ne}$ , the relative intensities reflecting their relative natural abundances.

Mass spectrometry confirmed the existence of isotopes for many elements and established a physical method for determining relative atomic masses. One consequence of this development was the realization that the relative atomic masses of the elements determined from the laws of chemical combination are actually averages of the relative atomic masses of its isotopes weighted by their relative natural abundances, averages that could now be calculated from its mass spectrum as follows. Suppose, for example, that there existed only the two neon isotopes identified so far and that 91% of the neon atoms were  $^{20}\text{Ne}$  and 9% were  $^{22}\text{Ne}$ . The average relative atomic mass would then be  $(0.91)(20) + (0.09)(22) = 20.18$ , which is close to the value reported in the table of relative atomic masses of the elements on the inside front cover of the book. Similarly, chlorine has two isotopes, about 75% being  $^{35}\text{Cl}$  and 25% being  $^{37}\text{Cl}$ , from which we calculate an average mass of 35.5, which is also close to the value reported in the table just cited. The average relative atomic mass of an element comprised of  $n$  isotopes with relative atomic masses  $A_i$  and relative fractional abundances  $p_i$  is given by

$$A = p_1A_1 + p_2A_2 + \cdots + p_nA_n = \sum_1^n p_iA_i$$

The discovery of isotopes created a major problem for chemists and physicists trying to establish a relative mass scale that was acceptable to both communities. Prior to the discovery of isotopes, and especially the isotopes of oxygen, the masses of the elements were determined from the laws of chemical composition using oxygen as the reference, whose relative atomic mass was defined to be exactly 16. Oxygen was a logical choice for the reference mass because it forms many compounds with the elements through combustion reactions. Having discovered a way to measure the relative atomic masses of the isotopes of all of the

elements, the physicists argued that it made more sense, on physical grounds, to set the relative atomic mass of the  $^{16}\text{O}$  isotope to 16, exactly. The problem with this choice, from the point of view of the chemists, was that reference data that had been generated for many decades would have to be revised because the error introduced by making this choice would be unacceptably high. A compromise was reached in 1961 in which the mass of the  $^{12}\text{C}$  isotope was defined to have a relative atomic mass of 12, exactly. This choice was appealing to the physicists because it was based upon a physical measurement of a particular isotope and it was acceptable to the chemists because a fortuitous distribution of the isotopes of both carbon and oxygen in natural abundance averaged out the errors and reduced them to an acceptable level.

*Relative atomic masses have no units* because they are ratios of two masses measured in whatever units we choose (grams, kilograms, pounds, and so forth). The **relative molecular mass** of a compound is the sum of the relative atomic masses of the elements that constitute it, each one multiplied by the number of atoms of that element in a molecule. For example, the formula of water is  $\text{H}_2\text{O}$ , so its relative molecular mass is

$$2 (\text{relative atomic mass of H}) + 1 (\text{relative atomic mass of O}) = \\ 2(1.0079) + 1(15.9994) = 18.0152$$

### EXAMPLE 1.2

Calculate the relative atomic mass of carbon, taking the relative atomic mass of  $^{13}\text{C}$  to be 13.003354 on the  $^{12}\text{C}$  scale.

#### Solution

Set up the following table:

Isotope	Isotopic Mass $\times$ Abundance
$^{12}\text{C}$	$12.000000 \times 0.98892 = 11.867$
$^{13}\text{C}$	$13.003354 \times 0.01108 = 0.144$
Chemical relative atomic mass = 12.011	

**Related Problems: 15, 16, 17, 18**

The number of significant figures in a table of chemical or natural relative atomic masses (see the inside front cover of this book) is limited not only by the accuracy of the mass spectrometric data but also by any variability in the natural abundances of the isotopes. If lead from one mine has a relative atomic mass of 207.18 and lead from another has a mass of 207.23, there is no way a result more precise than 207.2 can be obtained. In fact, geochemists now use small variations in the  $^{16}\text{O}:^{18}\text{O}$  ratio as a “thermometer” to deduce the temperatures at which different oxygen-containing rocks were formed in the Earth’s crust over geological time scales. They also find anomalies in the oxygen isotopic compositions of certain meteorites, implying that their origins may lie outside our solar system. Temperature variations over the past million years of the earth’s history have been established by measuring the  $^{16}\text{O}:^{18}\text{O}$  and  $^2\text{H}:^1\text{H}$  ratios as a function of depth in the Greenland and Antarctic ice cores and correlated with atmospheric  $\text{CO}_2$  concentration, providing important clues as to the origins of climate change (see Section 20.6).

## 1.5.1 Structure of the Nucleus: Protons, Neutrons, and Isotopes

The experiments described earlier led to the discovery of electrons and nuclei and to the planetary model of the atom, but they did not provide sufficient evidence to establish a model for the structure of the nucleus. Subsequent experiments, of the same general type we have discussed, identified the two other

elementary particles, the proton and the neutron, whose properties we describe here. A full discussion of the nature of those experiments is beyond the scope of this textbook. The smallest and simplest nucleus is that of the hydrogen atom—the proton (from the Greek *protos* [“first”])—so named because it is a fundamental component of all nuclei. The proton has a positive charge of  $+e$ , where  $e$  is the elementary charge, but its mass is  $1.67262 \times 10^{-27}$  kg, which is 1836 times greater than the electron mass. Nuclei of the other elements contain an integral number of protons, which is given by their **atomic number**  $Z$ ; thus, the charge on the nucleus is  $+Ze$ . The existence of isotopes, elements with the same atomic number but different masses, implied that there was another nuclear particle whose mass was the same as the proton mass but with no charge—that particle is the neutron. The **mass number**  $A$  of a particular isotope is the sum of the numbers of protons and neutrons for the isotope.  $A = Z + N$ . We write chemical symbols for the isotopes (nuclides) as follows:  ${}^A_ZX$ , where  $X$  is the chemical symbol for the element. The isotopes of hydrogen, for example, are written as:  ${}^1_1\text{H}$ ,  ${}^2_1\text{H}$ , and  ${}^3_1\text{H}$  for hydrogen, deuterium, and tritium, respectively. It is customary, though redundant, to include the atomic number in addition to the symbol for the element, primarily because it is helpful when balancing nuclear chemical reactions (see Chapter 19).

### EXAMPLE 1.3

Radon-222 ( ${}^{222}\text{Rn}$ ) has recently received publicity because its presence in basements may increase the number of cancer cases in the general population, especially among smokers. State the number of electrons, protons, and neutrons that make up an atom of  ${}^{222}\text{Rn}$ .

#### Solution

From the table on the inside front cover of the book, the atomic number of radon is 86; thus, the nucleus contains 86 protons and  $222 - 86 = 136$  neutrons. The atom has 86 electrons to balance the positive charge on the nucleus.

**Related Problems:** 19, 20, 21, 22

## 1.6 The Mole: Counting Molecules by Weighing

The laws of chemical combination assert that chemical reactions occur in such a way that the number of atoms of a given type is conserved in every chemical reaction, except nuclear reactions. It is impractical to count the numbers of atoms or molecules in laboratory or industrial scale reactions, however, so we must find a way to relate the masses of the reactants and products in those reactions to the numbers of atoms or molecules involved. Chemists established a scale of relative atomic masses in the 19th century, while developing the laws of chemical combination; the accuracy of that scale was greatly improved upon in the 20th century using mass spectrometry. That relative atomic mass scale must be converted to a macroscopic scale that allows us to count atoms and molecules by weighing. The concept and methods that allow us to do this are developed in this section.

### 1.6.1 Relation between Atomic and Macroscopic Masses: Avogadro's Number

Laboratory or industrial chemical reactions are carried out with quantities that range from milligrams to tons, so we must be able to relate the relative atomic mass scale to the macroscopic scales used in practice. The link between the two

scales is provided by **Avogadro's number** ( $N_A$ ), defined as the number of atoms in exactly 12 g of  $^{12}\text{C}$ , the currently accepted value of which is

$$N_A = 6.02214129 \times 10^{23}$$

The mass of a single  $^{12}\text{C}$  atom is then found by dividing exactly 12 g carbon (C) by  $N_A$ :

$$\text{Mass of a } ^{12}\text{C} \text{ atom} = \frac{12.00000 \text{ g}}{6.02214129 \times 10^{23}} = 1.9926467 \times 10^{-23} \text{ g}$$

The masses of individual atoms are truly small and any macroscopic quantity of mass contains an amazingly large number of atoms.

Avogadro's number is defined relative to the  $^{12}\text{C}$  atom because that isotope has been chosen by international agreement to form the basis for the modern scale of relative atomic masses. We can find the masses of Avogadro's number of the other elements by simply taking ratios, as follows. Consider sodium, which has a relative atomic mass of 22.98977. A sodium atom is 22.98977/12 times as heavy as a  $^{12}\text{C}$  atom. If the mass of  $N_A$  atoms of  $^{12}\text{C}$  is 12 g, then the mass of  $N_A$  atoms of sodium must be

$$\frac{22.98977}{12} (12 \text{ g}) = 22.98977 \text{ g}$$

The mass (in grams) of  $N_A$  atoms of *any* element is numerically equal to the relative atomic mass of that element. The same conclusion applies to molecules. From the relative molecular mass of water determined earlier, the mass of  $N_A$  molecules of water is 18.0152 g.

#### EXAMPLE 1.4

One of the heaviest atoms found in nature is  $^{238}\text{U}$ . Its relative atomic mass is 238.0508 on a scale in which 12 is the atomic mass of  $^{12}\text{C}$ . Calculate the mass (in grams) of one  $^{238}\text{U}$  atom.

#### Solution

Because the mass of  $N_A$  atoms of  $^{238}\text{U}$  is 238.0508 g and  $N_A$  is  $6.02214129 \times 10^{23}$ , the mass of one  $^{238}\text{U}$  atom must be

$$\frac{238.0508 \text{ g}}{6.02214129 \times 10^{23}} = 3.952926 \times 10^{-22} \text{ g}$$

**Related Problems: 23, 24**

### 1.6.2 The Mole

Because the masses of atoms and molecules are so small, laboratory scale chemical reactions must involve large numbers of atoms and molecules. It is convenient to group atoms or molecules in counting units of  $N_A = 6.02214129 \times 10^{23}$  to measure the **number of moles** of a substance. One of these counting units is called a **mole** (abbreviated mol, whether singular or plural, derived from Latin *moles*, meaning “heap” or “pile”). One mole of a substance is the amount that contains Avogadro's number of atoms, molecules, or other entities. That is, 1 mol of  $^{12}\text{C}$  contains  $N_A$   $^{12}\text{C}$  atoms, 1 mol of water contains  $N_A$  water molecules, and so forth. We must be careful in some cases, because a phrase such as “1 mol of oxygen” is ambiguous. We should refer instead to “1 mol of  $\text{O}_2$ ” if there are  $N_A$  oxygen *molecules*, and “1 mol of O” if there are  $N_A$  oxygen *atoms*. Henceforth, for *any* species we use “number of moles of a particular species” to describe the number of moles in a sample of that species.

We define the **molar mass** of an element (often called the atomic mass or the atomic weight) as the mass of one mole of that element in grams; it is determined by taking the ratio of the relative atomic mass of the element to that of  $^{12}\text{C}$  and multiplying the result by 12 g. The same procedure is used to calculate the molar masses (often called the molecular weights) for molecules. Thus, the relative molecular mass of water is 18.0152, and its molar mass is  $18.0152 \text{ g mol}^{-1}$ .

To determine the number of moles of a given substance, we use the chemist's most powerful tool, the laboratory balance. If a sample of iron weighs 8.232 g, then

$$\begin{aligned} \text{moles of iron} &= \frac{\text{number of grams of iron}}{\text{molar mass of iron}} \\ &= \frac{8.232 \text{ g Fe}}{55.847 \text{ g mol}^{-1}} \\ &= 0.1474 \text{ mol Fe} \end{aligned}$$

where the molar mass of iron was obtained from the periodic table of the elements or a table of relative atomic masses (see the inside front and back covers of this book). The calculation can be turned around as well. Suppose a certain amount, for example, 0.2000 mol, of water is needed in a chemical reaction. We have

$$\begin{aligned} (\text{moles of water}) \times (\text{molar mass of water}) &= \text{mass of water} \\ (0.2000 \text{ mol H}_2\text{O}) \times (18.015 \text{ g mol}^{-1}) &= 3.603 \text{ g H}_2\text{O} \end{aligned}$$

We simply weigh 3.603 g water to get the 0.2000 mol needed for the reaction. In both cases, the molar mass is the conversion factor between the mass of the substance and the number of moles of the substance.

Although the number of moles in a sample is generally determined by weighing, it is still preferable to think of a mole as a fixed number of atoms or molecules (Avogadro's number) rather than as a fixed mass. The term *mole* is thus analogous to a term such as *dozen*: the mass of one dozen pennies is 26 g, which is substantially less than the mass of one dozen nickels, 60 g; each group contains 12 coins. Figure 1.18 shows mole quantities of several

**FIGURE 1.18** One mole of a number of different substances. Clockwise from top: graphite (C), potassium permanganate ( $\text{KMnO}_4$ ), copper sulfate pentahydrate ( $\text{CuSO}_4 \cdot 5 \text{ H}_2\text{O}$ ), copper (Cu), sodium chloride (NaCl), and potassium dichromate ( $\text{K}_2\text{Cr}_2\text{O}_7$ ). Antimony (Sb) is at the center.

© Cengage Learning/Leon Lewandowski

substances. A mole of most common household substances (water, sugar, salt) is about a tablespoon.

### EXAMPLE 1.5

Nitrogen dioxide ( $\text{NO}_2$ ) is a major component of urban air pollution. For a sample containing 4.000 g  $\text{NO}_2$ , calculate (a) the number of moles of  $\text{NO}_2$  and (b) the number of molecules of  $\text{NO}_2$ .

#### Solution

- (a) From the tabulated molar masses of nitrogen ( $14.007 \text{ g mol}^{-1}$ ) and oxygen ( $15.999 \text{ g mol}^{-1}$ ), the molar mass of  $\text{NO}_2$  is

$$14.007 \text{ g mol}^{-1} + (2 \times 15.999 \text{ g mol}^{-1}) = 46.005 \text{ g mol}^{-1}$$

The number of moles of  $\text{NO}_2$  is then

$$\text{mol of NO}_2 = \frac{4.000 \text{ g NO}_2}{46.005 \text{ g mol}^{-1}} = 0.08695 \text{ mol NO}_2$$

- (b) To convert from moles to number of molecules, multiply by Avogadro's number:

$$\begin{aligned} \text{molecules of NO}_2 &= (0.08695 \text{ mol NO}_2) \times 6.0221 \times 10^{23} \text{ mol}^{-1} \\ &= 5.236 \times 10^{22} \text{ molecules NO}_2 \end{aligned}$$

**Related Problems:** 29, 30

TABLE 1.1

Densities of Selected Substances

Substance	Density ( $\text{g cm}^{-3}$ )
Hydrogen	0.000082
Oxygen	0.00130
Water	1.00
Magnesium	1.74
Sodium chloride	2.16
Quartz	2.65
Aluminum	2.70
Iron	7.86
Copper	8.96
Silver	10.5
Lead	11.4
Mercury	13.5
Gold	19.3
Platinum	21.4

These densities were measured at room temperature and at average atmospheric pressure near sea level.

### 1.6.3 Density and Molecular Size

The **mass density** of a substance, hereafter density, is the ratio of its mass to its volume:

$$\text{density} = \frac{\text{mass}}{\text{volume}} \quad [1.11]$$

The base unit of mass in the International System of Units (SI; see discussion of base units in Appendix B) is the kilogram (kg), but when discussing solubility or mass density the gram often is used instead; moreover, the gram is used in tables of molar masses. Several units for volume are in frequent use. The base SI unit of the cubic meter ( $\text{m}^3$ ) is unwieldy for laboratory purposes ( $1 \text{ m}^3$  water weighs 1000 kg, or 1 metric ton). We use the gram (g) for mass and the liter ( $1 \text{ L} = 10^{-3} \text{ m}^3$ ) or the cubic centimeter ( $\text{cm}^3$  or milliliter, mL) for volume ( $1 \text{ cm}^3 = 1 \text{ mL} = 10^{-3} \text{ L} = 10^{-6} \text{ m}^3$ ). Table 1.1 lists the densities of some substances in units of grams per cubic centimeter.

The density of a substance is not a fixed, invariant property of the substance; its value depends on the pressure and temperature at the time of measurement. For some substances (especially gases and liquids), the volume may be more convenient to measure than the mass, and the density provides the conversion factor between volume and mass. For example, the density of liquid benzene ( $\text{C}_6\text{H}_6$ ) is  $0.8765 \text{ g cm}^{-3}$  near room temperature. Suppose that we wanted to find the mass of benzene contained in a volume that measured 0.2124 L. We simply multiply the volume by the density as follows:

$$m = \rho V$$

where  $m$  is the mass,  $\rho$  is the density, and  $V$  is the volume. Therefore, the value of the mass of benzene is

$$m = 0.2124 \text{ L} \times (1 \times 10^3 \text{ cm}^3 \text{ L}^{-1}) \times (0.8765 \text{ g cm}^{-3}) = 186.2 \text{ g}$$

If we wanted to know the number of moles of benzene in that sample we would simply divide the mass by the molar mass of benzene ( $78.114 \text{ g mol}^{-1}$ ) to get 2.384 mol.

Knowing the density and molar mass of a substance, we can readily compute its **molar volume**,  $V/n$ , that is, the volume occupied by one mole of a substance:

$$\frac{V}{n} = \frac{\text{molar mass (g mol}^{-1}\text{)}}{\text{density (g cm}^{-3}\text{)}} = \text{molar volume (cm}^3 \text{ mol}^{-1}\text{)}$$

For example, near  $0^\circ\text{C}$ , ice has a density of  $0.92 \text{ g cm}^{-3}$ ; thus, the molar volume of solid water under these conditions is

$$\frac{V}{n} = \frac{18.0 \text{ g mol}^{-1}}{0.92 \text{ g cm}^{-3}} = 20 \text{ cm}^3 \text{ mol}^{-1}$$

The molar volume of a gas is much larger than that of either a liquid or a solid. For  $\text{O}_2$  under room conditions, the data in Table 1.1 give a molar volume of  $24,600 \text{ cm}^3 \text{ mol}^{-1} = 24.6 \text{ L mol}^{-1}$ , which is more than 1000 times larger than the molar volume just computed for ice under the same conditions of temperature and pressure. (You should remember this ratio because you will use it often later on, when making estimates of the properties of gases, liquids, and solids.) How can we interpret this fact on a microscopic level? We also note that the volumes of liquids and solids do not shift much with changes in temperature or pressure, but that the volumes of gases are quite sensitive to these changes. One hypothesis that would explain these observations is that the molecules in liquids and solids are close enough to touch one another, but that they are separated by large distances in gases. If this hypothesis is correct (as has been well established by further study), then the sizes of the molecules themselves can be estimated from the volume occupied per molecule in the liquid or solid state. The volume per molecule is the molar volume divided by Avogadro's number; for ice, this gives

$$\text{Volume per H}_2\text{O molecule} = \frac{20 \text{ cm}^3 \text{ mol}^{-1}}{6.02 \times 10^{23} \text{ mol}^{-1}} = 3.3 \times 10^{-23} \text{ cm}^3$$

This volume corresponds to that of a cube with edges about  $3.2 \times 10^{-8} \text{ cm}$  (0.32 nm) on a side. We conclude from this and other density measurements that the characteristic size of atoms and small molecules is about  $10^{-8} \text{ cm}$ , or about 0.1 nm. This length, 0.1 nm or  $1 \times 10^{-10} \text{ m}$ , occurs so frequently in chemistry that it has been given a special name, the ångström (Å), in honor of the Swedish physicist Anders Ångström. Avogadro's number provides the link between the length and mass scales of laboratory measurements and the masses and volumes of single atoms and molecules.

## CONNECTION TO NANOTECHNOLOGY

## Imaging Atoms, Molecules, and Chemical Reactions by Scanning Tunneling Microscopy

The laws of chemical combination provided indirect evidence for the existence of atoms. The experiments of Thomson, Wien, and Rutherford provided direct physical evidence for the existence of the elementary particles that make up the atom. We conclude this chapter by describing an experimental method that allows us not only to image individual atoms and molecules but also to observe and control a chemical reaction at the single molecule level—a feat only dreamed of as recently as the mid-1980s. The ability to manipulate single atoms, molecules, and nanoparticles has developed into a set of technologies that allows scientists and engineers to create two-dimensional arrays of these entities with applications in materials science, biology, and medicine.

Microscopy began with the fabrication of simple magnifying glasses; the development of the compound microscope in the late 17th century made it possible to observe single biological cells, enabling the study of biology on the cellular level for the first time. The invention of the electron microscope in the 1930s opened the way to observe objects with dimensions much smaller than the wavelength of light, the resolution limit of optical microscopes. Unfortunately, however, sample damage caused by the high energy of the electron beam required is still a limitation of the technique for certain applications. Gerd Binnig and Heinrich Rohrer developed the scanning tunneling microscope (STM), which images atoms using low-energy electrons, for which they received

the 1986 Nobel Prize in Physics. The STM measures small currents produced by electrons that tunnel between a very sharp conducting tip and the sample at very small tip-surface separations, as shown in Figure C1.1. The tunneling current is an exponential function of the tip-surface separation. A feedback loop monitors the tunneling current, which is fed to the piezoelectric element to keep the tip-surface separation constant as the tip is scanned across the sample. The three-dimensional STM images shown are plots of the tip height as a function of the tip position in the plane of the sample. Individual atoms of the single crystal metal surface are clearly resolved, as are some missing atoms (defects) shown in the inset.

Scanning tunneling microscope images have visually confirmed many properties of solids, surfaces, and adsorbed species, such as the sizes of atoms and the distances between them, which are already known from other techniques. But, much new information has been obtained as well. The STM images have shown the positions and shapes of molecules undergoing chemical reactions on surfaces, which helps guide the search for new ways of carrying out such reactions. They have also revealed the shape of the surface of the molecules of the nucleic acid DNA, which plays a central role in genetics.

### Images of Single Molecules in Chemical Reactions

The STM has been used to image the surfaces of materials since the mid-1980s, but only recently has it been used to image single molecules and to initiate chemical reactions at the single molecule level, as we illustrate with the

**FIGURE C1.1** Schematic of STM experiment. The distance from the atoms on the STM tip (blue) and the atoms on the surface being studied (green) is typically a few angstroms. The electrostatic potential difference between the tip and the surface is controlled, in this figure, by a battery, but normally one would use a tunable voltage supply.

following example. Although the STM can be used to image objects in air, the experiments described here were conducted in ultrahigh vacuum (extremely low pressure) to ensure that only the reactants of interest were present on the surface. Figure C1.2 shows an STM tip hovering over a silver (Ag) surface on which an iron (Fe) atom and a carbon monoxide (CO) molecule have been chemically bonded (adsorbed), and a series of steps that leads to the formation of a product molecule Fe(CO).

Figure C1.2(a) shows the tip positioned over a single carbon monoxide (CO) molecule, ready to pluck it from the silver (Ag) surface; in part (b) CO is adsorbed onto the tip, bonded via the carbon (C) atom, and the tip is then translated across the surface to a region near an iron (Fe) atom; part (c) shows CO being transferred to the Fe atom and forming an Fe-CO bond; and finally, in part (d) the tip

**FIGURE C1.2** Moving a CO molecule adsorbed to a surface with an STM tip. In (a) the electrostatic potential difference (provided by a “battery” in the schematic in Fig C1.1) is biased so that an electron tunnels from the tip to the adsorbed CO molecule. In (b) this results in the CO molecule being picked up by the STM tip (note that the CO molecule flips direction), and the experimenter then moves the STM tip toward another part of the surface where an iron atom resides. In (c), changing the bias of the electrostatic potential (by reversing the direction of the “battery”) allows an electron to tunnel from the iron atom adsorbed on the surface to the CO molecule on the STM tip; finally in (d) CO transfers from the STM tip back to the iron atom on the surface and they react with each other to make FeCO.

is withdrawn with the product molecule, FeCO, remaining bound to the Ag surface. Bonding between the carbon monoxide and the tip is controlled by the tip voltage and current. CO is plucked from the surface when electrons flow from the tip to the surface and it is released to the surface when electrons flow in the opposite direction.

The schematic serves as a guide to the eye for interpreting the real STM images shown in Figure C1.3. Each image represents an area of the surface that measures  $6.3 \times 6.3$  nm. The false color scale reflects the height of the objects above the plane of the silver surface atoms; the red end of the scale represents protrusions, whereas the purple end represents depressions. The identity of each chemical species was established by the nature of the image and also by the way in which the current varied with the applied voltage. That variation provides a chemical signature.

In part A of Figure C1.3, five Fe atoms and five CO molecules are clearly seen; the red arrow identifies one Fe atom that is a bit difficult to see otherwise. The curved white arrow shows a CO molecule in close proximity to an Fe atom. Part B shows the FeCO molecule formed as a result of the transfer of that CO molecule to the Fe atom by the tip, as well as another potentially reactive pair identified by the white curved arrow. From the shape of the resulting image in part C, we can see that another FeCO molecule has been formed. The white curved

**FIGURE C1.3** Single molecule STM results.

arrow suggests the possibility of adding an additional CO molecule to the first FeCO synthesized to form Fe(CO)<sub>2</sub>, which, indeed, occurs as shown in part D. This remarkable sequence of images shows clearly the synthesis of a pair of distinct Fe(CO) molecules, as well as an Fe(CO)<sub>2</sub> molecule, from the reactants Fe and CO adsorbed onto a silver surface. These syntheses were accomplished by manipulating single CO molecules to place them sufficiently close to Fe atoms to initiate a chemical reaction, demonstrating our ability to observe and control chemical reactions at the single molecule level.

The ability to manipulate single molecules and nanoparticles has led to the recent development of **dip-pen lithography**, a promising approach for synthesizing two-dimensional arrays of a wide variety of materials of interest. The method relies upon the forces between molecules and surfaces (the basis of **atomic force microscopy**) instead of tunneling to assemble arrays of inorganic materials for catalysis, sensing or microelectronics applications as well as arrays of biomolecules for rapid throughput screening.

## CHAPTER SUMMARY

We have come a long way since the attempts of the alchemists to turn base metals into gold, to transmute one element into another. Through the early chemical experiments of Dalton, Gay-Lussac, and Avogadro, we have learned that matter is ultimately indivisible, at least as far as its physical and chemical properties are concerned. The experiments of Thomson, Wien, and Rutherford confirmed, from the results of physical measurements, the existence of the atom. These experiments also identified and characterized the elementary particles from which the atom is made, and this led to the modern model of the atom as an object with a small, dense nucleus surrounded by a much larger volume occupied by electrons. Physicists in the 21st century have developed tools of unprecedented power with which to analyze and synthesize single molecules, an achievement that has already led to exciting new applications in almost every area of modern science and engineering. We have also shown you how chemists count molecules by weighing macroscopic quantities of substances. Avogadro's number connects the nanoscopic world of atoms and molecules to the macroscopic world of the laboratory:  $1 \text{ mol} = 6.022 \times 10^{23}$  atoms or molecules.

## CONCEPTS AND SKILLS

### Section 1.1 – The Nature of Modern Chemistry

*State and interpret the laws of conservation of energy and conservation of mass and distinguish between macroscopic and nanoscopic length scales.*

- Energy and mass are separately conserved in ordinary (not nuclear) chemical reactions. The total mass of the products equals the total mass of the reactants. The total amount of energy contained in the products is equal to the total amount of energy contained in the reactants. Chemical reactions occur on the scale of nanometers with masses of the order  $10^{-26}$  kg, but we observe them in the laboratory on a scale of grams and centimeters.

### Section 1.2 – Elements: The Building Blocks of Matter

*Describe in operational terms how to distinguish among mixtures, compounds, and elements (Problems 1–4).*

- Mixtures may be separated into simpler substances by *physical* processes like filtration or distillation. Substances that can be separated into simpler substances by chemical reactions are called compounds; those that cannot are called elements.

### Section 1.3 – Indirect Evidence for the Existence of Atoms: Laws of Chemical Combination

*Outline Dalton's atomic theory of matter and describe its experimental foundation.*

- Dalton asserted that matter consisted of indivisible atoms and that all atoms of a given element were identical in mass and all other physical and chemical properties. Atoms of different elements have different characteristic physical and chemical properties, such as mass, that distinguish them from each other. Atoms are indestructible and retain their identities in chemical reactions. Compounds are formed from atoms in the elements combined in small whole-number ratios. Dalton's atomic theory was developed to explain the law of conservation of mass and the law of definite proportions.

*Describe how chemical methods lead to the determination of chemical formulas (Problems 7–10).*

- The laws of chemical combination, which include the law of multiple proportions and Avogadro's hypothesis, provided the basis for developing a procedure with which to determine chemical formulas. The ratios of the masses of elements in particular compounds were always fixed, and the ratios of the masses of the elements in compounds that contained the same elements were themselves also a ratio of small integers. Empirical (simplest) chemical formulas were established on the basis of these ratios.

### Section 1.4 – The Physical Structure of Atoms

*Describe the experiments that led to the discovery and characterization of electrons, nuclei, and isotopes (Problems 15–16).*

- Cathode rays, emitted from the cathodes in glow discharge tubes, were shown to be negatively charged particles whose charge-to-mass ratio was first measured by Thomson. Millikan measured the charge on these particles, thus determining both the charge and the mass of the electron. Canal rays were shown to be massive, positively charged particles whose charge-to-mass ratio depended on the gas used in the discharge. Radioactive decay suggested, and mass spectroscopy confirmed, the existence of isotopes of the elements, with similar physical and chemical properties but different masses.

*Describe the experiments that led to the planetary model of the atom and discuss its features.*

- The scattering of  $\alpha$  particles by thin gold films established the planetary model of the atom, with a small, dense nucleus surrounded by electrons that occupied most of the volume of the atom.

### Section 1.5 – Mass Spectrometry, Isotopes, and Relative Masses

*State the numbers of protons, neutrons, and electrons for any atom in the periodic table (Problems 19–22).*

### Section 1.6 – The Mole: Counting Molecules by Weighing

*Interconvert mass, number of moles, number of molecules, and (using density) the molar volume of a substance (Problems 23–34).*

- Avogadro's number ( $6.02 \times 10^{23}$ ) is the conversion factor between moles and numbers of molecules. The molar mass is the conversion factor between moles and mass. Setting up calculations to convert any of these quantities can be done by inspection, using dimensional analysis to guide you. Molar volumes are calculated by dividing the molar mass by the density.

*Describe in a general way the operation of the scanning tunneling microscope (STM) and the kinds of information it provides.*

## PROBLEMS

Answers to problems whose numbers are red appear in Appendix G. Problems that are more challenging are indicated with asterisks.

### 1.2 Elements: The Building Blocks of Matter

- Classify the following materials as substances or mixtures: table salt, wood, mercury, air, water, seawater, sodium chloride, and mayonnaise. If they are mixtures, subclassify them as homogeneous or heterogeneous; if they are substances, subclassify them as compounds or elements.
- Classify the following materials as substances or mixtures: absolute (pure) alcohol, milk (as purchased in a store), copper wire, rust, barium bromide, concrete, baking soda, and baking powder. If they are mixtures, subclassify them as homogeneous or heterogeneous; if they are substances, subclassify them as compounds or elements.
- A 17th-century chemist wrote of the “simple bodies which enter originally into the composition of mixtures and into which these mixtures resolve themselves or may be finally resolved.” What is being discussed?
- Since 1800, almost 200 sincere but erroneous reports of the discovery of new chemical elements have been made. Why have mistaken reports of new elements been so numerous? Why is it relatively easy to prove that a material is not a chemical element, but difficult to prove absolutely that a material is an element?

### 1.3 Indirect Evidence for the Existence of Atoms: Laws of Chemical Combination

- A sample of ascorbic acid (vitamin C) is synthesized in the laboratory. It contains 30.0 g carbon and 40.0 g oxygen. Another sample of ascorbic acid, isolated from lemons (an excellent source of the vitamin), contains 12.7 g carbon. Compute the mass of oxygen (in grams) in the second sample.
- A sample of a compound synthesized and purified in the laboratory contains 25.0 g hafnium and 31.5 g tellurium. The identical compound is discovered in a rock formation. A sample from the rock formation contains 0.125 g hafnium. Determine how much tellurium is in the sample from the rock formation.
- Nitrogen (N) and silicon (Si) form two binary compounds with the following compositions:

Compound	Mass % N	Mass % Si
1	33.28	66.72
2	39.94	60.06

- (a) Compute the mass of silicon that combines with 1.0000 g of nitrogen in each case.

- (b) Show that these compounds satisfy the law of multiple proportions. If the second compound has the formula  $\text{Si}_3\text{N}_4$ , what is the formula of the first compound?

8. Iodine (I) and fluorine (F) form a series of binary compounds with the following compositions:

Compound	Mass % I	Mass % F
1	86.979	13.021
2	69.007	30.993
3	57.191	42.809
4	48.829	51.171

- (a) Compute in each case the mass of fluorine that combines with 1.0000 g iodine.
- (b) By figuring out small whole-number ratios among the four answers in part (a), show that these compounds satisfy the law of multiple proportions.
9. Vanadium (V) and oxygen (O) form a series of compounds with the following compositions:

Mass % V	Mass % O
76.10	23.90
67.98	32.02
61.42	38.58
56.02	43.98

What are the relative numbers of atoms of oxygen in the compounds for a given mass of vanadium?

10. Tungsten (W) and chlorine (Cl) form a series of compounds with the following compositions:

Mass % W	Mass % Cl
72.17	27.83
56.45	43.55
50.91	49.09
46.36	53.64

If a molecule of each compound contains only one tungsten atom, what are the formulas for the four compounds?

11. A liquid compound containing only hydrogen and oxygen is placed in a flask. Two electrodes are dipped into the liquid and an electric current is passed between them. Gaseous hydrogen forms at one electrode and gaseous oxygen at the other. After a time, 14.4 mL hydrogen has evolved at the negative terminal, and 14.4 mL oxygen has evolved at the positive terminal.
- (a) Assign a chemical formula to the compound in the cell.
- (b) Explain why more than one formula is possible as the answer to part (a).

12. A sample of liquid  $\text{N}_2\text{H}_4$  is decomposed to give gaseous  $\text{N}_2$  and gaseous  $\text{H}_2$ . The two gases are separated, and the nitrogen occupies 13.7 mL at room conditions of pressure and temperature. Determine the volume of the hydrogen under the same conditions.
13. Pure nitrogen dioxide ( $\text{NO}_2$ ) forms when dinitrogen oxide ( $\text{N}_2\text{O}$ ) and oxygen ( $\text{O}_2$ ) are mixed in the presence of a certain catalyst. What volumes of  $\text{N}_2\text{O}$  and oxygen are needed to produce 4.0 L  $\text{NO}_2$  if all gases are held at the same conditions of temperature and pressure?
14. Gaseous methanol ( $\text{CH}_3\text{OH}$ ) reacts with oxygen ( $\text{O}_2$ ) to produce water vapor and carbon dioxide. What volumes of water vapor and carbon dioxide will be produced from 2.0 L methanol if all gases are held at the same temperature and pressure conditions?

### 1.4 The Physical Structure of Atoms

15. In J. J. Thompson's experiment depicted in Figures 1.10 and 1.11, assume that the electrons are initially traveling at a speed of  $8.00 \times 10^6 \text{ m s}^{-1}$  in the  $+x$  direction and the electrostatic plates have a length of  $\ell = 0.10 \text{ m}$ , between which the electrons are deflected toward the  $-y$  direction (downward) by an electric field of magnitude  $200 \text{ V m}^{-1}$ . (Note that  $1 \text{ volt} = 1 \text{ V} = 1 \text{ J C}^{-1}$ .) Calculate  $S$ , the magnitude of the downward displacement, if the fluorescent screen is located 0.90 m beyond the exit of the region between the two electrostatic plates. No magnetic field is applied to counteract the electrostatic force. (Caution:  $L$  is not 1.0 m nor 0.9 m; see Figure 1.11.)
16. In the problem 15 above, what is  $v_y$ , the  $y$ -component of the electron's velocity, when it has reached the right edge of the plates? Note that  $a_y = \frac{\Delta v_y}{\Delta t}$  (be careful with the sign). How is the ratio  $S/L$  related to  $v_x$  and  $v_y$ , if  $v_y$  is calculated at the right edge of the plates? The distances  $S$  and  $L$  are shown in Figure 1.11.

### 1.5 Mass Spectrometry, Isotopes, and the Measurement of Relative Mass

17. The natural abundances and isotopic masses of the element silicon (Si) relative to  $^{12}\text{C} = 12.00000$  are

Isotope	% Abundance	Isotopic Mass
$^{28}\text{Si}$	92.21	27.97693
$^{29}\text{Si}$	4.70	28.97649
$^{30}\text{Si}$	3.09	29.97376

Calculate the atomic mass of naturally occurring silicon.

18. The natural abundances and isotopic masses of the element neon (Ne) are

Isotope	% Abundance	Isotopic Mass
$^{20}\text{Ne}$	90.00	19.99212
$^{21}\text{Ne}$	0.27	20.99316
$^{22}\text{Ne}$	9.73	21.99132

Calculate the atomic mass of naturally occurring neon.

19. Only two isotopes of boron (B) occur in nature; their atomic masses and abundances are given in the following table. Complete the table by computing the relative atomic mass of  $^{11}\text{B}$  to four significant figures, taking the tabulated relative atomic mass of natural boron as 10.811.

Isotope	% Abundance	Atomic Mass
$^{10}\text{B}$	19.61	10.013
$^{11}\text{B}$	80.39	?

20. More than half of all the atoms in naturally occurring zirconium are  $^{90}\text{Zr}$ . The other four stable isotopes of zirconium have the following relative atomic masses and abundances:

Isotope	% Abundance	Atomic Mass
$^{91}\text{Zr}$	11.27	90.9056
$^{92}\text{Zr}$	17.17	91.9050
$^{94}\text{Zr}$	17.33	93.9063
$^{96}\text{Zr}$	2.78	95.9083

Compute the relative atomic mass of  $^{90}\text{Zr}$  to four significant digits, using the tabulated relative atomic mass 91.224 for natural zirconium.

21. The isotope of plutonium used for nuclear fission is  $^{239}\text{Pu}$ . Determine (a) the ratio of the number of neutrons in a  $^{239}\text{Pu}$  nucleus to the number of protons, and (b) the number of electrons in a single plutonium atom.
22. The last "missing" element from the first six periods was promethium, which was finally discovered in 1947 among the fission products of uranium. Determine (a) the ratio of the number of neutrons in a  $^{145}\text{Pm}$  nucleus to the number of protons, and (b) the number of electrons in a single promethium atom.
23. The americium isotope  $^{241}\text{Am}$  is used in smoke detectors. Describe the composition of a neutral atom of this isotope for protons, neutrons, and electrons.
24. In 1982, the production of a single atom of  $^{266}_{109}\text{Mt}$  (meitnerium-266) was reported. Describe the composition of a neutral atom of this isotope for protons, neutrons, and electrons.

### 1.6 The Mole: Counting Molecules by Weighing

25. Compute the mass (in grams) of a single iodine atom if the relative atomic mass of iodine is 126.90447 on the accepted scale of atomic masses (based on 12 as the relative atomic mass of  $^{12}\text{C}$ ).
26. Determine the mass (in grams) of exactly 100 million atoms of fluorine if the relative atomic mass of fluorine is 18.998403 on a scale on which exactly 12 is the relative atomic mass of  $^{12}\text{C}$ .
27. Compute the relative molecular masses of the following compounds on the  $^{12}\text{C}$  scale:
- (a)  $\text{P}_4\text{O}_{10}$                       (b)  $\text{BrCl}$   
 (c)  $\text{Ca}(\text{NO}_3)_2$                   (d)  $\text{KMnO}_4$   
 (e)  $(\text{NH}_4)_2\text{SO}_4$
28. Compute the relative molecular masses of the following compounds on the  $^{12}\text{C}$  scale:
- (a)  $[\text{Ag}(\text{NH}_3)_2]\text{Cl}$             (b)  $\text{Ca}_3[\text{Co}(\text{CO}_3)_3]_2$   
 (c)  $\text{OsO}_4$                             (d)  $\text{H}_2\text{SO}_4$   
 (e)  $\text{Ca}_3\text{Al}_2(\text{SiO}_4)_3$
29. Suppose that a person counts out gold atoms at the rate of one each second for the entire span of an 80-year life. Has the person counted enough atoms to be detected with an ordinary balance? Explain.
30. A gold atom has a diameter of  $2.88 \times 10^{-10}$  m. Suppose the atoms in 1.00 mol of gold atoms are arranged just touching their neighbors in a single straight line. Determine the length of the line.
31. The vitamin A molecule has the formula  $\text{C}_{20}\text{H}_{30}\text{O}$ , and a molecule of vitamin  $\text{A}_2$  has the formula  $\text{C}_{20}\text{H}_{28}\text{O}$ . Determine how many moles of vitamin  $\text{A}_2$  contain the same number of atoms as 1.000 mol vitamin A.
32. Arrange the following in order of increasing mass: 1.06 mol  $\text{SF}_4$ ; 117 g  $\text{CH}_4$ ;  $8.7 \times 10^{23}$  molecules of  $\text{Cl}_2\text{O}_7$ ; and  $417 \times 10^{23}$  atoms of argon (Ar).
33. Mercury is traded by the “flask,” a unit that has a mass of 34.5 kg. Determine the volume of a flask of mercury if the density of mercury is  $13.6 \text{ g cm}^{-3}$ .
34. Gold costs \$400 per troy ounce, and 1 troy ounce = 31.1035 g. Determine the cost of  $10.0 \text{ cm}^3$  gold if the density of gold is  $19.32 \text{ g cm}^{-3}$  at room conditions.
35. Aluminum oxide ( $\text{Al}_2\text{O}_3$ ) occurs in nature as a mineral called corundum, which is noted for its hardness and resistance to attack by acids. Its density is  $3.97 \text{ g cm}^{-3}$ . Calculate the number of atoms of aluminum in  $15.0 \text{ cm}^3$  corundum.
36. Calculate the number of atoms of silicon (Si) in  $415 \text{ cm}^3$  of the colorless gas disilane at  $0^\circ\text{C}$  and atmospheric pressure, where its density is  $0.00278 \text{ g cm}^{-3}$ . The molecular formula of disilane is  $\text{Si}_2\text{H}_6$ .

## ADDITIONAL PROBLEMS

37. Soft wood chips weighing 17.2 kg are placed in an iron vessel and mixed with 150.1 kg water and 22.43 kg sodium hydroxide. A steel lid seals the vessel, which is then placed in an oven at  $250^\circ\text{C}$  for 6 hours. Much of the wood fiber decomposes under these conditions; the vessel and lid do not react.
- (a) Classify each of the materials mentioned as a substance or mixture. Subclassify the substances as elements or compounds.
- (b) Determine the mass of the contents of the iron vessel after the reaction.
38. In a reproduction of the Millikan oil-drop experiment, a student obtains the following values for the charges on nine different oil droplets.
- |                                   |                                   |                                   |
|-----------------------------------|-----------------------------------|-----------------------------------|
| $6.563 \times 10^{-19} \text{ C}$ | $13.13 \times 10^{-19} \text{ C}$ | $19.71 \times 10^{-19} \text{ C}$ |
| $8.204 \times 10^{-19} \text{ C}$ | $16.48 \times 10^{-19} \text{ C}$ | $22.89 \times 10^{-19} \text{ C}$ |
| $11.50 \times 10^{-19} \text{ C}$ | $18.08 \times 10^{-19} \text{ C}$ | $26.18 \times 10^{-19} \text{ C}$ |
- (a) Based on these data alone, what is your best estimate of the number of electrons on each of the above droplets? (*Hint*: Begin by considering differences in charges between adjacent data points, and see into what groups these are categorized.)
- (b) Based on these data alone, what is your best estimate of the charge on the electron?
- (c) Is it conceivable that the actual charge is half the charge you calculated in (b)? What evidence would help you decide one way or the other?
39. A rough estimate of the radius of a nucleus is provided by the formula  $r = kA^{1/3}$ , where  $k$  is approximately  $1.3 \times 10^{-13} \text{ cm}$  and  $A$  is the mass number of the nucleus. Estimate the density of the nucleus of  $^{127}\text{I}$  (which has a nuclear mass of  $2.1 \times 10^{-22} \text{ g}$ ) in grams per cubic centimeter. Compare with the density of solid iodine,  $4.93 \text{ g cm}^{-3}$ .
40. In a neutron star, gravity causes the electrons to combine with protons to form neutrons. A typical neutron star has a mass half that of the sun, compressed into a sphere of radius 20 km. If such a neutron star contains  $6.0 \times 10^{56}$  neutrons, calculate its density in grams per cubic centimeter. Compare this with the density inside a  $^{232}\text{Th}$  nucleus, in which 142 neutrons and 90 protons occupy a sphere of radius  $9.1 \times 10^{-13} \text{ cm}$ . Take the mass of a neutron to be  $1.675 \times 10^{-24} \text{ g}$  and that of a proton to be  $1.673 \times 10^{-24} \text{ g}$ .

41. Dalton's 1808 version of the atomic theory of matter included five general statements (see Section 1.3). According to modern understanding, four of those statements require amendment or extension. List the modifications that have been made to four of the five original postulates.
42. Naturally occurring rubidium (Rb) consists of two isotopes:  $^{85}\text{Rb}$  (atomic mass 84.9117) and  $^{87}\text{Rb}$  (atomic mass 86.9092). The atomic mass of the isotope mixture found in nature is 85.4678. Calculate the percentage abundances of the two isotopes in rubidium.
43. A sample of a gaseous binary compound of boron and chlorine weighing 2.842 g occupies 0.153 L. This sample is decomposed to give 0.664 g solid boron and enough gaseous chlorine ( $\text{Cl}_2$ ) to occupy 0.688 L at the same temperature and pressure. Determine the number of atoms of boron and the number of atoms of chlorine in a molecule of this compound.

Charles D. Winters. Balance courtesy of Chandler Museum at Columbia University

An “assay balance of careful construction” of the type used by Lavoisier before 1788. This balance became the production model that served as a general, all-purpose balance for approximately 40 years. Users of this type of balance included Sir Humphrey Davy and his young assistant Michael Faraday.

Chapter 1 explained how chemical and physical methods are used to establish chemical formulas and relative atomic and molecular masses. We also developed the concept of the mole, which allows us to count molecules by weighing macroscopic quantities of matter. This chapter begins our study of chemical reactions. We examine the balanced chemical equations that summarize these reactions and show how to relate the masses of substances consumed to the masses of substances produced. This is an immensely practical and important subject. The questions that ask how much of a substance will react with a given amount of another substance and then how much product will be generated are central to all chemical processes, whether industrial, geological, or biological.

## 2.1 Empirical and Molecular Formulas

According to the laws of chemical combination, each substance may be described by a chemical formula that specifies the relative numbers of atoms of the elements in that substance. We now distinguish between two types of formulas: the molecular formula and the empirical formula. The **molecular formula** of a substance specifies the number of atoms of each element in one molecule of that substance. Thus, the molecular formula of carbon dioxide is  $\text{CO}_2$ ; each molecule of carbon dioxide contains 1 atom of carbon and 2 atoms of oxygen. The molecular formula of glucose is  $\text{C}_6\text{H}_{12}\text{O}_6$ ; each glucose molecule contains 6 atoms of carbon, 6 atoms of oxygen, and 12 atoms of hydrogen. Molecular formulas can be defined for all gaseous substances and for those liquids or solids that, like glucose, possess well-defined molecular structures.

In contrast, the **empirical formula** of a compound is the simplest formula that gives the correct relative numbers of atoms of each kind in a compound. For example, the empirical formula for glucose is  $\text{CH}_2\text{O}$ , indicating that the numbers of atoms of carbon, hydrogen, and oxygen are in a ratio of 1:2:1. Molecular formulas, when known, are clearly preferable to empirical formulas because they provide more detailed information. In some solids and liquids, however, distinct small molecules do not exist, and the only meaningful chemical formula is an empirical one. Solid cobalt(II) chloride, which has the empirical formula  $\text{CoCl}_2$ , is an example. There are strong attractive forces between a cobalt atom and two adjoining chlorine (Cl) atoms in solid cobalt(II) chloride, but it is impossible to distinguish the forces *within* such a “molecule” of  $\text{CoCl}_2$  from those operating *between* it and a neighbor; the latter are equally strong. Consequently, cobalt(II) chloride is represented with an empirical formula and referred to by a **formula unit** of  $\text{CoCl}_2$ , rather than by “a molecule of  $\text{CoCl}_2$ .” Many solids can be represented only by their formula units because it is not possible to identify a molecular unit in a unique way; other examples include sodium chloride ( $\text{NaCl}$ ), the major component in table salt, and silicon dioxide ( $\text{SiO}_2$ ), the major component of sand (see Figure 3.3). In some cases, small molecules are incorporated into a solid structure, and the chemical formula is written to show this fact explicitly. Thus, cobalt and chlorine form not only the anhydrous salt  $\text{CoCl}_2$  mentioned earlier but also the hexahydrate  $\text{CoCl}_2 \cdot 6 \text{H}_2\text{O}$ , in which six water molecules are incorporated per  $\text{CoCl}_2$  formula unit (Fig. 2.1). The dot in this formula is used to set off a well-defined molecular component of the solid, such as water.

**FIGURE 2.1** When cobalt(II) chloride crystallizes from solution, it brings with it six water molecules per formula unit, producing a red solid with the empirical formula  $\text{CoCl}_2 \cdot 6 \text{H}_2\text{O}$ . This solid melts at  $86^\circ\text{C}$ ; it loses some of the water when heated above  $110^\circ\text{C}$  to form a lavender solid with the empirical formula  $\text{CoCl}_2 \cdot 2 \text{H}_2\text{O}$ .

## 2.2 Chemical Formula and Percentage Composition

The empirical formula  $\text{H}_2\text{O}$  specifies that for every atom of oxygen in water, there are two atoms of hydrogen. Equivalently, one mole of  $\text{H}_2\text{O}$  contains two moles of hydrogen atoms and one mole of oxygen atoms. The number of atoms and the number of moles of each element are present in the same ratio, namely, 2:1. The empirical formula for a substance is clearly related to the percentage composition by mass of that substance. This connection can be used in various ways.

### 2.2.1 Empirical Formula and Percentage Composition

The empirical formula of a compound can be simply related to the mass percentage of its constituent elements using the mole concept. For example, the empirical formula for ethylene (molecular formula  $\text{C}_2\text{H}_4$ ) is  $\text{CH}_2$ . Its composition by mass is calculated from the masses of carbon and hydrogen in 1 mol of  $\text{CH}_2$  formula units:

$$\text{mass of C} = 1 \text{ mol C} \times (12.011 \text{ g mol}^{-1}) = 12.011 \text{ g}$$

$$\text{mass of H} = 2 \text{ mol H} \times (1.00794 \text{ g mol}^{-1}) = 2.0159 \text{ g}$$

Adding these masses together gives a total mass of 14.027 g. The mass percentages of carbon and hydrogen in the compound are then found by dividing each of their masses by this total mass and multiplying by 100%, giving 85.628% C and 14.372% H by mass, respectively.

### 2.2.2 Determination of Empirical Formula from Mass Composition

We can reverse the procedure just described and determine the empirical formula from the elemental analysis of a compound, as illustrated by Example 2.1.

#### EXAMPLE 2.1

A 60.00-g sample of a dry-cleaning fluid was analyzed and found to contain 10.80 g carbon, 1.36 g hydrogen, and 47.84 g chlorine. Determine the empirical formula of the compound using a table of atomic masses.

#### Solution

The amounts of each element in the sample are

$$\text{carbon: } \frac{10.80 \text{ g C}}{12.011 \text{ g mol}^{-1}} = 0.8992 \text{ mol C}$$

$$\text{hydrogen: } \frac{1.36 \text{ g H}}{1.008 \text{ g mol}^{-1}} = 1.35 \text{ mol H}$$

$$\text{chlorine: } \frac{47.84 \text{ g Cl}}{35.453 \text{ g mol}^{-1}} = 1.349 \text{ mol Cl}$$

The ratio of the amount of carbon to that of chlorine (or hydrogen) is  $0.8992:1.349 = 0.6666$ , which is close to 2:3. The numbers of moles form the ratio 2:3:3; therefore, the empirical formula is  $\text{C}_2\text{H}_3\text{Cl}_3$ . Additional measurements would be necessary to find the actual molecular mass and the correct *molecular* formula from among  $\text{C}_2\text{H}_3\text{Cl}_3$ ,  $\text{C}_4\text{H}_6\text{Cl}_6$ , or any higher multiples  $(\text{C}_2\text{H}_3\text{Cl}_3)_n$ .

**Related Problems: 7, 8, 9, 10, 11, 12**

**FIGURE 2.2** A combustion train used to determine the relative amounts of carbon and hydrogen in hydrocarbons. A sample of known weight is burned in a flow of oxygen to produce water and carbon dioxide. These combustion products pass over a drying agent, such as magnesium perchlorate,  $\text{Mg}(\text{ClO}_4)_2$ , which absorbs the water. The carbon dioxide then passes through to the second stage where it is absorbed on finely divided particles of sodium hydroxide,  $\text{NaOH}$ , mixed with calcium chloride,  $\text{CaCl}_2$ . The masses of the water and carbon dioxide produced in the reaction are determined by weighing the absorption tubes before and after the reaction.

### 2.2.3 Empirical Formula Determined from Elemental Analysis by Combustion

A **hydrocarbon** is a compound that contains only carbon and hydrogen. Its empirical formula can be determined by using the combustion train shown in Figure 2.2. In this device, a known mass of the hydrocarbon is burned completely in oxygen, producing carbon dioxide and water whose masses are measured. The empirical formula for the compound is then calculated from these data by the procedure illustrated in Example 2.2.

#### EXAMPLE 2.2

A certain compound, used as a welding fuel, contains only carbon and hydrogen. Burning a small sample of this fuel completely in oxygen produces 3.38 g  $\text{CO}_2$ , 0.692 g water, and no other products. What is the empirical formula of the compound?

#### Solution

We first compute the amounts of  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . Because all the carbon has been converted to  $\text{CO}_2$  and all the hydrogen to water, the amounts of C and H in the unburned gas can be determined:

$$\begin{aligned}\text{mol of C} &= \text{mol of CO}_2 = \frac{3.38 \text{ g}}{44.01 \text{ g mol}^{-1}} = 0.0768 \text{ mol} \\ \text{mol of H} &= 2(\text{mol of H}_2\text{O}) = 2\left(\frac{0.692 \text{ g}}{18.02 \text{ g mol}^{-1}}\right) = 0.0768 \text{ mol}\end{aligned}$$

Because each water molecule contains two hydrogen atoms, it is necessary to multiply the number of moles of water by 2 to find the number of moles of hydrogen atoms. Having found that the compound contains equal numbers of moles of carbon and hydrogen, we have determined that its empirical formula is  $\text{CH}$ . Its molecular formula may be  $\text{CH}$ ,  $\text{C}_2\text{H}_2$ ,  $\text{C}_3\text{H}_3$ , and so on.

**Related Problems:** 13, 14

### 2.2.4 Connection between Empirical and Molecular Formulas

The molecular formula is some whole-number multiple of the empirical formula. To determine the molecular formula, you must know the approximate molar mass of the compound under study. From Avogadro's hypothesis, the ratio of molar masses of two gaseous compounds is the same as the ratio of their densities, provided that those densities are measured at the same temperature and pressure. (This is true because a given volume contains the same number of molecules of the two gases.) The density of the welding gas from Example 2.2 is  $1.06 \text{ g L}^{-1}$  at  $25^\circ\text{C}$  and atmospheric pressure. Under the same conditions, the density of gaseous oxygen (which exists as diatomic  $\text{O}_2$  molecules with molar mass of  $32.0 \text{ g mol}^{-1}$ ) is  $1.31 \text{ g L}^{-1}$ . The approximate molar mass of the welding gas is, therefore,

$$\text{molar mass of welding gas} = \frac{1.06 \text{ g L}^{-1}}{1.31 \text{ g L}^{-1}} (32.0 \text{ g mol}^{-1}) = 25.9 \text{ g mol}^{-1}$$

The molar mass corresponding to the *empirical* formula CH is  $13.0 \text{ g mol}^{-1}$ . Because  $25.9 \text{ g mol}^{-1}$  is approximately twice this value, there must be two CH units per molecule; therefore, the molecular formula is  $\text{C}_2\text{H}_2$ . The gas is acetylene.

## 2.3 Writing Balanced Chemical Equations

Chemical reactions combine elements into compounds, decompose compounds back into elements, and transform existing compounds into new compounds. Because atoms are indestructible in chemical reactions, the same number of atoms (or moles of atoms) of each element must be present before and after any ordinary (as opposed to nuclear) chemical reaction. The conservation of matter in a chemical change is represented in a balanced chemical equation for that process. The study of the relationships between the numbers of reactant and product molecules is called **stoichiometry** (derived from the Greek *stoicheion*, meaning "element," and *metron*, meaning "measure"). Stoichiometry is fundamental to all aspects of chemistry.

An equation can be balanced using stepwise reasoning. Consider the decomposition of ammonium nitrate ( $\text{NH}_4\text{NO}_3$ ) when heated gently to produce dinitrogen oxide ( $\text{N}_2\text{O}$ ) and water. An *unbalanced* equation for this reaction is

Substances on the left side of the arrow are called reactants, and those on the right side are called products. We read chemical equations just like we read sentences; reactions progress from left to right. This equation is unbalanced because there are 3 mol of oxygen atoms on the left side of the equation (and 4 mol of hydrogen atoms), but only 2 mol of oxygen atoms and 2 mol of hydrogen atoms on the right side. To balance the equation, begin by assigning 1 as the coefficient of one species, usually the species that contains the most elements—in this case,  $\text{NH}_4\text{NO}_3$ . Next, look for elements in that substance that appear only once elsewhere in the equation and assign coefficients to balance the number of moles of that element on both sides. The only other species in this reaction that contains nitrogen is  $\text{N}_2\text{O}$ , and assigning a coefficient of 1 for the  $\text{N}_2\text{O}$  ensures that there are 2 mol of nitrogen atoms on each side of the equation.

Hydrogen appears in  $\text{H}_2\text{O}$ ; thus, its coefficient is 2 to balance the 4 mol of hydrogen atoms on the left side. This gives

Finally, verify that the last element, oxygen, is also balanced by noting that there are 3 mol of oxygen atoms on each side. The coefficients of 1 in front of the  $\text{NH}_4\text{NO}_3$  and  $\text{N}_2\text{O}$  are omitted by convention.

As a second example, consider the reaction in which butane ( $\text{C}_4\text{H}_{10}$ ) is burned in oxygen to form carbon dioxide and water:

Spaces have been left for the coefficients that specify the number of moles of each reactant and product. Begin with 1 mol of butane,  $\text{C}_4\text{H}_{10}$ . It contains 4 mol of carbon atoms and must produce 4 mol of carbon dioxide molecules to conserve the number of carbon atoms in the reaction. Therefore, the coefficient for  $\text{CO}_2$  is 4. In the same way, the 10 mol of hydrogen *atoms* must form 5 mol of water *molecules*, because each water molecule contains 2 hydrogen atoms; thus, the coefficient for the  $\text{H}_2\text{O}$  is 5:

Four moles of  $\text{CO}_2$  contain 8 mol of oxygen atoms, and 5 mol of  $\text{H}_2\text{O}$  contain 5 mol of oxygen atoms, resulting in a total of 13 mol of oxygen atoms. Thirteen moles of oxygen atoms are equivalent to  $\frac{13}{2}$  moles of oxygen molecules; therefore, the coefficient for  $\text{O}_2$  is  $\frac{13}{2}$ . The balanced equation is

There is nothing wrong with fractions such as  $\frac{13}{2}$  in a balanced equation, because fractions of moles are perfectly meaningful. It is often customary, however, to eliminate such fractions because the equation can be interpreted on the molecular level as well as on the macroscopic level. Your instructor will very likely have a preference on this matter, so make sure that you know what it is and balance equations accordingly. In this case, multiplying all coefficients in the equation by 2 gives

The procedure may be summarized as follows:

1. Assign 1 as the coefficient of one species. The best choice is the most complicated species; that is, the species with the largest number of elements.
2. Identify, in sequence, elements that appear in only one chemical species, the coefficient of which has not yet been determined. Choose that coefficient to balance the number of moles of atoms of that element. Continue until all coefficients have been identified.
3. If desired, multiply the whole equation by the smallest integer that will eliminate any fractions.

This method of balancing equations “by inspection” works in many, but not all, cases. Section 11.4 (the number before the period refers to the chapter number) presents techniques for balancing certain more complex chemical equations.

Once the reactants and products are known, balancing chemical equations is a routine, mechanical process of accounting. We often tell students something like “if you have three dimes, two nickels, and a penny before the reaction, make sure that you have three dimes, two nickels, and a penny after the reaction” to give them a visual image. The difficult part (and the part where chemistry comes in) is to know which substances will react with each other

## CONNECTION TO CHEMICAL ENGINEERING

## Sulfuric Acid Manufacturing

Chemistry is big business. The chemical industry in the United States alone generates nearly a trillion dollars per year in annual sales—a significant component of the U.S. gross domestic product. It is impossible to overstate the importance of the chemical industry to our modern way of life; we depend on chemicals for energy, materials, agriculture, and health. The chemical and petrochemical industries transform raw ingredients, such as minerals and petroleum, into a variety of products on truly large scales. The process by which sulfuric acid is manufactured illustrates the practical importance of the topics developed in this chapter.

Sulfuric acid is produced in greater quantity than any other chemical; about 200 million metric tonnes ( $10^3$  kg) were manufactured worldwide in 2010. Most sulfuric acid plants are located near their product's point of use—phosphate fertilizer manufacturing plants, nickel ore leaching plants, and petroleum refineries—because it is less expensive to transport elemental sulfur (the starting material) than it is to transport sulfuric acid (the product). Sulfuric acid is also used in a variety of industrial chemical processes that include the manufacture of commodity and specialty chemicals, polymers, pharmaceuticals, soaps, and detergents and in the pulp and paper industry. The lead acid storage battery in your car is one of the few consumer products that actually contains sulfuric acid as such.

Elemental sulfur mined from historically important locations like Sicily, and later Indonesia, Chile, and Japan, used to be the dominant source of the raw material. Most sulfur occurs as fine powders or in polycrystalline form, but brightly colored yellow single crystals of sulfur are occasionally found. Virtually all of the sulfur used to manufacture sulfuric acid today was removed from petroleum fuels or feedstocks by a process called hydrosulfurization, because sulfur poisons the catalysts

used in petroleum refining and other processes. Canada has become the world's largest exporter of elemental sulfur. Figure C2.1 shows a stockpile of bright yellow sulfur awaiting shipment.

Most sulfuric acid produced today is made by the contact process, which got its name because the second step in the reaction is carried out in contact with a catalyst, typically vanadium pentoxide ( $V_2O_5$ ) mixed with proprietary (secret) additives. The main steps of the overall reaction sequence are:

The first step (the double arrows indicating an equilibrium) is the combustion of elemental sulfur in air to produce sulfur dioxide, which is further oxidized catalytically in the second reaction to produce sulfur trioxide. The second step is the key reaction of the process, and considerable effort has been devoted to optimizing the conditions under which this reaction takes place. Sulfuric acid is produced by the reaction between sulfur trioxide and water in the final step of the sequence. As you will see later in this textbook, optimizing the yields and rates of industrial chemical processes requires careful consideration of both the thermodynamics (Chapter 13) and the kinetics (Chapter 18) of the reactions. As is often the case in industrial chemical processes, thermodynamic considerations favor low temperatures, whereas kinetic considerations favor high temperatures, so the operating temperatures of sulfuric acid plants represent a compromise between those competing factors. The catalyst (something that speeds up a chemical reaction) is required for the conversion of  $SO_2$  to  $SO_3$ , because the reaction rate would be unacceptably slow without it.

The schematic in Figure C2.2 shows two stages of a typical modern multi-stage sulfuric acid plant that is designed to achieve maximum conversion yields at acceptable rates; these plants typically convert 99.7% of the elemental sulfur into sulfuric acid. The high yields are due to several important design features. First, and most important, the temperature of the  $SO_2$  produced by the initial combustion reaction is lowered prior to subsequent reaction with molecular oxygen. This step is taken to enhance the conversion of  $SO_2$  to  $SO_3$ , and it would be repeated several times in a multistage plant. Second, unreacted  $SO_3$  is absorbed by sulfuric acid in one or more absorbing towers, which allows any unreacted  $SO_2$  to make one or more passes over the catalytic reactor to

© Gunter Marx Photography/CORBIS

**FIGURE C2.1** A stockpile of yellow sulfur.

increase the amount converted. Finally, most modern plants have scrubbers that remove trace amounts of  $\text{SO}_2$  from the exhaust gases, primarily for environmental reasons (see Section 20.6), but also to recover a marketable product.

Understanding reaction stoichiometries is clearly essential in order to design and operate chemical plants efficiently. The masses of raw materials necessary to produce the desired quantity of products is calculated using basic stoichiometry relationships, taking into account the limiting reactant(s) involved. Many practical reactions are run with an excess of one or more of the reactants to ensure complete conversion. Designing the air handling system to provide sufficient oxygen for the combustion

and subsequent oxidation of sulfur requires quantitative understanding of the reaction stoichiometry.

To give you a feel for the amount of material converted in a modern sulfuric acid plant, let's calculate the amount of sulfur needed as raw material for a new plant under construction in Saudi Arabia in 2010. This plant, when complete, will produce 13,500 tons of sulfuric acid *per day* with the entire output devoted to phosphate fertilizer manufacture.  $\text{H}_2\text{SO}_4$  is 32.7% S by weight, so we need  $(.327) \times (13,500 \text{ tons}) = 4400 \text{ tons}$  of sulfur *per day*. A typical rail car holds 100 tons, so the owners of this plant need to provide 44 rail cars of sulfur per day, or a full trainload of sulfur every three days—truly a staggering amount!

**FIGURE C2.2** Schematic showing the contact process for producing sulfuric acid.

and to determine which products are formed. We return to this question many times throughout this book.

### EXAMPLE 2.3

Hargreaves process is an industrial procedure for making sodium sulfate ( $\text{Na}_2\text{SO}_4$ ) for use in papermaking. The starting materials are sodium chloride ( $\text{NaCl}$ ), sulfur dioxide ( $\text{SO}_2$ ), water, and oxygen. Hydrogen chloride ( $\text{HCl}$ ) is generated as a by-product. Write a balanced chemical equation for this process.

#### Solution

The unbalanced equation is

Begin by assigning a coefficient of 1 to  $\text{Na}_2\text{SO}_4$  because it is the most complex species, composed of 3 different elements. There are 2 mol of sodium atoms on the right;

(Continued)

therefore, the coefficient for NaCl must be 2. Following the same argument, the coefficient for SO<sub>2</sub> must be 1 to balance the 1 mol of sulfur on the right. This gives

Next, we note that there are 2 mol of Cl atoms on the left (reactant) side; therefore, the coefficient for HCl must be 2. Hydrogen is the next element to balance, with 2 mol on the right side, and therefore a coefficient of 1 for the H<sub>2</sub>O:

Finally, the oxygen atoms must be balanced. There are 4 mol of oxygen atoms on the right side, but there are 2 mol from SO<sub>2</sub> and 1 mol from H<sub>2</sub>O on the left side; therefore, 1 mol of oxygen *atoms* must come from O<sub>2</sub>. Therefore, the coefficient for O<sub>2</sub> is  $\frac{1}{2}$ :

Multiplying all coefficients in the equation by 2 gives

In balancing this equation, oxygen was considered last because it appears in several places on the left side of the equation.

**Related Problems: 19, 20**

## 2.4 Mass Relationships in Chemical Reactions

A balanced chemical equation makes a quantitative statement about the relative masses of the reacting substances. The chemical equation for the combustion of butane,

can be interpreted as either

or

Multiplying the molar mass of each substance in the reaction by the number of moles represented in the balanced equation gives

The coefficients in a balanced chemical equation relate the amounts of substances consumed in or produced by a chemical reaction. If 6.16 mol butane react according to the preceding equation, the amounts of O<sub>2</sub> consumed and CO<sub>2</sub> generated are

$$\text{mol O}_2 = 6.16 \text{ mol C}_4\text{H}_{10} \times \left( \frac{13 \text{ mol O}_2}{2 \text{ mol C}_4\text{H}_{10}} \right) = 40.0 \text{ mol O}_2$$

$$\text{mol CO}_2 = 6.16 \text{ mol C}_4\text{H}_{10} \times \left( \frac{8 \text{ mol CO}_2}{2 \text{ mol C}_4\text{H}_{10}} \right) = 24.6 \text{ mol CO}_2$$

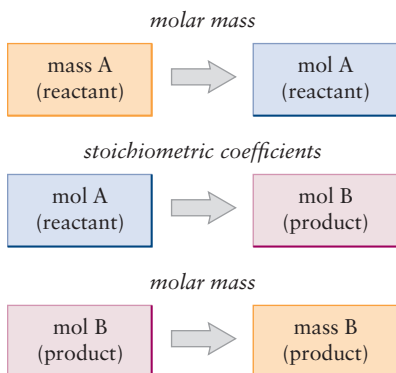

For most practical purposes we are interested in the *masses* of reactants and products, because those are the quantities that are directly measured. In this case, the molar masses (calculated from a table of atomic masses) are used to

convert the number of moles of a substance (in moles) to its mass (in grams), as illustrated by Example 2.4. Sometimes, however, we are also interested in knowing the number of molecules in a sample. The mole concept allows us to convert easily from mass to numbers of molecules as follows:

$$\text{mass} \xleftrightarrow{\text{molar mass}} \text{moles} \xleftrightarrow{N_A} \text{number of molecules}$$

Mass and moles are related by the molar mass; Avogadro's number  $N_A$  relates number and moles. You should practice using these relationships to calculate any desired quantity from any given quantity. You can use dimensional analysis to help you figure out whether to divide or multiply in any given problem.

**FIGURE 2.3** The steps in a stoichiometric calculation. In a typical calculation, the mass of one reactant or product is known and the masses of one or more other reactants or products are to be calculated using the balanced chemical equation and a table of relative atomic masses.

### EXAMPLE 2.4

Calcium hypochlorite,  $\text{Ca}(\text{OCl})_2$ , is used as a bleaching agent. It is produced from sodium hydroxide, calcium hydroxide, and chlorine according to the following overall equation:

How many grams of chlorine and sodium hydroxide react with 1067 g  $\text{Ca}(\text{OH})_2$ , and how many grams of calcium hypochlorite are produced?

#### Solution

The amount of  $\text{Ca}(\text{OH})_2$  consumed is

$$\frac{1067 \text{ g Ca}(\text{OH})_2}{74.09 \text{ g mol}^{-1}} = 14.40 \text{ mol Ca}(\text{OH})_2$$

where the molar mass of  $\text{Ca}(\text{OH})_2$  has been obtained from the molar masses of calcium, oxygen, and hydrogen as

$$40.08 \text{ g mol}^{-1} + 2(15.999 \text{ g mol}^{-1}) + 2(1.0079 \text{ g mol}^{-1}) = 74.09 \text{ g mol}^{-1}$$

According to the balanced equation, 1 mol  $\text{Ca}(\text{OH})_2$  reacts with 2 mol  $\text{NaOH}$  and 2 mol  $\text{Cl}_2$  to produce 1 mol  $\text{Ca}(\text{OCl})_2$ . If 14.40 mol of  $\text{Ca}(\text{OH})_2$  reacts completely, then

$$\begin{aligned} \text{mol NaOH} &= 14.40 \text{ mol Ca}(\text{OH})_2 \left( \frac{2 \text{ mol NaOH}}{1 \text{ mol Ca}(\text{OH})_2} \right) \\ &= 28.80 \text{ mol NaOH} \end{aligned}$$

$$\begin{aligned} \text{mol Cl}_2 &= 14.40 \text{ mol Ca}(\text{OH})_2 \left( \frac{2 \text{ mol Cl}_2}{1 \text{ mol Ca}(\text{OH})_2} \right) \\ &= 28.80 \text{ mol Cl}_2 \end{aligned}$$

$$\begin{aligned} \text{mol Ca}(\text{OCl})_2 &= 14.40 \text{ mol Ca}(\text{OH})_2 \left( \frac{1 \text{ mol Ca}(\text{OCl})_2}{1 \text{ mol Ca}(\text{OH})_2} \right) \\ &= 14.40 \text{ mol Ca}(\text{OCl})_2 \end{aligned}$$

From the number of moles and molar masses of reactants and products, the following desired masses are found:

$$\begin{aligned} \text{Mass NaOH reacting} &= (28.80 \text{ mol})(40.00 \text{ g mol}^{-1}) = 1152 \text{ g} \\ \text{Mass Cl}_2 \text{ reacting} &= (28.80 \text{ mol})(70.91 \text{ g mol}^{-1}) = 2042 \text{ g} \\ \text{Mass Ca}(\text{OCl})_2 \text{ produced} &= (14.40 \text{ mol})(142.98 \text{ g mol}^{-1}) = 2059 \text{ g} \end{aligned}$$

**Related Problems:** 21, 22, 23, 24

In calculations such as the one illustrated in Example 2.4, we are given a known mass of one substance and are asked to calculate the masses of one or more of the other reactants or products. Figure 2.3 summarizes the three-step process used. With experience, it is possible to write down the answers in a shorthand form so that all three conversions are conducted at the same time. The amount of NaOH reacting in the preceding example can be written as

$$\left( \frac{1067 \text{ g Ca(OH)}_2}{74.10 \text{ g mol}^{-1}} \right) \times \left( \frac{2 \text{ mol NaOH}}{1 \text{ mol Ca(OH)}_2} \right) \times 40.00 \text{ g mol}^{-1} = 1152 \text{ g NaOH}$$

At first, however, it is better to follow a stepwise procedure for such calculations.

## 2.5 Limiting Reactant and Percentage Yield

In the cases we have considered so far, the reactants were present in the exact ratios necessary for them all to be completely consumed in forming products. This is not the usual case, however. It is necessary to have methods for describing cases in which one of the reactants may not be present in sufficient amount and in which conversion to products is less than complete.

### 2.5.1 Limiting Reactant

Suppose arbitrary amounts of reactants are mixed and allowed to react. The one that is used up first is called the **limiting reactant** (limiting reagent in some texts); some quantity of the other reactants remains after the reaction has gone to completion. These other reactants are present **in excess**. An increase in the amount of the limiting reactant leads to an increase in the amount of product formed. This is not true of the other reactants. In an industrial process, the limiting reactant is often the most expensive one, to ensure that none of it is wasted. For instance, the silver nitrate used in preparing silver chloride for photographic film by the reaction

is far more expensive than the sodium chloride (ordinary salt). Thus, it makes sense to perform the reaction with an excess of sodium chloride to ensure that as much of the silver nitrate as possible reacts to form products.

There is a systematic method to find the limiting reactant and determine the maximum possible amounts of products. Take each reactant in turn, assume that it is used up completely in the reaction, and calculate the mass of one of the products that will be formed. Whichever reactant gives the *smallest* mass of this product is the limiting reactant. Once it has reacted fully, no further product can be formed.

#### EXAMPLE 2.5

Sulfuric acid ( $\text{H}_2\text{SO}_4$ ) forms in the chemical reaction

Suppose 400 g  $\text{SO}_2$ , 175 g  $\text{O}_2$ , and 125 g  $\text{H}_2\text{O}$  are mixed and the reaction proceeds until one of the reactants is used up. Which is the limiting reactant? What mass of  $\text{H}_2\text{SO}_4$  is produced, and what masses of the other reactants remain?

(Continued)

**Solution**

The number of moles of each reactant originally present is calculated by dividing each mass by the corresponding molar mass:

$$\frac{400 \text{ g SO}_2}{64.06 \text{ g mol}^{-1}} = 6.24 \text{ mol SO}_2$$

$$\frac{175 \text{ g O}_2}{32.00 \text{ g mol}^{-1}} = 5.47 \text{ mol O}_2$$

$$\frac{125 \text{ g H}_2\text{O}}{18.02 \text{ g mol}^{-1}} = 6.94 \text{ mol H}_2\text{O}$$

If all the SO<sub>2</sub> reacted, it would give

$$6.24 \text{ mol SO}_2 \times \left( \frac{2 \text{ mol H}_2\text{SO}_4}{2 \text{ mol SO}_2} \right) = 6.24 \text{ mol H}_2\text{SO}_4$$

If all the O<sub>2</sub> reacted, it would give

$$5.47 \text{ mol O}_2 \times \left( \frac{2 \text{ mol H}_2\text{SO}_4}{1 \text{ mol O}_2} \right) = 10.94 \text{ mol H}_2\text{SO}_4$$

Finally, if all the water reacted, it would give

$$6.94 \text{ mol H}_2\text{O} \times \left( \frac{2 \text{ mol H}_2\text{SO}_4}{2 \text{ mol H}_2\text{O}} \right) = 6.94 \text{ mol H}_2\text{SO}_4$$

In this case, SO<sub>2</sub> is the limiting reactant because the computation based on its amount produces the smallest amount of product (6.24 mol H<sub>2</sub>SO<sub>4</sub>). Oxygen and water are present in excess. After reaction, the amount of each reactant that remains is the original amount minus the amount reacted:

$$\begin{aligned} \text{mol O}_2 &= 5.47 \text{ mol O}_2 - \left( 6.24 \text{ mol SO}_2 \times \frac{1 \text{ mol O}_2}{2 \text{ mol SO}_2} \right) \\ &= 5.47 - 3.12 \text{ mol O}_2 = 2.35 \text{ mol O}_2 \end{aligned}$$

$$\begin{aligned} \text{mol H}_2\text{O} &= 6.94 \text{ mol H}_2\text{O} - \left( 6.24 \text{ mol SO}_2 \times \frac{2 \text{ mol H}_2\text{O}}{2 \text{ mol SO}_2} \right) \\ &= 6.94 - 6.24 \text{ mol H}_2\text{O} = 0.70 \text{ mol H}_2\text{O} \end{aligned}$$

The masses of reactants and products after the reaction are

$$\text{mass H}_2\text{SO}_4 \text{ produced} = (6.24 \text{ mol})(98.07 \text{ g mol}^{-1}) = 612 \text{ g}$$

$$\text{mass O}_2 \text{ remaining} = (2.35 \text{ mol})(32.00 \text{ g mol}^{-1}) = 75 \text{ g}$$

$$\text{mass H}_2\text{O remaining} = (0.70 \text{ mol})(18.02 \text{ g mol}^{-1}) = 13 \text{ g}$$

The total mass at the end is 612 g + 13 g + 75 g = 700 g, which is, of course, equal to the total mass originally present, 400 g + 175 g + 125 g = 700 g, as required by the law of conservation of mass.

**Related Problems: 35, 36**

## 2.5.2 Percentage Yield

The amounts of products calculated so far have been **theoretical yields**, determined by assuming that the reaction goes cleanly and completely. The **actual yield** of a product (that is, the amount present after separating it from other products and reactants and purifying it) is less than the theoretical yield. There are several

possible reasons for this. The reaction may stop short of completion, so reactants remain unreacted. There may be competing reactions that give other products, and therefore reduce the yield of the desired one. Finally, in the process of separation and purification, some of the product is invariably lost, although that amount can be reduced by careful experimental techniques. The ratio of the actual yield to the theoretical yield (multiplied by 100%) gives the **percentage yield** for that product in the reaction.

### EXAMPLE 2.6

The sulfide ore of zinc (ZnS) is reduced to elemental zinc by “roasting” it (heating it in air) to give ZnO, and then heating the ZnO with carbon monoxide. The two reactions can be written as

Suppose 5.32 kg ZnS is treated in this way and 3.30 kg pure Zn is obtained. Calculate the theoretical yield of zinc and its actual percentage yield.

#### Solution

From the molar mass of ZnS ( $97.46 \text{ g mol}^{-1}$ ), the number of moles of ZnS initially present is

$$\frac{5320 \text{ g ZnS}}{97.46 \text{ g mol}^{-1}} = 54.6 \text{ mol ZnS}$$

Because each mole of ZnS gives 1 mol of ZnO in the first chemical equation, and each mole of ZnO then gives 1 mol of Zn, the theoretical yield of zinc is 54.6 mol. In grams, this is

$$54.6 \text{ mol Zn} \times 65.39 \text{ g mol}^{-1} = 3570 \text{ g Zn}$$

The ratio of actual yield to theoretical yield, multiplied by 100%, gives the percentage yield of zinc:

$$\% \text{ yield} = \left( \frac{3.30 \text{ kg}}{3.57 \text{ kg}} \right) \times 100\% = 92.4\%$$

**Related Problems: 37, 38**

It is clearly desirable to achieve the highest percentage yield of product possible to reduce the consumption of raw materials. In some synthetic reactions (especially in organic chemistry), the final product is the result of many successive reactions. In such processes, the yields in the individual steps must be quite high if the synthetic method is to be a practical success. Suppose, for example, that ten consecutive reactions must be performed to reach the product, and that each has a percentage yield of only 50% (a fractional yield of 0.5). The overall yield is the product of the fractional yields of the steps:

$$(0.5) \times (0.5) \times \dots \times (0.5) = (0.5)^{10} = 0.001$$

10 terms

This overall percentage yield of 0.1% makes the process useless for synthetic purposes. If all the individual percentage yields could be increased to 90%, however, the overall yield would then be  $(0.9)^{10} = 0.35$ , or 35%. This is a much more reasonable result, and one that might make the process worth considering.

## CHAPTER SUMMARY

We have shown you how the relative number of atoms in a molecule or solid is given by its empirical or its molecular formula, and how these formulas are determined experimentally. The principle of conservation of mass has been sharpened a bit in our discussion of balancing chemical reactions. Not only is the total mass conserved in ordinary (as opposed to nuclear) chemical reactions, but the total number of atoms of every element is also conserved. Balancing a chemical reaction requires nothing more than assuring that the same numbers of atoms (or moles of atoms) of each element appear on each side of the

balanced equation. Because chemists weigh macroscopic quantities of reactants and products, it is important to understand how mass ratios relate to mole ratios in chemical reactions. Finally, we point out that not every reactant is completely consumed in a chemical reaction, and that the limiting reactant determines the maximum theoretical yield; the percentage yield may be somewhat less.

## CONCEPTS AND SKILLS

---

### Section 2.1 – Empirical and Molecular Formulas

*Distinguish between empirical and molecular formulas.*

### Section 2.2 – Chemical Formula and Percentage Composition

*Given the percentages by mass of the elements in a compound, determine its empirical formula and vice versa (Problems 1–12).*

- Determine the number of moles of each element in a compound by dividing the mass of each element (from mass percentages) by the molar mass of the element and then take ratios, reducing them to the smallest ratio of integers.

*Use the masses of products obtained in combustion train measurements to determine empirical formulas (Problems 12 and 13).*

*Use ratios of gas densities to estimate molar mass and determine molecular formulas (Problems 15–18).*

- The ratio of the density of an unknown gas to that of a known gas (using Avogadro's hypothesis) gives an approximate molar mass.

### Section 2.3 – Writing Balanced Chemical Equations

*Balance simple chemical equations (Problems 19 and 20).*

- Choose the substance with the most elements and assign it a stoichiometric coefficient of 1.
- Choose an element that appears in only one other substance in the reaction and balance it with respect to the first substance. Continue in this way until all of the elements have been balanced.

### Section 2.4 – Mass Relationships in Chemical Reactions

*Given the mass of a reactant or product in a chemical reaction, use a balanced chemical equation to calculate the masses of other reactants consumed and other products formed (Problems 21–34).*

- Use the flowchart (Figure 2.3).
- Convert masses of reactants to moles of reactants using their molar masses.
- Convert moles of reactants to moles of products using stoichiometry.
- Convert moles of products to masses of products using their molar masses.

### Section 2.5 – Limiting Reactant and Percentage Yield

*Given a set of initial masses of reactants and a balanced chemical equation, determine the limiting reactant and calculate the masses of reactants and products after the reaction has gone to completion (Problems 35 and 36).*

- Calculate the number of moles of each reactant and determine which one would produce the smallest amount of product if the reaction went to completion.
- Calculate the number of moles of reactants consumed and products produced using the number of moles of this limiting reactant and the reaction stoichiometry.

## CUMULATIVE EXERCISE

**FIGURE 2.4** A jet engine fan blade made of a single-crystal titanium alloy.

### Titanium in Industry

Metallic titanium and its alloys (especially those with aluminum and vanadium) combine the advantages of high strength and lightweight and are therefore used widely in the aerospace industry for the bodies and engines of airplanes (Figure 2.4). The major natural source for titanium is the ore rutile, which contains titanium dioxide ( $\text{TiO}_2$ ).

- An intermediate in the preparation of elemental titanium from  $\text{TiO}_2$  is a volatile chloride of titanium (boiling point  $136^\circ\text{C}$ ) that contains 25.24% titanium by mass. Determine the empirical formula of this compound.
- At  $136^\circ\text{C}$  and atmospheric pressure, the density of this gaseous chloride is  $5.6 \text{ g L}^{-1}$ . Under the same conditions, the density of gaseous nitrogen ( $\text{N}_2$ , molar mass  $28.0 \text{ g mol}^{-1}$ ) is  $0.83 \text{ g L}^{-1}$ . Determine the molecular formula of this compound.
- The titanium chloride dealt with in parts (a) and (b) is produced by the reaction of chlorine with a hot mixture of titanium dioxide and coke (carbon), with carbon dioxide generated as a by-product. Write a balanced chemical equation for this reaction.
- What mass of chlorine is needed to produce 79.2 g of the titanium chloride?
- The titanium chloride then reacts with liquid magnesium at  $900^\circ\text{C}$  to give titanium and magnesium chloride ( $\text{MgCl}_2$ ). Write a balanced chemical equation for this step in the refining of titanium.
- Suppose the reaction chamber for part (e) contains 351 g of the titanium chloride and 63.2 g liquid magnesium. Which is the limiting reactant? What maximum mass of titanium could result?
- Isotopic analysis of the titanium from a particular ore gave the following results:

Isotope	Relative Mass	Abundance (%)
$^{46}\text{Ti}$	45.952633	7.93
$^{47}\text{Ti}$	46.95176	7.28
$^{48}\text{Ti}$	47.947948	73.94
$^{49}\text{Ti}$	48.947867	5.51
$^{50}\text{Ti}$	49.944789	5.34

Calculate the mass of a single  $^{48}\text{Ti}$  atom and the *average* mass of the titanium atoms in this ore sample.

### Answers

- $\text{TiCl}_4$
- $\text{TiCl}_4$
- $\text{TiO}_2 + \text{C} + 2 \text{Cl}_2 \longrightarrow \text{TiCl}_4 + \text{CO}_2$
- 59.2 g
- $\text{TiCl}_4 + 2 \text{Mg} \longrightarrow \text{Ti} + 2 \text{MgCl}_2$
- Mg; 62.3 g
- $7.961949 \times 10^{-23} \text{ g}$ ;  $7.950 \times 10^{-23} \text{ g}$

## PROBLEMS

Answers to problems whose numbers are red appear in Appendix G. Problems that are more challenging are indicated with asterisks.

### 2.2 Chemical Formula and Percentage Composition

- A newly synthesized compound has the molecular formula  $\text{ClF}_2\text{O}_2\text{PtF}_6$ . Compute, to four significant figures, the mass percentage of each of the four elements in this compound.
- Acetaminophen is the generic name of the pain reliever in Tylenol and some other headache remedies. The compound has the molecular formula  $\text{C}_8\text{H}_9\text{NO}_2$ . Compute, to four significant figures, the mass percentage of each of the four elements in acetaminophen.
- Arrange the following compounds from left to right in order of increasing percentage by mass of hydrogen:  $\text{H}_2\text{O}$ ,  $\text{C}_{12}\text{H}_{26}$ ,  $\text{N}_4\text{H}_6$ ,  $\text{LiH}$ .
- Arrange the following compounds from left to right in order of increasing percentage by mass of fluorine:  $\text{HF}$ ,  $\text{C}_6\text{HF}_5$ ,  $\text{BrF}$ ,  $\text{UF}_6$ .
- “Q-gas” is a mixture of 98.70% helium and 1.30% butane ( $\text{C}_4\text{H}_{10}$ ) by mass. It is used as a filling for gas-flow Geiger counters. Compute the mass percentage of hydrogen in Q-gas.
- A pharmacist prepares an antiulcer medicine by mixing 286 g  $\text{Na}_2\text{CO}_3$  with water, adding 150 g glycine ( $\text{C}_2\text{H}_5\text{NO}_2$ ), and stirring continuously at  $40^\circ\text{C}$  until a firm mass results. The pharmacist heats the mass gently until all the water has been driven away. No other chemical changes occur in this step. Compute the mass percentage of carbon in the resulting white crystalline medicine.
- Zinc phosphate is used as a dental cement. A 50.00-mg sample is broken down into its constituent elements and gives 16.58 mg oxygen, 8.02 mg phosphorus, and 25.40 mg zinc. Determine the empirical formula of zinc phosphate.
- Bromoform is 94.85% bromine, 0.40% hydrogen, and 4.75% carbon by mass. Determine its empirical formula.
- Fulgurites are the products of the melting that occurs when lightning strikes the earth. Microscopic examination of a sand fulgurite shows that it is a globule with variable composition that contains some grains of the definite chemical composition Fe 46.01%, Si 53.99%. Determine the empirical formula of these grains.
- A sample of a “suboxide” of cesium gives up 1.6907% of its mass as gaseous oxygen when gently heated, leaving pure cesium behind. Determine the empirical formula of this binary compound.
- Barium and nitrogen form two binary compounds containing 90.745% and 93.634% barium, respectively. Determine the empirical formulas of these two compounds.
- Carbon and oxygen form no fewer than five different binary compounds. The mass percentages of carbon in the five compounds are as follows: A, 27.29; B, 42.88; C, 50.02; D, 52.97; and E, 65.24. Determine the empirical formulas of the five compounds.
- A sample of 1.000 g of a compound containing carbon and hydrogen reacts with oxygen at elevated temperature to yield 0.692 g  $\text{H}_2\text{O}$  and 3.381 g  $\text{CO}_2$ .
  - Calculate the masses of C and H in the sample.
  - Does the compound contain any other elements?
  - What are the mass percentages of C and H in the compound?
  - What is the empirical formula of the compound?
- Burning a compound of calcium, carbon, and nitrogen in oxygen in a combustion train generates calcium oxide ( $\text{CaO}$ ), carbon dioxide ( $\text{CO}_2$ ), nitrogen dioxide ( $\text{NO}_2$ ), and no other substances. A small sample gives 2.389 g  $\text{CaO}$ , 1.876 g  $\text{CO}_2$ , and 3.921 g  $\text{NO}_2$ . Determine the empirical formula of the compound.
- The empirical formula of a gaseous fluorocarbon is  $\text{CF}_2$ . At a certain temperature and pressure, a 1-L volume holds 8.93 g of this fluorocarbon, whereas under the same conditions, the 1-L volume holds only 1.70 g gaseous fluorine ( $\text{F}_2$ ). Determine the molecular formula of this compound.
- At its boiling point ( $280^\circ\text{C}$ ) and at atmospheric pressure, phosphorus has a gas density of  $2.7\text{ g L}^{-1}$ . Under the same conditions, nitrogen has a gas density of  $0.62\text{ g L}^{-1}$ . How many atoms of phosphorus are there in one phosphorus molecule under these conditions?
- A gaseous binary compound has a vapor density that is 1.94 times that of oxygen at the same temperature and pressure. When 1.39 g of the gas is burned in an excess of oxygen, 1.21 g water is formed, removing all the hydrogen originally present.
  - Estimate the molecular mass of the gaseous compound.
  - How many hydrogen atoms are there in a molecule of the compound?
  - What is the maximum possible value of the atomic mass of the second element in the compound?
  - Are other values possible for the atomic mass of the second element? Use a table of atomic masses to identify the element that best fits the data.
  - What is the molecular formula of the compound?
- A gaseous binary compound has a vapor density that is 2.53 times that of nitrogen at  $100^\circ\text{C}$  and atmospheric pressure. When 8.21 g of the gas reacts with  $\text{AlCl}_3$  at  $100^\circ\text{C}$ , 1.62 g gaseous nitrogen is produced, removing all of the nitrogen originally present.
  - Estimate the molecular mass of the gaseous compound.
  - How many nitrogen atoms are there in a molecule of the compound?
  - What is the maximum possible value of the atomic mass of the second element?
  - Are other values possible for the atomic mass of the second element? Use a table of atomic masses to identify the element that best fits the data.
  - What is the molecular formula of the compound?

### 2.3 Writing Balanced Chemical Equations

19. Balance the following chemical equations:
- $\text{H}_2 + \text{N}_2 \longrightarrow \text{NH}_3$
  - $\text{K} + \text{O}_2 \longrightarrow \text{K}_2\text{O}_2$
  - $\text{PbO}_2 + \text{Pb} + \text{H}_2\text{SO}_4 \longrightarrow \text{PbSO}_4 + \text{H}_2\text{O}$
  - $\text{BF}_3 + \text{H}_2\text{O} \longrightarrow \text{B}_2\text{O}_3 + \text{HF}$
  - $\text{KClO}_3 \longrightarrow \text{KCl} + \text{O}_2$
  - $\text{CH}_3\text{COOH} + \text{O}_2 \longrightarrow \text{CO}_2 + \text{H}_2\text{O}$
  - $\text{K}_2\text{O}_2 + \text{H}_2\text{O} \longrightarrow \text{KOH} + \text{O}_2$
  - $\text{PCl}_5 + \text{AsF}_3 \longrightarrow \text{PF}_5 + \text{AsCl}_3$
20. Balance the following chemical equations:
- $\text{Al} + \text{HCl} \longrightarrow \text{AlCl}_3 + \text{H}_2$
  - $\text{NH}_3 + \text{O}_2 \longrightarrow \text{NO} + \text{H}_2\text{O}$
  - $\text{Fe} + \text{O}_2 + \text{H}_2\text{O} \longrightarrow \text{Fe}(\text{OH})_2$
  - $\text{HSbCl}_4 + \text{H}_2\text{S} \longrightarrow \text{Sb}_2\text{S}_3 + \text{HCl}$
  - $\text{Al} + \text{Cr}_2\text{O}_3 \longrightarrow \text{Al}_2\text{O}_3 + \text{Cr}$
  - $\text{XeF}_4 + \text{H}_2\text{O} \longrightarrow \text{Xe} + \text{O}_2 + \text{HF}$
  - $(\text{NH}_4)_2\text{Cr}_2\text{O}_7 \longrightarrow \text{N}_2 + \text{Cr}_2\text{O}_3 + \text{H}_2\text{O}$
  - $\text{NaBH}_4 + \text{H}_2\text{O} \longrightarrow \text{NaBO}_2 + \text{H}_2$

### 2.4 Mass Relationships in Chemical Reactions

21. For each of the following chemical reactions, calculate the mass of the underlined reactant that is required to produce 1.000 g of the underlined product.
- $\text{Mg} + 2 \text{HCl} \longrightarrow \underline{\text{H}_2} + \text{MgCl}_2$
  - $2 \underline{\text{CuSO}_4} + 4 \text{KI} \longrightarrow 2 \text{CuI} + \underline{\text{I}_2} + 2 \text{K}_2\text{SO}_4$
  - $\underline{\text{NaBH}_4} + 2 \text{H}_2\text{O} \longrightarrow \text{NaBO}_2 + \underline{4 \text{H}_2}$
22. For each of the following chemical reactions, calculate the maximum mass of the underlined product that could be produced from 1.000 g of the underlined reactant.
- $\underline{\text{CaCO}_3} + \text{H}_2\text{O} \longrightarrow \underline{\text{Ca}(\text{OH})_2} + \text{CO}_2$
  - $\underline{\text{C}_3\text{H}_8} + 5 \text{O}_2 \longrightarrow 3 \underline{\text{CO}_2} + 4 \text{H}_2\text{O}$
  - $2 \underline{\text{MgNH}_4\text{PO}_4} \longrightarrow \underline{\text{Mg}_2\text{P}_2\text{O}_7} + 2 \text{NH}_3 + \text{H}_2\text{O}$
23. An 18.6-g sample of  $\text{K}_2\text{CO}_3$  was treated in such a way that all of its carbon was captured in the compound  $\text{K}_2\text{Zn}_3[\text{Fe}(\text{CN})_6]_2$ . Compute the mass (in grams) of this product.
24. A chemist dissolves 1.406 g pure platinum (Pt) in an excess of a mixture of hydrochloric and nitric acids and then, after a series of subsequent steps involving several other chemicals, isolates a compound of molecular formula  $\text{Pt}_2\text{C}_{10}\text{H}_{18}\text{N}_2\text{S}_2\text{O}_6$ . Determine the maximum possible yield of this compound.
25. Disilane ( $\text{Si}_2\text{H}_6$ ) is a gas that reacts with oxygen to give silica ( $\text{SiO}_2$ ) and water. Calculate the mass of silica that would form if  $25.0 \text{ cm}^3$  disilane (with a density of  $2.78 \times 10^{-3} \text{ g cm}^{-3}$ ) reacted with excess oxygen.
26. Tetrasilane ( $\text{Si}_4\text{H}_{10}$ ) is a liquid with a density of  $0.825 \text{ g cm}^{-3}$ . It reacts with oxygen to give silica ( $\text{SiO}_2$ ) and water. Calculate the mass of silica that would form if  $25.0 \text{ cm}^3$  tetrasilane reacted completely with excess oxygen.
27. Cryolite ( $\text{Na}_3\text{AlF}_6$ ) is used in the production of aluminum from its ores. It is made by the reaction
- $$6 \text{NaOH} + \text{Al}_2\text{O}_3 + 12 \text{HF} \longrightarrow 2 \text{Na}_3\text{AlF}_6 + 9 \text{H}_2\text{O}$$
- Calculate the mass of cryolite that can be prepared by the complete reaction of 287 g  $\text{Al}_2\text{O}_3$ .

28. Carbon disulfide ( $\text{CS}_2$ ) is a liquid that is used in the production of rayon and cellophane. It is manufactured from methane and elemental sulfur via the reaction

Calculate the mass of  $\text{CS}_2$  that can be prepared by the complete reaction of 67.2 g sulfur.

29. Potassium nitrate ( $\text{KNO}_3$ ) is used as a fertilizer for certain crops. It is produced through the reaction

Calculate the minimum mass of KCl required to produce 567 g  $\text{KNO}_3$ . What mass of  $\text{Cl}_2$  will be generated as well?

30. Elemental phosphorus can be prepared from calcium phosphate via the overall reaction

Calculate the minimum mass of  $\text{Ca}_3(\text{PO}_4)_2$  required to produce 69.8 g  $\text{P}_4$ . What mass of  $\text{CaSiO}_3$  is generated as a by-product?

31. An element X has a dibromide with the empirical formula  $\text{XBr}_2$  and a dichloride with the empirical formula  $\text{XCl}_2$ . The dibromide is completely converted to the dichloride when it is heated in a stream of chlorine according to the reaction

When 1.500 g  $\text{XBr}_2$  is treated, 0.890 g  $\text{XCl}_2$  results.

- Calculate the atomic mass of the element X.
  - By reference to a list of the atomic masses of the elements, identify the element X.
- \*32. An element A has a triiodide with the formula  $\text{AI}_3$  and a trichloride with the formula  $\text{ACl}_3$ . The triiodide is quantitatively converted to the trichloride when it is heated in a stream of chlorine, according to the reaction

If 0.8000 g  $\text{AI}_3$  is treated, 0.3776 g  $\text{ACl}_3$  is obtained.

- Calculate the atomic mass of the element A.
  - Identify the element A.
- \*33. A mixture consisting of only sodium chloride ( $\text{NaCl}$ ) and potassium chloride ( $\text{KCl}$ ) weighs 1.0000 g. When the mixture is dissolved in water and an excess of silver nitrate is added, all the chloride ions associated with the original mixture are precipitated as insoluble silver chloride ( $\text{AgCl}$ ). The mass of the silver chloride is found to be 2.1476 g. Calculate the mass percentages of sodium chloride and potassium chloride in the original mixture.
- \*34. A mixture of aluminum and iron weighing 9.62 g reacts with hydrogen chloride in aqueous solution according to the parallel reactions

A 0.738-g quantity of hydrogen is evolved when the metals react completely. Calculate the mass of iron in the original mixture.

## 2.5 Limiting Reactant and Percentage Yield

35. When ammonia is mixed with hydrogen chloride (HCl), the white solid ammonium chloride ( $\text{NH}_4\text{Cl}$ ) is produced. Suppose 10.0 g ammonia is mixed with the same mass of hydrogen chloride. What substances will be present after the reaction has gone to completion, and what will their masses be?
36. The poisonous gas hydrogen cyanide (HCN) is produced by the high-temperature reaction of ammonia with methane ( $\text{CH}_4$ ). Hydrogen is also produced in this reaction.
- Write a balanced chemical equation for the reaction that occurs.
  - Suppose 500.0 g methane is mixed with 200.0 g ammonia. Calculate the masses of the substances present after the reaction is allowed to proceed to completion.

37. The iron oxide  $\text{Fe}_2\text{O}_3$  reacts with carbon monoxide (CO) to give iron and carbon dioxide:

The reaction of 433.2 g  $\text{Fe}_2\text{O}_3$  with excess CO yields 254.3 g iron. Calculate the theoretical yield of iron (assuming complete reaction) and its percentage yield.

38. Titanium dioxide,  $\text{TiO}_2$ , reacts with carbon and chlorine to give gaseous  $\text{TiCl}_4$ :

The reaction of 7.39 kg titanium dioxide with excess C and  $\text{Cl}_2$  gives 14.24 kg titanium tetrachloride. Calculate the theoretical yield of  $\text{TiCl}_4$  (assuming complete reaction) and its percentage yield.

## ADDITIONAL PROBLEMS

39. Human parathormone has the impressive molecular formula  $\text{C}_{691}\text{H}_{898}\text{N}_{125}\text{O}_{164}\text{S}_{11}$ . Compute the mass percentages of all the elements in this compound.
40. A white oxide of tungsten is 79.2976% tungsten by mass. A blue tungsten oxide also contains exclusively tungsten and oxygen, but it is 80.8473% tungsten by mass. Determine the empirical formulas of white tungsten oxide and blue tungsten oxide.
41. A dark brown binary compound contains oxygen and a metal. It is 13.38% oxygen by mass. Heating it moderately drives off some of the oxygen and gives a red binary compound that is 9.334% oxygen by mass. Strong heating drives off more oxygen and gives still another binary compound, which is only 7.168% oxygen by mass.
- Compute the mass of oxygen that is combined with 1.000 g of the metal in each of these three oxides.
  - Assume that the empirical formula of the first compound is  $\text{MO}_2$  (where M represents the metal). Give the empirical formulas of the second and third compounds.
  - Name the metal.
42. A binary compound of nickel and oxygen contains 78.06% nickel by mass. Is this a stoichiometric or a non-stoichiometric compound? Explain.
43. Two binary oxides of the element manganese contain, respectively, 30.40% and 36.81% oxygen by mass. Calculate the empirical formulas of the two oxides.
44. A possible practical way to eliminate oxides of nitrogen (such as  $\text{NO}_2$ ) from automobile exhaust gases uses cyanuric acid,  $\text{C}_3\text{N}_3(\text{OH})_3$ . When heated to the relatively low temperature of 625°F, cyanuric acid converts to gaseous isocyanic acid (HNCO). Isocyanic acid reacts with  $\text{NO}_2$  in the exhaust to form nitrogen, carbon dioxide, and water, all of which are normal constituents of the air.
- Write balanced equations for these two reactions.
  - If the process described earlier became practical, how much cyanuric acid (in kilograms) would be required to absorb the  $1.7 \times 10^{10}$  kg  $\text{NO}_2$  generated annually in auto exhaust in the United States?
45. Aspartame (molecular formula  $\text{C}_{14}\text{H}_{18}\text{N}_2\text{O}_5$ ) is a sugar substitute in soft drinks. Under certain conditions, 1 mol of aspartame reacts with 2 mol of water to give 1 mol of aspartic acid (molecular formula  $\text{C}_4\text{H}_7\text{NO}_4$ ), 1 mol of methanol (molecular formula  $\text{CH}_3\text{OH}$ ), and 1 mol of phenylalanine. Determine the molecular formula of phenylalanine.
46. 3'-Methylphthalanilic acid is used commercially as a "fruit set" to prevent premature drop of apples, pears, cherries, and peaches from the tree. It is 70.58% carbon, 5.13% hydrogen, 5.49% nitrogen, and 18.80% oxygen. If eaten, the fruit set reacts with water in the body to produce an innocuous product, which contains carbon, hydrogen, and oxygen only, and *m*-toluidine ( $\text{NH}_2\text{C}_6\text{H}_4\text{CH}_3$ ), which causes anemia and kidney damage. Compute the mass of the fruit set that would produce 5.23 g *m*-toluidine.
47. Aluminum carbide ( $\text{Al}_4\text{C}_3$ ) reacts with water to produce gaseous methane ( $\text{CH}_4$ ). Calculate the mass of methane formed from 63.2 g  $\text{Al}_4\text{C}_3$ .
48. Citric acid ( $\text{C}_6\text{H}_8\text{O}_7$ ) is made by fermentation of sugars such as sucrose ( $\text{C}_{12}\text{H}_{22}\text{O}_{11}$ ) in air. Oxygen is consumed and water generated as a by-product.
- Write a balanced equation for the overall reaction that occurs in the manufacture of citric acid from sucrose.
  - What mass of citric acid is made from 15.0 kg sucrose?
49. A sample that contains only  $\text{SrCO}_3$  and  $\text{BaCO}_3$  weighs 0.800 g. When it is dissolved in excess acid, 0.211 g carbon dioxide is liberated. What percentage of  $\text{SrCO}_3$  did the sample contain? Assume all the carbon originally present is converted to carbon dioxide.
50. A sample of a substance with the empirical formula  $\text{XBr}_2$  weighs 0.5000 g. When it is dissolved in water and all its bromine is converted to insoluble  $\text{AgBr}$  by addition of an excess of silver nitrate, the mass of the resulting  $\text{AgBr}$  is found to be 1.0198 g. The chemical reaction is

- (a) Calculate the molecular mass (that is, formula mass) of  $XBr_2$ .
- (b) Calculate the atomic mass of X and give its name and symbol.
51. A newspaper article about the danger of global warming from the accumulation of greenhouse gases such as carbon dioxide states that “reducing driving your car by 20 miles a week would prevent release of over 1000 pounds of  $CO_2$  per year into the atmosphere.” Is this a reasonable statement? Assume that gasoline is octane (molecular formula  $C_8H_{18}$ ) and that it is burned completely to  $CO_2$  and  $H_2O$  in the engine of your car. Facts (or reasonable guesses) about your car’s gas mileage, the density of octane, and other factors will also be needed.

52. In the Solvay process for producing sodium carbonate ( $Na_2CO_3$ ), the following reactions occur in sequence:

How many metric tons of sodium carbonate would be produced per metric ton of  $NH_3$  if the process were 100% efficient (1 metric ton = 1000 kg)?

53. A yield of 3.00 g  $KClO_4$  is obtained from the (unbalanced) reaction

when 4.00 g of the reactant is used. What is the percentage yield of the reaction?

54. An industrial-scale process for making acetylene consists of the following sequence of operations:

What is the percentage yield of the overall process if 2.32 metric tons  $C_2H_2$  is produced from 10.0 metric tons limestone (1 metric ton = 1000 kg)?

55. Silicon nitride ( $Si_3N_4$ ), a valuable ceramic, is made by the direct combination of silicon and nitrogen at high temperature. How much silicon must react with excess nitrogen to prepare 125 g silicon nitride if the yield of the reaction is 95.0%?

# Chemical Bonding and Molecular Structure

Courtesy of Dr. Richard P. Muller and Professor William A. Goddard III, California Institute of Technology.

The electron density in a delocalized three-center bond for  $\text{H}_3^+$  calculated by quantum mechanics.

Unit II is a journey into the nanoscopic realm of atoms and molecules where the fundamental events of chemistry take place. A molecule is a tiny physical object that has a specific structure, with dimensions in the range 0.1 nm to about 2 nm, held together by a delicate balance of electrical forces. In polymeric and biological materials, molecular dimensions may be as large as micrometers or even millimeters. The structure takes a characteristic three-dimensional shape, usually of a type already familiar in geometry, and frequently with a high degree of symmetry. Molecular attributes—structure, electron density, shape—can be predicted by theory and observed in experiments. They determine the physical properties and chemical reactivity of molecules in situations ranging from pure chemistry to materials science to biology.

## Unit Chapters

### CHAPTER 3

Atomic Shells and Classical Models of Chemical Bonding

### CHAPTER 4

Introduction to Quantum Mechanics

### CHAPTER 5

Quantum Mechanics and Atomic Structure

### CHAPTER 6

Quantum Mechanics and Molecular Structure

### CHAPTER 7

Bonding in Organic Molecules

### CHAPTER 8

Bonding in Transition Metal Compounds and Coordination Complexes

## Unit Goals

- To introduce the classical theory of chemical bonding as a tool for describing the structures and shapes of molecules
- To convey the basic concepts and methods of quantum mechanics that describe the restrictions on the energy and the physical motions of microscopic systems
- To develop an intuition for the behavior of quantum systems and an appreciation for the magnitudes of physical properties in the quantum regime
- To use quantum mechanics to:
  - Describe the allowed energies and electron densities in atoms
  - Explain the structure of the periodic table and periodic trends in the properties of atoms
  - Describe covalent bond formation and the structures of diatomic and small polyatomic molecules
  - Describe covalent bond formation and the structures of organic molecules
  - Describe bonding in more complex structures that include transition metal complexes

(a)

(b)

(a) The shape of the molecule triphenyl-phosphine,  $(C_6H_5)_3P$ , is determined by locating the valence shell electron pairs in those positions that minimize the overall energy of the molecule. (b) The space-filling representation aids the analysis and understanding of the steric environment responsible for the specific molecular geometry observed.

The previous chapters showed how the laws of conservation of mass and conservation of atomic identity, together with the concept of the mole, determine quantitative mass relationships in chemical reactions. That discussion assumed prior knowledge of the chemical formulas of the reactants and products in each equation. The far more open-ended questions of which compounds are found in nature (or which can be made in the laboratory) and what types of reactions they undergo now arise. Why are some elements and compounds violently reactive and others inert? Why are there compounds with chemical formulas  $H_2O$  and  $NaCl$ , but never  $H_3O$  or  $NaCl_2$ ? Why are helium and the other noble gases monatomic, but molecules of hydrogen and chlorine diatomic? All of these questions can be answered by examining the formation of chemical bonds between atoms.

When two atoms come sufficiently close together, the electrons of each atom experience the additional attractive force of the nucleus in the other atom, the electrons repel each other, and the positively charged nuclei repel each other. A stable chemical bond between two atoms in the gas phase is formed only when the total energy of the resulting molecule is lower than that of the two isolated atoms. **Quantum mechanics**—the fundamental branch of physics that describes the properties, interactions, and motions of atomic and subatomic particles—is necessary to explain the re-distribution of electrons that leads to formation of chemical bonds between atoms.

Before the quantum explanation of bonding was available, chemists had developed a powerful set of concepts and tools based on classical mechanics—covalent bonds, ionic bonds, polar covalent bonds, electronegativity, Lewis electron dot diagrams, and valence shell electron-pair repulsion (VSEPR) theory—that rationalized a great deal of information about the structure of molecules and patterns of chemical reactivity. This set of concepts and tools constitutes the *classical description of the chemical bond*, and it is part of the daily vocabulary of every working chemist, especially in organic and biological chemistry. These tools are the foundation of chemical intuition, by which we mean the ability to explain and even predict chemical phenomena. Intuition is judgment informed by experience. Extensive practice in applying these tools to interpret factual information is essential to develop your own chemical intuition.

The classical theory of chemical bonding and molecular shapes starts with conceptual models of the chemical bond which can be understood on the basis of simple electrostatics—the forces between and energies of systems of stationary charged particles. Chemical bonds form by sharing or transferring electrons between atoms. Chemists generally identify two extreme cases. In a **covalent bond**, the electrons are shared more or less equally between the two atoms comprising the bond. In an **ionic bond**, one or more electrons is completely transferred from one atom to the other, and the dominant contribution to the strength of the bond is the electrostatic attraction between the resulting positive and negative ions. Although many real chemical bonds are well described by these idealized models, most bonds are neither completely ionic nor completely covalent and are best described as having a mixture of ionic and covalent character. In a **polar covalent bond**, a partial transfer of charge from one atom to the other occurs. **Electronegativity**, the tendency of an atom in a molecule to attract electrons from other atoms, explains whether a given pair of atoms forms an ionic, covalent, or polar covalent bond.

Two simple tools are used to implement the classical theory of bonding and structure. First, the **Lewis electron dot diagram** shows the number of **valence** (outermost) electrons associated with each atom in a molecule and indicates whether they are bonding (shared) or nonbonding. These diagrams are useful in predicting the structural formula—that is, which atoms are bonded to each other in polyatomic molecules—but they do not describe the three-dimensional shapes of molecules. Second, **VSEPR (valence shell electron pair repulsion) theory** predicts molecular shapes, based on the electrostatic argument that electron pairs in a molecule will arrange themselves to be as far apart as possible.

We start with a brief survey of the images used to represent molecular structure, then we describe the **periodic table**, a list of the elements arranged to display at a glance patterns of their physical properties and chemical reactivity. Relating bond formation between a pair of atoms to their positions in the periodic table reveals trends that build up chemical intuition. Next, we invoke Rutherford's planetary model of the atom and show how electrical forces control the gain or loss of electrons by the atom. We then examine the electrical forces within molecules and show how they lead to the ionic and covalent models of the chemical bond. The use of Lewis diagrams to describe bond formation and the VSEPR theory to describe molecular shapes complete the classical theory of bonding. We conclude with a brief survey of the procedures for assigning proper names to chemical compounds.

The foundations of classical bonding theory have been successfully explained by quantum mechanics. Today it is largely a matter of preference whether you first learn the classical theory and then gain deeper insight from the quantum explanations, or you first learn the quantum theory and then see the classical theory as a limiting case. We prefer to present the classical description first, and this chapter is devoted to that subject. That way, we establish the language and vocabulary of the chemical bond and allow you to become familiar with the

properties of a broad array of real molecules *before* attempting to explain these results using quantum mechanics in Chapters 4, 5, and 6. Your instructor may prefer the opposite sequence, in which case you will read Chapters 4 and 5 before this chapter. We wrote this textbook to accommodate either approach.

## 3.1 Representations of Molecules

We discussed the distinction between empirical and molecular formulas for compounds in Chapter 2 and introduced you to combustion analysis, a classical method for the determination of empirical formulas. Compounds may either be discrete molecules or extended solids. A **molecule** is a collection of atoms bonded together, with the elements in fixed proportions and with a (typically) well-defined three-dimensional structure. Molecules are stable in the gas phase and can be condensed to form liquids and solids while preserving their identities. Individual molecules of molecular liquids or solids can be uniquely identified; Figure 1.2 shows two water molecules outlined by closed lines that separate them from other water molecules. Molecules are characterized by their molecular formulas, which we discuss here. It is not possible, however, to identify a “molecule” in extended solids (see later in this section) and we can only characterize them by their empirical formulas.

The molecular formula specifies the number of atoms of each element present in one molecule of a compound. The molecular formula for glucose is  $C_6H_{12}O_6$ ; each molecule of glucose contains 6 atoms of carbon, 12 atoms of hydrogen, and 6 atoms of oxygen. The molecular formula is the starting point for predicting the existence of particular molecules, explaining their structures and shapes, and describing their reactions.

How do we determine a molecular formula? In order to prove that a substance is a compound, we must identify the elements present and confirm that the relative composition satisfies the law of definite proportions. Historically this proof was accomplished by combustion analysis but today is done primarily by mass spectrometry (see *Connection to Instrumental Analysis*). From this information we deduce the empirical formula, which lists the atoms present and gives their relative numbers. But the empirical formula alone does not uniquely describe a molecule. For example, the empirical formula  $CH_2O$  characterizes not only glucose  $C_6H_{12}O_6$  but also acetic acid  $C_2H_4O_2$  and formaldehyde  $CH_2O$ . To determine the molecular formula, we measure the molar mass of the compound under study from its gas-law behavior or by mass spectrometry. We take the ratio of that molar mass to the molar mass of the empirical formula, and obtain the molecular formula as a simple integral multiple of the empirical formula. (See Sections 2.1 and 2.2 for a more detailed discussion.)

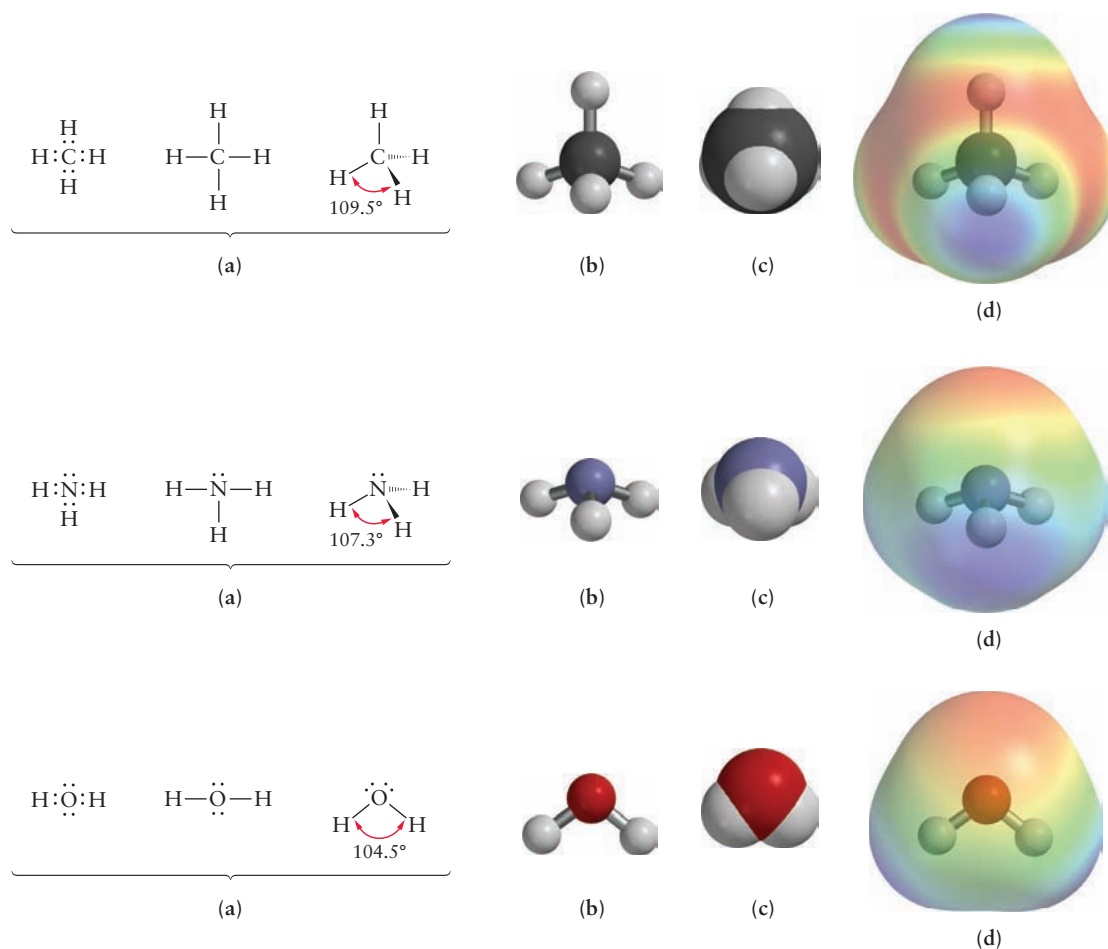

Once we have determined that a molecule has a specific and well-defined composition, with a known mass, we can begin to ask interesting and important questions about its behavior. For example, why does it contain only the particular numbers of atoms stated in its formula? How are these atoms held together in the molecule? What is the three-dimensional structure and the shape of the molecule? We study each of these questions in the chapters in Unit II.

The first step in understanding the properties of a molecule is to find its **condensed structural formula**, which specifies which atoms are bonded to each other and by what types of bonds. For example, the molecular formula for ethanol is  $C_2H_6O$  and its condensed structural formula is  $CH_3CH_2OH$ . The condensed structural formula tells us (by convention) that the two carbon atoms are bonded to one another, and that the second carbon atom is also bonded to the oxygen atom. Three hydrogen atoms are bonded to the first carbon atom, two hydrogen atoms are bonded to the second carbon atom, and one hydrogen atom is bonded to the oxygen atom. We also represent structural formulas as simple

two-dimensional line drawings, as shown in Figure 3.1a. We use the Lewis model to find structural formulas; this model defines each bond as a pair of electrons localized between two particular atoms and represents structural formulas using Lewis dot diagrams. Figure 3.1a shows examples of Lewis dot diagrams and their elaboration as two-dimensional simple line drawings for molecules with the condensed structural formulas  $\text{CH}_4$  (methane),  $\text{NH}_3$  (ammonia), and  $\text{H}_2\text{O}$  (water).

Despite its name, the structural formula fails to convey the detailed structure of a molecule as a three-dimensional object in space. For this purpose we use ball-and-stick models in which the balls represent the atoms and the sticks represent the bonds between them. The lengths of the bonds are represented by the lengths of the sticks and the bond angles are the angles between the sticks attached to particular spheres (see Figure 3.1b). Ball-and-stick figures can be drawn on paper or they can be constructed as three-dimensional structural models. In either case they provide a clear picture of the geometrical relationship between bonds at each atom, but they do not provide any detail about the sizes of the atoms. The bond lengths and bond angles represented in these structures can be measured experimentally, and they can be predicted at various levels of detail by the different theories of chemical bonding.

The shapes of molecules influence their behavior and function, especially the ease with which they can fit into various guest-host configurations important in biology and biochemistry. We describe the shapes of molecules by recognizing

**FIGURE 3.1** Different molecular representations of methane, ammonia, and water. (a) Lewis dot diagrams, line structures, and line angle representations. (b) Ball-and-stick models. (c) Space-filling models. (d) Electrostatic potential energy diagrams (elpots), shown, for clarity, over a larger volume than the space-filling models in (c).

that the positions of the atoms and the bonds define polyhedra or other shapes familiar to us from geometry. Frequently these shapes show a high degree of symmetry. Molecular shapes can be determined from experiment, and predicted by bonding theories.

Molecules have size, or volume, and occupy space due to the volume occupied by the electrons in the atoms of the molecule. This important property is represented by space-filling models, which show that the atoms have specific sizes that physically contact each other in molecules (see Fig. 3.1c). The images in that figure are constructed from computer calculations of the three-dimensional distribution of electron density around the molecule, made possible by quantum mechanical theories of chemical bonding.

The final representation we introduce to display molecular properties is the **electrostatic potential energy diagram** (sometimes called “elpot” diagram). This diagram displays the electrostatic potential energy that a small positive “test charge” would experience at every position on the electron density surface that defines the space-filling model. The results are displayed by color-coding the space-filling model to represent the local variations in electrostatic potential measured by the test charge (see Fig. 3.1d). Elpot diagrams give us a feel for the spatial distribution of electrons in molecules; these images are generated by computer calculations based on quantum mechanical theories of chemical bonding. The elpot diagrams are extremely helpful for evaluating the chemical reactivity of different sites on molecules.

We use all these representations throughout the chapters in Unit II as we develop the theoretical and experimental methods to explain the sizes, structures, and shapes of molecules. We encourage you to use them to develop the skill to visualize molecules as three-dimensional objects.

It frequently occurs that different compounds found in nature or in the laboratory have the same molecular formula but different molecular structures and therefore different properties. Such compounds, called **isomers**, are named and characterized independently. The structural formula, detailed molecular structure, and shape must be worked out for each isomer. The existence of isomers illustrates dramatically that the properties of compounds are determined by the structures of their molecules (see Fig. 3.2). Several different classes of isomeric

**FIGURE 3.2** Structures of the optical isomers of carvone. D-carvone is on the left and L-carvone is on the right. Their mirror images are not superimposable. D-carvone has the odor of spearmint oil and L-carvone has the odor of caraway and dill seed oil.

## CONNECTION TO INSTRUMENTAL ANALYSIS

## Mass Spectrometry

We introduced you to mass spectrometry in Section 1.4, in which we showed how atoms of different masses could be separated from each another on the basis of their mass-to-charge ratios. J. J. Thomson immediately recognized the potential of mass spectrometry for chemical analysis (J.J. Thomson, *Rays of Positive Electricity and their Application to Chemical Analyses* [London, New York: Longmans, Green and Co., 1913]) but it was not until commercial instruments became available in the 1950s that mass spectrometry began to be used routinely for that purpose. Modern mass spectrometry is undoubtedly our most important technique for the accurate determination of molecular masses but it also provides us with valuable information about chemical formulas and molecular structure, including, for example, the determination of the sequences of amino acids in proteins.

The schematic of a mass spectrometer shown in Figure 1.16 shows the three elements common to all mass spectrometers: a source region, a mass analyzer, and a detector. Modern instruments vary considerably in the means by which ions are produced and masses are analyzed, with specialized instruments having been designed for specific purposes. It is beyond the scope of this book to discuss these instruments in any detail so we introduce you to the basic elements, point out the special features of a couple of the most widely used specialized spectrometers, and introduce you to the interpretation of mass spectra. Mass spectrometers are operated under high to ultrahigh vacuum conditions to minimize contamination and to ensure that ions do not suffer collisions in the mass analyzer. Samples are introduced into the source by a variety of methods that depend upon their physical state and vapor pressure; the gases are ionized and enter the mass analyzer, which separates them spatially. The ion current is measured by a detector that can count single ions and the mass spectrum produced is a plot of the ion current versus the mass-to-charge ratio  $m/z$ . (In mass spectrometry, the ratio  $m/z$  is calculated by dividing the mass  $m$  of the ion in atomic mass units by  $z$ , an integer corresponding to the total charge on the species divided by  $e = 1.602 \times 10^{-19}$  C.) We introduce you to three different ionization methods and two different levels of mass resolution, the kinds of analyses for which each of these methods are used, and how the resulting spectra are interpreted.

### Ionization Methods

Electron impact (EI) ionization has historically been the most important ionization method in which electrons

emitted from a hot filament are accelerated to give them sufficient kinetic energy to ionize molecules in the source. 70 eV has been chosen as the standard kinetic energy because it is sufficiently high to ionize any molecule and also because it provides enough excess kinetic energy to cause fragmentation, which provides important information about molecular structure. Fragmentation patterns at specified ionization energies are characteristic of a particular molecule, enabling the identification of unknowns in a mixture (after separation by gas chromatography, see Figure 14.17) by comparing their spectra with those in mass spectral databases. It is often desirable, on the other hand, to use soft ionization techniques to prevent fragmentation and to ensure that the parent molecular ion dominates the mass spectrum. Matrix-assisted laser desorption ionization (MALDI) is among the most popular and powerful of the soft ionization techniques because of its ability to handle molecules with large molar masses and provide high mass resolution. Compounds of interest (the analyte) are dissolved in a solution that also contains molecules that absorb laser radiation of a particular wavelength (the matrix). Evaporating the solvent leaves the analyte trapped in the solid matrix, which is then introduced into the mass spectrometer. A pulsed laser deposits energy into the matrix, ionizing and ejecting the analyte into the gas phase, with the singly charged parent molecular ion dominating. Electrospray (ES) ionization is particularly useful for analyzing high molecular weight polymers, including biological macromolecules such as proteins and nucleic acids. A solution containing the analyte is sprayed through a pair of coaxial needles with a large voltage difference between them. The solvent evaporates, producing charged analytes that enter the mass analyzer.

### Mass Resolution

Mass analyzers are generally classified into two broad categories based upon their mass resolution: low-resolution instruments generally require that two masses differ by more than 0.1% to be separated whereas high-resolution instruments are capable of mass resolution of one part in  $10^4$  or better. Low-resolution instruments are generally used for the identification of compounds in mixtures by comparison to standard reference spectra, or to determine the chemical formulas and molecular structures of newly synthesized compounds. The low-resolution EI mass spectrum of the neurotransmitter dopamine is shown in Figure C3.1.

The most intense (base) peak, from a fragment of the molecular ion, appears at  $m/z = 124$ , with a relative abundance of 100. The fragmentation mechanism that

**FIGURE C3.1** Low-resolution EI mass spectrum of dopamine. (Adapted from *Organic Chemistry* 5th ed. W. H. Brown, C. S. Foote, B. L. Iverson, and E. Anslyn. Brooks Cole/Cengage, 2009, Chapter 14, Figure 14.2, p. 523.)

produces this ion is hard to explain but the peak at 123 amu is easy to explain; it is due to the loss of the  $\text{CH}_2\text{NH}_2$  group. Characteristic losses like these are used to help identify molecular structures. The spectra of linear alkanes (see Section 7.2), for example, have a series of peaks separated by 14 amu due to the loss of  $\text{CH}_2$  groups. Common fragmentation patterns for cyclic alkanes include the loss of side groups, for example methyl at 15 amu, and the elimination of  $\text{CH}_2\text{CH}_2$  groups as ethylene, producing a peak at  $M - 28$ , where  $M$  is the mass of the molecular ion. A common fragmentation mechanism for alcohols (see Section 7.6) is the elimination of water to produce an  $M - 18$  peak. Finally, the mass spectra of molecules with  $\pi$  bonds often show prominent molecular ion peaks because the bond in the resulting ion is still quite strong and the molecular ion quite stable.

The electrospray mass spectrum of a small polypeptide (see Section 7.6) is shown in Figure C3.2. Note the simplicity of this spectrum compared with that of dopamine; much less fragmentation is observed. Polypeptides

typically fragment by cleaving peptide bonds as shown by the dashed lines in the figure. The peak at  $M - 17$  is due to the loss of either  $-\text{OH}$  or  $-\text{NH}_3$  and the peaks at lower masses arise from cleavage of one or more peptide bonds. The  $M + 1$  and  $M + 23$  peaks arise from proton or sodium ion attachment.

High-resolution mass spectrometry provides not only accurate molecular weights but, perhaps more importantly, molecular formulas. The molecules  $\text{CO}$ ,  $\text{N}_2$ ,  $\text{CH}_2\text{N}$  and  $\text{C}_2\text{H}_4$  all have nominal masses of 28 amu and are indistinguishable at low resolution. The precise masses of  $^{12}\text{C}^{16}\text{O}$ ,  $^{14}\text{N}_2$ ,  $^{12}\text{C}^{1}\text{H}_2^{14}\text{N}$  and  $^{12}\text{C}_2^{1}\text{H}_4$  (see Table 19.1) are actually 27.9949, 28.0062, 28.0187 and 28.0312 amu, respectively, are readily separated at high resolution (1 part per  $10^4 - 10^6$  is common). More complicated molecules have significantly more possibilities than this but measuring exact masses alone at high resolution is sufficient to determine molecular formulas uniquely, supplanting chemical methods such as combustion analysis (see Figure 2.2) which is now used primarily to establish the purity of newly synthesized compounds.

compounds appear in organic, inorganic, and biological chemistry where an appreciation of the three-dimensional structures of molecules is essential for explaining the behavior of compounds.

The representations just described are appropriate for compounds formed by covalent bonding primarily between non-metallic elements. These compounds have discrete molecules which are stable in the gas phase. These gaseous molecules can be condensed to liquids and sometimes also into solids while maintaining their identities.

By contrast, ionic bonding between metallic and non-metallic atoms produces extended solid-state ionic compounds, which exist at room temperature, in which each ion is surrounded by a group of ions of opposite charge. The formula unit (see Section 2.1) of such a solid reflects the composition given by the empirical formula for the solid. The formula unit is also the smallest collection of ions that is electrically neutral. Thus solid sodium chloride contains not “a molecule of NaCl” but rather a formula unit of NaCl. Similarly, solid silicon dioxide contains a formula unit of  $\text{SiO}_2$  (see Fig. 3.3).

## 3.2 The Periodic Table

The number of known chemical compounds is already huge, and it continues to increase rapidly as the result of significant investments in chemical research. An unlimited number of chemical reactions are available among these compounds. The resultant body of chemical knowledge, viewed as a collection of facts, is overwhelming in its size, range, and complexity. It has been made manageable by the observation that the properties of the elements naturally display certain regularities. These regularities enable the classification of the elements into families whose members have similar chemical and physical properties. When the elements are arranged in order of increasing atomic number,  $Z$ , remarkable patterns emerge. Families of elements with similar chemical properties are easily identified by their locations in this arrangement. This discovery is summarized concisely by the **periodic law**:

*The chemical properties of the elements are periodic functions of the atomic number  $Z$ .*

Consequently, the elements listed in order of increasing  $Z$  can be arranged in a chart called the periodic table, which displays, at a glance, the patterns of chemical similarity. The periodic table then permits systematic classification, interpretation, and prediction of all chemical information.

The modern periodic table (Fig. 3.4 and the inside front cover of this book) places elements in both a **group** (arranged vertically) and a **period** (arranged horizontally).

There are eight groups of **representative elements**, or “main-group” elements. In addition to the representative elements, there are ten groups (and three periods) of **transition-metal elements**, a period of elements with atomic numbers 57 through 71 called the rare-earth or **lanthanide elements**, and a period of elements from atomic numbers 89 through 103 called the **actinide elements**, all of which are unstable and most of which must be produced artificially. The lanthanide and actinide elements are usually placed below the rest of the table to conserve space. The groups of representative elements are numbered (using Roman numerals) from I to VIII, with the letter A sometimes added to differentiate them from the transition-metal groups, which are labeled from IB to VIIIB. This book uses group numbers exclusively for the representative elements (dropping the A) and refers to the transition-metal elements by the first element in the corresponding group. For example, the

**FIGURE 3.4** The modern periodic table of the elements. Below each symbol is the year in which that element was discovered; elements with no dates have been known since ancient times. Above each symbol is the atomic number. The color coding indicates the relative abundance by mass of the elements in the world (the atmosphere, oceans and fresh water bodies, and the Earth's crust to a depth of 40 km). Oxygen alone comprises almost 50% of the mass, and silicon comprises more than 25%.

elements in the carbon group (C, Si, Ge, Sn, Pb) are designated as Group IV, and the elements chromium (Cr), molybdenum (Mo), and tungsten (W) as the chromium group.<sup>1</sup>

### 3.2.1 Survey of Physical and Chemical Properties: The Representative Elements

Lothar Meyer and Dmitri Mendeleev independently and simultaneously organized the elements into tables based on their atomic weights. Meyer was more interested in the periodic variation in the physical properties of the elements, whereas Mendeleev was more interested in patterns of chemical reactivity. Therefore, most chemists consider Mendeleev to be responsible for the creation of the modern periodic table.

<sup>1</sup>We do not use the group numbers 1-18 recommended by the International Union of Pure and Applied Chemistry in their 1990 publication *Nomenclature of Inorganic Chemistry IUPAC Recommendations 1990*. An update of this reference (also called the Red Book) was published in 2005.

The elements have been classified empirically based on similarities in their physical or chemical properties. **Metals** and **nonmetals** are distinguished by the presence (or absence) of a characteristic metallic luster, good (or poor) ability to conduct electricity and heat, and malleability (or brittleness). Certain elements (boron, silicon, germanium, arsenic, antimony, and tellurium) resemble metals in some respects and nonmetals in others, and are therefore called **metalloids** (or sometimes **semimetals**). Their ability to conduct electricity, for example, is much worse than metals, but is not essentially zero like the nonmetals.

The empirical formulas of the binary compounds formed by the elements with chlorine (their *chlorides*), with oxygen (their *oxides*), and with hydrogen (their *hydrides*) show distinct periodic trends.

Group I, the **alkali metals** (lithium, sodium, potassium, rubidium, and cesium), are all relatively soft metals with low melting points that form 1:1 compounds with chlorine, with chemical formulas such as NaCl and RbCl. The alkali metals react with water to liberate hydrogen; potassium, rubidium, and cesium liberate enough heat upon reaction to ignite the hydrogen. Group II, the **alkaline-earth metals** (beryllium, magnesium, calcium, strontium, barium, and radium), react in a 1:2 atomic ratio with chlorine, producing compounds such as MgCl<sub>2</sub> and CaCl<sub>2</sub>.

Of the nonmetallic elements, Group VI, the **chalcogen elements** (oxygen, sulfur, selenium, and tellurium), forms 1:1 compounds with the alkaline-earth metals (such as CaO and BaS) but 2:1 compounds with the alkali metals (such as Li<sub>2</sub>O and Na<sub>2</sub>S). Members of Group VII, the **halogen elements** (fluorine, chlorine, bromine, and iodine), differ significantly in their physical properties (fluorine and chlorine are gases at room temperature, bromine is a liquid, and iodine a solid), but their chemical properties are similar. Any alkali metal will combine with any halogen in 1:1 proportion to form a compound such as LiF or RbI, which is called an **alkali halide**.

The remaining elements fall into three additional groups whose chemical and physical properties are somewhat less clearly delineated than those already discussed. Group III includes a metalloid (boron) and four metals (aluminum, gallium, indium, and thallium). The metals form 1:3 chlorides (such as GaCl<sub>3</sub>) and 2:3 oxides (such as Al<sub>2</sub>O<sub>3</sub>). Group IV comprises the elements carbon, silicon, germanium, tin, and lead. All of these elements form 1:4 chlorides (such as SiCl<sub>4</sub>), 1:4 hydrides (such as GeH<sub>4</sub>), and 1:2 oxides (such as SnO<sub>2</sub>). Tin and lead are metals with low melting points, and silicon and germanium are **semiconductors**. Although we classified silicon and germanium as metalloids earlier, their electrical properties can be finely tuned by incorporating small amounts of impurities. These two elements form the basis for the modern semiconductor industry, which manufactures computer chips and other solid-state devices. Several different allotropes of elemental carbon exist (for example, graphite, diamond, and the recently discovered fullerenes). *Allotropes* are modifications of an element with differing atomic arrangements that lead to different physical and chemical properties. For example, ozone (O<sub>3</sub>) and ordinary diatomic oxygen (O<sub>2</sub>) are also allotropes. Group V includes nitrogen, phosphorus, arsenic, antimony, and bismuth. These elements form binary compounds with hydrogen and oxygen that have empirical formulas such as PH<sub>3</sub> and N<sub>2</sub>O<sub>5</sub>. The hydrides become increasingly unstable as their molar masses increase, and BiH<sub>3</sub> is stable only below 45°C. A similar trend exists for the oxides, and Bi<sub>2</sub>O<sub>3</sub> has never been obtained in pure form. The lighter members of this group are clearly nonmetals (nitrogen and phosphorus), bismuth is clearly a metal, and arsenic and antimony are classified as semimetals.

Group VIII, the **noble gases** (helium, neon, argon, krypton, xenon, and radon), are sometimes called the **inert gases** because of their relative inertness toward chemical combination. They are all monatomic, in contrast with the other elements that exist as gases at room temperature and atmospheric

pressure (hydrogen, oxygen, nitrogen, fluorine, chlorine), which are diatomic molecules.

Systematic trends in both the physical and chemical properties of the elements give important clues as to the structure of the atom. In addition to the properties that distinguish metals from nonmetals (electrical and thermal conductivity, malleability, luster, and ductility), there are a number of other physical properties that show clear periodic trends; these properties include melting and boiling points, densities, atomic sizes, and the energy changes that occur when an electron is added to or removed from a neutral atom. Numerical values for most of these properties are tabulated in Appendix F. In general, the elements on the left side of the table (especially in the later periods) are metallic solids and good conductors of electricity. On the right side (especially in earlier periods), they are poor conductors of electricity and are generally gases at room temperature and atmospheric pressure. The semimetals occupy a region of the periodic table located between the metals and the nonmetals that is represented by a diagonal band (see the inside front cover of this textbook).

Patterns in chemical reactivity of the elements correlate with patterns in the physical structure of the atom; they are both periodic functions of  $Z$ . Reading across the periodic table (horizontally) shows that each main-group element (Groups I-VIII) in Period 3 has exactly 8 more electrons than the element immediately above it in Period 2. Similarly, each main-group element in Periods 4 and 5 has exactly 18 more electrons than the corresponding element in the period above. The sequence of numbers, 8, 8, 18, 18, and so forth, that organize the periodic table into groups (columns), whose elements have similar physical and chemical properties, arises from the quantum theory of atomic structure (see discussion in Chapter 5).

### 3.3 Forces and Potential Energy in Atoms

The atom arose in the domain of chemistry, its existence inferred indirectly from the laws of chemical combination. Beginning with the work of Thomson and Rutherford, understanding the atom also fell within the province of physics, which sought to explain its structure and behavior as consequences of the electrical forces between the electrons and the nucleus. Modern chemistry combines these themes to explain chemical behavior in terms of the electrical forces within the atom. The purpose of this section is to give you an appreciation for the nature and magnitudes of these forces, and the associated potential energy, in preparation for your studies of chemical bond formation. It is essential that you understand and learn to use potential energy diagrams for atoms. We suggest that you review the background material on force, work, potential energy, potential energy diagrams, and electricity and magnetism in Appendix B.2 before continuing to study this section. Appendix C.7 gives an introduction to vectors.

Rutherford's planetary model describes the atom as a dense, central nucleus of positive charge  $+Ze$  surrounded by a total of  $Z$  electrons, each in motion like the planets around the sun. The attractive force between each electron and the nucleus, and the repulsive force between each pair of the electrons, are all determined by Coulomb's law. Figure 3.5 shows an example of an atom with just one electron; the vector  $\vec{r}$  points from the nucleus to the instantaneous position of the electron. The distance from the nucleus to the electron is the length of the vector  $\vec{r}$ , which we will denote as  $r$  without the over-arrow. (Mathematics texts would give the symbol  $\|\vec{r}\|$  for the length, or norm, and denote the vector by bolding it.)

Looking at Figure 3.5, when the electron is at the top of the circular orbit the velocity  $\vec{v}$  is in the  $+x$  direction ( $\vec{v} = (v_x, v_y) = (v_x, 0)$ , where  $v_x = dx/dt$  is positive at this point in the orbit) and the force attracting the electron is

**FIGURE 3.5** An electron, with charge  $-e$ , undergoing a clockwise circular orbit around a nucleus with charge  $+Ze$ . The red arrows show the force that the electron feels at each point in its trajectory; the force felt by the electron changes direction as the electron moves from one position to the next (four positions on the circular orbit are shown), but the force felt by the electron always points toward the nucleus. The velocity vector (blue) is always tangent to the circular orbit.

downward, in the  $-y$  direction. Thus the force  $\vec{F}$  does not slow the electron down, it changes the *direction* of the velocity. When the electron reaches the point in the circular orbit at about  $20^\circ$ , you can see that the attractive force has tilted the velocity vector downward, so it now has a velocity vector with a negative component  $v_y$ , but the speed of the electron has not changed. The kinetic energy of the electron,  $\frac{1}{2}mv^2$ , is thus constant as the electron orbits around the nucleus. The force  $\vec{F}$  (shown by the red vectors in Figure 3.5) always points from the electron to the nucleus because the electrostatic potential energy is lower when two particles with opposite charges (one positive and one negative) get closer to each other. Thus the Coulomb force  $\vec{F}$  on the electron, always attracted to the nucleus, points in the opposite direction of  $\vec{r}$ , the vector from the nucleus to the electron.

In general, for two particles, one with charge  $q_1$  and the other with charge  $q_2$ , separated by distance  $r$ , the electrostatic potential energy given by Coulomb's law is

$$V(r) = \frac{q_1 q_2}{4\pi\epsilon_0 r} \quad [3.1]$$

where  $\epsilon_0$ , called the *permittivity of vacuum*, is a proportionality constant with a numerical value of  $8.854 \times 10^{-12} \text{ C}^2 \text{ J}^{-1} \text{ m}^{-1}$  in the International System of Units (SI) described in Appendix B.1. Charge is measured in coulombs (C), distance in meters (m), and force in newtons (N). By convention,  $V(r) \rightarrow 0$  as  $r \rightarrow \infty$ . This is a logical choice for the zero of potential energy because there is no interaction between the particles at such large distances. If the charges have the same sign, the potential energy, as expressed by Equation 3.1, is positive and it decreases as  $r$  increases. Thus  $dV/dr$  is negative if the two charges have the same sign, and the potential energy decreases if the charged particles move farther away from each other. (Like a bicycle that starts at the top of a hill [high potential energy] with zero kinetic energy and then rolls downhill, if you hold two protons close to each other and then let them loose, they will repel each other and start moving away from each other, gaining kinetic energy as the distance between them increases and the potential energy decreases.) The upper curve in Figure 3.6, a calculation using Equation 3.1 of the potential energy between two protons as a function of the distance  $r$  between them, shows that the potential energy  $V(r)$  decreases when the distance between the protons increases. But what about a proton, with charge  $+e$  and an electron with charge  $-e$ ? These two charges have opposite signs, so using Equation 3.1, the potential energy is negative when the electron is near the proton (your bicycle is in a deep

**FIGURE 3.6** Potential energy curves for pairs of charged particles interacting according to Coulomb's law.

hole or “potential energy well”!) and it increases (becomes less negative) as  $r$  increases. Thus for an electron interacting with a proton,  $dV/dr$  is positive; the potential energy gets higher (less negative) as you try to move an electron farther from the proton. This is a reflection of the fact that the electron feels an attractive force from the proton.

Typical distances between nuclei and electrons in atoms are about  $10^{-10}$  m. Figure 3.6 thus gives the distance between the charged particles in a distance unit called an angstrom ( $\text{\AA}$ ), where  $1 \text{\AA} = 10^{-10}$  m. The potential energy of the hydrogen atom ( $Z = 1$ ) when the proton and electron are separated by  $1 \text{\AA}$  is

$$\begin{aligned} V(1\text{\AA}) &= -\frac{(1.602 \times 10^{-19} \text{ C})^2}{4\pi(8.854 \times 10^{-12} \text{ C}^2 \text{ J}^{-1} \text{ m}^{-1})(1 \times 10^{-10} \text{ m})} & [3.2] \\ &= -\frac{(8.988 \times 10^9)(1.602 \times 10^{-19})^2}{(1 \times 10^{-10})} \text{ J} \\ V(1\text{\AA}) &= -2.307 \times 10^{-18} \text{ J} \end{aligned}$$

Energy values in this range appear in many branches of science because of the small quantities of electrical charge found in individual atoms and molecules, so it is convenient to define a new energy unit for these applications. An **electron volt** (eV) is the kinetic energy gained by an electron when it is accelerated through a potential difference of magnitude 1 volt (V), where  $1 \text{ V} = 1 \text{ J/C}$ . Thus  $1 \text{ eV} = (1.602177 \times 10^{-19} \text{ C})(1 \text{ V}) = 1.602177 \times 10^{-19} \text{ J}$ . Using this conversion factor between joules and electron volts, the potential energy of a proton and electron separated by  $1 \text{\AA}$  in a hydrogen atom is  $-2.307 \times 10^{-18} \text{ J} = -14.40 \text{ eV}$ . This is the energy unit used on the vertical axis in Figure 3.6. The potential energy scale is defined so that  $V(r) \rightarrow 0$  as  $r \rightarrow \infty$ , where the particles do not interact with one another. (If you need to define the potential energy at large  $r$  as other than zero, as we do later in this chapter when considering the Coulomb interaction between  $\text{K}^+$  and  $\text{F}^-$ , you need only add the appropriate energy offset to the expression in Equation 3.1.) Figure 3.6 also shows the potential energy function for an electron interacting with a lithium nucleus ( $Z = 3$ ); at the same distance  $r$  the potential energy is lower because the attractive forces between the electron and the Li nucleus as they were approaching each other were stronger. Using Equation 3.1, the electrostatic potential energy between a nucleus of charge  $+Ze$  and an electron (charge  $-e$ ) is

$$V(r) = -\frac{Ze^2}{4\pi\epsilon_0 r} \quad [3.3]$$

Once we know the potential energy function  $V(r)$ , we can use it to predict the motions of the particles. The direction of the force exerted by one particle on another, either attractive or repulsive, is determined by the slope (the derivative) of the potential energy function with respect to the distance between the two particles (see Appendix B.2). If  $\frac{dV}{dr}$  is positive at a particular distance  $r$  between the two particles, the two particles have an attractive force between them, and if  $\frac{dV}{dr}$  is negative, the two particles have a repulsive force between them. The resulting equations are particularly simple if the particle exerting the force is at the origin of your coordinate system, as in Figure 3.5, and the vector  $\vec{r}$  points from the origin to the particle experiencing the force. However this will not generally be the case—even diatomic molecules have two nuclei and many electrons, all of which are experiencing Coulomb forces. So let's consider how to calculate the force on both particles involved, where particle number 1 is at the position given by  $\vec{r}_1 = (x_1, y_1, z_1)$  and particle number 2 is at the position given by  $\vec{r}_2 = (x_2, y_2, z_2)$ . The relationship between the force  $\vec{F}_2$  on the electron (calling the electron particle number 2 and calling the nucleus with charge  $+Ze$  particle number 1) is given by

$$\vec{F}_2(r) = -\frac{dV}{dr} \hat{r}_{12} = -\frac{d\left(\frac{q_1 q_2}{4\pi\epsilon_0 r}\right)}{dr} \hat{r}_{12} = -\frac{d\left(\frac{(+Ze)(-e)}{4\pi\epsilon_0 r}\right)}{dr} \hat{r}_{12} = -\frac{Ze^2}{4\pi\epsilon_0 r^2} \hat{r}_{12} \quad [3.4]$$

where  $\vec{r}_{12} = \vec{r}_2 - \vec{r}_1$  is the vector pointing from particle 1 to particle 2 and  $\hat{r}_{12}$  is the unit vector pointing the same direction ( $\hat{r}_{12} = \vec{r}_{12}/r_{12}$ ). Thus when  $dV/dr$  is positive (the potential energy increases if the two particles move farther from each other), as it is for an electron and a proton, the force on the electron is in the opposite direction as the vector pointing from the proton to the electron. (You can see this clearly in Figure 3.5; the red force vector  $\vec{F}$  on the electron is opposite in direction to the vector pointing from the positively charged nucleus to the electron.) Note that if you wish to calculate the force on the proton, particle 1, it is just  $\vec{F}_1(r) = -\frac{dV}{dr} \hat{r}_{21}$ , but now the unit vector  $\hat{r}_{21} (= -\hat{r}_{12})$  is pointing from the electron to the proton, so  $\vec{F}_2(r) = -\vec{F}_1(r)$  and you recover Newton's second law. Here the magnitude of both  $\vec{r}_{12} = \vec{r}_2 - \vec{r}_1$  and  $\vec{r}_{21} = \vec{r}_1 - \vec{r}_2$  is given simply as the distance  $r$ , but in equations later in this chapter, when we have several particles, we'll be careful to put subscripts on the distance  $r$  to indicate the two particles it is a distance between.

### EXAMPLE 3.1

Assume in Figure 3.6 that some sort of clamp is applied to hold an electron fixed at the distance of  $2.5 \text{ \AA}$  from a lithium nucleus  $\text{Li}^{3+}$ , which is also clamped in its position.

- Calculate the potential energy of the system of these two fixed particles.
- If the lithium atom is at the coordinates  $(x_1, y_1) = (1.5 \text{ \AA}, 0 \text{ \AA})$  and the electron is located at  $(x_2, y_2) = (-1.0 \text{ \AA}, 0)$ , calculate the direction of the force  $\vec{F}_2$  on the electron by giving its components  $F_x$  and  $F_y$ . Does the electron move toward or away from the nucleus? Is the force attractive or repulsive? Then calculate the force  $\vec{F}_1$  on the nucleus and give its magnitude.
- Make a plot like Figure 3.5 to show the position of the electron and the position of the nucleus, and superimpose on your plot the vector force  $\vec{F}_2$  on the electron as we did for the electron in Figure 3.5. Also show the vector force  $\vec{F}_1$  on the nucleus.

(Continued)

**Solution**

(a) We use Equation 3.1 or Equation 3.3 to calculate the potential energy as follows:

$$\begin{aligned} V(2.5 \text{ \AA}) &= \frac{(+3e)(-e)}{4\pi(8.854 \times 10^{-12} \text{ C}^2 \text{ J}^{-1} \text{ m}^{-1})(2.5 \times 10^{-10} \text{ m})} \\ &= -\frac{3(1.602 \times 10^{-19} \text{ C})^2}{(2.782 \times 10^{-20} \text{ C}^2 \text{ J}^{-1})} \end{aligned}$$

$$V(2.5 \text{ \AA}) = -2.768 \times 10^{-18} \text{ J} = -17.28 \text{ eV}$$

The potential energy at 2.5 Å is negative (i.e., lower than the value at infinite separation) because these oppositely charged particles attract one another.

(b) First calculate  $\vec{r}_{12}$ , the vector pointing from particle number 1, the  $\text{Li}^{3+}$  nucleus, to particle number 2, the electron.  $\vec{r}_{12} = \vec{r}_2 - \vec{r}_1 = (-1 \text{ \AA}, 0) - (1.5 \text{ \AA}, 0 \text{ \AA}) = (-2.5 \text{ \AA}, 0 \text{ \AA})$ . The magnitude of  $\vec{r}_{12} = \sqrt{(-2.5)^2 + (0)^2} \text{ \AA} = 2.5 \text{ \AA}$ , so the distance between the two particles,  $r$ , is 2.5 Å. The unit vector  $\hat{r}_{12} = (-2.5 \text{ \AA}, 0 \text{ \AA})/2.5 \text{ \AA} = (-1, 0)$ , so this vector is indeed a unit vector pointing from the  $\text{Li}^{3+}$  nucleus toward the electron. Using the expression for Coulomb's law in Equation 3.4 to calculate the force on particle number 2, the electron (exerted by particle number 1, the  $\text{Li}^{3+}$  nucleus).

$$\begin{aligned} \vec{F}_2 &= \frac{(+3e)(-e)}{4\pi(8.854 \times 10^{-12} \text{ C}^2 \text{ J}^{-1} \text{ m}^{-1})(2.5 \times 10^{-10} \text{ m})^2}(-1, 0) \\ &= \left( -\frac{3(1.602 \times 10^{-19})^2}{(1.113 \times 10^{-10})(2.5 \times 10^{-10})^2} \text{ J m}^{-1} \right)(-1, 0) \end{aligned}$$

$$\vec{F}_2(2.5 \text{ \AA}) = (-1.1 \times 10^{-8} \text{ N})(-1, 0) = (1.1 \times 10^{-8} \text{ N}, 0 \text{ N})$$

The SI unit of force is the **newton** (N);  $1 \text{ N} = 1 \text{ kg m s}^{-2} = 1 \text{ J m}^{-1}$ . The  $x$ -component of the force,  $F_x = 1.1 \times 10^{-8} \text{ N}$ , so the force on the electron is in the  $+x$  direction, toward the nucleus. The electron is attracted toward the nucleus. This force accelerates the electron in the  $+x$  direction, as  $F_x = m_e a_x = m_e dv_x/dt$ . The  $y$ -component of the force,  $F_y$ , is 0 N. The force on the nucleus is  $\vec{F}_1 = -\vec{F}_2$ , so  $\vec{F}_1 = (-1.1 \times 10^{-8} \text{ N}, 0 \text{ N})$ . The nucleus thus feels a force in the  $-x$  direction, and so would be accelerated toward the electron, but its mass is more than 10,000 times the mass of an electron, so it barely moves. For both particles the force is attractive (see Figure 3.7), because the slope of the potential energy curve in Figure 3.6,  $dV/dr$ , is positive at all values of  $r$  for oppositely charged particles.

(c) See Figure 3.7. The positions of the electron and the  $\text{Li}^{3+}$  nucleus given in the problem are plotted on the  $x$ -axis, and the force on the electron  $\vec{F}_2$  is shown in red while the force on the nucleus,  $\vec{F}_1$ , is shown in green. Because we are superimposing force in newtons on a coordinate system that shows positions of the particles in distance units (Å), the lengths of the force vectors shown are arbitrary. The directions are important, however, as is the fact that the magnitude of  $\vec{F}_1$  is equal to the magnitude of  $\vec{F}_2$ ,  $1.1 \times 10^{-8} \text{ N}$ .

**Related Problems: 5, 6, 7, 8**

**FIGURE 3.7** An electron at the location  $(x_2, y_2) = (-1.0 \text{ \AA}, 0 \text{ \AA})$  experiencing a force  $\vec{F}_2$  (red vector) due to the electrostatic attraction to the  $\text{Li}^{3+}$  nucleus, with charge  $+3e$ , located at the point  $(x_1, y_1) = (1.5 \text{ \AA}, 0 \text{ \AA})$ . The force the electron feels (red vector) is equal in magnitude to, but opposite in direction to, the force  $\vec{F}_1$  that the nucleus feels (green vector).

**FIGURE 3.8** Potential energy curve for  $\text{He}^{2+}$  ions interacting with  $\text{Au}^{79+}$  ions. The initial kinetic energy of the alpha particles is 200 eV. The vertical arrows represent their decreasing kinetic energy as the alpha particles are slowed by repulsive force.

We can use the inset in Figure 3.6 to describe Rutherford's experiment (see Section 1.4) if we make the approximation that the alpha particles,  $\text{He}^{2+}$  collide with bare  $\text{Au}^{79+}$  nuclei in the gold foil, thus neglecting the electrons in the gold atoms. Imagine that we aim a beam of alpha particles at the foil, each particle moving with kinetic energy of 200 eV. With the stated approximation, we can represent one of these incoming alpha particles by drawing a solid line on the inset across the energy graph at the value +200 eV (see Figure 3.8).

In Figure 3.8, the red line represents the total energy of the alpha particle, because at infinite distance from the foil all of the energy of the particle is kinetic energy. As the alpha particle comes closer to the foil, it will lose some of its kinetic energy because the repulsive Coulomb force exerted by a gold nucleus slows down the particle. The particle has to give up some of its energy to overcome the repulsive force from the gold nuclei and keep moving toward the foil. If you think of an alpha particle moving directly toward a single gold nucleus, at any position along the  $r$ -axis the kinetic energy of the alpha particle is the difference between 200 eV and the value of the potential energy at that point: kinetic energy  $\mathcal{T}$  at distance  $r = 200 \text{ eV} - V(r)$ . We can represent the changes in the kinetic energy of the alpha particle by drawing a series of vertical arrows from the potential energy curve to the horizontal red line at total  $E = 200 \text{ eV}$  at several different positions for the alpha particle. These arrows become progressively shorter as the alpha particle comes closer to the gold nucleus, because the particle is slowed more and more. Somewhere near 12 Å, the potential energy curve intersects the line for 200 eV. At this point the kinetic energy goes to zero, the alpha particle stops, turns around, and heads back away from the foil because of the repulsive force exerted by the gold nucleus. The position where the particle stops is called the *turning point*, and its value can be calculated by setting the potential energy equal to 200 eV. If we do this experiment again with higher kinetic-energy alpha particles, the turning point gets closer to the gold nucleus. In Rutherford's experiment, the kinetic energy of the alpha particles was  $2.0 \times 10^6 \text{ eV}$ , abbreviated as 2.0 MeV. Example 3.2 calculates the turning point in Rutherford's experiment to get some sense of how close his alpha particle could get to a gold nucleus if it was initially headed straight toward that nucleus. (If the alpha particle were not headed straight toward the nucleus, but instead underwent a glancing collision, its trajectory would be a curved one; the speed would never become zero, but it would be deflected.)

### EXAMPLE 3.2

Calculate the turning point of an alpha particle ( $Z = 2$ ) directed with initial kinetic energy of 2.0 MeV, if the trajectory of the alpha particle was headed directly toward a single gold nucleus ( $Z = 79$ ) (the nuclei in the gold foil in Rutherford's experiment). How close could the alpha particle in Rutherford's experiment get to the center of a gold nucleus?

#### Solution

At the turning point  $r_{\text{tp}}$  the alpha particle stops for an instant before it turns back. Total energy is conserved, so if the total energy of the two particles when they were far apart was Kinetic Energy + Potential Energy = 20 MeV + 0 MeV (since  $V(r)$  is zero for large  $r$ ), then at the separation  $r_{\text{tp}}$ , the kinetic energy of the alpha particle is equal to zero, so the total energy, 20 MeV = 0 +  $V(r_{\text{tp}})$ . Thus  $V(r_{\text{tp}}) = 20 \text{ MeV}$ ; all of the initial alpha particle's kinetic energy has been converted to potential energy at  $r = r_{\text{tp}}$ . (Here we assume that the gold nucleus is so much more massive than the alpha particle that we can assume it does not move; in reality the equation below is

(Continued)

only correct if the initial kinetic energy were the relative kinetic energy (see Chapter 18.) From Equation 3.1 we obtain the relation  $V(r_{\text{tp}}) = \frac{q_1 q_2}{4\pi\epsilon_0 r_{\text{tp}}} = 20 \text{ MeV}$ .

Solving this for  $r_{\text{tp}}$  and substituting  $q_1 = +2e$  and  $q_2 = +79e$  gives

$$r_{\text{tp}} = \frac{(+2e)(+79e)}{4\pi(8.854 \times 10^{-12} \text{ C}^2 \text{ J}^{-1} \text{ m}^{-1})(2.0 \times 10^6 \text{ eV})}$$

$$r_{\text{tp}} = \frac{(2)(79)(1.602 \times 10^{-19})^2 \text{ J m}}{(1.114 \times 10^{-10})(2.0 \times 10^6 \text{ eV})(1.602 \times 10^{-19} \text{ J eV}^{-1})}$$

$$r_{\text{tp}} = 11.4 \times 10^{-14} \text{ m} = 11.4 \times 10^{-12} \text{ cm} = 11.4 \times 10^{-4} \text{ \AA}$$

The initial kinetic energy was large enough that at the turning point the alpha particle came close to, but did not penetrate, the gold nucleus. (Experimental and theoretical studies suggest that the radius of a nucleus is on the order of  $10^{-14} \text{ m}$ .)

**Related Problems: 5, 6, 7, 8**

Now let's examine the motion of the electron in the hydrogen atom, which has only one proton and one electron. The total energy (kinetic and potential) of the electron in the atom is

$$E = \frac{1}{2} m_e v^2 - \frac{Ze^2}{4\pi\epsilon_0 r} \quad [3.7]$$

The total energy  $E$  of the atom is fixed (assuming no external forces or radiative processes). It is informative to represent this condition by a horizontal line on the potential energy curve and show the kinetic energy  $\mathcal{T}$  at each point as a vertical arrow connecting  $V$  to  $E$ . (See Appendix B.2 for background.)

Figure 3.9a shows the total energy set to  $+10.0 \text{ eV}$ . The graph shows that the electron has significant kinetic energy everywhere, so the case of positive total  $E$  corresponds to *unbound motion* in which the electron approaches the proton but passes by without becoming trapped or attached.

Figure 3.9b shows the total energy set to  $-13.6 \text{ eV}$ . The kinetic energy is large at small values of  $r$  and decreases to zero at the point where this line intersects  $V$ . For values of  $r$  larger than this, the kinetic energy is negative, which is not allowed in Newtonian mechanics. Thus, at this total energy, the motion of the electron is *bound*; the electron is said to be “trapped within a potential well centered on the proton,” and its motions are limited to the range between  $r = 0$  and the distance at which the total energy  $E = V(r)$ . We describe the hydrogen atom using quantum mechanics in Chapter 5, where we see that only certain specific values of the bound state energy are allowed, one of which is  $-13.6 \text{ eV}$ . (Note that in this simple example we do not have the electron circling the nucleus, as it would in Rutherford's planetary model of the atom. Then conservation of angular momentum keeps the orbit at even smaller distances than the distance at which the total energy  $E = V(r)$ , because the kinetic energy is never zero during the bound motion.)

### EXAMPLE 3.3

Assume that a hydrogen atom has bound state energy  $E = -13.6 \text{ eV}$ . Calculate the maximum distance  $r_{\text{max}}$  of the electron from the nucleus allowed by Newtonian mechanics.

(Continued)

**FIGURE 3.9** Potential energy, total energy, and kinetic energy for interaction of an electron with a proton. When the total energy is fixed, the kinetic energy at each point is represented by a vertical arrow from the potential energy curve to the value of the total energy shown by the red horizontal line. (a) If the potential energy is 0 at large  $r$ , a total energy  $E > 0$  corresponds to unbound motion, characterized by significant kinetic energy at all positions. (b) Total energy  $E < 0$  corresponds to bound motion where the electron is confined to distances smaller than the point at which the potential and total energy are equal and the kinetic energy is 0.

#### Solution

When the electron is located at  $r_{\max}$  the potential energy is equal to the bound state energy of the atom. From Equation 3.3 we obtain the following relations:

$$V(r_{\max}) = -\frac{e^2}{4\pi\epsilon_0 r_{\max}} = -13.6 \text{ eV}$$

$$r_{\max} = \frac{e^2}{4\pi\epsilon_0 (13.6 \text{ eV})}$$

$$r_{\max} = \frac{(1.602 \times 10^{-19} \text{ C})^2}{4\pi(8.854 \times 10^{-12} \text{ C}^2 \text{ J}^{-1} \text{ m}^{-1})(13.6 \text{ eV})(1.602 \times 10^{-19} \text{ J eV}^{-1})}$$

$$r_{\max} = 1.06 \times 10^{-10} \text{ m} = 1.06 \text{ \AA}$$

It is tempting to interpret  $r_{\max}$  as a measure of the “size” of the hydrogen atom, but that idea has to be refined when we describe the hydrogen atom by quantum mechanics. In Chapter 5 we see that quantum mechanics describes the position of the electron around the nucleus by a probability function and that 99% of the probability lies within a sphere of radius  $2.2\text{\AA}$  centered on the nucleus when the bound state energy is  $-13.6 \text{ eV}$ . Quantum mechanics allows small particles such as electrons to penetrate into regions where classical mechanics forbids them to go.

**Related Problems:** 5, 6, 7, 8

### 3.4 Ionization Energies, the Shell Model of the Atom, and Shielding

To begin our discussion of bond formation, we note that electron distributions change during the course of all chemical reactions. The simplest possible chemical reactions are those in which an electron is either removed from or added to a neutral atom to form a positively charged **cation** or negatively charged **anion**, respectively. Although these might be considered to be physical processes, the reactants and products in both cases have different chemical properties, so these are clearly also chemical changes. This section focuses on the process that creates positively charged ions, and Section 3.5 discusses formation of anions and removal of electrons from anions. The energy changes associated with each of these processes show clear periodic trends that correlate with the trends in chemical reactivity discussed in Section 3.2. This correlation suggests that a qualitative explanation of chemical bonding may begin by understanding the factors that control the loss or gain of electrons by atoms.

The **ionization energy**,  $IE_1$ , of an atom (also referred to as the first ionization energy, or in some textbooks, the ionization potential) is the minimum energy necessary to remove an electron from a neutral atom in the gas phase and form a positively charged ion in the gas phase. It is the change in energy,  $\Delta E$  (see Figure 3.10) for the process

The Greek letter capital delta,  $\Delta$ , is widely used to symbolize the difference in the value of a property that results from a physical or chemical process. Here  $\Delta E = [\text{energy of products}] - [\text{energy of reactants}]$ ; it is positive when energy must be provided for the process to occur, and it is negative if the process liberates energy. To achieve the ionization of  $X(g)$  to form the products  $X^+(g) + e^-$ , it is necessary to supply energy to the neutral atom  $X(g)$ . The energy added enables the electron to escape from the potential energy well that holds it in the atom. Therefore, the energy of the final state [the electron  $e^-$  and the ion  $X^+(g)$ ] is greater than that of the initial state (the neutral atom).

$\Delta E$  for ionization reactions is always positive. The ionization energy is a measure of the stability of the free atom. Those atoms with larger ionization energies are more stable than those atoms with smaller ionization energies because their electrons must be removed from deeper potential energy wells.

Figure 3.11 shows the measured ionization energies of the elements plotted as a function of their atomic numbers. The left vertical scale is the energy in eV per atom and the right vertical scale is the energy in kJ per mole of atoms. Recall from the discussion in Section 3.2 that 1 eV per atom equals 96.48 kJ per mole of atoms.

The values generally increase moving across a period (from left to right), becoming large for each noble gas atom, and then fall abruptly for the alkali atom at the beginning of the next period. The large values for the noble gas atoms demonstrate that their electron configurations are extremely stable, and that considerable energy is required to liberate their electrons. Moreover, the electron configurations of the noble gas atoms are more stable than those of the atoms immediately before and after them in the periodic table.

Ionization energy is thus a periodic property of the elements (see Section 3.2). The small local increases and decreases superimposed on the generally increasing trend across a period are explained in detail by the quantum description of atomic structure in Chapter 5. Our primary objective here is to demonstrate the experimental result that the energy required to remove the first

**FIGURE 3.10** Ionization requires sufficient energy to enable the electron to escape from the potential energy well of the atom.

**FIGURE 3.11** First ionization energy plotted versus atomic number shows periodic behavior. Symbols for the noble gases are shown in red; those for alkali metals are shown in blue.

electron is periodic in the atomic number  $Z$ . It is not necessary to consider the small local variations observed in the data for this purpose.

The *second* ionization energy,  $IE_2$ , is the minimum energy required to remove a second electron, as represented by the process

(Thus the reactant in this chemical equation is the cation formed from removing the first electron from the neutral atom.)

The third, fourth, and higher ionization energies are defined in an analogous fashion. Successive ionization energies always increase due to the greater electrostatic attraction of the electron to the product ions, which have increasingly greater positive charges.

Examination of successive ionization energies suggests the idea that the electrons in an atom are organized in a very interesting structure. This hypothesis arises from patterns revealed in Table 3.1, which shows the first ten ionization energies for the elements H through Ar. Ionization energies are only expressed in eV (per atom) in this table, rather than in  $\text{kJ mol}^{-1}$  (see Figure 3.11) to make it easier to display them in tabular form.

Let's first consider He.  $IE_1$  for He is 24.59 eV, which is much greater than that of H (13.60 eV) or Li (5.39 eV). The electronic structure of He is thus much more stable than that of either H or Li. Further disruption of the stable He structure by removing a second electron requires  $IE_2 = 54.42$  eV.

Next, let's consider Li, for which  $IE_1$  is 5.39 eV and  $IE_2$  is 75.64 eV. This is a far greater difference between  $IE_1$  and  $IE_2$  than for He. One electron is removed easily from Li to form  $\text{Li}^+$ , which has two electrons that are more tightly held than those in neutral He. Note that the difference  $IE_3 - IE_2$  for Li is about 1.5 times the difference  $IE_2 - IE_1$  for He. The last electron to be removed from Li is more strongly bound than the last electron removed from He.

As we proceed across the 2nd period, an interesting pattern develops. The ionization energies for Be show a large jump between  $IE_2$  and  $IE_3$ , demonstrating that Be easily loses two electrons to form  $\text{Be}^{2+}$ , which has two electrons and

displays helium-like stability. Boron ionization energies have a large jump between  $IE_3$  and  $IE_4$ , showing that three electrons are easily removed, and carbon has a large jump between  $IE_4$  and  $IE_5$ , showing that four electrons are easily removed. The pattern continues, showing that fluorine has seven electrons that can be removed more easily than the last two electrons, and neon has eight. This pattern is shown in Table 3.1 by highlighting the ionization energies for the more easily removed electrons in each atom. These results suggest that the electrons in each atom of the 2nd period are arranged in two groups: two electrons exist in a stable, helium-like configuration, while the others are less tightly bound. It is reasonable to assume that the two most tightly bound electrons are located close to the nucleus, where the attractive Coulomb force is very strong, and the others are much farther away from the nucleus. We hypothesize from these experimental results that electrons in the atoms of 2nd period are organized as a stable, helium-like *inner core*, surrounded by less tightly bound electrons whose number increases from one to eight as the atomic number increases from three to ten.

Examination of the atoms in the 3rd period, Na through Ar, reveals a similar pattern of relatively more easily removed electrons outside a stable core, which resembles the Ne atom. This pattern is shown in Table 3.1 by highlighting the ionization energy values for the more easily removed electrons in each atom in the 3rd period. (The beginning of this pattern in the 4th period is shown by highlighting the ionization energy values for the easily removed electrons in K, Ca, and Sc.) Na appears to have a single weakly bound electron outside

**FIGURE 3.12** Logarithm of successive ionization energies for Na versus number of electrons removed suggests a three-shell electronic structure.

a neon-like core. Also note the large difference between  $IE_9$  and  $IE_{10}$  for Na. Further insight into the physical origin of this arrangement is obtained by plotting the successive ionization energies of Na versus  $n$ , the total number of electrons that have been removed at each step. It is convenient to plot the logarithm of ionization energy versus  $n$  to compress the vertical scale. The result (Fig. 3.12) suggests that the electrons in the Na atom are arranged in three groups. The first electron is easily removed to produce  $\text{Na}^+$ , which has neon-like stability as indicated by the large jump between  $IE_1$  and  $IE_2$ . Electrons 2 through 9 are in the second group, and all of them are more tightly bound than the first electron. A big jump between  $IE_9$  and  $IE_{10}$  suggests that the last two electrons occupy a third group, the electrons of which are the most tightly bound of all. This is the helium-like stable core identified in our analysis of the 2nd period.

We summarize these results by proposing the **shell model for atomic structure**. The electrons are grouped into shells based upon the energy required to remove them from the atom. The shells correspond to the periods of the periodic table: the first shell contains at most 2 electrons, the second shell contains at most 8 electrons, and the third shell contains at most 8 electrons. We assume that these shells are spherical and concentric, centered at the nucleus. We also assume that the ionization energies of the electrons in each shell decrease as we move outward from the nucleus. The shell model predicts that the sulfur atom (S,  $Z = 16$ ) would have 6 electrons in its third (outer) shell, 8 electrons in its second (middle) shell, and 2 electrons in its first (innermost) shell.

### 3.4.1 The Shell Model of the Atom

Examining the ionization process as a simple chemical reaction leads us to conclude that electrons occupy a set of shells that surround the nucleus. This is a remarkable experimental result. All of the electrons in an atom are identical, and they all interact with the same nucleus. Why should they be arranged in shells, and what determines the number of electrons that can occupy a given shell?

We begin to seek an explanation by considering the forces that act within many-electron atoms, and the potential energy functions associated with these forces. Consider Li, for which  $Z = 3$ .

Each of the electrons is attracted to the nucleus and repelled by the other electrons via the Coulomb interaction. If we put the Li nucleus at the origin of our coordinate system, the vector  $\vec{r}_1$  shown in Figure 3.13 points from the nucleus to electron number 1, labeled  $e_1$  in the figure. (The vector  $\vec{r}_1$  gives the position of that electron by its Cartesian coordinates  $(x_1, y_1, z_1) = \vec{r}_1$ .) The distance from the nucleus to that electron is then the length  $r_1$  of the vector  $\vec{r}_1$ . (Thus  $r_1 = +\sqrt{x_1^2 + y_1^2 + z_1^2}$  according to the Pythagorean theorem.) The distance from electron number 1 to electron number 2 is  $r_{12}$ , the length of the

**FIGURE 3.13** Li atom with three electrons.

vector  $\vec{r}_{12} = \vec{r}_2 - \vec{r}_1$  pointing from electron number 1 to electron number 2. The total potential energy  $V$  due to Coulomb interactions is then given by

$$V = \frac{e^2}{4\pi\epsilon_0} \left( -\frac{Z}{r_1} - \frac{Z}{r_2} - \frac{Z}{r_3} + \frac{1}{r_{12}} + \frac{1}{r_{13}} + \frac{1}{r_{23}} \right) \quad [3.8]$$

We can use Equation 3.8 to calculate the potential energy for any configuration of the Li atom; for example, we could place the electrons at the vertices of an equilateral triangle with sides of a given length, centered on the nucleus (see Figure 3.13). Unlike the case of the hydrogen atom, there is no simple way to relate the potential energy in this example to the bound motion of all of the electrons in the atom and to use it to calculate the energy required to remove one of them from the atom.

To make progress, let's invent a simple one-electron model by assuming that each electron moves under the influence of forces that can be derived from an **effective potential energy** function that takes into account both the attractive electron-nuclear forces and the average of the repulsive force among the electrons. To see how this idea works out, let's assume that electron 2 is located between electron 1 and the nucleus at some particular time (see Figure 3.14). The real effect of electron 2 is to *screen* or *shield* electron 1 from the full strength of the Coulomb force exerted by the nucleus with  $Z = 3$ . It is useful to think of the Coulomb interaction as strictly "line of sight," so intrusion by another electron will reduce its strength. In effect, the charge of the nucleus, as seen by electron 1, has been reduced by the presence of the other electrons. Suppose electrons 2 and 3 get between electron 1 and the nucleus. The extent of screening is even greater, and the magnitude of  $Z_{\text{eff}}$  is smaller. We can set  $Z_{\text{eff}} = Z - S$ , where the screening constant  $S$  measures the extent to which the other electrons screen out the nuclear charge felt by electron 1. We interpret  $S$  physically as the average number of electrons spending time between the nucleus and the electron we have labeled as 1. By making estimates for  $S$ , we can then find the effective potential energy using the formula for the Coulomb potential energy but with an *effective charge*  $Z_{\text{eff}}$  on the nucleus:

$$V_{\text{eff}}(r) = -\frac{Z_{\text{eff}}e^2}{4\pi\epsilon_0 r} \quad [3.9]$$

Let's make some simple estimates of the effective potential energy to illustrate the effects of screening, beginning with the lithium atom. The simplest model predicts  $Z_{\text{eff}} = 3 - 2 = 1$ ; this is very close to  $Z_{\text{eff}} = 1.3$ , which can be extracted from Equation 3.9 and the experimental ionization energy for Li. Electrons in the innermost shell each contribute about  $-0.85 e$  to screen the outer electrons from the full nuclear charge. The amount of shielding experienced by an electron in more complicated atoms depends on its position in the atom and the arrangement of the other electrons with respect to that electron

**FIGURE 3.14** Electron 1 is partially shielded from the full force of the nuclear attraction when electron 2 comes between electron 1 and the nucleus.

**FIGURE 3.15** Curves for the effective potential energy  $V_{\text{eff}}(r)$  for electrons in Na ( $Z = 11$ ) when  $Z_{\text{eff}} = 1, 5, 11$ . An electron at any location is more strongly bound in the atom as the value of  $Z_{\text{eff}}$  increases.

and the nucleus. An electron that spends most of its time very near the nucleus will be screened only very slightly, so its screening constant will be small and it will experience an effective nuclear charge  $Z_{\text{eff}}$  that is very nearly equal to the actual nuclear charge  $Z$  of the atom. An electron that spends most of its time in the outermost regions of the atom experiences  $Z_{\text{eff}}$  in the range 1–2, because most of the other  $(Z - 1)$  electrons provide significant amounts of screening. An electron that spends most of its time in the intermediate region of the atom is partly screened and experiences an intermediate value of  $Z_{\text{eff}}$ . Consider Na, for which  $Z = 11$ . Let's examine cases of significant screening ( $Z_{\text{eff}} = 1$ ), intermediate screening ( $Z_{\text{eff}} = 5$ ), and no screening ( $Z = 11$ ). Figure 3.15 shows plots of  $V_{\text{eff}}$  curves for  $Z_{\text{eff}} = 1, 5, 11$ . Clearly, those electrons that experience the lower values of  $Z_{\text{eff}}$  are more weakly bound than those with higher values of  $Z_{\text{eff}}$ , as can be seen by comparing the values of the potential energy for the three curves at particular values of  $r$ . Each shell in an atom is characterized by a value of  $Z_{\text{eff}}$  that varies only slightly for the electrons in that shell; the value of  $Z_{\text{eff}}$  is dramatically different for electrons in different shells.

**FIGURE 3.16** Shell model of the atom. The outer electron is partially shielded from the nuclear attraction by the electrons in the inner shell.

The shell model (see Figure 3.16) is a refinement of Rutherford's planetary model because it describes the  $Z$  electrons as being organized into a series of concentric shells based on their ionization energies. The shell model is inspired by patterns in experimental measurements of successive ionization energies. Our one-electron approximation based on  $Z_{\text{eff}}$  and simple classical electrostatics provides a qualitative physical interpretation of the shell model. Altogether, this is a very physical and intuitively appealing picture of the electronic structure within the atom. We have great confidence in this picture and use it to organize and interpret vast amounts of chemical information.

In Chapter 5 we treat Rutherford's model by quantum mechanics and see that the shell structure is completely justified by quantum mechanics. We see why each specific shell contains 2, 8, or 18 electrons. We generate values for the screening constant  $S$  and  $Z_{\text{eff}}$  systematically, and see that they range from 1 to the full, unscreened nuclear charge  $Z$  for an atom.

### 3.4.2 The Shell Model of the Atom and Periodic Behavior in Chemical Bonding

Examining the ionization process as the prototype of a simple chemical reaction led us to the shell model. Now we use the shell model and the concept of  $Z_{\text{eff}}$  to explain the general increase of  $IE_1$  across each period, followed by an abrupt

decrease at the end of the period as shown in Figure 3.11. As we move across a period, at each atom we add one unit of positive charge to the nucleus and one electron to the outer shell. If the electrons in a shell are located at roughly the same distance from the nucleus, then the attractive electrostatic forces increase nearly monotonically with increasing  $Z$ .  $Z_{\text{eff}}$  always increases moving across a period, therefore, because  $Z$  increases and there is never perfect shielding. For example, the “outer electrons” are progressively more strongly bound as we move across the 2nd period from Li to F, and  $IE_1$  increases until it achieves its maximum value at Ne, the next “stable core.” The ionization energy shows a large decrease between Ne and Na because at Na we are now removing an electron from the next shell in the progression. We know that these electrons are easier to remove than those in the second shell. As we continue across the 3rd period  $IE_1$  increases because  $Z_{\text{eff}}$  increases until we achieve the maximum value at Ar, the next “stable core.” The local fluctuations result from a delicate balance between magnitude of  $Z_{\text{eff}}$  and the details of the electron distributions in atoms, which is explained only by quantum mechanics.

There is a strong correlation between the ease of removing electrons from an atom and the chemistry of that atom. The electrons that are easiest to remove are most likely to participate in chemical bond formation and in chemical reactions. We now know, for every atom, that there is a very large energy difference in the energies of the electrons in the outermost shell and those in the inner shells. This difference is displayed dramatically in Table 3.1 as the right-hand end of the highlighted  $IE$  values for each atom. Electrons in the inner shells (called **core electrons**) do not participate significantly in chemical reactions because they are quite difficult to remove from the atom. The outermost, partially filled shell (called the **valence shell**) contains the electrons involved in chemical bonding, the **valence electrons**. The number of valence electrons in a neutral atom of a main-group element (those in Groups I–VIII) of the second and third periods is equal to the group number of the element in the periodic table. However, the main-group elements that follow a series of transition-metal elements require some special attention. Atoms of bromine, for example, have 17 more electrons than atoms of argon, the preceding noble gas, but only 7 are considered to be valence electrons. This is true for two reasons. First, in the fourth, fifth, and sixth rows, the 10 electrons added to complete the transition metal series (although they are important for the bonding of those elements) have become *core* electrons by the time the end of the transition-metal series is reached. They are closer to the nucleus, on average, than the electrons that fill the rest of the shells of those periods, and it might be useful to visualize them as occupying a subshell. Second, and more importantly, the chemical properties of the main group elements in this part of the periodic table are characteristic of the group to which they belong. The bonding properties of an element such as bromine, for example, resemble those of the lighter elements in its group.

Progressing through the elements in order of increasing atomic number along a period, we see that stability increases from left to right, as indicated by increasing values of the ionization energy. As we progress across a period, the valence shell of that period becomes a filled shell, which is the stable configuration of the noble gases helium, neon, argon, and so on. Atoms with filled shells are extremely stable chemically, as shown by the large values of their ionization energies. The 2nd period ends with a filled valence shell of 8 electrons in Ne, and the 3rd period ends with a filled valence shell of 8 electrons in Ar. These two configurations, called the *stable octets*, play a key role in theories of chemical bond formation. To a large extent the bond forming possibilities for atoms in the 2nd and 3rd periods can be categorized by their ability to lose, gain or share electrons in order to achieve stable octets in their valence shells, and therefore the great stability of a noble gas configuration.

The American chemist G. N. Lewis introduced a useful notation that describes the electronic structure of atoms. The Lewis model represents the valence electrons as dots arranged around the chemical symbol for an atom; the core electrons are not shown. The first four dots are arranged individually around the four sides of the symbol for each element. If an atom has more than four valence electrons, dots representing them are then paired with those already present. The result is a **Lewis dot symbol** for that atom. The Lewis notation for the elements of the first two periods is

The Lewis symbols vividly display how the valence shell structure changes across a period and suggest at a glance the bonding possibilities that would establish stable octets about each atom.

## 3.5 Electron Affinity

(a)

(b)

**FIGURE 3.17** (a) When an electron attaches to a neutral atom to form a stable anion (as shown), the electron gets trapped in the potential well of the atom, and the energy of the products is lower than the energy of the reactants. Thus the  $\Delta E$  for the reaction  $X(g) + e^- \rightarrow X^-(g)$  is negative; when you add an electron to a neutral atom such as Cl that has a positive electron affinity, energy is released. This  $\Delta E = -EA_X$  (b)  $\Delta E$  for the reaction  $X^-(g) \rightarrow X(g) + e^-$ ; this  $\Delta E = EA_X$ .

Section 3.4 describes the prototypical chemical reaction in which an electron is removed from a neutral atom in the gas phase to form a cation. Ionization energy (IE) measures the difficulty with which an atom gives up an electron to form a cation. The present section describes a different prototypical reaction, in which an electron is attached to a neutral gas phase atom to form an anion. The ease with which an atom accepts an extra electron to form an anion is measured by the electron affinity (EA) of the atom, to be defined shortly.

An anion is formed by the electron attachment reaction,

for which the energy change  $\Delta E$  (see definition in Section 3.4) is called the **electron attachment energy**. This reaction is represented on a plot that shows the potential energy of the atom  $X(g)$  and the electron versus the distance between them, similar to those shown in Figure 3.15. Initially, the atom and the electron are very far apart and do not interact, at which point the potential energy is defined to be zero. They approach one another and form the anion  $X^-(g)$ , whose energy is usually lower than that of the separated atom and electron. When  $X$  is, for example, a halogen, the energy of the products is lower than the energy of the reactants,  $\Delta E$  is negative, energy is usually released in the reaction, and the anion is stable (see Figure 3.17a). Electron attachment is an example of a reaction type called an **exothermic reaction**, which means energy is released. The anion is stable because the neutral atom can accommodate an extra electron, which is strongly bound by the effective potential  $V_{\text{eff}}$ . The energy change,  $\Delta E$ , for the reverse reaction, in which the electron is removed from  $X^-(g)$  to give the neutral atom  $X(g)$ , is positive because energy must be supplied to overcome  $V_{\text{eff}}$  that holds the electron in the anion (see Figure 3.17b).

It is difficult to measure the electron attachment energy directly. It is easier to investigate the reverse reaction: start with the gaseous anion and measure the energy required to remove the electron in the same way that ionization energies are measured in Section 3.3. For example, the reaction

requires  $\Delta E = +349 \text{ kJ mol}^{-1}$  to remove the electron from  $\text{Cl}^-$ .

The **electron affinity**  $EA_X$  of atom X is defined as the energy required to detach the electron from the anion  $X^-$  and give the neutral atom:

Thus,  $EA$  for Cl is  $349 \text{ kJ mol}^{-1}$ . The electron affinity is a property of the neutral atom, but it is measured directly by removing an electron from the anion. The  $EA$  value defined and measured this way is positive because it is the energy that must be invested to remove an electron from a stable species, the anion. Removing an electron from a stable species is always an endothermic reaction, as seen in Section 3.4.

Values of electron affinity for selected elements are shown in Table 3.2. We choose not to include “negative” electron affinities, which you might see tabulated in other textbooks or reference data collections. An atom with a negative electron affinity would require some external force to hold the electron on the atom. While this situation could provide interesting opportunities to study the forces between electrons and atoms, such an “anion” would be unstable and therefore not particularly useful as a prototypical chemical reaction product in our view.

The periodic trends in electron affinity largely parallel those in ionization energy, increasing across a period to become large for the halogens, then decreasing abruptly to essentially zero for the noble gases. A notable difference between the trends in ionization energy and electron affinity is that the dramatic decreases in electron affinities occur between atoms whose atomic numbers are one lower than the corresponding breaks in ionization energy. The following examples illustrate and explain this point. Attaching an electron to F gives  $F^-$ , which has the same electron arrangement as Ne, and is therefore very stable. (Recall the discussion of ionization energy in Section 3.3 as a measure of stability.) Similarly, the noble gases have essentially zero electron affinities for the same reason that the alkali metals have small ionization energies; the outermost electron in  $Ne^-$  or  $Xe^-$  would reside in a new shell, and the resulting ion would be less stable than the neutral parent atom. Indeed,  $Ne^-$  has a nuclear charge of  $+10e$  while Na has a nuclear charge of  $+11e$ , so  $Ne^-$  is not a stable anion at all. Chlorine has the highest electron affinity, and that of Ne is zero.

No gaseous atom has a positive electron affinity for a *second* electron, because a gaseous ion with a net charge of  $-2e$  is always unstable with respect

TABLE 3.2

Electron Affinity of Selected Atoms (in  $\text{kJ mol}^{-1}$ )

H							He
73							*
Li	Be	B	C	N	O	F	Ne
60	*	27	122	*	141	328	*
Na	Mg	Al	Si	P	S	Cl	Ar
53	*	42	134	72	200	349	*
K	Ca	Ga	Ge	As	Se	Br	Kr
48	2	41	119	79	195	325	*
Rb	Sr	In	Sn	Sb	Te	I	Xe
47	5	29	107	101	190	295	*
Cs	Ba	Tl	Pb	Bi	Po	At	Rn
46	14	19	35	91	183	270	*

\*No stable anion  $A^-$  exists for this element in the gas phase.

to ionization. Attaching a second electron means bringing it close to a species that is already negatively charged. The two repel each other, and the potential energy of the system increases. In crystalline environments, however, doubly negative ions such as  $O^{2-}$  can be stabilized by electrostatic interactions with neighboring positive ions.

### EXAMPLE 3.4

Consider the elements selenium (Se) and bromine (Br). Without consulting tables of data, predict which one should have the higher value of ionization energy  $IE_1$ . Predict which should have the higher value of electron affinity  $EA$ .

#### Solution

These elements are in adjacent groups in the 4th period of the periodic table. Progressing from selenium to bromine adds one unit of positive charge, which increases  $Z_{\text{eff}}$ . At the same time we add one more electron into the 4th shell like the valence electrons in Se. Since the nuclear attraction is greater for the added electron in bromine and its distance from the

nucleus is about the same, it will be more tightly bound than the valence electrons in selenium. Therefore bromine will have the larger value of  $IE_1$ .

If we place an additional electron in the 4th shell of each atom to form an anion, the additional electron on bromine will experience a larger value of  $Z_{\text{eff}}$ , and the  $Br^-$  anion will have greater stability than the  $Se^-$  anion. Moreover,  $Br^-$  has a stable octet configuration whereas  $Se^-$  does not. So Br has the larger value of  $EA$ .

**Related Problems: 9, 10, 11, 12, 13, 14**

In other textbooks you may see electron affinity defined as the energy change that occurs when an electron is added to a gaseous atom, which is the same as the electron attachment energy defined above. That definition gives  $EA$  values with signs opposite from the definition we have adopted. To avoid possible confusion, be sure to check whether the data source defines electron affinity as the electron attachment energy for formation of an anion or as the electron detachment energy for removing the electron from an anion. We prefer the definition adopted here because it is the original definition of electron affinity in the scientific literature, and it is still used in most data tabulations and current research papers. Moreover, because the word “affinity” in common language implies an attractive or favorable relationship between two entities, understanding technical usage is easier if “affinity” is a positive number whose magnitude increases as the interaction becomes more favorable.

## 3.6 Electronegativity: The Tendency of Atoms to Attract Electrons in Molecules

Classical models of the chemical bond generally identify three categories of bonds formed between a pair of atoms, based upon the degree of charge separation in the bond. Ionic bonds are those that result from the complete transfer of one or more valence electrons from one atom to the other atom, creating a positive ion and a negative ion that are bound to one another by electrostatic forces. Covalent bonds are those in which the electrons are shared evenly between the atoms with no (or very little) charge separation. Polar covalent bonds represent the intermediate situation, in which the degree of charge separation is expressed by imagining that a fraction of an elementary charge is transferred between the atoms to establish a partial charge separation or polarization along the bond axis, but not to produce ions. Each of these models is defined in more detail and illustrated later in this chapter.

Let's figure out how to qualitatively predict whether a pair of atoms might form (1) a covalent bond, with electrons equally shared between the two atoms, or (2) a polar covalent bond with unequally shared electrons, or (3) an ionic

bond. In homonuclear diatomics like  $H_2$  or  $Cl_2$ , the shared electrons are equally shared, so the bond is a covalent one and the resulting molecule is non-polar (the electrons in the molecule are distributed equally between the two atoms). At the other extreme are bonds between an atom with very high electron affinity, such as a Cl atom, and an atom with a low ionization energy, such as a K atom. Then an electron may be easily transferred from the K atom to the Cl atom, so an ionic bond results; it almost looks like an electron has been fully transferred from the K atom to the Cl atom, then the  $K^+$  and the  $Cl^-$  are drawn together by electrostatic attraction. This is most likely to be the case when a Group I atom (with low ionization energy) is bonded to a Group VII atom, with high electron affinity. Intermediate between these two cases are atoms that form a polar covalent bond in which the electron affinity of one atom is modest and the ionization energy of the other atom is modest, so one imagines that an electron is not fully transferred from one to the other, but rather, on average, there is a partial negative charge on one atom and a partial positive charge on the other atom. A bond between N and O is expected to be a polar covalent bond. These ideas lead to the concept of **electronegativity** developed below.

### 3.6.1 Mulliken's Electronegativity Scale

The American physicist Robert Mulliken proposed, in 1934, that the ionization energy and the electron affinity of atoms could be used to define a new quantity called the **electronegativity** that would measure their tendency to attract electrons. He observed that elements located in the lower left corner of the periodic table have both small ionization energies and small electron affinities. This means that they give up electrons readily (to form positive ions) but do not readily accept electrons (to form negative ions). They tend to act as electron *donors* when forming bonds with other elements. In contrast, elements in the upper right corner of the periodic table have large ionization energies and also (except for the noble gases) large electron affinities. As a result, these elements accept electrons easily but give them up only reluctantly; they act as electron *acceptors* when forming bonds with other elements. Mulliken simply *defined* electronegativity, based on these observations, as a quantity that is proportional to the average of the ionization energy and the electron affinity:

$$EN (\text{Mulliken}) = \frac{1}{2} C(IE_1 + EA) \quad [3.10]$$

Electronegativity is defined to be a pure number, so the proportionality constant  $C$  must have dimensions of  $(\text{energy})^{-1}$ . Once  $C$  has been evaluated, we can calculate the EN for any atom using the values for  $IE$  and  $EA$  in Tables 3.1 and 3.2. Electron acceptors (such as the halogens) have both large ionization energies and large electron affinities; they are highly **electronegative**. Electron donors (such as the alkali metals) have small ionization energies and small electron affinities, and therefore low electronegativities; they are **electropositive**. The noble gases rarely participate in chemical bonding. Their large ionization energies and small (essentially zero) electron affinities mean that they are neither electron donors nor acceptors and are not predicted to bond to other elements. Electronegativities therefore are not generally assigned to the noble gases. Mulliken's procedure is intuitively very appealing because it is based upon the simple shell model of the atom. Unfortunately, reliable measurements of the electron affinities of the elements were very difficult to obtain at the time, with data being available for only about 20 elements. This situation greatly limited use of Mulliken's definition in chemistry. Chemists rely on Mulliken's method

for fundamental understanding of the EN concept and use other measures of EN in practical applications.

### 3.6.2 Pauling's Electronegativity Scale

The American chemist Linus Pauling had proposed a different electronegativity scale two years before Mulliken's work was first published. Pauling's method was based on a comparison of the bond dissociation energies of a large number of homonuclear and heteronuclear bonds in which one atom of the bond was the same (HF, HCl, and HBr compared with H<sub>2</sub>, F<sub>2</sub>, Cl<sub>2</sub> and Br<sub>2</sub> for example). Pauling observed that bonds formed between elements from opposite sides of the periodic table were stronger than those between identical elements or even those located close to one another. He suggested that this extra stability was provided by partial charge separation in the bond, called **ionic character**. This separation enabled the bonding electrons to be pulled closer toward one nucleus, experience its effective nuclear charge more strongly, and make an *ionic* contribution to the bond strength. Pauling constructed an empirical formula to calculate electronegativities of the elements that was based on the additional stabilization energy provided by the ionic character of the bond, which he calculated by the following procedure.

Let the bond dissociation energy of an A—A bond be symbolized by  $\Delta E_{AA}$ , and that of a B—B bond by  $\Delta E_{BB}$ ; both bonds are covalent because the two atoms are identical. Pauling proposed that the *covalent* contribution to the bond dissociation energy of an A—B bond is the (geometric) mean of the two bond dissociation energies,  $\sqrt{\Delta E_{AA}\Delta E_{BB}}$ . He reasoned that the A—B bond must also include some ionic character, due to partial charge transfer between the atoms, that contributes to the strength of the bond and that this **excess bond energy**  $\Delta$  could be calculated as follows

$$\Delta = \Delta E_{AB} - \sqrt{\Delta E_{AA}\Delta E_{BB}} \quad [3.11]$$

Finally, Pauling defined the electronegativity difference as

$$\chi_A - \chi_B = 0.102\Delta^{1/2} \quad [3.12]$$

where  $\chi_A$  and  $\chi_B$  (Greek letter small chi) are the EN values of A and B, respectively, to account for the ionic contribution to the bond strength. The coefficient 0.102 is appropriate when  $\Delta$  is measured in kilojoules per mole ( $\text{kJ mol}^{-1}$ ). The choice of the geometric mean to estimate the covalent contribution was originally inspired by elementary valence bond theory (see Section 6.8) arguments, but Pauling states explicitly in his published work that he retained it simply because it gave better agreement with experiment than the arithmetic mean. Note that the formula, as defined, only allows the calculation of electronegativity differences but identifies the more electronegative element as the one with the larger value of  $\chi$ . Modern electronegativity (now abbreviated EN) scales, like the one shown in Figure 3.18, were developed by assigning an arbitrary value to an element (fluorine is the current choice) and stating electronegativities of the other elements relative to that choice.

Eighty years later, Pauling electronegativities are still among the chemist's most powerful guides for predicting the charge distributions and the nature of the bond between two atoms. Bonds between elements with EN differences of greater than 2 are generally considered to be largely ionic whereas bonds between elements with EN differences close to zero are considered to be covalent. Those with EN differences in the range between 0.2 and 2 are considered to be polar covalent bonds. We present a more quantitative discussion in Section 3.9 in which we connect the predictions based on EN values to experimental measurements of the degree of charge separation, the dipole moment of the molecule.

**FIGURE 3.18** Average electronegativity of atoms, computed with the method that Linus Pauling developed. Electronegativity values have no units.

### EXAMPLE 3.5

Without consulting tabulated values of electronegativity and guided only by the periodic table, arrange these atoms in order of increasing electronegativity: H, F, Al, O. Give a brief explanation of your answer.

#### Solution

The sequence of increasing electronegativity values is Al < H < O < F. Al is a metal and therefore electropositive, with a

low value of electronegativity. In general, electronegativity increases from left to right in the periodic table. As the effective nuclear charge increases, the ability to accommodate an extra electron also increases.

**Related Problems: 15, 16**

It is informative to compare Mulliken's and Pauling's approaches to the development of their electronegativity scales. Mulliken's approach was based on the physical properties of isolated, individual atoms, and could not take into account any effects attributable to the properties of the other atom of the bond. In contrast, Pauling's method took into account both the covalent and ionic contributions to the character of the bond to arrive at a scale that, in some sense, represented the average electronegativity of an element, when bonded to a wide range of other elements. By explicitly separating the ionic and covalent contributions that determine the character of the chemical bond, Pauling provided the framework for our contemporary understanding of the polar covalent bond, in particular, and its effect on the measurable properties of molecules, including their dipole moments. These considerations, which also determine the nature of the forces between molecules, are discussed in Section 3.9.

Despite the differences between their two approaches, Mulliken's and Pauling's scales produce EN values that are very nearly proportional to one another. Pauling's scale has been more widely adopted simply because the data on which it is based are more complete and considered to be more reliable. Electronegativity as a concept has been criticized over the years because it is not measurable and must be constructed indirectly. Nonetheless, it is extremely useful because it succinctly summarizes the most characteristic chemical properties of an atom in a single parameter. Research to refine the concept continues to this day, relying on advanced methods for calculating molecular electronic structure and advanced laser spectroscopy for high-precision measurements of EA values through electron detachment from anions.

## 3.7 Forces and Potential Energy in Molecules: Formation of Chemical Bonds

In the previous sections we investigated the energetics of the loss and gain of electrons as prototype chemical reactions. Here, we want to define the energetics of more general types of bond formation. Then we will have all the necessary background to describe in detail the formation of ionic bonds, covalent bonds, and polar covalent bonds in the following sections.

What determines the stability of a chemical bond? Why is the  $\text{H}_2$  molecule more stable than a pair of separated hydrogen atoms in the gas phase at normal temperatures and pressures?

Experience shows that physical objects move spontaneously toward configurations that reduce their potential energy. A car rolls downhill, converting its gravitational potential energy into kinetic energy. We have already learned in Section 3.2 that microscopic charged particles move in directions that will reduce their electrostatic (Coulomb) potential energy. But formation of a chemical bond is more subtle than ordinary motion of charged particles under Coulomb's force law, because it involves a special event. Two atoms flying toward each other have a certain total energy that includes contributions from their internal structure, their potential energy relative to each other, and their kinetic energy. To enter into what the distinguished chemist and author George C. Pimentel has called "the blissful state of bondedness"—in which the atoms fly together as a bonded pair forever after—they must give up some of their total energy. A diatomic molecule is more stable than the separated atoms from which it was formed because its *total energy* is less than that of the two separated atoms. You can reach the same conclusion by examining the reverse process; dissociation of a diatomic molecule requires input of energy.

Let's interpret this fact in terms of the potential energy changes in formation of the molecule, illustrated with the specific example of  $\text{H}_2$  shown in Figure 3.19. The nuclei are labeled A and B, and the electrons are labeled 1 and 2. The distance between each electron and each proton ( $r_{1A}$ ,  $r_{1B}$ ,  $r_{2A}$ ,  $r_{2B}$ ) is shown in blue in Figure 3.19, while the distance between the two electrons and the distance between the two protons ( $R_{AB}$ ) are shown in red. The potential energy of the molecule is most conveniently expressed in terms of these distances.

**FIGURE 3.19** Coordinates for the hydrogen molecule. The nuclei are assumed stationary at fixed positions separated by the distance  $R_{AB}$ . The distance of electron 1 from nuclei A and B is given by  $r_{1A}$ ,  $r_{1B}$ ; the distance of electron 2 from nuclei A and B is given by  $r_{2A}$ ,  $r_{2B}$ ; the distance between the electrons is given by  $r_{12}$ . Note that all the blue vectors pointing from the nuclei to the electrons are of the form  $\vec{r}_{A1} = \vec{r}_1 - \vec{r}_A = -\vec{r}_{1A}$ , but because the length of  $\vec{r}_{A1}$  equals the length of  $\vec{r}_{1A}$  ( $r_{A1} = r_{1A}$ ), the labels on the picture showing the distances are correct.

$$V = -\frac{e^2}{4\pi\epsilon_0} \left( \frac{1}{r_{1A}} + \frac{1}{r_{2A}} + \frac{1}{r_{1B}} + \frac{1}{r_{2B}} \right) + \frac{e^2}{4\pi\epsilon_0} \left( \frac{1}{r_{12}} \right) + \frac{e^2}{4\pi\epsilon_0} \left( \frac{1}{R_{AB}} \right) \quad [3.13]$$

$$V = V_{\text{en}} + V_{\text{ee}} + V_{\text{nn}}$$

The first four terms in Equation 3.13 represent the attractions between the electrons and the nuclei,  $V_{\text{en}}$ , and all are negative. The last two terms represent the repulsions between the pair of electrons,  $V_{\text{ee}}$ , and the pair of protons,  $V_{\text{nn}}$ , and both are positive. The value of  $V$  can be calculated for any internuclear distance  $R_{AB}$ , if the positions of the electrons were known. Then the total energy would be the sum of the kinetic energies of all the electrons, the relative kinetic energy of the nuclei, and the potential energies in Equation 3.13. However, when a diatomic molecule such as  $\text{H}_2$  dissociates to  $\text{H} + \text{H}$ , the electrons change their kinetic energies and positions, one electron going with each H atom, as  $R_{AB}$  increases! Chemists are typically interested in the motion of the A and B nuclei relative to each other (for example, could the A-B bond stretch and break?), so we define a new effective potential energy function,  $V_{\text{eff}}$ , that includes the change in electron kinetic energies as the bond stretches. We define this  $V_{\text{eff}}$  so that the total energy

$E$  of the non-rotating H-H molecule is the sum of only two terms, the relative kinetic energy of the two nuclei and  $V_{\text{eff}}$ . Thus  $V_{\text{eff}}$  includes all the terms in Equation 3.13 and the sum the kinetic energies of all the electrons, arranged in orbits around the separating nuclei, that readjust as the nuclei move apart or together. Thus  $V_{\text{eff}}$  must depend on  $R_{\text{AB}}$ , which tracks the transition from a diatomic molecule to two separated atoms. Since  $V_{\text{eff}}$  includes kinetic energies of the electrons and, for  $\text{H}_2$ , one electron is close to each H atom at large  $R_{\text{AB}}$ , the zero of  $V_{\text{eff}}$  is not naturally 0 at large  $R_{\text{AB}}$  (it is  $-27.2$  eV for large  $R_{\text{AB}}$  for H + H). Two conventions are common, adding an offset to the potential energy at all  $R_{\text{AB}}$  so that  $V_{\text{eff}} = 0$  at large  $R_{\text{AB}}$  (see Figure 3.20) or adding a larger offset so that  $V_{\text{eff}} = 0$  at  $R_{\text{AB}} = R_e$ , the equilibrium internuclear distance for the molecule (see Figure 20.15 and Equation 20.12). At large distances the slope  $dV/dR_{\text{AB}} = 0$  because the isolated atoms do not interact. Assuming you set  $V_{\text{eff}} = 0$  at large  $R_{\text{AB}}$ , as  $R_{\text{AB}}$  decreases,  $V_{\text{eff}}$  must become negative because the atoms begin to attract each other, thanks to the two electrons interacting with both nuclei. At very small distances,  $V_{\text{eff}}$  must become positive and large as  $V_{\text{eff}} \rightarrow \infty$  due to the repulsion between the protons. Therefore, at some intermediate internuclear separation that we label as  $R_e$  the decreasing potential function must reach a minimum and change its slope as it heads upward toward positive values. Figure 3.20 is a sketch of a generic  $V_{\text{eff}}$  versus  $R_{\text{AB}}$  that shows all these features.

The slope  $dV/dR_{\text{AB}}$  of the effective potential energy curve in Figure 3.20 is negative at small  $R_{\text{AB}}$ , so the two atoms in the diatomic molecule feel a repulsive force between them. The positively charged protons are too close together for the surrounding electrons to keep them together. At the minimum of  $V(R_{\text{AB}})$ , at  $R_{\text{AB}} = R_e$ , the atoms in the diatomic molecule neither attract or repel each other, the force is 0, so the molecule is most stable at that internuclear distance. For internuclear distances  $R_{\text{AB}} > R_e$ , the slope  $\Delta V/\Delta R_{\text{AB}}$  is positive, so the atoms feel an attractive force between them. Therefore, we identify  $R_e$  as the *equilibrium bond length* of the molecule. If you start with the atoms in the diatomic molecule at the separation  $R_e$ , where  $V_{\text{eff}}$  is a minimum, and if the relative kinetic energy at that point is small, you must add energy to separate the atoms (pulling against this attractive force). The energy you must add to fully separate the atoms in the molecule, or break the bond, is called the **bond dissociation energy**,  $\Delta E_d$ . Figure 3.20 shows that the deeper the well in  $V_{\text{eff}}$ , the more energy you must add to break the bond, and the larger the bond dissociation energy. Thus very stable molecules have deep potential energy wells, effectively holding the atoms together.

**FIGURE 3.20** Dependence of the effective potential energy curve  $V_{\text{eff}}$  for a diatomic molecule on the internuclear separation  $R_{\text{AB}}$ . The location of the minimum corresponds to the equilibrium bond length. If the well is low, or deep, relative to the energy of the separated atoms, then the AB molecule is particularly stable, as it would require more energy to break the A-B bond.

At this point, you might wonder how a chemical bond is ever formed, since if two atoms collide with each other, by virtue of conservation of energy they have enough total energy to separate again, even if they would have the lowest potential energy at  $R_{AB} = R_c$ . When the two atoms are close together during the collision, they must transfer energy to another molecule or atom in the surroundings. In a gas phase system, such as a collision between a Cl atom in the atmosphere and an  $\text{NO}_2$  radical, another molecule, such as  $\text{N}_2$ , must collide with the Cl- $\text{NO}_2$  complex when the internuclear distance is small enough that the potential energy between the Cl and  $\text{NO}_2$  is low. Then some of the energy in the complex can be transferred to the  $\text{N}_2$  molecule, and the Cl $\text{NO}_2$  molecule is then confined in the potential energy well. The energy lost by the Cl- $\text{NO}_2$  complex is transferred to the random thermal motion of the surrounding molecules. This process is very efficient if the reaction is happening in solution; the solvent molecules take away energy from the A-B system as the A-B bond is formed. Energy is thus released to the surrounding molecules as the bond is formed between atom A and atom B.

## 3.8 Ionic Bonding

An **ionic bond** forms between atoms with large differences in electronegativity, such as sodium and fluorine. A practical definition of an ionic bond is one in which the dominant contribution to the strength of the bond is the electrostatic attraction between the ions. Conceptually, the formation of an ionic bond from neutral gas-phase atoms can be thought of as the result of two sequential processes. The more electropositive ion transfers an electron to the more electronegative atom, forming an ion pair that is then drawn together by the attractive electrostatic force. Although we focus our discussion on ionic bonding in a gaseous diatomic molecule where we can clearly identify the forces responsible, most ionic compounds are solids under normal conditions. In an ionic solid, ions of one charge are surrounded by an orderly array of ions of the opposite charge, resulting in extremely large Coulomb stabilization energies. They generally have high melting and boiling points (for example, NaCl melts at  $801^\circ\text{C}$  and boils at  $1413^\circ\text{C}$ ) and can form large crystals. Solid ionic compounds usually conduct electricity poorly, but their melts (molten salts) conduct well.

The creation of positive and negative ions is represented using the Lewis dot symbols for the valence shell of atoms introduced at the end of Section 3.4, by removing or adding dots and also by writing the net electric charge of the ion as a right superscript. For example:

As demonstrated in Section 3.4, special stability results when an atom, by either losing or gaining electrons, forms an ion whose outermost shell has the same number of electrons as the outermost shell of a noble-gas atom. Except for hydrogen and helium, whose valence shells are completed with two electrons, atoms of the first few periods of the periodic table have a maximum of eight

electrons in their valence shells. We say that a chlorine ion ( $:\ddot{\text{Cl}}:^-$ ) or an argon atom ( $:\ddot{\text{Ar}}:$ ) has a completed octet in its valence shell.

The tendency of atoms to achieve valence octets describes and organizes a large amount of chemical reaction data. Atoms of elements in Groups I and II achieve an octet by losing electrons to form cations; atoms of elements in Groups VI and VII do so by gaining electrons to form anions. Reactions of the metallic elements on the left side of the periodic table with the nonmetallic elements on the right side always transfer just enough electrons to form ions with completed octets. The following equations use Lewis symbols to show the formation first of a cation and an anion and then of an **ionic compound**.

Another example is the formation of  $\text{CaBr}_2$ :

The total charge on the compound must be zero, thus the stoichiometry is determined by charge balance. The model predicts a 1:1 compound between Na and Cl and a 1:2 compound between Ca and Br, in agreement with experiment. By invoking the octet rule, the Lewis electron dot model predicts the formula for ionic compounds formed between atoms from Groups I and II and atoms from Groups VI and VII.

Ionic compounds are named by a systematic procedure. Elemental cations retain the name of the parent element, whereas the suffix *-ide* is added to the root name of the element that forms the anion. For example,  $\text{Cl}^-$  is chloride, and the compound it forms with  $\text{Na}^+$  is sodium chloride, the major ingredient in table salt. For this reason, ionic solids are often called salts. Simple, binary ionic compounds are easily named by inspection. Calcium bromide is a binary ionic compound with two  $\text{Br}^-$  anions per  $\text{Ca}^{2+}$  cation, to maintain electrical neutrality. Thus the formula unit of this ionic solid is  $\text{CaBr}_2$ . A more comprehensive discussion of inorganic nomenclature is presented in Section 3.13.

Let's consider the energetics of formation of an ionic bond from two neutral gas-phase atoms, potassium and fluorine to be specific. When the atoms are infinitely far apart, their interactions are negligible and we assign their potential energy of interaction as zero (see discussion in Section 3.5). Ionizing potassium requires energy, whereas attaching an electron to fluorine releases energy. The relevant reactions and their energy changes are

and

The total energy cost for the creation of this ion pair, when the parent atoms are infinitely far apart, is

$$\Delta E_\infty = IE_1(\text{K}) - EA(\text{F}) = +91 \text{ kJ mol}^{-1}$$

**FIGURE 3.21** The potential energy of the ions  $K^+$  and  $F^-$ , and the atoms  $K$  and  $F$ , as a function of their internuclear separation  $R_{12}$ .

Note that even for this case, in which one element is highly electronegative and the other is highly electropositive, it still *costs* energy to transfer an electron from a potassium atom to a fluorine atom. This is always true. Because the smallest ionization energy of any element (Cs,  $376 \text{ kJ mol}^{-1}$ ) is larger than the largest electron affinity of any element (Cl,  $349 \text{ kJ mol}^{-1}$ ), creating an ion pair from neutral atoms always requires energy. This fact is illustrated by the higher energy of the red curve as compared to the blue curve at large internuclear distances in Figure 3.21. The blue curve in Figure 3.21 shows how the potential energy of interaction between neutral  $F$  and  $K$  atoms depends on their separation. When the atoms are very far apart (right side of the figure), they have essentially no interaction, and their potential energy is by convention set to zero. As the atoms approach one another more closely, their potential energy becomes negative due to attractive forces. When the atoms are very close, their potential energy becomes positive due to repulsive forces. The minimum value in the curve occurs at the separation where attractive and repulsive forces exactly balance. The nature of the short-range attractive and repulsive forces between neutral atoms that do not share electrons to form a covalent bond is explained in Section 10.2. The minimum value of the blue curve in Figure 3.21 represents a very modest reduction in potential energy compared with the noninteracting free atoms.

Now let's start from an ion pair separated by a large distance and see what interaction and mechanism will reduce the potential energy of the system to form an ionic bond. The ions are attracted to one another (because they have opposite charges) by the electrostatic force, and the potential energy of the system is described by Coulomb's law:

$$V(R_{12}) = \frac{q_1 q_2}{4\pi\epsilon_0 R_{12}} \text{ (J per ion pair)} + V(\infty) \quad [3.19]$$

where  $q_1$  and  $q_2$  are the charges on the ions,  $R_{12}$  is the separation between the ions, and  $\epsilon_0$  is defined in Equation 3.1. We have added the potential energy

offset to the Coulomb potential of Equation 3.1 because we have already defined the zero of potential energy to be the potential energy of the neutral atoms at long distances from each other. The potential energy of the ion pair  $A^+ + B^-$  must be higher by  $IE(A) - EA(B)$  when  $A^+$  and  $B^-$  are far from each other. This energy, expressed in joules per ion pair, can be converted to  $\text{kJ mol}^{-1}$  by multiplying by Avogadro's number,  $N_A$ , and dividing by  $10^3$  to get

$$V(R_{12}) = \frac{q_1 q_2}{4\pi\epsilon_0 R_{12}} \frac{N_A}{10^3} (\text{kJ mol}^{-1}) + V(\infty) \quad [3.20]$$

For the  $K^+ + F^-$  potential energy curve,  $V(\infty) = +91 \text{ kJ mol}^{-1}$ . Figure 3.21 shows the actual potential energy as a function of the distance between the ions, choosing as zero the potential energy of the neutral atoms when they are infinitely far apart. You can see that the potential energy between  $K^+$  and  $F^-$  drops as they begin to get closer together, in agreement with the attractive Coulomb potential. However, well before the two ions reach  $R_{12} = R_e$  the ionic (red) potential energy curve is not well described by the simple Coulomb potential in Equation 3.20. This is because there is some sharing of the transferred electron between the two species as the ions near each other.

Both the neutral potential energy curve shown in blue and the ionic potential energy curve shown in red have a repulsive region at small  $R_{12}$ ; at these short distances the two positively charged nuclei (and the inner shells of electrons) are too close to each other for the shared electrons in the covalent bond or the Coulomb potential, respectively, to counterbalance this repulsion, so the potential energy goes up at small internuclear distances. The equilibrium bond distance  $R_e$  on the ionic (red) potential energy curve is shorter than that on the covalent (blue) potential energy curve because en route from large internuclear distances to  $R_{12} = R_e$  there has been a strong electrostatic attraction between the two ions, lowering the potential energy as  $R$  decreases from large to near  $R_e$ .

Starting at the right side of the curve in Figure 3.21, the potential energy of the pair of ions is greater than that of the neutral atoms by

$$\Delta E_\infty = IE_1(K) - EA(F) = +91 \text{ kJ mol}^{-1}$$

Moving toward the left side of Figure 3.21, the potential energy decreases rapidly as one follows the red curve to smaller  $R_{12}$ , due largely to the attractive *Coulomb stabilization energy* and reaches a minimum value at the equilibrium bond length,  $R_e = 2.17 \text{ \AA}$ . If we were to try to force the ions to move closer together, we would encounter the resistance depicted by the steep repulsive wall on the left side of the curve, which arises from the repulsive interactions between the core electrons of each of the ions. The equilibrium bond length,  $R_e$ , is determined by the balance between the attractive and repulsive forces.

At last, we can very roughly estimate the stabilization of an ionic bond such as KF relative to the neutral atoms, which is the key to formation of an ionic bond from two neutral atoms. From Figure 3.21, if the red ionic curve followed a Coulomb potential with  $q_1 = +e$  and  $q_2 = -e$  all the way from large  $R_{12}$  to  $R_{12} = R_e$ ,

$$\Delta E_d \approx -\frac{q_1 q_2}{4\pi\epsilon_0 R_e} \frac{N_A}{10^3} - \Delta E_\infty \quad [3.22]$$

where  $\Delta E_\infty = IE_1(K) - EA(F)$ . This energy measures the strength of the ionic bond and is approximately equal to the bond dissociation energy, which is the energy required to break the ionic bond and liberate neutral atoms.

**EXAMPLE 3.6**

Estimate the energy of dissociation to neutral atoms for KF, which has a bond length of  $2.17 \times 10^{-10}$  m. For KF,  $\Delta E_{\infty} = IE_1(\text{K}) - EA(\text{F}) = 91 \text{ kJ mol}^{-1}$ .

**Solution**

$$\begin{aligned}\Delta E_{\text{d}} &\approx -\frac{q_1 q_2}{4\pi\epsilon_0 R_{\text{c}}} \frac{N_{\text{A}}}{10^3} - \Delta E_{\infty} \\ &= -\frac{-(1.602 \times 10^{-19} \text{ C})^2 (6.022 \times 10^{23} \text{ mol}^{-1})}{(4)(3.1416)(8.854 \times 10^{-12} \text{ C}^2 \text{ J}^{-1} \text{ m}^{-1})(2.17 \times 10^{-10} \text{ m})(10^3 \text{ J kJ}^{-1})} \\ &\quad - 91 \text{ kJ mol}^{-1} \\ &= 640 \text{ kJ mol}^{-1} - 91 \text{ kJ mol}^{-1} \\ &= 549 \text{ kJ mol}^{-1}\end{aligned}$$

This estimate compares fairly well with the experimentally measured dissociation energy of  $498 \text{ kJ mol}^{-1}$ .

**Related Problems:** 23, 24, 25, 26

As shown in Example 3.6, our simple model for ionic bonding in KF predicts a bond dissociation energy  $\Delta E_{\text{d}}$  (the energy required to dissociate the molecule into neutral atoms, starting from the equilibrium bond length  $R_{\text{c}}$ ) of  $549 \text{ kJ mol}^{-1}$ , which agrees reasonably well with the experimental value of  $498 \text{ kJ mol}^{-1}$ . We can conclude that the bonding is predominantly ionic, and that the driving force for the formation of the bond is indeed the reduction of the potential energy of the system, relative to that of the separated atoms. The formation of the ions is a key intermediate step between the separated atoms and the stable ionic bond.

There are several reasons why this simple model does not do a better job in calculating the bond energy. First, all bonds have some degree of covalent character, which involves electron sharing between the atoms. Second, we have assumed that each ion is a point charge. In reality, the distribution of electrons around the fluoride ion is distorted by presence of the potassium ion; this distortion is called **polarization**. The effect of the nonsymmetric shape of the charge distribution on the bond energy is accounted for in more detailed calculations.

The mechanism by which an ionic bond forms from gas-phase atoms is interesting. The explanation is provided by comparing the potential energy curves for the ionic and neutral states in Figure 3.21 to determine which has the lower value at each separation  $R$ . For large separations the neutral atoms are always more stable than the ions. As the atoms draw closer together, their potential energy decreases slowly following the blue curve, until it approaches the red curve for ionic interactions at a particular distance. At distances shorter than this intersection point, the ionic species are favored because the Coulomb attraction between the ions more than compensates for the energy required to transfer the electron between the neutral atoms, and an ionic bond forms. At these shorter distances, the atom pair become ions and follow the red curve because it provides much lower potential energy. At very short distances the electrons of the two ions begin to repel each other and their potential energy rises steeply. The equilibrium bond length  $R_{\text{c}}$  of an ionic bond is determined by a balance of attractive and repulsive forces at the minimum of the red curve.

The Canadian chemist and Nobel Laureate John Polanyi proposed the following intriguing possibility. Electron transfer takes place when the neutral K and F atoms get close enough to each other, reaching the point at which the red and blue curves in Figure 3.21 intersect. The strong Coulombic attraction of the newly created ion pair then rapidly pulls the reactants together, where they form an ionic bond. The metal has sent its electron to “harpoon” the halogen, pulling it in with the “rope” of the Coulomb interaction. This **harpoon mechanism** has been studied extensively for a variety of systems and is generally agreed to provide a satisfactory semiquantitative description of the formation of gas-phase alkali halide molecules.

You should keep in mind that although gas-phase molecules with predominantly ionic bonding can be prepared and are stable at high temperatures and low pressures, most ionic bonds occur in ionic solids. In an ionic solid, ions of one charge are surrounded by an orderly array of ions of the opposite charge, resulting in extremely large Coulomb stabilization energies. See Figure 3.3 in Section 3.1.

### 3.9 Covalent and Polar Covalent Bonding

We have discussed how ionic bonding results from electron transfer and Coulomb stabilization of the resulting ions and that the propensity of a pair of atoms to form an ionic bond is determined by the difference in their electronegativities. What kinds of bonds are formed between elements of identical or comparable electronegativities to give compounds such as  $\text{H}_2$  or  $\text{CO}$ ?

For example, carbon (electronegativity 2.55) and hydrogen (electronegativity 2.20) react to form methane ( $\text{CH}_4$ ). Unlike ionic compounds, methane is a gas at room temperature, not a solid. Therefore, it is possible to prepare isolated methane molecules and determine their structure by experiment. Cooling methane to low temperatures condenses it to a solid in which the  $\text{CH}_4$  molecules do not strongly interact, so retain their identities. Methane dissolves in water to a slight extent, but it does not ionize. Thus, it is not useful to think of methane as an ionic substance made up of  $\text{C}^{4-}$  and  $\text{H}^+$  ions (or  $\text{C}^{4+}$  and  $\text{H}^-$  ions). Methane molecules are formed by covalent, not ionic, bonding.

What is the driving force for covalent bond formation from separated atoms in the gas phase? Section 3.7 provides a general argument for how a chemical bond forms from a pair of isolated atoms by arriving at an arrangement of electrons around the nuclei, which reduces the energy of the molecule below that of the isolated atoms. We have used that argument to show that for ionic compounds the driving force is the Coulomb stabilization of the ion pair. We present a plausibility argument to suggest why a covalent bond might form, by focusing on the *forces* acting on the nuclei due to the electrons.

Let's consider the simplest possible molecule,  $\text{H}_2^+$  (the hydrogen molecule ion), which has only one electron. In Figure 3.22,  $\text{H}_A$  identifies the position of nucleus A, and  $\text{H}_B$  that of nucleus B. The distance between the two nuclei is  $R_{AB}$ , represented by the dashed black line. The distances between the electron and each nucleus are  $r_{Ae}$  and  $r_{Be}$ , respectively, and are represented by the dashed red lines.

Let's identify all the forces between the three particles. There is the internuclear repulsive force,  $F_{AB} \propto (+Z_Ae)(+Z_Be)/R_{AB}^2$ , and two electron-nuclear attractive forces,  $F_{Ae} \propto (-e)(+Z_Ae)/r_{Ae}^2$  and  $F_{Be} \propto (-e)(+Z_Be)/r_{Be}^2$ . The internuclear repulsive force always opposes formation of a chemical bond (Fig. 3.22a), so we must identify some force that overcomes this repulsion. We need only consider the attractive forces and ask, “Over what region in space does the electron exert

**FIGURE 3.22** The forces between the particles in  $\text{H}_2^+$ . (a) The internuclear repulsion always opposes bonding the nuclei together. (b) An electron positioned in a region that will tend to bond the nuclei together, as shown by the force (red) that the electron exerts on each nucleus, and the component (blue) of each force along the internuclear axis. (c) An electron positioned in a region that will tend to pull the nuclei apart. (Adapted from G.C. Pimentel and R.D. Spratley, *Chemical Bonding Clarified through Quantum Mechanics*, Holden-Day Inc., San Francisco, 1969. Page 74.)

forces on the nuclei that will tend to pull them together?” Only the component of the attractive force directed along the internuclear axis is effective in drawing them together. In Figure 3.22b, the component of the attractive force that the electron exerts on each nucleus is shown in blue. When an electron is located in a region “between” the nuclei, as in Figure 3.22b, these blue components of the forces act to pull the nuclei together. In contrast, when the electron is “outside” the internuclear region (for example, see Fig. 3.22c), it exerts a greater force on the nearer nucleus than the farther, pulling the nuclei apart. The shared electrons in a covalent chemical bond might be postulated to be found at positions like that depicted in Figure 3.22b, not Figure 3.22c. Then the component of the force along the internuclear axis exerted on each nucleus by the electron is attractive, encouraging bonding. This simple model is supported by experimental data for  $\text{H}_2^+$ . Its equilibrium bond length  $R_e$  is 1.06 Å, and its bond dissociation energy  $\Delta E_d$  is 255.5 kJ mol<sup>-1</sup>, which is characteristic of a stable covalent bond.

This picture of covalent bonding in the  $\text{H}_2^+$  molecular ion can be applied to other molecules. For example, the  $\text{H}_2$  molecule is quite stable (its bond dissociation energy is 432 kJ mol<sup>-1</sup>), yet it consists of two identical atoms. There is no possibility of a net charge transfer from one to the other to form an ionic bond. The stability of  $\text{H}_2$  arises from the sharing of electrons between atoms in a covalent bond.

Any classical theory of chemical bond formation must explain certain properties of the chemical bond, explain trends observed in bonding, and most importantly, predict likely bonding properties of molecules not yet made. The most important classical descriptors of the chemical bond are the bond length, energy, order, and polarity.

### 3.9.1 Bond Lengths

For a diatomic molecule, the only relevant structural parameter is the bond length, that is, the distance between the nuclei of the two atoms. Table 3.3 lists the equilibrium bond lengths  $R_e$  of a number of diatomic molecules, expressed in units of angstroms ( $1 \text{ \AA} = 10^{-10} \text{ m}$ ). Certain systematic trends are immediately obvious. Among the members of a group in the periodic table, bond lengths usually increase with increasing atomic number  $Z$ . The  $\text{I}_2$  bond is longer than the  $\text{F}_2$  bond, for example, and those of  $\text{Cl}_2$  and  $\text{Br}_2$  fall in line, as they should. A particularly significant result from experiment is that the length of a bond of the same type (see later) between a given pair of atoms changes little from one molecule to another. For example, C—H bond lengths in acetylsalicylic acid (aspirin,  $\text{C}_9\text{H}_8\text{O}_4$ ) are about the same as they are in methane ( $\text{CH}_4$ ), although

TABLE 3.3

## Properties of Diatomic Molecules

Molecule	Bond Length (Å)	Bond Energy (kJ mol <sup>-1</sup> )
H <sub>2</sub>	0.751	432
N <sub>2</sub>	1.100	942

the molecules have different structures and physical and chemical properties. Table 3.4 shows that the lengths of O—H, C—C, and C—H bonds in a number of molecules are constant to within a few percent.

### 3.9.2 Bond Energies

The stability of a molecule is determined by the energy required to dissociate the molecule into its constituent atoms. The greater the energy required, the more stable the molecule. The **bond energy**, also called the bond dissociation energy, is the energy required to break one mole of the particular bond under

TABLE 3.4

## Reproducibility of Bond Lengths

Bond	Molecule	Bond Length (Å)
O—H	H <sub>2</sub> O	0.958
	H <sub>2</sub> O <sub>2</sub>	0.960

Bond lengths measured experimentally by rotational spectroscopy.

## CONNECTION TO INSTRUMENTAL ANALYSIS

### Molecular Spectroscopy

Much, if not most, of what we know about the structures and properties of molecules has been provided by molecular spectroscopy (see Chapter 20). We introduce you here to the interactions between electromagnetic radiation and matter and show how rotational and vibrational spectroscopy provide the experimental values of bond lengths (see Tables 3.3–3.6) as well as bond force constants (bond stiffness). Electromagnetic radiation may be absorbed, emitted, or scattered by molecules at frequencies that are characteristic of particular molecular motions. We ask you to simply accept, for now, three assertions about quantum mechanics: 1) that only certain values of the energy associated with these motions are allowed; 2) that electromagnetic radiation can be thought of as a beam of particles called photons, each of which has energy  $E = h\nu$ , where  $h$  is Planck's constant and the frequency  $\nu$  is the speed of light  $c$  divided by its wavelength (see Section 4.1), and 3) that absorbing, emitting, or scattering photons causes transitions between these “energy levels.” We can then introduce simple classical models that allow us to extract molecular properties from spectra.

Molecules in the gas phase rotate about their centers of mass at frequencies of  $10^{10}$ – $10^{12}$  Hz ( $s^{-1}$ ); absorbing microwave radiation at these frequencies excites them to higher energy rotational levels. Chemical bonds can be thought of as springs connecting atoms that are oscillating back and forth. Absorbing infrared radiation ( $10^{12}$ – $10^{13}$  Hz) forces these oscillators to vibrate with more energy. Let's consider the mechanisms by which absorption and scattering induce molecular motion. Electromagnetic radiation (see Section 4.1) consists of oscillating electric and magnetic fields oriented perpendicular to one another and to the direction in which they are travelling; the interactions between the electric fields and molecules are the most important. We showed earlier that charges are unevenly distributed in chemical bonds if the electronegativities of the atoms are different. Electric fields exert forces on charged particles, moving the positive charges in the direction of the field and the negative charges in the opposite direction. Figure C3.3 shows the forces exerted by an electric field on a heteronuclear diatomic molecule, with partial charges  $\delta^+$  and  $\delta^-$  on the two atoms. Figure C3.3a shows how an oscillating electric field induces rotation and Figure C3.3b shows how it induces vibration. Atoms of opposite charge move in opposite directions under the influence of the field; these directions reverse when the field direction reverses as it oscillates. Inelastic light scattering by molecules (Raman scattering) also induces molecular

**FIGURE C3.3** In (a), the applied electric would cause a molecule nonzero dipole moment to rotate, if you change the direction of the field in sync with the rotational period. In (b) changing the direction of the applied electric field during the vibrational motion of the polar diatomic molecule can induce it to vibrate with more energy. Thus the frequency  $\nu$  at which the applied electric field oscillates must be equal to the natural vibrational frequency of the diatomic molecule.

motion, even in nonpolar, homonuclear diatomic molecules. The energy difference between the incident and scattered photons is equal to the difference between the molecular energy levels.

### Rotational Spectroscopy: Bond Lengths and Bond Angles

Rotations of diatomic molecules are analyzed using the rigid rotor model (see Section 20.3) in which the atoms are represented as point masses attached to one another by a massless rigid rod with moment of inertia  $I = \mu R_c^2$ , where  $\mu = m_1 m_2 / (m_1 + m_2)$  is the reduced mass and  $R_c$  is the equilibrium bond length. Rotational spectra, obtained by microwave absorption or Raman spectroscopy, comprise a series of lines separated by  $2\tilde{B} = h/8\pi^2 c I$  where  $\tilde{B}$  ( $\text{cm}^{-1}$ ) is the rotational constant, which is proportional to energy. Each line in the microwave absorption spectrum of carbon monoxide shown in Figure C3.4 corresponds to the absorption of microwave radiation that excites molecules from one level to the next higher energy level. Many such transitions are allowed, as shown in Figure C3.4, but we are only interested in the value of  $\tilde{B}$  for now.

Rotational constants for  $\text{H}_2$ ,  $\text{N}_2$ ,  $\text{O}_2$ , and  $\text{CO}$  are 59.2, 1.99, 1.44, and 1.9  $\text{cm}^{-1}$ , respectively, from which you can calculate the bond lengths shown in Table 3.3 using the formulas introduced above. Rotational spectra of polyatomic molecules are much more complicated than those of diatomic molecules but they provide not only bond lengths but also bond angles and thus complete three-dimensional structures of gas-phase polyatomic molecules.

**FIGURE C3.4** Microwave absorption spectrum of carbon monoxide (CO). The horizontal axis gives the inverse of the wavelength of the light that is absorbed (multiply that by  $hc = 2 \times 10^{-23} \text{ J cm}$  to obtain the energy of the photon absorbed).

### Vibrational Spectroscopy: Force Constants and Molecular Structure

The harmonic oscillator model (see Section 20.3) is used to interpret vibrational spectra. Diatomic molecules are represented by two atomic masses, of reduced mass  $\mu$ , connected by a spring with stiffness (force constant)  $k$ . The fundamental frequency of a harmonic oscillator is given by  $\nu = \frac{1}{2\pi} \sqrt{\frac{k}{\mu}}$ . The energy levels of a harmonic oscillator are equally spaced with the separation between adjacent levels being given by  $\Delta E = h\nu$ , where  $h = 6.626 \times 10^{-34} \text{ J s}$ . Only transitions between adjacent levels are allowed, as for rotational spectroscopy, but they all occur at the same energy, resulting in spectra that are much simpler to interpret than rotational spectra. Figure C3.5 shows the Raman spectra of  $\text{H}_2$ ,  $\text{N}_2$ ,  $\text{O}_2$ , and  $\text{CO}$  to illustrate the ability of the technique to measure vibrational spectra of both homonuclear and heteronuclear diatomic molecules. Of these molecules, infrared absorption spectroscopy could measure only  $\text{CO}$ , because the mechanism discussed earlier requires that there be charge separation in the molecule to interact with the electric field of the radiation.

The spectra clearly reveal the dependence of the vibrational frequencies observed on both the reduced mass and the force constant. The vibrational frequency of  $\text{H}_2$  ( $4160 \text{ cm}^{-1}$ ) is the highest of the group because it is the lightest molecule and has only a single bond. The correlation between bond order and vibrational frequencies among a series of molecules with comparable reduced masses is clearly shown by the spectra of  $\text{N}_2$ ,  $\text{CO}$ , and  $\text{O}_2$ , with vibrational frequencies of 2331, 2143, and  $1550 \text{ cm}^{-1}$ , respectively. The vibrational frequencies of  $\text{N}_2$  and  $\text{CO}$  are comparable and much higher than

that of  $\text{O}_2$ , providing solid evidence for the greater strength of the triple bond in those molecules compared with the double bond in  $\text{O}_2$ . The ratio of the frequencies is very nearly  $3/2$ , the ratio of the bond orders.

Infrared spectroscopy is also widely used in chemical analysis to identify and characterize polyatomic molecules on the basis of distinctive functional group (see Section 7.4) frequencies. For example, the infrared spectrum of an amide shows the characteristic  $\text{N-H}$  and  $\text{C=O}$  stretching vibrations of the amide group as well as the  $\text{C-H}$  stretching vibrations of the methyl ( $\text{CH}_3$ ) and methylene ( $\text{CH}_2$ ) groups.

**FIGURE C3.5** Absorption of radiation by  $\text{O}_2$ ,  $\text{CO}$ ,  $\text{N}_2$ , and  $\text{H}_2$  molecules as a function of the frequency of the radiation. The frequency shown on the horizontal axis is  $\nu/c$ .

discussion (see Section 3.7). The bond energy is denoted by  $\Delta E_d$  (“d” stands for *dissociation* here) and is measured directly as the energy change for the dissociation reaction, for example

Bond energy is measured as part of the science of thermochemistry, described in Section 12.6. In essence, one mole of the compound is placed in a closed container and heated sufficiently to dissociate it completely into atoms. The amount of energy required is measured in units of  $\text{kJ mol}^{-1}$ . Table 3.3 lists bond energies for selected diatomic molecules. Again, certain systematic trends with changes in atomic number are evident. Bonds generally grow weaker with increasing atomic number, as shown by the decrease in the bond energies of the hydrogen halides in the order  $\text{HF} > \text{HCl} > \text{HBr} > \text{HI}$ . Note, however, the unusual weakness of the bond in the fluorine molecule,  $\text{F}_2$ . Its bond energy is significantly *smaller* than that of  $\text{Cl}_2$  and comparable with that of  $\text{I}_2$ . Bond strength decreases dramatically in the diatomic molecules from  $\text{N}_2$  ( $942 \text{ kJ mol}^{-1}$ ) to  $\text{O}_2$  ( $495 \text{ kJ mol}^{-1}$ ) to  $\text{F}_2$  ( $155 \text{ kJ mol}^{-1}$ ). What accounts for this behavior? A successful theory of bonding must explain both the general trends and the reasons for particular exceptions.

Bond energies, like bond lengths, are fairly reproducible (within about 10%) from one compound to another. It is therefore possible to tabulate *average* bond energies from measurements on a series of compounds. The energy required to break the O—H bond, for example, in each of the compounds shown in Table 3.4, is roughly  $465 \text{ kJ mol}^{-1}$ .

### 3.9.3 Bond Order

Sometimes, the length and energy of the bond between two specific kinds of atoms are *not* comparable among different compounds, but rather are sharply different. Table 3.5 shows the great differences in bond lengths and bond energies of carbon–carbon bonds in ethane ( $\text{H}_3\text{CCH}_3$ ), ethene ( $\text{H}_2\text{CCH}_2$ ), and ethyne ( $\text{HCCH}$ , commonly called acetylene). Carbon–carbon bonds from many other molecules all fit into one of the three classes given in the table (that is, some carbon–carbon bond lengths are close to  $1.54 \text{ \AA}$ , others are close to  $1.34 \text{ \AA}$ , and still others are close to  $1.20 \text{ \AA}$ ). This observation confirms the existence of not one, but three types of carbon–carbon bonds. We classify these as single, double, and triple bonds, respectively, based on their bond lengths and bond dissociation energies. The longest and weakest (as in ethane) is a single bond represented by  $\text{C}-\text{C}$ ; that of intermediate strength (as in ethene) is a double bond,  $\text{C}=\text{C}$ ; and the shortest and strongest (as in acetylene) is a triple bond,  $\text{C}\equiv\text{C}$ . We define the **bond order** as the number of shared electron pairs between the two atoms. Bond order is predicted by models of covalent bond formation.

Even these three types do not cover all the carbon–carbon bonds found in nature, however. In benzene ( $\text{C}_6\text{H}_6$ ), the experimental carbon–carbon bond length is  $1.397 \text{ \AA}$ , and its bond dissociation energy is  $505 \text{ kJ mol}^{-1}$ . This bond is intermediate between a single bond and a double bond (its bond order is  $1\frac{1}{2}$ ). In fact, the bonding in compounds such as benzene differs from that in many other

TABLE 3.5

Three Types of Carbon–Carbon Bonds

Bond	Molecule	Bond Length ( $\text{\AA}$ )	Bond Energy ( $\text{kJ mol}^{-1}$ )
$\text{C}-\text{C}$	$\text{C}_2\text{H}_6$ (or $\text{H}_3\text{CCH}_3$ )	1.536	345
$\text{C}=\text{C}$	$\text{C}_2\text{H}_4$ (or $\text{H}_2\text{CCH}_2$ )	1.337	612
$\text{C}\equiv\text{C}$	$\text{C}_2\text{H}_2$ (or $\text{HCCH}$ )	1.204	809

TABLE 3.6

Average Bond Lengths (in Å)

C—C	1.54	N—N	1.45	C—H	1.10
C=C	1.34	N=N	1.25	N—H	1.01
C≡C	1.20	N≡N	1.10	O—H	0.96
C—O	1.43	N—O	1.43	C—N	1.47
C=O	1.20	N=O	1.18	C≡N	1.16

compounds (see Chapter 7). Although many bonds have properties that depend primarily on the two atoms that form the bond (and thus are similar from one compound to another), bonding in benzene and related molecules, and a few other classes of compounds, depends on the nature of the whole molecule.

Multiple bonds occur between atoms other than carbon and even between unlike atoms. Some representative bond lengths are listed in Table 3.6.

The bond order is not measured experimentally. To test various theoretical predictions of bond order, we compare with a quantity called the **bond force constant**,  $k$ , which is measured experimentally by the technique of molecular vibration spectroscopy (see *Connection to Instrumental Analysis*). Experimental results show that the force constant increases with bond order. Comparing this result with Tables 3.5 and 3.6 shows that increased force constant correlates with higher bond energy and smaller bond length: stiffer bonds are stronger and shorter if the identity of the two atoms bonded together is unchanged. Comparing the theoretical quantity, bond order, with the experimental quantity, force constant, is one of the main ways to evaluate the accuracy of theoretical models of covalent bond formation.

### 3.9.4 Polar Covalent Bonding: Electronegativity and Dipole Moments

Laboratory measurements show that most real bonds are neither fully ionic nor fully covalent, but instead possess a mixture of ionic and covalent character. A bond in which there is a partial transfer of charge is called a **polar covalent bond**. This section provides an approximate description of the polar covalent bond based on the relative ability of each atom to attract the electron pair toward its nucleus. This ability is estimated by comparing the electronegativity values for the two atoms.

On the Pauling scale (see Fig. 3.18 and Appendix F), electronegativities range from 3.98 (for fluorine) to 0.79 (for cesium). These numerical values are useful for exploring periodic trends and for making semiquantitative comparisons. They represent the average tendency of an atom to attract electrons within a molecule, based on the properties of the bond it makes in a large range of compounds.

The absolute value of the difference in electronegativity of two bonded atoms tells the degree of *polarity* in their bond. A large difference (greater than about 2.0) means that the bond is ionic and that an electron has been transferred completely or nearly completely to the more electronegative atom. A small difference (less than about 0.4) means that the bond is largely covalent, with electrons in the bond shared fairly evenly. Intermediate values of the difference signify a polar covalent bond with intermediate character. These suggested dividing points between bond types are not hard and fast rules, and your instructor may suggest alternative values.

**EXAMPLE 3.7**

Using Figure 3.10, arrange the following bonds in order of decreasing polarity: H—C, O—O, H—F, I—Cl, Cs—Au.

**Solution**

The differences in electronegativity among the five pairs of atoms (without regard to sign) are 0.35, 0.00, 1.78, 0.50, and

1.75, respectively. The order of decreasing polarity is the same as the order of decrease in this difference: H—F, Cs—Au, I—Cl, H—C, and O—O. The last bond in this listing is nonpolar.

**Related Problems: 31, 32, 33, 34**

### 3.9.5 Dipole Moments and Percent Ionic Character

A bond that is almost purely ionic, such as that of KF, can be thought of as arising from the nearly complete transfer of one electron from the electropositive to the electronegative species. KF can be described fairly accurately as  $K^+F^-$ , with charges  $+e$  and  $-e$  on the two ions. However, characterizing the charge distribution for a molecule such as HF, which has significant covalent character, is more complex. If we wish to approximate the bond by its ionic character, it is best described as  $H^{\delta+}F^{\delta-}$ , where some fraction,  $\delta$  of the full charge,  $e$ , is on each nucleus. A useful measure of the ionic character of a bond, arising from electronegativity differences, especially for diatomic molecules, is the dipole moment of the molecule. If two charges of equal magnitude and opposite sign,  $+q$  and  $-q$ , are separated by a distance  $R$ , the **dipole moment**  $\bar{\mu}$  (Greek letter lowercase mu) of that charge distribution is

$$\bar{\mu} = q\bar{R} \quad [3.23]$$

$\bar{R}$  is the vector from the atom with partial negative charge to the atom with partial positive charge. In SI units the magnitude  $\mu$  of the dipole moment is measured in Coulomb meters, an inconveniently large unit for discussing molecules. The unit most often used is the debye (D), which is related to SI units by

$$1 \text{ D} = 3.336 \times 10^{-30} \text{ C m}$$

(This apparently peculiar definition arises from the transition from electrostatic units to SI units.) The debye can also be defined as the dipole moment of two charges  $\pm e$  separated by 0.2082 Å. If  $\delta$  is the fraction of a unit charge on each atom in a diatomic molecule ( $q = \delta e$ ) and  $R$  is the equilibrium bond length, then

$$\mu(\text{D}) = [R(\text{\AA})/0.2082 \text{\AA}] \delta \quad [3.24]$$

This equation can, of course, be inverted to determine the fraction ionic character from the experimental value of the dipole moment. Dipole moments are measured experimentally by electrical and spectroscopic methods and provide useful information about the nature of bonding. In HF, for example, the value of  $\delta$  calculated from the dipole moment ( $\mu = 1.82 \text{ D}$ ) and bond length ( $R = 0.917 \text{\AA}$ ) is 0.41, substantially less than the value of 1 for a purely ionic bond. We convert  $\delta$  to a “percent ionic character” by multiplying by 100% and say that the bond in HF is 41% ionic. Deviations from 100% ionic bonding occur for two reasons: (1) covalent contributions lead to electron sharing between atoms, and (2) the electronic charge distribution around one ion may be distorted by the electric field of the other ion (polarization). When polarization is extreme, regarding the ions as point charges is no longer a good approximation, and a more accurate description of the distribution of electric charge is necessary.

Table 3.7 provides a scale of ionic character for diatomic molecules, based on the definition of  $\delta$ . The degree of ionic character inferred from the dipole moment is reasonably well correlated with the Pauling electronegativity

TABLE 3.7

Dipole Moments of Diatomic Molecules

Molecule	Bond Length (Å)	Dipole Moment (D)	% Ionic Character (100 $\delta$ )
H <sub>2</sub>	0.751	0	0
CO	1.131	0.112	2
NO	1.154	0.159	3
HI	1.620	0.448	6
ClF	1.632	0.888	11
HBr	1.424	0.828	12
HCl	1.284	1.109	18
HF	0.926	1.827	41
CsF	2.347	7.884	70
LiCl	2.027	7.129	73
LiH	1.604	5.882	76
KBr	2.824	10.628	78
NaCl	2.365	9.001	79
KCl	2.671	10.269	82
KF	2.176	8.593	82
LiF	1.570	6.327	84
NaF	1.931	8.156	88

differences (Fig. 3.23). A great deal of ionic character usually corresponds to a large electronegativity difference, with the more electropositive atom carrying the charge  $+\delta e$ . There are exceptions to this general trend, however. Carbon is less electronegative than oxygen, so one would predict a charge distribution of  $C^{\delta+}O^{\delta-}$  in the CO molecule. In fact, the measured dipole moment is quite small in magnitude and is oriented in the opposite direction:  $C^{\delta-}O^{\delta+}$  with  $\delta = 0.02$ . The discrepancy arises because of the lone-pair electron density on the carbon atom (which is reflected in the formal charge of  $-1$  carried by that atom, as discussed in Section 3.10).

In summary, the properties of a covalent chemical bond are often quite similar in a variety of compounds, but we must be alert for exceptions that may signal new types of chemical bonding.

**FIGURE 3.23** Two measures of ionic character for diatomic molecules are the electronegativity difference (from Fig. 3.18) and the percent ionic character  $100 \delta$ , calculated from the observed dipole moment and bond length. The curve shows that the two correlate approximately but that there are many exceptions.

## 3.10 Electron Pair Bonds and Lewis Diagrams for Molecules

The goal of the Lewis model is to predict the *structural formula* for a molecule whose molecular formula is already known. In what sequence are the atoms bonded to each other, and by what kinds of bonds? The Lewis model approaches this goal by considering covalent bonds to be shared pairs of valence electrons positioned between two nuclei, where they can help attract the nuclei together and to contribute to the bond strength through the mechanism described in Fig. 3.14b. This bonding model is visually described with the Lewis electron dot symbols for the valence electrons in atoms introduced at the end of Section 3.4.

The Lewis model for covalent bonding starts with the recognition that electrons are not transferred from one atom to another in a nonionic compound, but rather are *shared* between atoms to form covalent bonds. Hydrogen and chlorine combine, for example, to form the **covalent compound** hydrogen chloride. This result can be indicated with a *Lewis diagram* for the molecule of the product, in which the valence electrons from each atom are redistributed so that one electron from the hydrogen atom and one from the chlorine atom are now shared by the two atoms. The two dots that represent this electron pair are placed between the symbols for the two elements:

The basic rule that governs Lewis diagrams is the **octet rule**: Whenever possible, the electrons in a covalent compound are distributed in such a way that each main-group element (except hydrogen) is surrounded by eight electrons (an *octet* of electrons). Hydrogen has two electrons in such a structure. When the octet rule is satisfied, the atom attains the special stability of a noble-gas shell. As a reminder, the special stability of the noble-gas configuration arises from the fact that electrons in a filled shell experience the maximum electron–nuclear attraction possible. In the structure for HCl shown earlier, the H nucleus has two valence electrons in its shell (like the noble gas, He), and Cl has eight (like Ar). Electrons that are shared between two atoms are counted as contributing to the filling of the valence shells of both atoms.

A shared pair of electrons is more typically represented by a short line (–)

The unshared electron pairs around the chlorine atom in the Lewis diagram are called **lone-pair electrons**, and they make no contribution to the bond between the atoms. Lewis diagrams of some simple covalent compounds are

Lewis diagrams show how bonds connect the atoms in a molecule, but they do not show the spatial geometry of the molecule. The ammonia molecule is not planar, but pyramidal, with the nitrogen atom at the apex. The water molecule

**FIGURE 3.24** Molecules of three familiar substances, drawn in ball-and-stick fashion. The sizes of the balls have been reduced somewhat to show the bonds more clearly, but the relative sizes of the balls are correct. (a) Ammonia,  $\text{NH}_3$ . (b) Water,  $\text{H}_2\text{O}$ . (c) Methane,  $\text{CH}_4$ .

**FIGURE 3.25** Ethane,  $\text{C}_2\text{H}_6$ , can be burned in oxygen as a fuel, and if strongly heated, it reacts to form hydrogen and ethylene.

**FIGURE 3.26** Ethene, also called ethylene,  $\text{C}_2\text{H}_4$ , is the largest volume organic (carbon-containing) chemical produced.

**FIGURE 3.27** Ethyne, or acetylene,  $\text{C}_2\text{H}_2$ , has a triple bond that makes it highly reactive.

is bent rather than straight. Three-dimensional geometries can be represented by ball-and-stick models (such as those shown in Fig. 3.24).

More than one pair of electrons may be shared by two atoms in a bond. For example, in the oxygen molecule, each atom has six valence electrons. Thus, for each to achieve an octet configuration, *two* pairs of electrons must be shared, making a **double bond** between the atoms:

Similarly, the  $\text{N}_2$  molecule has a **triple bond**, involving three shared electron pairs:

In contrast, the  $\text{F}_2$  molecule has only a single bond. The number of shared electron pairs in a bond determines the order of the bond, which has already been connected with bond energy and bond length in Section 3.9. The decrease in bond order from 3 to 2 to 1 explains the dramatic reduction in the bond energies of the sequence of diatomic molecules  $\text{N}_2$ ,  $\text{O}_2$ , and  $\text{F}_2$ . A carbon–carbon bond can involve the sharing of one, two, or three electron pairs. A progression from single to triple bonding is found in the hydrocarbons ethane ( $\text{C}_2\text{H}_6$ , Fig. 3.25), ethene ( $\text{C}_2\text{H}_4$ , Fig. 3.26), and ethyne ( $\text{C}_2\text{H}_2$ , Fig. 3.27):

This progression corresponds to the three types of carbon–carbon bonds with properties that are related to bond order in Section 3.9 and are summarized in Tables 3.4 and 3.5.

Multiple bonding to attain an octet most frequently involves the elements carbon, nitrogen, oxygen, and, to a lesser degree, sulfur. Double and triple bonds are shorter than a single bond between the same pair of atoms (see illustrative examples in Table 3.5).

### 3.10.1 Formal Charges

In a **homonuclear diatomic molecule** (in which both atoms are the same, as in  $\text{H}_2$  and  $\text{Cl}_2$ ), the electrons are shared equally between the two atoms, and the covalency is nearly ideal for such molecules.

Consider, however, a molecule of carbon monoxide ( $\text{CO}$ ). Its Lewis diagram has a triple bond

that uses the ten valence electrons (four from the C and six from the O) and gives each atom an octet. If the six bonding electrons were shared equally, the carbon atom would own five valence electrons (one *more* than its group number) and the oxygen atom would own five electrons (one *less* than its group number). Equal sharing implies that, formally, the carbon atom must gain an electron and the oxygen atom must lose an electron. This situation is described by assigning a **formal charge** to each atom, defined as the charge an atom in a molecule would have if the electrons in its Lewis diagram were divided equally among the atoms that share them. Thus, in  $\text{CO}$ , C has a formal charge of  $-1$  and O has a formal charge of  $+1$ :

**FIGURE 3.28** Carbon monoxide, CO, is a colorless, odorless, and toxic gas produced by the incomplete burning of hydrocarbons in air. It is used in the production of elemental metals from their oxide ores.

Carbon monoxide (Fig. 3.28) is a covalent compound, and the assignment of formal charges does not make it ionic. Formal charges are not real charges, and they are not measured. They appear only in the context of drawing Lewis diagrams, where they guide us in deciding whether a proposed diagram represents a reasonable structural formula for a real compound.

We emphasize that the idea of equal sharing of electrons in the bond of a **heteronuclear diatomic molecule**, such as CO, has no experimental basis. It is merely assumed as a starting point for estimating the possibility for separation of positive and negative charge that would arise in a proposed molecular structure solely from the difference in valence (group number) of the participating atoms. If the formal charges in a proposed Lewis diagram differ significantly from what we see in ordinary chemical experience, that diagram should be considered a poor candidate for describing a real molecule, and other possible Lewis diagrams must be examined. There are no hard and fast rules, but here are some general guidelines. Diagrams with like formal charges on adjacent atoms would correspond to unstable molecules and should be discarded. Diagrams with opposite formal charges on adjacent atoms are good so long as the negative charge is on the more electronegative atom and the positive charge is on the more electropositive atom. (The example of CO above shows that this guideline cannot always be achieved.) Diagrams with positive formal charges on the more electronegative atom and negative charges on the more electropositive atom are less favorable. Opposite formal charges are more favorable if they are located on atoms close together than if they are located on atoms farther apart. Diagrams with low formal charges (0, +1, -1) on atoms are favorable.

The formal charge on an atom in a Lewis diagram is simple to calculate. If the valence electrons were removed from an atom, it would have a positive charge equal to its group number in the periodic table (elements in Group VI, the chalcogens, have six valence electrons, and therefore a charge of +6 when those electrons are removed). From this positive charge, subtract the number of lone-pair valence electrons possessed by the atom in the Lewis diagram, and then subtract half of the number of bonding electrons it shares with other atoms:

$$\text{formal charge} = \text{number of valence electrons} - \text{number of electrons in lone pairs} - \frac{1}{2} (\text{number of electrons in bonding pairs})$$

### EXAMPLE 3.8

Compute the formal charges on the atoms in the following Lewis diagram, which represents the azide ion ( $\text{N}_3^-$ ).

#### Solution

Nitrogen is in Group V. Hence, each N atom contributes 5 valence electrons to the bonding, and the negative charge on the ion contributes 1 more electron. The Lewis diagram correctly represents 16 electrons.

Each of the terminal nitrogen atoms has four electrons in lone pairs and four bonding electrons (which comprise a double bond) associated with it. Therefore,

$$\text{formal charge}_{(\text{terminal N})} = 5 - 4 - \frac{1}{2}(4) = -1$$

The nitrogen atom in the center of the structure has no electrons in lone pairs. Its entire octet comprises the eight bonding electrons:

$$\text{formal charge}_{(\text{central N})} = 5 - 0 - \frac{1}{2}(8) = +1$$

The sum of the three formal charges is -1, which is the true overall charge on this polyatomic ion. Failure of this check indicates an error either in the Lewis diagram or in the arithmetic.

**Related Problems: 39, 40, 41, 42**

## 3.10.2 Drawing Lewis Diagrams

When drawing Lewis diagrams, we shall assume that the molecular “skeleton” (that is, a plan of the bonding of specific atoms to other atoms) is known. In this

respect, it helps to know that hydrogen and fluorine bond to only one other atom and are always terminal atoms in Lewis diagrams. A systematic procedure for drawing Lewis diagrams can then be followed, as expressed by the following guidelines:

1. Count the total number of valence electrons available by first using the group numbers to add the valence electrons from all the atoms present. If the species is a negative ion, *add* additional electrons to achieve the total charge. If it is a positive ion, *subtract* enough electrons to result in the total charge.
2. Calculate the total number of electrons that would be needed if each atom had its *own* noble-gas shell of electrons around it (two for hydrogen, eight for carbon and heavier elements).
3. Subtract the number in step 1 from the number in step 2. This is the number of shared (or bonding) electrons present.
4. Assign two bonding electrons (one pair) to each bond in the molecule or ion.
5. If bonding electrons remain, assign them in pairs by making some double or triple bonds. In some cases, there may be more than one way to do this. In general, double bonds form only between atoms of the elements C, N, O, and S. Triple bonds are usually restricted to C, N, or O.
6. Assign the remaining electrons as lone pairs to the atoms, giving octets to all atoms except hydrogen.
7. Determine the formal charge on each atom and write it next to that atom. Check that the formal charges add up to the correct total charge on the molecule or polyatomic ion. (This step not only guides you to the better diagrams, it also provides a check for inadvertent errors such as the wrong number of dots).
8. If more than one diagram is possible, choose the one with the smallest magnitudes of formal charges (0, +1, -1) and with any negative formal charges placed on the most electronegative atoms.

The use of these guidelines is illustrated by Example 3.9.

### EXAMPLE 3.9

Write a Lewis electron dot diagram for phosphoryl chloride,  $\text{POCl}_3$  (Fig. 3.29). Assign formal charges to all the atoms.

#### Solution

The first step is to calculate the total number of valence electrons available in the molecule. For  $\text{POCl}_3$ , it is

$$5 \text{ (from P)} + 6 \text{ (from O)} + [3 \times 7 \text{ (from Cl)}] = 32$$

Next, calculate how many electrons would be necessary if each atom were to have its own noble-gas shell of electrons around it. Because there are 5 atoms in the present case (none of them hydrogen), 40 electrons would be required. From the difference of these numbers ( $40 - 32 = 8$ ), each atom can achieve an octet only if 8 electrons are shared between pairs of atoms. The 8 electrons correspond to 4 electron pairs, so each of the four linkages in  $\text{POCl}_3$  must be a single bond. (If the number of shared electron pairs were *larger* than the number of bonds, double or triple bonds would be present.)

**FIGURE 3.29** Phosphoryl chloride,  $\text{POCl}_3$ , is a reactive compound used to introduce phosphorus into organic molecules in synthesis reactions. Experimental studies show that the P—O bond is more like a double bond than a single bond. Lewis diagrams rationalizing the existence of the P=O double bond can be constructed as an example of valence shell expansion. See the discussion in Section 3.10.4.

(Continued)

The other 24 valence electrons are assigned as lone pairs to the atoms in such a way that each achieves an octet configuration. The resulting Lewis diagram is

Formal charges are already indicated in blue in this diagram. Phosphorus has the group number V, and it shares eight electrons with no lone-pair electrons, so

$$\text{formal charge on P} = 5 - 4 = +1$$

Oxygen has the group number VI with six lone-pair electrons and two shared electrons, so

$$\text{formal charge on O} = 6 - 6 - \frac{1}{2}(2) = -1$$

All three chlorine atoms have zero formal charge, computed by

$$\text{formal charge on Cl} = 7 - 6 - \frac{1}{2}(2) = 0$$

**Related Problems: 43, 44, 45, 46, 47, 48, 49, 50**

**FIGURE 3.30** Ozone,  $\text{O}_3$ , is a pale blue gas with a pungent odor. It condenses to a dark blue liquid below  $-112^\circ\text{C}$ .

### 3.10.3 Resonance Forms

For certain molecules or molecular ions, two or more equivalent Lewis diagrams can be written. An example is ozone ( $\text{O}_3$ , Fig. 3.30), for which there are two possible Lewis diagrams:

These diagrams suggest that one O—O bond is a single bond and the other one is a double bond, so the molecule would be asymmetric. In fact, the two O—O bond lengths are found experimentally to be identical, with a bond length of  $1.28 \text{ \AA}$ , which is intermediate between the O—O single bond length in  $\text{H}_2\text{O}_2$  ( $1.49 \text{ \AA}$ ) and the O=O double bond length in  $\text{O}_2$  ( $1.21 \text{ \AA}$ ).

The Lewis model fails to predict the correct structural formula for  $\text{O}_3$ . The Lewis model handles such cases by saying that the actual bonding in  $\text{O}_3$  is represented as a **resonance hybrid** of the two Lewis diagrams in each of which one of the bonds is intermediate between a single bond and a double bond. This hybrid is represented by connecting the diagrams with a double-headed arrow:

The term *resonance* does not mean that the molecule physically oscillates back and forth from one of these bonding structures to the other. Rather, within the limitations of the Lewis dot model of bonding, the best representation of the actual bonding is a hybrid diagram that includes features of each of the acceptable individual diagrams. This concept of resonance arises because the Lewis model very strictly defines a chemical bond as a pair of electrons localized between two nuclei. In cases like  $\text{O}_3$  where the electrons are delocalized over the entire molecule, we seek another bonding model to overcome this limitation in the Lewis model. The need for resonance is avoided by using molecular orbital theory to describe chemical bonding (see Chapter 6).

## EXAMPLE 3.10

Draw three resonance forms for the nitrate ion  $\text{NO}_3^-$ , (Fig. 3.31), and estimate the bond lengths.

**Solution**

$\text{NO}_3^-$  contains 24 valence electrons. For each atom to have its own octet,  $4 \times 8 = 32$  electrons would be required. Therefore,

**FIGURE 3.31** The nitrate ion,  $\text{NO}_3^-$  has a symmetric planar structure.

$32 - 24 = 8$  electrons must be shared between atoms, implying a total of four bonding pairs. These can be distributed in one double and two single bonds, leading to the equivalent resonance diagrams:

The two singly bonded oxygen atoms carry formal charges of  $-1$ , and the charge of the nitrogen atom is  $+1$ . The bond lengths should all be equal and should lie between the values given in Table 3.6 for  $\text{N}-\text{O}$  ( $1.43 \text{ \AA}$ ) and  $\text{N}=\text{O}$  ( $1.18 \text{ \AA}$ ). The experimentally measured value is  $1.24 \text{ \AA}$ .

**Related Problems:** 51, 52, 53, 54, 55, 56

## 3.10.4 Breakdown of the Octet Rule

Lewis diagrams and the octet rule are useful tools for predicting the types of molecules that will be stable under ordinary conditions of temperature and pressure. For example, we can write a simple Lewis diagram for water ( $\text{H}_2\text{O}$ ),

in which each atom has a noble-gas configuration. It is impossible to do this for  $\text{OH}$  or for  $\text{H}_3\text{O}$ , which suggests that these species are either unstable or highly reactive.

There are several situations in which the octet rule is *not* satisfied.

**Case 1: Odd-Electron Molecules**

The electrons in a Lewis diagram that satisfies the octet rule must occur in pairs—bonding pairs or lone pairs. Any molecule that has an odd number of electrons cannot satisfy the octet rule. Most stable molecules have even numbers of electrons, but a few have odd numbers. An example is nitrogen oxide ( $\text{NO}$ ), a stable (although reactive) molecule that is an important factor in air pollution. Nitrogen oxide has 11 electrons, and the best electron dot diagram for it is

in which only the oxygen atom has a noble-gas configuration. The stability of  $\text{NO}$  contradicts the octet rule.

**Case 2: Octet-Deficient Molecules**

Some molecules are stable even though they have too few electrons to achieve an octet. For example, the standard rules for  $\text{BF}_3$  (Figure 3.32) would lead to the Lewis diagram

**FIGURE 3.32** Boron trifluoride,  $\text{BF}_3$ , is a highly reactive gas that condenses to a liquid at  $-100^\circ\text{C}$ . Its major use is in speeding up a large class of reactions that involve carbon compounds.

but experimental evidence strongly suggests there are no double bonds in  $\text{BF}_3$  (fluorine never forms double bonds).

Moreover, the placement of a positive formal charge on fluorine is highly non-favored. The following diagram avoids both problems:

Although this Lewis diagram denies an octet to the boron atom, it does at least assign zero formal charges to all atoms.

**FIGURE 3.33** Sulfur hexafluoride,  $\text{SF}_6$ , is an extremely stable, dense, and nonreactive gas. It is used as an insulator in high-voltage generators and switches.

### Case 3: Valence Shell Expansion

Lewis diagrams become more complex in compounds formed from elements in the third and subsequent periods. For example, sulfur forms some compounds that are readily described by Lewis diagrams that give closed shells to all atoms. An example is hydrogen sulfide ( $\text{H}_2\text{S}$ ), which is analogous to water in its Lewis diagram. In sulfur hexafluoride ( $\text{SF}_6$ ) (Figure 3.33), however, the central sulfur is bonded to six fluorine atoms.

This molecule cannot be described by a Lewis diagram unless more than eight electrons are allowed around the sulfur atom, a process called **valence shell expansion**. The resulting Lewis diagram is

The fluorine atoms have octets, but the central sulfur atom shares a total of 12 electrons.

In the standard procedure for writing Lewis diagrams, the need for valence shell expansion is signaled when the number of shared electrons is not sufficient to place a bonding pair between each pair of atoms that are supposed to be bonded. In  $\text{SF}_6$ , for example, 48 electrons are available, but 56 are needed to form separate octets on 7 atoms. This means that  $56 - 48 = 8$  electrons would be shared. Four electron pairs are not sufficient to make even single bonds between the central S atom and the 6 terminal F atoms. In this case, we still follow rule 4 (assign one bonding pair to each bond in the molecule or ion; see earlier), even though it requires that we use more than 8 electrons. Rule 5 becomes irrelevant because there are no extra shared electrons. Rule 6 is now replaced with a new rule:

*Rule 6': Assign lone pairs to the terminal atoms to give them octets. If any electrons still remain, assign them to the central atoms as lone pairs if the central atom is not one from the 2nd period.*

The effect of rule 6' is to abandon the octet rule for the central atom but preserve it for the terminal atoms.

### EXAMPLE 3.11

Write a Lewis diagram for  $\text{I}_3^-$ , the linear (tri-iodide) ion.

#### Solution

There are 7 valence electrons from each iodine atom plus 1 from the overall ion charge, giving a total of 22. Because  $3 \times 8 = 24$  electrons would be needed in separate octets,

$24 - 22 = 2$  are shared according to the original rules. Two electrons are not sufficient to make two different bonds, however, so valence expansion is necessary.

(Continued)

A pair of electrons is placed in each of the two bonds, and rule 6' is used to complete the octets of the two terminal I atoms. This leaves

At this stage, 16 valence electrons have been used. The remaining 6 are placed as lone pairs on the central I atom. A formal charge of  $-1$  then resides on this atom:

Note the valence expansion on the central atom: It shares or owns a total of 10 electrons, rather than the 8 required by adherence to the octet rule.

**Related Problems: 57, 58**

The Lewis model represents covalent bonds as shared valence-electron pairs positioned between two nuclei, where they presumably are involved in net attractive interactions that pull the nuclei together and contribute to the strengthening of the bond. The bonding mechanism cannot be explained by classical physics, and is examined through quantum mechanics in Chapter 6.

Despite its uncertainties and limitations, the Lewis model is still the best starting point for a systematic exploration of the bonding and structure in a molecule. Most working chemists draw a Lewis diagram to propose a structural formula as the first step of this exploration described in Section 3.1.

### 3.11 The Shapes of Molecules: Valence Shell Electron-Pair Repulsion Theory

When two molecules approach one another to begin a chemical reaction, the probability of a successful encounter can depend critically on the three-dimensional shapes and the relative orientation of the molecules, as well as on their chemical identities. Shape is especially important in biological and biochemical reactions, in which molecules must fit precisely onto specific sites on membranes and templates; drug and enzyme activity are important examples. Characterization of molecular shape is therefore an essential part of the study of molecular structure.

The structure of a stable molecule is defined by the three-dimensional arrangement of its constituent atoms. Pictorial representations of molecular structure—for example, the familiar “ball-and-stick” models and sketches—show the positions of the nuclei of the constituent atoms, but not the positions of their electrons. The electrons are responsible for the chemical bonds that hold the atomic nuclei together as the molecule. Several properties characterize the three-dimensional structure of molecules (Fig. 3.34). The bond length measures the distance between the atomic nuclei in a particular bond; summing bond lengths projected along the three Cartesian axes provides a measure of the size and shape of the molecule. Bond angles, defined as the angle between the axes of adjacent bonds, provide a more detailed view of the three-dimensional structures of molecules. Finally, the relationships between two planes, each defined by three atoms with the planes having two atoms in common (the angle between these planes is the *dihedral angle*) provide additional insights into the topology of simple molecules. However, molecules are not rigid entities, with structures that are precisely defined by the coordinates of their nuclei. Their atoms vibrate about their equilibrium positions, albeit with relatively small displacements. Average bond lengths and angles are measured by spectroscopic techniques (see Chapter 20) and X-ray diffraction (see Section 21.1).

Molecular shape or geometry is governed by energetics; a molecule assumes the geometry that gives it the lowest potential energy. Sophisticated quantum

**FIGURE 3.34** Three-dimensional molecular structures of (a) H<sub>2</sub>, (b) SO<sub>2</sub>, (c) NH<sub>3</sub>, and (d) C<sub>2</sub>H<sub>4</sub>O<sub>2</sub>, showing bond lengths and angles. (Courtesy of Prof. Andrew J. Pounds, Mercer University, Macon, GA, and Dr. Mark A. Iken, Scientific Visualization Laboratory, Georgia Institute of Technology, Atlanta, GA.)

**FIGURE 3.35** The positions of minimum energy for electron pairs on a sphere centered on the nucleus of an atom. The angles between the electron pairs are indicated. For two, three, and four electron pairs they are 180°, 120°, and 109.47°, respectively.

mechanical calculations consider numerous possible geometrical arrangements for a molecule, calculate the total potential energy of the molecule for each arrangement, and identify the arrangement that gives the lowest potential energy. This procedure can be mimicked within the approximate classical model described in this chapter by considering numerous possible arrangements of bond angles and then identifying the one that corresponds to the lowest potential energy of the molecule. Because a covalent bond is formed by the sharing of a pair of electrons between two atoms (as described by the Lewis model in Section 3.10), changes in bond angles change the relative positions of the electron pairs around a given central atom. Electron pairs tend to repel each other through the electrostatic (Coulomb) repulsion between like charges and through quantum mechanical effects. Consequently, it is desirable in terms of energy for electrons to avoid each other. The VSEPR theory provides procedures for predicting molecular geometry by minimizing the potential energy due to electron-pair repulsions.

### 3.11.1 The Valence Shell Electron-Pair Repulsion Theory

The VSEPR theory starts with the fundamental idea that electron pairs in the valence shell of an atom repel each other. These include both lone pairs, which are localized on the atom and are not involved in bonding, and bonding pairs, which are shared covalently with other atoms. The electron pairs position themselves as far apart as possible to minimize their repulsions. The molecular geometry, which is defined by the positions of the *nuclei*, is then traced from the relative locations of the electron pairs.

The arrangement that minimizes repulsions naturally depends on the number of electron pairs. Figure 3.35 shows the minimum energy configuration for two to six electron pairs located around a central atom. Two electron pairs place themselves on opposite sides of the atom in a linear arrangement, three pairs form a trigonal planar structure, four arrange themselves at the corners of a tetrahedron, five define a trigonal bipyramid, and six define an octahedron. To find which geometry applies, we determine the **steric number**, SN, of the central atom, which is defined as

$$\text{SN} = \left( \begin{array}{c} \text{number of atoms} \\ \text{bonded to central atom} \end{array} \right) + \left( \begin{array}{c} \text{number of lone pairs} \\ \text{on central atom} \end{array} \right)$$

The steric number of an atom in a molecule can be determined by inspection from the Lewis diagram of the molecule.

## EXAMPLE 3.12

Calculate steric numbers for iodine in  $\text{IF}_4^-$  and for bromine in  $\text{BrO}_4^-$ . These molecular ions have central I or Br surrounded by the other four atoms.

**Solution**

The central  $\text{I}^-$  atom has eight valence electrons.

Each F atom has seven valence electrons of its own and needs to share one of the electrons from  $\text{I}^-$  to achieve a noble-gas configuration. Thus, four of the  $\text{I}^-$  valence electrons take part

in covalent bonds, leaving the remaining four to form two lone pairs. The steric number is given by

$$\text{SN} = 4 (\text{bonded atoms}) + 2 (\text{lone pairs}) = 6$$

In  $\text{BrO}_4^-$ , each oxygen atom needs to share two of the electrons from  $\text{Br}^-$  to achieve a noble-gas configuration.

Because this assignment accounts for all eight of the  $\text{Br}^-$  valence electrons, there are no lone pairs on the central atom and

$$\text{SN} = 4 (\text{bonded atoms}) + 0 (\text{lone pairs}) = 4$$

Double-bonded or triple-bonded atoms count the same as single-bonded atoms in determining the steric number. In  $\text{CO}_2$ , for example, two double-bonded oxygen atoms are attached to the central carbon and there are no lone pairs on that atom, so  $\text{SN} = 2$ .

The steric number is used to predict molecular geometries. In molecules  $\text{XY}_n$ , in which there are no lone pairs on the central atom X (the simplest case),

$$\text{SN} = \text{number of bonded atoms} = n$$

The  $n$  bonding electron pairs (and therefore the outer atoms) position themselves (see Fig. 3.35) to minimize electron-pair repulsion. Thus,  $\text{CO}_2$  is predicted (and found experimentally) to be linear,  $\text{BF}_3$  is trigonal planar,  $\text{CH}_4$  is tetrahedral,  $\text{PF}_5$  is trigonal bipyramidal, and  $\text{SF}_6$  is octahedral.

When lone pairs are present, the situation changes slightly. There can now be three different types of repulsions: (1) bonding pair against bonding pair, (2) bonding pair against lone pair, and (3) lone pair against lone pair. Consider the ammonia molecule ( $\text{NH}_3$ ), which has three bonding electron pairs and one lone pair (Fig. 3.36a). The steric number is 4, and the electron pairs arrange themselves into an approximately tetrahedral structure. The lone pair is not identical to the three bonding pairs, however, so there is no reason for the electron-pair structure to be *exactly* tetrahedral. It is found that lone pairs tend to occupy more space than bonding pairs (because the bonding pairs are held closer to the central atom), so the angles of bonds opposite to them are reduced. The geometry of the *molecule*, as distinct from that of the electron pairs, is named for the sites occupied by actual atoms. The description of the molecular geometry makes no reference to lone pairs that may be present on the central atom, even

**FIGURE 3.36** (a) Ammonia ( $\text{NH}_3$ ) has a pyramidal structure in which the bond angles are less than  $109.5^\circ$ . (b) Water ( $\text{H}_2\text{O}$ ) has a bent structure with a bond angle less than  $109.5^\circ$  and smaller than that of  $\text{NH}_3$ . (c)  $\text{CH}_3\text{Cl}$  has a distorted tetrahedral structure.

**FIGURE 3.37** Molecules with steric number 5. The molecular geometry is named for the sites occupied by the atoms, not the underlying trigonal-bipyramidal structure of electron pairs.

though their presence affects that geometry. The structure of the ammonia molecule is thus predicted to be a trigonal pyramid in which the H—N—H bond angle is smaller than the tetrahedral angle of  $109.5^\circ$ . The observed structure has an H—N—H bond angle of  $107.3^\circ$ . The H—O—H bond angle in water, which has two lone pairs and two bonding pairs, is still smaller at  $104.5^\circ$  (see Fig. 3.36b).

A similar distortion takes place when two types of outer atoms are present. In  $\text{CH}_3\text{Cl}$ , the bonding electron pair in the C—Cl bond is not the same as those in the C—H bonds, so the structure is a distorted tetrahedron (see Fig. 3.36c). Because Cl is more electronegative than H, it tends to attract electrons away from the central atom, reducing the electron-pair repulsion. This allows the Cl—C—H bond angles to become  $108.5^\circ$ , which is smaller than tetrahedral, whereas the H—C—H angles become  $110.5^\circ$ , which is larger than tetrahedral. In effect, electropositive substituents repel other substituents more strongly than do electronegative substituents.

The fluorides  $\text{PF}_5$ ,  $\text{SF}_4$ ,  $\text{ClF}_3$ , and  $\text{XeF}_2$  all have steric number 5 but have different numbers of lone pairs (0, 1, 2, and 3, respectively). What shapes do their molecules have? We have already mentioned that  $\text{PF}_5$  is trigonal bipyramidal. Two of the fluorine atoms occupy **axial sites** (see Fig. 3.37a), and the other three occupy **equatorial sites**. Because the two kinds of sites are not equivalent, there is no reason for all of the P—F bond lengths to be equal. Experiment shows that the equatorial P—F bond length is  $1.534 \text{ \AA}$ , which is shorter than the  $1.577 \text{ \AA}$  axial P—F lengths.

$\text{SF}_4$  has four bonded atoms and one lone pair. Does the lone pair occupy an axial or an equatorial site? In the VSEPR theory, when electron pairs form a  $90^\circ$  angle to the central atom, they repel each other much more strongly than when the angle is larger. A single lone pair therefore finds a position that minimizes the number of  $90^\circ$  repulsions it has with bonding electron pairs. It occupies an equatorial position with two  $90^\circ$  repulsions (see Fig. 3.37b), rather than an axial position with three  $90^\circ$  repulsions (see Fig. 3.37c). The axial S—F bonds are bent slightly away from the lone pair; consequently, the molecular structure of  $\text{SF}_4$  is a distorted seesaw. A second lone pair (in  $\text{ClF}_3$ , for example) also takes an equatorial position, leading to a distorted T-shaped molecular structure (see Fig. 3.37d). A third lone pair (in  $\text{XeF}_2$  or  $\text{I}_3^-$ , for example) occupies the third equatorial position, and the molecular geometry is linear (see Fig. 3.37e). Table 3.8 summarizes the molecular shapes predicted by VSEPR and provides examples of each.

### EXAMPLE 3.13

Predict the geometry of the following molecules and ions: (a)  $\text{ClO}_3^+$ , (b)  $\text{ClO}_2^+$ , (c)  $\text{SiH}_4$ , (d)  $\text{IF}_5$ .

#### Solution

- (a) The central Cl atom has all of its valence electrons (six, because the ion has a net positive charge) involved in bonds to the surrounding three oxygen atoms and has no lone pairs. Its steric number is 3. In the molecular ion, the central Cl should be surrounded by the three O atoms arranged in a trigonal planar structure.
- (b) The central Cl atom in this ion also has a steric number of 3, comprising two bonded atoms and a single lone pair. The predicted molecular geometry is a bent molecule with an angle somewhat less than  $120^\circ$ .
- (c) The central Si atom has a steric number of 4 and no lone pairs. The molecular geometry should consist of the Si atom surrounded by a regular tetrahedron of H atoms.

(Continued)

**FIGURE 3.38** The structure of  $\text{IF}_5$ . Note the distortions of  $\text{F—I—F}$  bond angles from  $90^\circ$  because of the lone pair at the bottom (not shown).

- (d) Iodine has seven valence electrons, of which five are shared in bonding pairs with F atoms. This leaves two electrons to form a lone pair, so the steric number is 5 (bonded atoms) + 1 (lone pair) = 6. The structure will be based on the octahedron of electron pairs from Figure 3.35, with five F atoms and one lone pair. The lone pair can be placed on any one of the six equivalent sites and will cause the four F atoms to bend away from it toward the fifth F atom, giving the distorted structure shown in Figure 3.38.

**Related Problems:** 59, 60, 61, 62, 63, 64

The VSEPR theory is a simple but remarkably powerful model for predicting the geometries and approximate bond angles of molecules that have a central atom. Its success is even more remarkable when we realize that the VSEPR theory is based purely on empirical arguments, not theoretical calculations.

**TABLE 3.8**

Molecular Shapes Predicted by the Valence Shell Electron-Pair Repulsion Theory

Molecule	Steric Number	Predicted Geometry	Example
$\text{AX}_2$	2	Linear	$180^\circ$ $\text{CO}_2$
$\text{AX}_3$	3	Trigonal planar	$120^\circ$ $\text{BF}_3$
$\text{AX}_4$	4	Tetrahedral	$109.5^\circ$ $\text{CF}_4$
$\text{AX}_5$	5	Trigonal bipyramidal	$120^\circ$ $90^\circ$ $\text{PF}_5$
$\text{AX}_6$	6	Octahedral	$90^\circ$ $\text{SF}_6$

**FIGURE 3.39** The total dipole moment of a molecule is obtained by vector addition of its bond dipoles. The net dipole moment vector is shown in red. (a)  $\text{CO}_2$ . (b)  $\text{OCS}$ . (c)  $\text{H}_2\text{O}$ . (d)  $\text{CCl}_4$ .

However, it has its limitations. The VSEPR theory does not account for the fact that observed bond angles in the Group V and VI hydrides  $\text{H}_2\text{S}$  ( $92^\circ$ ),  $\text{H}_2\text{Se}$  ( $91^\circ$ ),  $\text{PH}_3$  ( $93^\circ$ ), and  $\text{AsH}_3$  ( $92^\circ$ ) are so far from tetrahedral ( $109.5^\circ$ ) and so close to right angles ( $90^\circ$ ).

### 3.11.2 Dipole Moments of Polyatomic Molecules

Polyatomic molecules, like the diatomic molecules considered in the previous section, may have dipole moments. Often, a good approximation is to assign a dipole moment (a vector, shown as an arrow pointing from the negative charge to the positive charge) to each bond, and then obtain the total dipole moment by carrying out a vector sum of the bond dipoles. In  $\text{CO}_2$ , for example, each C—O has a bond dipole (Fig. 3.39a). However, because the dipoles are equal in magnitude and point in opposite directions, the total molecular dipole moment vanishes. In  $\text{OCS}$ , which is also linear with a central carbon atom, the C—O and C—S bond dipole moments have different magnitudes, leaving a net non-zero dipole moment (see Fig. 3.39b). In the water molecule (Fig. 3.39c), the two bond dipoles add vectorially to give a net molecular dipole moment. The more symmetric molecule  $\text{CCl}_4$ , on the other hand, has no net dipole moment (see Fig. 3.39d). Even though each of the four C—Cl bonds (pointing from the four corners of a tetrahedron) has a dipole moment, their vector sum is zero. Molecules such as  $\text{H}_2\text{O}$  and  $\text{OCS}$ , with nonzero dipole moments, are **polar**; those such as  $\text{CO}_2$  and  $\text{CCl}_4$ , with no net dipole moment, are **nonpolar**, even though they contain polar bonds. Intermolecular forces differ between polar and nonpolar molecules (see discussion in Chapter 10), a fact that significantly affects their physical and chemical properties.

#### EXAMPLE 3.14

Predict whether the molecules  $\text{NH}_3$  and  $\text{SF}_6$  will have dipole moments.

#### Solution

The  $\text{NH}_3$  molecule has a dipole moment because the three N—H bond dipoles add to give a net dipole pointing downward from the N atom to the base of the pyramid that defines

the  $\text{NH}_3$  structure. The  $\text{SF}_6$  molecule has no dipole moment because each S—F bond dipole is balanced by one of equal magnitude pointing in the opposite direction on the other side of the molecule.

## 3.12 Oxidation Numbers

The terms *ionic* and *covalent* have been used in this chapter as though they represent the complete transfer of one or more electrons from one atom to another or the equal sharing of pairs of electrons between atoms in a molecule. In reality, both types of bonding are idealizations that rarely apply exactly. To account for the transfer of electrons from one molecule or ion to another in oxidation–reduction reactions and to name different binary compounds of the same elements, it is not necessary to have detailed knowledge of the exact electron distributions in molecules, whether they are chiefly ionic or covalent. Instead, we can assign a convenient fictitious charge to each atom in a molecule and call each the **oxidation number** of the corresponding atom, making certain that the law of charge conservation is strictly observed. Oxidation numbers are chosen so that in ionic compounds the sum of the oxidation numbers on all the atoms equals the charge on the ion. The following simple conventions are useful:

1. The oxidation numbers of the atoms in a neutral molecule must add up to zero, and those in an ion must add up to the charge on the ion.
2. Alkali-metal atoms are assigned the oxidation number +1, and the alkaline-earth atoms +2, in their compounds.
3. Fluorine is always assigned oxidation number  $-1$  in its compounds. The other halogens are generally assigned oxidation number  $-1$  in their compounds, except those containing oxygen and other halogens in which the halogen can have a positive oxidation number.
4. Hydrogen is assigned oxidation number +1 in its compounds, except in metal hydrides such as LiH, where convention 2 takes precedence and the oxidation number of hydrogen is  $-1$ .
5. Oxygen is assigned oxidation number  $-2$  in nearly all compounds. However, there are two exceptions: In compounds with fluorine, convention 3 takes precedence, and in compounds that contain O–O bonds, conventions 2 and 4 take precedence. Thus, the oxidation number for oxygen in  $\text{OF}_2$  is +2; in peroxides (such as  $\text{H}_2\text{O}_2$  and  $\text{Na}_2\text{O}_2$ ), it is  $-1$ . In superoxides (such as  $\text{KO}_2$ ), the oxidation number of oxygen is  $-\frac{1}{2}$ .

Convention 1 is fundamental because it guarantees charge conservation: The total number of electrons must remain constant in chemical reactions. This rule also makes the oxidation numbers of the neutral atoms of all elements zero. Conventions 2 to 5 are based on the principle that in ionic compounds the oxidation number should equal the charge on the ion. Note that fractional oxidation numbers, although uncommon, are allowed and, in fact, are necessary to be consistent with this set of conventions.

With the preceding conventions in hand, chemists can assign oxidation numbers to the atoms in most compounds. Apply conventions 2 through 5 as listed previously, noting the exceptions given, and then assign oxidation numbers to the other elements in such a way that convention 1 is always obeyed. Note that convention 1 applies not only to free ions, but also to the components that make up ionic solids. Chlorine has oxidation number  $-1$  not only as a free  $\text{Cl}^-$  ion, but in the ionic solid  $\text{AgCl}$  and in covalent  $\text{CH}_3\text{Cl}$ . It is important to recognize common ionic species (especially molecular ions) and to know the total charges they carry. Table 3.9 lists the names and formulas of many common anions. Inspection of the table reveals that several elements exhibit different oxidation numbers in different compounds. In  $\text{Ag}_2\text{S}$ , sulfur appears as the sulfide ion and

TABLE 3.9

## Formulas and Names of Some Common Anions

F <sup>-</sup>	Fluoride	CO <sub>3</sub> <sup>2-</sup>	Carbonate
Cl <sup>-</sup>	Chloride	HCO <sub>3</sub> <sup>-</sup>	Hydrogen carbonate
Br <sup>-</sup>	Bromide	NO <sub>2</sub> <sup>-</sup>	Nitrite
I <sup>-</sup>	Iodide	NO <sub>3</sub> <sup>-</sup>	Nitrate
H <sup>-</sup>	Hydride	SiO <sub>4</sub> <sup>4-</sup>	Silicate
O <sup>2-</sup>	Oxide	PO <sub>4</sub> <sup>3-</sup>	Phosphate
S <sup>2-</sup>	Sulfide	HPO <sub>4</sub> <sup>2-</sup>	Hydrogen phosphate
O <sub>2</sub> <sup>2-</sup>	Peroxide	H <sub>2</sub> PO <sub>4</sub> <sup>-</sup>	Dihydrogen phosphate
O <sub>2</sub> <sup>-</sup>	Superoxide	SO <sub>3</sub> <sup>2-</sup>	Sulfite
OH <sup>-</sup>	Hydroxide	SO <sub>4</sub> <sup>2-</sup>	Sulfate
CN <sup>-</sup>	Cyanide	HSO <sub>4</sub> <sup>-</sup>	Hydrogen sulfate
CNO <sup>-</sup>	Cyanate	ClO <sup>-</sup>	Hypochlorite
SCN <sup>-</sup>	Thiocyanate	ClO <sub>2</sub> <sup>-</sup>	Chlorite
MnO <sub>4</sub> <sup>-</sup>	Permanganate	ClO <sub>3</sub> <sup>-</sup>	Chlorate
CrO <sub>4</sub> <sup>2-</sup>	Chromate	ClO <sub>4</sub> <sup>-</sup>	Perchlorate
Cr <sub>2</sub> O <sub>7</sub> <sup>2-</sup>	Dichromate		

has oxidation number  $-2$ , but in  $\text{Ag}_2\text{SO}_4$ , it appears as part of a sulfate ( $\text{SO}_4^{2-}$ ) ion. In this case,

(oxidation number of S) +  $[4 \times (\text{oxidation number of O})]$  = total charge on ion

$$x + [4(-2)] = -2$$

$$\text{oxidation number of S} = x = +6$$

A convenient way to indicate the oxidation number of an atom is to write it directly above the corresponding symbol in the formula of the compound:

## EXAMPLE 3.15

Assign oxidation numbers to the atoms in the following chemical compounds and ions:  $\text{NaCl}$ ,  $\text{ClO}^-$ ,  $\text{Fe}_2(\text{SO}_4)_3$ ,  $\text{SO}_2$ ,  $\text{I}_2$ ,  $\text{KMnO}_4$ ,  $\text{CaH}_2$ .

## Solution

$+1 \quad -1$   
 $\text{NaCl}$  From conventions 2 and 3.

$+1 \quad -2$   
 $\text{ClO}^-$  From conventions 1 and 5.

$+3 \quad +6 \quad -2$   
 $\text{Fe}_2(\text{SO}_4)_3$  From conventions 1 and 5. This is solved by recognizing the presence of sulfate  $\text{SO}_4^{2-}$  groups.

$+4 \quad -2$   
 $\text{SO}_2$  From conventions 1 and 5.

$0$   
 $\text{I}_2$  From convention 1 ( $\text{I}_2$  is an element).

$+1 \quad +7 \quad -2$   
 $\text{KMnO}_4$  From conventions 1, 2, and 5.

$+2 \quad -1$   
 $\text{CaH}_2$  From conventions 1 and 2 (metal hydride case).

**Related Problems: 71, 72**

Oxidation numbers must not be confused with the formal charges on Lewis dot diagrams (see Section 3.10). They resemble formal charges to the extent that both are assigned, by arbitrary conventions, to symbols in formulas for specific purposes. The purposes differ, however. Formal charges are used solely to identify preferred Lewis diagrams. Oxidation numbers are used in nomenclature, in identifying oxidation–reduction reactions, and in exploring trends in chemical reactivity across the periodic table. Oxidation numbers are often not the same

© Leon Levandowski/Cengage Learning

**FIGURE 3.40** Several oxides of manganese. They are arranged in order of increasing oxidation number of the Mn, counterclockwise from the bottom left:  $\text{MnO}$ ,  $\text{Mn}_2\text{O}_4$ ,  $\text{Mn}_2\text{O}_3$ , and  $\text{MnO}_2$ . A compound of still higher oxidation state,  $\text{Mn}_2\text{O}_7$ , is a dark red liquid that explodes easily.

as the true charges on atoms. In  $\text{KMnO}_4$  or  $\text{Mn}_2\text{O}_7$ , for example, Mn has the oxidation number +7, but the actual net charge on the atom is much less than +7. A high oxidation state usually indicates significant covalent character in the bonding of that compound. The oxides of manganese with lower oxidation states (Fig. 3.40) have more ionic character.

Figure 3.41 shows the most common oxidation states of the elements of the main groups. The strong diagonal lines for these elements reflect the stability of closed electron octets. For example, the oxidation states +6 and -2 for sulfur would correspond to losing or gaining enough electrons to attain a noble gas configuration, in this case that of Ar. The octet-based Lewis model is not useful for compounds of the transition elements (see Chapter 8 for further discussion).

### 3.13 Inorganic Nomenclature

Sections 3.8 and 3.9 used the periodic table and the Lewis model to describe the transfer and sharing of electrons in chemical compounds. We conclude this chapter by discussing the systematic nomenclature of inorganic compounds. The definitive source for the naming of inorganic compounds is *Nomenclature of Inorganic Chemistry—IUPAC Recommendations 2005* (N. G. Connelly and T. Damhus, Sr., eds. Royal Society of Chemistry, 2005). Of the wide variety of inorganic compounds, we discuss only simple covalent and ionic compounds and emphasize current usage.

**FIGURE 3.41** Important oxidation states of the main-group elements.

### 3.13.1 Names and Formulas of Ionic Compounds

Ionic compounds are made from ions, bound by electrostatic forces such that the total charge of the compound is zero. The stoichiometry of an ionic compound is determined by inspection, to satisfy charge neutrality. As mentioned earlier, gas-phase ionic compounds exist, but most ionic compounds are solids in which each ion is strongly bound to a number of the nearest neighbor ions of the opposite sign. An ionic compound is named by listing the name of the cation followed by that of the anion. Ions can either be monatomic or polyatomic; the latter are also referred to as molecular ions.

A monatomic cation bears the name of the parent element. We have already encountered the sodium ion ( $\text{Na}^+$ ) and the calcium ion ( $\text{Ca}^{2+}$ ); ions of the other elements in Groups I and II are named in the same way. The transition metals and the metallic elements of Groups III, IV, and V differ from the Group I and II metals in that they often form several stable ions in compounds and in solution. Although calcium compounds never contain  $\text{Ca}^{3+}$  (always  $\text{Ca}^{2+}$ ), the element iron forms both  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$ , and thallium forms both  $\text{Tl}^+$  and  $\text{Tl}^{3+}$ . When a metal forms ions of more than one charge, we distinguish them by placing a Roman numeral in parentheses after the name of the metal, indicating the charge on the ion:

$\text{Cu}^+$	copper(I) ion	$\text{Fe}^{2+}$	iron(II) ion	$\text{Sn}^{2+}$	tin(II) ion
$\text{Cu}^{2+}$	copper(II) ion	$\text{Fe}^{3+}$	iron(III) ion	$\text{Sn}^{4+}$	tin(IV) ion

An earlier method for distinguishing between such pairs of ions used the suffixes *-ous* and *-ic* added to the root of the (usually Latin) name of the metal to indicate the ions of lower and higher charge, respectively. Thus,  $\text{Fe}^{2+}$  was called the ferrous ion and  $\text{Fe}^{3+}$  the ferric ion. This method, although still used occasionally, is not recommended for systematic nomenclature and is not used in this book.

A few polyatomic cations are important in inorganic chemistry. These include the ammonium ion,  $\text{NH}_4^+$  (obtained by adding  $\text{H}^+$  to ammonia); the hydronium ion,  $\text{H}_3\text{O}^+$  (obtained by adding  $\text{H}^+$  to water); and the particularly interesting molecular ion formed by mercury,  $\text{Hg}_2^{2+}$  the mercury(I) ion. This species must be carefully distinguished from  $\text{Hg}^{2+}$ , the mercury(II) ion. The Roman numeral I in parentheses means, in this case, that the average charge on each of the two mercury atoms is +1. Compounds with the empirical formulas  $\text{HgCl}$  and  $\text{HgBr}$  have molecular formulas  $\text{Hg}_2\text{Cl}_2$  and  $\text{Hg}_2\text{Br}_2$ , respectively.

A monatomic anion is named by adding the suffix *-ide* to the first portion of the name of the element. Thus, *chlorine* becomes the *chloride* ion, and *oxygen* becomes the *oxide* ion. The other monatomic anions of Groups V, VI, and VII are named similarly. Many polyatomic anions exist, and the naming of these species is more complex. The names of the oxoanions (each contains oxygen in combination with a second element) are derived by adding the suffix *-ate* to the stem of the name of the second element. Some elements form two oxoanions. The *-ate* ending is then used for the oxoanion with the larger number of oxygen atoms (such as  $\text{NO}_3^-$ , *nitrate*), and the ending *-ite* is added for the name of the anion with the smaller number (such as  $\text{NO}_2^-$  *nitrite*). For elements such as chlorine, which form more than two oxoanions, we use the additional prefixes *per-* (largest number of oxygen atoms) and *hypo-* (smallest number of oxygen atoms). An oxoanion that contains hydrogen as a third element includes that word in its name. For example, the  $\text{HCO}_3^-$  oxoanion is called the hydrogen carbonate ion in preference to its common (nonsystematic) name, “bicarbonate ion,” and  $\text{HSO}_4^-$ , often called “bisulfate ion,” is better designated as the hydrogen sulfate ion. Table 3.9 lists some of the most important anions. It is important to

be able to recognize and name the ions from that table, bearing in mind that the electric charge is an essential part of the formula.

It is customary (and recommended) to name ionic compounds (salts) using the Roman numeral notation, based on group numbers or oxidation states.  $\text{CuSO}_4$  is copper(I) sulfate,  $\text{Fe}(\text{NO}_3)_2$  is iron(II) nitrate and  $\text{KMnO}_4$  is potassium permanganate, the Roman numeral being omitted in the last example because potassium cations always carry only +1 charge.

The composition of an ionic compound is determined by overall charge neutrality. The total positive charge on the cations must exactly balance the total negative charge on the anions. The following names and formulas of ionic compounds illustrate this point:

Tin(II) bromide	One 2+ cation, two 1- anions	$\text{SnBr}_2$
Potassium permanganate	One 1+ cation, one 1- anion	$\text{KMnO}_4$
Ammonium sulfate	Two 1+ cations, one 2- anion	$(\text{NH}_4)_2\text{SO}_4$
Iron(II) dihydrogen phosphate	One 2+ cation, two 1- anions	$\text{Fe}(\text{H}_2\text{PO}_4)_2$

### EXAMPLE 3.16

Give the chemical formulas of (a) calcium cyanide and (b) copper(II) phosphate.

#### Solution

(a) Calcium cyanide is composed of  $\text{Ca}^{2+}$  and  $\text{CN}^-$ . For the overall charge to be 0, there must be two  $\text{CN}^-$  for each  $\text{Ca}^{2+}$ . Thus, the chemical formula of calcium cyanide is  $\text{Ca}(\text{CN})_2$ .

(b) The ions present in copper(II) phosphate are  $\text{Cu}^{2+}$  and  $\text{PO}_4^{3-}$ . To ensure charge neutrality, there must be three  $\text{Cu}^{2+}$  (total charge +6) and two  $\text{PO}_4^{3-}$  (total charge -6) per formula unit. Thus, the chemical formula of copper(II) phosphate is  $\text{Cu}_3(\text{PO}_4)_2$ .

**Related Problems: 73, 74, 75, 76, 77, 78**

### 3.13.2 Naming Binary Covalent Compounds

How do we name covalent (nonionic) compounds? If a pair of elements forms only one compound, begin with the name of the element that appears first in the chemical formula, followed by the second element, with the suffix *-ide* added to its root. This is analogous to the naming of ionic compounds. Just as NaBr is sodium bromide, so the following names designate typical covalent compounds:

HBr	hydrogen bromide
$\text{BeCl}_2$	beryllium chloride
$\text{H}_2\text{S}$	hydrogen sulfide
BN	boron nitride

Many well-established nonsystematic names continue to be used (even the strictest chemist does not call water “hydrogen oxide”!) They include:

$\text{H}_2\text{O}$	water
$\text{NH}_3$	ammonia
$\text{N}_2\text{H}_4$	hydrazine
$\text{PH}_3$	phosphine
$\text{AsH}_3$	arsine
$\text{COCl}_2$	phosgene

TABLE 3.10

## Prefixes Used for Naming Binary Covalent Compounds

Number	Prefix
1	<i>mono-</i>
2	<i>di-</i>
3	<i>tri-</i>
4	<i>tetra-</i>
5	<i>penta-</i>
6	<i>hexa-</i>
7	<i>hepta-</i>
8	<i>octa-</i>
9	<i>nona-</i>
10	<i>deca-</i>

If a pair of elements forms more than one compound, two methods can be used to distinguish between them:

1. Use Greek prefixes (Table 3.10) to specify the number of atoms of each element in the molecular formula of the compound (*di-* for two, *tri-* for three, and so forth). If the compound is a solid without well-defined molecules, name the empirical formula in this way. The prefix for one (*mono-*) is omitted, except in the case of carbon monoxide.
2. Write the oxidation number of the first-named element in Roman numerals and place it in parentheses after the name of that element.

Applying the two methods to the oxides of nitrogen gives

$N_2O$	dinitrogen oxide	nitrogen(I) oxide
$NO$	nitrogen oxide	nitrogen(II) oxide
$N_2O_3$	dinitrogen trioxide	nitrogen(III) oxide
$NO_2$	nitrogen dioxide	nitrogen(IV) oxide
$N_2O_4$	dinitrogen tetraoxide	nitrogen(IV) oxide
$N_2O_5$	dinitrogen pentaoxide	nitrogen(V) oxide

The first method has some advantages over the second and is recommended. It distinguishes between  $NO_2$  (nitrogen dioxide) and  $N_2O_4$  (dinitrogen tetraoxide), two distinct compounds that would both be called nitrogen(IV) oxide under the second system of nomenclature. Two of these oxides have common (nonsystematic) names that may be encountered elsewhere:  $N_2O$  is often called nitrous oxide, and  $NO$  is called nitric oxide.

## CHAPTER SUMMARY

The classical description of chemical bonding provides the conceptual framework and language used by all chemists in their daily work. The classical description is based largely on simple electrostatics. We can understand a great deal about the nature of the chemical bond by examining the forces and potential energy of interaction between the electrons and the nuclei, which are governed by Coulomb's law. Potential energy diagrams will help you understand the interactions between and among electrons and nuclei that determine a wide variety of properties of atoms and molecules. We encourage you to learn to interpret and use these diagrams, because they will appear over and over again in this text and in subsequent chemistry courses.

The periodic table organizes the elements in a way that shows similar physical and chemical properties of groups and the variations of these properties across periods. Examination of periodic trends in ionization energies suggests that the electrons in an atom are organized in a series of concentric shells around the nucleus. These trends can be explained by the decreased electron–nuclear attraction in successive shells, as well as the screening or shielding of the outer electrons from the full nuclear charge by the inner electrons. Electron affinity is a measure of the tendency of an atom to form a stable anion. Periodic trends in electron affinities are explained in the same way as those observed for ionization energies.

Chemical bonds are generally classified according to the amount of charge separation in the bond. The character of a particular chemical bond—ionic, covalent, or polar covalent—can be predicted by comparing the electronegativities of the atoms involved. The electronegativity of an element is a measure of

its relative propensity to attract electrons in a chemical bond. Elements with large ionization energies and large electron affinities tend to attract electrons, whereas those with small ionization energies and small electron affinities tend to donate electrons. Bonds formed between two atoms with large electronegativity differences tend to be ionic, whereas those formed between those atoms with nearly the same electronegativities tend to be covalent. Most bonds are somewhere in between—that is, they are polar covalent.

The arrangements of atoms in a molecule and the three-dimensional shape of a molecule can be rationalized or predicted using the Lewis dot model and the VSEPR theory, respectively. The Lewis model predicts the most likely arrangement of atoms in a molecule, the existence of multiple bonds, and charge distributions using the idea of formal charges. It is based on the idea that the representative elements (except hydrogen) are most stable with a filled octet of valence electrons (hydrogen needs only two). This stability can be understood from the empirical fact that eight electrons is the maximum each valence shell can hold, and that each electron added to a shell decreases the energy of the atom via the Coulomb interaction with the nucleus. Each element is represented by its chemical symbol, with its valence electrons arranged as dots. The atoms are combined in a way that creates the maximum number of filled octets around each representative element and a pair of electrons around each hydrogen atom. The VSEPR theory predicts the three-dimensional structures of molecules by arranging electron pairs to minimize their mutual repulsion.

Oxidation numbers are used to track the gain and loss of electrons in chemical reactions and are used in the systematic naming of inorganic compounds.

The concepts introduced in this chapter provide a sound basis for understanding a great deal of chemistry. A firm understanding of these concepts is essential for you to conduct and interpret experiments, read the chemical literature, and develop a deeper understanding based on quantum mechanics, which we develop in Chapters 4–6.

## CONCEPTS AND SKILLS

---

### Section 3.2 – The Periodic Table

*Describe the structure of the periodic table, and predict chemical and physical properties of an element based on those of others in its group and period (Problems 1–4).*

- The periodic table organizes the elements into eighteen groups, with the main-group elements labeled I to VIII in this text, with similar physical and chemical properties based on the experimental observations that these properties are periodic functions of the atomic number  $Z$  of the elements.
- The dependence of properties on  $Z$  suggests that periodic behavior originates in the electronic structure of the atom, since  $Z$  is the number of electrons in the atom and also the magnitude of the positive charge on the nucleus.
- Experiments (summarized below) that measure gain or loss of electrons by atoms exhibit periodic behavior and thereby confirm that periodicity originates in the electronic structure of the atom.
- Quantum mechanics (in Chapter 5) connects periodic behavior of physical and chemical properties directly to electronic structure and provides a complete theoretical explanation for the organization of the periodic table.

### Section 3.3 – Forces and Potential Energy in Atoms

Calculate the force and potential energy between a pair of charged particles, and predict the direction of relative motion of the particles (Problems 5–8).

- The force on a charged particle, number 2, with charge  $q_2$ , exerted by particle number 1, with charge  $q_1$ , separated by distance  $r$  is calculated from Coulomb's law as  $\vec{F}_2(r) = -\frac{dV}{dr} \hat{r}_{12} = \frac{q_1 q_2}{4\pi\epsilon_0 r^2} \hat{r}_{12}$
- The potential energy of the system of two charged particles is calculated from Coulomb's law as  $V(r) = \frac{q_1 q_2}{4\pi\epsilon_0 r}$  [3.2]
- The force between the particles is obtained by calculating the slope of the potential energy function  $\frac{dV}{dr}$ . When the slope of the potential energy is negative the force is repulsive and pushes the particles apart. When the slope of the potential energy is positive, the force is attractive and pulls the particles together.
- The physical structure of the atom, as determined by experiments, is summarized in the planetary model. In a neutral atom with atomic number  $Z$ , there are  $Z$  electrons moving around a dense nucleus, which has positive charge  $+Ze$ .
- The physical interactions inside the atom can be understood using Coulomb's law, which describes the forces between each electron and the nucleus and the forces between the electrons in many-electron atoms.
- The stable physical structure of the atom can be explained only by quantum mechanics (Chapter 5). Classical physics predicts that such a structure would not be stable.

### Section 3.4 – Ionization Energies, the Shell Model of the Atom, and Shielding

Describe the trends in ionization energy across the periodic table (Problems 9–10).

- The ionization energy  $IE_1$  is the minimum energy required to remove the first electron from an atom and place it infinitely far away with zero kinetic energy.
- The value of  $IE_1$  increases across each period and reaches a maximum value at the noble gas element. It falls back to a minimum for the alkali element at the beginning of the next period, and increases across this period to reach a maximum at the noble gas element. Small variations appear within this general increasing trend across each period.

Describe the shell structure of the atom, and represent valence shell electrons of an atom by its Lewis electron dot symbol (Problems 11–12).

- Periodic trends in successive ionization energies suggest the shell model of the atom in which electrons occupy concentric shells located at increasing distances from the nuclei.
- Valence shell electrons are represented by dots (from 1 to 8 in number) arranged around the chemical symbol for the element.
- Each electron is shielded from the full positive charge of the nucleus as other electrons come between it and the nucleus. Consequently each electron experiences an effective nuclear charge  $Z_{\text{eff}} = Z - S$ , where the shielding constant  $S$  is essentially the average number of electrons that intervene. The amount of shielding is larger, and the magnitude of  $Z_{\text{eff}}$  is smaller, for electrons in outer shells than for those in inner shells.

- Periodic trends in  $Z_{\text{eff}}$  explain the periodic trends in the ionization energy across the periodic table. Passing across a period, at each element the nuclear charge  $Z$  increases by one unit and one more electron is added to the outer shell. The added electron therefore feels a stronger  $Z$ . Thus at each element in a given period the value of  $Z_{\text{eff}}$  increases, the added electron is more tightly bound, and the value of  $IE_1$  increases to reach a maximum at the noble gas element. The large value of  $IE_1$  at the noble gas element reflects the special stability of the filled octet electronic structure in the valence shell of that atom.

### Section 3.5 to 3.6 – Electron Affinity and Electronegativity: The Tendency of Atoms to Attract Electrons in Molecules

*Describe the trends in electron affinity and electronegativity across the periodic table (Problems 13–16).*

- The electron affinity of an atom is the energy required to detach an electron from the stable anion of that atom.
- The electron affinity increases across a period for the same reason  $IE_1$  increases; at each element the increase in  $Z_{\text{eff}}$  binds the electron added to form the anion more strongly. The increasing pattern lags behind that for  $IE_1$  because adding one more electron to form the anion fills the shell one step sooner. Electron affinity reaches its maximum at the halogen element because the anion has the special stability of the filled octet electronic structure.
- Electronegativity is the relative tendency of atoms in a chemical bond to attract electrons. Mulliken's scale is based on a simple physical model for a gas-phase atom that averages the ionization energy and the electron affinity for a single element. Pauling's scale averages this tendency over a variety of bonding partners.
- Electronegativity increases across a period because the increase in  $Z_{\text{eff}}$  makes it energetically more difficult to form a positive ion and energetically more favorable to form an anion.

### Section 3.7 – Forces and Potential Energy in Molecules: Formation of Chemical Bonds

*Correlate the shape of the effective potential energy function between the nuclei with trends in the bond length and bond energies of diatomic molecules (Problems 17–20).*

- The bond energy of a diatomic molecule is the amount of energy you must add to a molecule, initially at the minimum of the effective potential energy function between the nuclei, to bring it up to the effective potential energy of the isolated atoms (which is often defined to be zero).
- For ionic bond formation, the reduction in potential energy relative to the free atoms is calculated easily using Coulomb's law.
- The formation of a covalent chemical bond can be rationalized in terms of classical physics by examining the forces between the electrons and the nuclei to identify bonding and antibonding regions in the locations of the electrons.
- The formation of a covalent bond is fully explained only by quantum mechanics, including the effects of the kinetic energy of electrons in the bond (Chapter 6).

### Section 3.8 – Ionic Bonding

*Use the principle of charge balance and Lewis diagrams to write chemical formulas for ionic compounds (Problems 21–22).*

- The composition of an ionic compound is determined by overall charge neutrality. The total positive charge on the cations must exactly balance the total negative charge on the anions.

Calculate the energy of dissociation of gaseous diatomic ionic compounds into neutral atoms and ions (Problems 23–26).

- Calculate the Coulomb stabilization energy of the ions as the difference between the minimum in their potential energy curve at  $R_e$  and the potential energy of the ions at infinity. Subtract the energy investment  $\Delta E_\infty$  required to create the two ions at infinite separation. The difference is the bond dissociation energy  $\Delta E_d$ . The method is illustrated in Example 3.6.

### Section 3.9 – Covalent and Polar Covalent Bonding

Describe the relations among bond order, length, and energy (Problems 27–32).

- Chemists generally distinguish among three types of chemical bonds based on the electronegativity differences between the atoms: covalent (nearly identical electronegativities), ionic (greatly different electronegativities), and polar covalent (anything in between these extremes). The percent ionic character can be determined by measuring experimentally the dipole moments of molecules.
- Important measurable properties of the chemical bond include its length, dissociation energy, stiffness (vibrational force constant), and dipole moment.
- Increased force constant correlates with higher bond energy and smaller bond length: stiffer bonds are stronger and shorter.
- Theoretical models of bond formation predict the bond order, the number of electron pairs participating in the bond. Comparing the theoretical quantity bond order with measured values of force constant is one of the best ways to evaluate the accuracy of theoretical models.
- Bond lengths and bond energies of the same type (for example, CH single bonds) are remarkably similar in all compounds in which they appear. Bond lengths decrease and bond dissociation energies increase for double and triple bonds formed between the same pairs of atoms.

Estimate the percent ionic character of a bond from its dipole moment (Problems 33–38).

- The percent ionic character can be determined by measuring experimentally the dipole moments of molecules in units of Debye and the bond length in Å. The calculated result is % Ionic Character =  $100 \delta = 0.2082 \mu/R$ .

### Section 3.10 – Electron Pair Bonds and Lewis Diagrams for Molecules

Given a molecular formula, draw a Lewis diagram for the molecule and assign a formal charge (Problems 39–50).

- Lewis dot diagrams are a tool for predicting the most likely connectivity, or arrangement of bonds between atoms, in a molecule. They are also useful for predicting the existence of multiple bonds and for determining qualitatively the distribution of charges in a molecule.
- An atom in a molecule is assigned a formal charge by assuming that all the electrons in the Lewis diagram are divided equally among the atoms that share them.
- Formal charges have no reality. They are simply calculational tools to assist in evaluating the best Lewis diagrams for a specific molecule. The procedures and useful guidelines are illustrated in Examples 3.8 and 3.9.

Assign formal charges and identify resonance diagrams for a given Lewis diagram (Problems 51–58).

- Two or more equivalent Lewis diagrams for a molecule are called resonance diagrams. Taken together as a “resonance hybrid” they suggest that the actual bond properties lie somewhere between the equivalent diagrams.

### Section 3.11 – The Shapes of Molecules: Valence Shell Electron-Pair Repulsion Theory

*Predict the geometries of molecules by use of the VSEPR model (Problems 59–64).*

- The VSEPR theory predicts the three-dimensional shapes of molecules. It is based on simple electrostatics: Electron pairs in a molecule will arrange themselves in such a way as to minimize their mutual repulsion. The steric number determines the geometry of the electron pairs (linear, trigonal pyramidal, tetrahedral, and so forth), whereas the molecular geometry is determined by the arrangement of the nuclei and may be less symmetric than the geometry of the electron pairs.

*Determine whether a polyatomic molecule is polar or nonpolar (Problems 65–70).*

- Identify the dipole moment for each polar bond in the molecule, and add up all these dipoles as a vector sum.
- If the sum is zero, the molecule is nonpolar. If the sum is not equal to zero, the molecule is polar.

### Section 3.12 – Oxidation Numbers

*Assign oxidation numbers to atoms in compounds (Problems 71–72).*

- Oxidation numbers are assigned to elements to name inorganic compounds, to keep track of electrons in electron transfer (oxidation–reduction) reactions, and to explore trends in chemical reactivity across the periodic table.

### Section 3.13 – Inorganic Nomenclature

*Name inorganic compounds, given their chemical formulas, and write chemical formulas for inorganic compounds (Problems 73–84).*

- Systematic procedures have been agreed upon for naming inorganic compounds based on their molecular and structural formulas. It is essential to translate smoothly and quickly between the name and the structural formula, and vice versa. The guidelines are summarized in Section 13.13 and the procedures are illustrated in Example 3.16.

## CUMULATIVE EXERCISE

---

### Structure and Bonding in Metal Oxides and Peroxides

Consider the three compounds  $\text{KO}_2$ ,  $\text{BaO}_2$ , and  $\text{TiO}_2$ . Each contains two oxygen atoms per metal atom, but the oxygen occurs in different forms in the three compounds.

- The oxygen in  $\text{TiO}_2$  occurs as  $\text{O}^{2-}$  ions. What is the Lewis dot symbol for this ion? How many valence electrons does this ion have? What is the chemical name for  $\text{TiO}_2$ ?
- Recall that Group II elements form stable  $2+$  ions. Using Table 3.9, identify the oxygen-containing ion in  $\text{BaO}_2$  and give the name of the compound. Draw a Lewis diagram for the oxygen-containing ion, showing formal charge. Is the bond in this ion a single or a double bond?
- Recall that Group I elements form stable  $1+$  ions. Using Table 3.9, identify the oxygen-containing ion in  $\text{KO}_2$  and give the name of the compound. Show that the oxygen-containing ion is an odd-electron species. Draw the best Lewis diagram you can for it.

## Answers

- (a) The ion  $:\ddot{\text{O}}:^{2-}$  has eight valence electrons (an octet).  $\text{TiO}_2$  is titanium(IV) oxide.
- (b) The ion in  $\text{BaO}_2$  must be the peroxide ion ( $\text{O}_2^{2-}$ ), and the compound is barium peroxide. The Lewis diagram for the peroxide ion is

and the O—O bond is a single bond.

- (c) The ion in  $\text{KO}_2$  must be the superoxide ion ( $\text{O}_2^-$ ), and the compound is potassium superoxide. The superoxide ion has 13 valence electrons. The best Lewis diagram is a pair of resonance diagrams

in which only one of the oxygen atoms attains an octet electron configuration.

## PROBLEMS

Answers to problems whose numbers are red appear in Appendix G. Problems that are more challenging are indicated with asterisks.

## 3.2 The Periodic Table

1. Before the element scandium was discovered in 1879, it was known as “eka-boron.” Predict the properties of scandium from averages of the corresponding properties of its neighboring elements in the periodic table. Compare your predictions with the observed values in Appendix F.

Element	Symbol	Melting Point (°C)	Boiling Point (°C)	Density (g cm <sup>-3</sup> )
Calcium	Ca	839	1484	1.55
Titanium	Ti	1660	3287	4.50
Scandium	Sc	?	?	?

2. The element technetium (Tc) is not found in nature but has been produced artificially through nuclear reactions. Use the data for several neighboring elements in the table below to estimate the melting point, boiling point, and density of technetium. Compare your predictions with the observed values in Appendix F.

Element	Symbol	Melting Point (°C)	Boiling Point (°C)	Density (g cm <sup>-3</sup> )
Manganese	Mn	1244	1962	7.2
Molybdenum	Mo	2610	5560	10.2
Rhenium	Re	3180	5627	20.5
Ruthenium	Ru	2310	3900	12.3

3. Use the group structure of the periodic table to predict the empirical formulas for the binary compounds that hydrogen forms with the elements antimony, bromine, tin, and selenium.
4. Use the group structure of the periodic table to predict the empirical formulas for the binary compounds that hydrogen forms with the elements germanium, fluorine, tellurium, and bismuth.

## 3.3 Forces and Potential Energy in Atoms

5. An electron is located at the origin of the coordinates, and a second electron is brought to a position 2 Å from the origin in the +y direction.
- (a) Calculate the force on the electron at the origin, giving the components  $F_x$  and  $F_y$ .
- (b) Calculate the potential energy of the two electrons.

6. A gold nucleus is located at the origin of coordinates, and an electron is brought to a position  $2 \text{ \AA}$  from the origin in the  $+y$  direction.
- Calculate the force on the gold nucleus exerted by the electron giving its components  $F_x$  and  $F_y$ .
  - Calculate the potential energy of the gold nucleus and the electron.
7. The electron in a hydrogen atom is initially at a distance  $2.12 \text{ \AA}$  from the proton, and then moves in the  $+x$  direction to a distance  $0.529 \text{ \AA}$  from the proton.
- Calculate the magnitude of the force on the electron at each separation.
  - Calculate the change in the potential energy between the proton and the electron.
  - Calculate the change in the speed of the electron if the electron was initially stationary.
8. A gold nucleus is located at the origin of coordinates, and a helium nucleus initially at the coordinates  $(0, 2 \text{ \AA})$  moves to the position  $(0, 1 \text{ \AA})$ .
- Calculate the magnitude of the force on the electron at each separation.
  - Calculate the change in the potential energy of the two nuclei.
  - Calculate the change in the kinetic energy of the helium nucleus assuming its value at  $2 \text{ \AA}$  is  $2.0 \text{ MeV}$  if you assume the gold nucleus is so massive that it stays at the origin.

### 3.4 Ionization Energies, the Shell Model of the Atom, and Shielding

9. For each of the following pairs of atoms, state which you expect to have the higher first ionization energy: (a) Rb or Sr; (b) Po or Rn; (c) Xe or Cs; (d) Ba or Sr.
10. For each of the following pairs of atoms, state which you expect to have the higher first ionization energy: (a) Bi or Xe; (b) Se or Te; (c) Rb or Y; (d) K or Ne.
11. Use the data in Table 3.1 to plot the logarithm of ionization energy versus the number of electrons removed for Be. Describe the electronic structure of the Be atom.
12. Use the data in Table 3.1 to plot the logarithm of ionization energy versus the number of electrons removed for Ne. Describe the electronic structure of the Ne atom.

### 3.5 Electron Affinity

### 3.6 Electronegativity: The Tendency of Atoms to Attract Electrons in Molecules

13. For each of the following pairs of atoms, state which you expect to have the greater electron affinity: (a) Xe or Cs; (b) Pm or F; (c) Ca or K; (d) Po or At.
14. For each of the following pairs of atoms, state which you expect to have the higher electron affinity: (a) Rb or Sr; (b) I or Rn; (c) Ba or Te; (d) Bi or Cl.

15. Ignoring tables of electronegativity values and guided only by the periodic table, arrange these atoms in order of increasing electronegativity: O, F, S, Si, K. Briefly explain your reasoning.
16. Ignoring tables of electronegativity values and guided only by the periodic table, arrange these atoms in order of increasing electronegativity: S, Cl, Sb, Se, In. Briefly explain your reasoning.

### 3.7 Forces and Potential Energy in Molecules: Formation of Chemical Bonds

17.  $\text{H}_2$  has equilibrium bond length of  $0.751 \text{ \AA}$  and bond dissociation energy of  $432 \text{ kJ mol}^{-1}$ , whereas  $\text{F}_2$  has equilibrium bond length of  $1.417 \text{ \AA}$  and bond dissociation energy of  $155 \text{ kJ mol}^{-1}$ . On the same graph show qualitative sketches of the effective potential energy curve  $V_{\text{eff}}$  for an  $\text{H}_2$  and an  $\text{F}_2$  molecule. In your solution, show the conversion from  $\text{kJ mol}^{-1}$  to the energy of a single molecule.
18.  $\text{N}_2$  has equilibrium bond length of  $1.100 \text{ \AA}$  and bond dissociation energy of  $942 \text{ kJ mol}^{-1}$ , whereas  $\text{O}_2$  has equilibrium bond length of  $1.211 \text{ \AA}$  and bond dissociation energy of  $495 \text{ kJ mol}^{-1}$ . On the same graph show qualitative sketches of the effective potential energy curve  $V_{\text{eff}}$  for an  $\text{N}_2$  and an  $\text{O}_2$  molecule. In your solution, show the conversion from  $\text{kJ mol}^{-1}$  to the energy of a single molecule.
19. HF has equilibrium bond length of  $0.926 \text{ \AA}$  and bond dissociation energy of  $565 \text{ kJ mol}^{-1}$ . Compare the effective potential curve for HF with those for  $\text{H}_2$  and  $\text{F}_2$  in Problem 17.
20. NO has equilibrium bond length of  $1.154 \text{ \AA}$  and bond dissociation energy of  $629 \text{ kJ mol}^{-1}$ . Compare the effective potential curve for NO with those for  $\text{N}_2$  and  $\text{O}_2$  in Problem 18.

### 3.8 Ionic Bonding

21. For each of the following atoms or ions, state the total number of electrons, the number of valence electrons, and the number of core electrons.  
(a) Rn                      (b)  $\text{Sr}^+$                       (c)  $\text{Se}^{2-}$                       (d)  $\text{Sb}^-$
22. For each of the following atoms or ions, state the total number of electrons, the number of valence electrons, and the number of core electrons.  
(a)  $\text{Ra}^{2+}$                       (b) Br                      (c)  $\text{Bi}^{2-}$                       (d)  $\text{Ga}^+$
23. Use the data in Figure 3.11 and Table 3.2 to calculate the energy changes ( $\Delta E$ ) for the following pairs of reactions:  
(a)  $\text{K}(g) + \text{Cl}(g) \longrightarrow \text{K}^+(g) + \text{Cl}^-(g)$   
 $\text{K}(g) + \text{Cl}(g) \longrightarrow \text{K}^-(g) + \text{Cl}^+(g)$   
(b)  $\text{Na}(g) + \text{Cl}(g) \longrightarrow \text{Na}^+(g) + \text{Cl}^-(g)$   
 $\text{Na}(g) + \text{Cl}(g) \longrightarrow \text{Na}^-(g) + \text{Cl}^+(g)$

Explain why  $\text{K}^+\text{Cl}^-$  and  $\text{Na}^+\text{Cl}^-$  form in preference to  $\text{K}^-\text{Cl}^+$  and  $\text{Na}^-\text{Cl}^+$ .

24. Use the data in Figure 3.11 and Table 3.2 to calculate the energy changes ( $\Delta E$ ) for the following pairs of reactions:

Explain why  $\text{Na}^+\text{I}^-$  and  $\text{Rb}^+\text{Br}^-$  form in preference to  $\text{Na}^-\text{I}^+$  and  $\text{Rb}^-\text{Br}^+$ .

25. In a gaseous KCl molecule, the equilibrium internuclear distance is  $2.67 \times 10^{-10}$  m. Using data from Appendix F and assuming that a Coulomb potential is a good approximation of the potential from  $\text{K}^+ + \text{Cl}^-$  to  $2.67 \times 10^{-10}$  m, estimate the dissociation energy of gaseous KCl into K and Cl atoms (in  $\text{kJ mol}^{-1}$ ). (Note: Table 3.7 shows that a Coulomb potential is only a good approximation to the potential between two charged atoms at long inter-atomic distances; the percent ionic character of KCl at equilibrium is only 82%.)
26. In a gaseous RbF molecule, the bond length is  $2.274 \times 10^{-10}$  m. Using data from Appendix F and making the same oversimplified assumption as in the prior problem on the shape of the potential curve from  $\text{Rb}^+ + \text{F}^-$  to an internuclear separation of  $2.274 \times 10^{-10}$  m, calculate the energy in  $\text{kJ mol}^{-1}$  required to dissociate RbF to neutral atoms.

### 3.9 Covalent and Polar Covalent Bonding

27. The bond lengths of the X—H bonds in  $\text{NH}_3$ ,  $\text{PH}_3$ , and  $\text{SbH}_3$  are 1.02, 1.42, and 1.71 Å, respectively. Estimate the length of the As—H bond in  $\text{AsH}_3$ , the gaseous compound that decomposes on a heated glass surface in Marsh's test for arsenic. Which of these four hydrides has the weakest X—H bond?
28. Arrange the following covalent diatomic molecules in order of the lengths of the bonds: BrCl, ClF, IBr. Which of the three has the weakest bond (the smallest bond energy)?
29. The bond length in H—I (1.62 Å) is close to the sum of the atomic radii of H (0.37 Å) and I (1.33 Å). What does this fact indicate about the polarity of the bond?
30. The bond length in  $\text{F}_2$  is 1.417 Å, instead of twice the atomic radius of F, which is 1.28 Å. What can account for the unexpected length of the F—F bond?
31. Use electronegativity values to arrange the following bonds in order of decreasing polarity: N—O, N—N, N—P, and C—N.
32. Use electronegativity values to rank the bonds in the following compounds from least ionic to most ionic in character: IF, ICl, ClF, BrCl, and  $\text{Cl}_2$ .
33. Ionic compounds tend to have higher melting and boiling points and to be less volatile (that is, have lower vapor pressures) than covalent compounds. For each of the following pairs, use electronegativity differences to predict which compound has the higher vapor pressure at room temperature.
- (a)  $\text{Cl}_4$  or KI  
 (b)  $\text{BaF}_2$  or  $\text{OF}_2$   
 (c)  $\text{SiH}_4$  or NaH
34. For each of the following pairs, use electronegativity differences to predict which compound has the higher boiling point.
- (a)  $\text{MgBr}_2$  or  $\text{PBr}_3$   
 (b)  $\text{OsO}_4$  or SrO  
 (c)  $\text{Cl}_2\text{O}$  or  $\text{Al}_2\text{O}_3$
35. Estimate the percent ionic character of the bond in each of the following diatomic molecules, based on the dipole moment.

	Bond Length (Å)	Dipole Moment (D)
ClO	1.573	1.239
KI	3.051	10.82
TlCl	2.488	4.543
InCl	2.404	3.79

36. Estimate the percent ionic character of the bond in each of the following species. All the species are unstable or reactive under ordinary laboratory conditions, but they can be observed in interstellar space.

	Bond Length (Å)	Dipole Moment (D)
OH	0.980	1.66
CH	1.131	1.46
CN	1.175	1.45
$\text{C}_2$	1.246	0

37. The percent ionic character of a bond can be approximated by the formula  $16\Delta + 3.5\Delta^2$ , where  $\Delta$  is the magnitude of the difference in the electronegativities of the atoms (see Fig. 3.18). Calculate the percent ionic character of HF, HCl, HBr, HI, and CsF, and compare the results with those in Table 3.7.
38. The percent ionic character of the bonds in several interhalogen molecules (as estimated from their measured dipole moments and bond lengths) are ClF (11%), BrF (15%), BrCl (5.6%), ICl (5.8%), and IBr (10%). Estimate the percent ionic characters for each of these molecules, using the equation in Problem 37, and compare them with the given values.

### 3.10 Electron Pair Bonds and Lewis Diagrams for Molecules

39. Assign formal charges to all atoms in the following Lewis diagrams.

40. Assign formal charges to all atoms in the following Lewis diagrams.

41. Determine the formal charges on all the atoms in the following Lewis diagrams.

Which one would best represent bonding in the molecule  $\text{HNO}$ ?

42. Determine the formal charges on all the atoms in the following Lewis diagrams.

Which one would best represent bonding in the molecule  $\text{Cl}_2\text{O}$ ?

43. In each of the following Lewis diagrams, Z represents a main-group element. Name the group to which Z belongs in each case and give an example of such a compound or ion that actually exists.

44. In each of the following Lewis diagrams, Z represents a main-group element. Name the group to which Z belongs in each case and give an example of such a compound or ion that actually exists.

45. Draw Lewis electron dot diagrams for the following species: (a)  $\text{AsH}_3$ ; (b)  $\text{HOCl}$ ; (c)  $\text{KrF}^+$ ; (d)  $\text{PO}_2\text{Cl}_2^-$  (central P atom).

46. Draw Lewis electron dot diagrams for the following species: (a) methane; (b) carbon dioxide; (c) phosphorus trichloride; (d) perchlorate ion.

47. Urea is an important chemical fertilizer with the chemical formula  $(\text{H}_2\text{N})\text{CO}(\text{NH}_2)$ . The carbon atom is bonded to both nitrogen atoms and the oxygen atom. Draw a Lewis diagram for urea and use Table 3.6 to estimate its bond lengths.

48. Acetic acid is the active ingredient of vinegar. Its chemical formula is  $\text{CH}_3\text{COOH}$ , and the second carbon atom is bonded to the first carbon atom and to both oxygen atoms. Draw a Lewis diagram for acetic acid and use Table 3.6 to estimate its bond lengths.

49. Under certain conditions, the stable form of sulfur consists of rings of eight sulfur atoms. Draw the Lewis diagram for such a ring.

50. White phosphorus ( $\text{P}_4$ ) consists of four phosphorus atoms arranged at the corners of a tetrahedron. Draw the valence electrons on this structure to give a Lewis diagram that satisfies the octet rule.

51. Draw Lewis electron dot diagrams for the following species, indicating formal charges and resonance diagrams where applicable.

- (a)  $\text{H}_3\text{NBF}_3$   
 (b)  $\text{CH}_3\text{COO}^-$  (acetate ion)  
 (c)  $\text{HCO}_3^-$  (hydrogen carbonate ion)

52. Draw Lewis electron dot diagrams for the following species, indicating formal charges and resonance diagrams where applicable.
- HNC (central N atom)
  - SCN<sup>-</sup> (thiocyanate ion)
  - H<sub>2</sub>CNN (the first N atom is bonded to the carbon and the second N)
53. Draw Lewis diagrams for the two resonance forms of the nitrite ion, NO<sub>2</sub><sup>-</sup>. In what range do you expect the nitrogen–oxygen bond length to fall? (*Hint*: Use Table 3.6.)
54. Draw Lewis diagrams for the three resonance forms of the carbonate ion, CO<sub>3</sub><sup>2-</sup>. In what range do you expect the carbon–oxygen bond length to fall? (*Hint*: Use Table 3.6.)
55. Methyl isocyanate, which was involved in the disaster in Bhopal, India, in 1984, has the chemical formula CH<sub>3</sub>NCO. Draw its Lewis diagram, including resonance forms. (*Note*: The N atom is bonded to the two C atoms.)
56. Peroxyacetyl nitrate (PAN) is one of the prime irritants in photochemical smog. It has the formula CH<sub>3</sub>COONO<sub>2</sub>, with the following structure:

Draw its Lewis diagram, including resonance forms.

57. Draw Lewis diagrams for the following compounds. In the formula the symbol of the central atom is given first. (*Hint*: The valence octet may be expanded for the central atom.)
- PF<sub>5</sub>
  - SF<sub>4</sub>
  - XeO<sub>2</sub>F<sub>2</sub>
58. Draw Lewis diagrams for the following ions. In the formula the symbol of the central atom is given first. (*Hint*: The valence octet may be expanded for the central atom.)
- BrO<sub>4</sub><sup>-</sup>
  - PCl<sub>6</sub><sup>-</sup>
  - XeF<sub>6</sub><sup>+</sup>

### 3.11 The Shapes of Molecules: Valence Shell Electron-Pair Repulsion Theory

59. For each of the following molecules, give the steric number and sketch and name the approximate molecular geometry. In each case, the central atom is listed first and the other atoms are all bonded directly to it.
- CBr<sub>4</sub>
  - SO<sub>3</sub>
  - SeF<sub>6</sub>
  - SOCl<sub>2</sub>
  - ICl<sub>3</sub>
60. For each of the following molecules or molecular ions, give the steric number and sketch and name the approximate molecular geometry. In each case, the central atom is listed first and the other atoms are all bonded directly to it.
- PF<sub>3</sub>
  - SO<sub>2</sub>Cl<sub>2</sub>
  - PF<sub>6</sub><sup>-</sup>
  - ClO<sub>2</sub><sup>-</sup>
  - GeH<sub>4</sub>
61. For each of the following molecules or molecular ions, give the steric number, sketch and name the approximate molecular geometry, and describe the directions of any *distortions* from the approximate geometry due to lone pairs. In each case, the central atom is listed first and the other atoms are all bonded directly to it.
- ICl<sub>4</sub><sup>-</sup>
  - OF<sub>2</sub>
  - BrO<sub>3</sub><sup>-</sup>
  - CS<sub>2</sub>
62. For each of the following molecules or molecular ions, give the steric number, sketch and name the approximate molecular geometry, and describe the direction of any *distortions* from the approximate geometry due to lone pairs. In each case, the central atom is listed first and the other atoms are all bonded directly to it.
- TeH<sub>2</sub>
  - AsF<sub>3</sub>
  - PCl<sub>4</sub><sup>+</sup>
  - XeF<sub>5</sub><sup>+</sup>
63. Give an example of a molecule or ion having a formula of each of the following types and structures.
- AB<sub>3</sub> (planar)
  - AB<sub>3</sub> (pyramidal)
  - AB<sub>2</sub><sup>-</sup> (bent)
  - AB<sub>3</sub><sup>2-</sup> (planar)
64. Give an example of a molecule or ion having a formula of each of the following types and structures.
- AB<sub>4</sub><sup>-</sup> (tetrahedral)
  - AB<sub>2</sub> (linear)
  - AB<sub>6</sub><sup>-</sup> (octahedral)
  - AB<sub>3</sub><sup>-</sup> (pyramidal)
65. For each of the answers in Problem 59, state whether the species is polar or nonpolar.
66. For each of the answers in Problem 60, state whether the species is polar or nonpolar.
67. The molecules of a certain compound contain one atom each of nitrogen, fluorine, and oxygen. Two possible structures are NOF (O as central atom) and ONF (N as central atom). Does the information that the molecule is bent limit the choice to one of these two possibilities? Explain.
68. Mixing SbCl<sub>3</sub> and GaCl<sub>3</sub> in a 1:1 molar ratio (using liquid sulfur dioxide as a solvent) gives a solid ionic compound of empirical formula GaSbCl<sub>6</sub>. A controversy arises over whether this compound is (SbCl<sub>2</sub><sup>+</sup>)(GaCl<sub>4</sub><sup>-</sup>) or (GaCl<sub>2</sub><sup>+</sup>)(SbCl<sub>4</sub><sup>-</sup>).
- Predict the molecular structures of the two anions.
  - It is learned that the cation in the compound has a bent structure. Based on this fact, which formulation is more likely to be correct?
69. (a) Use the VSEPR theory to predict the structure of the NNO molecule.
- (b) The substance NNO has a small dipole moment. Which end of the molecule is more likely to be the positive end, based only on electronegativity?
70. Ozone (O<sub>3</sub>) has a nonzero dipole moment. In the molecule of O<sub>3</sub>, one of the oxygen atoms is directly bonded to the other two, which are not bonded to each other.
- Based on this information, state which of the following structures are possible for the ozone molecule: symmetric linear, nonsymmetric linear (for example,

different O—O bond lengths), and bent. (Note: Even an O—O bond can have a bond dipole if the two oxygen atoms are bonded to different atoms or if only one of the oxygen atoms is bonded to a third atom.)

- (b) Use the VSEPR theory to predict which of the structures of part (a) is observed.

### 3.12 Oxidation Numbers

71. Assign oxidation numbers to the atoms in each of the following species:  $\text{SrBr}_2$ ,  $\text{Zn}(\text{OH})_4^{2-}$ ,  $\text{SiH}_4$ ,  $\text{CaSiO}_3$ ,  $\text{Cr}_2\text{O}_7^{2-}$ ,  $\text{Ca}_3(\text{PO}_4)_2$ ,  $\text{KO}_2$ ,  $\text{CsH}$ .
72. Assign oxidation numbers to the atoms in each of the following species:  $\text{NH}_4\text{NO}_3$ ,  $\text{CaMgSiO}_4$ ,  $\text{Fe}(\text{CN})_6^{4-}$ ,  $\text{B}_2\text{H}_6$ ,  $\text{BaH}_2$ ,  $\text{PbCl}_2$ ,  $\text{Cu}_2\text{O}(\text{SO}_4)$ ,  $\text{S}_4\text{O}_6^{2-}$ .

### 3.13 Inorganic Nomenclature

73. Give the name and formula of an ionic compound involving only the elements in each pair that follows. Write Lewis symbols for the elements both before and after chemical combination.
- (a) Chlorine and cesium      (b) Calcium and astatine  
(c) Aluminum and sulfur      (d) Potassium and tellurium
74. Give the name and formula of an ionic compound involving only the elements in each pair that follows. Write Lewis symbols for the elements both before and after chemical combination.
- (a) Gallium and bromine      (b) Strontium and polonium  
(c) Magnesium and iodine      (d) Lithium and selenium
75. Give systematic names to the following compounds:
- (a)  $\text{Al}_2\text{O}_3$                       (b)  $\text{Rb}_2\text{Se}$   
(c)  $(\text{NH}_4)_2\text{S}$                       (d)  $\text{Ca}(\text{NO}_3)_2$   
(e)  $\text{Cs}_2\text{SO}_4$                       (f)  $\text{KHCO}_3$
76. Give systematic names to the following compounds:
- (a)  $\text{KNO}_2$                       (b)  $\text{Sr}(\text{MnO}_4)_2$   
(c)  $\text{MgCr}_2\text{O}_7$                       (d)  $\text{NaH}_2\text{PO}_4$   
(e)  $\text{BaCl}_2$                       (f)  $\text{NaClO}_3$
77. Write the chemical formulas for the following compounds:
- (a) Silver cyanide  
(b) Calcium hypochlorite  
(c) Potassium chromate  
(d) Gallium oxide  
(e) Potassium superoxide  
(f) Barium hydrogen carbonate
78. Write the chemical formulas for the following compounds:
- (a) Cesium sulfite  
(b) Strontium thiocyanate  
(c) Lithium hydride  
(d) Sodium peroxide  
(e) Ammonium dichromate  
(f) Rubidium hydrogen sulfate
79. Trisodium phosphate (TSP) is a heavy-duty cleaning agent. Write its chemical formula. What would be the systematic name for this ionic compound?
80. Monoammonium phosphate is the common name for a compound made up of  $\text{NH}_4^+$  and  $\text{H}_2\text{PO}_4^-$ ; it is used as a flame retardant. (Its use for this purpose was first suggested by Gay-Lussac in 1821.) Write its chemical formula. What is the systematic chemical name of this compound?
81. Write the chemical formula for each of the following compounds:
- (a) Silicon dioxide  
(b) Ammonium carbonate  
(c) Lead(IV) oxide  
(d) Diphosphorus pentoxide  
(e) Calcium iodide  
(f) Iron(III) nitrate
82. Write the chemical formula for each of the following compounds:
- (a) Lanthanum(III) sulfide  
(b) Cesium sulfate  
(c) Dinitrogen trioxide  
(d) Iodine pentafluoride  
(e) Chromium(III) sulfate  
(f) Potassium permanganate
83. Give the systematic name for each of the following compounds:
- (a)  $\text{Cu}_2\text{S}$  and  $\text{CuS}$                       (b)  $\text{Na}_2\text{SO}_4$   
(c)  $\text{As}_4\text{O}_6$                       (d)  $\text{ZrCl}_4$   
(e)  $\text{Cl}_2\text{O}_7$                       (f)  $\text{Ga}_2\text{O}$
84. Give the systematic name for each of the following compounds:
- (a)  $\text{Mg}_2\text{SiO}_4$                       (b)  $\text{Fe}(\text{OH})_2$  and  $\text{Fe}(\text{OH})_3$   
(c)  $\text{As}_2\text{O}_5$                       (d)  $(\text{NH}_4)_2\text{HPO}_4$   
(e)  $\text{SeF}_6$                       (f)  $\text{Hg}_2\text{SO}_4$

## ADDITIONAL PROBLEMS

85. Refer to Figure 3.18 and compute the difference in electronegativity between the atoms in  $\text{LiCl}$  and those in  $\text{HF}$ . Based on their physical properties (see below), are the two similar or different in terms of bonding?

	LiCl	HF
Melting point	605°C	83.1°C
Boiling point	1350°C	19.5°C

86. Ordinarily, two metals, when mixed, form alloys that show metallic character. If the two metals differ sufficiently in electronegativity, they can form compounds with significant ionic character. Consider the solid produced by mixing equal chemical amounts of Cs and Rb, compared with that produced by mixing Cs and Au. Compute the electronegativity difference in each case, and determine whether either mixture has significant ionic character. If either compound is ionic or partially ionic, which atom

carries the net negative charge? Are there alkali halides with similar or smaller electronegativity differences?

87. At large interatomic separations, an alkali halide molecule  $MX$  has a lower energy as two neutral atoms,  $M + X$ ; at short separations, the ionic form  $(M^+)(X^-)$  has a lower energy. At a certain distance,  $R_c$ , the energies of the two forms become equal, and it is near this distance that the electron will jump from the metal to the halogen atom during a collision. Because the forces between neutral atoms are weak at large distances, a reasonably good approximation can be made by ignoring any variation in potential  $V(R)$  for the neutral atoms between  $R_c$  and  $R = \infty$ . For the ions in this distance range,  $V(R)$  is dominated by their Coulomb attraction.
- (a) Express  $R_c$  for the first ionization energy of the metal  $M$  and the electron affinity of the halogen  $X$ .
- (b) Calculate  $R_c$  for LiF, KBr, and NaCl using data from Appendix F.
88. Use the data in Appendix F to compute the energy changes ( $\Delta E$ ) of the following pairs of reactions:
- (a)  $\text{Na}(g) + \text{I}(g) \longrightarrow \text{Na}^+(g) + \text{I}^-(g)$   
 $\text{Na}(g) + \text{I}(g) \longrightarrow \text{Na}^-(g) + \text{I}^+(g)$
- (b)  $\text{K}(g) + \text{Cl}(g) \longrightarrow \text{K}^+(g) + \text{Cl}^-(g)$   
 $\text{K}(g) + \text{Cl}(g) \longrightarrow \text{K}^-(g) + \text{Cl}^+(g)$

Explain why  $\text{Na}^+\text{I}^-$  and  $\text{K}^+\text{Cl}^-$  form in preference to  $\text{Na}^-\text{I}^+$  and  $\text{K}^-\text{Cl}^+$ .

89. The carbon–carbon bond length in  $\text{C}_2\text{H}_2$  is 1.20 Å, that in  $\text{C}_2\text{H}_4$  is 1.34 Å, and that in  $\text{C}_2\text{H}_6$  is 1.53 Å. Near which of these values would you predict the bond length of  $\text{C}_2$  to lie? Is the experimentally observed value, 1.31 Å, consistent with your prediction?
90. Two possible Lewis diagrams for sulfine ( $\text{H}_2\text{CSO}$ ) are

- (a) Compute the formal charges on all atoms.
- (b) Draw a Lewis diagram for which all the atoms in sulfine have formal charges of zero.
91. There is persuasive evidence for the brief existence of the unstable molecule  $\text{OPCl}$ .
- (a) Draw a Lewis diagram for this molecule in which the octet rule is satisfied on all atoms and the formal charges on all atoms are zero.
- (b) The compound  $\text{OPCl}$  reacts with oxygen to give  $\text{O}_2\text{PCl}$ . Draw a Lewis diagram of  $\text{O}_2\text{PCl}$  for which all formal charges are equal to zero. Draw a Lewis diagram in which the octet rule is satisfied on all atoms.
92. The compound  $\text{SF}_3\text{N}$  has been synthesized.
- (a) Draw the Lewis diagram of this molecule, supposing that the three fluoride atoms and the nitrogen atom surround the sulfur atom. Indicate the formal charges. Repeat, but assume that the three fluorine atoms and the sulfur atom surround the nitrogen atom.
- (b) From the results in part (a), speculate about which arrangement is more likely to correspond to the actual molecular structure.

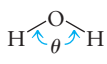

93. In nitryl chloride ( $\text{NO}_2\text{Cl}$ ), the chlorine atom and the two oxygen atoms are bonded to a central nitrogen atom, and all the atoms lie in a plane. Draw the two electron dot resonance forms that satisfy the octet rule and that together are consistent with the fact that the two nitrogen–oxygen bonds are equivalent.

94. The molecular ion  $\text{S}_3\text{N}_3^-$  has the cyclic structure

All S–N bonds are equivalent.

- (a) Give six equivalent resonance hybrid Lewis diagrams for this molecular ion.
- (b) Compute the formal charges on all atoms in the molecular ion in each of the six Lewis diagrams.
- (c) Determine the charge on each atom in the polyatomic ion, assuming that the true distribution of electrons is the *average* of the six Lewis diagrams arrived at in parts (a) and (b).
- (d) An advanced calculation suggests that the actual charge resident on each N atom is  $-0.375$  and on each S atom is  $+0.041$ . Show that this result is consistent with the overall  $+1$  charge on the molecular ion.
- \*95. The two compounds nitrogen dioxide and dinitrogen tetraoxide are introduced in Section 3.13.
- (a)  $\text{NO}_2$  is an odd-electron compound. Draw the best Lewis diagrams possible for it, recognizing that one atom cannot achieve an octet configuration. Use formal charges to decide whether that should be the (central) nitrogen atom or one of the oxygen atoms.
- (b) Draw resonance forms for  $\text{N}_2\text{O}_4$  that obey the octet rule. The two N atoms are bonded in this molecule.
96. Although magnesium and the alkaline-earth metals situated below it in the periodic table form ionic chlorides, beryllium chloride ( $\text{BeCl}_2$ ) is a covalent compound.
- (a) Follow the usual rules to write a Lewis diagram for  $\text{BeCl}_2$  in which each atom attains an octet configuration. Indicate formal charges.
- (b) The Lewis diagram that results from part (a) is an extremely unlikely one because of the double bonds and formal charges it shows. By relaxing the requirement of placing an octet on the beryllium atom, show how a Lewis diagram without formal charges can be written.
97. (a) The first noble-gas compound, prepared by Neil Bartlett in 1962, was an orange-yellow ionic solid that consisted of  $\text{XeF}^+$  and  $\text{PtF}_6^-$ . Draw a Lewis diagram for  $\text{XeF}^+$ .
- (b) Shortly after the preparation of the ionic compound discussed in part (a), it was found that the irradiation of mixtures of xenon and fluorine with sunlight produced white crystalline  $\text{XeF}_2$ . Draw a Lewis diagram for this molecule, allowing valence expansion on the central xenon atom.

- \*98. Represent the bonding in SF<sub>2</sub> (F—S—F) with Lewis diagrams. Include the formal charges on all atoms. The dimer of this compound has the formula S<sub>2</sub>F<sub>4</sub>. It was isolated in 1980 and shown to have the structure F<sub>3</sub>S—SF. Draw a possible Lewis diagram to represent the bonding in the dimer, indicating the formal charges on all atoms. Is it possible to draw a Lewis diagram for S<sub>2</sub>F<sub>4</sub> in which all atoms have valence octets? Explain why or why not.
- \*99. A stable triatomic molecule can be formed that contains one atom each of nitrogen, sulfur, and fluorine. Three bonding structures are possible, depending on which is the central atom: NSF, SNF, and SFN.
- (a) Write a Lewis diagram for each of these molecules, indicating the formal charge on each atom.
- (b) Often, the structure with the least separation of formal charge is the most stable. Is this statement consistent with the observed structure for this molecule—namely, NSF, which has a central sulfur atom?
- (c) Does consideration of the electronegativities of N, S, and F from Figure 3.18 help rationalize this observed structure? Explain.
100. The gaseous potassium chloride molecule has a measured dipole moment of 10.3 D, which indicates that it is a very polar molecule. The separation between the nuclei in this molecule is 2.67 Å. What would the dipole moment of a KCl molecule be if there were opposite charges of one fundamental unit ( $1.60 \times 10^{-19}$  C) at the nuclei?
101. (a) Predict the geometry of the SbCl<sub>5</sub><sup>2-</sup> ion, using the VSEPR method.
- (b) The ion SbCl<sub>6</sub><sup>3-</sup> is prepared from SbCl<sub>5</sub><sup>2-</sup> by treatment with Cl<sup>-</sup>. Determine the steric number of the central antimony atom in this ion, and discuss the extension of the VSEPR theory that would be needed for the prediction of its molecular geometry.
102. The element xenon (Xe) is by no means chemically inert; it forms a number of chemical compounds with electronegative elements such as fluorine and oxygen. The reaction of xenon with varying amounts of fluorine produces XeF<sub>2</sub> and XeF<sub>4</sub>. Subsequent reaction of one or the other of these compounds with water produces (depending on conditions) XeO<sub>3</sub>, XeO<sub>4</sub>, and H<sub>4</sub>XeO<sub>6</sub>, as well as mixed compounds such as XeOF<sub>4</sub>. Predict the structures of these six xenon compounds, using the VSEPR theory.
103. Predict the arrangement of the atoms about the sulfur atom in F<sub>4</sub>SPO, assuming that double-bonded atoms require more space than single-bonded atoms.
104. Draw Lewis diagrams and predict the geometries of the following molecules. State which are polar and which are nonpolar.
- (a) ONCl    (b) O<sub>2</sub>NCl  
(c) XeF<sub>2</sub>    (d) SCl<sub>4</sub>  
(e) CHF<sub>3</sub>
- \*105. Suppose that any given kind of bond, such as O—H, has a characteristic electric dipole. That is, suppose that electric dipole moments can be assigned to bonds just as bond energies can be. Both are usefully accurate approximations. Consider the water molecule
- 
- Show that if  $\mu_{\text{OH}}$  is the dipole moment of the OH bond, then the dipole moment of water is  $\mu(\text{H}_2\text{O}) = 2\mu_{\text{OH}} \cos(\theta/2)$ . What is the dipole moment  $\mu_{\text{OH}}$  if  $\mu(\text{H}_2\text{O})$  is 1.86 D?
106. A good method of preparing pure oxygen on a small scale is the decomposition of KMnO<sub>4</sub> in a vacuum above 215°C:
- $$2 \text{KMnO}_4(\text{s}) \longrightarrow \text{K}_2\text{MnO}_4(\text{s}) + \text{MnO}_2(\text{s}) + \text{O}_2(\text{g})$$
- Assign an oxidation number to each atom and verify that the total number of electrons lost is equal to the total number gained.
107. Bismuth forms an ion with the formula Bi<sub>5</sub><sup>3+</sup>. Arsenic and fluorine form a complex ion [AsF<sub>6</sub>]<sup>-</sup>, with fluorine atoms arranged around a central arsenic atom. Assign oxidation numbers to each of the atoms in the bright yellow crystalline solid with the formula Bi<sub>5</sub>(AsF<sub>6</sub>)<sub>3</sub> · 2SO<sub>2</sub>.
108. In some forms of the periodic table, hydrogen is placed in Group I; in others, it is placed in Group VII. Give arguments in favor of each location.
- \*109. (a) Determine the oxidation number of lead in each of the following oxides: PbO, PbO<sub>2</sub>, Pb<sub>2</sub>O<sub>3</sub>, Pb<sub>3</sub>O<sub>4</sub>.
- (b) The only known lead ions are Pb<sup>2+</sup> and Pb<sup>4+</sup>. How can you reconcile this statement with your answer to part (A)?
110. There have been some predictions that element 114 will be relatively stable in comparison with many other elements beyond uranium in the periodic table. Predict the maximum oxidation state of this element. Based on the trends in the oxidation states of other members of its group, is it likely that this oxidation state will be the dominant one?

## CUMULATIVE PROBLEMS

111. A certain element, M, is a main-group metal that reacts with chlorine to give a compound with the chemical formula MCl<sub>2</sub> and with oxygen to give the compound MO.
- (a) To which group in the periodic table does element M belong?
- (b) The chloride contains 44.7% chlorine by mass. Name the element M.
- \*112. An ionic compound used as a chemical fertilizer has the composition (by mass) 48.46% O, 23.45% P, 21.21% N, 6.87% H. Give the name and chemical formula of the compound and draw Lewis diagrams for the two types of ions that make it up.

- 113.** A compound is being tested for use as a rocket propellant. Analysis shows that it contains 18.54% F, 34.61% Cl, and 46.85% O.
- Determine the empirical formula for this compound.
  - Assuming that the molecular formula is the same as the empirical formula, draw a Lewis diagram for this molecule. Review examples elsewhere in this chapter to decide which atom is most likely to lie at the center.
  - Use the VSEPR theory to predict the structure of the molecule from part (b).
- 114.** Many important fertilizers are ionic compounds that contain the elements nitrogen, phosphorus, and potassium because these are frequently the limiting plant-growth nutrients in soil.
- Write the chemical formulas for the following chemical fertilizers: ammonium phosphate, potassium nitrate, ammonium sulfate.
  - Calculate the mass percentage of nitrogen, phosphorus, and potassium for each of the compounds in part (a).

Colloidal solutions of CdSe/ZnSe core/shell nanoparticles are synthesized with different size distributions then excited with UV light. The nanocrystals in the different vials show different colors in visible light because the wavelength at which they emit is determined by their size. This size-dependent behavior in the nanometer regime can be explained only by quantum mechanics. Such nanocrystals, also called “quantum dots,” are incorporated into new optical and electronic device designs.

Science can advance in different ways. Usually, the slow and steady accumulation of experimental results supports and refines existing models, which leads to a more satisfactory description of natural phenomena. Occasionally, however, the results of new experiments directly contradict previously accepted theories. In this case, a period of uncertainty ensues; it is resolved only through the eventual emergence of a new and more complete theory that explains both the previously understood results and the new experiments. This process is called a *scientific revolution*. In the first 25 years of the 20th century, a revolution in physics led to the development of the quantum theory, which also profoundly affected the science of chemistry.

One of the fundamental assumptions of early science was that nature is continuous; that is, nature does not make “jumps.” On the macroscopic scale, this appears to be true enough. We can measure out an amount of graphite (carbon) of mass 9, or 8.23, or 6.4257 kg, and it appears that the mass can have any value provided that our balance is sufficiently accurate. On the atomic scale, however, this apparently continuous behavior breaks down. An analogy may be useful here. A sand beach from a distance appears smooth and continuous, but a close look reveals that it is made up of individual grains of sand. This same “graininess” is found in matter observed on the atomic scale. The mass of

carbon ( $^{12}\text{C}$ ) comes in “packets,” each of which weighs  $1.99265 \times 10^{-26}$  kg. In principle, two, three, or any integral number of such packets can be “weighed out,” but we cannot obtain  $1\frac{1}{2}$  packets. Carbon is not a continuous material. It comes in chunks, each containing the minimum measurable mass of carbon—that of an atom. Similarly, electric charge comes in packets of size  $e$ , as shown in Section 1.4, and fractional charges are never observed in chemical reactions.

The central idea of quantum theory is that energy, like matter, is not continuous but it exists only in discrete packets. Discreteness of matter and charge on the microscopic scale seems entirely reasonable and familiar to us, based on the modern picture of atomic structure. But, the idea that energy also exists only in discrete chunks is contrary to our experience of the macroscopic world. The motions of a soccer ball rolling up and down the sides of a gully involve arbitrary amounts of kinetic and potential energy; nothing in ordinary human experience suggests that the energy of a system should change abruptly by “jumps.” Understanding quantum mechanics requires that we develop a new kind of physical intuition, based on the results of experiments that are impossible to understand using classical mechanics. These results are completely divorced from ordinary human experience in the macroscopic world around us, and our physical intuition from the macroscopic world cannot be transferred to the quantum domain. We must resist the urge to interpret these quantum results in terms of ordinary experience.

To understand the far-reaching nature of the quantum revolution, you should consider the state of physics at the end of the 19th century. The 200 years that followed the seminal work (published in 1687) of Isaac Newton were the classical period in the study of mechanics, the branch of physics that predicts the motions of particles and the collections of particles that make up working mechanisms. By the end of that period, about 1900, physicists had achieved a deep understanding that successfully dealt with problems ranging from the motions of the planets in their orbits to the design of a bicycle. These achievements make up the field now called **classical mechanics**.

Classical mechanics can predict the future positions of a group of particles from their present positions and velocities if the forces among them are known. At the end of the 19th century, it was naturally thought that the motion of elementary particles—such as the recently discovered electron—could be described by classical mechanics. Once the correct force laws operating between the elementary particles were discovered, the properties of atoms and molecules could be predicted to any desired accuracy by solving Newton’s equations of motion. It was believed that all the fundamental laws of physics had been discovered. At the dedication of the Ryerson Physics Laboratory at the University of Chicago in 1894, the American physicist A. A. Michelson said, “Our future discoveries must be looked for in the sixth decimal place.” Little did he imagine the revolutionary changes that would shake physics and chemistry during the following 30 years.

Central to those changes was not only the recognition that energy is quantized but also the discovery that all particles display wavelike properties in their motions. The effects of wavelike properties are most pronounced for small, low-mass particles such as electrons in atoms. **Quantum mechanics** incorporated both the ideas of “wave–particle duality” and energy quantization into a single comprehensive theory that superseded classical mechanics to describe the properties of matter on the nanometer length scale. Quantum mechanics is one of the greatest intellectual achievements of the 20th century.

This chapter describes the origins of the quantum theory, summarizes its techniques, and demonstrates their application to simple model systems. Our goals are to help you become skilled and confident in using the language, concepts, and tools of quantum theory. With these skills, we will guide you to develop an intuitive understanding of the behavior of quantum systems—so

foreign to our ordinary human experience—and the magnitudes of the observable quantities (energy, momentum, length) in the quantum domain. Chapter 5 shows how quantum mechanics explains the structure of atoms and the periodic table, and Chapter 6 shows how the quantum theory explains the formation of chemical bonds.

## 4.1 Preliminaries: Wave Motion and Light

Many kinds of waves are studied in physics and chemistry. Familiar examples include water waves stirred up by the winds over the oceans, set off by a stone dropped into a quiet pool, or created for teaching demonstrations by a laboratory water-wave machine. Sound waves are periodic compressions of the air that move from a source to a detector such as the human ear. Light waves, as discussed later in this chapter, consist of oscillating electric and magnetic fields moving through space. Even some chemical reactions occur in such a way that waves of color pass through the sample as the reaction proceeds. Common to all these wave phenomena is the oscillatory variation of some property with time at a given fixed location in space (Table 4.1). All of these waves are described by the same equations.

Wave	Oscillating Quantity
Water	Height of water surface
Sound	Density of air
Light	Electric and magnetic fields
Chemical	Concentrations of chemical species

A snapshot of a water wave (Fig. 4.1) records the crests and troughs present at some instant in time. The **amplitude**,  $A$ , of the wave is the maximum height or the maximum displacement of the water surface compared with the undisturbed level of the water; this undisturbed height is customarily chosen as the reference height and assigned the value zero. Positive vertical displacements increase the level of the water, whereas negative vertical displacements decrease the level of the water. We define the amplitude as either the height of a crest or the depth of a trough, and it is always given as an absolute value. The distance between two successive crests (or troughs) is called the **wavelength**,  $\lambda$  (Greek lambda), of the wave, provided that this distance is reproducible from peak to peak. The **frequency** of a water wave can be measured by counting the number of peaks or troughs observed moving past a fixed point in space per second. The frequency,  $\nu$  (Greek symbol, pronounced nu), is measured in units of waves (or cycles) per second, or simply  $\text{s}^{-1}$ . The fundamental frequency unit one cycle per second has been named the **hertz (Hz)** in honor of the German physicist Heinrich Hertz. For example, if 12 water-wave peaks are observed to pass a certain point in 30 seconds, the frequency is

$$\text{frequency} = \nu = \frac{12}{30 \text{ s}} = 0.40 \text{ s}^{-1} = 0.40 \text{ Hz}$$

The wavelength and frequency of a wave are related through its speed—the rate at which a particular wave crest moves through the medium. In Figure 4.1, the crest at the left end of the horizontal black arrow will move forward exactly one wavelength in one cycle of the wave. By definition, the time required for the crest to travel this distance is the reciprocal of the frequency,  $\tau = \nu^{-1}$ , so the speed (the distance traveled divided by the time elapsed) is given by

$$\text{speed} = \frac{\text{distance traveled}}{\text{time elapsed}} = \frac{\lambda}{\nu^{-1}} = \lambda \nu$$

The speed of a wave is the product of its wavelength and its frequency.

The dependence of the vertical displacement,  $h(x,t) - h_0$ , of the water as a function of both position  $x$  and time  $t$  in Figure 4.1 for a wave traveling in the  $+x$  direction may be summarized by the expression  $h(x,t) - h_0 = A(\cos 2\pi x/\lambda - 2\pi t/\tau)$  where  $A$  is the amplitude of the wave.

**FIGURE 4.1** As a water wave moves across an otherwise calm tank, its amplitude and wavelength can be determined. Its speed is found as the ratio of the distance traveled by a particular wave crest to the time elapsed.

### 4.1.1 Electromagnetic Radiation

By the end of the 18th century, the behavior of light was well described by a wave model. The signature properties of light—diffraction, interference, and polarization—were understood as consequences of wave propagation. In 1865, the Scottish physicist James Clerk Maxwell proposed a theory that described visible light as a propagating wave of **electromagnetic radiation** that carries both energy and momentum. Unlike water and sound waves, electromagnetic waves are not sustained by some “propagating medium” such as water or air. Rather, a beam of light consists of oscillating *electric* and *magnetic fields* oriented perpendicular to one another and to the direction in which the light is propagating (Fig. 4.2). These fields are produced by the motion of charged particles in the source of the light. These oscillating fields can transfer energy and momentum to other charged particles that intercept the beam in some location that is remote from the source. Electromagnetic waves carry information from a broadcast source to a remote receiver in wireless communication. Indeed, one

**FIGURE 4.2** Light consists of waves of oscillating electric and magnetic fields that are perpendicular to each other and to the direction of propagation of the light.

FIGURE 4.3 The electromagnetic spectrum. Note the small fraction that is visible to the human eye.

of the early triumphs of Maxwell’s theory was the development of the radio, based largely on the experimental work of Heinrich Hertz. We will see that electromagnetic radiation is both emitted and absorbed by atoms and molecules. It is, therefore, one of our most effective tools for probing the nature of atoms and molecules.

Electromagnetic waves are described by the equations introduced earlier. A detector located at any point  $x$  along the  $x$ -axis in Figure 4.2 will see the electric field  $E(x,t)$  oscillate with time as the wave propagates along the  $x$ -axis according to the equation

$$E(x, t) = E_{\max} \cos[2\pi(x/\lambda - \nu t)]$$

where  $E_{\max}$  is the amplitude of the wave. The speed,  $c$ , of light passing through a vacuum is equal to the product  $\lambda\nu$ , and its value is

$$c = \lambda\nu = 2.99792458 \times 10^8 \text{ m s}^{-1} \quad [4.1]$$

The speed,  $c$ , is a universal constant; it is the same for all types of radiation in the electromagnetic spectrum (Fig. 4.3). Regions of the electromagnetic spectrum are characterized by different values of wavelength and frequency. The region visible to the eye, which is a small fraction of the entire spectrum, comprises bands of colored light that cover particular ranges of wavelength and frequency. The band of light we perceive as green is centered about  $5.7 \times 10^{14}$  Hz with wavelengths near  $5.3 \times 10^{-7}$  m (530 nm). Red light is characterized by a lower frequency and a longer wavelength than green light, and violet light is characterized by a higher frequency and shorter wavelength than green light. A laser, such as the one shown in Figure 4.4, emits nearly monochromatic light (light of a

FIGURE 4.4 A laser emits a well-collimated beam of light with a narrow range of wavelengths. The direction of motion of a laser beam can be manipulated by inserting mirrors in the path of the beam.

**FIGURE 4.5** When white light is passed through slits to produce a narrow beam and then refracted in a glass prism, the various colors are dispersed, or separated from one another, because each wavelength is refracted through a different angle.

single frequency and wavelength). White light contains the full range of visible wavelengths; it can be resolved into its component wavelengths, or refracted, by passing it through a prism (Fig. 4.5).

Electromagnetic radiation that lies outside the visible region is also familiar to us (see Fig. 4.3). The warmth radiated from a stone pulled from a fire is largely due to infrared radiation, whose wavelength is longer than that of visible light. Microwave ovens use radiation whose wavelength is longer than infrared wavelengths, and radio communication uses still longer wavelengths. Radio stations are identified by their broadcast frequencies. FM stations typically broadcast at frequencies of tens to hundreds of megahertz ( $1 \text{ MHz} = 10^6 \text{ s}^{-1}$ ), whereas AM stations broadcast at lower frequencies, from hundreds to thousands of kilohertz ( $1 \text{ kHz} = 10^3 \text{ s}^{-1}$ ). You might check the frequencies of some of your favorite radio stations; ours include a classical music station broadcasting at 90.5 MHz (FM) and a sports station broadcasting at 1300 kHz (AM). Radiation with wavelengths shorter than that of visible light includes ultraviolet light, X-rays, and gamma rays; radiation in these regions of the electromagnetic spectrum (with wavelengths shorter than about 340 nm) can cause ionization and damage in biological tissue and are often collectively called **ionizing radiation**.

#### EXAMPLE 4.1

Almost all commercially available microwave ovens use radiation with a frequency of  $2.45 \times 10^9 \text{ Hz}$ . Calculate the wavelength of this radiation.

#### Solution

The wavelength is related to the frequency as follows:

$$\lambda = \frac{c}{\nu} = \frac{3.00 \times 10^8 \text{ m s}^{-1}}{2.45 \times 10^9 \text{ s}^{-1}} = 0.122 \text{ m}$$

Thus, the wavelength is 12.2 cm.

**Related Problems: 3, 4**

The wave theory of light is based on experimental demonstrations of interference and diffraction, results that can only be explained as consequences of wave motion. When two light waves pass through the same region of space, they interfere to create a new wave called the *superposition* of the two. If the crests of the waves are aligned, the superposition wave is their sum and has greater amplitude than the original waves. This process is called **constructive interference**. If the crest of one wave is aligned with the trough of the other, the superposition wave is their difference, and the waves cancel through **destructive interference** (Fig. 4.6a, b). If the waves are not perfectly aligned for either constructive or destructive interference, the superposition wave has amplitude

**FIGURE 4.6** Interference of waves (a) Constructive interference. When two waves are in phase their crests and troughs add to produce a new wave of greater amplitude. (b) Destructive interference. When two waves are out of phase, their crests and troughs cancel each other and the net amplitude is 0. (Adapted from Zumdahl/DeCoste, *Chemical Principles*, 6e, Fig. 12.7; Cengage Learning.)

**FIGURE 4.7** Diffraction of waves. The double slit experiment demonstrates diffraction as a consequence of constructive and destructive interference of waves arriving from the slits. The diffraction pattern on the screen behind the slits shows alternating bright regions (constructive interference) and dark regions (destructive interference). (Adapted from Moore/Staniitski/Jurs, *Chemistry: The Molecular Science 4e*, Fig. 7.5, p. 278; Cengage Learning.)

intermediate between the two extreme results. When a monochromatic beam of light, such as that from a laser (see Fig. 4.4), passes through two open slits in a solid wall, each slit becomes the source of new light waves. These outgoing new waves interfere to produce a **diffraction pattern**, which has alternating bright and dark regions. The dark regions are the result of destructive interference, and the bright regions arise from constructive interference. The solid lines in Figure 4.7 trace one set of points in space where two outgoing waves undergo constructive interference and another set where they show destructive interference. We see later (Section 21.1) that electromagnetic waves interact with the atoms in a crystalline solid to generate outgoing waves that produce diffraction patterns. From the dimensions of these patterns we can determine the distances between atoms in the solid.

## 4.2 Evidence for Energy Quantization in Atoms

Rutherford's planetary model of the atom was inconsistent with the laws of classical physics (see discussion in Section 3.3). According to Maxwell's electromagnetic theory, accelerated charges must emit electromagnetic radiation. An electron in orbit around the nucleus is accelerating because its direction is constantly changing. It must, therefore, emit electromagnetic radiation, lose energy, and eventually spiral into the nucleus. The very existence of stable atoms was perhaps the most fundamental of all the conceptual challenges facing physicists in the early 1900s. The recognition that energy is quantized in atoms was the first step toward resolving the conceptual conflicts.

This section begins with a discussion of blackbody radiation, the experiment that introduced energy quantization into science. Next, two sets of experiments that demonstrated quantization of energy in free atoms in the gas phase are described. We describe these experiments using energy level diagrams, which represent the discrete energy states of the atom. Our goal here is to introduce you to the relationship between the experimental evidence for energy quantization and the energy-level diagrams used to describe these experiments. Later in the chapter, we use the quantum theory to explain how energy is quantized and to predict the allowed values of the energy for several model problems. We have organized our discussion to group key concepts together, for better coherence and to provide physical insight; it does not strictly follow the historical development of the field.

### 4.2.1 Blackbody Radiation and Planck's Quantum Hypothesis

We are about to discuss a monumental achievement in the development of modern science, which changed forever the way we look at the world. This was the recognition that objects cannot gain or lose energy in arbitrary or continuous amounts, but instead transfer energy only in discrete, discontinuous amounts that are multiples of some fundamental quantity of energy. The German physicist Max Planck achieved this insight in 1901 while trying to explain some puzzling new experimental measurements on the interaction of solid objects with radiant energy, which was known as **blackbody radiation**. You will shortly see that you are already familiar with blackbody radiation in various guises, and we relate the discussion closely to the experimental results so that you can always see the problem exactly as Planck saw it. We invite you to read and think along with Planck and to witness an important demonstration of how science advances. When experimental results do not agree with established scientific theories, the theories must be either modified or discarded and replaced with new ones, to account for both the new and the old experimental results. This process leads to the development of theories that provide a more fundamental understanding of a wider range of phenomena than their predecessors.

Every object emits energy from its surface in the form of thermal radiation. This energy is carried by electromagnetic waves; the distribution of the wavelengths of electromagnetic waves depends on the temperature of the object. At ordinary temperatures, thermal radiation falls within the infrared portion of the electromagnetic spectrum; images formed by this radiation are used to map the surface of Earth from satellites in space and for tracking the movement of people in darkness using “night vision” detectors. As objects are heated to higher temperatures, the total intensity of radiation emitted over all frequencies increases, and the frequency distribution of the intensity also changes. The solid curves in Figure 4.8 show how the measured radiation intensity depends on frequency and temperature. There are two important features of these curves. First, the maximum in the radiation intensity distribution moves to higher frequency (shorter wavelength) as the temperature increases. This phenomenon is observed in familiar objects such as the heating element on an electric kitchen

**FIGURE 4.8** The dependence of the intensity of blackbody radiation on wavelength for two temperatures: 5000 K (red curve) and 7000 K (blue curve). The sun has a blackbody temperature near 5780 K, and its light-intensity curve lies between the two shown. The classical theory (dashed curves) disagrees with observation at shorter wavelengths.

range or the filament in an incandescent lightbulb. As these objects are heated, they first glow red, then orange, then yellow, and finally, white. It also explains the differences in color among stars; the hottest stars appear to be nearly white, whereas the colors of cooler stars can range from red to yellow. Second—and this is a key result—the radiation intensity falls to zero at extremely high frequencies for objects heated to any temperature.

The sources of blackbody radiation, according to classical physics, are oscillating electrical charges in the surfaces of these objects that have been accelerated by ordinary thermal motion. Each motion persists for a certain period, producing radiation whose frequency is inversely related to that period. A number of scientists used different methods to calculate the radiation intensity curves using this simplified model and arrived at the following result:

$$\rho_T(\nu) = \frac{8\pi k_B T \nu^2}{c^3} \quad [4.2]$$

where  $\rho_T(\nu)$  is the intensity of the radiation at the frequency  $\nu$ ;  $k_B$  is a fundamental constant called the Boltzmann constant, which is discussed in Sections 9.5 and 9.6;  $T$  is the temperature in degrees Kelvin (K) and  $c$  is the speed of light.

These calculated results, shown for 5000 and 7000 K by the dashed curves in Figure 4.8, agree well with experiment at lower frequency. But the theory does not predict a maximum in the intensity distribution, and even worse, it disagrees badly with the experimental results at high frequencies. This feature of the result was called the “ultraviolet catastrophe” because it predicts an infinite intensity at very short wavelengths, whereas the experimental intensities always remain finite and actually fall to zero at very short wavelengths (very high frequencies). The calculated result failed completely to explain the frequency distribution in blackbody radiation; yet, it is a direct consequence of the laws of classical physics. How could this conflict be resolved?

Blackbody radiation was explained by Max Planck in 1901, but only by overthrowing the very foundations of classical mechanics. Planck reasoned that the very high-frequency oscillators must not be excited by the thermal energy of the hot body to the same degree as the lower frequency oscillators. This was a challenge to explain because classical mechanics allows an oscillator to have any energy. Planck’s argument involved two steps, which are explained as follows.

For simplicity in following Planck’s hypothesis, let us focus on just one of the oscillating charged particles and visualize it as a ball of mass,  $m$ , held in place by a spring (Fig. 4.9). As the particle moves in response to the thermal motion of the atoms in the hot body, the spring exerts a “restoring force,”  $F$ , which returns the particle to its equilibrium position, which we will call  $x_0$ . As discussed in Appendix B for this same model problem, the restoring force is directly proportional to the displacement, and the force law is  $F = -k(x - x_0)$ , where the constant  $k$  measures the “stiffness” of the spring. The displacement of the particle oscillates about  $x_0$  in a periodic motion of frequency  $\nu = (1/2\pi)\sqrt{k/m}$ , and the associated potential energy of the particle is  $V(x) = \frac{1}{2}k(x - x_0)^2$ . (Fig. 4.10). This model is the simple harmonic oscillator described in Appendix B. Classical mechanics puts no restrictions on the value of the total energy,  $E$ . The total energy can be large or small, and it can be changed smoothly and continuously from one arbitrary value to another.

Planck’s first step was to pose a daring hypothesis: It is *not* possible to put an arbitrary amount of energy into an oscillator of frequency  $\nu$ . Instead, he postulated that the oscillator must gain and lose energy in “packets,” or *quanta*, of magnitude  $h\nu$ , and that the total energy of an oscillator,  $\epsilon_{\text{osc}}$ , can take only discrete values that are integral multiples of  $h\nu$ :

$$\epsilon_{\text{osc}} = nh\nu \quad n = 1, 2, 3, 4, \dots \quad [4.3]$$

**FIGURE 4.9** A charged particle of mass  $m$  bound to a solid surface by a spring is a model for the oscillatory motions of the surface atoms of a black body. The particle is shown at its rest position  $x_0$ , at a position closer to the surface ( $x < x_0$ ), and at one farther from the surface ( $x > x_0$ ).

**FIGURE 4.10** The potential energy curve for an oscillator is a consequence of the “restoring force” that always drives the oscillator toward its equilibrium position.

**FIGURE 4.11** An oscillator obeying classical mechanics has continuous values of energy and can gain or lose energy in arbitrary amounts.

**FIGURE 4.12** An oscillator described by Planck's postulate has discrete energy levels. It can gain or lose energy only in amounts that correspond to the difference between two energy levels.

In Planck's hypothesis,  $h$  was a constant with physical units  $\text{energy} \times \text{frequency}^{-1} = \text{energy} \times \text{time}$ , but the value of which was yet to be determined.

You can easily visualize the consequences of Planck's hypothesis using the simple harmonic oscillator model. Replace the spring and ball with a rubber band stretched between your fingers. Experience shows that you can stretch the band to any arbitrary length by applying the right amount of energy (so long as you do not rupture the band). But under Planck's hypothesis, the band would accept only certain specific values of energy. The rubber band would behave as if it could be stretched only to certain specific positions. It simply would not respond to attempts to give it energy between these specific values. This fact is contrary to all ordinary human experience with tangible, macroscopic objects. And yet, this is how energy transfer operates in the microscopic world of atoms, electrons, and molecules.<sup>1</sup>

The dramatic contrast between the energy values allowed by classical mechanics and those that arise from Planck's postulate is illustrated using **energy-level diagrams**, in which a horizontal line represents an allowed energy value for a system. The height of each line above the zero of energy represents the total energy in that level. In macroscopic systems that are well described by classical mechanics, all energies are allowed; the upper energy level diagram in Figure 4.11 represents the continuum of energies that the rubber band can accept up to the point where it breaks. For the quantum oscillators that Planck proposed, only those levels shown on the lower energy level diagram are allowed (Fig. 4.12).

Planck's second step was to predict the radiation intensity curves by calculating the average energy in these quantized oscillators at each frequency as a function of temperature. The key idea is that the excitation of a particular oscillator is an all-or-nothing event; there is either enough thermal energy to cause it to oscillate or there is not. According to Planck, the falloff in the intensity with frequency at a given temperature of the blackbody radiation is due to a diminishing probability of exciting the high-frequency oscillators. Planck's distribution for the intensity of radiation connected with the surface oscillators is

$$\rho_T(\nu) = \frac{8\pi h\nu^3}{c^3} \frac{1}{e^{h\nu/k_B T} - 1} \quad [4.4]$$

All of the symbols in Equation 4.4 have been identified earlier in this chapter. The value of  $h$  was determined by finding the best fit between this theoretical expression and the experimental results. Figure 4.13 shows the fit for  $T = 1646$  K, resulting in the value  $h = 6.63 \times 10^{-34}$  J s. The value of  $h$ , a fundamental constant of nature, has been measured to very high precision over the years by a number of other techniques. It is referred to as **Planck's constant**, and the currently accepted value is

$$h = 6.62606957 \times 10^{-34} \text{ J s}$$

We ask you to accept that the second fraction on the right-hand side of Equation 4.4 is the probability that an oscillator of frequency  $\nu$  is activated at a given temperature  $T$ . Chapter 12 presents the origin of this probability in the famous Boltzmann distribution, but in this chapter we want to use the result to demonstrate some additional consequences of Planck's hypothesis.

Before proceeding to explore the implications of the Planck distribution, we need to check whether it reduces to the classical expression under the appropriate conditions. It is always important to check whether new concepts can be matched with old concepts under appropriate conditions; this demonstrates that

<sup>1</sup>We will see later that energy transfer into macroscopic objects is also quantized. However, the discrete values are so closely spaced that they appear continuous, and the system behaves as if it obeys classical mechanics. This demonstrates the classical limit of quantum mechanics.

**FIGURE 4.13** Experimental test of Planck's distribution for blackbody radiation. The dots represent experimental data acquired at  $T = 1646$  K. The continuous curve represents Planck's predicted distribution, with the parameter  $h = 6.63 \times 10^{-34}$  J s. Agreement between experiment and theory is spectacular, demonstrating the validity of Planck's theory and also determining the value of the previously unknown parameter  $h$ .

the new concepts represent an orderly advance in knowledge. We can imagine that all of the oscillators would be excited at sufficiently high temperatures, in which case, the system should behave according to the laws of classical physics. We express this condition mathematically by setting  $h\nu/k_B T \ll 1$ , a ratio that is nearly zero. You will soon learn in calculus that most functions can be represented by simpler forms as the argument of the function approaches zero. For the exponential function,  $\exp(x) \approx 1 + x$  when  $x$  is nearly zero. Using this approximation, we obtain the high temperature limit of Planck's distribution

$$\rho_T(\nu) = \frac{8\pi h\nu^3}{c^3} \frac{1}{e^{h\nu/k_B T} - 1} \approx \frac{8\pi h\nu^3}{c^3} \frac{1}{([1 + h\nu/k_B T] - 1)} = \frac{8\pi k_B T \nu^2}{c^3} \quad [4.5]$$

which is valid as  $T \rightarrow \infty$ . This is indeed the classical result quoted in Equation 4.2.

Physically, Planck's dramatic explanation of blackbody radiation includes three fundamentally new ideas:

1. The energy of a system can take only discrete values, which are represented on its energy-level diagram.
2. A quantized oscillator can gain or lose energy only in discrete amounts  $\Delta\epsilon$ , which are related to its frequency by  $\Delta\epsilon = h\nu$ .
3. To emit energy from higher energy states, the temperature of a quantized system must be sufficiently high to excite those states.

These three ideas have permeated all areas of science and technology. They are the basis for our understanding that energy (like matter) is discrete, not continuous, and that it can be transferred only in discrete chunks and not by arbitrary amounts. Every system has its own energy-level diagram that describes the allowed energy values and the possible values of energy transfers.

**FIGURE 4.14** When a gas is excited in an electrical discharge, it glows as it emits light. The colors of the light emitted by three gases are shown: (a) neon, (b) argon, and (c) mercury. Each emission consists of several wavelengths of light, and the perceived color depends on which wavelength predominates.

### 4.2.2 Atomic Spectra and Transitions between Discrete Energy States

Light that contains a number of different wavelengths (see Fig. 4.5) can be resolved into its components by passing it through a prism, because each wavelength is refracted through a different angle. In the last quarter of the 19th century, experiments showed that elemental gases excited in electrical discharges emitted light in characteristic colors (Fig. 4.14). To understand this process, physicists sought to resolve this light into its component wavelengths. One instrument used for this purpose is called a **spectrograph** (Fig. 4.15a). The spectrograph is enclosed in a boxlike container to exclude stray light. The light to be analyzed enters through a narrow slit in the walls. The light passes to the prism, where it is dispersed into its components, and then falls on a photographic plate or other detector. The detector records the position and intensity of an image of the slit formed by each component wavelength. The recorded array of images is called the *spectrum* of the incoming light. If the incoming light contained all wavelengths, the spectrum would be continuous bands of dispersed colors as in Figure 4.5. Instead, the light emitted from gaseous atoms excited in flames or in electrical discharges gives discrete emission spectra, that is, a series of parallel lines. Each line is an image of the slit at a specific wavelength (see Fig. 4.15a), and the spectrum is unique for each element (Fig. 4.16). If white light is passed through a sample of gaseous atoms and the transmitted light is then sent into the spectrograph, the resulting absorption spectrum consists of dark slit images superimposed on the continuous spectrum of white light (see Fig. 4.15b). These experiments show that atoms emit and absorb light at a discrete set of frequencies characteristic of a particular element. For example, in 1885, J. J. Balmer discovered that hydrogen atoms emit a series of lines in the visible region, with frequencies that fit the following simple formula:

$$\nu = \left[ \frac{1}{4} - \frac{1}{n^2} \right] \times 3.29 \times 10^{15} \text{ s}^{-1} \quad n = 3, 4, 5, \dots \quad [4.6]$$

The hydrogen atom lines shown in Figure 4.16 fit this equation with  $n = 3, 4, 5,$  and  $6$  corresponding to the red, green, blue, and violet lines in the spectrum, respectively. Trying to understand the existence of discrete line spectra

**FIGURE 4.15** (a) The emission spectrum of atoms is measured by passing the light emitted from an excited sample through a prism to separate it according to wavelength, then recording the image on photographic film or an electronic detector. The spectrum consists of discrete bright lines against a dark background. (b) In absorption spectroscopy, white light from a source passes through the unexcited sample, which absorbs certain discrete wavelengths of light. Dark lines appear on a bright background.

and the various empirical equations that relate the frequencies of the lines challenged physicists for more than three decades.

The first explanation for these surprising experimental results was provided in 1913 by the Danish physicist Niels Bohr. He proposed a model of the hydrogen atom that allowed only discrete energy states to exist. He also proposed that light absorption resulted from a *transition* of the atoms between two of these states. The frequency of the light absorbed is connected to the energy of the

**FIGURE 4.16** Atoms of hydrogen, mercury, and neon emit light at discrete wavelengths. The pattern seen is characteristic of the element under study.  $1 \text{ \AA} = 10^{-10} \text{ m}$ .

initial and final states by the expression  $E_i + h\nu = E_f$ , where  $h\nu$  is the energy of the absorbed light (see Section 4.4.1). This gives

$$\nu = \frac{E_f - E_i}{h} \quad \text{or} \quad \Delta E = h\nu \quad (\text{absorption}) \quad [4.7]$$

**FIGURE 4.17** An atom makes a transition from state  $E_i$  to  $E_f$  and emits a photon of frequency  $\nu = [E_i - E_f]/h$ .

where  $h$  is Planck's constant. In absorption, the energy of the final state,  $E_f$ , is greater than that of the initial state so the signs work out correctly;  $\nu$  is a positive number as it must be. For emission, however,  $E_f < E_i$ , and energy conservation gives  $E_i = E_f + h\nu$ . The energy of the light is now on the final (product) side of the equation, as the light is produced or emitted (not absorbed). This gives  $\Delta E = E_f - E_i = -h\nu$  for emission (Fig. 4.17). Thus  $\Delta E > 0$  for absorption, whereas  $\Delta E < 0$  for emission. The Bohr model also accounts for the values of the discrete energy levels in the hydrogen atom (see Section 4.3).

The atoms of every element can be represented by an energy-level diagram in which the energy difference between two levels is related by Equation 4.7 to the frequency of a specific line in the experimental spectrum of the atom. Except for the simplest case of hydrogen, however, constructing the energy-level diagram from the experimental spectrum is difficult because numerous transitions are involved. Nonetheless, spectroscopists have assigned the atomic spectra of most of the elements in the periodic table, and extensive tabulations of the results are readily available.

### 4.2.3 The Franck–Hertz Experiment and the Energy Levels of Atoms

In 1914, the German physicists James Franck and Gustav Hertz (nephew of Heinrich Hertz) conducted an experiment to test Bohr's hypothesis that the energy of atoms is quantized by measuring the energy transferred to an atom in collisions with electrons. In their apparatus (Fig. 4.18), electrons of known energy collided with gaseous atoms, and the energy lost from the electrons was measured. Electrons were emitted from the heated cathode C and accelerated toward the anode A. Holes in the anode allowed electrons to pass toward the collector plate P with known kinetic energy controlled by the accelerating voltage between C and A. The apparatus was filled to a low pressure with the gas to be studied. The current arriving at P was studied as a function of the kinetic energy of the electrons by varying the accelerating voltage.

The experiment was started using a very low accelerating voltage, and the current was found to increase steadily as the accelerating voltage was increased.

**FIGURE 4.18** Apparatus of Franck and Hertz that demonstrates the quantization of energy in atoms. Gaseous atoms collide with electrons and gain energy by collisions only when the energy of the electron exceeds a certain threshold. The excited atom then emits a photon whose frequency is determined by the energy transferred to the atom during the collision.

**FIGURE 4.19** The current in the Franck–Hertz experiment shows a sharp change at a particular value of the accelerating voltage, corresponding to the threshold for energy transfer from the electron to a gaseous atom.

**FIGURE 4.20** The Franck–Hertz experiment measures directly the separation between energy levels of the atom by measuring the energy lost by an electron colliding with the atom.

**FIGURE 4.21** Simplified energy-level diagram for mercury.

At a certain voltage,  $V_{\text{thr}}$ , the current dropped sharply, going nearly to zero (Fig. 4.19). This observation implied that most of the electrons had lost their kinetic energy in collisions with the gas atoms and were unable to reach the collector. As the voltage was increased above  $V_{\text{thr}}$ , the current rose again. This result indicated that electrons were reaccelerated after collisions and gained sufficient energy to reach the collector.

The abrupt fall in the plot of current versus voltage at  $V_{\text{thr}}$  suggested that the kinetic energy of the electrons must reach a threshold  $eV_{\text{thr}}$  to transfer energy to the gas atoms, suggesting that the energy of the atoms must be quantized in discrete states. The **first excited state** must lie above the **ground state** (the state with lowest energy) (Fig. 4.20) by the amount  $eV_{\text{thr}}$ . Continuing the experiment with higher values of accelerating voltage revealed additional energy thresholds corresponding to excited states with higher energies.

To confirm their interpretation, Franck and Hertz used a spectrograph to analyze light that was emitted by the excited atoms. When the accelerating voltage was below  $V_{\text{thr}}$ , no light was observed. When the accelerating voltage was slightly above  $V_{\text{thr}}$ , a single emission line was observed whose frequency was very nearly equal to

$$\nu = \frac{E_{\text{upper}} - E_{\text{lower}}}{h} = \frac{eV_{\text{thr}}}{h} \quad [4.8]$$

At higher accelerating voltages, additional spectral emission lines appeared as each additional excitation energy threshold was reached.

#### EXAMPLE 4.2

The first two excitation voltage thresholds in the Franck–Hertz study of mercury vapor were found at 4.9 and 6.7 V. Calculate the wavelength of light emitted by mercury atoms after excitation past each of these thresholds.

#### Solution

The emitted wavelength at a particular value of  $V_{\text{thr}}$  is given by the following equation:

$$\begin{aligned} \lambda &= \frac{hc}{E_{\text{upper}} - E_{\text{lower}}} = \frac{hc}{eV_{\text{thr}}} \\ &= \frac{(6.6261 \times 10^{-34} \text{ J s})(2.9979 \times 10^8 \text{ m s}^{-1})(1 \times 10^9 \text{ nm m}^{-1})}{(1.6022 \times 10^{-19} \text{ C})(V_{\text{thr}})} \\ &= \frac{1239.8 \text{ nm J C}^{-1}}{V_{\text{thr}}} \end{aligned}$$

The value of each emission wavelength is calculated by substituting in a particular value of  $V_{\text{thr}}$  expressed in units of volts (V). The units in the numerator simplify to  $\text{nm J C}^{-1} = \text{nm V}$ .

At  $V_{\text{thr}} = 4.9 \text{ V}$ , the calculated wavelength is  $\lambda = 250 \text{ nm}$ . The wavelength actually observed above this threshold was 253.7 nm.

At  $V_{\text{thr}} = 6.7 \text{ V}$ , the calculated wavelength is  $\lambda = 180 \text{ nm}$ . The wavelength actually observed above this threshold was 184.9 nm.

Energy differences measured by the Franck–Hertz method and by optical emission spectroscopy agree quite closely. The optical measurements are more precise. These results enable us to begin to construct the energy diagram for mercury, showing the location of the first two excited states relative to the ground state (Fig. 4.21).

**Related Problems:** 17, 18

The significance of the Franck–Hertz experiment in the development of modern science cannot be exaggerated. It demonstrated that atoms absorb energy in collisions with electrons only in discrete, quantized amounts. The energy is then released only in discrete, quantized amounts by light emission. The Franck–Hertz experiment provided dramatic confirmation of Bohr’s hypothesis that the energy of atoms is quantized in discrete states. It also provided a direct electrical method for measuring the energy differences between these states and for constructing the energy-level diagram starting with the ground state. The technique continues to be used today to construct energy-level diagrams for molecules in the methods called “electron impact spectroscopy” or “electron energy loss spectroscopy.”

### 4.3 The Bohr Model: Predicting Discrete Energy Levels in Atoms

Atomic spectra and Franck–Hertz experiments measure the differences between energy levels, and they enable the energy level diagrams to be constructed from the experimental data using Equations 4.7 and 4.8. In 1913, Niels Bohr developed the first theoretical model to predict the energy levels of the hydrogen atom and one-electron ions such as  $\text{He}^+$ ,  $\text{Li}^{2+}$ , and  $\text{Be}^{3+}$ . You should review Section 3.3 before continuing further in this chapter. Pay careful attention to the definition of an absolute energy scale for atoms by choosing a reference state whose energy we set as zero. The logical choice, as discussed in Section 3.3, is the electron at rest located infinitely far from the nucleus.

The Bohr theory started from Rutherford’s planetary model of the atom. Bohr supplemented Rutherford’s planetary model with the assumption that an electron of mass  $m_e$  moves in a circular orbit of radius  $r$  about a fixed nucleus. The total energy of the hydrogen atom, kinetic plus potential, is given by Equation 3.7, which we reproduce and renumber here as Equation 4.9 for convenience:

$$E = \frac{1}{2} m_e v^2 - \frac{Z e^2}{4 \pi \epsilon_0 r} \quad [4.9]$$

The expression for the Coulomb force that attracts the electron to the nucleus is  $\vec{F} = F_{\text{coul}} \hat{r}$ , where  $\hat{r}$  is a unit vector pointing from the nucleus to the electron and  $F_{\text{coul}}$  is the negative derivative of the potential energy with respect to the separation  $r$ :  $F_{\text{coul}} = -Z e^2 / 4 \pi \epsilon_0 r^2$ . Newton’s second law relating force and acceleration is  $\vec{F} = m_e \vec{a}$ , and for uniform circular motion, the acceleration,  $\vec{a}$ , of the electron has magnitude  $v^2 / r$ . Combining these results gives the following relation for the *magnitude* of the force:

$$|F_{\text{Coulomb}}| = |m_e \vec{a}| \quad [4.10a]$$

$$\frac{Z e^2}{4 \pi \epsilon_0 r^2} = m_e \frac{v^2}{r} \quad [4.10b]$$

**FIGURE 4.22** Classical theory states that atoms constructed according to Rutherford’s nuclear model are not stable. The motion of electrons around the nucleus would cause them to radiate energy and quickly spiral into the nucleus.

As mentioned earlier, classical physics requires that an accelerated electron emit electromagnetic radiation, thereby losing energy and eventually spiraling into the nucleus (Fig. 4.22). Bohr avoided this conflict by simply *postulating* that only certain discrete orbits (characterized by radius  $r_n$  and energy  $E_n$ ) are allowed, and that light is emitted or absorbed only when the electron “jumps” from one stable orbit to another. This bold assertion was Bohr’s attempt to

explain the existence of stable atoms, a well-established experimental fact. Faced with the contradiction between the experimental results and the requirements of classical electrodynamics, he simply discarded the latter in the formulation of his model.

The next step in the development of the Bohr model was his assertion that the angular momentum of the electron is quantized. This was an *ad hoc* assumption designed to produce stable orbits for the electron; it had no basis in either classical theory or experimental evidence. The magnitude of the **linear momentum** of an electron is the product of its mass and its speed,  $m_e v$ . The **angular momentum**,  $\vec{L}$ , is a different quantity that describes rotational motion about an axis. An introduction to angular momentum is provided in Appendix B. For the circular paths (see Fig. 3.5) of the Bohr model, the magnitude of the angular momentum of the electron is the product of its mass, its speed, and the radius of the orbit ( $L = m_e v r$ ). Bohr postulated that the angular momentum is quantized in integral multiples of  $h/2\pi$ , where  $h$  is Planck's constant:

$$L = m_e v r = n \frac{h}{2\pi} \quad n = 1, 2, 3, \dots \quad [4.11]$$

The existence of discrete orbits and quantized energies follows directly as a consequence of the quantization of angular momentum.

We can determine the properties of these discrete orbits as follows. Equations 4.9 and 4.10 contain two unknowns,  $v$  and  $r$ . Solving Equation 4.11 for  $v$  ( $= nh/2\pi m_e r$ ), inserting it into Equation 4.10, and solving for  $r$  gives the allowed values for radius of the orbits:

$$r_n = \frac{\epsilon_0 n^2 h^2}{\pi Z e^2 m_e} = \frac{n^2}{Z} a_0 \quad [4.12]$$

where  $a_0$ , the **Bohr radius**, has the numerical value  $5.29 \times 10^{-11} \text{ m} = 0.529 \text{ \AA}$ . (The Bohr radius ( $a_0 = \epsilon_0 h^2 / \pi e^2 m_e$ ) is a convenient, fundamental unit of length in atomic physics that relieves us from the burden of carrying along all of the constants in Eq. 4.12.) This first prediction of the Bohr model is the existence of a series of orbits whose distances from the nucleus increase dramatically with increasing  $n$ . Substituting  $r_n$  from Equation 4.12 into Equation 4.11 allows us to calculate the speed  $v_n$  corresponding to the orbit with radius  $r_n$ .

$$v_n = \frac{nh}{2\pi m_e r_n} = \frac{Ze^2}{2\epsilon_0 nh} \quad [4.13]$$

The results obtained for  $r_n$  and  $v_n$  can now be substituted into Equation 4.9 to give us the allowed values of the energy:

$$E_n = \frac{-Z^2 e^4 m_e}{8\epsilon_0^2 n^2 h^2} = -(2.18 \times 10^{-18} \text{ J}) \frac{Z^2}{n^2} \quad n = 1, 2, 3, \dots \quad [4.14a]$$

That these energies are negative is a consequence of our choice for the zero of energy, as discussed in Section 3.3 and shown in Figure 3.6. For the same reason that we introduced the Bohr radius, it is convenient to express atomic energy levels using a unit known as a **rydberg**, where  $1 \text{ rydberg} = 2.18 \times 10^{-18} \text{ J}$ . The energy level expression then becomes

$$E_n = -\frac{Z^2}{n^2} \quad (\text{rydberg}) \quad n = 1, 2, 3, \dots \quad [4.14b]$$

**FIGURE 4.23** The potential energy of the electron and nucleus in the hydrogen atom has its lowest (most negative) value when the electron is closest to the nucleus. (Compare with the one-dimensional plot in Fig. 3.6.) The electron moving away from the nucleus can be seen as moving up the sides of a steep potential energy well. In the Bohr theory, the electron moves in a circular orbit which can have only specific allowed values of  $r$ , the radius, and  $E$ , the energy. The first three of these are shown qualitatively by rings.

The Bohr model thus predicts a discrete energy-level diagram for the one-electron atom (Figs. 4.23 and 4.24). The ground state is identified by  $n = 1$ , and the excited states have higher values of  $n$  (see Fig. 4.23).

The **ionization energy** is the minimum energy required to remove an electron from an atom (see Section 3.4). In the Bohr model, ionization involves a transition from the  $n = 1$  state to the  $n = \infty$  state, in which  $E_n = 0$ . The associated energy change is

$$\Delta E = E_{\text{final}} - E_{\text{initial}} = 0 - (-2.18 \times 10^{-18} \text{ J}) = 2.18 \times 10^{-18} \text{ J}$$

Multiplying this result by Avogadro's number gives the ionization energy,  $IE$ , per mole of atoms:

$$IE = (6.022 \times 10^{23} \text{ atoms mol}^{-1})(2.18 \times 10^{-18} \text{ J atom}^{-1}) = 1.31 \times 10^6 \text{ J mol}^{-1} = 1310 \text{ kJ mol}^{-1}$$

This prediction agrees with the experimentally observed ionization energy of hydrogen atoms and provides confidence in the validity of the Bohr model. Note that the allowed values of the energy  $E_n$  given in Equation 4.14 are the sum of the kinetic and potential energy, with the speed of the electron decreasing as  $n$  increases (see Eqn. 4.13). The Bohr model was the first physical theory that could predict ionization energies with remarkable accuracy.

### EXAMPLE 4.3

Consider the  $n = 2$  state of  $\text{Li}^{2+}$ . Using the Bohr model, calculate the radius of the electron orbit, the electron speed, and the energy of the ion relative to that of the nucleus and electron separated by an infinite distance.

#### Solution

Because  $Z = 3$  for  $\text{Li}^{2+}$  (the nuclear charge is  $+3e$ ) and  $n = 2$ , the radius is

$$\begin{aligned} r_2 &= \frac{n^2}{Z} a_0 \\ &= \frac{4}{3} a_0 = \frac{4}{3} (0.529 \text{ \AA}) = 0.705 \text{ \AA} \end{aligned}$$

The speed is

$$\begin{aligned} v_2 &= \frac{nh}{2\pi m_e r_2} \\ &= \frac{2(6.626 \times 10^{-34} \text{ J s})}{2\pi(9.11 \times 10^{-31} \text{ kg})(0.705 \times 10^{-10} \text{ m})} \\ &= 3.28 \times 10^6 \text{ m s}^{-1} \end{aligned}$$

The energy is

$$E_2 = -\frac{(3)^2}{(2)^2} (2.18 \times 10^{-18} \text{ J}) = -4.90 \times 10^{-18} \text{ J}$$

Typically, atomic sizes fall in the range of angstroms, and atomic excitation energies in the range of  $10^{-18}$  J. This is consistent with the calculations of Coulomb potential energies in electron volts and dimensions in angstroms in Section 3.3.

**Related Problems:** 19, 20

### 4.3.1 Atomic Spectra: Interpretation by the Bohr Model

When a one-electron atom or ion undergoes a transition from a state characterized by quantum number  $n_i$  to a state lower in energy with quantum number  $n_f$  ( $n_i > n_f$ ), light of frequency  $\nu$  is emitted to carry off the energy  $h\nu$  lost by the atom. By conservation of energy,  $E_i = E_f + h\nu$ ; thus,

$$h\nu = \frac{Z^2 e^4 m_e}{8\epsilon_0^2 h^2} \left[ \frac{1}{n_f^2} - \frac{1}{n_i^2} \right] \quad (\text{emission}) \quad [4.15]$$

As  $n_i$  and  $n_f$  take on a succession of integral values, lines are seen in the emission spectrum (see Fig. 4.24) with frequencies

$$\nu = \frac{Z^2 e^4 m_e}{8\epsilon_0^2 h^3} \left( \frac{1}{n_f^2} - \frac{1}{n_i^2} \right) = (3.29 \times 10^{15} \text{ s}^{-1}) Z^2 \left( \frac{1}{n_f^2} - \frac{1}{n_i^2} \right) \quad [4.16]$$

$n_i > n_f = 1, 2, 3, \dots$  (emission)

Conversely, an atom can *absorb* energy  $h\nu$  from a photon as it undergoes a transition to a *higher* energy state ( $n_f > n_i$ ). In this case, conservation of energy requires  $E_i + h\nu = E_f$ ; thus, the absorption spectrum shows a series of lines at frequencies

$$\nu = (3.29 \times 10^{15} \text{ s}^{-1}) Z^2 \left( \frac{1}{n_i^2} - \frac{1}{n_f^2} \right) \quad [4.17]$$

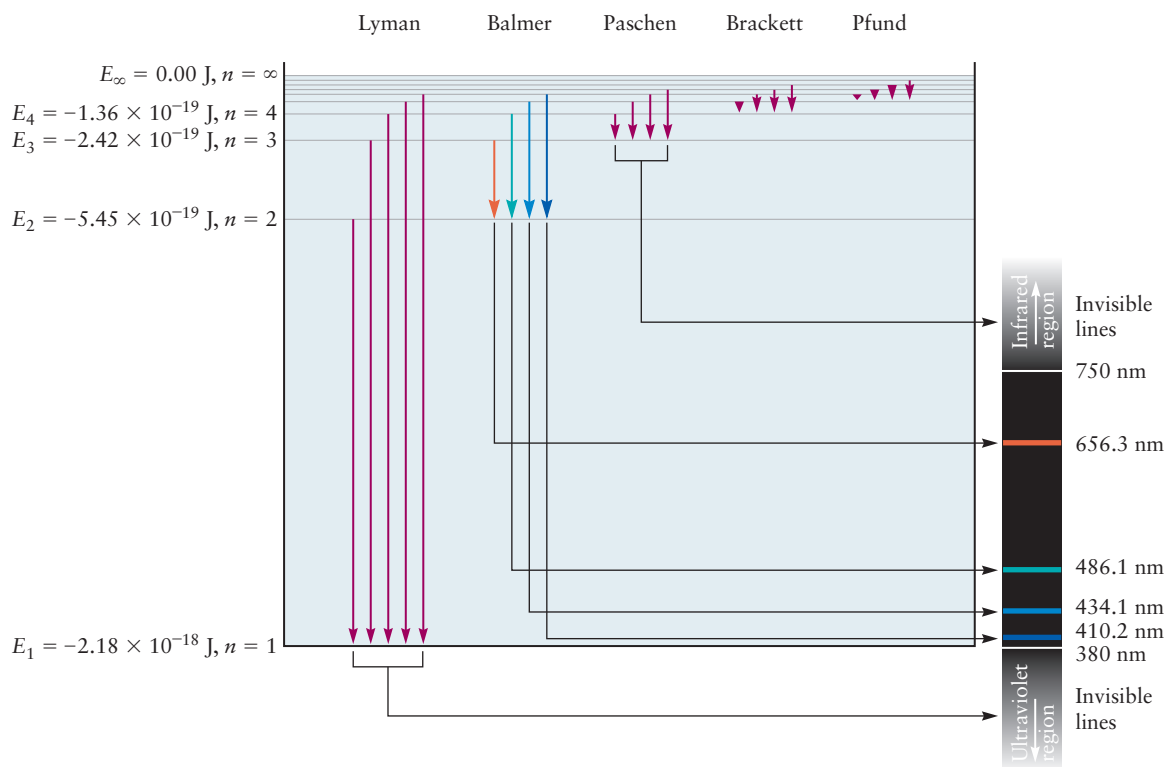

$n_f > n_i = 1, 2, 3, \dots$  (absorption)

For hydrogen, which has an atomic number of  $Z = 1$ , the predicted emission spectrum with  $n_f = 2$  corresponds to the series of lines in the visible region measured by Balmer and shown in Figure 4.24. A series of lines at higher frequencies (in the ultraviolet region) is predicted for  $n_f = 1$  (the Lyman series), and other series are predicted at lower frequencies (in the infrared region) for  $n_f = 3, 4, \dots$ . In fact, the predicted and observed spectra of hydrogen and one-electron ions are in excellent agreement—a major triumph of the Bohr theory.

Despite these successes, the Bohr theory has a number of shortcomings. Most important, it cannot predict the energy levels and spectra of atoms and ions with more than one electron. Also, more fundamentally, it was an uncomfortable hybrid of classical and nonclassical concepts. The postulate of quantized angular momentum—which led to only certain circular orbits being allowed—had no fundamental basis and was simply grafted onto classical physics to force the predictions of classical physics to agree with the experimental results. In 1926, the Bohr theory was replaced by modern quantum mechanics in which the quantization of energy and angular momentum arise as natural consequences of the basic postulates and require no additional assumptions. The circular orbits of the Bohr theory do not appear in quantum mechanics. The Bohr theory provided the conceptual bridge from classical theoretical physics to the new quantum mechanics. Its historical and intellectual importance cannot be exaggerated.

## 4.4 Evidence for Wave–Particle Duality

The Bohr theory provided a prescription for calculating the discrete energy levels of a one-electron atom or ion, but it did not explain the origin of energy quantization. A key step toward the development of modern quantum mechanics was

**FIGURE 4.24** In the energy levels of the hydrogen atom, the separated electron and proton are arbitrarily assigned zero energy, and all other energies are more negative than that. Atoms emit light as they fall from higher to lower energy levels as indicated by the arrows. Each series of related transitions is named after the person who discovered it. The arrows identifying transitions in the Balmer series are color-coded to match the emission lines to which they correspond. These lines in the Balmer series are shown in the hydrogen emission spectrum in Figure 4.16.

the concept of **wave-particle duality**—the idea that particles sometimes behave as waves, and vice versa. Experiments were forcing physicists to recognize that physical systems could display either particle or wave characteristics, depending on the experimental conditions to which they were subjected. The physicist Albert Einstein introduced wave-particle duality to explain the photoelectric effect, in which light acted as a particle. French physicist Louis de Broglie suggested that particles could exhibit wavelike properties, and the stage was set for the new quantum mechanics to synthesize wave-particle duality and energy quantization into a comprehensive new theory.

#### 4.4.1 The Photoelectric Effect

In addition to the conceptual problems with the planetary model of the atom and the difficulties with blackbody radiation, another conflict between experiment and classical theory arose in the early 20th century from the observation of the **photoelectric effect**. A beam of light shining onto a metal surface (called the *photocathode*) can eject electrons (called *photoelectrons*) and cause an electric current (called a *photocurrent*) to flow (Fig. 4.25). The photocurrent shows an extremely interesting dependence on the frequency and intensity of the incident light (Fig. 4.26). Regardless of the light intensity, no photocurrent flows until the frequency exceeds a particular threshold value  $\nu_0$ , which is unique for each metal. Low-frequency (long wavelength; for example, red) light apparently cannot provide enough energy to eject the electrons, no matter how intense it is. When the frequency of the light is increased through the threshold value (corresponding, perhaps, to green or blue light), electrons are

**FIGURE 4.25** In a photoelectric cell (photocell), light strikes a metal surface in an evacuated space and ejects electrons. The electrons are attracted to a positively charged collector, and a current flows through the cell.

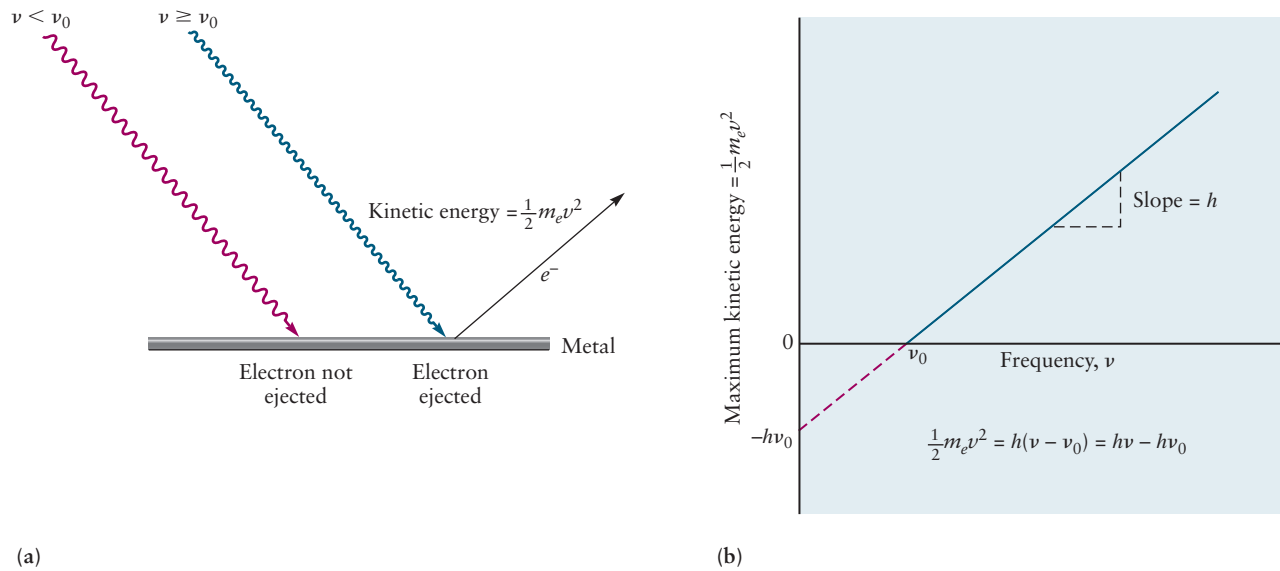

emitted and above threshold the photocurrent is directly proportional to the light intensity. The frequency of the light apparently is the key to delivering enough energy to eject the electrons; no electrons are emitted when the surface is excited by light whose frequency is below the threshold frequency, but electrons are readily emitted for all frequencies above the threshold frequency. These results could not be explained by classical physics. According to classical electromagnetic theory, the energy associated with electromagnetic radiation depends on only the intensity of the radiation, not on its frequency. Why, then, could a low-intensity (dim) beam of blue light (high frequency) eject electrons from sodium when a high-intensity (bright) beam of red light (low frequency) had no effect at all (Fig. 4.27a)? The key to the explanation is to relate the energy imparted by the light at the threshold frequency,  $\nu_0$ , to the energy with which the photoelectrons are emitted from atoms in the metal.

The photoelectrons leaving the metal surface and traveling toward the detector have a range of kinetic energies. Let's assume that those photoelectrons arriving at the collector with  $E_{\max}$  were emitted from atoms at the surface of the

**FIGURE 4.26** Frequency and intensity dependence of the photoelectric effect. Only light above the threshold frequency can eject photoelectrons from the surface. Once the frequency threshold has been passed, the total current of photoelectrons emitted depends on the intensity of the light, not on its frequency.

**FIGURE 4.27** (a) Two key aspects of the photoelectric effect. Blue light is effective in ejecting electrons from the surface of this metal, but red light is not. (b) The maximum kinetic energy of the ejected electrons varies linearly with the frequency of light used.

metal. Assume those arriving with lower kinetic energy were emitted deeper in the metal but lost some kinetic energy through collisions with other metal atoms before escaping from the surface. Then, the value of  $E_{\text{max}}$  should be directly related to the energy acquired by the photoelectron during the ejection process. We determine this maximum kinetic energy as follows. When the frequency and intensity of the beam are held constant, the magnitude of the photocurrent depends on the electrical potential (voltage) of the collector relative to the photocathode (Fig. 4.28). At sufficiently positive potentials, all of the photoelectrons are attracted to the collector and the current–voltage curve becomes flat, or saturated. As the potential of the collector is made more negative, photoelectrons arriving with kinetic energies less than the maximum are repelled and the photocurrent decreases. Only those photoelectrons with sufficient kinetic energy to overcome this repulsion reach the collector. As the collector is made still more negative, the photocurrent drops sharply to zero at  $-V_{\text{max}}$ , identifying the maximum in the kinetic energy of the photoelectrons:  $E_{\text{max}} = eV_{\text{max}}$ . The potential required to stop all of the electrons from arriving at the collector is thus a direct measure of their maximum kinetic energy, expressed in units of electron volts (eV) (see Section 3.3). But what was the connection between  $\nu_0$  and  $E_{\text{max}}$ ?

**FIGURE 4.28** The current in a photo-cell depends on the potential between cathode and collector.

In 1905, Einstein used Planck’s quantum hypothesis to explain the photoelectric effect. First, he suggested that a light wave of frequency  $\nu$  consists of quanta of energy (a quantum of light was later called a **photon** by G. N. Lewis), each of which carries energy,  $E_{\text{photon}} = h\nu$ . Second, Einstein assumed that, in the photoelectric effect, an electron in the metal absorbs a photon of light and thereby gains the energy required to escape from the metal. A photoelectron emitted from beneath the surface will lose energy  $E'$  in collisions with other atoms and  $\Phi$  in escaping from the surface, after which it travels through the vacuum to the detector with kinetic energy  $E_{\text{kin}}$ . Conservation of energy leads to the relation  $h\nu = E' + \Phi + E_{\text{kin}}$  for the process. Electrons with the maximum kinetic energy are emitted at the surface, so for them  $E' = 0$ . Therefore, Einstein’s theory predicts that the maximum kinetic energy of photoelectrons emitted by light of frequency  $\nu$  is given by

$$E_{\text{max}} = \frac{1}{2} m v_e^2 = h\nu - \Phi \quad [4.18]$$

where  $\Phi = h\nu_0$  is a constant characteristic of the metal. The key idea of Einstein's explanation is that the interaction of a photon with an electron is a single event and the result is all or nothing; either the photon does or does not have enough energy to overcome the forces that bind the electron to the solid.

Einstein's theory predicts that the maximum kinetic energy is a linear function of the frequency, which provides a means for testing the validity of the theory. Experiments conducted at several frequencies demonstrated that the relation between  $E_{\max}$  and frequency is indeed linear (see Fig. 4.27b). The slope of the experimental data determined the numerical value of  $h$  to be identical to the value that Planck found by fitting the experimental data to his theoretical blackbody radiation intensity distribution. Einstein's interpretation also provided a means to obtain the value of the quantity  $\Phi$  from the experimental data as the "energy intercept" of the linear graph.  $\Phi$ , called the **work function** of the metal, represents the binding energy, or energy barrier, that electrons must overcome to escape from the metal surface after they have absorbed a photon inside the metal.  $\Phi$  governs the extraction of electrons from metal surfaces by heat and by electric fields, as well as by the photoelectric effect, and it is an essential parameter in the design of numerous electronic devices.

#### EXAMPLE 4.4

Light with a wavelength of 400 nm strikes the surface of cesium in a photocell, and the maximum kinetic energy of the electrons ejected is  $1.54 \times 10^{-19}$  J. Calculate the work function of cesium and the longest wavelength of light that is capable of ejecting electrons from that metal.

#### Solution

The frequency of the light is

$$\nu = \frac{c}{\lambda} = \frac{3.00 \times 10^8 \text{ m s}^{-1}}{4.00 \times 10^{-7} \text{ m}} = 7.50 \times 10^{14} \text{ s}^{-1}$$

The binding energy  $h\nu_0$  can be calculated from Einstein's formula:

$$\begin{aligned} E_{\max} &= h\nu - h\nu_0 \\ 1.54 \times 10^{-19} \text{ J} &= (6.626 \times 10^{-34} \text{ J s})(7.50 \times 10^{14} \text{ s}^{-1}) - h\nu_0 \\ &= 4.97 \times 10^{-19} \text{ J} - h\nu_0 \\ \Phi = h\nu_0 &= (4.97 - 1.54) \times 10^{-19} \text{ J} = 3.43 \times 10^{-19} \text{ J} \end{aligned}$$

The minimum frequency  $\nu_0$  for the light to eject electrons is then

$$\nu_0 = \frac{3.43 \times 10^{-19} \text{ J}}{6.626 \times 10^{-34}} = 5.18 \times 10^{14} \text{ s}^{-1}$$

From this, the maximum wavelength  $\lambda_0$  is

$$\lambda_0 = \frac{c}{\nu_0} = \frac{3.00 \times 10^8 \text{ m s}^{-1}}{5.18 \times 10^{14} \text{ s}^{-1}} = 5.79 \times 10^{-7} \text{ m} = 579 \text{ nm}$$

**Related Problems:** 27, 28

Planck and Einstein proposed quantum hypotheses to explain experimental data in two very different areas of physics. The fact that data from both of these experiments led to the same value of  $h$  inspired great confidence in the validity of these hypotheses, despite their conflicts with established scientific principles. Einstein's bold assertion that light consisted of a stream of bundles of energy that

**FIGURE 4.29** A guitar string of length  $L$  with fixed ends can vibrate in only a restricted set of ways. The position of the string at the turning points of the motion are shown here. In standing waves such as these, the whole string is in motion except at its ends and at the nodes.

appeared to transfer their energy through collisions like those of material particles was completely at odds with the classical wave representation of light, which had already been amply confirmed by experimental studies. How could light be both a wave and a particle?

By 1930, these paradoxes had been resolved by quantum mechanics, which superseded Newtonian mechanics. The classical wave description of light is adequate to explain phenomena such as interference and diffraction, but the emission of light from matter and the absorption of light by matter are described by the particlelike photon picture. A hallmark of quantum, as opposed to classical, thinking is not to ask “What *is* light?” but instead “How does light behave under particular experimental conditions?” Thus, wave–particle duality is not a contradiction, but rather part of the fundamental nature of light and also of matter.

#### 4.4.2 De Broglie Waves

Thus far, this chapter has considered only one type of wave, a **traveling wave**. Electromagnetic radiation (light, X-rays, and gamma rays) is described by such a traveling wave moving through space at speed  $c$ . Another type of wave is a **standing wave**, of which a simple example is a guitar string with fixed ends (an example of a physical *boundary condition*). A plucked string vibrates, but only certain oscillations of the string are possible. Because the ends are fixed, the only oscillations that can persist are those in which an integral number of half-wavelengths fits into the length of string,  $L$  (Fig. 4.29). The condition on the allowed wavelengths is

$$n \frac{\lambda}{2} = L \quad n = 1, 2, 3, \dots \quad [4.19]$$

It is impossible to create a wave with any other value of  $\lambda$  if the ends of the string are fixed. The oscillation with  $n = 1$  is called the **fundamental** or first harmonic, and higher values of  $n$  correspond to higher harmonics. At certain points on the standing wave, the amplitude of oscillation is zero; any of these points is called a **node**. (The fixed ends are not counted as nodes.) The higher the number of the harmonic  $n$ , the more numerous the nodes, the shorter the wavelength, the higher the frequency, and the higher the energy of the standing wave.

De Broglie realized that such standing waves are examples of quantization: Only certain discrete vibrational modes, characterized by the “quantum number”  $n$ , are allowed for the vibrating string. He suggested that the quantization of energy in a one-electron atom might have the same origin, and that the electron might be associated with a standing wave, in this case, a *circular* standing wave oscillating about the nucleus of the atom (Fig. 4.30). For the amplitude of the wave to be well defined (single valued and smooth), an integral number of wavelengths must fit into the circumference of the circle ( $2\pi r$ ). The condition on the allowed wavelengths for standing circular waves is

$$n\lambda = 2\pi r \quad n = 1, 2, 3, \dots \quad [4.20]$$

**FIGURE 4.30** A circular standing wave on a closed loop. The state shown has  $n = 7$ , with seven full wavelengths around the circle.

Bohr's assumption about quantization of the angular momentum of the electron was

$$m_e v r = n \frac{h}{2\pi} \quad [4.21]$$

which can be rewritten as

$$2\pi r = n \left[ \frac{h}{m_e v} \right] \quad [4.22]$$

Comparison of de Broglie's equation (see Eq. 4.20) with Bohr's equation (see Eq. 4.22) shows that the wavelength of the standing wave is related to the magnitude of the linear momentum,  $p$ , of the electron by the following simple formula:

$$\lambda = \frac{h}{m_e v} = \frac{h}{p} \quad [4.23]$$

De Broglie used the theory of relativity to show that exactly the same relationship holds between the wavelength and momentum of a *photon*. De Broglie therefore proposed as a generalization that any particle—no matter how large or small—moving with magnitude of linear momentum  $p$  has wavelike properties and a wavelength of  $\lambda = h/p$  associated with its motion.

#### EXAMPLE 4.5

Calculate the de Broglie wavelengths of (a) an electron moving with speed  $1.0 \times 10^6 \text{ m s}^{-1}$  and (b) a baseball of mass  $0.145 \text{ kg}$ , thrown with a speed of  $30 \text{ m s}^{-1}$ .

#### Solution

$$\begin{aligned} \text{(a)} \quad \lambda &= \frac{h}{p} = \frac{h}{m_e v} = \frac{6.626 \times 10^{-34} \text{ J s}}{(9.11 \times 10^{-31} \text{ kg})(1.0 \times 10^6 \text{ m s}^{-1})} \\ &= 7.3 \times 10^{-10} \text{ m} = 7.3 \text{ \AA} \end{aligned}$$

$$\begin{aligned} \text{(b)} \quad \lambda &= \frac{h}{mv} = \frac{6.626 \times 10^{-34} \text{ J s}}{(0.145 \text{ kg})(30 \text{ m s}^{-1})} \\ &= 1.5 \times 10^{-34} \text{ m} = 1.5 \times 10^{-24} \text{ \AA} \end{aligned}$$

The latter wavelength is far too small to be observed. For this reason, we do not recognize the wavelike properties of baseballs or other macroscopic objects, even though they are always present. However, on a microscopic level, electrons moving in atoms show wavelike properties that are essential for explaining atomic structure.

**Related Problems:** 31, 32

### 4.4.3 Electron Diffraction

Under what circumstances does the wavelike nature of particles become apparent? When two waves pass through the same region of space, they interfere with each other. Consider water waves as an example. When two crests meet, constructive interference occurs and a higher crest (greater amplitude) appears; where a crest of one wave meets a trough of the other, destructive interference (smaller or even zero amplitude) occurs (Fig. 4.6). Light waves passing through two slits in a solid barrier produce a diffraction pattern of alternating bright and

**FIGURE 4.31** X-ray diffraction by a crystal produces a Laue diffraction pattern. (Adapted from Zumdahl/DeCoste, *Chemical Principles*, 6e, Fig. 12.7; Cengage Learning.)

dark spots as the result of constructive and destructive interference (Fig. 4.7). A way to test de Broglie’s hypothesis is to see whether a beam of electrons will generate a diffraction pattern similar to a beam of light.

As discussed in more detail in Chapter 21, it was known by 1914 that X-rays diffract from the lattice planes of a single crystal solid because the spacing between successive planes of atoms is comparable to the wavelength of the X-rays used in the experiment (Fig. 4.31). As the high energy X-rays penetrate deeply into the solid, a new “wavelet” is generated at each atom, much as water waves colliding with the posts supporting a dock in a lake generate new waves originating at the posts. Because the spacing between the successive atomic scattering centers is comparable to the wavelength of the X-rays, these “wavelets” interfere constructively and destructively to generate a diffraction pattern in the outgoing wave.

If the de Broglie hypothesis is correct, particles whose de Broglie wavelengths are comparable with lattice spacings should also diffract from crystals. This result was demonstrated in 1927 by the American physicists C. Davisson and L. H. Germer. In their experiment, a beam of low-energy electrons was directed toward a single crystal nickel sample in vacuum. The kinetic energy of the electrons could be varied continuously over the range 20 eV to 200 eV to change their wavelengths. Let’s confirm that the de Broglie wavelength of the electrons used in this experiment is comparable with atomic lattice spacings, as required for the electrons to diffract from the planes of atoms in the solid. The kinetic energy of an electron accelerated from rest to a final voltage  $V$  is  $\mathcal{T} = eV$ , where  $e$  is the magnitude of the charge on the electron. Recalling that  $p = mv$  and  $\mathcal{T} = \frac{1}{2}mv^2$ , we can set  $\mathcal{T} = p^2/2m_e$  and solve for the magnitude of the momentum of the electron to get  $p = \sqrt{2m_e eV}$ . The de Broglie wavelength of the electron is therefore  $\lambda = h/\sqrt{2m_e eV}$ . Calculations using these formulas must express the kinetic energy of the electron in joules ( $1 \text{ eV} = 1.6 \times 10^{-19} \text{ J}$ ) in order to obtain the proper units for momentum and wavelength. An electron with kinetic energy of 50 eV (typical of the Davisson–Germer experiment) has a de Broglie wavelength of  $1.73 \text{ \AA}$ , which is comparable to the spacing between atomic planes in metal crystals.

The geometry for electron diffraction is sketched in Figure 4.32. Because these low-energy electrons do not penetrate deeply into the solid, the diffraction pattern originates primarily at the surface atoms due to interference between “wavelets” originating from *adjacent* atoms. Figure 4.32a shows a side view of

**FIGURE 4.32** Geometry for diffraction of electrons at a solid surface. (a) Incident waves representing the incoming electron beam are shown as lines for simplicity. (b) Scattered waves after electrons collide with the surface illustrate constructive interference by which the diffracted beams are generated.

the crystal in which atoms in the top two planes are represented as dots. The distance between atoms in each plane is  $a$ . The electron beam comes in normal (perpendicular) to the surface, and the outgoing waves are at angle  $\theta$  with respect to the surface normal. Line AD represents a wave front of electron waves that are in phase as they approach the crystal. To prevent clutter in the diagram we represent each wave as a straight line that shows its direction of motion. The wave that is scattered at atom B follows the path ABC, while the wave scattered at E follows the path DEFG. This second wave travels a greater distance than the first, and the difference in path length is EF. The construction in the figure shows that  $EF = a \sin \theta$ . In order for the outgoing waves to be in phase at the wave front CG, this extra distance must correspond to an integral multiple of the wavelength of the electron. This relationship between the two outgoing waves is shown in Figure 4.32b. The diffraction condition is thus

$$n\lambda = a \sin \theta \quad [4.24]$$

For a particular choice of crystal sample (the value  $a$ ) and X-ray wavelength  $\lambda$ , the diffracted intensity appears in the direction defined by  $\theta$ . The two-dimensional surface may have a periodic spacing  $a$  between atoms along the  $x$ -axis and  $b$  between atoms along the  $y$ -axis. This situation gives two diffraction conditions that must be satisfied at the same time:

$$n_a \lambda_a = a \sin \theta_a \quad \text{and} \quad n_b \lambda_b = b \sin \theta_b$$

The interference of waves in two dimensions to produce diffracted beams departing the surfaces is suggested by the sketch in Figure 4.33.

A modern apparatus for demonstrating electron diffraction is sketched in Figure 4.34. The diffraction pattern on the phosphor screen is observed visually through the viewport. Some portion of the pattern may be blocked from view by

**FIGURE 4.33** When two waves (a) and (b) moving at right angles to one another meet and overlap, their amplitudes add. Where two crests meet, there is constructive interference and the resultant amplitude is greater than that of either wave alone (shown by the peaks in part (c)). Where a crest meets a trough, destructive interference gives a value of zero for the sum of the two waves. At positions where the resulting wave oscillates in time with a large amplitude, you are likely to find a scattered electron.

**FIGURE 4.34** Apparatus for demonstrating diffraction of electrons by solid surfaces. The incoming electron beam is oriented perpendicular (normal) to the plane of the surface. Electrons are back-scattered after collisions with the surface. Voltages applied to the grids reject back-ground electrons and allow only those electrons that have been diffracted by the surface to arrive at the phosphor screen. The diffracted beams stimulate emission from the screen and thereby display the diffraction pattern of the surface as an array of bright spots against a dark background. (Adapted from L. M. Feldman and J. M. Mayer, *Thin Film and Surface Analysis*, Fig. 7.6, p. 163, North Holland, 1984.)

the electron gun. Figure 4.35 shows the electron diffraction pattern for the surface of a crystal of silicon.

The original experiments of Davisson and Germer demonstrated electron diffraction, and thereby provided a striking confirmation of de Broglie's hypothesis about the wavelike nature of matter. The modern form of their experiments described here enables a technique called low-energy electron diffraction (LEED) that is now used widely to study the atomic structure of solid surfaces. Measurements of the diffraction angle for electrons with a specific value of kinetic energy gives the atomic spacing  $a$  by using Equation 4.24.

The Davisson-Germer experiments remind us that “waves” and “particles” are idealized models that describe objects found in nature, and that wave-particle duality is a fact of nature. Photons, electrons, and even helium atoms all have both wave and particle character; which aspect they display depends strongly on the conditions under which they are observed.

### 4.4.4 Indeterminacy and Uncertainty: The Heisenberg Principle

An inevitable consequence of de Broglie's standing-wave description of an electron in an orbit around the nucleus is that the position and momentum of a particle cannot be known both precisely and simultaneously. The magnitude of the momentum of the circular standing wave shown in Figure 4.30 is given exactly by  $p = h/\lambda$ , but because the wave is spread uniformly around the circle, we cannot specify the angular position of the electron on the circle at all. We say the angular position is **indeterminate** because it has no definite value. This conclusion is in stark contrast with classical physics where the positions and momenta are all known precisely and the trajectories of particles are well defined. How was this paradox resolved?

In 1927, the German physicist Werner Heisenberg proposed that **indeterminacy** is a general feature of quantum systems. Indeterminacy presents a fundamental limit to the “knowability” of the properties of these systems that is intrinsic and not just a limitation of our ability to make more precise measurements. In particular, it influences which combinations of properties can be measured together. Heisenberg identified pairs of properties that *cannot* be measured together with complete precision, and estimated the best precision we can hope to obtain when we do measure them. For example, we cannot measure position and momentum simultaneously and obtain sharp, definite values for each. The same is true for energy and time. Notice that the combination of dimensions *length*  $\times$  *momentum* is the same as the combination *energy*  $\times$  *time*. (You should verify this by simple dimensional analysis.) Either combination is called *action*, and it has the same dimensions as Planck's constant. The **Heisenberg indeterminacy principle** states that when we measure two properties, *A* and *B*, the product of which has dimensions of action, we will obtain a spread in results for each identified by  $\sigma_A$  and  $\sigma_B$  that will satisfy the following condition:

$$(\sigma_A)(\sigma_B) \geq h/4\pi \quad [4.25]$$

If we try to measure *A* precisely and make  $\sigma_A$  nearly zero, then the spread in  $\sigma_B$  will have to increase to satisfy this condition. Trying to determine the angular position of the orbiting electron described by the de Broglie wave discussed earlier is a perfect illustration. Indeterminacy is intrinsic to the quantum description of matter and applies to all particles no matter how large or small.

The practical consequence of indeterminacy for the outcome of measurements is best seen by applying the Heisenberg principle in specific cases. How are the position and momentum of a macroscopic object such as a baseball in motion determined? The simplest way is to take a series of snapshots at different times, with each picture recording the light (photons) scattered by the baseball. This is true for imaging any object; we must scatter something (like a photon) from the object and then record the positions of the scattered waves or particles (Fig. 4.36). Scattering a photon from a baseball does not change the trajectory of the baseball appreciably (see Fig. 4.36a) because the momentum of the photon is negligible compared with that of the baseball, as shown in Example 4.6. Scattering photons from an electron, however, is another thing altogether. To locate the *position* of any object, we must use light with a wavelength that is comparable with or shorter than the size of the object. Thus, to measure the position of an electron in an atom to a precision of, say, 1% of the size of the atom, we would need a probe with a wavelength of order  $10^{-12}$  m. The magnitude of the momentum of such a wave, given by the de Broglie relation, is  $6.625 \times 10^{-22}$  kg m s<sup>-1</sup>. The magnitude of the linear momentum of the electron in a ground state ( $n = 1$ ) hydrogen atom using the Bohr model is  $2.0 \times 10^{-24}$  kg m s<sup>-1</sup>. Trying to measure the position of an electron to a precision of  $10^{-12}$  m with a photon of sufficiently short wavelength turns out to be

**FIGURE 4.36** A photon, which has a negligible effect on the trajectory of a baseball (a), significantly perturbs the trajectory of the far less massive electron (b).

roughly equivalent to trying to measure the position of a marble using a bowling ball as a probe! So on the length and mass scale of elementary particles, it is clear that we cannot measure simultaneously, to arbitrary precision, the values of the momentum and the position of a particle.

To make a rough estimate of the precision allowed by the indeterminacy principle, let us take as our spread of values in the position,  $\sigma_x$ , the wavelength of our probe  $\lambda$ . This choice means that we can locate the particle somewhere between two crests of the wave. Let us take as our estimate of the spread in the momentum,  $\sigma_p$ , the value of the momentum itself,  $p$ ; that is, we know  $p$  to within  $\pm p$ . Their product is therefore  $\sigma_x \sigma_p = h$ , but because we have asserted that this is the *best* we can do, we write  $\sigma_x \sigma_p \geq h$ . If, instead of these estimates, you properly calculate the spread in both variables as one standard deviation or the root mean square deviation from a very large number of measurements, the result becomes

$$\sigma_x \sigma_p \geq h/4\pi \quad [4.26]$$

which is in agreement with the Heisenberg principle.

At last, we can resolve the paradox between de Broglie waves and classical orbits, which started our discussion of indeterminacy. The indeterminacy principle places a *fundamental limit* on the precision with which the position and momentum of a particle can be known simultaneously. It has profound significance for how we think about the motion of particles. According to classical physics, the position and momentum are fully known simultaneously; indeed, we must know both to describe the classical trajectory of a particle. The indeterminacy principle forces us to abandon the classical concepts of trajectory and orbit. The most detailed information we can possibly know is the statistical spread in position and momentum allowed by the indeterminacy principle. In quantum mechanics, we think not about particle trajectories, but rather about the probability distribution for finding the particle at a specific location.

### EXAMPLE 4.6

Suppose photons of green light (wavelength  $5.3 \times 10^{-7}$  m) are used to locate the position of the baseball from Example 4.5 with precision of one wavelength. Calculate the minimum spread in the *speed* of the baseball.

#### Solution

The Heisenberg relation,

$$\sigma_x \sigma_p \geq h/4\pi$$

with the very crude estimate of  $\lambda$  for  $\sigma_x$  gives

$$\begin{aligned} \sigma_p &\geq \frac{h}{4\pi\sigma_x} \\ &= \frac{6.626 \times 10^{-34} \text{ J s}}{4\pi(5.3 \times 10^{-7} \text{ m})} = 9.9 \times 10^{-29} \text{ kg m s}^{-1} \end{aligned}$$

Because the momentum is just the mass (a constant) times the speed, the spread in the speed is

$$\begin{aligned} \sigma_v &= \frac{\sigma_p}{m} \geq \frac{9.9 \times 10^{-29} \text{ kg m s}^{-1}}{(0.145 \text{ kg})} \\ &= 6.8 \times 10^{-28} \text{ m s}^{-1} \end{aligned}$$

This is such a tiny fraction of the speed of the baseball ( $30 \text{ m s}^{-1}$ ) that indeterminacy plays a negligible role in the measurement of the baseball's motion. Such is the case for all macroscopic objects.

**Related Problems: 35, 36**

Describing the indeterminacy principle presents certain challenges to language. Clearly, when a property of the system is indeterminate, measurements will produce a statistical spread of values for that property. In a colloquial sense, there will be *uncertainty* in the measurement, because its outcome is not precisely predictable, just as there is uncertainty in the outcome of playing a game of chance. In almost all English-language books on quantum mechanics, the

spread in value of a property  $\sigma_A$  is called the *uncertainty in A*, and the relation in Equation 4.25 is called the *Heisenberg uncertainty principle*. A property is indeterminate if it has no definite value, whereas it is uncertain if it does have a definite value, but that value is not known to the experimenter. We prefer the phrase *indeterminacy principle* because it more accurately conveys that a fundamental limitation on measurements is being described, whereas *uncertainty principle* suggests that the uncertainty could be reduced by conducting more carefully designed experiments.

## 4.5 The Schrödinger Equation

De Broglie's work attributed wavelike properties to electrons in atoms, which inspired the Austrian physicist Erwin Schrödinger to think about how to describe electrons as waves. Schrödinger, a recognized authority on the theory of vibrations and the associated "quantization" of standing waves, reasoned that an electron (or any other particle with wavelike properties) might well be described by a wave function. A **wave function** maps out what the wave looks like in three dimensions; it may also be a function of time. Ocean waves have displacements from sea level that vary in both space and time. An electromagnetic wave has an electrical field whose component along its direction of polarization oscillates in both space and time. Schrödinger's wave function, symbolized by the Greek letter psi ( $\psi$ ), characterizes the wave associated with a particle, at a position located by the coordinates  $x, y, z$  at time  $t$ . It is important to emphasize that a particle's wave function may oscillate in time, like an ordinary water wave or electromagnetic wave, and that at a particular time  $t$  the value of a particle's wave function may be positive, negative, or zero at different possible positions of the particle. We'll call the latter function of position  $\psi(x)$  if the particle is restricted to lie along a line, or  $\psi(x,y,z)$  if the particle is to be found in three dimensional coordinate space. The value of  $\psi(x)$  may be positive or negative, and at coordinates where the value of  $\psi(x)$  is zero (where it changes from positive to negative) one says there is a **node** in the wave function. The next section describes what the wave function for a particle  $\psi(x)$  tells you physically about the particle's position and total energy. It also allows us to describe how two particles might interfere with each other as two waves might, constructively if the value of the wave function for both particles have the same sign at a particular position, and destructively if the wave function for both particles have opposite signs. This allows one to quantitatively describe diffraction experiments done with electrons, similar to diffraction of light in Figure 4.7. This constructive and destructive interference also plays an important role in how shared electrons form covalent bonds! After working a few simple examples to help you get used to wave functions for particles in this chapter, we'll examine wave functions for electrons in atoms (Chapter 5) and in covalent bonds (Chapter 6).

### 4.5.1 Origins of the Schrödinger Equation

Although it is beyond the scope of this text to explain the origins of the **Schrödinger equation**, it is nevertheless worthwhile to work through the logic that might have stimulated Schrödinger's thinking and, more importantly, to explore some of the properties of the mathematical form of the Schrödinger equation. Having been trained in the classical theory of waves and inspired by de Broglie's hypothesis, it was natural for Schrödinger to seek a wave equation that described the properties of matter on the atomic scale. Classical wave equations relate the

second derivatives of the wave function with respect to position  $x$  to the second derivatives with respect to time (or in quantum mechanics, the first derivative with respect to time). For simplicity let's see if we can find a wave equation that relates the second derivative of a function with respect to position to the function itself, leaving the time dependence for more advanced work.

We begin by considering a particle moving freely in one dimension (along the  $x$ -axis) with classical momentum,  $p$ . Such a particle is associated with a wave of wavelength  $\lambda = h/p$ . Two “wave functions” that describe such a wave are

$$\psi(x) = A \sin \frac{2\pi x}{\lambda} \quad \text{and} \quad \psi(x) = B \cos \frac{2\pi x}{\lambda} \quad [4.27]$$

where  $A$  and  $B$  are constants. Choosing the sine function, for example, let's see what its second derivative with respect to  $x$  looks like. From differential calculus, the derivative (or slope) of the first  $\psi(x)$  in Equation 4.27 is

$$\frac{d\psi(x)}{dx} = A \frac{2\pi}{\lambda} \cos \frac{2\pi x}{\lambda}$$

The slope of *this* function is given by the second derivative of  $\psi$ , written  $\frac{d^2\psi(x)}{dx^2}$ , which is equal to

$$\frac{d^2\psi(x)}{dx^2} = -A \left( \frac{2\pi}{\lambda} \right)^2 \sin \frac{2\pi x}{\lambda}$$

This is just a constant,  $-(2\pi/\lambda)^2$ , multiplied by the original wave function  $\psi(x)$ :

$$\frac{d^2\psi(x)}{dx^2} = - \left( \frac{2\pi}{\lambda} \right)^2 \psi(x)$$

This is an equation (called a *differential equation*) that is satisfied by the function  $\psi(x) = A \sin (2\pi x/\lambda)$ . It is easy to verify that this equation is also satisfied by the function  $\psi(x) = B \cos (2\pi x/\lambda)$ .

Let's now replace the wavelength  $\lambda$  with  $h$  divided by the momentum  $p$  from the de Broglie relation:

$$\frac{d^2\psi(x)}{dx^2} = - \left( \frac{2\pi}{h} p \right)^2 \psi(x) \quad [4.28]$$

We can rearrange this equation into a suggestive form by multiplying both sides by  $-h^2/8\pi^2 m$ , giving

$$-\frac{h^2}{8\pi^2 m} \frac{d^2\psi(x)}{dx^2} = \frac{p^2}{2m} \psi(x) = \mathcal{T}\psi(x)$$

where  $\mathcal{T} = p^2/2m$  is the kinetic energy of the particle. This form of the equation suggests that there is a fundamental relationship between the second derivative of the wave function (also called its *curvature*) and the kinetic energy,  $\mathcal{T}$ .

If external forces are present, a potential energy term  $V(x)$  (due to the presence of walls enclosing the particle or to the presence of fixed charges, for example) must be included. Writing the total (kinetic + potential) energy as  $E$  the analog to the previous equation is

$$-\frac{h^2}{8\pi^2 m} \frac{d^2\psi(x)}{dx^2} + V(x)\psi(x) = E\psi(x) \quad [4.29]$$

This is the Schrödinger equation for a particle moving in one dimension. The development provided here is not a derivation of this central equation of quantum mechanics; rather, it is a plausibility argument based on the idea that the motions of particles can be described by a wave function with the wavelength of the particle being given by the de Broglie relation.

### 4.5.2 The Validity of the Schrödinger Equation

The validity of any scientific theory must be tested by extensive comparisons of its predictions with a large body of experimental data. Although we have presented a plausibility argument that suggests how Schrödinger might have initially developed his equation, understanding the source of his inspiration is not nearly as important as evaluating the accuracy of the theory. It is the same for all great scientific discoveries; the story of Newton and the apple is not nearly as important as the fact that classical mechanics has been shown to describe the behavior of macroscopic systems to astonishingly high accuracy. Quantum mechanics superseded Newtonian mechanics because the latter failed to account for the properties of atoms and molecules. We believe that quantum mechanics is correct because its predictions agree with experiment, in many cases to better than  $10^{-10}\%$ . It is generally considered to be among the most accurate theories of nature because of this astonishingly good agreement. But even quantum mechanics began to fail as scientists were able to make more accurate measurements than those made in the early part of the 20th century. Relativistic corrections to Schrödinger's equations improved the situation dramatically, but only with the development of **quantum electrodynamics**—in which matter and radiation are treated completely equivalently—did complete agreement between theory and experiment occur. Quantum electrodynamics is an extremely active field of research today, and it continues to ask questions such as, “How does the system know that it is being measured?” and “How can we use quantum mechanics to make computers of unprecedented power?” The fundamental ideas of quantum mechanics—energy quantization and wave–particle duality—appear to be universally true in science. Although these properties of nature are less evident in the macroscopic world, the predictions of quantum mechanics agree well with those of classical mechanics on the relevant length and mass scales for macroscopic systems.

### 4.5.3 Interpretation of the Energy in the Schrödinger Equation

The Schrödinger equation can be solved exactly for any number of model problems and for a few real problems, notably the hydrogen atom. What do the solutions of this equation tell us about the energies and other properties of quantum systems? Or, to phrase the question slightly differently, how do we interpret  $\psi$ , and what information does it contain?

Let's focus initially on the energy. For all systems confined in space by a potential  $V(x)$  (or, more generally  $V(x, y, z)$ ) that does not vary in time, solutions of the Schrödinger equation given in Equation 4.29 can be found only for certain discrete values of the energy; energy quantization is a natural consequence of the Schrödinger equation. Any state described by these time-independent wave functions is called a **stationary state**. For a given system, there may be many states with different energies characterized by different wave functions. The solution that corresponds to the lowest energy is called the ground state (just as in the Bohr model), and higher energy solutions are called excited states.

### 4.5.4 Interpretation of the Wave Function in the Schrödinger Equation

What is the physical meaning of the wave function  $\psi$ ? We have no way of measuring  $\psi$  directly, just as in classical wave optics we have no direct way of measuring the oscillating electric and magnetic fields that constitute the light wave (see Fig. 4.2). What *can* be measured in the latter case is the intensity of the light wave, which, according to the classical theory of electromagnetism, is proportional to the square of the amplitude of the electric field:

$$\text{intensity} \propto (E_{\max})^2$$

However, if we view electromagnetic radiation as a collection of *particles* (photons), then the intensity is simply proportional to the density of photons in a region of space. Connecting the wave and particle views of the electromagnetic field suggests that the *probability* of finding a photon is proportional to the square of the amplitude of the electric field.

By analogy, we interpret the square of the wave function  $\psi^2$  for a particle as a probability density for that particle. That is,  $|\psi(x, y, z)|^2 dV$  is the probability that the particle will be found in a small volume  $dV = dx dy dz$  centered at the point  $(x, y, z)$ . This probabilistic interpretation of the wave function, proposed by the German physicist Max Born, is now generally accepted because it provides a consistent picture of particle motion on a microscopic scale.

The probabilistic interpretation requires that any function must meet three mathematical conditions before it can be used as a wave function. The next section illustrates how these conditions are extremely helpful in solving the Schrödinger equation. To keep the equations simple, we will state these conditions for a single particle moving in only one dimension. All the conditions extend immediately to three dimensions when proper coordinates and notation are used. (You should read Appendix C6, which reviews probability concepts and language, before proceeding further with this chapter.)

When the possible outcomes of a probability experiment are continuous (for example, the position of a particle along the  $x$ -axis) as opposed to discrete (for example, flipping a coin), the distribution of results is given by the probability density function  $P(x)$ . The product  $P(x)dx$  gives the probability that the result falls in the interval of width  $dx$  centered about the value  $x$ . The first condition, that the probability density must be **normalized**, ensures that probability density is properly defined (see Appendix C6), and that all possible outcomes are included. This condition is expressed mathematically as

$$\int_{-\infty}^{+\infty} P(x) dx = \int_{-\infty}^{+\infty} |\psi(x)|^2 dx = 1 \quad [4.30]$$

The second and third conditions are subsidiary to the first, in that they must be satisfied to enable the first one to be satisfied. The second condition is that  $P(x)$  must be continuous at each point  $x$ . At some specific point, call it  $x_a$ , the form of the probability density may change for physical reasons, but its value at  $x_a$  must be the same regardless of whether  $x_a$  is approached from the left or from the right. This translates into the condition that  $\psi(x)$  and its first derivative  $\psi'(x)$  are continuous at each point  $x$  (with the exception that  $d\psi/dx$  is not required to be continuous where the slope of  $V(x)$  approaches infinity). The third condition is that if the particle is in a bound state (due to a potential energy function  $V(x)$ ),  $\psi(x)$  must be bounded at large values of  $x$ . This is stated mathematically as

$$\psi \longrightarrow 0 \quad \text{as} \quad x \longrightarrow \pm \infty \quad [4.31]$$

The requirement that  $\psi(x)$  be continuous results in **boundary conditions**, which are restrictions that must be satisfied by the solutions to differential equations such as the Schrödinger equation. A differential equation does not completely define a physical problem until the equation is supplemented with boundary conditions. These conditions invariably arise from physical analysis, and they help to select from the long list of possible solutions to the differential equation those that apply specifically to the problem being studied.

We must acknowledge that our information about the location of a particle is limited, and that it is statistical in nature. So not only are we restricted by the indeterminacy principle as to what we can measure, but we must also come to grips with the fact that fundamental properties of quantum systems are unknowable, except in a statistical sense. If this notion troubles you, you are in good company. Many of the best minds of the 20th century, notably Einstein, never became comfortable with this central conclusion of the quantum theory.

### 4.5.5 Procedures for Solving the Schrödinger Equation

The application of quantum mechanics to solve for the properties of any particular system is straightforward in principle. You need only substitute the appropriate potential energy term for that system into the Schrödinger equation and solve the equation to obtain two principal results: the allowed energy values and the corresponding wave functions. You will find that solutions exist only for specific, discrete energy values. Energy quantization arises as a direct consequence of the boundary conditions imposed on the Schrödinger equation (see later discussion) with no need for extra assumptions to be grafted on. Each energy value corresponds to one or more wave functions; these wave functions describe the distribution of particles when the system has a specific energy value.

We illustrate this procedure in detail for a simplified model in the next section so that you will see how energy levels and wave functions are obtained. We also use the model problem to illustrate important general features of quantum mechanics including restrictions imposed on the form of the wave function by the Schrödinger equation and its physical interpretation.

## 4.6 Quantum Mechanics of Particle-in-a-Box Models

We are about to show you how to solve the Schrödinger equation for a simple but important model for which we can carry out every step of the complete solution using only simple mathematics. We will convert the equations into graphical form and use the graphs to provide physical interpretations of the solutions. It is important for you to develop a physical understanding from the graphical forms of the solution. Later in this textbook we present the solutions for more complex applications only in graphical form, and you will rely on the skills you develop here to see the physical interpretation for a host of important chemical applications of quantum mechanics. This section is, therefore, one of the most important sections in the entire textbook.

### 4.6.1 One-Dimensional Boxes

The simplest model problem for which the Schrödinger equation can be solved, and in which energy quantization appears, is the so-called particle in a box. It consists of a particle confined by potential energy barriers to a certain region of

**FIGURE 4.37** (a) The potential energy for a particle in a box of length  $L$ , with the first three energy levels marked. (b) Wave functions showing the ground state  $\psi_1$  and the first two excited states. The more numerous the nodes, the higher the energy of the state. (c) The squares of the wave functions from (b), equal to the probability density for finding the particle at a particular point in the box.

space (the “box”). In one dimension, the model is visualized easily as a bead sliding along a wire between barriers at the ends of the wire. The particle is located on the  $x$ -axis in the interval between 0 and  $L$ , where  $L$  is the length of the box (Fig. 4.37a). If the particle is to be completely confined in the box, the potential energy  $V(x)$  must rise abruptly to an infinite value at the two end walls to prevent even fast-moving particles from escaping. Conversely, inside the box, the motion of the particle is free, so  $V(x) = 0$  everywhere inside the box. This means that the total energy,  $E = \mathcal{T} + V$ , must be positive at each point inside the box. We will determine the possible values of  $E$  by solving the Schrödinger equation. The solution for this model illustrates the general methods used for other more difficult potential energy functions.

A quick inspection of the potential energy function tells us the general nature of the solution. Wherever the potential energy  $V$  is infinite, the probability of finding the particle must be zero. Hence,  $\psi(x)$  and  $\psi^2(x)$  must be zero in these regions:

$$\psi(x) = 0 \text{ for } x \leq 0 \text{ and } x \geq L \tag{4.32}$$

Inside the box, where  $V = 0$ , the Schrödinger equation has the following form:

$$-\frac{\hbar^2}{8\pi^2 m} \frac{d^2\psi(x)}{dx^2} = E\psi(x)$$

(This is often written as  $\mathcal{H}\psi = E\psi$  where  $\mathcal{H}$  is called the **Hamiltonian operator**.  $\mathcal{H}$  is neither a number or a function, it is an expression that tells you to take a second derivative of the function to the right of it, then multiply the result by a constant. Typically it would also have a  $V(x)$  term added to it, but in this problem  $V(x) = 0$  inside the box. The result of  $\mathcal{H}\psi$  will be the total energy  $E$  multiplied by the same wave function  $\psi$  for every  $\psi$  that solves the Schrödinger equation.) Simplifying the equation above gives

$$\frac{d^2\psi(x)}{dx^2} = -\frac{8\pi^2 m E}{\hbar^2} \psi(x)$$

As shown earlier, the sine and cosine functions are two possible solutions to this equation, because the second derivative of each function is the function itself multiplied by a (negative) constant.

Now let us apply the conditions defined in Section 4.5 to select the allowed solutions from these possibilities. The boundary conditions require that  $\psi(x) = 0$  at  $x = 0$  and  $x = L$ . An acceptable wave function must be continuous at both these points. The cosine function can be eliminated because it cannot satisfy the condition that  $\psi(x)$  must be 0 at  $x = 0$ . The sine function does, however, satisfy this boundary condition since  $\sin(0) = 0$  so

$$\psi(x) = A \sin kx \quad [4.33]$$

is a potentially acceptable wave function.

If the wave function is also to be continuous at  $x = L$ , then we must have

$$\psi(L) = 0 \quad [4.34]$$

or

$$\psi(L) = A \sin kL = 0$$

This can be true only if

$$kL = n\pi \quad n = 1, 2, 3, \dots$$

because  $\sin(n\pi) = 0$ . Thus, the combination of the boundary conditions and continuity requirement gives the allowed solutions as

$$\psi(x) = A \sin \left( \frac{n\pi x}{L} \right) \quad n = 1, 2, 3, \dots \quad [4.35]$$

where the constant  $A$  is still to be determined. (Note that  $n = 0$  is not a possibility as it would give  $\psi = 0$  at all  $x$  axis values. Negative integers are not included as they give the same set of wave functions.) The restriction of the solutions to this form in which  $n$  is an integer quantizes the energy and the wave functions.

As explained in Section 4.5, the wave function must be normalized. This condition is not always satisfied by solutions to the Schrödinger equation; thus, we must see how we can enforce it. To normalize the wave function just obtained we set

$$A^2 \int_0^L \sin^2 \left( \frac{n\pi x}{L} \right) dx = 1$$

and solve for  $A$ . Evaluating the definite integral gives  $L/2$ , so

$$A^2 \left( \frac{L}{2} \right) = 1$$

and

$$A = \sqrt{\frac{2}{L}}$$

The normalized wave function for the one-dimensional particle in a box is

$$\psi_n(x) = \sqrt{\frac{2}{L}} \sin \left( \frac{n\pi x}{L} \right) \quad n = 1, 2, 3, \dots \quad [4.36]$$

where  $n$  labels a particular allowed solution of the Schrödinger equation.

To find the energy  $E_n$  for a particle described by the wave function  $\psi_n$ , we calculate the second derivative:

$$\begin{aligned}\frac{d^2\psi_n(x)}{dx^2} &= \frac{d^2}{dx^2} \left[ \sqrt{\frac{2}{L}} \sin \left( \frac{n\pi x}{L} \right) \right] \\ &= - \left( \frac{n\pi}{L} \right)^2 \left[ \sqrt{\frac{2}{L}} \sin \left( \frac{n\pi x}{L} \right) \right] \\ &= - \left( \frac{n\pi}{L} \right)^2 \psi_n(x)\end{aligned}$$

This must be equal to  $-\frac{8\pi^2 m E_n}{h^2} \psi_n(x)$ . Setting the coefficients equal to one another gives

$$\frac{8\pi^2 m E_n}{h^2} = \frac{n^2 \pi^2}{L^2} \quad \text{or}$$

$$E_n = \frac{n^2 h^2}{8mL^2} \quad n = 1, 2, 3, \dots \quad [4.37]$$

This solution of the Schrödinger equation demonstrates that the energy of a particle in the box is quantized. The energy,  $E_n$ , and wave function  $\psi_n(x)$  are unique functions of the quantum number  $n$ , which must be a positive integer. These are the only allowed stationary states of the particle in a box. The allowed energy levels are plotted together with the potential energy function in Figure 4.37a. A system described by the particle-in-a-box model will have an emission or absorption spectrum that consists of a series of frequencies given by

$$h\nu = |E_n - E_{n'}| \quad [4.38]$$

where  $n$  and  $n'$  are positive integers, and the  $E_n$  values are given by Equation 4.37.

The wave functions  $\psi_n(x)$  plotted in Figure 4.37b for the quantum states  $n$  are the standing waves of Figure 4.29. The guitar string and the particle in the box are physically analogous. The boundary condition that the value of the wave function  $\psi$  must be zero at each end of the guitar string (where its amplitude of oscillation with time is zero) or at each wall of the box is responsible for the quantization of energy and the restriction on the motions allowed.

Following Born's interpretation that the probability of finding the particle near a particular position is proportional to the square of its wave function evaluated at that position, we can study the probability distributions for the particle in a box in various quantum states. Figure 4.37c shows the probability distributions for the first three states of the particle in a box. For the ground state ( $n = 1$ ), we see that the most likely place to find the particle is in the middle of the box, with a small chance of finding it near either wall. In the first excited state ( $n = 2$ ), the probability is a maximum when it is near  $L/4$  and  $3L/4$  and zero near  $0$ ,  $L/2$ , and  $L$ . And for the  $n = 3$  state, the maxima are located at  $L/6$ ,  $3L/6$ , and  $5L/6$ , with nodes located at  $L/3$  and  $2L/3$ . Wherever there is a node in the wave function, the probability is zero that the particle will be found at that location. To be more precise, the probability of finding the particle between the position  $x = x_1$  and  $x = x_2$  is calculated with the following integral:

$$\text{Probability of finding particle between } x_1 \text{ and } x_2 = \int_{x_1}^{x_2} |\psi(x)|^2 dx$$

where  $\psi(x)$  is the wave function of the particle. If you are not yet comfortable with integrals, you can calculate the probability from the area under the curve in a plot of  $|\psi(x)|^2$  versus  $x$  between  $x_1$  and  $x_2$ . If the interval  $\Delta x = x_2 - x_1$  is small, this integral has a value close to  $|\psi(x_0)|^2 \Delta x$ , where  $x_0$  is evaluated in the middle of the range from  $x_1$  to  $x_2$ . Checking the units on this expression is helpful. The unit of  $|\psi(x)|^2$  is  $\text{m}^{-1}$  (or  $\text{\AA}^{-1}$ ) and  $\Delta x$  has units of  $\text{m}$  (or  $\text{\AA}$ ), so the probability has no units; a probability of 0.1 means that there is a 10% chance of finding the particle in this range of positions.

### EXAMPLE 4.7

The Lewis dot structure of 1,3-butadiene,  $\text{CH}_2=\text{CH}-\text{CH}=\text{CH}_2$  has two double bonds. Four electrons make two of the single bonds into double bonds, the extra pair of bonding electrons on the first, and the extra pair on the third of the carbon-carbon bonds. In a simple particle-in-a-box model for these four electrons, they may move freely along all three carbon-carbon bonds in the molecule but not past the end C atoms. If you draw a line along the carbon-carbon-carbon backbone of this molecule and label the center of one end C atom as  $x = 0$ , this corresponds to a one-dimensional box of length equal to the sum of the carbon-carbon bond lengths: C=C bond + C-C bond + C=C bond =  $1.34 \text{\AA} + 1.54 \text{\AA} + 1.34 \text{\AA} = 4.22 \text{\AA}$ . When two electrons are in the  $n = 1$  state and two electrons are in the  $n = 2$  state:

- Calculate the most likely and the least likely positions of one of the  $n = 2$  electrons.
- Calculate the probability of finding this electron between the first two carbon atoms, between the second two carbon atoms, and between the third two carbon atoms.

#### Solution

- Using Equation 4.36 the wave function for an electron in this  $n = 2$  state is

$$\psi_2 = \sqrt{\frac{2}{4.22 \text{\AA}}} \sin\left(\frac{2\pi x}{4.22 \text{\AA}}\right) \quad \text{between } x = 0 \text{\AA} \text{ and } x = 4.22 \text{\AA}$$

To find the probability density, you first square the wave function

$$|\psi_2|^2 = \frac{2}{4.22 \text{\AA}} \sin^2\left(\frac{2\pi x}{4.22 \text{\AA}}\right) \quad \text{between } x = 0 \text{\AA} \text{ and } x = 4.22 \text{\AA}$$

The maximum values of  $|\psi_2|^2$  occur when the sin function is  $+1$  and  $-1$ , so at  $2\pi x/(4.22 \text{\AA}) = \pi/2$  and  $3\pi/2$ . Thus the most likely positions of this  $n = 2$  electron are  $x = 1.055 \text{\AA}$  and  $x = 3.165 \text{\AA}$ . The minimum value of  $|\psi_2|^2$  occurs at  $x = 2.11 \text{\AA}$ , so this is the least likely position of the  $n = 2$  electron.

- The probability of finding this electron between the first two carbon atoms equals the area under the curve of  $|\psi(x)|^2$  vs.  $x$  from  $x_1 = 0 \text{\AA}$  to  $x_2 = 1.34 \text{\AA}$ ; this is the shaded area in Figure 4.38.

$$\int_{0 \text{\AA}}^{1.34 \text{\AA}} \frac{2}{4.22 \text{\AA}} \sin^2\left(\frac{2\pi x}{4.22 \text{\AA}}\right) dx = 0.38 = 38\%$$

If you are not yet comfortable with integrals, you can estimate the shaded area curve as 190 rectangles multiplied by the area per rectangle,  $(0.02 \text{\AA}^{-1})(0.1 \text{\AA}) = 0.002$ . This gives a probability of  $0.38 = 38\%$ , the same result you get by integrating  $|\psi(x)|^2$  from  $x_1 = 0 \text{\AA}$  to  $x_2 = 1.34 \text{\AA}$ .

The probability of finding the electron between the third and the fourth carbon is also 38%. The probability of finding the electron between the second and the third carbon should be much smaller, as you can see by estimating the area under the curve in Figure 4.38 from  $x_1 = 1.34 \text{\AA}$  to  $x_2 = 2.88 \text{\AA}$ . The integration

(Continued)

**FIGURE 4.38** Integrating the probability density to calculate the probability of finding the particle between  $x = 0$  and  $x = 1.34 \text{ \AA}$ .

over this range gives a probability of  $0.25 = 25\%$ . If you sum all three probabilities they should sum to  $1 = 100\%$  (We get 101% due to rounding errors.) This is because the wave function is normalized, meaning that if we look for the particle everywhere, there should be 100% chance of finding it.

**Related Problems: 37, 38**

The number of nodes in the wave function is important not only for helping us understand probability distributions but also because it provides an important, and perfectly general, criterion for ordering the energy levels in any quantum system. The wave function  $\psi_n$  has  $n - 1$  nodes, and it is clear from Figure 4.37c that the number of nodes increases with the energy of each state. This is a general feature in quantum mechanics: For a given system, the relative ordering of the energy levels can be determined simply by counting the number of nodes. The particle-in-a-box model provides a useful interpretation for experimental systems in which electrons are free to move in one dimension over a relatively short distance between two barriers that constitute the walls of the “box.” A very interesting example is shown in Figure 4.39. The scanning tunneling microscope (STM) was used to assemble a linear chain of 20 Pd atoms to form a “wire” of length 6.0 nm on the surface of a NiAl crystal as described in Chapter 1. The STM was then used to measure the probability density for locating electrons along the chain of atoms. Figure 4.39a shows two-dimensional images of this density for the first four quantum states. The number of nodes increases from 0 to 3. Figure 4.39b shows linear scans of the probability density along the chain for these same four quantum states. Figure 4.39c shows the probability density for the particle-in-a-box model from Figure 4.37c calculated for a box of length  $L = 6.0 \text{ nm}$ .

Can a particle in a box have zero energy? Setting  $n = 0$  and solving for  $E$  using the equation  $E_n = n^2 h^2 / 8mL^2$  gives  $E_0 = 0$ . But this is not possible. Setting  $n$  equal to zero in  $\psi_n(x) = A \sin(n\pi x/L)$  makes  $\psi_0(x)$  zero everywhere. In this case,  $\psi_0^2(x)$  would be zero everywhere in the box, and thus there would be no particle in the box. The same conclusion comes from the indeterminacy principle. If the energy of the lowest state could be zero, the momentum of the particle would also be zero. Moreover, the uncertainty or spread in the particle

**FIGURE 4.39** Quantized energy states for electrons in a linear chain of 20 atoms of Pd on the surface of a NiAl crystal. The atoms were assembled using a scanning tunneling microscope (STM). (a) These images show the two-dimensional probability distribution measured by the STM. (b) These curves are line scans across the measured probability densities, showing their variation along the chain. (c) These curves show the predictions of the one-dimensional particle-in-a-box model for this system. (Courtesy of Professor Wilson Ho, University of California, Irvine.)

momentum,  $\sigma_{p_x}$ , would also be zero, requiring that  $\sigma_x$  be infinite, which contradicts our assertion that the particle is confined to a box of length  $L$ . Even at the absolute zero of temperature, where classical kinetic theory would suggest that all motion ceases, a finite quantity of energy remains for a bound system. It is required by the indeterminacy principle and is called the **zero-point energy**.

The wave functions for a particle in a box illustrate another important principle of quantum mechanics: the correspondence principle. We have already stated earlier (and will often repeat) that all successful physical theories must reproduce the explanations and predictions of the theories that preceded them on the length and mass scales for which they were developed. Figure 4.40 shows the probability density for the  $n = 5, 10,$  and  $20$  states of the particle in a box. Notice how the probability becomes essentially uniform across the box, and at  $n = 20$  there is little evidence of quantization. The **correspondence principle** requires that the results of quantum mechanics reduce to those of classical mechanics for large values of the quantum numbers, in this case,  $n$ .

**FIGURE 4.40** The probability distribution for a particle in a box of length  $L$  in the quantum states  $n = 5, 10,$  and  $20$ . Compare these results with those shown in Figure 4.37c.

### 4.6.2 Energy Levels for Particles in Two- and Three-Dimensional Boxes

The Schrödinger equation is readily generalized to describe a particle in a box of two or three dimensions. A particle in a two-dimensional box can be visualized as a marble moving in the  $x$ - $y$  plane at the bottom of a deep elevator shaft, with infinite potential walls confining its motion in the  $x$  and  $y$  directions. A particle in a three-dimensional rectangular box has infinite potential walls confining its motion in the  $x, y,$  and  $z$  directions. In both cases, the potential energy function is zero throughout the interior of the box. The wave function  $\psi$  and potential  $V$  now depend on as many as three coordinates ( $x, y, z$ ), and derivatives with respect to each coordinate appear in the Schrödinger equation. Because the potential energy is constant in all directions inside the box, the

motions in the  $x$  direction are independent of the motions in the  $y$  and  $z$  directions, and vice versa. For potential functions of this type, the Schrödinger equation can be solved by the method of *separation of variables*, and the results are quite interesting. The wave function is the product of the wave functions for independent motion in each direction, and the energy is the sum of the energies for independent motion in each direction. Therefore, we can immediately apply the results for the one-dimensional motions developed earlier to discuss, in turn, the energies and wave functions for multidimensional boxes.

The allowed energies for a particle in a three-dimensional rectangular box are

$$E_{n_x, n_y, n_z} = \frac{h^2}{8m} \left[ \frac{n_x^2}{L_x^2} + \frac{n_y^2}{L_y^2} + \frac{n_z^2}{L_z^2} \right] \quad \begin{cases} n_x = 1, 2, 3, \dots \\ n_y = 1, 2, 3, \dots \\ n_z = 1, 2, 3, \dots \end{cases} \quad [4.39]$$

where  $L_x$ ,  $L_y$ , and  $L_z$  are the side lengths of the box. Here the state is designated by a set of three quantum numbers,  $(n_x, n_y, n_z)$ . Each quantum number ranges independently over the positive integers. We can obtain the energy levels for a particle in a two-dimensional box in the  $x$ - $y$  plane from Equation 4.39 by setting  $n_z = 0$  and restrict the box to be a square by setting  $L_x = L_y = L$ . Similarly, we can specialize Equation 4.39 to a cubic box by setting  $L_x = L_y = L_z = L$ .

$$E_{n_x, n_y, n_z} = \frac{h^2}{8mL^2} [n_x^2 + n_y^2 + n_z^2] \quad \begin{cases} n_x = 1, 2, 3, \dots \\ n_y = 1, 2, 3, \dots \\ n_z = 1, 2, 3, \dots \end{cases} \quad [4.40]$$

Figure 4.41 plots the first few energy levels from Equation 4.40. We see that certain energy values appear more than once because the squares of different sets of quantum numbers can add up to give the same total. Such energy levels, which correspond to more than one quantum state, are called **degenerate**. Degenerate energy levels appear in systems with potential energy functions that have symmetric features. In Chapters 5 and 6, we encounter many examples of degenerate energy levels in atomic and molecular systems, as consequences of symmetry. As an exercise, we suggest that you apply Equation 4.40 to determine the energy levels in a square box and examine their degeneracy.

**FIGURE 4.41** The energy levels for a particle in a cubic box. The quantum numbers identifying the quantum states and the degeneracy values are given for each energy level.

## EXAMPLE 4.8

Consider the following two systems: (a) an electron in a one-dimensional box of length  $1.0 \text{ \AA}$  and (b) a helium atom in a cube  $30 \text{ cm}$  on an edge. Calculate the energy difference between ground state and first excited state, expressing your answer in  $\text{kJ mol}^{-1}$ .

## Solution

(a) For a one-dimensional box,

$$E_{\text{ground state}} = \frac{h^2}{8mL^2} (1^2)$$

$$E_{\text{first excited state}} = \frac{h^2}{8mL^2} (2^2)$$

Then, for one electron in the box,

$$\Delta E = \frac{3h^2}{8mL^2}$$

$$= \frac{3(6.626 \times 10^{-34} \text{ J s})^2}{8(9.11 \times 10^{-31} \text{ kg})(1.0 \times 10^{-10} \text{ m})^2}$$

$$= 1.8 \times 10^{-17} \text{ J}$$

Multiplying this result by  $10^{-3} \text{ kJ J}^{-1}$  and by  $N_A = 6.022 \times 10^{23} \text{ mol}^{-1}$  gives

$$\Delta E = 1.1 \times 10^4 \text{ kJ mol}^{-1}$$

(b) For a three-dimensional cube,  $L_x = L_y = L_z = L$ , and

$$E_{\text{ground state}} = \frac{h^2}{8mL^2} (1^2 + 1^2 + 1^2)$$

$$E_{\text{first excited state}} = \frac{h^2}{8mL^2} (2^2 + 1^2 + 1^2)$$

In this case, the three states  $(2, 1, 1)$ ,  $(1, 2, 1)$ , and  $(1, 1, 2)$  have the same energy.

$$\Delta E = \frac{3h^2}{8mL^2}$$

$$= \frac{3(6.626 \times 10^{-34} \text{ J s})^2}{8(6.64 \times 10^{-27} \text{ kg})(0.30 \text{ m})^2}$$

$$= 2.8 \times 10^{-40} \text{ J}$$

$$= 1.7 \times 10^{-19} \text{ kJ mol}^{-1}$$

The energy levels are so close together in the latter case (due to the larger mass of the particle and the much larger dimensions of the box) that they appear continuous, and quantum effects play no role. The properties are almost those of a classical particle.

Related Problems: 39, 40

## 4.7 A DEEPER LOOK Wave Functions for Particles in Two- and Three-Dimensional Boxes

### 4.7.1 Wave Functions for Particles in Square Boxes

The wave function for a particle in a square box of length  $L$  on each side in the  $x$ - $y$  plane, which we denote as  $\Psi$ , is given by

$$\Psi_{n_x n_y}(x, y) = \psi_{n_x}(x)\psi_{n_y}(y) = \frac{2}{L} \sin\left(\frac{n_x \pi x}{L}\right) \sin\left(\frac{n_y \pi y}{L}\right) \quad [4.41]$$

as explained earlier. To generate a graphical representation, we calculate the value of  $\Psi$  at each point  $(x, y)$  in the plane and plot this value as a third dimension above the  $x$ - $y$  plane. To make our graphs apply to square boxes of any size, we show them for dimensionless variables  $\tilde{x} = x/L$  and  $\tilde{y} = y/L$ , which range from 0 to 1. We also plot the value of the wave function as a dimensionless function  $\tilde{\Psi}$ , defined as the ratio of the value of  $\Psi$  to its maximum value,  $\tilde{\Psi}(\tilde{x}, \tilde{y}) = \Psi(\tilde{x}, \tilde{y})/\Psi_{\text{max}}$ . The value of  $\tilde{\Psi}$  ranges from  $-1$  to  $1$ . We show three examples in Figure 4.42.

The wave function for the ground state  $\tilde{\Psi}_{11}(\tilde{x}, \tilde{y})$  (see Fig. 4.42a) has no nodes and has its maximum at the center of the box, as you would expect from the one-dimensional results in Figure 4.37 from which  $\tilde{\Psi}_{11}(\tilde{x}, \tilde{y})$  is constructed.

**FIGURE 4.42** Wave function for a particle in a square box in selected quantum states. Dimensionless variables are used. (a) Three-dimensional plot for the ground state  $\tilde{\Psi}_{11}(\tilde{x}, \tilde{y})$ . (b) Contour plot for  $\tilde{\Psi}_{11}(\tilde{x}, \tilde{y})$ . (c) Three-dimensional plot for the first excited state  $\tilde{\Psi}_{21}(\tilde{x}, \tilde{y})$ . (d) Contour plot for  $\tilde{\Psi}_{21}(\tilde{x}, \tilde{y})$ . (e) Three-dimensional plot for the second excited state  $\tilde{\Psi}_{22}(\tilde{x}, \tilde{y})$ . (f) Contour plot for  $\tilde{\Psi}_{22}(\tilde{x}, \tilde{y})$ .

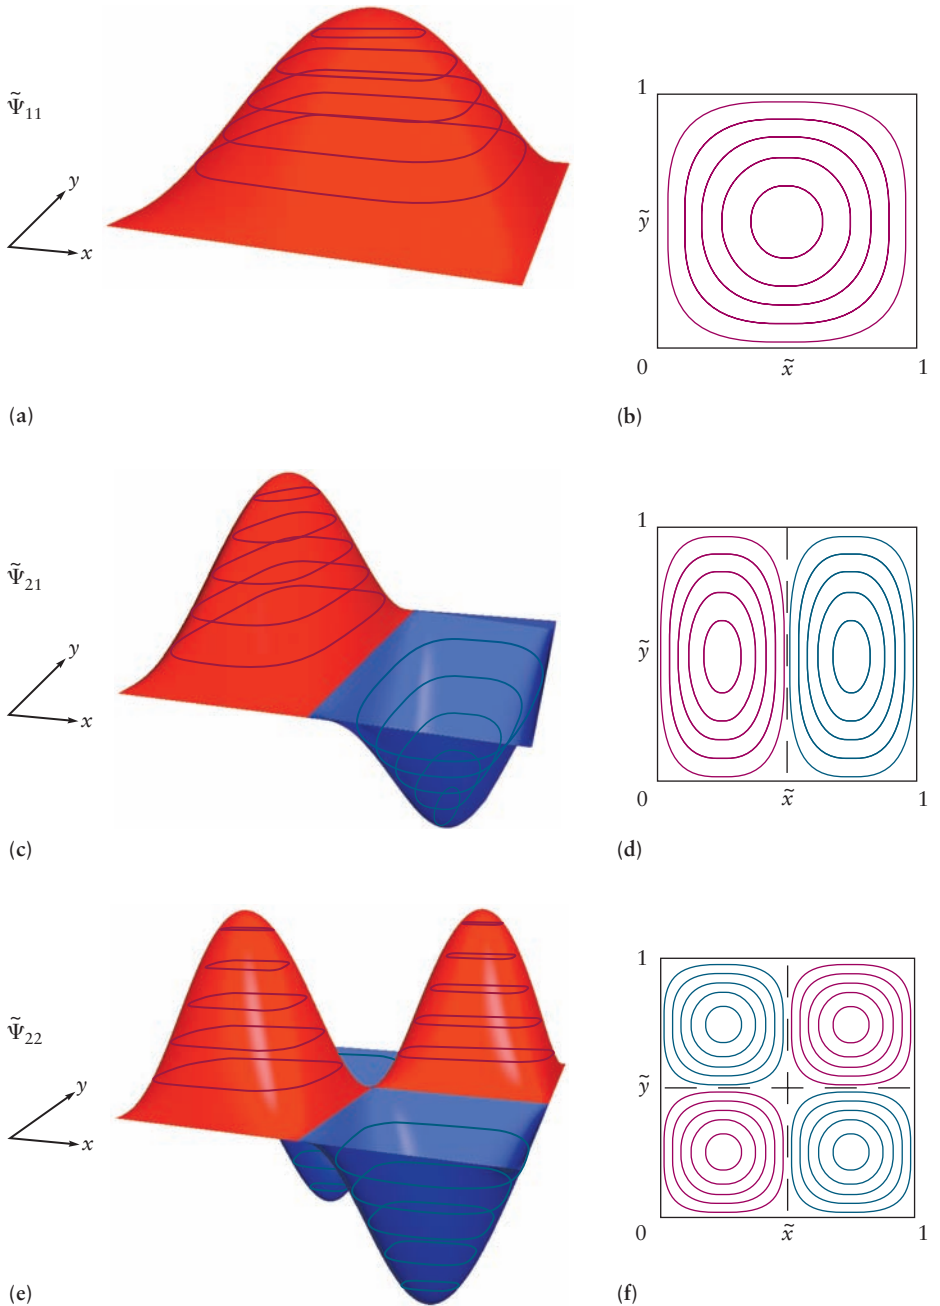

Figure 4.42b shows  $\tilde{\Psi}_{11}(\tilde{x}, \tilde{y})$  as a contour plot in the  $x$ - $y$  plane, generated by choosing a particular value of the wave function in Figure 4.42a, “slicing” its three-dimensional image at that value, and projecting each point on the edge of that slice down to the  $x$ - $y$  plane to form a closed contour in that plane. The contour then defines all points in the  $x$ - $y$  plane for which  $\tilde{\Psi}_{11}(\tilde{x}, \tilde{y})$  has the particular value selected. The process is continued by selecting other values of  $\tilde{\Psi}_{11}(\tilde{x}, \tilde{y})$  until the entire three-dimensional image has been collapsed into a set of concentric contours in the two-dimensional  $x$ - $y$  plane. Mountain climbers throughout the world use this method to generate contour maps of mountain ranges. The outermost contour identifies points at which the wave function has 10% of its maximum value. The second contour identifies points with 30% of the maximum value, and so on to the innermost contour that identifies points

with 90% of the maximum value. Note that the contours in Figure 4.42d, which correspond to uniform increases in amplitude, become much closer together as we approach the node. This indicates the value of the wave function is changing rapidly as it passes through zero. Notice in Figure 4.42b that the contours are circular at the large values of  $\tilde{\Psi}_{11}(\tilde{x}, \tilde{y})$ , but at lower values, they become squarish and approach perfect squares as  $\tilde{\Psi}_{11}(\tilde{x}, \tilde{y}) \rightarrow 0$ , as required by the boundary conditions imposed by the square box.

The wave function for the first excited state  $\tilde{\Psi}_{21}(\tilde{x}, \tilde{y})$  is shown in Figure 4.42c. It has a maximum (positive) at  $\tilde{x} = 0.25, \tilde{y} = 0.50$  and a minimum (negative) at  $\tilde{x} = 0.75, \tilde{y} = 0.50$ . The wave function changes sign as it moves along  $\tilde{x}$  for any value of  $\tilde{y}$ . There is a *nodal line* that lies along  $\tilde{x} = 0.5$ . The wave function does not change sign as it moves along  $\tilde{y}$  for any value of  $\tilde{x}$ . Make sure you see how these characteristics trace back to the one-dimensional solutions in Figure 4.37. Be especially mindful that nodal points in one dimension have become nodal lines in two dimensions. Figure 4.42d shows the contour plot for  $\tilde{\Psi}_{21}(\tilde{x}, \tilde{y})$ . Note that the contours are nearly circular near the maximum and minimum values, and they become ellipsoidal at smaller values of the wave function. This asymmetry in shape occurs because the motion in the  $x$  dimension occurs at a higher level of excitation than that in the  $y$  direction. At still lower values of the wave function, the contours begin to resemble rectangles. They approach perfect rectangles as  $\tilde{\Psi}_{21}(\tilde{x}, \tilde{y}) \rightarrow 0$  to match the nodal line along  $\tilde{x} = 0.5$  and the boundary conditions enforced by the box. To build up your expertise, construct and examine the wave function  $\tilde{\Psi}_{12}(\tilde{x}, \tilde{y})$  in a square box. Convince yourself it is degenerate with  $\tilde{\Psi}_{21}(\tilde{x}, \tilde{y})$ , and that its plots are the same as those of  $\tilde{\Psi}_{21}(\tilde{x}, \tilde{y})$  rotated by 90 degrees in the  $x$ - $y$  plane. Give a physical explanation why the two sets of plots are related in this way.

Finally, we plot the wave function for the second excited state  $\tilde{\Psi}_{22}(\tilde{x}, \tilde{y})$  (see Fig. 4.42e). It has two maxima (positive) and two minima (negative) located at the values 0.25 and 0.75 for  $\tilde{x}$  and  $\tilde{y}$ . There are two nodal lines, along  $\tilde{x} = 0.5$  and  $\tilde{y} = 0.5$ . They divide the  $x$ - $y$  plane into quadrants, each of which contains a single maximum (positive) or minimum (negative) value. Make sure that you see how these characteristics trace back to the one-dimensional solutions in Figure 4.37. Figure 4.42f shows the contour plots for  $\tilde{\Psi}_{22}(\tilde{x}, \tilde{y})$ . As the magnitude (absolute value) of  $\tilde{\Psi}_{22}(\tilde{x}, \tilde{y})$  decreases, the contours distort from circles to squares to match the nodal lines and boundary conditions of the box.

The pattern is now clearly apparent. You can easily produce hand sketches, in three dimensions and as contour plots, for any wave function for a particle in a square box. You need only pay attention to the magnitude of the quantum numbers  $n_x$  and  $n_y$ , track the number of nodes that must appear along the  $x$  and  $y$  axes, and convert these into nodal lines in the  $x$ - $y$  plane.

The probability of locating the particle in a small element of area of size  $d\tilde{x}d\tilde{y}$  centered on the point  $(\tilde{x}, \tilde{y})$  is given by  $|\tilde{\Psi}_{n_x n_y}(\tilde{x}, \tilde{y})|^2 d\tilde{x}d\tilde{y}$  when the system is in the quantum state described by  $n_x$  and  $n_y$ . For the wave functions shown in Figures 4.42a, c, and e,  $\tilde{\Psi}^2$  will show 1, 2, and 4 peaks above the  $x$ - $y$  plane, respectively. You should make hand sketches of these probability functions and also of their contour plots in the  $x$ - $y$  plane. The physical interpretation is straightforward. In the ground state, the probability has a global maximum at the center of the box. In progressively higher excited states, the probability spreads out from the center into a series of local maxima, just as in the one-dimensional case in Figure 4.37. These local maxima are arranged in a pattern determined by the quantum numbers in the  $x$  and  $y$  directions. If  $n_x = n_y$ , the local maxima will form a highly symmetric arrangement with pairs separated by nodal lines. If  $n_x \neq n_y$ , the pattern will not be symmetric. As  $n_x$  and  $n_y$  take on larger values, the probability becomes more nearly uniform through the box, and the motion becomes more like that predicted by classical mechanics (see the one-dimensional case in

Fig. 4.41). As an exercise, we suggest that you determine the number of nodal lines and the number of local probability maxima for the highly excited state  $\tilde{\Psi}_{20,20}(\tilde{x}, \tilde{y})$  and predict the nature of the motion of the particle.

### 4.7.2 Wave Functions for Particles in Cubic Boxes

The wave function for a particle in a cubic box of length  $L$  on each side, with one corner located at the origin of coordinates, is given by

$$\Psi_{n_x, n_y, n_z}(x, y, z) = \left(\frac{2}{L}\right)^{3/2} \sin\left(\frac{n_x \pi x}{L}\right) \sin\left(\frac{n_y \pi y}{L}\right) \sin\left(\frac{n_z \pi z}{L}\right) \quad [4.42]$$

**FIGURE 4.43** Contour plots for  $\tilde{\Psi}_{123}(\tilde{x}, \tilde{y}, \tilde{z})$  for a particle in a cubic box. (a) Contours generated in a cut at  $\tilde{z} = 0.5$ . (b) Contours generated in a cut at  $\tilde{y} = 0.25$ . (c) Contours generated in a cut at  $\tilde{x} = 0.5$ . The location of nodal lines and shapes of the contours are explained in the text.

where each of the quantum numbers  $n_x$ ,  $n_y$ , and  $n_z$  can be any of the positive integers. Graphical representation of these wave functions requires some care. Equation 4.42 tells us simply to go to the point  $(x, y, z)$ , evaluate the wave function there, and draw a graph showing the results of visiting many such points. However, all three spatial dimensions have already been used up to define the location; thus, we would need a fourth dimension to display the value of the wave function. Alternatively, we could set up a table of numbers giving the value of the wave function at each point  $(x, y, z)$ , but it would be difficult to develop any intuition about shapes and structures from this table. We will get around these problems by slicing up three-dimensional space into various two- and one-dimensional regions, evaluating the wave function from Equation 4.42 at each point in these restricted regions, and generating graphical representations over these restricted regions. From the behavior of the wave function in these regions, we draw inferences about its overall behavior, even though we cannot graphically display its overall behavior in complete detail. For example, we could evaluate Equation 4.42 only at points in the  $x$ - $y$  plane, and thereby generate contour maps of these wave functions in the  $x$ - $y$  plane similar to those for the two-dimensional case shown in Figures 4.42b, d, and f. We could repeat this operation at several other “cut planes” through the box, and the resulting series of contour plots would provide considerable insight into the characteristics of the wave function.

In Figure 4.43, we examine the behavior of  $\tilde{\Psi}_{123}(\tilde{x}, \tilde{y}, \tilde{z})$  using dimensionless variables defined earlier. Figure 4.43a shows a contour plot generated in a cut plane parallel to the  $x$ - $y$  axis at  $\tilde{z} = 0.5$ . It demonstrates two sets of ellipses separated by one nodal line, arising because  $n_x = 1$ ,  $n_y = 2$ . Figure 4.43b shows a contour plot generated in a cut plane at  $\tilde{y} = 0.25$  or  $0.75$  parallel to the  $x$ - $z$  plane. It shows three sets of ellipses separated by two nodal lines, as a consequence of  $n_x = 1$ ,  $n_z = 3$ . Figure 4.43c shows a contour plot in the cut plane at  $\tilde{x} = 0.5$ . It shows six circles and three nodal lines, due to  $n_y = 2$ ,  $n_z = 3$ . All of this suggests that  $\tilde{\Psi}_{123}(\tilde{x}, \tilde{y}, \tilde{z})$  is an interesting object indeed!

How can we get some sense of the three-dimensional shape of a wave function? We can do something similar to the level curves in the contour plots shown at the right of Figure 4.42 for the particle in a two-dimensional box. But of course for particle in a three-dimensional box, rather than level curves, these will be level surfaces, or surfaces plotted in three dimensions that show where the wave function has a certain value. The result is a set of concentric “blimp-shaped” surfaces in three dimensions. Each of them identifies a surface of points  $(x, y, z)$  at every one of which  $\tilde{\Psi}_{123}(\tilde{x}, \tilde{y}, \tilde{z})$  has the same value. These surfaces are called *isosurfaces* because the wave function has constant value at each point on them. In practice, one generates these isosurfaces by evaluating  $\tilde{\Psi}_{123}(\tilde{x}, \tilde{y}, \tilde{z})$  at many points in the cubic box and tracking in the computer all points that have, for example, the value  $\tilde{\Psi} = \pm 0.9$ . Then the computer plots the resulting

**FIGURE 4.44** Isosurfaces for  $\tilde{\Psi}_{123}(\tilde{x}, \tilde{y}, \tilde{z})$  for a particle in a cubic box. (a) Isosurfaces for wave function value  $\tilde{\Psi}_{123} = \pm 0.8$ . (b) Isosurfaces for wave function value  $\tilde{\Psi}_{123} = \pm 0.2$ . Each isosurface is shown in the same color as the corresponding contour in Figure 4.43.

isosurfaces in three dimensions. Figure 4.44 shows the isosurfaces for  $\tilde{\Psi}_{123}(\tilde{x}, \tilde{y}, \tilde{z})$  at the values  $\tilde{\Psi} = \pm 0.8, \pm 0.2$ .

Figure 4.45 briefly summarizes key images for  $\tilde{\Psi}_{222}(\tilde{x}, \tilde{y}, \tilde{z})$  for a particle in a cubic box. Figure 4.45a shows a contour plot in a cut plane at  $\tilde{z} = 0.75$ . Convince yourself that the contour plot in a cut at  $\tilde{z} = 0.25$  would have the same pattern but each positive peak would become negative, and vice versa. Why should we not take a cut at  $\tilde{z} = 0.5$ ? Be sure you understand the same concerns for cut planes perpendicular to the  $x$ -axis or the  $y$ -axis. Figures 4.45b and c shows the isosurfaces for the maxima and minima of  $\tilde{\Psi}_{222}(\tilde{x}, \tilde{y}, \tilde{z})$  at the values  $\tilde{\Psi} = \pm 0.9, \pm 0.3$ .

Notice how in Figures 4.44 and 4.45 the shape depends on the value selected for the isosurface. This demonstrates an important point about plots of wave functions for a particle moving in three dimensions: It is not possible to show the shape of the wave function in three dimensions. You should be mindful that the appearance of the wave function in three-dimensional representations depends strongly on choices made by the illustrator. Be certain you understand these choices in each image you examine (or create!). These same issues appear in Chapter 5 when we discuss the wave functions for electrons in atoms, called *atomic orbitals*. Throughout this book, we have taken great care to generate accurate contour plots and isosurfaces for them from computer calculations to guide your thinking about the distribution of electrons in atoms and molecules.

**FIGURE 4.45** Representations of  $\tilde{\Psi}_{222}(\tilde{x}, \tilde{y}, \tilde{z})$  for a particle in a cubic box. (a) Contour plots for a cut taken at  $\tilde{z} = 0.75$ . (b) Isosurfaces for wave function value  $\tilde{\Psi}_{222} = \pm 0.9$ . (c) Isosurfaces for wave function value  $\tilde{\Psi}_{222} = \pm 0.3$ . Each isosurface is shown in the same color as the corresponding contour in (a).

## CHAPTER SUMMARY

---

The concepts and methods of quantum mechanics were developed to explain the behavior of matter on the nanometer-length scale. The results of a number of key experiments demanded the creation of a new physical theory in the first third of the 20th century because classical mechanics and electrodynamics failed completely to account for these new observations. These experimental facts included the wavelength and temperature dependence of blackbody radiation, the very existence of stable atoms and their discrete line spectra, the photoelectric effect, and electron diffraction. Taken together, these experiments demonstrated unequivocally the existence of energy quantization (blackbody radiation and atomic spectra) and wave–particle duality (photoelectric effect and electron diffraction), which would become the central concepts of the new theory quantum mechanics.

Explaining each of these experiments required scientists to abandon long-held concepts from classical physics. Particularly striking were Planck’s explanation of blackbody radiation and Bohr’s model of the hydrogen atom. Both scientists started afresh and made whatever assumptions were necessary to fit the experimental results, ignoring any conflicts with classical physics. Only after their models agreed so well with experiment did they and other scientists begin to consider the radical philosophical implications of quantum mechanics and develop a new way of thinking about nature on the nanometer-length scale. This was undoubtedly one of the most significant shifts in the history of science.

The key new concepts developed in quantum mechanics include the quantization of energy, a probabilistic description of particle motion, wave–particle duality, and indeterminacy. These ideas appear foreign to us because they are inconsistent with our experience of the macroscopic world. Nonetheless, we have accepted their validity because they provide the most comprehensive account of the behavior of matter and radiation and because the agreement between theory and the results of all experiments conducted to date has been impressively accurate.

Energy quantization arises for all systems whose motions are confined by a potential well. The one-dimensional particle-in-a-box model shows why quantization only becomes apparent on the atomic scale. Because the energy level spacing is inversely proportional to the mass and to the square of the length of the box, quantum effects become too small to be observed for macroscopic systems, like a ball in a squash court.

Wave–particle duality accounts for the probabilistic nature of quantum mechanics and for indeterminacy. Once we accept that particles can behave as waves, we can form analogies with classical electromagnetic wave theory to describe the motion of particles. For example, the probability of locating the particle at a particular location is the square the spatial part of its wavefunction (the square of the amplitude of the wave function plotted as a function of time, as it oscillates at a particular point in coordinate space). Zero-point energy is a consequence of the Heisenberg indeterminacy relation; all particles bound in potential wells have finite energy even at the absolute zero of temperature.

Particle-in-a-box models illustrate a number of important features of quantum mechanics. The energy-level structure depends on the nature of the potential,  $E_n \propto n^2$ , for the particle in a one-dimensional box, so the separation between energy levels increases as  $n$  increases. The probability density distribution is different from that for the analogous classical system. The most probable location for the particle-in-a-box model in its ground state is the center of the box, rather than uniformly over the box as predicted by classical mechanics. Normalization ensures that the probability of finding the particle at some

position in the box, summed over all possible positions, adds up to 1. Finally, for large values of  $n$ , the probability distribution looks much more classical, in accordance with the correspondence principle.

Different kinds of energy level patterns arise from different potential energy functions, for example the hydrogen atom (see Section 5.1) and the harmonic oscillator (see Section 20.3).

These concepts and principles are completely general; they can be applied to explain the behavior of any system of interest. In the next two chapters, we use quantum mechanics to explain atomic and molecular structure, respectively. It is important to have a firm grasp of these principles because they are the basis for our comprehensive discussion of chemical bonding in Chapter 6.

## CONCEPTS AND SKILLS

### Section 4.1 – Preliminaries: Wave Motion and Light

*Relate the frequency, wavelength, and speed of light waves. Do the same for other kinds of waves (Problems 1–8).*

- Waves are oscillating disturbances in space and time which are characterized by their amplitude, wavelength, and frequency. The speed of a wave is given by the product  $\lambda\nu$ , where  $\lambda$  and  $\nu$  are the wavelength and frequency, respectively. Light waves are propagating waves of electromagnetic radiation. For this case the speed is given by  $c = \lambda\nu$ , where  $c$  is the speed of light ( $3 \times 10^8 \text{ m s}^{-1}$ ).

### Section 4.2 – Evidence for Energy Quantization in Atoms

*Describe blackbody radiation and discuss how related paradoxes of classical physics were resolved by quantum mechanics (Problems 9–10).*

- Blackbody radiation emitted from hot sources has a characteristic frequency distribution that is temperature-dependent. The spectrum of cooler objects has a comparatively narrow band that peaks near the red end of the visible spectrum, whereas that of hotter objects has a much broader band that is shifted toward the blue.
- The peak observed in the frequency distribution of blackbody radiation is completely inconsistent with the predictions of classical electromagnetic theory. This failure of classical physics is called the ultraviolet catastrophe.
- The only way that Planck could fit the experimental spectrum was to postulate that:
  - the oscillating charges responsible for the radiation were restricted to discrete energies

$$\epsilon_{\text{osc}} = nh\nu \quad (n = 1, 2, 3, 4, \dots), \quad [4.3]$$

- an oscillator was either excited or not
- the probability of an oscillator being excited depends on the temperature.

*Use experimental emission and absorption spectra to determine spacing between energy levels in atoms (Problems 11–16).*

- Atoms emit and absorb energy in discrete amounts. The frequency  $\nu$  of the light absorbed or emitted is related to the difference between two energy levels as

$$\nu = \frac{E_f - E_i}{h} \quad \text{or} \quad \Delta E = h\nu \quad (\text{for absorbed light}) \quad [4.7]$$

Use the Franck–Hertz method to determine spacings between adjacent energy levels in atoms (Problems 17–18).

- Electrons can excite atoms from one quantum state to another by energy transferred during collisions. The threshold energy for excitation exactly matches the emission of light as the atom drops back down to the lower state, thus confirming the existence of quantized states and showing that they may be excited by either mechanical impact of electrons or absorption of photons.

$$\nu = \frac{E_{\text{upper}} - E_{\text{lower}}}{h} = \frac{eV_{\text{thr}}}{h} \quad [4.8]$$

### Section 4.3 – The Bohr Model: Predicting Discrete Energy Levels in Atoms

Use the Bohr model to calculate the energy levels of one-electron atoms and to find the frequencies and wavelengths of light emitted in transitions between energy levels (Problems 19–22).

- Bohr postulated quantization of the angular momentum:

$$L = m_e v r = n \frac{h}{2\pi} \quad n = 1, 2, 3, \dots \quad [4.11]$$

- He used this relation with the classical equations of motion, and correctly predicted the energy levels of one-electron atoms:

$$E_n = \frac{-Z^2 e^4 m_e}{\epsilon_0^2 n^2 h^2} = -(2.18 \times 10^{-18} \text{ J}) \frac{Z^2}{n^2} \quad n = 1, 2, 3, \dots \quad [4.14a]$$

- Bohr assumed that emission or absorption of light by atoms involved in transitions between energy levels of the atom and the frequency of the light was related to the energy difference between levels as  $\Delta E = h\nu$ . Combining this relation with his equation for the energy levels predicted the frequencies of light absorbed or emitted by the atom.

$$\nu = \frac{Z^2 e^4 m_e}{8\epsilon_0^2 h^3} \left( \frac{1}{n_f^2} - \frac{1}{n_i^2} \right) = (3.29 \times 10^{15} \text{ s}^{-1}) Z^2 \left( \frac{1}{n_f^2} - \frac{1}{n_i^2} \right) \quad [4.16]$$

$$n_i > n_f = 1, 2, 3, \dots \text{ (emission)}$$

$$\nu = (3.29 \times 10^{15} \text{ s}^{-1}) Z^2 \left( \frac{1}{n_i^2} - \frac{1}{n_f^2} \right) \quad [4.17]$$

$$n_f > n_i = 1, 2, 3, \dots \text{ (absorption)}$$

- Bohr's model could not account for the spectra of many-electron atoms.

### Section 4.4 – Evidence for Wave–Particle Duality

Describe the photoelectric effect, and discuss how related paradoxes of classical physics were resolved by quantum mechanics (Problems 23–24).

- In the photoelectric effect, light shines on a metal surface in a vacuum. The kinetic energy and photocurrent (number of electrons per second) emitted are measured as a function of frequency and intensity of the light.
- Experimental results of the photoelectric effect:
  - No electrons are emitted below a threshold frequency  $\nu_0$  regardless of intensity.
  - Above the threshold, the photocurrent is proportional to the light intensity.

- Interpretation of the photoelectric effect: Light behaves like a stream of particles called photons, each with an energy  $E = h\nu$ . A photon of a given energy either does or does not provide enough energy to overcome the forces binding the electron to the metal.
- Above the threshold, the excess energy goes into the kinetic energy of the photoelectron  $\frac{1}{2}mv^2 = h\nu - h\nu_0$ , where  $h$  is Planck's constant  $6.625 \times 10^{-34} \text{ J sec}^{-1}$ .
- The photoelectric effect demonstrated the particle nature of electromagnetic radiation (formerly described only as waves).

*Using the law of conservation of energy, relate the work function of a metal to the wavelength of light used to eject electrons in the photoelectric effect and the kinetic energy of those electrons (Problems 25–28).*

- Above the threshold, the maximum kinetic energy of the electron is  $E_{\text{max}} = \frac{1}{2}mv_c^2 = h\nu - \Phi$ , where  $h$  is Planck's constant  $6.625 \times 10^{-34} \text{ J sec}^{-1}$ .
- $\Phi = h\nu_0$  is the work function of the metal, which is the energy barrier the electron must overcome to escape from the metal.

*Discuss the de Broglie relation and use it to calculate the wavelengths associated with particles in motion (Problems 29–32).*

- Wave-particle duality: De Broglie postulated that the motion of an electron in an atom could be described as a circular standing wave, which required an integral number of wavelengths to fit the circumference,  $n\lambda = 2\pi r$ . Combining this result with Bohr's quantization of angular momentum led to the de Broglie relation  $\lambda = h/p$ .
- The de Broglie relation asserts that a particle moving with magnitude of momentum  $p$  can behave as if it were a wave of wavelength  $\lambda = h/p$ . This relation is the origin of wave-particle duality, which means that matter can show either particlelike or wavelike behavior depending on the conditions of the observation.

*Describe interference between wave functions for an electron. Explain how constructive and destructive interference influence the probability for finding the electron at a particular location (Problems 33–34).*

- Diffraction of low energy electrons at solid surfaces confirms the wavelike nature of the electron. Electrons departing the surface after collisions with atoms in the surface are described by wave functions whose wavelengths depend on the energies of the electrons. The outgoing waves can interfere constructively to define the bright spots on the display, or destructively to produce no image on the display. The probability of finding an electron at a particular location is highest at locations where the wave functions interfere constructively.

*State the Heisenberg indeterminacy principle and use it to establish bounds within which the position and momentum of a particle can be known (Problems 35–36).*

- The Heisenberg indeterminacy relation  $\sigma_x\sigma_p \geq h/4\pi$  is the quantitative statement of a fundamental limit on our ability to know simultaneously the values of two properties of a particle with an arbitrarily high precision.
- For example, if the position of a particle is known to fall within the range  $(\Delta x)_0$ , the uncertainty in the momentum cannot be smaller than  $\sigma_p = h/[4\pi(\Delta x)_0]$ .

### Section 4.5 – The Schrödinger Equation

State the conditions a function must satisfy in order to be a solution of the Schrödinger equation. Explain how these conditions provide the probability interpretation of the wave function.

- The wave function and its first derivative must be continuous at each point in space.
- The wave function must be bounded at very large values of  $x$  (if the particle is not free). This means that

$$\psi \longrightarrow 0 \quad \text{as} \quad x \longrightarrow \pm \infty \quad [4.31]$$

- The square of the wave function gives the probability of finding the particle at a particular position in space. Normalization of the wave function by requiring that  $\int_{\text{all space}} \psi^2 dV = 1$  ensures that the particle will be found somewhere.

### Section 4.6 – Quantum Mechanics of Particle-in-a-Box Models

Determine the energy levels for particles confined in boxes with rigid walls that are infinite potential barriers (Problems 37–40).

- In one-dimensional boxes the energy of the particle is characterized by a single quantum number, and the energy-level spacing is

$$E_n = \frac{h^2 n^2}{8mL^2} \quad n = 1, 2, 3, \dots \quad [4.37]$$

- The wave functions for a particle in a one-dimensional box are given by

$$\psi_n(x) = \sqrt{\frac{2}{L}} \sin\left(\frac{n\pi x}{L}\right) \quad n = 1, 2, 3, \dots \quad [4.36]$$

In a one-dimensional problem, the probability of finding the particle between the position  $x = x_1$  and  $x = x_2$  is calculated with the following integral

$$\int_{x_1}^{x_2} |\psi(x)|^2 dx$$

If the interval  $\Delta x = x_2 - x_1$  is small, this integral has a value close to  $|\psi(x_0)|^2 \Delta x$ , where  $x_0$  is evaluated in the middle of the range from  $x_1$  to  $x_2$ .

- In three-dimensional boxes the energy of the particle is characterized by three quantum numbers, one each for motion in the  $x$ ,  $y$ , and  $z$  directions. The energy levels in a cubic box are

$$E_{n_x, n_y, n_z} = \frac{h^2}{8mL^2} [n_x^2 + n_y^2 + n_z^2] \quad \begin{cases} n_x = 1, 2, 3, \dots \\ n_y = 1, 2, 3, \dots \\ n_z = 1, 2, 3, \dots \end{cases} \quad [4.40]$$

### Section 4.7 – A Deeper Look . . . Wave Functions for Particles in Two- and Three-Dimensional Boxes

Prepare hand-drawn sketches for contour diagrams and isosurfaces of the wave functions for particles in square and cubic boxes. Relate the number and locations of the nodes, maxima, and minima to the quantum numbers for the wave function (Problems 41–44).

- In square boxes, the quantum numbers  $n_x$  and  $n_y$  give the number of nodes ( $n_x - 1$  and  $n_y - 1$  respectively) that appear along the  $x$  and  $y$  axes, and convert these into nodal lines in the  $x$ - $y$  plane.
- In cubic boxes, show how the quantum numbers  $n_x$ ,  $n_y$ , and  $n_z$  are related to the number of nodes that must appear along the  $x$ ,  $y$ , and  $z$  axes, and convert these into nodal planes in the  $x$ - $y$ - $z$  space.

FIGURE 4.46 The conjugated molecule octatetraene.

## CUMULATIVE EXERCISE

### Conjugated Molecules in Dyestuffs and Biological Materials

An interesting class of carbon-containing molecules called *conjugated molecules* have structures that consist of a sequence of alternating single and double bonds (Fig. 4.46). These chainlike molecules are represented as zigzag structures in which the angle between adjacent segments is determined by the geometry of the C—C double bond. Various properties to be explored in later chapters indicate that the electrons forming the double bonds are “de-localized” over the entire chain. Such molecules absorb light in the visible and ultraviolet regions of the electromagnetic spectrum. Many dyestuffs and molecules with biological significance have these structures. The properties of these molecules can be described approximately by the particle-in-a-box model in which we assume there is no interaction between the electrons, the potential energy is constant along the chain, and the potential energy is infinite at the ends of the chain. Assume the length of the potential well is  $Nd$ , where  $N$  is the number of carbon atoms in the chain, and  $d$  is half the sum of the lengths of a C—C single bond and a C—C double bond. In a conjugated molecule of  $N$  carbon atoms in the chain, there will be  $N$  electrons involved in the double bonds.

- Write the equation for the energy levels of an electron in this potential well.
- Write the equation for the wave function of an electron in this potential well.

To describe the placement of  $N$  electrons in the energy levels, we anticipate a principle to be developed in Chapter 5 that requires that no more than two electrons can occupy a level. Therefore, levels will be occupied from the ground state up to level  $n = N/2$ . Absorption of light can cause one electron to move to the next level  $n = (N/2) + 1$ .

- Write the equation for the frequency of light that will cause this transition.
- The molecule butadiene has four carbon atoms with conjugated structure; thus,  $N = 4$ . Calculate the wavelength of light in the first transition of butadiene.
- The molecular structure of vitamin A is conjugated with  $N = 10$ . Calculate the wavelength of light in the first transition of vitamin A.
- The molecule  $\beta$ -carotene has  $N = 22$ . Calculate the wavelength of light in the first transition of  $\beta$ -carotene.

We see in part (c) that the frequency of light absorbed should be inversely proportional to the length of the chain. Short-chain conjugated molecules absorb in the ultraviolet, whereas longer chain molecules absorb in the visible. This qualitative trend is predicted by the simple particle-in-a-box model. Later chapters detail how these results can be improved.

### Answers

$$(a) E_n = \frac{n^2 h^2}{8mN^2 d^2}$$

$$(b) \psi_n(x) = A \sin\left(\frac{n\pi x}{Nd}\right)$$

$$(c) h\nu = E_{(N/2)+1} - E_{N/2} = \frac{h^2(N+1)}{8md^2N^2} \approx \frac{h^2}{8md^2N}$$

$$(d) \lambda = 2050 \text{ \AA}$$

$$(e) \lambda = 3150 \text{ \AA}$$

$$(f) \lambda = 4410 \text{ \AA}$$

## PROBLEMS

Answers to problems whose numbers are red appear in Appendix G. Problems that are more challenging are indicated with asterisks.

### 4.1 Preliminaries: Wave Motion and Light

- Some water waves reach the beach at a rate of one every 3.2 s, and the distance between their crests is 2.1 m. Calculate the speed of these waves.
  - The spacing between bands of color in a chemical wave from an oscillating reaction is measured to be 1.2 cm, and a new wave appears every 42 s. Calculate the speed of propagation of the chemical waves.
  - An FM radio station broadcasts at a frequency of  $9.86 \times 10^7 \text{ s}^{-1}$  (98.6 MHz). Calculate the wavelength of the radio waves.
  - The gamma rays emitted by  $^{60}\text{Co}$  are used in radiation treatment of cancer. They have a frequency of  $2.83 \times 10^{20} \text{ s}^{-1}$ . Calculate their wavelength, expressing your answer in meters and in angstroms.
  - Radio waves of wavelength  $6.00 \times 10^2 \text{ m}$  can be used to communicate with spacecraft over large distances.
    - Calculate the frequency of these radio waves.
    - Suppose a radio message is sent home by astronauts in a spaceship approaching Mars at a distance of  $8.0 \times 10^{10} \text{ m}$  from Earth. How long (in minutes) will it take for the message to travel from the spaceship to Earth?
  - An argon ion laser emits light of wavelength of 488 nm.
    - Calculate the frequency of the light.
    - Suppose a pulse of light from this laser is sent from Earth, is reflected from a mirror on the moon, and returns to its starting point. Calculate the time elapsed for the round trip, taking the distance from Earth to the moon to be  $3.8 \times 10^5 \text{ km}$ .
  - The speed of sound in dry air at  $20^\circ\text{C}$  is  $343.5 \text{ m s}^{-1}$ , and the frequency of the sound from the middle C note on a piano is  $261.6 \text{ s}^{-1}$  (according to the American standard pitch scale). Calculate the wavelength of this sound and the time it will take to travel 30.0 m across a concert hall.
  - Ultrasonic waves have frequencies too high to be detected by the human ear, but they can be produced and detected by vibrating crystals. Calculate the wavelength of an ultrasonic wave of frequency  $5.0 \times 10^4 \text{ s}^{-1}$  that is propagating through a sample of water at a speed of  $1.5 \times 10^3 \text{ m s}^{-1}$ . Explain why ultrasound can be used to probe the size and position of the fetus inside the mother's abdomen. Could audible sound with a frequency of  $8000 \text{ s}^{-1}$  be used for this purpose?
- ### 4.2 Evidence for Energy Quantization in Atoms
- The maximum in the blackbody radiation intensity curve moves to shorter wavelength as temperature increases. The German physicist Wilhelm Wien demonstrated the relation to be  $\lambda_{\text{max}} \propto 1/T$ . Later, Planck's equation showed the maximum to be  $\lambda_{\text{max}} = 0.20 \text{ hc}/kT$ . In 1965, scientists researching problems in telecommunication discovered "background radiation" with maximum wavelength 1.05 mm (microwave region of the EM spectrum) throughout space. Estimate the temperature of space.
  - Use the data in Figure 4.8 to estimate the ratio of radiation intensity at  $10,000 \text{ \AA}$  (infrared) to that at  $5000 \text{ \AA}$  (visible) from a blackbody at  $5000 \text{ K}$ . How will this ratio change with increasing temperature? Explain how this change occurs.
  - Excited lithium atoms emit light strongly at a wavelength of 671 nm. This emission predominates when lithium atoms are excited in a flame. Predict the color of the flame.
  - Excited mercury atoms emit light strongly at a wavelength of 454 nm. This emission predominates when mercury atoms are excited in a flame. Predict the color of the flame.
  - Barium atoms in a flame emit light as they undergo transitions from one energy level to another that is  $3.6 \times 10^{-19} \text{ J}$  lower in energy. Calculate the wavelength of light emitted and, by referring to Figure 4.3, predict the color visible in the flame.
  - Potassium atoms in a flame emit light as they undergo transitions from one energy level to another that is  $4.9 \times 10^{-19} \text{ J}$  lower in energy. Calculate the wavelength of light emitted and, by referring to Figure 4.3, predict the color visible in the flame.
  - The sodium D-line is actually a pair of closely spaced spectroscopic lines seen in the emission spectrum of sodium atoms. The wavelengths are centered at 589.3 nm. The intensity of this emission makes it the major source of light (and causes the yellow color) in the sodium arc light.
    - Calculate the energy change per sodium atom emitting a photon at the D-line wavelength.
    - Calculate the energy change per mole of sodium atoms emitting photons at the D-line wavelength.
    - If a sodium arc light is to produce 1.000 kilowatt ( $1000 \text{ J s}^{-1}$ ) of radiant energy at this wavelength, how many moles of sodium atoms must emit photons per second?
  - The power output of a laser is measured by its wattage, that is, the number of joules of energy it radiates per second ( $1 \text{ W} = 1 \text{ J s}^{-1}$ ). A 10-W laser produces a beam of green light with a wavelength of 520 nm ( $5.2 \times 10^{-7} \text{ m}$ ).
    - Calculate the energy carried by each photon.
    - Calculate the number of photons emitted by the laser per second.
  - In a Franck–Hertz experiment on sodium atoms, the first excitation threshold occurs at 2.103 eV. Calculate the wavelength of emitted light expected just above this threshold. (Note: Sodium vapor lamps used in street lighting emit spectral lines with wavelengths 5891.8 and 5889.9 Å.)
  - In a Franck–Hertz experiment on hydrogen atoms, the first two excitation thresholds occur at 10.1 and 11.9 eV. Three optical emission lines are associated with these levels. Sketch an energy-level diagram for hydrogen atoms

based on this information. Identify the three transitions associated with these emission lines. Calculate the wavelength of each emitted line.

### 4.3 The Bohr Model: Predicting Discrete Energy Levels in Atoms

- Use the Bohr model to calculate the radius and the energy of the  $B^{4+}$  ion in the  $n = 3$  state. How much energy would be required to remove the electrons from 1 mol of  $B^{4+}$  in this state? What frequency and wavelength of light would be emitted in a transition from the  $n = 3$  to the  $n = 2$  state of this ion? Express all results in SI units.
  - $He^+$  ions are observed in stellar atmospheres. Use the Bohr model to calculate the radius and the energy of  $He^+$  in the  $n = 5$  state. How much energy would be required to remove the electrons from 1 mol of  $He^+$  in this state? What frequency and wavelength of light would be emitted in a transition from the  $n = 5$  to the  $n = 3$  state of this ion? Express all results in SI units.
  - The radiation emitted in the transition from  $n = 3$  to  $n = 2$  in a neutral hydrogen atom has a wavelength of 656.1 nm. What would be the wavelength of radiation emitted from a doubly ionized lithium atom ( $Li^{2+}$ ) if a transition occurred from  $n = 3$  to  $n = 2$ ? In what region of the spectrum does this radiation lie?
  - $Be^{3+}$  has a single electron. Calculate the frequencies and wavelengths of light in the emission spectrum of the ion for the first three lines of each of the series that are analogous to the Lyman and the Balmer series of neutral hydrogen. In what region of the spectrum does this radiation lie?
- ### 4.4 Evidence for Wave–Particle Duality
- Both blue and green light eject electrons from the surface of potassium. In which case do the ejected electrons have the higher average kinetic energy?
  - When an intense beam of green light is directed onto a copper surface, no electrons are ejected. What will happen if the green light is replaced with red light?
  - Cesium frequently is used in photocells because its work function ( $3.43 \times 10^{-19}$  J) is the lowest of all the elements. Such photocells are efficient because the broadest range of wavelengths of light can eject electrons. What colors of light will eject electrons from cesium? What colors of light will eject electrons from selenium, which has a work function of  $9.5 \times 10^{-19}$  J?
  - Alarm systems use the photoelectric effect. A beam of light strikes a piece of metal in the photocell, ejecting electrons continuously and causing a small electric current to flow. When someone steps into the light beam, the current is interrupted and the alarm is triggered. What is the maximum wavelength of light that can be used in such an alarm system if the photocell metal is sodium, with a work function of  $4.41 \times 10^{-19}$  J?
  - Light with a wavelength of  $2.50 \times 10^{-7}$  m falls on the surface of a piece of chromium in an evacuated glass tube. If the work function of chromium is  $7.21 \times 10^{-19}$  J, determine (a) the maximum kinetic energy of the emitted

photoelectrons and (b) the speed of photoelectrons that have this maximum kinetic energy.

- Calculate the maximum wavelength of electromagnetic radiation if it is to cause detachment of electrons from the surface of metallic tungsten, which has a work function of  $7.29 \times 10^{-19}$  J. If the maximum speed of the emitted photoelectrons is to be  $2.00 \times 10^6$  m  $s^{-1}$ , what should the wavelength of the radiation be?
  - A guitar string with fixed ends has a length of 50 cm.
    - Calculate the wavelengths of its fundamental mode of vibration (that is, its first harmonic) and its third harmonic.
    - How many nodes does the third harmonic have?
  - Suppose we picture an electron in a chemical bond as being a wave with fixed ends. Take the length of the bond to be 1.0 Å.
    - Calculate the wavelength of the electron wave in its ground state and in its first excited state.
    - How many nodes does the first excited state have?
  - Calculate the de Broglie wavelength of the following:
    - an electron moving at a speed of  $1.00 \times 10^3$  m  $s^{-1}$
    - a proton moving at a speed of  $1.00 \times 10^3$  m  $s^{-1}$
    - a baseball with a mass of 145 g, moving at a speed of 75 km  $hr^{-1}$
  - Calculate the de Broglie wavelength of the following:
    - electrons that have been accelerated to a kinetic energy of  $1.20 \times 10^7$  J  $mol^{-1}$
    - a helium atom moving at a speed of 353 m  $s^{-1}$  (the root-mean-square speed of helium atoms at 20 K)
    - a krypton atom moving at a speed of 299 m  $s^{-1}$  (the root-mean-square speed of krypton atoms at 300 K)
  - In a particular Low Energy Electron Diffraction (LEED) study of a solid surface, electrons at 45 eV were diffracted at  $\theta = 53^\circ$ .
    - Calculate the crystal spacing  $a$ .
    - Calculate the diffraction angle for 90 eV electrons on this same surface.
  - What electron energy is required to obtain the diffraction pattern for a surface with crystal spacing of 4.0 Å?
  - The position of an electron is known to be within  $10 \text{ \AA}$  ( $1.0 \times 10^{-9}$  m). What is the minimum uncertainty in its velocity component in this direction?
    - Repeat the calculation of part (a) for a helium atom.
  - No object can travel faster than the speed of light, so it would appear evident that the uncertainty in the speed of any object is at most  $3 \times 10^8$  m  $s^{-1}$ .
    - What is the minimum uncertainty in the position of an electron, given that we know nothing about its speed except that it is slower than the speed of light?
    - Repeat the calculation of part (a) for the position of a helium atom.
- ### 4.6 Quantum Mechanics of Particle-in-a-Box Models
- Using Equation 4.36, make a graph of the  $n = 3$  wave function and the square of this wave function for a particle in a box with the edges at  $x = 0$  and  $x = 7 \text{ \AA}$ . Estimate the probability of finding the particle between

- $x_1 = 3 \text{ \AA}$  and  $x_2 = 4 \text{ \AA}$ . You may either do an integral or find the area under the curve by counting the number of rectangular boxes (roughly estimating the fractional boxes), and then multiply by the area of each box, watching your units. Show your calculation with units for credit.
- (b) Verify that the  $n = 3$  wave function in (a) is an allowed quantum state (sometimes called an *eigenfunction*) of  $\mathcal{H}$  by substituting it for  $\psi$  in the left side of the equation for  $\mathcal{H}\psi = E\psi$  immediately following Eq. 4.32. Calculate the derivatives to see if your result  $E\psi$  is a constant multiplied by the original  $n = 3$  wavefunction. What does the constant you get tell you about the energy of this eigenstate? Is it in agreement with the energy for the  $n = 3$  level you would calculate from Equation 4.37?
38. Using a simple particle-in-a-box model for the multiple bonding in 1,2-butadiene (see Example 4.7) and the  $n = 2$  wave function for the weakest bound electron, calculate the probability of finding the electron in an 0.1 interval centered midway between the two inner carbon atoms (that is, the center is at  $x = 2.11 \text{ \AA}$ , so this interval is from  $x_1 = 2.06 \text{ \AA}$  to  $x_2 = 2.16 \text{ \AA}$ ). Then calculate the probability of finding the electron in an 0.1 interval centered midway between an end carbon atom and the carbon atom that is double-bonded to it in the Lewis dot structure. (You may calculate the appropriate integrals or estimate the relevant areas under the curve graphically.) Then recalculate the probabilities by approximating the integral as  $|\psi(x_0)|^2 \Delta x$ , where  $x_0$  is evaluated in the middle of the range from  $x_1$  to  $x_2$ . Finally, explain why you can't approximate the integral needed for Problem 37(a) in this way.
39. Chapter 3 introduced the concept of a double bond between carbon atoms, represented by  $\text{C}=\text{C}$ , with a length near  $1.34 \text{ \AA}$ . The motion of an electron in such a bond can be treated crudely as motion in a one-dimensional box. Calculate the energy of an electron in each of its three lowest allowed states if it is confined to move in a one-dimensional box of length  $1.34 \text{ \AA}$ . Calculate the wavelength of light necessary to excite the electron from its ground state to the first excited state.
40. When metallic sodium is dissolved in liquid sodium chloride, electrons are released into the liquid. These dissolved electrons absorb light with a wavelength near  $800 \text{ nm}$ . Suppose we treat the positive ions surrounding an electron crudely as defining a three-dimensional cubic box of edge  $L$ , and we assume that the absorbed light excites the electron from its ground state to the first excited state. Calculate the edge length  $L$  in this simple model.

#### 4.7 Wave Functions for Particles in Two- and Three-Dimensional Boxes

41. Write the wave function  $\tilde{\Psi}_{12}(\tilde{x}, \tilde{y})$  for a particle in a square box.
- Convince yourself it is degenerate with  $\tilde{\Psi}_{21}(\tilde{x}, \tilde{y})$ .
  - Convince yourself that its plots are the same as those of  $\tilde{\Psi}_{21}(\tilde{x}, \tilde{y})$  rotated by  $90$  degrees in the  $x$ - $y$  plane.
  - Give a physical explanation why the two sets of plots are related in this way.
42. Write the wave function for the highly excited state  $\tilde{\Psi}_{100,100}(\tilde{x}, \tilde{y})$  for a particle in a square box.
- Determine the number of nodal lines and the number of local probability maxima for this state.
  - Describe the motion of the particle in this state.
43. Consider the wave function  $\tilde{\Psi}_{222}(\tilde{x}, \tilde{y}, \tilde{z})$  for a particle in a cubic box. Figure 4.45a shows a contour plot in a cut plane at  $\tilde{z} = 0.75$ .
- Convince yourself that the contour plot in a cut at  $\tilde{z} = 0.25$  would have the same pattern, but each positive peak would become negative, and vice versa.
  - Describe the shape of this wave function in a plane cut at  $\tilde{y} = 0.5$ .
44. Consider the wave function  $\tilde{\Psi}_{222}(\tilde{x}, \tilde{y}, \tilde{z})$  for a particle in a cubic box. Figure 4.45a shows a contour plot in a cut plane at  $\tilde{z} = 0.75$ .
- Describe the shape of this wave function in a cut plane at  $\tilde{x} = 0.5$ .
  - Describe the shape of this wave function in a cut plane at  $\tilde{y} = 0.5$ .

## ADDITIONAL PROBLEMS

45. A piano tuner uses a tuning fork that emits sound with a frequency of  $440 \text{ s}^{-1}$ . Calculate the wavelength of the sound from this tuning fork and the time the sound takes to travel  $10.0 \text{ m}$  across a large room. Take the speed of sound in air to be  $343 \text{ m s}^{-1}$ .
46. The distant galaxy called Cygnus A is one of the strongest sources of radio waves reaching Earth. The distance of this galaxy from Earth is  $3 \times 10^{24} \text{ m}$ . How long (in years) does it take a radio wave of wavelength  $10 \text{ m}$  to reach Earth? What is the frequency of this radio wave?
47. Hot objects can emit blackbody radiation that appears red, orange, white, or bluish white, but never green. Explain.
48. Compare the energy (in joules) carried by an X-ray photon (wavelength  $\lambda = 0.20 \text{ nm}$ ) with that carried by an AM radio wave photon ( $\lambda = 200 \text{ m}$ ). Calculate the energy of  $1.00 \text{ mol}$  of each type of photon. What effect do you expect each type of radiation to have for inducing chemical reactions in the substances through which it passes?
49. The maximum in Planck's formula for the emission of blackbody radiation can be shown to occur at a wavelength  $\lambda_{\text{max}} = 0.20 hc/kT$ . The radiation from the surface of the sun approximates that of a blackbody with  $\lambda_{\text{max}} = 465 \text{ nm}$ . What is the approximate surface temperature of the sun?

50. Photons of wavelength 315 nm or less are needed to eject electrons from a surface of electrically neutral cadmium.
- What is the energy barrier that electrons must overcome to leave an uncharged piece of cadmium?
  - What is the maximum kinetic energy of electrons ejected from a piece of cadmium by photons of wavelength 200 nm?
  - Suppose the electrons described in (b) were used in a diffraction experiment. What would be their wavelength?
51. When ultraviolet light of wavelength 131 nm strikes a polished nickel surface, the maximum kinetic energy of ejected electrons is measured to be  $7.04 \times 10^{-19}$  J. Calculate the work function of nickel.
52. Express the speed of the electron in the Bohr model in terms of the fundamental constants ( $m_e$ ,  $e$ ,  $h$ ,  $\epsilon_0$ ), the nuclear charge  $Z$ , and the quantum number  $n$ . Evaluate the speed of an electron in the ground states of  $\text{He}^+$  ion and  $\text{U}^{91+}$ . Compare these speeds with the speed of light  $c$ . As the speed of an object approaches the speed of light, relativistic effects become important. In which kinds of atoms do you expect relativistic effects to be greatest?
53. Photons are emitted in the Lyman series as hydrogen atoms undergo transitions from various excited states to the ground state. If ground-state  $\text{He}^+$  are present in the same gas (near stars, for example), can they absorb these photons? Explain.
54. Name a transition in  $\text{C}^{5+}$  that will lead to the absorption of green light.
55. The energies of macroscopic objects, as well as those of microscopic objects, are quantized, but the effects of the quantization are not seen because the difference in energy between adjacent states is so small. Apply Bohr's quantization of angular momentum to the revolution of Earth (mass  $6.0 \times 10^{24}$  kg), which moves with a speed of  $3.0 \times 10^4$  m s<sup>-1</sup> in a circular orbit (radius  $1.5 \times 10^{11}$  m) about the sun. The sun can be treated as fixed. Calculate the value of the quantum number  $n$  for the present state of the Earth–sun system. What would be the effect of an increase in  $n$  by 1?
56. Sound waves, like light waves, can interfere with each other, giving maximum and minimum levels of sound. Suppose a listener standing directly between two loudspeakers hears the same tone being emitted from both. This listener observes that when one of the speakers is moved 0.16 m farther away, the perceived intensity of the tone decreases from a maximum to a minimum.
- Calculate the wavelength of the sound.
  - Calculate its frequency, using  $343$  m s<sup>-1</sup> as the speed of sound.
57. (a) If the kinetic energy of an electron is known to lie between  $1.59 \times 10^{-19}$  J and  $1.61 \times 10^{-19}$  J, what is the smallest distance within which it can be known to lie? (b) Repeat the calculation of part (a) for a helium atom instead of an electron.
58. It has been suggested that spacecraft could be powered by the pressure exerted by sunlight striking a sail. The force exerted on a surface is the momentum  $p$  transferred to the surface per second. Assume that photons of 6000 Å light strike the sail perpendicularly. How many must be reflected per second by 1 cm<sup>2</sup> of surface to produce a pressure of  $10^{-6}$  atm?
59. It is interesting to speculate on the properties of a universe with different values for the fundamental constants.
- In a universe in which Planck's constant had the value  $h = 1$  J s, what would be the de Broglie wavelength of a 145-g baseball moving at a speed of  $20$  m s<sup>-1</sup>?
  - Suppose the speed of the ball from part (a) is known to lie between 19 and 21 m s<sup>-1</sup>. What is the smallest distance within which it can be known to lie?
  - Suppose that in this universe the mass of the electron is 1 g and the charge on the electron is 1 C. Calculate the Bohr radius of the hydrogen atom in this universe.
60. The normalized wave function for a particle in a one-dimensional box in which the potential energy is zero is  $\psi(x) = \sqrt{2/L} \sin(n\pi x/L)$ , where  $L$  is the length of the box (with the left wall at  $x = 0$ ). What is the probability that the particle will lie between  $x = 0$  and  $x = L/4$  if the particle is in its  $n = 2$  state?
61. A particle of mass  $m$  is placed in a three-dimensional rectangular box with edge lengths  $2L$ ,  $L$ , and  $L$ . Inside the box the potential energy is zero, and outside it is infinite; therefore, the wave function goes smoothly to zero at the sides of the box. Calculate the energies and give the quantum numbers of the ground state and the first five excited states (or sets of states of equal energy) for the particle in the box.

Fireworks above Paris; La Grande Arche is in the foreground. Many of the colors in fireworks are produced from atomic emission: red from strontium, orange from calcium, yellow from sodium, green from barium, and blue from copper. The sharp lines observed in the emission spectra of atoms can only be explained using the quantum theory of atomic structure.

The atom is the most fundamental concept in the science of chemistry. The prior chapters have given many examples of chemical reactions in which bonds between atoms in the reactants are broken, and new bonds are formed between atoms in the products. Although the Bohr model for Rutherford's planetary atom, rooted in the laws of classical physics, gives an excellent prediction for the emission and absorption spectra of one-electron atoms, it fails even for helium. Although simple electrostatics motivates why a positive  $\text{Na}^+$  ion might be drawn to form a bond with a  $\text{Cl}^-$  ion, it cannot explain why the effective potential energy between two H atoms goes down as the two atoms near each other and the electrons rearrange themselves around the two nuclei. The stability of atoms and molecules could not be explained until quantum mechanics was developed.

The goal of this chapter is to describe the structure and properties of atoms using quantum mechanics. We couple the physical insight into the atom developed in Sections 3.3, 3.4, 3.5, and 3.6 with the quantum methods of Chapter 4 to develop a quantitative description of atomic structure.

We begin with the hydrogen atom, for which the Schrödinger equation can be solved exactly because it has only one electron. The method of solving the Schrödinger equation for the hydrogen atom is the same as that used for the particle-in-a-box models in Section 4.6. Because the mathematics is more complicated, we do not show the details here, but we present the solutions in both analytic and graphical form. We obtain exact expressions for the energy levels and the wave functions. Each wave function that solves the Schrödinger equation for the H atom is called a **hydrogen atomic orbital**. The square of a wave function gives the probability per unit volume of locating the electron in a small volume located at a particular distance from the nucleus and in a given direction. This reveals the sizes and shapes of hydrogen atomic orbitals; these orbitals are the starting points for understanding multielectron atoms and covalent bonding in polyatomic molecules.

There is no exact solution for any other atom, so we must develop approximate solutions. We treat each electron in a many-electron atom as if it were moving in an *effective force field* that results from averaging its interactions with all the other electrons and the nucleus. The effective field was introduced by purely physical arguments in Section 3.4. Here, we develop this concept systematically and from it obtain approximate one-electron wave functions called **Hartree atomic orbitals** (to honor the English physicist Douglas Hartree who pioneered the method), which include the effect of all the other electrons in the atom. The shapes of the Hartree orbitals are similar to those of the hydrogen atomic orbitals, but their sizes and their energy level patterns are quite different. We use the Hartree orbitals to explain the shell model of the atom, the structure of the periodic table, and the periodic behavior of atomic properties. The result is a comprehensive, approximate quantum description of atomic structure, which serves as the starting point for the quantum description of the chemical bond in Chapter 6.

Your primary objective in this chapter should be to understand the shapes and structures of the hydrogen atomic orbitals and the Hartree orbitals from these graphical representations. You should be able to predict how the probability distribution for the electrons depends on the properties of the orbitals, as specified by their quantum numbers. Always keep in mind the distinction between the hydrogen atomic orbitals and the Hartree orbitals. The former apply only to the hydrogen atom, and the latter only to many-electron atoms. Be aware of their differences, as well as their similarities.

## 5.1 The Hydrogen Atom

The hydrogen atom is the simplest example of a one-electron atom or ion; other examples are  $\text{He}^+$ ,  $\text{Li}^{2+}$ , and other ions in which all but one electron have been stripped off. They differ only in the charge  $+Ze$  on the nucleus, and therefore in the magnitude of the attractive force experienced by the electron.

The potential energy for the one-electron atom, discussed in the context of the planetary model in Section 3.3 and of the Bohr model in Section 4.3, depends only on the distance of the electron from the nucleus; it does not depend on angular orientation (see Fig. 4.23). Solution of the Schrödinger equation is most easily carried out in coordinates that reflect the natural symmetry of the potential energy function. For an isolated one-electron atom or ion,

**FIGURE 5.1** The relationship between spherical coordinates  $(r, \theta, \phi)$  and Cartesian coordinates  $(x, y, z)$ . Here,  $\theta$  is the angle with respect to the Cartesian  $z$ -axis, which ranges from  $0$  to  $\pi$ , and  $\phi$  is the azimuthal angle (the angle between the  $x$ -axis and the projection onto the  $x$ - $y$  plane of the arrow from the origin to  $P$ ), which ranges from  $0$  to  $2\pi$ . Here,  $r$  is the distance of the electron from the nucleus at the origin, and ranges from  $0$  to  $\infty$ .

spherical coordinates are more appropriate than the more familiar Cartesian coordinates. Spherical coordinates are defined in Figure 5.1:  $r$  is the distance of the electron at  $P$  from the nucleus at  $O$ , and the angles  $\theta$  and  $\phi$  are similar to those used to locate points on the surface of the globe;  $\theta$  is related to the latitude, and  $\phi$  is related to the longitude.

The Schrödinger equation for H is similar to that in Equation 4.29, except in three dimensions. The potential energy  $V(x)$  in Equation 4.29 is replaced by the Coulomb potential  $V(r)$  given in Equation 3.1. The variable  $r$  is the distance from the nucleus to the electron, or the magnitude of the red vector  $\vec{r}$  shown in Figure 5.1. After rewriting the second derivatives in the Schrödinger equation in spherical coordinates  $(r, \theta, \phi)$ , using the relationships in the caption of Figure 5.1, the equation looks impressively complicated, but it can be solved using the method outlined in Section 4.5. The solution must be continuous in all three coordinates, and the radial portion must satisfy the boundary condition:  $\psi \rightarrow 0$  as  $r \rightarrow \infty$ . This procedure leads to quantization of the energy and to equations for the associated wave functions just as we saw with the particle-in-a-box models in Section 4.6. We describe these parts of the solution in turn in the remainder of this section.

### 5.1.1 Energy Levels

Solutions of the Schrödinger equation for the one-electron atom exist only for particular values of the energy<sup>1</sup>:

$$E = E_n = -\frac{Z^2 e^4 m_e}{8\epsilon_0^2 n^2 h^2} \quad n = 1, 2, 3, \dots \quad [5.1a]$$

In energy units of rydbergs ( $1 \text{ rydberg} = 2.18 \times 10^{-18} \text{ J}$ ), this equation becomes (see Eqs. 4.14a and 4.14b):

$$E_n = -\frac{Z^2}{n^2} \quad (\text{rydberg}) \quad n = 1, 2, 3, \dots \quad [5.1b]$$

The integer  $n$ , called the **principal quantum number**, indexes the individual energy levels. These are identical to the energy levels predicted by the Bohr theory. Quantization arises because of the physical boundary conditions imposed on the solutions to the Schrödinger equation rather than from making arbitrary assumptions about the angular momentum.

The energy of a one-electron atom depends only on the principal quantum number  $n$ , because the potential energy depends only on the radial distance. The Schrödinger equation also quantizes  $L^2$ , the square magnitude of the angular momentum, as well as  $L_z$ , the projection of the angular momentum along the  $z$ -axis. (A review of elementary aspects of angular momentum in Appendix B provides useful background for this discussion.) Quantization of the square of the angular momentum as well as its projection along the  $z$ -axis requires two additional quantum numbers. The **angular momentum quantum number**  $\ell$  may take on any integral value from  $0$  to  $n - 1$ , and the angular momentum projection quantum number  $m$  may take on any integral value from  $-\ell$  to  $\ell$ . The quantum number  $m$  is referred to as the **magnetic quantum number** because its value helps determine how the energy of the atom would shift when placed in

<sup>1</sup>Strictly speaking, the electron mass  $m_e$  in the expressions for the energy levels of one-electron atoms should be replaced by the *reduced mass*  $\mu$ , equal to  $m_e m_N / (m_e + m_N)$ , where  $m_N$  is the nuclear mass;  $\mu$  differs from  $m_e$  by less than 0.1%.

an external magnetic field. The allowed values of the square of the angular momentum  $L$  and its  $z$  projection are given by

$$\text{Allowed values of } L^2 = \ell(\ell + 1) \frac{h^2}{4\pi^2} \quad \ell = 0, 1, \dots, n - 1 \quad [5.2a]$$

$$\text{Allowed values of } L_z = m \frac{h}{2\pi} \quad m = -\ell, -\ell + 1, \dots, 0, \dots, \ell - 1, \ell \quad [5.2b]$$

For  $n = 1$  (the ground state), the only allowed values for the angular momentum quantum numbers are ( $\ell = 0, m = 0$ ). For  $n = 2$ , there are  $n^2 = 4$  allowed sets of quantum numbers:

$$(\ell = 0, m = 0), (\ell = 1, m = 1), (\ell = 1, m = 0), (\ell = 1, m = -1)$$

The restrictions on  $\ell$  and  $m$  give rise to  $n^2$  sets of quantum numbers for every value of  $n$ . Each set  $(n, \ell, m)$  identifies a specific **quantum state** of the atom in which the electron has energy equal to  $E_n$ , angular momentum equal to  $\sqrt{\ell(\ell + 1)} h/2\pi$ , and  $z$ -projection of angular momentum equal to  $mh/2\pi$ . When  $n > 1$ , a total of  $n^2$  specific quantum states correspond to the single energy level  $E_n$ ; consequently, this set of states is said to be **degenerate**.

It is conventional to label specific states by replacing the angular momentum quantum number with a letter; we signify  $\ell = 0$  with  $s$ ,  $\ell = 1$  with  $p$ ,  $\ell = 2$  with  $d$ ,  $\ell = 3$  with  $f$ ,  $\ell = 4$  with  $g$ , and on through the alphabet. Thus, a state with  $n = 1$  and  $\ell = 0$  is called a  $1s$  state, one with  $n = 3$  and  $\ell = 1$  is a  $3p$  state, one with  $n = 4$  and  $\ell = 3$  is a  $4f$  state, and so forth. The letters  $s$ ,  $p$ ,  $d$ , and  $f$  derive from early (pre-quantum mechanics) spectroscopy, in which certain spectral lines were referred to as sharp, principal, diffuse, and fundamental. These terms are not used in modern spectroscopy, but the historical labels for the values of the quantum number  $\ell$  are still followed. Table 5.1 summarizes the allowed combinations of quantum numbers.

**TABLE 5.1**

Allowed Values of Quantum Numbers for One-Electron Atoms

$n$	1		2		3		
$\ell$	0	0	1		0	1	2
$m$	0	0	-1, 0, +1		0	-1, 0, +1	-2, -1, 0, +1, +2
Number of degenerate states for each $\ell$	1	1	3		1	3	5
Number of degenerate states for each $n$	1		4			9	

### EXAMPLE 5.1

Give the names of all the orbitals with  $n = 4$ , and state how many  $m$  values correspond to each type of orbital.

#### Solution

The quantum number  $\ell$  may range from 0 to  $n - 1$ ; thus, its allowed values in this case are 0, 1, 2, and 3. The labels for the groups of orbitals are then:

$$\begin{array}{llll} \ell = 0 & 4s & \ell = 2 & 4d \\ \ell = 1 & 4p & \ell = 3 & 4f \end{array}$$

The quantum number  $m$  ranges from  $-\ell$  to  $+\ell$ ; thus, the number of  $m$  values is  $2\ell + 1$ . This gives one  $4s$  orbital, three  $4p$  orbitals, five  $4d$  orbitals, and seven  $4f$  orbitals for a total of  $16 = 4^2 = n^2$  orbitals with  $n = 4$ . They all have the same energy, but they differ in shape.

**Related Problems: 3, 4**

**FIGURE 5.2** The energy-level diagram of the H atom predicted by quantum mechanics is arranged to show the degeneracy of the energy levels. At each value of  $n$  there are  $n$  states with different values of  $\ell$ . At each value of  $\ell$  there are  $2\ell + 1$  states with different values of  $m$ . Altogether, each value of  $n$  corresponds to  $n^2$  degenerate states.

The energy levels, including the degeneracy due to  $m$  and with states labeled by the spectroscopic notation, are conventionally displayed on a diagram as shown in Figure 5.2. Compare this diagram with the energy level diagram for the hydrogen atom obtained by the Bohr model in Figure 4.24 which shows only the dependence on the principal quantum number  $n$ .

### 5.1.2 Wave Functions

For each quantum state  $(n, \ell, m)$ , solution of the Schrödinger equation provides a wave function of the form

$$\psi_{n\ell m}(r, \theta, \phi) = R_{n\ell}(r)Y_{\ell m}(\theta, \phi) \quad [5.3]$$

in which the total wave function is the product of a radial part,  $R_{n\ell}(r)$ , and an angular part,  $Y_{\ell m}(\theta, \phi)$ . This product form is a consequence of the spherically symmetric potential energy function, and it enables separate examination of the angular and radial contributions to the wave function. The functions  $Y_{\ell m}(\theta, \phi)$  are called **spherical harmonics**. They appear in many physical problems with spherical symmetry and were already well known before the advent of the Schrödinger equation. The angular motions of the electron described by  $\theta$  and  $\phi$  influence the *shape* of the wave function through the angular factor  $Y_{\ell m}$ , even though they do not influence the energy.

The wave function itself is not measured. It is to be viewed as an intermediate step toward calculating the physically significant quantity  $\psi^2$ , which is the probability density for locating the electron at a particular point in the atom. More precisely,

$$(\psi_{n\ell m})^2 dV = [R_{n\ell}(r)]^2 [Y_{\ell m}(\theta, \phi)]^2 dV \quad [5.4]$$

gives the probability of locating the electron within a small three-dimensional volume,  $dV$ , located at the position  $(r, \theta, \phi)$  when it is known that the atom is in the state  $n, \ell, m$ . Specific examples are presented in succeeding paragraphs. The volume element  $dV = dx dy dz$  (using volume = length  $\times$  width  $\times$  height) in Cartesian coordinates may be converted to spherical coordinates (see Figure 5.3) to give

$$dV = dx dy dz = r^2 \sin \theta dr d\theta d\phi \quad [5.5]$$

**FIGURE 5.3** The differential volume element in spherical polar coordinates.

A wave function  $\psi_{n\ell m}(r, \theta, \phi)$  for a one-electron atom in the state  $(n, \ell, m)$  is called an **orbital**. This term recalls the circular orbits of the Bohr atom, but there is no real resemblance. An orbital is *not* a trajectory traced by an individual electron. When the one-electron atom is in state  $(n, \ell, m)$ , it is conventional to say the electron is “in an  $(n, \ell, m)$  orbital.” This phrase is merely a shorthand way of making the precise but cumbersome statement: “When an electron has energy, total angular momentum, and  $z$  component of angular momentum values corresponding to the quantum numbers  $n, \ell, m$ , the probability density of finding the electron at the point  $(r, \theta, \phi)$  is given by  $\psi_{n\ell m}^2(r, \theta, \phi)$ .” Do not allow this verbal shorthand to mislead you into thinking an orbital is some sort of “region in space” inside which the electron is confined. The orbitals are labeled  $1s, 2s, 2p, 3s, \dots$  by the spectroscopic notation previously introduced.

Table 5.2 gives the allowed stationary states for the electron in the H atom, or any one-electron atom, obtained from solving the Schrödinger equation, where each  $\psi(r, \theta, \phi)$  is obtained by choosing a radial wave function  $R(r)$  from the right column and multiplying it by an angular wave function  $Y(\theta, \phi)$  from the left column. (But keep in mind the rules in Table 5.1; e.g., if  $n = 1$  you can

TABLE 5.2

Angular and Radial Parts of Wave Functions for One-Electron Atoms

Angular Part $Y(\theta, \phi)$	Radial Part $R_{n\ell}(r)$
$\ell = 0 \left\{ Y_s = \left( \frac{1}{4\pi} \right)^{1/2} \right.$	$R_{1s} = 2 \left( \frac{Z}{a_0} \right)^{3/2} \exp(-\sigma)$ $R_{2s} = \frac{1}{2\sqrt{2}} \left( \frac{Z}{a_0} \right)^{3/2} (2 - \sigma) \exp(-\sigma/2)$ $R_{3s} = \frac{2}{81\sqrt{3}} \left( \frac{Z}{a_0} \right)^{3/2} (27 - 18\sigma + 2\sigma^2) \exp(-\sigma/3)$
$\ell = 1 \left\{ \begin{array}{l} Y_{p_x} = \left( \frac{3}{4\pi} \right)^{1/2} \sin \theta \cos \phi \\ Y_{p_y} = \left( \frac{3}{4\pi} \right)^{1/2} \sin \theta \sin \phi \\ Y_{p_z} = \left( \frac{3}{4\pi} \right)^{1/2} \cos \theta \end{array} \right.$	$R_{2p} = \frac{1}{2\sqrt{6}} \left( \frac{Z}{a_0} \right)^{3/2} \sigma \exp(-\sigma/2)$ $R_{3p} = \frac{4}{81\sqrt{6}} \left( \frac{Z}{a_0} \right)^{3/2} (6\sigma - \sigma^2) \exp(-\sigma/3)$
$\ell = 2 \left\{ \begin{array}{l} Y_{d_{z^2}} = \left( \frac{5}{16\pi} \right)^{1/2} (3 \cos^2 \theta - 1) \\ Y_{d_{xz}} = \left( \frac{15}{4\pi} \right)^{1/2} \sin \theta \cos \theta \cos \phi \\ Y_{d_{yz}} = \left( \frac{15}{4\pi} \right)^{1/2} \sin \theta \cos \theta \sin \phi \\ Y_{d_{xy}} = \left( \frac{15}{16\pi} \right)^{1/2} \sin^2 \theta \sin 2\phi \\ Y_{d_{x^2-y^2}} = \left( \frac{15}{16\pi} \right)^{1/2} \sin^2 \theta \cos 2\phi \end{array} \right.$	$R_{3d} = \frac{4}{81\sqrt{30}} \left( \frac{Z}{a_0} \right)^{3/2} \sigma^2 \exp(-\sigma/3)$
$\sigma = \frac{Zr}{a_0} \quad a_0 = \frac{\epsilon_0 h^2}{\pi e^2 m_e} = 0.529 \times 10^{-10} \text{ m}$	

only use the  $\ell = 0$  angular function,  $Y_s$ , in Table 5.2, making the  $1s$  orbital. A  $1p$  orbital ( $n = 1, \ell = 1$ ) does not exist, since for a given  $n$ ,  $\ell$  is an integer ranging from 0 to  $n - 1$  only.) Note that each of the angular functions  $Y(\theta, \phi)$  in Table 5.2 has a specific  $\ell$  quantum number, given by the s, p, or d subscript, but the functions are linear combinations (see Section 5.1.3) of two or more of the spherical harmonics  $Y_{\ell m}$  in Equation 5.3. This results in those orbitals not having a well-defined quantum number  $m$ , but they are the familiar orbitals like  $2p_x$ ,  $2p_y$ , and  $2p_z$  commonly used in introductory texts.

The electronic wave function for an atom or molecule allows you to calculate where the negative charge density is largest; you simply multiply the charge of an electron,  $-1.6 \times 10^{-19}$  C, by the electron probability density  $\psi^2$ , where  $\psi^2$  is evaluated at a particular location in the atom or molecule. This allows you to predict the dipole moment of a molecule and the location of unpaired electron density in a molecule. For example, if you integrate the unpaired electron density of the allyl radical,  $\text{CH}_2\text{CHCH}_2$ , over a volume centered near the first carbon atom, or centered near the middle carbon atom, or centered near the third carbon atom, you find that there is a 50% probability of finding the unpaired electron near each end carbon, and 0% probability of finding unpaired electron on the center carbon atom. The example below shows you how to integrate the electron density over a small volume for an H atom in its ground electronic state, and for an H atom that has been electronically excited by absorbing a 121-nm photon polarized in the  $z$  direction. The method is similar to Example 4.7b, where we integrated  $\psi^2$  between  $x_1$  and  $x_2$  to calculate the probability of finding the electron in that range of  $x$  values. However, in three dimensions we have to integrate  $\psi^2$  (with units of  $\text{m}^{-3}$ ) over a volume with units of  $\text{m}^3$  to find the probability of finding the electron in that volume. Formally, this is the triple integral, but if you are searching for the electron in a small volume centered at a position  $\vec{r}_0 = (x_0, y_0, z_0)$ , it reduces to the following simple expression:

$$\int_V |\psi|^2 dV = \int_{z_1}^{z_2} \int_{y_1}^{y_2} \int_{x_1}^{x_2} |\psi(x, y, z)|^2 dx dy dz$$

$$\approx |\psi(x_0, y_0, z_0)|^2 \Delta x \Delta y \Delta z = |\psi(x_0, y_0, z_0)|^2 \times \text{Volume searched} \quad [5.6]$$

Here we have used the fact that as long as the numerical value of the wave function does not change much over the volume searched you can approximate the integral by treating the wave function as a constant at the value  $\psi(x_0, y_0, z_0)$ . The product  $\Delta x \Delta y \Delta z$  is simply the volume over which you are searching for the electron. Example 5.2 demonstrates how to use Equation 5.6, one that also shows how to go between Cartesian and spherical coordinates using the relations given in Figure 5.1.

### EXAMPLE 5.2

- What is the probability of finding the electron in the ground state of the H atom in a small cubical volume =  $0.5 \text{ pm}^3$  centered at a distance of 20 pm from the nucleus in the  $-y$  direction?
- If you move the volume searched closer to the nucleus, to only 10 pm from the nucleus, does the probability of finding the electron increase?
- If the electron in your H atom is in the  $2p_z$  orbital, an excited electronic state of the H atom, what is the probability now?

(Continued)

**Solution**

- (a) In Cartesian coordinates  $(x, y, z)$ , the volume is centered at  $\vec{r}_0 = (0, -20 \text{ pm}, 0)$ . The distance from the nucleus is  $r = \sqrt{x^2 + y^2 + z^2}$ , so you are searching for the electron in a volume centered at a distance of  $\sqrt{0^2 + (-20 \text{ pm})^2 + 0^2} = 20 \text{ pm}$  from the nucleus. The volume of  $0.5 \text{ pm}^3$  is very small (think of trying to trap the electron in a little cage with length = width = height =  $\sqrt[3]{0.5 \text{ pm}^3} = 0.79 \text{ pm}$ , so the value of  $\psi$  is roughly constant in the entire volume searched. The approximation in Equation 5.6 is thus good, so the probability =  $|\psi(x_0, y_0, z_0)|^2 \times \text{Volume searched}$ , =  $|\psi(x_0, y_0, z_0)|^2 \times 0.5 \text{ pm}^3$ . To calculate  $\psi^2$ , note that ground state H atoms have the lowest energy, so  $n = 1$ . The electron is thus in the 1s orbital ( $n = 1, \ell = 0$ ) with  $\psi = R_{1s}(r)Y_s$ . Using these functions from Table 5.2 with  $Z = 1$  gives, at  $r = 20 \text{ pm}$ ,

$$\psi = 2 \left( \frac{1}{52.9 \text{ pm}} \right)^3 e^{-\frac{20 \text{ pm}}{52.9 \text{ pm}}} \sqrt{\frac{1}{4\pi}} = 0.0010 \text{ pm}^{-3/2}$$

Squaring this and multiplying by the volume searched gives the probability of finding the electron =  $(0.0000010 \text{ pm}^{-3})(0.5 \text{ pm}^3) = 5 \times 10^{-7}$ .

- (b) There is a higher probability of finding the electron in the same size volume but closer to the nucleus, because  $\psi^2$  is larger at  $r = 10 \text{ pm}$ .
- (c) If the electron is in the  $2p_z$  orbital, the wave function  $R(r)Y(\theta, \phi)$  has angular part  $Y(\theta, \phi) = (3/4\pi)^{1/2}\cos\theta$ . To evaluate this, note that the volume is in which you are searching for the electron is centered at  $\vec{r}_0 = (0, -20 \text{ pm}, 0)$ . So the corresponding red vector in Figure 5.1 would be pointing from the origin to this point, in the negative  $y$  direction. Any point in the  $x$ - $y$  plane is at an angle of 90 degrees =  $\pi/2$  from the  $z$ -axis, so  $\theta = \pi/2$ . To point over in the negative  $y$  direction, the  $\phi$  angle must be  $3\pi/2$ . (In the spherical coordinates defined in Figure 5.1, the range of  $\theta$  is 0 to  $\pi$  and the range of  $\phi$  is 0 to  $2\pi$ , so that you don't double count any points in space.) Thus the angular part of the wave function at  $\theta = \pi/2$  is  $(3/4\pi)^{1/2}\cos(\pi/2) = 0$ . This is a node in the wave function (indeed  $\psi = 0$  in the entire  $xy$  plane), so the probability of finding the electron near  $\vec{r}_0 = (0, -20 \text{ pm}, 0)$  is approximately 0; the  $2p_z$  wave function is 0 at the center of the volume searched and the volume searched is small.

**Related Problems: 5, 6**

### 5.1.3 Sizes and Shapes of Orbitals

The sizes and shapes of the hydrogen atom orbitals are important in chemistry because they provide the foundations for the quantum description of chemical bonding and the molecular shapes to which it leads. Sizes and shapes of the orbitals are revealed by graphical analysis of the wave functions, of which the first few are given in Table 5.2. Note that the radial functions are written in terms of the dimensionless variable  $\sigma$ , which is the ratio of  $Zr$  to  $a_0$ , the Bohr radius (Eq. 4.12). For  $Z = 1$ ,  $\sigma = 1$  at the radius of the first Bohr orbit of the hydrogen atom.

Graphical representation of the orbitals requires some care. Equation 5.3 tells us simply to go to the point  $(r, \theta, \phi)$ , evaluate the wave function there, and draw a graph showing the results of visiting many such points. But all three spatial dimensions have already been used to define the location; thus we would need a fourth dimension to display the value of the wave function at that point. Alternatively, we could create a table of numbers giving the value of the wave function at each point  $(r, \theta, \phi)$ , but it would be difficult to develop intuition about shapes and structures from this table.

One way we get around these problems is by slicing up three-dimensional space into various two- and one-dimensional regions and examining the value

**FIGURE 5.4** Representations of the hydrogen 1s orbital for points in the  $x$ - $y$  plane. (a) The value of the orbital at each point in the  $x$ - $y$  plane (where  $\theta = 0$ , see Fig. 5.1) is plotted above the point. (b) Slices through the image in (a) define contours of the image in the  $x$ - $y$  plane.

**FIGURE 5.5** Plot of the hydrogen 1s orbital against distance from the nucleus. The distance is measured in units of the Bohr radius  $a_0$ .

of the wave function at each point in these regions. This means we look at the wave function when the motion of the electron is restricted to the specific regions we select. For example, suppose in Figure 5.1 we look only at points in the  $x$ - $y$  plane and evaluate the wave function at each point and plot this value as a third dimension above the  $x$ - $y$  plane. We obtain a mountain-like shape above the plane. Figure 5.4a shows this result for the 1s orbital,  $\psi_{100}(r, \theta, \phi)$ . Figure 5.4b shows this function as a contour plot in the  $x$ - $y$  plane, generated by choosing a particular value of the wave function in Figure 5.4a, “slicing” its three-dimensional image perpendicular to the  $z$ -axis at that value, and projecting each point on the edge of that slice down to the  $x$ - $y$  plane to form a closed contour in that plane. The contour then defines all points in the  $x$ - $y$  plane for which  $\psi_{100}(r, \theta, \phi)$  has the particular value selected. The process is continued by selecting other values of  $\psi_{100}(r, \theta, \phi)$  until the entire three-dimensional image has been collapsed into a set of concentric contours in the two-dimensional  $x$ - $y$  plane. Mountain climbers throughout the world use this method to generate contour maps of mountain ranges. The outermost contour in Fig. 5.4b identifies points at which the wave function has 10% of its maximum value. The second contour identifies points with 30% of the maximum value, and so on to the innermost contour that identifies points with 90% of the maximum value. Note that these contours, which correspond to uniform increases in the value of  $\psi$ , become much closer together as we approach the origin of the coordinates. This indicates that the value of the wave function is increasing rapidly as the electron gets closer to the proton. The contours are circles because  $\psi_{100}(r, \theta, \phi)$  does not depend on the angles, as we see from its defining equation. We can generate contour maps in any other “cut planes” in the same way. We rely on contour plots to display the angular shapes of wave functions. As we examine other orbitals that do have angular dependence, the contours will no longer be circular. Displaying the contours in different “cut planes” gives great insight into the shapes of such orbitals, and we exploit that technique throughout the chapter.

A second approach is to look only at the radial behavior. We start at the origin in Figure 5.1 and move out along the specific direction  $(r, \theta, \phi)$ , holding  $(\theta, \phi)$  constant, and plot the wave function calculated from Table 5.2 at each value of  $r$ . Figure 5.5 shows the result for the 1s orbital. This image is a “vertical slice” through the plot shown in Figure 5.4a. The radial behavior of  $\psi_{100}(r, \theta, \phi)$  is an exponential decrease as  $r$  increases, as shown by its defining equation. We rely on such two-dimensional graphs of the wave function versus  $r$  to display radial behavior of each of the hydrogen orbitals.

We use the same techniques to generate graphical representations of  $(\psi_{n\ell m})^2$ , where,  $|\psi_{n\ell m}|^2 dV$  is the probability of finding the electron in a small volume element  $dV$  (see Eq. 5.4). The electron density for the 1s orbital is spherical, because the wave function does not depend on the angles, and its contours in the  $x$ - $y$  plane are circles. The radial dependence of  $(\psi_{100})^2$  is shown in Figure 5.6.a. We can combine the radial dependence and the contours to generate a three-dimensional image of the electron density by heavily shading the regions where  $\psi^2$  is largest and lightly shading the regions where  $\psi^2$  is smallest. Figure 5.6b shows a cross-section of this three-dimensional image in the  $x$ - $y$  plane.

In the remainder of this section we use the methods just described to examine systematically the shapes of the hydrogen orbitals and the probability densities they define. Images that combine these angular and radial effects display size and shape in three-dimensional space. We always state the conditions and limitations of such three-dimensional images. Because three dimensions have already been used up to specify the location of the electron, the appearance of the wave function in three-dimensional representations depends strongly on choices made by the illustrator. Be certain you understand these choices in each image you examine (or create!).

**FIGURE 5.6** Representations of the probability density for the hydrogen 1s orbital. (a) Plot of  $[\psi_{100}(r)]^2$  against distance from the nucleus. A contour map (not shown here) can be generated in the  $x$ - $y$  plane just as in Figure 5.4. (b) In three dimensions the probability density can be represented by varying the intensity of a color. The color is most intense where the probability is highest. A sphere drawn around the nucleus with radius of  $4.2 a_0$  will enclose 99% of the probability density.

### s Orbitals

Let's begin with the **s orbital**, corresponding to  $\psi_{n\ell m}$  with  $\ell = 0$  (therefore,  $m = 0$  as well). For all s orbitals, the angular part  $Y$  is a constant (see Table 5.2). Because  $\psi$  does not depend on either  $\theta$  or  $\phi$ , all s orbitals are spherically symmetric about the nucleus. This means that the value of the wave function for an s orbital (and therefore also the probability of finding the electron near some point in space) depends only on its distance,  $r$ , from the nucleus and not on its direction in space. There are several ways to visualize the  $ns$  orbitals with  $n = 1, 2, 3, \dots$ , and the probability density they describe.

Figure 5.7 displays the relationships between the radial dependence of  $\psi$  and  $\psi^2$  and the electron density representation for the 1s, 2s, and 3s orbitals. These schematic images display key features of these functions, but the radial dependence shown is not quantitative. The 2s and 3s orbitals have nodes, values of  $r$  at which the value of the wave function is 0, with lobes of positive phase and negative phase separated by the nodes. See Figure 5.7b. This behavior is contained in their equations in Table 5.2. The radial function  $R_{2s}$  has a node where  $\sigma = 2$  which corresponds to  $r = 2a_0$ . The function  $R_{3s}$  has a node where  $27 - 18\sigma + 2\sigma^2 = 0$  which occurs at  $r = 1.9a_0$  and  $r = 7.1a_0$ . Figure 5.7c shows that  $\psi^2$  passes through a local maximum value after  $r$  crosses each node, and then continues to fall off after the final node as  $r$  approaches very large values. From this behavior we generate the electron density representations in Figure 5.7a, in which the intensity of shading indicates the magnitude of the electron density in each region. The shading will be greatest at the local maximum values in  $\psi^2$  and must fade to white at the nodes.

Having established the key features of these orbitals and their probability functions, we examine them once more to demonstrate *quantitatively* their dependence on  $r$ . Quantitative information is essential for comparing behavior of these three orbitals in chemical applications. Figure 5.8 compares various representations of the 1s, 2s, and 3s orbitals all on the same length scale. Figure 5.8a shows contour plots for these three orbitals in the  $x$ - $y$  plane. The contours are circles because the wave functions do not depend on the angles. In each plot, the outermost contour identifies points at which the amplitude of  $\psi$  is 5% of its maximum value. The second circle identifies points with  $\psi$  at 10% of the maximum, and so on in steps of 20% to the innermost contour, which identifies points with  $\psi$  at 90% of the maximum. Contours with positive phase (positive sign for the wave function) are shown in red, whereas negative phase (negative

**FIGURE 5.7** Qualitative representations of hydrogen  $s$  orbitals. (a) An electron probability density representation of a hydrogen atom in its  $1s$ ,  $2s$ , and  $3s$  states. The spheres are cut off at a radius that encloses 90% of the probability density. (b) The radial wave functions plotted against distance from the nucleus,  $r$ . (c) Dependence of the probability density on the distance from the nucleus, given by the square of the wave function (prior to integrating over a thin spherical shell a distance  $r$  from the nucleus).

sign for the wave function) is represented in blue. Note that these contours, which identify uniform increases in magnitude, become much closer together as we approach the origin. The numerical value of the wave function increases rapidly as we approach the nucleus. The  $x$ - $y$  plane corresponds to  $\theta = \pi/2$  in Figure 5.1. Because the wave function does not depend on angles, this same contour plot could be obtained by tilting the  $x$ - $y$  plane to any value of  $\theta$ . It could also be obtained by starting with the  $x$ - $z$  plane and the  $y$ - $z$  plane and tilting either of them to any value of  $\theta$ . Therefore, we can rotate the contour plot in Figure 5.8a to generate a set of concentric spheres in three dimensions. Each sphere identifies a surface of points in  $(r, \theta, \phi)$  at each of which the wave function has the same value. These spheres (not shown here) are called *isosurfaces*.

Figure 5.8b shows the radial portions of the  $1s$ ,  $2s$ , and  $3s$  wave functions  $\psi_{n00} \propto R_{n0}(r)$  directly. These curves quantitatively represent how  $\psi$  changes as a function of the distance from the nucleus and identify the locations of the nodes.

Figure 5.8c plots the **radial probability density**  $r^2[R_{n0}(r)]^2$ , which we introduce here for the first time. This is the probability density of finding the electron at any point in space at a distance  $r$  from the nucleus, after integrating over all angles  $\theta$  and  $\phi$ . More precisely, the product  $r^2[R_{n0}(r)]^2 dr$  gives the probability of finding the electron anywhere within a thin spherical shell of thickness  $dr$ , located at distance  $r$  from the nucleus. This spherical shell is easily visualized with the aid of Figure 5.3. As the angle  $\phi$  runs through its entire range from 0 to  $2\pi$ , a circular annulus of width  $dr$  located between  $r$  and  $r + dr$  is traced out in the  $x$ - $y$  plane. This annulus will become a spherical shell as the angle  $\theta$  runs through its range from 0 to  $\pi$ . The factor  $r^2$  in front accounts for the increasing volume of spherical shells at greater distances from the nucleus. The radial probability distribution is small near the nucleus, where the shell volume (proportional to  $r^2$ ) is small, and reaches its maximum value at the distance where

**FIGURE 5.8** Three quantitative representations of hydrogen  $s$  orbitals. (a) A contour plot of the radial part of the wave function for a hydrogen atom in its  $1s$ ,  $2s$ , and  $3s$  states. (For the  $1s$  orbital, we have omitted the  $+0.9$  contour for clarity; for the  $2s$  and  $3s$  orbitals, we have omitted some contours near  $r = 0$  and near the nodes for clarity.) The contours identify points at which  $\psi$  takes on  $\pm 0.05$ ,  $\pm 0.1$ ,  $\pm 0.3$ ,  $\pm 0.5$ ,  $\pm 0.7$ , and  $\pm 0.9$  of its maximum value. Contours with positive phase are shown in red; those with negative phase are shown in blue. Nodal contours, where the amplitude of the wave function is zero, are shown in black. They are connected to the nodes in the lower plots by the vertical green lines. (b) The radial part of the wave functions plotted against distance from the nucleus,  $r$ . (c) The radial probability density, equal to the square of the radial part of the wave function multiplied by  $r^2$ . We have divided the function  $r^2R^2$  by its maximum value,  $(r^2R^2)_{\max}$ , to rescale the peaks to 1 on the vertical axis. Undo that to recover the properly normalized probability densities.  $(r^2R_{10}^2)_{\max} = 1.0233 \text{ \AA}^{-1}$ ,  $(r^2R_{20}^2)_{\max} = 0.361 \text{ \AA}^{-1}$ , and  $(r^2R_{30}^2)_{\max} = 0.192 \text{ \AA}^{-1}$ .

the electron is most likely to be found. This maximum arises from two contributions. The probability density for finding the electron at a specific location decreases as we move out from the nucleus (see Fig. 5.8b). But the volume of the spherical shell inside which we are adding up probability density increases as  $r$  increases. These two competing contributions determine the maximum in the radial probability function at some distance out from the nucleus.

Finally, we want to describe the size of the orbital. What is meant by the *size* of an orbital? Strictly speaking, the wave function of an electron in an atom stretches out to infinity, so an atom has no clear boundary. We define the size of

an atom as the extent of a “balloon skin” inside which 90% of the probability density of the electron is contained. Calculations show that spheres containing 90% of the probability density for an electron in the 1s, 2s, and 3s orbitals of the hydrogen atom have radii equal to 1.41 Å, 4.83 Å, and 10.29 Å, respectively. These results show that the size of an orbital increases with increasing quantum number  $n$ . A 3s orbital is larger than a 2s orbital, which, in turn, is larger than a 1s orbital. This is the quantum analog of the increase in radius of the Bohr orbits with increasing  $n$ .

Let’s see how to verify, using the functions plotted in Figure 5.8c, that when you integrate all the 2s orbital’s electron density over a sphere of radius 4.83 Å, that it encloses 90% of the electron density. You might be wondering why the function plotted in Figure 5.8c does not have the angular part of the wave function  $Y_s(\theta, \phi) = (1/(4\pi))^{1/2}$  in it. This is easy to see from a combination of Equations 5.5 and 5.6, replacing  $dV$  by  $r^2 \sin\theta dr d\theta d\phi$  instead of  $dx dy dz$ . Because you are now looking for the electron at all values of  $\theta$  and  $\phi$ , you integrate from  $\phi = 0$  to  $2\pi$  and from  $\theta = 0$  to  $\pi$  as  $r$  ranges from 0 to 4.83 Å. This gives

$$\begin{aligned} \int_V |\psi_{2s}|^2 dV &= \int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi} \int_{r=0}^{4.83\text{Å}} |R_{2s}(r)Y_s(\theta, \phi)|^2 r^2 \sin\theta dr d\theta d\phi \\ &= \int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi} \frac{1}{4\pi} \sin\theta d\theta d\phi \left[ \int_{r=0}^{4.83\text{Å}} |R_{2s}(r)|^2 r^2 dr \right] \quad [5.7] \\ &= (2\pi)(2) \left( \frac{1}{4\pi} \right) \left[ \int_{r=0}^{4.83\text{Å}} |R_{2s}(r)|^2 r^2 dr \right] \\ &= \int_{r=0}^{4.83\text{Å}} |R_{2s}(r)|^2 r^2 dr \end{aligned}$$

So all you need to do is to integrate the function  $r^2|R_{2s}(r)|^2$ , or estimate the area under the curve in Figure 5.8c from  $r = 0$  to  $r = 4.83$  Å. (You’ll need to multiply the numbers on the vertical axis by  $0.361 \text{ Å}^{-1}$  because the figure plots a rescaled function  $(r^2 R_{2s}^2)/(r^2 R_{2s}^2)_{\text{max}}$ .) This gives the integral as 0.90, or 90%. (Note that all of the  $Y(\theta, \phi)$  functions in Table 5.2 have constants in them, which ensures that the integral of  $|Y(\theta, \phi)|^2 \sin\theta d\theta d\phi$ , from  $\phi = 0$  to  $2\pi$  and  $\theta = 0$  to  $\pi$ , equals 1.)

### EXAMPLE 5.3

What is the probability of finding the electron in the ground state of the H atom closer to the nucleus than  $r = a_0 = 0.529$  Å? Compare this with the probability of finding the electron in the ground state of the  $\text{He}^+$  closer to the nucleus than  $r = a_0 = 0.529$  Å.

#### Solution

Using the result of Equation 5.7, the probability is

$$\int_V |\psi_{1s}|^2 dV = \int_{r=0}^{r=a_0} |R_{1s}(r)|^2 r^2 dr$$

For the H atom,

$$R_{1s} = 2 \left( \frac{1}{0.529 \text{ Å}} \right)^{3/2} e^{-\frac{r}{0.529 \text{ Å}}}$$

Substituting this into the integral gives

$$\int_{r=0}^{r=0.529 \text{ Å}} 4 \left( \frac{1}{0.529 \text{ Å}} \right)^3 e^{-\frac{2r}{0.529 \text{ Å}}} r^2 dr = 0.32 = 32\%$$

(Use an integrator app or a table of integrals to evaluate this. Alternatively try integrating by parts, or estimating the area under the curve in Figure 5.8c, but remember to rescale the values on the vertical axis with the  $(r^2 R^2)_{\text{max}}$  given in the figure caption.)

For the  $\text{He}^+$  ion,

$$R_{1s} = 2 \left( \frac{2}{0.529 \text{ Å}} \right)^{3/2} e^{-\frac{2r}{0.529 \text{ Å}}}$$

(Continued)

Substituting this into the integral gives

$$\int_{r=0}^{r=0.529 \text{ \AA}} 4 \left( \frac{2}{0.529 \text{ \AA}} \right)^3 e^{-\frac{4r}{0.529 \text{ \AA}}} r^2 dr = 0.76 = 76\%$$

The higher nuclear charge draws the 1s electron closer to the nucleus, so there is a higher probability of finding it within a distance of 0.529 Å from the nucleus.

**Related Problem: 48**

Another measure of the size of an orbital is the most probable distance of the electron from the nucleus in that orbital. Figure 5.8c shows that the most probable location of the electron is progressively farther from the nucleus in  $ns$  orbitals for larger  $n$ . Nonetheless, there is a finite probability density for finding the electron at the nucleus in both 2s and 3s orbitals. This happens because electrons in  $s$  orbitals have no angular momentum ( $\ell = 0$ ), and thus can approach the nucleus along the radial direction. The ability of electrons in  $s$  orbitals to “penetrate” close to the nucleus has important consequences in the structure of many-electron atoms and molecules (see later).

Finally, note that an  $ns$  orbital has  $n - 1$  radial nodes; a **radial node** is a spherical surface about the nucleus on which  $\psi$  and  $\psi^2$  are 0. These spherical surfaces are the analogues of the nodal planes in the wave functions for a particle in a cubic box (Fig. 4.43). The more numerous the nodes in an orbital, the higher the energy of the corresponding quantum state of the atom. Just as for the particle in a box, the energies of orbitals increase as the number of nodes increases.

### p Orbitals

Orbitals with angular quantum numbers different from 0 are not spherically symmetric. Interesting angular effects arise from the quantization of angular momentum. The angular wave function  $Y_{\ell m}(\theta, \phi)$  has separate lobes with positive and negative phase, with a node between them. Equation 5.2b specifies  $2\ell + 1$  projections of these angular momentum values along the  $z$ -axis. The three angular wave functions with  $\ell = 1$ , for which the allowed  $m$  values are  $-1, 0$ , and  $+1$ , lead to three orbitals (each called a **p orbital**) with the same shapes but different orientations in space.

The angular wave function  $Y_{10}(\theta, \phi)$  with the combination  $\ell = 1, m = 0$  is called the angular portion of the  $p_z$  orbital here because it is oriented along the  $z$ -axis. The wave function  $Y_{p_z}$  for the  $p_z$  orbital (see Table 5.2) is proportional to  $\cos \theta$ . From the relation between spherical and Cartesian coordinates illustrated in Figure 5.1, you can see that  $\cos \theta \propto z$ ; thus, the maximum probability density for this orbital (Figure 5.9b) is along the  $z$ -axis (where  $\theta = 0$  or  $\pi$ ). There is a node in the  $x$ - $y$  plane (where  $\theta = \pi/2$ , so  $\cos \theta = 0$ ) (Fig. 5.9a). This nodal plane is called an **angular node**; the wave function changes sign across it. The  $p_z$  orbital therefore points along the  $z$ -axis, with its positive phase (red in Fig. 5.9a) on the side of the  $x$ - $y$  plane where the  $z$ -axis is positive and negative phase (blue in Fig. 5.9a) on the side where the  $z$ -axis is negative.

The angular wave functions  $Y_{11}(\theta, \phi)$  for  $\ell = 1, m = 1$  and  $Y_{1,-1}(\theta, \phi)$  for  $\ell = 1, m = -1$  do not have a simple geometrical interpretation. However, their sum and their difference, which are also allowed solutions of the Schrödinger equation for the hydrogen atom, do have simple interpretations. Therefore, we form two new angular wave functions:

$$\begin{aligned} Y_{p_x} &= c_1(Y_{11} + Y_{1,-1}) \\ Y_{p_y} &= c_2(Y_{11} - Y_{1,-1}) \end{aligned} \quad [5.8]$$

where  $c_1$  and  $c_2$  are appropriate constants. The resulting expressions for  $Y_{p_x}$  and  $Y_{p_y}$  are given in Table 5.2. A comparison of these expressions with Figure 5.1 shows that  $Y_{p_x}$  lies along the  $x$ -axis and  $Y_{p_y}$  lies along the  $y$ -axis, but otherwise

**FIGURE 5.9** Two aspects of hydrogen  $p$  orbitals. (a) The angular wave function for the  $p_z$  orbital. The  $p_x$  and  $p_y$  orbitals are the same, but are oriented along the  $x$ - and  $y$ -axis, respectively. (b) The square of the angular wave function for the  $p_z$  orbital. Results for the  $p_x$  and  $p_y$  orbitals are the same, but are oriented along the  $x$ - and  $y$ -axis, respectively.

**FIGURE 5.10** Radial wave functions  $R_{n\ell}$  for  $np$  orbitals and the corresponding radial probability densities  $r^2 R_{n\ell}^2$ .

have the same shape as  $Y_{p_z}$ . They have nodes at the  $y$ - $z$  and  $x$ - $z$  planes, respectively.

The radial parts of the  $np$  wave functions (represented by  $R_{n\ell}$ ) are illustrated in Figure 5.10. The  $p$  orbitals, like the  $s$  orbitals, may have radial nodes, at which the probability density vanishes at certain distances from the nucleus regardless of direction. From Figure 5.10, the  $R_{21}$  wave function has no radial nodes, and the  $R_{31}$  function has one radial node; the  $R_{41}$  (not shown) function has two radial nodes. The  $R_{n\ell}$  wave functions have  $n - \ell - 1$  radial nodes. Because the angular part of the  $np$  wave function always has a nodal plane, the total wave function has  $n - 1$  nodes ( $n - 2$  radial and 1 angular), which is the same number as an  $s$  orbital with the same principal quantum number. The  $R_{21}(r)$  function (that is,  $R_{2p}$ ) in Table 5.2 contains the factor  $\sigma$ , which is proportional to  $r$  ( $\sigma = Zr/a_0$ ) and causes it to vanish at the nucleus. This is true of all the radial wave functions except the  $ns$  functions, and it means that the probability density is zero for the electron to be at the nucleus for all wave functions with  $\ell > 0$  ( $p$ ,  $d$ ,  $f$ , ...). Physically, electrons with angular momentum are moving around the nucleus, not toward it, and cannot “penetrate” toward the nucleus.

Finally, we combine the angular and radial dependence to get a sense of the shape of the complete orbital,  $\psi_{n\ell m} = R_{n\ell} Y_{\ell m}$ . Let’s examine the  $2p_z$  orbital at points  $(r, \theta, \phi)$  confined to the  $x$ - $z$  plane. At each point, we calculate the value of  $R_{21}$  (as in Fig. 5.10) and the value of  $Y_{2p_z}$  (as in Fig. 5.9a). Then we multiply these values together to obtain the value of  $\psi_{2p_z}$  at that point. We continue this process and generate a contour plot for  $\psi_{2p_z}$  in the  $x$ - $z$  plane. The results are shown in Figure 5.11. Contours identify points at which  $\psi_{2p_z}$  takes on  $\pm 0.1, \pm 0.2, \pm 0.3, \pm 0.4, \pm 0.5, \pm 0.6, \pm 0.7, \pm 0.8, \pm 0.9$  of its maximum value. Contours with positive phase are shown in red; blue contours represent negative phase. The radial wave function from Figure 5.10 has dramatically changed the circular angular wave function from Figure 5.9a. The contours are not concentric, but rather bunch together on the sides nearest the  $x$ - $y$  plane. This reflects

**FIGURE 5.11** Contour plot of  $\psi$  for the  $2p_z$  orbital for the hydrogen atom. This plot lies in the  $x$ - $z$  plane. The  $z$ -axis (not shown) would be vertical in this figure, and the  $x$ -axis (not shown) would be horizontal. The lobe with positive phase is shown in red, and the lobe with negative phase in blue. The  $x$ - $y$  nodal plane is shown as a dashed black line. Compare with Figure 5.9a.

the rapid decrease in the absolute value of the wave function near the nucleus (see Fig. 5.10) and the much slower decrease at longer distances beyond the maximum in the radial function.

Finally, we can represent the  $2p_z$  orbital as a three-dimensional object by rotating Figure 5.11 about the  $z$ -axis. Each of the closed contours in Figure 5.11 will then trace out a three-dimensional isosurface on which all the points  $(r, \theta, \phi)$  have the same amplitude and phase of the wave function. The same analysis generates isosurfaces for  $2p_x$  and  $2p_y$ . Figures 5.12a, b, and c show plots of all three, with the phases and nodal planes indicated, as isosurfaces at  $\pm 0.2$  times the maximum amplitude. Each  $2p$  orbital appears, loosely speaking, as a pair of flattened and distorted spheres, with opposite phase, facing each other across their nodal plane.

### **d Orbitals**

When  $\ell = 2$  Equation 5.2b specifies five projections of the angular momentum along the  $z$ -axis. As with the  $p$  orbitals, we take linear combinations of the angular wave functions to obtain orbitals with specific orientations relative to the Cartesian axes. The conventionally chosen linear combinations of the solutions with  $m = -2, -1, +1, +2$  give four orbitals (the **d orbitals**) with the same shape but different orientations with respect to the Cartesian axes:  $d_{xy}$ ,  $d_{yz}$ ,  $d_{xz}$ , and  $d_{x^2-y^2}$  (Fig. 5.13).

For example, a  $d_{xy}$  orbital (see Fig. 5.13a) has four lobes, two with positive phase and two with negative phase; the maximum amplitude is at  $45^\circ$  to the  $x$ - and  $y$ -axes. The  $d_{x^2-y^2}$  orbital has maximum amplitude along the  $x$ - and  $y$ -axes. The “down-axis” view of these four  $d$  orbitals, illustrated for one of them ( $d_{xy}$ ) in Figure 5.13f, shows that they all have the same shape when viewed down the appropriate axis. The fifth orbital,  $d_{z^2}$ , which corresponds to  $m = 0$ , has a different shape from the rest, with maximum amplitude along the  $z$ -axis and a little “doughnut” in the  $x$ - $y$  plane. Each  $d$  orbital has two angular nodes (for example, the  $d_{xy}$  orbital has the  $x$ - $z$  and  $y$ - $z$  planes as its nodal surfaces). The radial functions,  $R_{n2}(r)$ , have  $n - 3$  radial nodes, giving once again  $n - 1$  total nodes.

The wave functions for  $f$  orbitals and orbitals of higher  $\ell$  can be calculated, but they play a smaller role in chemistry than do the  $s$ ,  $p$ , and  $d$  orbitals.

**FIGURE 5.12** The shapes of the three  $2p$  orbitals, with phases and nodal planes indicated. The isosurfaces in (a), (b), and (c) identify points where value of each wave function is  $\pm 0.2$  of its maximum value. (a)  $2p_z$  orbital. (b)  $2p_x$  orbital. (c)  $2p_y$  orbital.

**FIGURE 5.13** The shapes of the five 3d orbitals, with phases and nodal surfaces indicated. The “down-axis” view shows the shapes of the first four orbitals (a)–(d) when viewed down the appropriate axis; the specific example shown here is the  $d_{xy}$  orbital viewed down the z-axis.

We summarize the important features of orbital shapes and sizes as follows:

1. For a given value of  $\ell$ , an increase in  $n$  leads to an increase in the average distance of the electron from the nucleus, and therefore in the size of the orbital (see Figs. 5.8 and 5.10).
2. An orbital with quantum numbers  $n$  and  $\ell$  has  $\ell$  angular nodes and  $n - \ell - 1$  radial nodes, giving a total of  $n - 1$  nodes. An angular node appears as a nodal plane in plots of  $p$  orbitals. The value of the radial or angular part of the wave function changes sign as you cross a radial or angular node respectively. For a one-electron atom or ion, the energy depends only on the number of nodes—that is, on  $n$  but not on  $\ell$  or  $m$ . The energy increases as the number of nodes increases.
3. As  $r$  approaches 0,  $\psi(r, \theta, \phi)$  vanishes for all orbitals except  $s$  orbitals; thus, only an electron in an  $s$  orbital can “penetrate to the nucleus,” that is, have a finite probability density right at the nucleus.

The next section shows that these general statements are important for determining the electronic structure of many-electron atoms even though they are deduced from the one-electron case.

The characteristics of the orbitals of a one-electron atom (or ion) are especially well displayed by a quantitative plot showing  $s$ ,  $p$ , and  $d$  orbitals all on the same scale (Fig. 5.14). The best quantitative measure of the size of an orbital is  $\bar{r}_{n\ell}$ , the average value of the distance of the electron from the nucleus in that orbital. Quantum mechanics calculates  $\bar{r}_{n\ell}$  as

$$\bar{r}_{n\ell} = \frac{n^2 a_0}{Z} \left\{ 1 + \frac{1}{2} \left[ 1 - \frac{\ell(\ell+1)}{n^2} \right] \right\} \quad [5.9]$$

**FIGURE 5.14** Dependence of radial probability densities on distance from the nucleus for one-electron orbitals with  $n = 1, 2, 3$ . The small arrow above each curve locates the value of  $\bar{r}_{n\ell}$  for that orbital. The distance axis is expressed in the same dimensionless variable introduced in Table 5.1. The value 1 on this axis is the first Bohr radius for the hydrogen atom. Because the radial probability density has dimensions  $(\text{length})^{-1}$ , the calculated values of  $r^2[R_{n\ell}(r)]^2$  are divided by  $(a_0)^{-1}$  to give a dimensionless variable for the probability density axis. (Adapted from Eisberg, R. *Fundamentals of Modern Physics*, page 306, Figure 10-2, Wiley, 1961.)

The leading term of this expression is the radius of the  $n$ th Bohr orbit (see Eq. 4.12). In Figure 5.14, the small arrow on each curve locates the value of  $\bar{r}_{n\ell}$  for that orbital.

### EXAMPLE 5.4

Compare the  $3p$  and  $4d$  orbitals of a hydrogen atom with respect to the (a) number of radial and angular nodes and (b) energy of the corresponding atom.

#### Solution

(a) The  $3p$  orbital has a total of  $n - 1 = 3 - 1 = 2$  nodes. Of these, one is angular ( $\ell = 1$ ) and one is radial. The  $4d$  orbital has  $4 - 1 = 3$  nodes. Of these, two are angular ( $\ell = 2$ ) and one is radial.

(b) The energy of a one-electron atom depends only on  $n$ . The energy of an atom with an electron in a  $4d$  orbital is higher than that of an atom with an electron in a  $3p$  orbital, because  $4 > 3$ .

**Related Problems: 7, 8**

## 5.1.4 Electron Spin

If a beam of hydrogen atoms in their ground state (with  $n = 1$ ,  $\ell = 0$ ,  $m = 0$ ) is sent through a magnetic field whose intensity increases in the plane perpendicular to the flight of the beam, it splits into two beams, each containing half of the atoms (Fig. 5.15). The pioneering experiment of this type is called the Stern–Gerlach experiment after the German physicists who performed it, Otto Stern and Walther Gerlach.

Recall that a magnet, unlike a single electric charge, has two poles, and that a magnetic dipole moment can be used to describe the interactions of a magnet with a magnetic field in the same way that an electric dipole moment is used to describe the interaction of a pair of charges with an electric field. You may recall from classical physics (or your own experience) that a small bar magnet will rotate to orient itself in the presence of an external magnetic field. If the magnetic field changes strength along a particular direction, then a force will be exerted on the bar magnet that will cause it to *move* in the direction of the changing field, and not just rotate to a new direction. If the magnetic dipole moments of the hydrogen atoms were randomly oriented in space (as predicted by classical physics), then the beam would be smeared out at the detector to reflect all possible orientations of the magnetic moment. That the original beam is split into only two well-defined beams in this experiment demonstrates the unexpected fact that the *orientation* of the magnetic moment of the electron is quantized. The result of this experiment is explained by introducing a *fourth* quantum number,  $m_s$ , which can take on two values, conventionally chosen to

**FIGURE 5.15** A beam of hydrogen atoms is split into two beams when it traverses a magnetic field, the value of which is not constant in the plane perpendicular to the path of the beam. The nonconstant field is created by the specially shaped cross section of the north and south poles of the magnet in the  $z$ - $y$  plane. The green curved lines trace the pattern over which the field is varied. Regions where the green lines are closer together are regions of greater magnetic field. Atoms with spin quantum number  $m_s = +\frac{1}{2}$  follow one trajectory, and those with  $m_s = -\frac{1}{2}$  follow another.

be  $+\frac{1}{2}$  and  $-\frac{1}{2}$ . For historical reasons, the fourth quantum number is referred to as the **spin quantum number**. When  $m_s = +\frac{1}{2}$ , the electron spin is said to be “up,” and when  $m_s = -\frac{1}{2}$ , the spin is “down.” The spin quantum number arises from relativistic effects that are not included in the Schrödinger equation. For most practical purposes in chemistry, it is sufficient simply to solve the ordinary Schrödinger equation, and then associate with each electron a spin quantum number  $m_s = +\frac{1}{2}$  or  $-\frac{1}{2}$  which does not affect the spatial probability distribution of the electron. Including the spin doubles the number of allowed quantum states with principal quantum number  $n$ , from  $n^2$  to  $2n^2$ . This fact will assume considerable importance when considering the many-electron atoms in the next section.

## 5.2 Shell Model for Many-Electron Atoms

As we move from one-electron to many-electron atoms, both the Schrödinger equation and its solutions become increasingly complicated. The simplest many-electron atom, helium (He), has two electrons and a nuclear charge of  $+2e$ . The positions of the two electrons in a helium atom can be described using two sets of Cartesian coordinates,  $(x_1, y_1, z_1)$  and  $(x_2, y_2, z_2)$ , relative to the same origin. The wave function  $\psi$  depends on all six of these variables:  $\psi = \psi(x_1, y_1, z_1, x_2, y_2, z_2)$ . Its square,  $\psi^2(x_1, y_1, z_1, x_2, y_2, z_2)$ , is the probability density of finding the first electron at point  $(x_1, y_1, z_1)$  and, simultaneously, the second electron at  $(x_2, y_2, z_2)$ . The Schrödinger equation is now more complicated, and an explicit solution for helium is not possible. Nevertheless, modern computers have enabled us to solve this equation numerically with high accuracy, and the predicted properties of helium are in excellent agreement with experiment.

Although these numerical calculations demonstrate conclusively the usefulness of the Schrödinger equation for predicting atomic properties, they suffer from two defects. First, they are somewhat difficult to interpret physically, and second, they become increasingly difficult to solve, even numerically, as the number of electrons increases. As a result, approximate approaches to the many-electron Schrödinger equation have been developed.

### 5.2.1 Hartree Orbitals

The **self-consistent field (SCF) orbital approximation method** developed by Hartree is especially well suited for applications in chemistry. Hartree’s method generates a set of approximate one-electron orbitals,  $\varphi_\alpha$ , and associated energy levels,  $\varepsilon_\alpha$ , reminiscent of those for the H atom. The subscript  $\alpha$  represents the appropriate set of quantum numbers (see later in this chapter for a definition). The electronic structure of a neutral atom with atomic number  $Z$  is then “built up” by placing  $Z$  electrons into these orbitals in accordance with certain rules (see later in this chapter for descriptions of these rules).

In this section, we introduce Hartree’s method and use it to describe the electron arrangements and energy levels in many-electron atoms. Later sections detail how this approximate description rationalizes periodic trends in atomic properties and serves as a starting point for descriptions of chemical bond formation.

For any atom, Hartree’s method begins with the exact Schrödinger equation in which each electron is attracted to the nucleus and repelled by all the other

electrons in accordance with the Coulomb potential. The following three simplifying assumptions are made immediately:

1. Each electron moves in an *effective field* created by the nucleus and all the other electrons, and the effective field for electron  $i$  depends only on its position  $r_i$ .
2. The effective field for electron  $i$  is obtained by averaging its Coulomb potential interactions with each of the other electrons over all the positions of the other electrons so that  $r_i$  is the only coordinate in the description.
3. The effective field is spherically symmetric; that is, it has no angular dependence.

Under the first assumption, each electron moves as an independent particle and is described by a one-electron orbital similar to those of the hydrogen atom. The wave function for the atom then becomes a product of these one-electron orbitals, which we denote  $\varphi_\alpha(r_i)$ . For example, the wave function for lithium (Li) has the form  $\psi_{\text{atom}} = \varphi_\alpha(r_1)\varphi_\beta(r_2)\varphi_\gamma(r_3)$ . This product form is called the **orbital approximation for atoms**. The second and third assumptions in effect convert the exact Schrödinger equation for the atom into a set of simultaneous equations for the unknown effective field and the unknown one-electron orbitals. These equations must be solved by iteration until a self-consistent solution is obtained. (In spirit, this approach is identical to the solution of complicated algebraic equations by the method of iteration described in Appendix C.) Like any other method for solving the Schrödinger equation, Hartree's method produces two principal results: energy levels and orbitals.

These Hartree orbitals resemble the atomic orbitals of hydrogen in many ways. Their angular dependence is identical to that of the hydrogen orbitals, so quantum numbers  $\ell$  and  $m$  are associated with each atomic orbital. The radial dependence of the orbitals in many-electron atoms differs from that of one-electron orbitals because the effective field differs from the Coulomb potential, but a principal quantum number  $n$  can still be defined. The lowest energy orbital is a  $1s$  orbital and has no radial nodes, the next lowest  $s$  orbital is a  $2s$  orbital and has one radial node, and so forth. Each electron in an atom has associated with it a set of four quantum numbers ( $n, \ell, m, m_s$ ). The first three quantum numbers describe its spatial distribution and the fourth specifies its spin state. The allowed quantum numbers follow the same pattern as those for the hydrogen atom. However, the number of states associated with each combination of ( $n, \ell, m$ ) is twice as large because of the two values for  $m_s$ .

### 5.2.2 Sizes and Shapes of Hartree Orbitals

The spatial properties of Hartree orbitals are best conveyed through a specific example. We present the results for argon (Ar), taken from Hartree's original work. The ground state of the argon atom has 18 electrons in the  $1s, 2s, 2p, 3s,$  and  $3p$  Hartree orbitals (see later). Figure 5.16 shows the radial probability density distributions for these five occupied orbitals as calculated by Hartree's method. The probability density distribution shown for the  $2p$  level is the sum of the distributions for the  $2p_x, 2p_y,$  and  $2p_z$  orbitals; similarly, the  $3p$  probability density distribution includes the  $3p_x, 3p_y,$  and  $3p_z$  orbitals. Comparing Figure 5.16 with Figure 5.14 shows that each Hartree orbital for argon is "smaller" than the corresponding orbital for hydrogen in the sense that the region of maximum probability density is closer to the nucleus. This difference occurs because the argon nucleus ( $Z = 18$ ) exerts a much stronger attractive force on

**FIGURE 5.16** Dependence of radial probability densities on distance from the nucleus for Hartree orbitals in argon with  $n = 1, 2, 3$ . The results were obtained from self-consistent calculations using Hartree's method. Distance is plotted in the same dimensionless variable used in Figure 5.14 to facilitate comparison with the results for hydrogen. The fact that the radial probability density for all orbitals with the same value of  $n$  have maxima very near one another suggests that the electrons are arranged in "shells" described by these orbitals. (Adapted from Eisberg, R. *Fundamentals of Modern Physics*, page 399, Figure 13-2, Wiley, 1961.)

electrons than does the hydrogen nucleus ( $Z = 1$ ). We develop a semiquantitative relation between orbital size and  $Z$  in the next subsection.

The fact that Hartree orbitals with the same value of  $n$  are large in the same narrow regions of space, despite their different values of  $\ell$ , has interesting consequences. The total radial probability density function for a many-electron atom gives (upon integration) the probability of finding an electron near a distance  $r$  from the nucleus regardless of which orbital it occupies. We obtain this function by summing up the radial probability density functions of all the occupied orbitals. The resulting probability function is proportional to the *radial charge density distribution function*  $\rho(r)$  for the atom. If the radial probability density functions in Figure 5.16 are all added together, the result reflects the contributions of electrons to the charge density  $\rho(r)$  in a thin spherical shell of radius  $r$ , regardless of the orbital to which the electron belongs. A plot of  $\rho(r)$  on the same scale as Figure 5.16 shows three peaks at  $r$  values of approximately 0.1, 0.3, and 1.2 in units of  $a_0$  (Fig. 5.17) The total electron density of the argon atom thus is concentrated in three concentric shells, where a **shell** is defined as all electrons with the same value of  $n$ . Each shell has a radius determined by the principal quantum number  $n$ . The shell model summarizes the coarse features of the electron density of an atom by averaging over all those local details not described by the principal quantum number  $n$ . Within each shell, a more detailed picture is provided by the subshells; a **subshell** is a group of orbitals that have the same value of both  $n$  and  $\ell$ .

The subshells (see Fig. 5.16) determine the structure of the periodic table and the formation of chemical bonds. In preparation for a discussion of these connections, it is necessary to describe the energy values for Hartree orbitals.

**FIGURE 5.17** The radial charge density in the argon atom as calculated by Hartree's method. The charge is arrayed into three shells corresponding to the values 1, 2, and 3 for the principal quantum number  $n$ .

### 5.2.3 Shielding Effects: Energy Sequence of Hartree Orbitals

The energy-level diagrams calculated for many-electron atoms by Hartree's method resemble the diagram for the hydrogen atom (see Fig. 5.2), but differ in two important respects. First, orbitals with the same  $n$  but different  $\ell$ , such as the  $2s$  and the  $2p$  orbital, no longer have the same energy. Because the effective field in Hartree's method is different from the Coulomb field in the hydrogen atom, the energy levels of Hartree orbitals depend on both  $n$  and  $\ell$ . Second, the energy values are distinctly shifted from the values of corresponding hydrogen orbitals because of the stronger attractive force exerted by nuclei with  $Z > 1$ .

These two effects can be explained qualitatively by a highly simplified one-electron model. Assume each of the electrons in shell  $n$  is moving in a Coulomb potential given approximately by

$$V_n^{\text{eff}}(r) \approx -\frac{Z_{\text{eff}}(n)e^2}{r} \quad [5.10]$$

where  $Z_{\text{eff}}(n)$  is the **effective nuclear charge** in that shell. To understand the origin and magnitude of  $Z_{\text{eff}}(n)$ , consider a particular electron  $e_1$  in an atom. Inner electrons near the nucleus *shield*  $e_1$  from the full charge  $Z$  of the nucleus by effectively canceling some of the positive nuclear charge.  $Z_{\text{eff}}(n)$  is thus the net reduced nuclear charge experienced by a particular electron, due to the presence of the other electrons. The effective nuclear charge  $Z_{\text{eff}}(n)$  is given by  $(Z-S)$  where  $Z$  is the nuclear charge and  $S$  is the shielding or screening constant for an orbital with principal quantum number  $n$ . (See Section 3.4.) For a neutral atom,  $Z_{\text{eff}}(n)$  can range from a maximum value of  $Z$  near the nucleus (no screening) to a minimum value of 1 far from the nucleus (complete screening by the other  $Z - 1$  electrons). The Hartree calculations for argon described above show that  $Z_{\text{eff}}(1) \sim 16$ ,  $Z_{\text{eff}}(2) \sim 8$ , and  $Z_{\text{eff}}(3) \sim 2.5$ . The effect of shielding on the energy and radius of a Hartree orbital is easily estimated in this simplified picture by using the hydrogen atom equations with  $Z$  replaced by  $Z_{\text{eff}}(n)$ . We use  $\varepsilon_n$  to distinguish a Hartree orbital energy from the H atom orbital  $E_n$ . Thus,

$$\varepsilon_n \approx -\frac{[Z_{\text{eff}}(n)]^2}{n^2} \quad (\text{rydbergs}) \quad [5.11]$$

and

$$\bar{r}_{n\ell} \approx \frac{n^2 a_0}{Z_{\text{eff}}(n)} \left\{ 1 + \frac{1}{2} \left[ 1 - \frac{\ell(\ell+1)}{n^2} \right] \right\} \quad [5.12]$$

Thus, electrons in inner shells (small  $n$ ) are tightly bound to the nucleus, and their average position is quite near the nucleus because they are only slightly shielded from the full nuclear charge of  $Z$  protons. Electrons in outer shells are only weakly attracted to the nucleus, and their average position is far from the nucleus because they are almost fully shielded from the nuclear charge.

This simple approximation can be used to estimate the energies and radii of orbitals in any atom for which the effective nuclear charge values are available. Slater developed a set of empirical rules for estimating the shielding constant for an electron in an  $ns$  or  $np$  orbital in order to assign effective nuclear charge values:

1. Write the electronic configuration for the atom with terms in the order and grouped as follows: (1s) (2s, 2p) (3s, 3p) (3d) (4s, 4p) (4d) (4f) (5s, 5p) etc.
2. Electrons in any group to the right of a ( $ns$ ,  $np$ ) group do not shield the ( $ns$ ,  $np$ ) electrons and therefore make no contribution to the shielding constant.
3. Each of the other electrons in a ( $ns$ ,  $np$ ) group contributes 0.35 to the shielding constant. (This includes how valence electrons in main group elements shield each other.)
4. Each electron in the ( $n - 1$ ) shell contributes 0.85 to the shielding constant.
5. Each electron in shells ( $n - 2$ ) or lower fully shield the outer electrons, contributing 1.00 to the shielding constant.
6. For He (1s)<sup>2</sup>, the shielding constant is 0.31.

Slater's rules in effect summarize and quantify the general properties of radial distributions functions presented above, and they provide great physical insight into the shielding process. Today, values of  $Z_{\text{eff}}$  for each element are obtained directly from advanced computer calculations that are more sophisticated than Hartree's method.

The results for the first two periods are shown in Table 5.3; the actual  $Z$  values are shown in parentheses after each atomic symbol.

### EXAMPLE 5.5

Estimate the energy and the average value of  $r$  in the 1s orbital of argon. Compare the results with the corresponding values for hydrogen.

#### Solution

Using Equation 5.11 and the value  $Z_{\text{eff}}(1) \sim 16$  leads to  $\epsilon_{1s} \sim -256$  rydbergs for argon. The Ar(1s) electron is more strongly bound than the H(1s) electron by a factor 256. (Compare Eq. 5.1b for the hydrogen atom.)

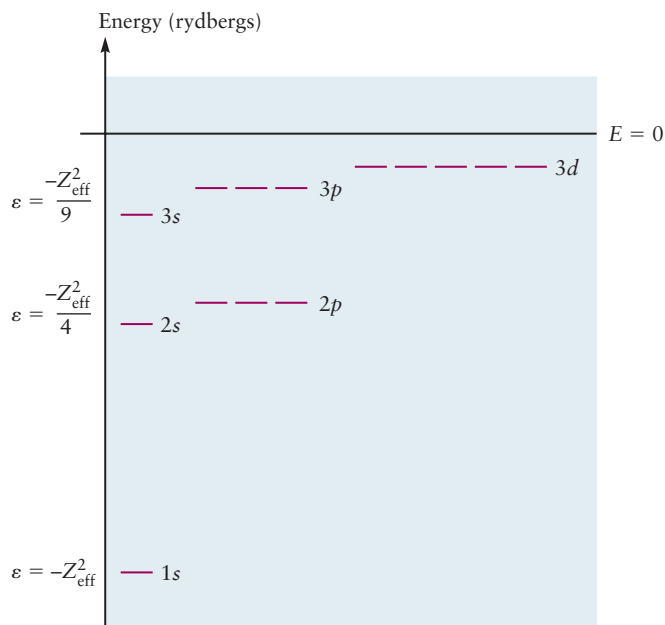

Using Equation 5.12 and the value  $Z_{\text{eff}}(1) \sim 16$  leads to  $\bar{r}_{1s} = \frac{3a_0}{2 \cdot 16}$  for argon.

This is smaller by a factor of 16 than  $\bar{r}_{1s}$  for hydrogen.

A comparison of Figure 5.16 with Figure 5.14 demonstrates that each Hartree orbital for argon is "smaller" than the corresponding orbital for hydrogen in the sense that the region of maximum probability is closer to the nucleus.

**Related Problems: 11, 12, 13, 14, 15, 16**

**FIGURE 5.18** Approximate energy-level diagram for Hartree orbitals, estimated by incorporating values of  $Z_{\text{eff}}$ . Energy values are in units of rydbergs. The result of electron–electron repulsion is to remove the degeneracy of the hydrogen atom states with different  $\ell$  values. Note that the value of  $Z_{\text{eff}}$  is different for each value of  $n$  (see Table 5.3).

**TABLE 5.3**

$Z_{\text{eff}}$  for Selected Atoms

	H(1)							He(2)
1s	1.00							1.69
	Li(3)	Be(4)	B(5)	C(6)	N(7)	O(8)	F(9)	Ne(10)
1s	2.69	3.68	4.68	5.67	6.66	7.66	8.65	9.64
2s	1.28	1.91	2.58	3.22	3.85	4.49	5.13	5.76
2p			2.42	3.14	3.83	4.45	5.10	5.76

The dependence of the energy on  $\ell$  in addition to  $n$  can be explained by comparing the extent of shielding in different subshells. Figures 5.8 through 5.14 show that only the  $s$  orbitals penetrate to the nucleus; both  $p$  and  $d$  orbitals have nodes at the nucleus. Consequently, the shielding will be smallest, and the electron most tightly bound, in  $s$  orbitals. Calculations show that

$$\epsilon_{ns} < \epsilon_{np} < \epsilon_{nd}$$

The energy-level diagram for Hartree orbitals is shown qualitatively in Figure 5.18. Energy levels for  $ns$  and  $np$  orbitals, can be estimated by using values for  $Z_{\text{eff}}$  such as those in Table 5.3 in Equation 5.11.

How do we use these Hartree energy levels and orbitals to describe the electrons in an atom? The answer is the subject of the next section.

## 5.3 Aufbau Principle and Electron Configurations

The ground-state electronic configuration of an atom with atomic number  $Z$  is built up by arranging the Hartree atomic orbitals in order of increasing energy and adding one electron at a time, starting with the lowest energy orbital, until

all  $Z$  electrons in the neutral atom are in place. The following additional restrictions are imposed at each step:

1. The **Pauli exclusion principle** states that no two electrons in an atom can have the same set of four quantum numbers ( $n, \ell, m, m_s$ ). Another way of stating this principle is that each Hartree atomic orbital (characterized by a set of three quantum numbers,  $n, \ell$ , and  $m$ ) holds at most two electrons, one with spin up and the other with spin down.
2. **Hund's rules** state that when electrons are added to Hartree orbitals of equal energy, a single electron enters each orbital before a second one enters any orbital. In addition, the lowest energy configuration is the one with parallel spins (see later discussion).

This procedure leads to the **electron configuration** for each atom, which gives the number of electrons “in” each Hartree orbital. Any proposed electron configuration that violates the Pauli principle is invalid. Any proposed configuration that violates Hund's rule will give an excited state of the atom, not its ground state. Although the Hartree model is commonly used and informative, the orbital and spin angular momenta of one electron in a multielectron atom can couple to those of the other electrons, resulting in quantum numbers different from the  $\ell, m$  and  $m_s$  for each individual electron.

### 5.3.1 Building Up from Helium to Argon

Let's see how the aufbau principle works for the atoms from helium (He) through neon (Ne). The lowest energy orbital is always the  $1s$  orbital; therefore, helium has two electrons (with opposite spins) in that orbital. The ground-state electron configuration of the helium atom is symbolized as  $1s^2$  and is conveniently illustrated by a diagram (for example, Fig. 5.19). The  $1s$  orbital in the helium atom is somewhat larger than the  $1s$  orbital in the helium ion ( $\text{He}^+$ ). In the ion, the electron experiences the full nuclear charge  $+2e$ , but in the atom, each electron partially screens or shields the other electron from the nuclear charge. The orbital in the helium atom can be described by the approximate equations given previously with an “effective” nuclear charge  $Z_{\text{eff}}$  of 1.69, which lies between  $+1$  (the value for complete shielding by the other electron) and  $+2$  (no shielding).

A lithium (Li) atom has three electrons. The third electron does not join the first two in the  $1s$  orbital. It occupies a different orbital because, by the Pauli principle, at most two electrons may occupy any one orbital. The third electron goes into the  $2s$  orbital, which is the next lowest in energy. The ground state of the lithium atom is therefore  $1s^2 2s^1$ , and  $1s^2 2p^1$  is an excited state.

The next two elements present no difficulties. Beryllium (Be) has the ground-state configuration  $1s^2 2s^2$  and the  $2s$  orbital is now filled. Boron (B), with five electrons, has the ground-state configuration  $1s^2 2s^2 2p^1$ . Because the three  $2p$  orbitals of boron have the same energy, there is an equal chance for the electron to be in each one.

With carbon (C), the sixth element, a new question arises. Will the sixth electron go into the same orbital as the fifth (for example, both into a  $2p_x$  orbital with opposite spins), or will it go into the  $2p_y$  orbital, which has equal energy? The answer is found in the observation that two electrons that occupy the same atomic orbital experience stronger electron–electron repulsion than they would if they occupied orbitals in different regions of space. Thus, putting the last two electrons of carbon into two different  $p$  orbitals, such as  $2p_x$  and  $2p_y$ , in accordance with Hund's rule, leads to lower energy than putting them into the same  $p$  orbital. The electron configuration of carbon is then  $1s^2 2s^2 2p_x^1 2p_y^1$ , or more simply,  $1s^2 2s^2 2p^2$ . This configuration is shown in Figure 5.20.

**FIGURE 5.19** The ground-state electron configurations of first- and second-period atoms. Each horizontal line represents a specific atomic orbital. Arrows pointing up represent electrons with spin quantum number  $m_s = +\frac{1}{2}$  and arrows pointing down represent electrons with spin quantum number  $m_s = -\frac{1}{2}$ .

The behavior of atoms in a magnetic field provides a test of their electron configuration. A substance is **paramagnetic** if it is attracted into a magnetic field. Any substance that has one or more unpaired electrons in the atoms, molecules, or ions that compose it is paramagnetic because a net magnetic moment arises from each of the unpaired electrons. (Recall the Stern–Gerlach experiment described in Section 5.1.) A substance in which all the electrons are paired is weakly **diamagnetic**: It is pushed *out* of a magnetic field, although the force it experiences is much smaller in magnitude than the force that pulls a typical

**FIGURE 5.20** For a many-electron atom such as carbon, orbitals with different  $\ell$  values (such as the 2s and 2p orbitals) have different energies (see Fig. 5.18). When two or more orbitals have the *same* energy (such as the three 2p orbitals here), electrons occupy different orbitals with parallel spins in the ground state.

paramagnetic substance into a magnetic field. Of the atoms discussed so far, hydrogen, lithium, boron, and carbon are known from experiments to be paramagnetic, whereas helium and beryllium are known to be diamagnetic. These results give us confidence in the validity of our description of atomic structure based on the orbital approximation and SCF calculations.

The electron configurations from nitrogen (N) through neon (Ne) follow from the stepwise filling of the  $2p$  orbitals. The six elements from boron to neon are each called a ***p*-block element** because their configurations involve filling of  $p$  orbitals in the building-up process. Each of the four elements that precedes them (hydrogen through beryllium) is called an ***s*-block element**.

The build-up of the third period, from sodium to argon, is an echo of what happened in the second; first the one  $3s$  orbital is filled, and then the three  $3p$  orbitals. As the number of electrons in an atom reaches 15 or 20, it is frequently the practice to explicitly include only those electrons added in the building up beyond the last preceding noble-gas element. The configuration of that noble gas is then represented by its chemical symbol enclosed in brackets. The ground-state configuration of silicon, for example, is written  $[\text{Ne}]3s^23p^2$  using this system.

### EXAMPLE 5.6

Write the ground-state electron configurations for magnesium and sulfur. Are the gaseous atoms of these elements paramagnetic or diamagnetic?

#### Solution

The noble-gas element preceding both elements is neon. Magnesium has two electrons beyond the neon core, which must be placed in the  $3s$  orbital, the next higher in energy, to give the ground-state configuration  $[\text{Ne}]3s^2$ . A magnesium atom is diamagnetic because all of its electrons are paired in orbitals.

Sulfur has six electrons beyond the neon core; the first two of these are in the  $3s$  orbital, and the next four are in the  $3p$  orbitals. The ground-state configuration of sulfur is  $[\text{Ne}]3s^23p^4$ . When four electrons are put into three  $p$  orbitals, two electrons must occupy one of the orbitals, and the other two occupy different orbitals to reduce electron–electron repulsion. According to Hund’s rules, these two electrons’ spins are parallel, and the sulfur atom is paramagnetic.

**Related Problems: 17, 18, 19, 20**

In summary, we remind you that the electron configuration for an atom is a concise, shorthand notation that represents a great deal of information about the structure and energy levels of the atom. Each configuration corresponds to an atomic wave function comprising a product of occupied Hartree orbitals. Each orbital has a well-defined energy (given by Eq. 5.11 and shown in Fig. 5.18) and average radius (given by Eq. 5.12). The orbitals are grouped into subshells that are characterized by radial distribution functions (see Fig. 5.16). Chapter 6 describes the formation of chemical bonds by starting with the electron configurations of the participating atoms. We encourage you to become expert with atomic electronic configurations and all the information that they summarize.

### EXAMPLE 5.7

The boron atom with  $Z = 5$  may have the electron configuration B:  $(1s)^2(2s)^2(2p_x)^1$ .

- Write the atomic wave function for a B atom.
- Estimate the energy level diagram for a B atom.
- Estimate the radius of the  $2s$  and  $2p_x$  orbitals.

#### Solution

- The atomic wave function for a B atom is

$$\psi_{\text{B}}(\vec{r}_1, \vec{r}_2, \vec{r}_3, \vec{r}_4, \vec{r}_5) = [\varphi_{1s}(\vec{r}_1)\varphi_{1s}(\vec{r}_2)][\varphi_{2s}(\vec{r}_3)\varphi_{2s}(\vec{r}_4)][\varphi_{2p_x}(\vec{r}_5)]$$

(Continued)

(b) Estimate the energy levels of a B atom.

$$\epsilon_{1s} \approx -\frac{(4.68)^2}{1^2} = -21.90 \text{ Ry}$$

$$\epsilon_{2s} \approx -\frac{(2.58)^2}{2^2} = -1.66 \text{ Ry}$$

$$\epsilon_{2p} \approx -\frac{(2.42)^2}{2^2} = -1.46 \text{ Ry}$$

(c) Use Equation 5.12 and  $Z_{\text{eff}}$  values for boron from Table 5.3 to estimate orbital radii as follows:

$$\bar{r}_{2s} \approx \frac{2^2 a_0}{(2.58)} \left\{ 1 + \frac{1}{2} \left[ 1 - \frac{0(0+1)}{2^2} \right] \right\} = \frac{4a_0}{(2.58)} \left\{ \frac{3}{2} \right\} = 2.33a_0$$

$$\bar{r}_{2p} \approx \frac{2^2 a_0}{(2.42)} \left\{ 1 + \frac{1}{2} \left[ 1 - \frac{1(1+1)}{2^2} \right] \right\} = \frac{4a_0}{(2.42)} \left\{ \frac{5}{4} \right\} = 2.07a_0$$

**Related Problems: 21, 22, 23, 24, 25, 26**

### 5.3.2 Transition-Metal Elements and Beyond

After the  $3p$  orbitals have been filled with six electrons, the natural next step is to continue the build-up process using the  $3d$  subshell. Advanced calculations for elements 19 (K) through 30 (Zn) predict that  $\epsilon_{3d}$  and  $\epsilon_{4s}$  are very close, so the build-up process becomes rather subtle. For K and Ca, the calculations show that  $\epsilon_{4s} < \epsilon_{3d}$ . Optical spectroscopy confirms that the ground state of K is  $[\text{Ar}]3d^04s^1$  and that of Ca is  $[\text{Ar}]3d^04s^2$ , as predicted by the sequence of calculated orbital energies. For Sc and the elements beyond, advanced calculations predict that  $\epsilon_{3d} < \epsilon_{4s}$ . Filling the  $3d$  orbitals first would give the configurations  $[\text{Ar}]3d^34s^0$  for Sc,  $[\text{Ar}]3d^44s^0$  for Ti, and so on to  $[\text{Ar}]3d^{10}4s^0$  for Ni. These configurations are inconsistent with numerous optical, magnetic, and chemical properties of these elements, so some consideration besides the energies of the individual orbitals must also influence the build-up process. Let's consider the alternative configuration  $[\text{Ar}]3d^14s^2$  for Sc and compare its total energy with that of the  $[\text{Ar}]3d^34s^0$  configuration. This comparison must add the electrostatic repulsion energy between the electrons to the sum of the energies of the occupied one-electron orbitals to find the total energy of the atom. Because the  $3d$  orbital is much more localized than the  $4s$  orbital, the much greater repulsion energy of the two electrons in the  $3d$  orbital outweighs the fact that  $\epsilon_{3d} < \epsilon_{4s}$  and the configuration with two  $d$  electrons has higher energy. Thus, the configuration  $[\text{Ar}]3d^14s^2$  has the lower energy and is the ground state for Sc. The same reasoning—minimizing the energy of the atom as a whole—predicts ground state electron configurations from  $[\text{Ar}]3d^14s^2$  for Sc to  $[\text{Ar}]3d^{10}4s^2$  for Zn that agree with experimental results. Each of the 10 elements from scandium to zinc is called a **d-block element** because its configuration involves the filling of a  $d$  orbital in the building-up process.

Experimental evidence shows that chromium and copper do not fit this pattern. In its ground state, chromium has the configuration  $[\text{Ar}]3d^54s^1$  rather than  $[\text{Ar}]3d^44s^2$ , and copper has the configuration  $[\text{Ar}]3d^{10}4s^1$  rather than  $[\text{Ar}]3d^94s^2$ . Similar anomalies occur in the fifth period and others, such as the ground-state configuration  $[\text{Kr}]4d^75s^1$  that is observed for ruthenium in place of the expected  $[\text{Kr}]4d^65s^2$ .

In the sixth period, the filling of the  $4f$  orbitals (and the generation of the **f-block elements**) begins as the rare-earth (lanthanide) elements from lanthanum

**FIGURE 5.21** The filling of shells and the structure of the periodic table. Only the “anomalous” electron configurations are shown.

to ytterbium are reached. The configurations determined from calculations and experiment can be recalled as needed by *assuming* that the orbitals are filled in the sequence  $1s \rightarrow 2s \rightarrow 2p \rightarrow 3s \rightarrow 3p \rightarrow 4s \rightarrow 3d \rightarrow 4p \rightarrow 5s \rightarrow 4d \rightarrow 5p \rightarrow 6s \rightarrow 4f \rightarrow 5d \rightarrow 6p \rightarrow 7s \rightarrow 5f \rightarrow 6d$ . The energies of the  $4f$ ,  $5d$ , and  $6s$  orbitals are comparable over much of the sixth period, and thus their order of filling is erratic.

The periodic table shown in Figure 5.21 classifies elements within periods according to the subshell that is being filled as the atomic number increases. Configurations are given explicitly for exceptions to this “standard” order of filling.

## 5.4 Shells and the Periodic Table: Photoelectron Spectroscopy

Our discussion of electronic structure began in Section 3.4 by analyzing patterns in the successive ionization energies of the atoms; these patterns suggested that the electrons are arranged in shells within the atom. In Section 5.2, we demonstrated that quantum theory *predicts* the shell structure of the atom. A shell is defined precisely as a set of orbitals that have the same principal quantum number, reflecting the fact that the average positions of the electrons in each of these shells are close to each other, but far from those of orbitals with different  $n$  values (see Fig. 5.16). Now we can accurately interpret the results in

**FIGURE 5.22** The energy of photoelectrons is determined by measuring the voltage required to deflect the electrons along a semicircular pathway between two charged metallic hemispherical plates in vacuum so that they arrive at the detector.

Figure 3.12 as showing that Na has two electrons in the  $n = 1$  shell, eight in the  $n = 2$  shell, and one in the  $n = 3$  shell.

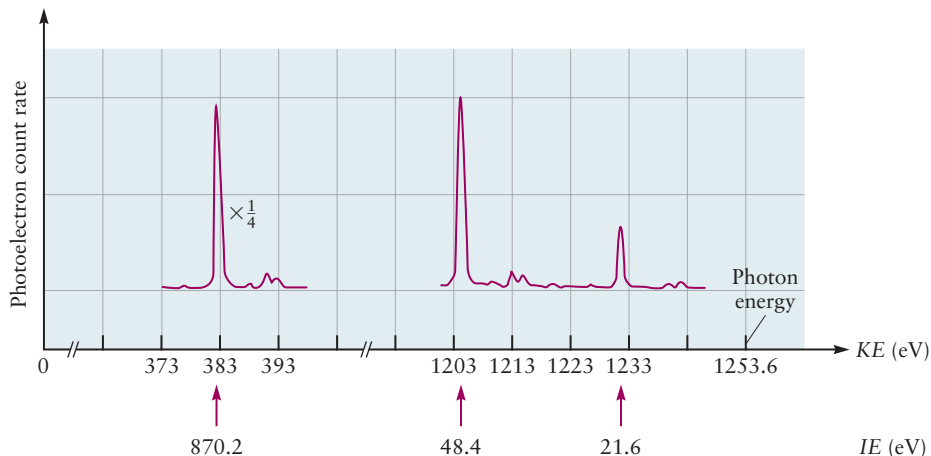

The shell structure shows that two elements in the same group (column) of the periodic table have related valence electron configurations. For example, sodium (configuration  $[\text{Ne}]3s^1$ ) and potassium (configuration  $[\text{Ar}]4s^1$ ) each have a single valence electron in an  $s$  orbital outside a closed shell; consequently, the two elements closely resemble each other in their chemical properties. A major triumph of quantum mechanics is its ability to account for the periodic trends discovered by chemists many years earlier and organized empirically in the periodic table by Mendeleev and others (see Section 3.2). The ubiquitous octets in the Lewis electron dot diagrams of second- and third-period atoms and ions in Chapter 3 arise from the eight available sites for electrons in the one  $s$  orbital and three  $p$  orbitals of the valence shell. The special properties of the transition-metal elements are ascribed to the partial filling of their  $d$  orbitals (see Chapter 8 for further discussion of this feature).

The shell structure is confirmed directly by an important experimental technique called **photoelectron spectroscopy**, or PES. Photoelectron spectroscopy determines the energy level of each orbital by measuring the ionization energy required to remove each electron from the atom. Photoelectron spectroscopy is simply the photoelectric effect of Section 4.4 applied not to metals, but instead to free atoms. If radiation of sufficiently high frequency  $\nu$  (in the ultraviolet or X-ray region of the spectrum) strikes an atom, an electron will be ejected with kinetic energy  $\frac{1}{2}m_e v^2$ . The kinetic energy of the ejected electrons is measured by an *energy analyzer*, which records the voltage required to deflect the electrons around a semicircular pathway in vacuum to reach the detector (Fig. 5.22). As the voltage between the hemispherical plates is changed, electrons with different values of kinetic energy will be deflected to the detector, and the spectrum of kinetic energy values can be recorded. Measuring the kinetic energy by deflection is analogous to measuring energy in the photoelectric effect experiments, and the results are conveniently expressed in units of electron volts (eV). Then the ionization energy spectrum,  $IE$ , is calculated by the principle of conservation of energy (see Section 4.4),

$$IE = h\nu_{\text{photon}} - \frac{1}{2} m_e v_{\text{electron}}^2 \quad [5.13]$$

Figure 5.23 shows the measured photoelectron spectrum for neon excited by X-rays with wavelength  $9.890 \times 10^{-10}$  m, and Example 5.8 shows how the

**FIGURE 5.23** Photoelectron spectrum of neon. The spectrum shows three peaks, demonstrating that the electrons of neon are organized in three bonding states of distinct energy values. The peak at 383.4 eV has been reduced by a factor of 4 for display on the same scale as the other two.

spectrum is obtained and interpreted. Three peaks appear with kinetic energy values 383.4, 1205.2, and 1232.0 eV. The corresponding ionization energy is shown beneath each peak. (See Example 5.8 for details.) Note that ionization energy increases from right to left in Figure 5.23, opposite to kinetic energy. The peak at lowest ionization energy (highest kinetic energy) is produced by the most weakly bound electrons (see Eq. 5.13). This is the minimum amount of energy required to detach an electron from an atom and is the same as the ionization energy  $IE_1$  introduced in Section 3.4. Clearly, there can be no signal in the photoelectron spectrum at ionization energies less than this value. Peaks at higher ionization energies correspond to electrons removed from more strongly bound states. This spectrum demonstrates that the ten electrons of neon are arranged in bonding states that produce three distinct, discrete energy levels.

These results are connected to the shell model by **Koopmans' approximation**, which asserts in a form suitable for our discussion that the ionization energy of an electron is the negative of the energy of the Hartree orbital of the electron:

$$IE_{\alpha} = -\varepsilon_{\alpha} \quad [5.14]$$

**FIGURE 5.24** The ionization energy  $IE_{n,\ell}$  is the energy required to remove an electron from this atomic state and set it free from the atom.

The Hartree orbital energies are intrinsically negative because they represent the energy stabilization of an electron bound in an atom relative to the free electron and a positive ion. The ionization energy is positive because it must be supplied to liberate the electron from the atom (Fig. 5.24). Therefore, we should be able to read off the orbital energies directly from the measured spectrum of ionization energies. Koopmans' approximation is not strictly valid because it assumes the orbital energies are the same in the ion as in the parent atom, despite the loss of an electron. This is called the **frozen orbital approximation**. The theorem assumes no energy is lost to *relaxation* of the electronic structure during the ionization process. In fact, relaxation effects are usually no larger than 1 – 3 eV. (The ionization of He is an obvious exception.) They can be included with orbital energies calculated by the more advanced Hartree–Fock method. So Koopmans' approximation and PES provide a quantitative test for advanced theoretical models of electronic structure.

These experimental results for neon are consistent with the electron configuration Ne:  $1s^2 2s^2 2p^6$  predicted by the aufbau principle. Ionization energies measured in this way are used to construct the energy-level diagram for atoms and to show explicitly the value of the ground-state energy.

**FIGURE 5.25** Energy-level diagram of neon as determined by photoelectron spectroscopy.

### EXAMPLE 5.8

Construct the energy-level diagram for neon from the data in Figure 5.23.

#### Solution

The ionization energy of each level is calculated as  $IE = E_{\text{photon}} - \mathcal{T}_{\text{electron}}$ . Because the measured kinetic energy values for the photoelectrons are reported in units of electron volts, the most convenient approach is to calculate the photon energy in electron volts and then subtract the kinetic energy values. The energy of the photon is given by

$$E_{\text{photon}} = \frac{hc}{\lambda} = \frac{(6.6261 \times 10^{-34} \text{ J s})(2.9979 \times 10^8 \text{ m s}^{-1})}{(9.890 \times 10^{-10} \text{ m})(1.6022 \times 10^{-19} \text{ J eV}^{-1})} = 1253.6 \text{ eV}$$

The calculated ionization energies for the peaks are summarized as follows:

Kinetic Energy (eV)	Ionization Energy (eV)
383.4	870.2
1205.2	48.4
1232.0	21.6

The energy-level diagram (Fig. 5.25) is drawn by showing the negative of each ionization energy value as the energy of an orbital, in accordance with Equation 5.14 and Koopmans' approximation.

**Related Problems:** 27, 28, 29, 30, 31, 32

This method has been used to determine the energy levels for orbitals in most neutral atoms (Fig. 5.26). The energies are reported in units of rydbergs and plotted on a logarithmic scale. These data confirm the existence of subshells, which are grouped into shells having similar energies. However, there are significant exceptions. The  $3d$  subshell for elements 21 through 29 (scandium through copper) lies substantially higher than  $3s$  and  $3p$  and only slightly lower than  $4s$ . This is consistent with the chemical observation that the  $3d$  electrons are valence electrons in these transition metals. As  $Z$  goes above 30, the energy of the  $3d$  subshell decreases rapidly, so the  $3d$  electrons are not valence electrons for zinc and higher elements. The  $4d$ ,  $5d$ ,  $4f$ , and  $5f$  subshells all behave similarly, so electrons in filled  $d$  and  $f$  subshells are not valence electrons. We can develop an approximate criterion for distinguishing valence and core electrons by examining the noble gases (elements 2, 10, 18, 36, 54, and 86), which participate poorly or not at all in chemical bonding. The highest-energy subshell for each of them lies below  $-1$  rydberg. Therefore,  $-1$  rydberg is a reasonable approximate boundary for the difference between valence and core electrons.

## 5.5 Periodic Properties and Electronic Structure

### 5.5.1 Sizes of Atoms and Ions

The sizes of atoms and ions influence how they interact in chemical compounds. Although atomic radius is not a precisely defined concept, these sizes can be estimated in several ways. If the electron density is known from theory or experiment, a contour surface of fixed electron density can be drawn, as demonstrated in Section 5.1 for one-electron atoms. Alternatively, if the atoms or

**FIGURE 5.26** The energies of different subshells in the first 97 elements, as determined by photoelectron spectroscopy. Negative values on the vertical axis correspond to the bound state orbital energies. Subshells having the same principal quantum number  $n$ , such as  $2s$  and  $2p$ , have similar energies and are well separated from orbitals of different  $n$ . Significant exceptions do exist, as explained in the text. Note the logarithmic energy scale. One rydberg is  $2.18 \times 10^{-18}$  J.

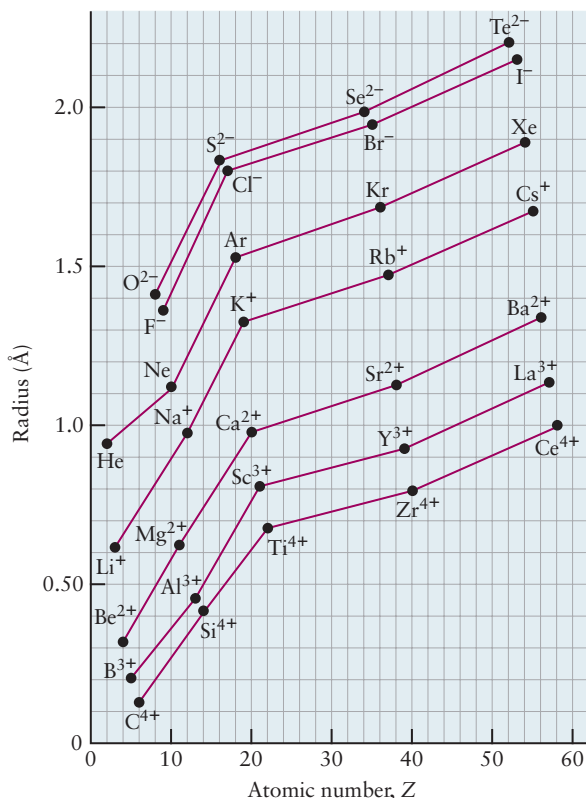

ions in a crystal are assumed to be in contact with one another, a size can be defined from the measured distances between their centers (this approach is explored in greater detail in Chapter 21). These and other measures of size are reasonably consistent with each other and allow for the tabulation of sets of atomic and ionic radii, many of which are listed in Appendix F.

Certain systematic trends appear in these radii. For a series of elements or ions in the same group (column) of the periodic table, the radius usually increases with increasing atomic number. This occurs mainly because the Pauli exclusion principle effectively excludes added electrons from the region occupied by the core electrons, thus forcing an increase in size as more distant electron shells are occupied. By contrast, Coulomb (electrostatic) forces cause the radii of atoms to *decrease* with increasing atomic number across a period. As the nuclear charge increases steadily, electrons are added to the same valence shell and are ineffective in shielding each other from its attraction. This “incomplete shielding” of the added proton by the added electron as we go from atomic number  $Z$  to  $Z + 1$  leads to an increase in  $Z_{\text{eff}}$  across a period.

Superimposed on these broad trends are some subtler effects that have significant consequences in chemistry. One dramatic example is shown in Figure 5.27. The radii of several sets of ions and atoms increase with atomic number in a given group (see earlier), but the *rate* of this increase changes considerably when the ions and atoms that contain the same number of electrons as argon are reached ( $S^{2-}$ ,  $Cl^-$ ,  $Ar$ ,  $K^+$ ,  $Ca^{2+}$ ,  $Sc^{3+}$ ,  $Ti^{4+}$ ). For example, the change in size from  $Li^+$  to  $Na^+$  to  $K^+$  is substantial, but the subsequent changes, to  $Rb^+$  and  $Cs^+$ , are

**FIGURE 5.27** Ionic and atomic radii plotted versus atomic number. Each line connects a set of atoms or ions that have the same charge; all species have noble-gas configurations.

significantly smaller due to the filling of the  $d$  orbitals, which begins after  $K^+$  is reached. Because atomic and ionic size decrease from left to right across a series of transition-metal elements (due to the increased effective nuclear charge), the radius of a main-group element is smaller than it would have been had the transition series not intervened. A similar phenomenon, called the **lanthanide contraction**, occurs during the filling of the  $4f$  orbitals in the lanthanide series. Its effect on the sizes of transition-metal atoms is discussed in Section 8.1.

A different measure of atomic size is the volume occupied by a mole of atoms of the element in the solid phase. Figure 5.28 shows the pronounced

periodicity of the molar volume, with maxima occurring for the alkali metals. Two factors affect the experimentally measured molar volume: the “size” of the atoms, and the geometry of the bonding that connects them. The large molar volumes of the alkali metals stem both from the large size of the atoms and the fact that they are organized in a rather open, loosely packed structure in the solid.

### EXAMPLE 5.9

Predict which atom or ion in each of the following pairs should be larger: (a) Kr or Rb, (b) Y or Cd, (c)  $F^-$  or  $Br^-$ .

#### Solution

(a) Rb should be larger because it has an extra electron in a 5s orbital beyond the Kr closed shell.

(b) Y should be larger because the effective nuclear charge increases through the transition series from Y to Cd.

(c)  $Br^-$  should be larger because the extra outer electrons are excluded from the core.

**Related Problems: 33, 34, 35, 36**

## 5.5.2 Periodic Trends in Ionization Energies

The ionization energy of an atom is defined as the minimum energy necessary to detach an electron from the neutral gaseous atom (see Section 3.4). It can be obtained directly from the photoelectron spectrum of an atomic gas. Appendix F lists measured ionization energies of the elements, and Figure 5.29 shows the periodic trends in first and second ionization energies with increasing atomic number.

Let's use insight from quantum mechanics to examine the periodic trends in the first ionization energy. We obtain deeper understanding of the stabilities of the various electron configurations using this approach than we did in our empirical discovery of shell structure in Section 3.4. There is a large reduction in  $IE_1$  from helium to lithium for two reasons: (1) a 2s electron is much farther from the nucleus than a 1s electron, and (2) the 1s electrons screen the nucleus

**FIGURE 5.29** First and second ionization energies of atoms of the first three periods.

in lithium so effectively that the 2s electron “sees” a net positive charge close to +1, rather than the larger charge seen by the electrons in helium. Beryllium shows an increase in  $IE_1$  compared with lithium because the effective nuclear charge has increased, but the electron being removed is still from a 2s orbital.

The  $IE_1$  of boron is somewhat less than that of beryllium because the fifth electron is in a higher energy (and therefore less stable) 2p orbital. In carbon and nitrogen, the additional electrons go into 2p orbitals as the effective nuclear charge increases to hold the outer electrons more tightly; hence,  $IE_1$  increases. The nuclear charge is higher in oxygen than in nitrogen, which would give it a higher ionization energy if this were the only consideration. However, oxygen must accommodate two electrons in the same 2p orbital, leading to greater electron–electron repulsion and diminished binding, thus more than compensating for the increased electron–nuclear interaction. Consequently, oxygen has a lower  $IE_1$  than nitrogen. Fluorine and neon have successively higher first ionization energies because of increasing effective nuclear charge. The general trends of increasing ionization energy across a given period, as well as the dips that occur at certain points, can thus be rationalized through the orbital description of many-electron atoms.

The ionization energy tends to decrease down a group in the periodic table (for example, from lithium to sodium to potassium). As the principal quantum number increases, so does the distance of the outer electrons from the nucleus. There are some exceptions to this trend, however, especially for the heavier elements in the middle of the periodic table. For example, the first ionization energy of gold is higher than that of silver or copper. This fact is crucial in making gold a “noble metal”; that is, one that is resistant to attack by oxygen.

Similar trends are observed in the second ionization energies, but they are shifted higher in atomic number by one unit (see Fig. 5.29). Thus,  $IE_2$  is large for lithium (because  $Li^+$  has a filled  $1s^2$  shell), but relatively small for beryllium (because  $Be^+$  has a single electron in the outermost 2s orbital).

### 5.5.3 Electron Affinity

The **electron affinity**,  $EA$ , of an atom X is the energy required to detach an electron from the anion  $X^-$  and give the neutral atom X (see Section 3.5). Appendix F lists the electron affinities of the elements.

The periodic trends in electron affinity (Fig. 5.30) parallel those in ionization energy for the most part, except that they are shifted one unit *lower* in atomic

H 73																			He *

**FIGURE 5.30** Electron affinities (measured in  $\text{kJ mol}^{-1}$ ) of gaseous atoms of the elements. An asterisk means that the element does not have a stable anion in the gas phase.

number. The reason is clear. Attaching an electron to F gives  $F^-$ , with the configuration  $1s^2 2s^2 2p^6$ , the same as that for neon. Fluorine has a large affinity for electrons because the added electron fills the  $n = 2$  shell, rather than being forced into the higher energy  $3s$  orbital. In contrast, the noble gases do not have well-defined electron affinities because the “extra” electron would reside in a new shell far from the nucleus and be almost totally screened from the nuclear charge.

### EXAMPLE 5.10

Consider the elements selenium (Se) and bromine (Br). Which has the higher first ionization energy? Which has the higher electron affinity?

#### Solution

These two atoms are adjacent to each other in the periodic table. Bromine has one more electron in the  $4p$  subshell, and this electron should be more tightly bound than the  $4p$  electrons in selenium because of the incomplete shielding and the extra unit of positive charge on the nucleus. Thus,  $IE_1$  should be greater for bromine.

Bromine has a greater electron affinity than selenium. Gaining the extra electron changes the Br atom into  $Br^-$ , which has a particularly stable closed-shell electron configuration (the same as that of the noble gas atom krypton [Kr]). No such configuration is created when a Se atom gains an additional electron.

**Related Problems: 37, 38, 39, 40**

## CHAPTER SUMMARY

The planetary model of the atom provided the first physical picture of the structure of the atom. This model, however, is rooted in classical mechanics, a theory that failed to predict the results of experiments conducted in the period roughly 1890 to 1915, an era of great excitement in the development of modern science. For example, the Bohr model was only able to predict the hydrogen atom emission spectra discovered by Balmer in 1885, not the emission spectra of multi-electron atoms. The theoretical explanation of the structure, properties, and behavior of atoms requires quantum mechanics. Quantum mechanics tells us that an atom can have only specific, discrete amounts of energy. Indeed, the very existence of quantum states explains the stability of the atom, which was predicted to collapse according to classical physics. Quantum mechanics also demonstrates that the concept of planetary orbits is simply not applicable on the atomic scale. We cannot know the detailed trajectory of an electron in the intuitive, classical sense familiar to ordinary human perception. Instead, we describe the probability for finding the electron at a particular location in the atom, based on knowing the quantum state of the atom.

For the hydrogen atom, we can solve the Schrödinger equation exactly to obtain the allowed energy levels and the hydrogen atomic orbitals. The sizes and shapes of these orbitals tell us the probability distribution for the electron in each quantum state of the atom. We are led to picture this distribution as a smeared cloud of electron density (probability density) with a shape that is determined by the quantum state.

For all other atoms, we have to generate approximations to solve the Schrödinger equation. The Hartree orbitals describe approximately the spatial distribution for each electron in the atom, moving under an effective force obtained by averaging over the interactions with all the other electrons. The Hartree orbitals have shapes similar to those of the hydrogen atomic orbitals—but very different sizes and energy values—and thus guide us to view the probability distribution for each electron as a smeared cloud of electron density.

The Hartree orbitals are the foundation of the quantum explanation of atomic structure. They justify the shell model of the atom, they explain the structure of the periodic table, and they provide the starting point for the quantum explanation of chemical bond formation in the following chapter.

## CONCEPTS AND SKILLS

### Section 5.1 – The Hydrogen Atom

*Define the quantum numbers that characterize one-electron atoms; discuss the shapes, sizes, and nodal properties of the corresponding orbitals; and calculate the probability of finding the electron in different regions of space around the nucleus. (Problems 1–8).*

- Quantum mechanics explains the physical stability of the atom by predicting its allowed discrete energy levels and defining the wave functions (also called atomic orbitals) associated with each energy level. The orbitals determine the probability density for finding the electrons at particular locations in the atom when the electrons are in a specific quantum state.
- The allowed energy levels for a one-electron atom or ion with atomic number  $Z$  are given by the expression

$$E_n = -\frac{Z^2 e^4 m_e}{8\epsilon_0^2 n^2 h^2} \quad n = 1, 2, 3, \dots \quad [5.1a]$$

These values are negative numbers because they measure the energy of the bound states of the stable atom relative to a separated electron and cation, which is defined to be the zero of the energy scale. The energy of the ground state of the hydrogen atom is  $-13.6$  eV, a number worth remembering.

- Because the potential energy in a one-electron atom depends only on  $r$ , the wave functions (atomic orbitals) have the product form  $\psi_{n\ell m}(r, \theta, \phi) = R_{n\ell}(r)Y_{\ell m}(\theta, \phi)$ . The quantum number  $\ell$  describes quantization of the total angular momentum of the electron, and the quantum number  $m$  describes quantization of the component of angular momentum along the  $z$ -axis. Whereas the quantum number  $n$  determines the allowed energy levels, the quantum number  $\ell$  determines the shapes of the orbitals, and  $m$  determines their orientation relative to the  $z$ -axis.
- The probability for finding an electron in the volume element  $dV = r^2 \sin \theta dr d\theta d\phi$  when the electron is in the specific quantum state  $(n, \ell, m)$  is given by

$$(\psi_{n\ell m})^2 dV = [R_{n\ell}(r)]^2 [Y_{\ell m}(\theta, \phi)]^2 dV \quad [5.4]$$

Examples 5.2 and 5.3 show how to use this equation for numerical calculations.

- Describe the shape, orientation, and size of the H atomic orbitals. Relate these properties to the following equation for the dependence of the size and shape on the nuclear charge:

$$\bar{r}_{n\ell} = \frac{n^2 a_0}{Z} \left\{ 1 + \frac{1}{2} \left[ 1 - \frac{\ell(\ell+1)}{n^2} \right] \right\} \quad [5.9]$$

- The Stern–Gerlach experiment demonstrates that the electron has a property called *spin*, which leads to a magnetic dipole moment. Spin is quantized with only two allowed values described by the quantum number  $m_s$ . Complete

determination of the quantum state of the electron requires values for all four quantum numbers ( $n, \ell, m, m_s$ ).

### Section 5.2 – Shell Model for Many-Electron Atoms

Prepare an approximate energy-level diagram for an atom using values for  $Z_{\text{eff}}$  (Problems 11–16).

- Atoms with many electrons are described by Hartree's SCF method, in which each electron is assumed to move under the influence of an effective potential  $V_{\text{eff}}(r)$  due to the spatial distribution of all the other electrons. This method generates a set of one-electron wave functions called the Hartree orbitals  $\varphi_{\alpha}(r)$  with energy values  $\varepsilon_{\alpha}$ , where  $\alpha$  represents the assumed set of one-electron quantum numbers. Hartree orbitals bear close relation to the hydrogen atomic orbitals but are not the same functions.

$$V_n^{\text{eff}}(r) = -\frac{Z_{\text{eff}}(n)e^2}{r} \quad [5.10]$$

- Energies of the Hartree orbitals are different from those of the corresponding hydrogen atomic orbitals. For an atom with atomic number  $Z$  they can be estimated as

$$\varepsilon_n \approx -\frac{[Z_{\text{eff}}(n)]^2}{n^2} \text{ (rydbergs)} \quad [5.11]$$

where the effective nuclear charge experienced by each electron is determined by screening of that electron from the full nuclear charge by other electrons.

- The Hartree orbitals have the same shapes as the corresponding hydrogen atomic orbitals, but their sizes are quite different, as described by the expression

$$\bar{r}_{n\ell} \approx \frac{n^2 a_0}{Z_{\text{eff}}(n)} \left\{ 1 + \frac{1}{2} \left[ 1 - \frac{\ell(\ell+1)}{n^2} \right] \right\} \quad [5.12]$$

### Section 5.3 – Aufbau Principle and Electron Configurations

Use the aufbau principle to predict electron configurations of atoms and ions and to account for the structure of the periodic table (Problems 17–26).

- The electron configuration for an atom with atomic number  $Z$  is determined by arranging the Hartree orbitals in order of increasing energy, then placing at most two electrons in each orbital in accordance with the Pauli exclusion principle and Hund's rule until all  $Z$  electrons have been placed. The configuration consists of specifying the set of four quantum numbers ( $n, \ell, m, m_s$ ) for each electron in the atom.
- The Hartree orbitals and their electron configurations justify the shell model of the atom; that is, the electrons are grouped into shells of 2, 8, or 18 electrons arranged concentrically around the nucleus at increasing distances from the nucleus. As we move outward from the nucleus, the electrons in each successive shell are bound progressively less strongly to the nucleus. Electrons in the outermost shell, called the valence electrons, are the least strongly bound, and they participate in the formation of chemical bonds.
- The Hartree orbitals and their electron configurations explain the structure of the periodic table.

### Section 5.4 – Shells and the Periodic Table: Photoelectron Spectroscopy

Construct the energy-level diagram for an atom using PES for orbital energies (Problems 27–32).

- Ionization energy is the amount of energy required to remove an electron from an atom and place it infinitely far away with zero kinetic energy. For any state  $n$  of a one-electron atom, the ionization energy  $IE_n$  is given by the relation  $IE_n = E_\infty - E_n$ . Ionization energy is intrinsically positive because the energy of the final state is higher than the energy of the initial state. The ionization energy of the ground state of the hydrogen atom is +13.6 eV.
- The shell model is verified experimentally by the technique of PES, in which ionization energy is measured for electrons in each shell:

$$IE = h\nu_{\text{photon}} - \frac{1}{2}m_e v_{\text{electron}}^2 \quad [5.13]$$

The results are connected to the shell model by Koopmans' theorem, which asserts that the orbital energy is the negative of the ionization energy,  $IE_\alpha = -\varepsilon_\alpha$ .

### Section 5.5 – Periodic Properties and Electronic Structure

Describe the trends in ionization energy and electron affinity across the periodic table and relate them to the electronic structure of atoms (Problems 35–40).

- The Hartree orbitals and the shell model explain periodic trends in ionization energy, electron affinity, and the radii of atoms and ions. Small changes in these properties within a period are further explained by detailed changes in  $Z_{\text{eff}}$  within that period.

## CUMULATIVE EXERCISE

### Atoms in Interstellar Space

The vast stretches of space between the stars are by no means empty. They contain both gases and dust particles at very low concentrations (Fig. 5.31). Interstellar space extends so far that these low-density species significantly affect the electromagnetic radiation arriving from distant stars and other sources, which is detected by telescopes. The gas in interstellar space consists primarily of hydrogen atoms (either neutral or ionized) at a concentration of about one atom per cubic centimeter. The dust (thought to be mostly solid water, methane, or ammonia) is even less concentrated, with typically only a few dust particles (each  $10^{-4}$  to  $10^{-5}$  cm in radius) per cubic kilometer.

- The hydrogen in interstellar space near a star is largely ionized by the high-energy photons from the star. Such regions are called H II regions. Suppose a ground-state hydrogen atom absorbs a photon with a wavelength of 65 nm. Calculate the kinetic energy of the electron ejected. (Note: This is the gas-phase analog of the photoelectric effect for solids.)
- What is the de Broglie wavelength of the electron from part (a)?
- Free electrons in H II regions can be recaptured by hydrogen nuclei. In such an event, the atom emits a series of photons of increasing energy as the electrons cascade down through the quantum states of the hydrogen atom. The particle densities are so low that extremely high quantum states can be detected in interstellar space. In particular, the transition from the state

J. J. Hester (Arizona State University), and NASA

**FIGURE 5.31** Clouds of gas surround hot stars in these galactic clusters. The red color arises from hydrogen radiation.

- $n = 110$  to  $n = 109$  for the hydrogen atom has been detected. What is the Bohr radius of an electron for hydrogen in the state  $n = 110$ ?
- (d) Calculate the wavelength of light emitted as an electron undergoes a transition from level  $n = 110$  to  $n = 109$ . In what region of the electromagnetic spectrum does this lie?
- (e) H II regions also contain ionized atoms that are heavier than hydrogen. Calculate the longest wavelength of light that will ionize a ground-state helium atom. Use data from Appendix F.
- (f) The regions farther from stars are called H I regions. There, almost all of the hydrogen atoms are neutral rather than ionized and are in the ground state. Will such hydrogen atoms absorb light in the Balmer series emitted by atoms in H II regions?
- (g) We stated in Section 5.1 that the energy of the hydrogen atom depends only on the quantum number  $n$ . In fact, this is not quite true. The electron spin ( $m_s$  quantum number) couples weakly with the spin of the nucleus, making the ground state split into two states of almost equal energy. The radiation emitted in a transition from the upper to the lower of these levels has a wavelength of 21.2 cm and is of great importance in astronomy because it allows the H I regions to be studied. What is the energy difference between these two levels, both for a single atom and for a mole of atoms?
- (h) The gas and dust particles between a star and the earth scatter the star's light more strongly in the blue region of the spectrum than in the red. As a result, stars appear slightly redder than they actually are. Will an estimate of the temperature of a star based on its apparent color give too high or too low a number?

### Answers

- (a)  $8.8 \times 10^{-19}$  J
- (b)  $0.52$  nm =  $5.2$  Å
- (c)  $6.40 \times 10^{-7}$  m =  $6400$  Å
- (d)  $5.98 \times 10^{-2}$  m =  $5.98$  cm, in the microwave region
- (e)  $50.4$  nm
- (f) No, because the lowest energy absorption for a ground-state hydrogen atom is in the ultraviolet region of the spectrum.
- (g)  $9.37 \times 10^{-25}$  J;  $0.564$  J mol<sup>-1</sup>
- (h) Too low, because red corresponds to emitted light of lower energy. Experience with blackbody radiation curves would assign a lower temperature to a star emitting lower energy light.

## PROBLEMS

Answers to problems whose numbers are red appear in Appendix G. Problems that are more challenging are indicated with asterisks.

### 5.1 The Hydrogen Atom

1. Which of the following combinations of quantum numbers are allowed for an electron in a one-electron atom? Which are not?
- (a)  $n = 2, \ell = 2, m = 1, m_s = \frac{1}{2}$
- (b)  $n = 3, \ell = 1, m = 0, m_s = -\frac{1}{2}$

- (c)  $n = 5, \ell = 1, m = 2, m_s = \frac{1}{2}$
- (d)  $n = 4, \ell = -1, m = 0, m_s = \frac{1}{2}$
2. Which of the following combinations of quantum numbers are allowed for an electron in a one-electron atom? Which are not?
- (a)  $n = 3, \ell = 2, m = 1, m_s = 0$
- (b)  $n = 2, \ell = 0, m = 0, m_s = -\frac{1}{2}$
- (c)  $n = 7, \ell = 2, m = -2, m_s = \frac{1}{2}$
- (d)  $n = 3, \ell = -3, m_s = -\frac{1}{2}$

3. Label the orbitals described by each of the following sets of quantum numbers:
- $n = 4, \ell = 1$
  - $n = 2, \ell = 0$
  - $n = 6, \ell = 3$
4. Label the orbitals described by each of the following sets of quantum numbers:
- $n = 3, \ell = 2$
  - $n = 7, \ell = 4$
  - $n = 5, \ell = 1$
5. Estimate the probability of finding an electron which is excited into the  $2s$  orbital of the H atom, looking in a cubical box of volume  $0.75 \times 10^{-36} \text{ m}^3$  centered at the nucleus. Then estimate the probability of finding the electron if you move the volume searched to a distance of 105.8 pm from the nucleus in the positive  $z$  direction. (Note that since these volumes are small, it does not matter whether the volume searched is cubical or spherical.)
6. Using Table 5.2, write down the mathematical expression for the  $2p_x$  wave function for an electronically excited H atom. Estimate the probability of finding the  $2p_x$  electron if you look in a cubical box of volume of  $0.8 \text{ (pm)}^3$  centered at a distance of  $0.500 \times 10^{-10} \text{ m}$  in the  $\theta = \pi/2, \phi = 0$  direction. Does this probability change as you change  $\phi$ ? At what  $\phi$  angles is the probability of finding the electron smallest and at what  $\phi$  angles is the probability the largest? (Note that  $\phi = 2\pi$  is the same location as  $\phi = 0$ , so don't double count.)
7. How many radial nodes and how many angular nodes does each of the orbitals in Problem 3 have?
8. How many radial nodes and how many angular nodes does each of the orbitals in Problem 4 have?
9. Use the mathematical expression for the  $2p_z$  wave function of a one-electron atom (see Table 5.2) to show that the probability of finding an electron in that orbital anywhere in the  $x$ - $y$  plane is 0. What are the nodal planes for a  $d_{xz}$  orbital and for a  $d_{x^2-y^2}$  orbital?
10. (a) Use the radial wave function for the  $3p$  orbital of a hydrogen atom (see Table 5.2) to calculate the value of  $r$  for which a node exists.  
 (b) Find the values of  $r$  for which nodes exist for the  $3s$  wave function of the hydrogen atom.
13. Spectroscopic studies show that Li can have electrons in its  $1s, 2s,$  and  $2p$  Hartree orbitals, and that  $Z_{\text{eff}}(2s) = 1.28$  for the  $1s^2 2s^1$  configuration. Estimate the energy of the  $2s$  orbital of Li. Calculate the average distance of the electron from the nucleus in the  $2s$  orbital of Li.
14. Spectroscopic studies of Li also show that  $Z_{\text{eff}}(2p) = 1.02$ . Estimate the energy of the  $2p$  orbital of Li. Calculate the average distance of the electron from the nucleus in the  $2p$  orbital of Li. Comparing your results with those in Problem 13 shows that the energy values differ by about 50%, whereas the average distances are nearly equal. Explain this observation.
15. Spectroscopic studies show that Na can have electrons in its  $1s, 2s, 2p,$  and  $3s$  Hartree orbitals, and that  $Z_{\text{eff}}(3s) = 1.84$ . Using data from Problem 13, compare the energies of the Na  $3s$  orbital, the Li  $2s$  orbital, and the H  $1s$  orbital.
16. Using data from Problems 13 and 15, calculate the average distance of the electron from the nucleus in the Na  $3s$  orbital, the Li  $2s$  orbital, and the H  $1s$  orbital. Explain the trend in your results.

### 5.3 Aufbau Principle and Electron Configurations

17. Give the ground-state electron configurations of the following elements:
- C
  - Se
  - Fe
18. Give the ground-state electron configurations of the following elements:
- P
  - Tc
  - Ho
19. Write ground-state electron configurations for the ions  $\text{Be}^+, \text{C}^-, \text{Ne}^{2+}, \text{Mg}^+, \text{P}^{2+}, \text{Cl}^-, \text{As}^+,$  and  $\text{I}^-$ . Which do you expect will be paramagnetic due to the presence of unpaired electrons?
20. Write ground-state electron configurations for the ions  $\text{Li}^-, \text{B}^+, \text{F}^-, \text{Al}^{3+}, \text{S}^-, \text{Ar}^+, \text{Br}^+,$  and  $\text{Te}^-$ . Which do you expect to be paramagnetic due to the presence of unpaired electrons?
21. Identify the atom or ion corresponding to each of the following descriptions:
- an atom with ground-state electron configuration  $[\text{Kr}]4d^{10}5s^25p^1$
  - an ion with charge  $-2$  and ground-state electron configuration  $[\text{Ne}]3s^23p^6$
  - an ion with charge  $+4$  and ground-state electron configuration  $[\text{Ar}]3d^3$
22. Identify the atom or ion corresponding to each of the following descriptions:
- an atom with ground-state electron configuration  $[\text{Xe}]4f^{14}5d^66s^2$
  - an ion with charge  $-1$  and ground-state electron configuration  $[\text{He}]2s^22p^6$
  - an ion with charge  $+5$  and ground-state electron configuration  $[\text{Kr}]4d^6$
23. Predict the atomic number of the (as yet undiscovered) element in the seventh period that is a halogen.

24. (a) Predict the atomic number of the (as yet undiscovered) alkali-metal element in the eighth period.  
 (b) Suppose the eighth-period alkali-metal atom turned out to have atomic number 137. What explanation would you give for such a high atomic number (recall that the atomic number of francium is only 87)?
25. Suppose that the spin quantum number did not exist, and therefore only one electron could occupy each orbital of a many-electron atom. Give the atomic numbers of the first three noble-gas atoms in this case.
26. Suppose that the spin quantum number had three allowed values ( $m_s = 0, +\frac{1}{2}, -\frac{1}{2}$ ). Give the atomic numbers of the first three noble-gas atoms in this case.

#### 5.4 Shells and the Periodic Table: Photoelectron Spectroscopy

27. Photoelectron spectra of mercury (Hg) atoms acquired with radiation from a helium lamp at  $584.4 \text{ \AA}$  show a peak in which the photoelectrons have kinetic energy of 11.7 eV. Calculate the ionization energy of electrons in that level.
28. Quantum mechanics predicts that the energy of the ground state of the H atom is  $-13.6 \text{ eV}$ . Insight into the magnitude of this quantity is gained by considering several methods by which it can be measured.
- (a) Calculate the longest wavelength of light that will ionize H atoms in their ground state.
- (b) Assume the atom is ionized by collision with an electron that transfers all its kinetic energy to the atom in the ionization process. Calculate the speed of the electron before the collision. Express your answer in meters per second ( $\text{m s}^{-1}$ ) and miles per hour ( $\text{miles h}^{-1}$ ).
- (c) Calculate the temperature required to ionize a H atom in its ground state by thermal excitation. (*Hint:* Recall the criterion for thermal excitation of an oscillator in Planck's theory of blackbody radiation is that  $h\nu \approx k_B T$ .)
29. Photoelectron spectroscopy studies of sodium atoms excited by X-rays with wavelength  $9.890 \times 10^{-10} \text{ m}$  show four peaks in which the electrons have speeds  $7.992 \times 10^6 \text{ m s}^{-1}$ ,  $2.046 \times 10^7 \text{ m s}^{-1}$ ,  $2.074 \times 10^7 \text{ m s}^{-1}$ , and  $2.009 \times 10^7 \text{ m s}^{-1}$ . (Recall that  $1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$ .)
- (a) Calculate the ionization energy of the electrons in each peak.
- (b) Assign each peak to an orbital of the sodium atom.
30. Photoelectron spectroscopy studies of silicon atoms excited by X-rays with wavelength  $9.890 \times 10^{-10} \text{ m}$  show four peaks in which the electrons have speeds  $2.097 \times 10^7 \text{ m s}^{-1}$ ,  $2.093 \times 10^7 \text{ m s}^{-1}$ ,  $2.014 \times 10^7 \text{ m s}^{-1}$ , and  $1.971 \times 10^7 \text{ m s}^{-1}$ . (Recall that  $1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$ .)
- (a) Calculate the ionization energy of the electrons in each peak.
- (b) Assign each peak to an orbital of the silicon atom.
31. Photoelectron spectroscopy studies have determined the orbital energies for fluorine atoms to be
- |    |         |
|----|---------|
| 1s | -689 eV |
| 2s | -34 eV  |
| 2p | -12 eV  |
- Estimate the value of  $Z_{\text{eff}}$  for F in each of these orbitals.
32. Photoelectron spectroscopy studies have determined the orbital energies for chlorine atoms to be
- |    |           |
|----|-----------|
| 1s | -2,835 eV |
| 2s | -273 eV   |
| 2p | -205 eV   |
| 3s | -21 eV    |
| 3p | -10 eV    |
- Estimate the value of  $Z_{\text{eff}}$  for Cl in each of these orbitals.

#### 5.5 Periodic Properties and Electronic Structure

33. For each of the following pairs of atoms or ions, state which you expect to have the larger radius.
- (a) Na or K                      (b) Cs or Cs<sup>+</sup>  
 (c) Rb<sup>+</sup> or Kr                  (d) K or Ca  
 (e) Cl<sup>-</sup> or Ar
34. For each of the following pairs of atoms or ions, state which you expect to have the larger radius.
- (a) Sm or Sm<sup>3+</sup>                (b) Mg or Ca  
 (c) I<sup>-</sup> or Xe                    (d) Ge or As  
 (e) Sr<sup>+</sup> or Rb
35. Predict the larger ion in each of the following pairs. Give reasons for your answers.
- (a) O<sup>-</sup>, S<sup>2-</sup>                      (b) Co<sup>2+</sup>, Ti<sup>2+</sup>  
 (c) Mn<sup>2+</sup>, Mn<sup>4+</sup>                (d) Ca<sup>2+</sup>, Sr<sup>2+</sup>
36. Predict the larger ion in each of the following pairs. Give reasons for your answers.
- (a) S<sup>2-</sup>, Cl<sup>-</sup>                      (b) Tl<sup>+</sup>, Tl<sup>3+</sup>  
 (c) Ce<sup>3+</sup>, Dy<sup>3+</sup>                  (d) S<sup>-</sup>, I<sup>-</sup>
37. The first ionization energy of helium is  $2370 \text{ kJ mol}^{-1}$ , the highest for any element.
- (a) Define *ionization energy* and discuss why for helium it should be so high.
- (b) Which element would you expect to have the highest *second* ionization energy? Why?
- (c) Suppose that you wished to ionize some helium by shining electromagnetic radiation on it. What is the maximum wavelength you could use?
38. The energy needed to remove one electron from a gaseous potassium atom is only about two-thirds as much as that needed to remove one electron from a gaseous calcium atom, yet nearly three times as much energy as that needed to remove one electron from K<sup>+</sup> as from Ca<sup>+</sup>. What explanation can you give for this contrast? What do you expect to be the relation between the ionization energy of Ca<sup>+</sup> and that of neutral K?

39. Without consulting any tables, arrange the following substances in order and explain your choice of order:
- $\text{Mg}^{2+}$ , Ar,  $\text{Br}^-$ ,  $\text{Ca}^{2+}$  in order of increasing radius
  - Na,  $\text{Na}^+$ , O, Ne in order of increasing ionization energy
  - H, F, Al, O in order of increasing electronegativity
40. Both the electron affinity and the ionization energy of chlorine are higher than the corresponding quantities for sulfur. Explain why in terms of the electronic structure of the atoms.
41. The cesium atom has the lowest ionization energy,  $375.7 \text{ kJ mol}^{-1}$ , of all the neutral atoms in the periodic table. What is the longest wavelength of light that could ionize a cesium atom? In which region of the electromagnetic spectrum does this light fall?
42. Until recently, it was thought that  $\text{Ca}^-$  was unstable, and that the Ca atom therefore had a negative electron affinity. Some new experiments have now measured an electron affinity of  $+2.0 \text{ kJ mol}^{-1}$  for calcium. What is the longest wavelength of light that could remove an electron from  $\text{Ca}^-$ ? In which region of the electromagnetic spectrum does this light fall?

## ADDITIONAL PROBLEMS

43. In the hydrogen atom, the transition from the  $2p$  state to the  $1s$  state emits a photon with energy  $16.2 \times 10^{-19} \text{ J}$ . In an iron atom, the same transition emits X-rays with wavelength  $0.193 \text{ nm}$ . Calculate the energy difference between these two states in iron. Explain the difference in the  $2p$ - $1s$  energy level spacing in these two atoms.
44. The energy needed to ionize an atom of element X when it is in its most stable state is  $500 \text{ kJ mol}^{-1}$ . However, if an atom of X is in its lowest excited state, only  $120 \text{ kJ mol}^{-1}$  is needed to ionize it. What is the wavelength of the radiation emitted when an atom of X undergoes a transition from the lowest excited state to the ground state?
45. Suppose an atom in an excited state can return to the ground state in two steps. It first falls to an intermediate state, emitting radiation of wavelength  $\lambda_1$ , and then to the ground state, emitting radiation of wavelength  $\lambda_2$ . The same atom can also return to the ground state in one step, with the emission of radiation of wavelength  $\lambda$ . How are  $\lambda_1$ ,  $\lambda_2$ , and  $\lambda$  related? How are the frequencies of the three radiations related?
46. For the Li atom, the energy difference between the ground state and the first excited state, in which the outermost electron is in a  $2p$  orbital, is  $2.96 \times 10^{-19} \text{ J}$ . In the  $\text{Li}^{2+}$  ion, the energy difference between the  $2s$  and  $2p$  levels is less than  $0.00002$  of this value. Explain this observation.
47. How does the  $3d_{xy}$  orbital of an electron in  $\text{O}^{7+}$  resemble the  $3d_{xy}$  orbital of an electron in a hydrogen atom? How does it differ?
48. The wave function of an electron in the lowest (that is, ground) state of the hydrogen atom is
- $$\psi(r) = \left( \frac{1}{\pi a_0^3} \right)^{1/2} \exp\left(-\frac{r}{a_0}\right)$$
- $$a_0 = 0.529 \times 10^{-10} \text{ m}$$
- What is the probability of finding the electron inside a sphere of volume  $1.0 \text{ pm}^3$ , centered at the nucleus ( $1 \text{ pm} = 10^{-12} \text{ m}$ )?
  - What is the probability of finding the electron in a volume of  $1.0 \text{ pm}^3$  at a distance of  $52.9 \text{ pm}$  from the nucleus, in a fixed but arbitrary direction?
  - What is the probability of finding the electron in a spherical shell of  $1.0 \text{ pm}$  in thickness, at a distance of  $52.9 \text{ pm}$  from the nucleus?
49. An atom of sodium has the electron configuration  $[\text{Ne}]6s^1$ . Explain how this is possible.
50. (a) The nitrogen atom has one electron in each of the  $2p_x$ ,  $2p_y$ , and  $2p_z$  orbitals. By using the form of the angular wave functions, show that the total electron density,  $\psi^2(2p_x) + \psi^2(2p_y) + \psi^2(2p_z)$ , is spherically symmetric (that is, it is independent of the angles  $\theta$  and  $\phi$ ). The neon atom, which has *two* electrons in each  $2p$  orbital, is also spherically symmetric.
- (b) The same result as in part (a) applies to  $d$  orbitals, thus a filled or half-filled subshell of  $d$  orbitals is spherically symmetric. Identify the spherically symmetric atoms or ions among the following:  $\text{F}^-$ , Na, Si,  $\text{S}^{2-}$ ,  $\text{Ar}^+$ , Ni, Cu, Mo, Rh, Sb, W, Au.
51. Chromium(IV) oxide is used in making magnetic recording tapes because it is paramagnetic. It can be described as a solid made up of  $\text{Cr}^{4+}$  and  $\text{O}^{2-}$ . Give the electron configuration of  $\text{Cr}^{4+}$  in  $\text{CrO}_2$ , and determine the number of unpaired electrons on each chromium ion.
52. Use the data from Appendix F to graph the variation of atomic radius with atomic number for the rare-earth elements from lanthanum to lutetium.
- What is the general trend in these radii? How do you account for it?
  - Which two elements in the series present exceptions to the trend?
53. Arrange the following seven atoms or ions in order of size, from smallest to largest: K,  $\text{F}^+$ , Rb,  $\text{Co}^{25+}$ , Br, F,  $\text{Rb}^-$ .
54. Which is higher, the third ionization energy of lithium or the energy required to eject a  $1s$  electron from a Li atom in a PES experiment? Explain.

55. The outermost electron in an alkali-metal atom is sometimes described as resembling an electron in the corresponding state of a one-electron atom. Compare the first ionization energy of lithium with the binding energy of a  $2s$  electron in a one-electron atom that has nuclear charge  $Z_{\text{eff}}$ , and determine the value of  $Z_{\text{eff}}$  that is necessary for the two energies to agree. Repeat the calculation for the  $3s$  electron of sodium and the  $4s$  electron of potassium.
56. In two-photon ionization spectroscopy, the combined energies carried by two different photons are used to remove an electron from an atom or molecule. In such an experiment, a K atom in the gas phase is to be ionized by two different light beams, one of which has a 650-nm wavelength. What is the maximum wavelength for the second beam that will cause two-photon ionization?
57. For the H atom, the transition from the  $2p$  state to the  $1s$  state is accompanied by the emission of a photon with an energy of  $16.2 \times 10^{-19}$  J. For an Fe atom, the same transition ( $2p$  to  $1s$ ) is accompanied by the emission of X-rays of 0.193-nm wavelengths. What is the energy difference between these states in iron? Comment on the reason for the variation (if any) in the  $2p$ - $1s$  energy-level spacing for these two atoms.
58. (a) Give the complete electron configuration ( $1s^2 2s^2 2p \dots$ ) of aluminum in the ground state.  
(b) The wavelength of the radiation emitted when the outermost electron of aluminum falls from the  $4s$  state to the ground state is about 395 nm. Calculate the energy separation (in joules) between these two states in the Al atom.  
(c) When the outermost electron in aluminum falls from the  $3d$  state to the ground state, the radiation emitted has a wavelength of about 310 nm. Draw an energy-level diagram of the states and transitions discussed here and in (b). Calculate the separation (in joules) between the  $3d$  and  $4s$  states in aluminum. Indicate clearly which has higher energy.
59. What experimental evidence does the periodic table provide that an electron in a  $5s$  orbital is slightly more stable than an electron in a  $4d$  orbital for the elements with 37 and 38 electrons?

Iodine in the Human Diet

Potential energy diagram for the decomposition of the methyl methoxy radical, an important intermediate in the combustion of dimethyl ether. Highly accurate computational quantum chemistry methods were used to calculate the configurations and the relative energies of the species shown. (Courtesy of Prof. Emily Carter, Princeton)

Chemists seek to understand the atomic interactions that form molecules and extended solid structures, to understand intermolecular interactions, and, most important, to understand chemical reactivity. Quantum mechanics provides a firm conceptual foundation for understanding these phenomena, all of which involve the chemical bond.

The concept of the chemical bond as an agent for holding atoms together in molecules was formulated around the middle of the 19th century. In the 1860s, the chemists August Wilhelm Hofmann and Edward Frankland used three-dimensional arrays of colored wooden balls as models for molecular structure in their lectures in Berlin and London. In 1875 the Dutch chemist Jacobus van't Hoff popularized these developments in a book entitled *Chemistry in Space*, and by 1885 the three-dimensional representation of molecules was universally accepted.

Today, chemistry is a sophisticated science, fully integrated with modern computer technology, and chemists use a broad array of display tools aided by computer graphics to describe various aspects of molecular structure. Even so, chemists continue to use “ball-and-stick models,” in which each ball represents an atom, centered on the position of the nucleus, and the sticks represent chemical bonds, to help them think about the geometry of molecular structure. Molecular geometry is defined by the lengths of the bonds between the nuclei and the angles between the bonds (see Figs. 3.1 and 3.24).

After J. J. Thomson discovered the electron in 1897, and especially after Ernest Rutherford formulated the planetary model of the atom in 1912, physicists and chemists sought to explain the chemical bond as special arrangements of the electrons around the nuclei. For example, G. N. Lewis considered the electrons to be “localized” in pairs to form covalent bonds between the nuclei. Nonetheless, these electron pairs are not explicitly included in the description of molecular structure. The electrons provide attractive forces that hold the molecule together in a geometry defined by a particular set of bond lengths and bond angles despite the repulsive forces that tend to push the nuclei apart. How the electrons hold the molecule together can only be explained by using quantum mechanics, as we shall show in Section 6.1 below.

Today, quantum chemistry provides very good approximate solutions to Schrödinger’s equation for molecules. Perhaps more important, it provides new qualitative concepts for representing and describing chemical bonds, molecular structure, and chemical reactivity. The quantum description of the chemical bond justifies the electron pair model, shows the limits of its validity, and points the way to advances beyond the pair model. The quantum description forms the basis for all modern studies in structural chemistry.

This chapter begins with a description of the quantum picture of the chemical bond and then applies this picture to the simplest possible molecule,  $\text{H}_2^+$ , which contains only one electron. Schrödinger’s equation for the motion of the electron in  $\text{H}_2^+$  can be solved exactly, and we use its solutions to display the general features of each **molecular orbital (MO)**, the one-electron wave functions that describe the electronic structure of molecules. Just as we used the **atomic orbitals (AOs)** of the H atom to suggest approximate AOs for complex atoms, we let the MOs for  $\text{H}_2^+$  guide us to develop approximations for the MOs of more complex molecules.

Guided by these insights, we then describe the two main ways to construct approximate molecular electronic wave functions from atomic orbitals, the **linear combination of atomic orbitals (LCAO)** method and the **valence bond (VB) method**. The LCAO method generates MOs that are *delocalized* over the entire molecule, and it builds up the electronic configurations of molecules using an aufbau principle just like the one for atoms. In contrast, the VB method describes electron pairs that are *localized* between a pair of atoms, and it provides a quantum mechanical foundation for the Lewis electron dot diagrams and for the valence shell electron pair repulsion (VSEPR) theory (see Ch. 3). We apply both of these methods to describe structure and bonding in a variety of molecules. We conclude the chapter by comparing the LCAO and VB methods and showing how each is the starting point for using modern methods for computational quantum chemistry. These are now sufficiently accurate and so easy to use that they are becoming part of every chemist’s set of tools for both research and education.

The central conceptual goal of this chapter is for you to understand that as two atoms approach each other and form a bond, their electron densities begin to interpenetrate and to form a new electron density characteristic of the molecule. We want you to see how to use the wave functions for electrons initially located on different atoms to form new wave functions that represent chemical bonds in molecules.

## 6.1 Quantum Picture of the Chemical Bond

Visualize two H atoms (labeled A and B), initially quite far apart, as they approach one another with the possibility of forming a chemical bond. We know from Chapter 3 that a bond can form only if the resulting molecule has lower energy than the pair of isolated atoms. Let's track progress by plotting the potential energy of the atoms as the distance between them  $R_{AB}$  decreases, using methods developed in Sections 3.3 and 3.7, and let's display the results in Figure 6.1. (We have already introduced this curve in a general, intuitive way in Figure 3.20.) At very large separation we define the energy of interaction to be zero. As the atoms come closer together, the potential energy decreases (becomes negative) due to attractive forces between the atoms. At very close distances the potential energy becomes positive due to repulsive forces between the atoms. At some intermediate but small distance between the atoms the attractive interactions dominate the repulsion, and the potential energy is negative; it reaches a minimum value where the attractive and repulsive forces balance exactly. This minimum is the signature of chemical bond formation. The value of the potential energy at this minimum measures the extent to which the bond is more stable than the separated atoms. The difference between this minimum and the value for the separated atoms is the amount of energy that must be invested to break the bond and liberate the free atoms. This is a positive number called the bond dissociation energy and denoted either  $D_e$  or  $\Delta E_d$ . The distance  $R_e$  at which the minimum occurs is the equilibrium length of the bond. For  $H_2$ , the bond dissociation energy  $D_e$  is  $458 \text{ kJ mol}^{-1}$ , or  $4.75 \text{ eV molecule}^{-1}$ , and experimental measurements show that the bond length is  $0.74 \text{ \AA}$ .

The total energy of the molecule is quantized, so we can visualize a set of energy levels superposed on the potential energy curve. Just as shown for the particle-in-a-box model (see Section 4.6), the uncertainty principle requires that there is a **zero-point energy** for the molecule. This is the lowest allowed value of the total energy, and is represented by the line  $E_0$ . Because the zero-point energy can never be removed from the molecule, it provides a reference point for the amount of energy required to dissociate the molecule. Relative to the zero-point energy, the **bond dissociation energy** is defined as  $D_0$ . Although both  $D_0$  and  $D_e$  are called dissociation energies, only the former is measurable experimentally as the energy needed to dissociate the molecule.  $D_e$  is useful as a parameter to construct model potentials and optimize geometry in calculations. The bond dissociation energy  $D_0$  for  $H_2$  is  $432 \text{ kJ mol}^{-1}$  (measured experimentally and calculated with quantum theory); it is smaller than  $D_e$  by the zero-point energy

**FIGURE 6.1** Schematic representation of the potential energy of two hydrogen atoms as a function of the distance between them. As distance decreases, the potential energy reaches a minimum value of  $-458 \text{ kJ mol}^{-1}$  at a distance of  $0.74 \text{ \AA}$ . The value of  $D_0$  for  $H_2$  is  $432 \text{ kJ mol}^{-1}$  or  $4.48 \text{ eV molecule}^{-1}$ .

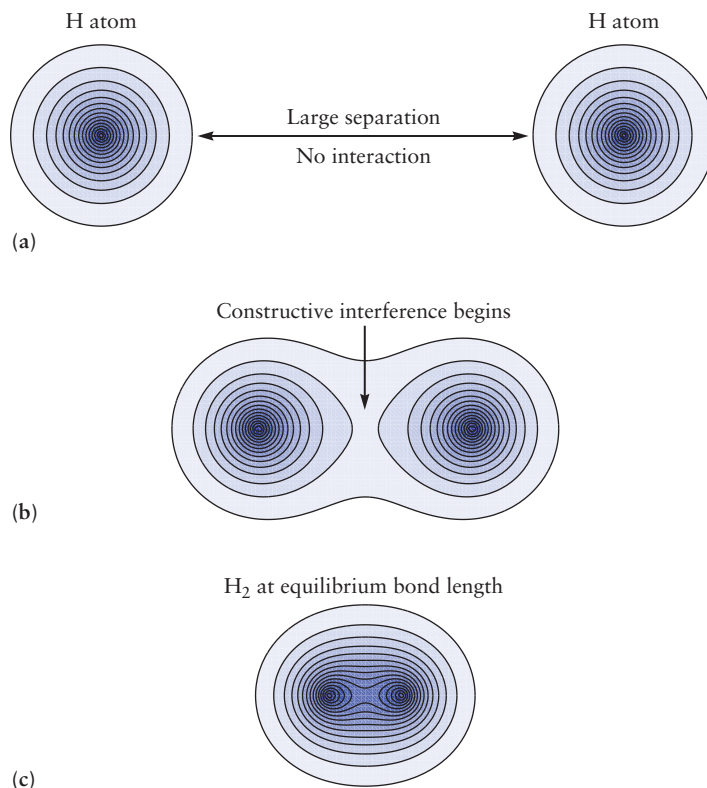

of  $H_2$  as shown in Figure 6.1. (If a polyatomic molecule dissociates,  $D_0$  is measured from the lowest quantum state of the reactants, called the zero-point level, to the zero-point level of the products, so again equals the experimentally measured bond dissociation energy at 0 K.)

The meaning of this curve is considerably more subtle than the simple description we gave to introduce it. Each atom contains one proton and one electron. Each of these four particles interacts with each of the others by a force described by Coulomb's law (see Fig. 3.19), and all these contributions must be included in the potential energy of the two atoms. However, the coordinates in Figure 6.1 track only the distance between the two protons, and do not describe the electrons at all.

The sequence of events traced in Figure 6.2 shows us what has happened. As the two atoms draw near, their electron densities interpenetrate and form a new electron density characteristic of the molecule. Because electrons behave like waves, the two atomic electronic wave functions can interfere either constructively or destructively. If the interference is constructive, the electron density in the region between the nuclei increases. The net result of this increased negative charge density between the nuclei is to attract them toward each other and offset their mutual Coulomb repulsion so they arrive at a stable position.

In fact, the curve in Figure 6.1 plots the *effective potential energy function* for the two protons in the molecule, against the distance between the protons. This effective potential energy function includes several contributions: (a) Coulomb repulsion between the protons; (b) Coulomb repulsion between the electrons; (c) Coulomb attractions of both electrons to both protons; (d) kinetic energies of the electrons. The contributions from the electrons have been averaged out in some sense, and their coordinates do not appear in the effective potential energy curve. The effective potential energy function governs the formation of the molecule (it gives the depth of the potential well relative to the isolated atoms), the structure of the molecule (by defining the equilibrium bond length), and the vibrations of the molecule (by defining the force that determines the relative

**FIGURE 6.2** The probability density for finding an electron in the  $H_2$  molecule, plotted at three internuclear distances: (a)  $8a_0$ , (b)  $3.5a_0$ , and (c)  $1.4a_0$ . At the equilibrium bond length (c) significant build up of electron density between the nuclei is visible. (Courtesy of Chad Heaps, David A. Mazziotti, The University of Chicago)

motions of the nuclei). If we can find a way to predict the effective potential energy curve as a function of the distance between the nuclei, we will know all the structural properties of the molecule.

The only justification for the effective potential energy curve for a molecule is provided by the quantum description of the chemical bond. Not only does this theory define the concept of the effective potential energy curve, it also provides an explicit procedure for calculating the curve. The quantum description of the chemical bond therefore has enormous predictive power. It can determine whether a particular molecule will exist, and if it does exist what will be its structure and properties.

The definition of the effective potential energy curve for a molecule, and the method for calculating it, arise naturally within the Born–Oppenheimer approximation, which is the foundation of molecular calculations in quantum mechanics. Now let's see how to obtain the effective potential energy curve and how to use it.

### 6.1.1 Born–Oppenheimer Approximation: Slow Nuclei, Fast Electrons

This approximation method was developed by the physicists Max Born (German) and J. Robert Oppenheimer (American) in 1927, just one year after Schrödinger's quantum solution for the H atom. Born and Oppenheimer recognized that because the nuclei are much more massive than the electrons (the mass of the proton is 1836 times the mass of the electron), the nuclei in molecules will move much more slowly than the electrons. This enables dividing the problem of describing the molecule in detail into two parts:

(A) Consider the nuclei to be fixed at a specific set of positions. (For the  $H_2$  molecule in Figure 6.1 this means a specific fixed value of  $R_{AB}$ .) Then solve Schrödinger's equation for the electrons moving around the fixed nuclei and obtain the allowed quantized energy levels,  $E_{el}$ , and wave functions,  $\psi_{el}$ , for the electrons. (For  $H_2$  this involves two electrons and six coordinates to track their positions in three-dimensional space.) Next we move the nuclei a bit, and repeat the calculation for the electrons at the new fixed location for the nuclei. The Schrödinger equation for this electronic problem includes the kinetic energies of the electrons, the Coulomb attraction of both electrons to both nuclei, the Coulomb repulsion between the electrons, and the Coulomb repulsion between the nuclei (at their fixed positions, which is the separation  $R$ , or  $R_{AB}$  in Fig. 6.1, for  $H_2$ ), so the only term left out is the kinetic energy of the nuclei. Then (B) use the resulting energy,  $E_{el}$ , from solving  $\mathcal{H}_{el}\psi_{el} = E_{el}\psi_{el}$ , as the effective potential energy for the motion of the nuclei. The lowest energy solution for  $E_{el}$  at each fixed internuclear position gives the  $V(R)$  shown in Figure 6.1, the effective potential energy as a function of internuclear distance for  $H_2$ . That gives us the bond dissociation energy and the equilibrium bond length. Using this potential energy function and the kinetic energy for the relative motion of the nuclei (that we left out previously), we construct and solve a Schrödinger equation for the nuclear motion. The resulting wave functions for the nuclei and their corresponding energies give the allowed energies for the vibrational motion (see Figure 12.23 and Section 20.3) and rotational motion (see Section 20.3) of the molecule.

The Born–Oppenheimer approximation invites a new interpretation of how electrons are distributed in molecules. Instead of the localized electron pairs visualized by Lewis, we visualize a group of electrons moving rapidly around the sluggish nuclei, to establish a distribution of electron density described by quantum mechanics. This distribution holds the molecule together with fixed bond lengths and bond angles.

The Born–Oppenheimer approximation is equally applicable to polyatomic molecules, but the details become complicated rapidly as the number of atoms

**FIGURE 6.3** Schematic representation of the Born–Oppenheimer approximation for methane. (a) The nuclei are assumed to be fixed at positions corresponding to the equilibrium bond distances, while the electrons move rapidly around them. The wave functions and allowed energy values are calculated for the electrons at many different positions of the nuclei. (b) The allowed energy values calculated in (a), with the internuclear repulsions added in, are viewed as the effective potential energy functions that govern the relative motions of the nuclei in the molecule, as occurs in vibrations. The electron density calculated in (a) is shown, with shades of red indicating electron densities between  $11 \times 10^{-3}$  and  $16.5 \times 10^{-3} \text{ \AA}^{-3}$  turning to yellow for electron densities greater than  $16.5 \times 10^{-3} \text{ \AA}^{-3}$ .

increases and require multidimensional spaces for their description. We illustrate the concepts schematically for the methane molecule  $\text{CH}_4$  (5 nuclei, 10 electrons) in Figure 6.3. During the calculations in Part A, 15 nuclear coordinates are held fixed at sequential positions, and 30 coordinates for the electrons are allowed to vary. All the electrons, both valence and core, in all the atoms are included in these calculations. That means the Schrödinger equation for Part A has 30 independent variables. The resulting  $\psi_{\text{el}}$ , when squared, gives the electron density in the methane molecule shown in Figure 6.3b. The corresponding energy  $E_{\text{el}}$  is the potential energy  $V$ , now a function of 3(5)-6 bond angles and internuclear distances in methane. This effective potential governs the nuclear motion (vibrations and bond-breaking).

Today chemists have very sophisticated computer programs to carry out calculations of this type, even for quite large molecules. The effective potential energy functions are represented as highly visual sections of multi-dimensional surfaces that, when used as the potential energy in the Schrödinger equation for the nuclear motion, allows you to predict not only vibrations of existing bonds but also the dynamics and kinetics of breaking old bonds and forming new bonds to describe chemical reactivity.

The Born–Oppenheimer approximation is a remarkable scientific achievement. It started out as a mathematical simplification for trying to solve the Schrödinger equation for a molecule, and turned out to provide the most important concept for describing a chemical bond. Even more remarkable, the approximation originates in the simple physical fact that protons are nearly 2000 times more massive than electrons, and therefore must move quite sluggishly while the electrons move very rapidly.

Most chemists need never work through the details of the Born–Oppenheimer approximation, but they must surely be aware of its scientific content and consequences: not only does it define the effective potential energy curve for a molecule, but it also defines the route for explicitly calculating that curve for any particular molecule.

In the remainder of Chapter 6 we introduce various methods to construct approximate wave functions that describe the distribution of electron density around the nuclei in a molecule. In each case we will obtain the effective potential energy curve and use it to interpret and predict molecular structure from the approximate wave function.

## 6.2 Exact Molecular Orbitals for the Simplest Molecule: $\text{H}_2^+$

Before we begin constructing approximate molecular orbitals for familiar molecules, it is useful to examine briefly the one molecule whose electronic wave function can be solved exactly by quantum mechanics.

The hydrogen molecular ion contains a single electron bound to two protons. It is a stable but highly reactive species produced by electrical discharge in  $\text{H}_2$  gas. Its bond length is  $1.06 \text{ \AA}$ , and its bond dissociation energy  $D_e$  to produce H and  $\text{H}^+$  is  $2.79 \text{ eV} = 269 \text{ kJ mol}^{-1}$ . The similarity of these values to those for more familiar molecules (see Chapter 3) suggests that the exact quantum solutions for  $\text{H}_2^+$  will provide insights into chemical bonding that can be transferred to more complex molecules. The solutions for  $\text{H}_2^+$  also introduce essential notation and terminology used in describing the covalent bonding in larger molecules.

The hydrogen molecular ion is sketched in Figure 6.4. The two nuclei, for convenience labeled A and B, are separated by the distance  $R_{AB}$  along the internuclear axis, chosen by convention to be the  $z$ -axis. The electron is located at distance  $r_A$  from nucleus A, and at distance  $r_B$  from nucleus B. The angle  $\phi$  describes the electron's location about the internuclear axis. For a fixed value of  $R_{AB}$ , the position of the electron is more conveniently specified by the values of  $(r_A, r_B, \phi)$  than by  $(x, y, z)$  since the former set reflects the natural symmetry of the system. The potential energy of the system is given by

$$V = -\frac{e^2}{4\pi\epsilon_0} \left( \frac{1}{r_A} + \frac{1}{r_B} \right) + \frac{e^2}{4\pi\epsilon_0} \left( \frac{1}{R_{AB}} \right) = V_{\text{en}} + V_{\text{nn}} \quad [6.1]$$

The first two terms in Equation 6.1 represent the attractions between the electron and the two nuclei,  $V_{\text{en}}$ , and the last term represents the repulsion between the pair of protons,  $V_{\text{nn}}$ . For each combination of values for  $r_A$  and  $r_B$

**FIGURE 6.4** Coordinates for the  $\text{H}_2^+$  molecular ion. The two nuclei are located along the  $z$ -axis, separated by the distance  $R_{AB}$ . The vectors  $\vec{r}_A$  and  $\vec{r}_B$  shown have lengths  $r_A$  and  $r_B$ , the distances of the electron from nuclei A and B, respectively;  $r_A$  and  $r_B$  range from 0 to  $\infty$ . The angle  $\theta$  is determined from  $r_A$ ,  $r_B$ , and  $R_{AB}$  by the law of cosines; it does not appear explicitly in the calculation. The angle  $\phi$  varies from 0 to  $2\pi$ .

the potential energy has the same value at all values of the angle  $\phi$ . The potential energy has cylindrical symmetry around the  $R_{AB}$  axis, and the angle  $\phi$  does not appear in the equation for potential energy.

The quantum treatment of this molecule appears to be a straightforward extension of that for the H atom (see Section 5.1 for the solutions). One more proton has been added, and the symmetry of the system has changed from spherical to ellipsoidal. The new feature is the internuclear distance  $R_{AB}$ , the bond length of the molecule. Since there is no exact solution that describes the motion of all three particles, let's use the Born–Oppenheimer approximation (described in Section 6.1). We assume that  $R_{AB}$  is held at the measured equilibrium bond length, and we find  $\psi_{el}(r_A, r_B, \phi; R_{AB})$  the *electronic wave function* for the electron around the fixed nuclei. The semicolon inside the parentheses indicates that the nuclear coordinates are held fixed as a *parameter* (for now at the equilibrium bond length 1.06 Å) while the electronic coordinates range over all values as we seek the solution for  $\psi_{el}$ . Because the potential energy is the same at all values of the angle  $\phi$ , the angular coordinate will influence the shape of the molecular orbital but not the energy levels of the electron, just as the angles ( $\theta, \phi$ ) in Figure 5.1 contributed to the shape of the hydrogen orbitals but not the energy levels. Therefore we omit  $\phi$  in subsequent equations for  $H_2^+$ .

The electronic wave function  $\psi_{el}$  lies at the heart of chemical bonding because its square gives the probability density for locating the electrons around the nuclei. To obtain  $\psi_{el}$  for  $H_2^+$ , we solve the Schrödinger equation for the electron by the same methods we applied to the H atom in Section 5.1. We require the solution to be smooth, single-valued, and finite in value in all regions of space so its square is a well-defined probability density function. We also enforce physical boundary conditions to guarantee that our solution describes a bound state of the electron ( $\psi_{el}$  must approach 0 as  $r_A \rightarrow \infty$  and as  $r_B \rightarrow \infty$ ). We find that solutions exist only when the total energy and the component of angular momentum directed along the internuclear axis are quantized. The complete set of quantum numbers is more extensive than that for the H atom, and will not be discussed here.

### 6.2.1 Electronic Wave Functions for $H_2^+$

We emphasize that the solutions for  $\psi_{el}$  are mathematically exact. Because of their ellipsoidal symmetry, they cannot be written as simple exponential and polynomial functions that are easily manipulated, as were the H atom solutions. Consequently we present and interpret these exact solutions in graphical form.

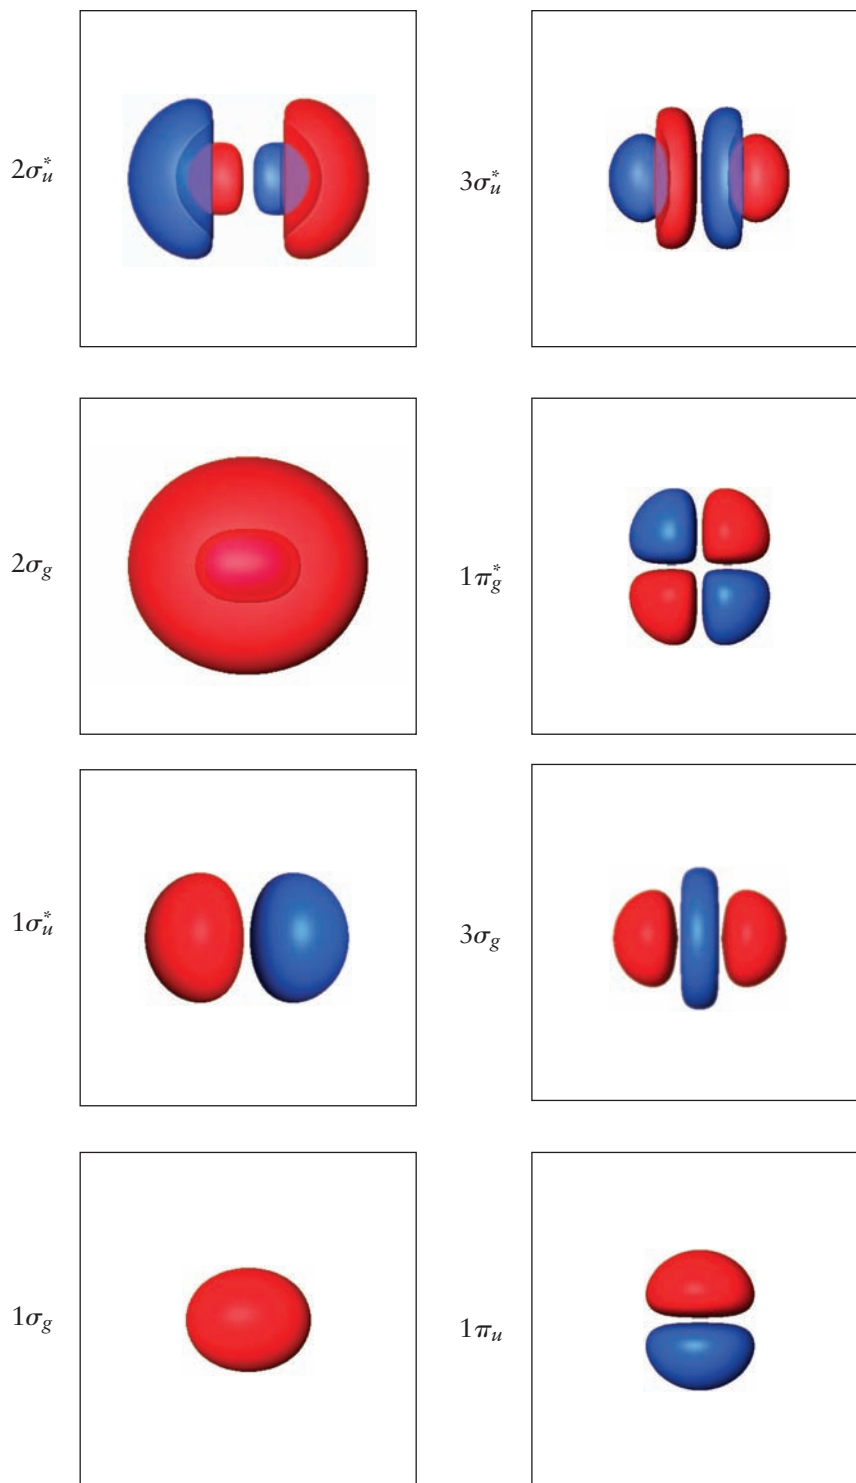

The first eight wave functions, starting with the ground state, are shown in Figure 6.5. These are plotted using the same coordinates as in Figure 6.4 (but with the axes reoriented so the  $z$ -axis is horizontal), where the two protons lie on the  $z$ -axis and the value of  $R_{AB}$  is the experimental bond length for  $H_2^+$ , which is 1.06 Å. Each wave function is shown as an isosurface comprising all those points in three-dimensional space where the wave function has the value equal to  $\pm 0.1$  of its maximum value. Regions where the wave function has a positive value are shown in red, and regions where the wave function has a negative value in blue, as in the display images of atomic orbitals in Chapter 5.

Each wave function is identified by four labels. By analogy with the quantum number subscripts on the hydrogen atomic orbitals, these labels summarize the energy and the shape of each wave function. Each provides insight into the shape and symmetry of the wave function and its corresponding probability density for locating the electron. They help us understand how the electron density has been shifted away from the spherical symmetry of the H atom to accommodate the second nucleus and the internuclear distance in the molecule.

First, the integer is an index that tracks the relative energies of the wave functions of each symmetry type. For example,  $1\sigma_g$  is the first (lowest on the

**FIGURE 6.5** Wave functions for the first eight energy levels of the  $H_2^+$  molecular ion, calculated exactly by quantum mechanics. The two nuclei lie along the z-axis, which is in the plane of the paper. Regions of positive and negative values of the wave function are shown in red and blue, respectively. The labels for each orbital are explained in the text. The images are isosurfaces corresponding to contours at  $\pm 0.1$  of the maximum value. The  $1\sigma_g$  is the orbital the electron occupies when  $H_2^+$  is in its ground electronic state, and the energies increase in the order  $1\sigma_g < 1\sigma_u^* < 2\sigma_g < 2\sigma_u^* < 1\pi_u < 3\sigma_g < 1\pi_g^* < 3\sigma_u^*$ .

(Courtesy of Mr. Hatem Helal and Professor William A. Goddard III, California Institute of Technology, and Dr. Kelly P. Gaiher, University of Texas at Austin.)

energy scale) of the  $\sigma_g$  wave functions, while  $2\sigma_u^*$  has the second lowest energy of the  $\sigma_u$  wave functions, and  $1\pi_u$  has the lowest energy of the  $\pi_u$  wave functions. The energy index integer is analogous to the principal quantum number  $n$  for atomic orbitals. As the index increases within each symmetry type, the number of nodes along the internuclear axis increases.

Second, the Greek letter tells us how the amplitude of the wave function is distributed around the internuclear axis. The letter  $\sigma$  indicates the amplitude has cylindrical symmetry around the axis; a cross-section of the orbital in a

plane perpendicular to the axis is a disc. The letter  $\pi$  signifies that the wave function has a nodal plane that contains the internuclear axis. A cross-section perpendicular to the axis shows a node at the axis with the wave function having positive values on one side of the axis and negative values on the other side. These properties originate in the angular momentum of the electron as it moves around the internuclear axis, and remind us of the  $s$  and  $p$  atomic orbitals. An electron in a  $\sigma$  wave function has no component of angular momentum along the axis and therefore can approach the axis. An electron described by a  $\pi$  wave function has a nonzero component of angular momentum along the axis and thus does not approach the axis.

Third, the subscript  $g$  or  $u$  describes how the wave function changes as we invert our point of observation through the center of the molecule. Imagine Cartesian coordinates with their origin at the center of the molecule, and compare the wave function at the point  $(x, y, z)$  and at the point  $(-x, -y, -z)$ . If the sign of the wave function is the same at these two points, it is called symmetric and labeled  $g$  for the German word *gerade* (even). If the sign of the wave function is opposite at these two points, it is called antisymmetric and labeled  $u$ , for the German word *ungerade* (odd). The sign of a wave function is critical because it determines whether, if there is an overlap in space with another atom's or molecule's wave function, the two waves interfere constructively or destructively (see Chapter 4) during the formation of a chemical bond.

Finally, we examine the behavior of the wave function when the point of observation is reflected through a plane perpendicular to the internuclear axis and located at the center of the molecule. If the wave function changes sign upon reflection, it receives the superscript  $*$ . If it does not change sign upon reflection, no symbol is added. Each wave function labeled  $*$  has a node on the internuclear axis at the center of the molecule, which means there is zero electron density at this point. We will see later that such nodes in the electronic wave function located between two atoms in a molecule have special significance in the description of chemical bonds. (Note that in a heteronuclear diatomic molecule, the electron density is not shared equally between the two atoms, so there is no plane of symmetry perpendicular to the internuclear axis between the two atoms; thus the nodal surface across which the wave function changes from positive to negative in value is closer to one atom, but a  $*$  is still used as a label.)

We call each of these exact one-electron wave functions a **molecular orbital**, just as we called the exact one-electron wave functions for the H atom atomic orbitals. These exact MOs play a fundamental role in the quantum description of chemical bonding. If you want to know more about these exact MOs, Figure 6.55 in Section 6.13, *A Deeper Look . . .*, provides several additional illustrations.

### EXAMPLE 6.1

In Section 5.1 we classified the atomic orbitals of H according to their number of angular nodes (each defined by a plane) and their radial nodes (each defined by a spherical surface). How do we extend this analysis to the molecular orbitals of  $\text{H}_2^+$ ?

#### Solution

As we move from atoms to diatomic molecules, the most important new feature is a unique choice for the  $z$ -axis of the coordinate system, defined along the internuclear axis of the molecule. We classify the molecular orbitals by their response to the symmetry operations of this cylindrical configuration. Rotating the

molecule about this axis does not change the  $\sigma$  MOs, but does change the  $\pi$  MOs. Inverting the coordinates through the center of the molecule does not change the  $g$  MOs, but does change the  $u$  MOs. Reflecting the coordinates through a plane perpendicular to the axis at the center of the molecule changes the  $*$  MOs, but does not change the MOs not labeled  $*$ . All these changes are described in the preceding text and are revealed by examining cross sections perpendicular to the  $z$ -axis. The cited problems illustrate these effects for specific MOs.

**Related Problems: 1, 2, 3, 4, 5, 6**

### 6.2.2 Nature of the Chemical Bond in $\text{H}_2^+$

Our intuitive understanding of the chemical bond is that the nuclei and electrons arrange themselves in a manner that reduces their total energy to a value lower than the total energy of the isolated atoms. Achieving this arrangement requires that new attractive interactions come into play to overcome the internuclear repulsion as the bond is formed. Naively, we expect this to occur when the electrons are arranged so they spend most of their time “between” the nuclei where they would experience maximum attraction to all the nuclei, not just the nucleus of the parent atom. We saw in Section 3.7 that classical electrostatics could not explain this stabilization mechanism, so we relied on the qualitative Lewis model of electron-shared pair bonds. Now we want to see how these ideas are handled by quantum mechanics in the simplest case. We recommend that you review Section 3.7 at this point.

First, let’s examine the electron density around the nuclei, assumed fixed at the equilibrium bond length, which is calculated by squaring each MO wave function in Figure 6.5. Detailed quantum calculations show that in the  $1\sigma_g$  orbital the electron density between the two nuclei in the  $\text{H}_2^+$  ion is greater than that of two noninteracting H atoms, and so is consistent with our expectations about chemical bonding. But in the  $1\sigma_u^*$  orbital the electron density between the nuclei is less than that for two noninteracting H atoms. Indeed, the electron density in the  $1\sigma_u^*$  orbital goes to zero halfway between the nuclei (clearly visible in the image of the orbital in Figure 6.5) and thus appears inconsistent with a chemical bond. If you want to know more about the electron density in these exact MOs, Figure 6.56 in Section 6.13, *A Deeper Look . . .* provides quantitative plots of electron density in each of the 8 MOs and some further discussion.

It appears that  $1\sigma_g$  supports formation of the bond by increasing electron density between the nuclei whereas  $1\sigma_u^*$  opposes bond formation by reducing electron density between the nuclei. Yet, both functions are part of the exact quantum solution for  $\text{H}_2^+$ . To understand the role each of them plays in forming the bond, we need to determine how the energy of these states compares to the energy of the isolated atom and proton. Reducing the energy relative to the separated particles is the key to bond formation.

To see how the energy depends on the internuclear separation, we simply fix the nuclei in space, solve Schrödinger’s equation for the electron with the nuclei fixed at that position (with the Coulomb repulsion between the nuclei at fixed  $R_{AB}$  included in  $\mathcal{H}_{el}$ ), then move the nuclei a bit, and repeat the calculation until we have covered all reasonable values of the nuclear positions. (This process is carried out systematically using the Born–Oppenheimer approximation which is described in Section 6.1.) This calculation gives the electronic energy  $E_{el}(R_{AB})$  as a function of the positions of the nuclei so is the effective potential energy that governs the motion of the nuclei shown in Figure 6.6. When the electron is in the  $1\sigma_u^*$  MO, the effective potential energy is greater than that of the separated atoms at all distances, and increases as the internuclear distance decreases. This energy represents a repulsive interaction, under which the nuclei would fly apart rather than remain close together.

In contrast, when the electron is in the  $1\sigma_g$  MO the effective potential energy is lower than that for noninteracting H atoms, and indeed reaches a minimum between the nuclei. When the electron is in this orbital, the molecular ion is energetically stable with a bond length that corresponds to the minimum in the potential energy curve.

Considered together, the increased electron density between the nuclei when the electron is in the  $1\sigma_g$  orbital and the resulting lowering of the potential energy at  $R_{AB} = R_e$  (the equilibrium bond length) indicate formation of a chemical bond. Consequently,  $1\sigma_g$  is called a **bonding molecular orbital**.

**FIGURE 6.6** The total energy (excluding nuclear kinetic energy) of  $\text{H}_2^+$  as a function of internuclear separation when the electron is in the  $1\sigma_g$  orbital (red curve), and when the electron is in the  $1\sigma_u^*$  orbital (blue curve), obtained in the exact solution of Schrödinger's equation for  $\text{H}_2^+$ . The internuclear separation is plotted in units of the Bohr radius. As explained in the text these curves are interpreted as the effective potential energy of the protons when the electron is in each of the respective orbitals. (Adapted from R. S. Berry, S. A. Rice, and J. Ross, *Physical Chemistry*, (2nd ed.), New York: Oxford, 2000, Figure 6.6.)

By contrast, when the electron is in the  $1\sigma_u^*$  orbital the molecular ion shows zero electron density halfway between the nuclei and an increase in the effective potential energy (the total energy less the nuclear kinetic energy) as the atoms approach each other. Consequently this is called an **antibonding molecular orbital**. We can gain physical insight into the nature of the antibonding MO by realizing that an electron in this MO has significant probability density in regions that are not “between the protons.” In the classical electrostatic picture depicted in Chapter 3, Figure 3.22, an electron in this orbital is still part of the molecule, but it spends most of its time tugging the protons apart rather than pulling them together. From this analysis we conclude that all the MOs labeled with \* in Figure 6.5 are antibonding. Because each has a nodal plane between the two atoms perpendicular to the internuclear axis, the effective potential energy curve will be repulsive.

### 6.2.3 Summary: Key Features of the Quantum Picture of Chemical Bonding

Key features of the quantum picture of the chemical bond are revealed by our study of the exact molecular orbitals for the  $\text{H}_2^+$  ion. In the remainder of this chapter, they guide the development of approximate molecular orbital methods for more complicated molecules. These features are

1. In representing molecular structures, we consider the nuclei to be fixed (more precisely, slowly vibrating around) at positions corresponding to the equilibrium geometry of the molecule while the electrons move rapidly around them (the Born–Oppenheimer approximation).
2. A molecular orbital is a one-electron wave function whose square describes the distribution of electron density around the nuclei in their equilibrium positions.
3. An electron in a bonding molecular orbital has increased electron density in the region between the nuclei when  $R = R_e$ , decreasing the effective potential energy relative to that of the separated atoms.
4. Each bonding molecular orbital is related to an antibonding molecular orbital which has zero amplitude on a surface between the nuclei and thus a node on the internuclear axis. An electron in an antibonding molecular orbital leads to effective potential energy higher than that of the separated atoms.

5. Bonding and anti-bonding molecular orbitals of type  $\sigma$  are those for which the electron density is distributed symmetrically about the internuclear axis. A  $\sigma$  orbital has cylindrical symmetry; cross-sections perpendicular to the internuclear axis are discs.
6. Bonding and anti-bonding molecular orbitals of type  $\pi$  are those for which the electron density has a nodal plane that contains the internuclear axis. Consequently, the amplitude is concentrated “off the axis” and the orbital does not have cylindrical symmetry about the internuclear axis.

## 6.3 Molecular Orbital Theory and the Linear Combination of Atomic Orbitals Approximation for $H_2^+$

The goal of this section is to introduce the first of the two main methods for generating approximate electronic wave functions for molecules. The LCAO method consists of selecting sums and differences (linear combinations) of atomic orbitals to generate the best approximation to each type of molecular orbital. The approximate MO constructed in this way is then used to calculate properties of the molecule using standard equations of quantum mechanics, by hand for simple cases and by computer for larger molecules.

The LCAO method is best explained with the help of a specific example, so we start with the hydrogen molecular ion  $H_2^+$ . We can evaluate the success of the method by comparing its results to the exact solution described in Section 6.2, and gain confidence in applying the method to more complex molecules.

The LCAO approximation is motivated by physical reasoning as follows. Consider the  $1\sigma_g$  MO shown in Figure 6.5. When the electron is close to nucleus A, it experiences a potential not very different from that in an isolated hydrogen atom. The ground-state MO in the region near A should therefore resemble a  $1s$  atomic wave function  $\varphi_{1s}^A$ . Near B, the MO should resemble  $\varphi_{1s}^B$ . (These atomic orbitals were given the symbol  $\psi_{1s}$  in Chapter 5.) The  $1s$  orbitals at A and B are identical (with the exception that the origin of each orbital’s coordinate system is on a different atom); the labels are attached to emphasize the presence of two nuclei. Note that A and B are merely labels, not exponents. A simple way to construct a MO with these properties is to approximate the  $1\sigma_g$  MO as a sum of the H  $1s$  orbitals with adjustable coefficients. Similarly, we can approximate the other exact MOs in Figure 6.5 by forming linear combinations of the H atomic orbitals which they resemble when the electron is near A or B.

The general form for an approximate MO for  $H_2^+$  is a linear combination of two atomic orbitals, obtained by adding or subtracting the two: with coefficients whose values depend on  $R_{AB}$ :

$$\psi_{MO} = C_A(R_{AB})\varphi_{1s}^A \pm C_B(R_{AB})\varphi_{1s}^B$$

For our purposes, it is adequate to ignore the dependence of the coefficients on  $R_{AB}$  and evaluate them by normalizing the wave function.

The coefficients  $C_A$  and  $C_B$  give the relative weights of the two atomic orbitals in determining the character of the MO. If  $C_A$  were greater in magnitude than  $C_B$ , the  $\varphi_{1s}^A$  orbital would be more heavily weighted and the electron would be more likely to be found near nucleus A and vice versa. But because the two nuclei in the  $H_2^+$  ion are identical, the electron is just as likely to be found near one nucleus as the other. Therefore, the magnitudes of  $C_A$  and  $C_B$  must be equal, so either  $C_A = C_B$  or  $C_A = -C_B$ . For both these choices  $(\psi_{MO})^2$  does not change if the A and B nuclei are interchanged.

To maintain the distinctions among the various orbitals, we will use the following notation in describing the LCAO approximation. Atomic orbitals will be represented by  $\varphi$  and molecular orbitals by  $\sigma$  or  $\pi$ . Generic wave functions will be represented by  $\psi$ . Occasionally,  $\psi$  will represent some special wave function, in which case appropriate subscripts will be attached.

### 6.3.1 LCAO Molecular Orbitals for $\text{H}_2^+$

Proceeding as described above, we construct approximate molecular orbitals for the exact  $1\sigma_g$  and  $1\sigma_u^*$  MOs in Figure 6.5:

$$1\sigma_g \approx \sigma_{g1s} = C_g[\varphi_{1s}^A + \varphi_{1s}^B] \quad [6.2a]$$

$$1\sigma_u^* \approx \sigma_{u1s}^* = C_u[\varphi_{1s}^A - \varphi_{1s}^B] \quad [6.2b]$$

TABLE 6.1

Molecular Orbitals for Homonuclear Diatomic Molecules

Exact MO Notation	LCAO MO Notation
$1\sigma_g$	$\sigma_{g1s}$
$1\sigma_u^*$	$\sigma_{u1s}^*$
$2\sigma_g$	$\sigma_{g2s}$
$2\sigma_u^*$	$\sigma_{u2s}^*$
$1\pi_u$	$\pi_{u2p_x}, \pi_{u2p_y}$
$3\sigma_g$	$\sigma_{g2p_z}$
$1\pi_g^*$	$\pi_{g2p_x}^*, \pi_{g2p_y}^*$
$3\sigma_u^*$	$\sigma_{u2p_z}^*$

where  $C_g$  and  $C_u$  are chosen to ensure that the total probability of finding the electron *somewhere* is unity and we have ignored their dependence on the choice of  $R_{AB}$  at which we have fixed the nuclei. Notice that we have introduced new symbols  $\sigma_{g1s}$  and  $\sigma_{u1s}^*$  for the approximate MOs not only to distinguish them from the exact MOs but also to indicate explicitly the AOs from which they were constructed. The symbols for the exact and approximate MOs are summarized in Table 6.1. To simplify the notation, henceforth we omit the dependence of  $\sigma_{g1s}$  and  $\sigma_{u1s}^*$  on  $R_{AB}$ .

The distribution of electron probability density is obtained by squaring each of the approximate MOs:

$$[\sigma_{g1s}]^2 = C_g^2[(\varphi_{1s}^A)^2 + (\varphi_{1s}^B)^2 + 2\varphi_{1s}^A\varphi_{1s}^B] \quad [6.3a]$$

$$[\sigma_{u1s}^*]^2 = C_u^2[(\varphi_{1s}^A)^2 + (\varphi_{1s}^B)^2 - 2\varphi_{1s}^A\varphi_{1s}^B] \quad [6.3b]$$

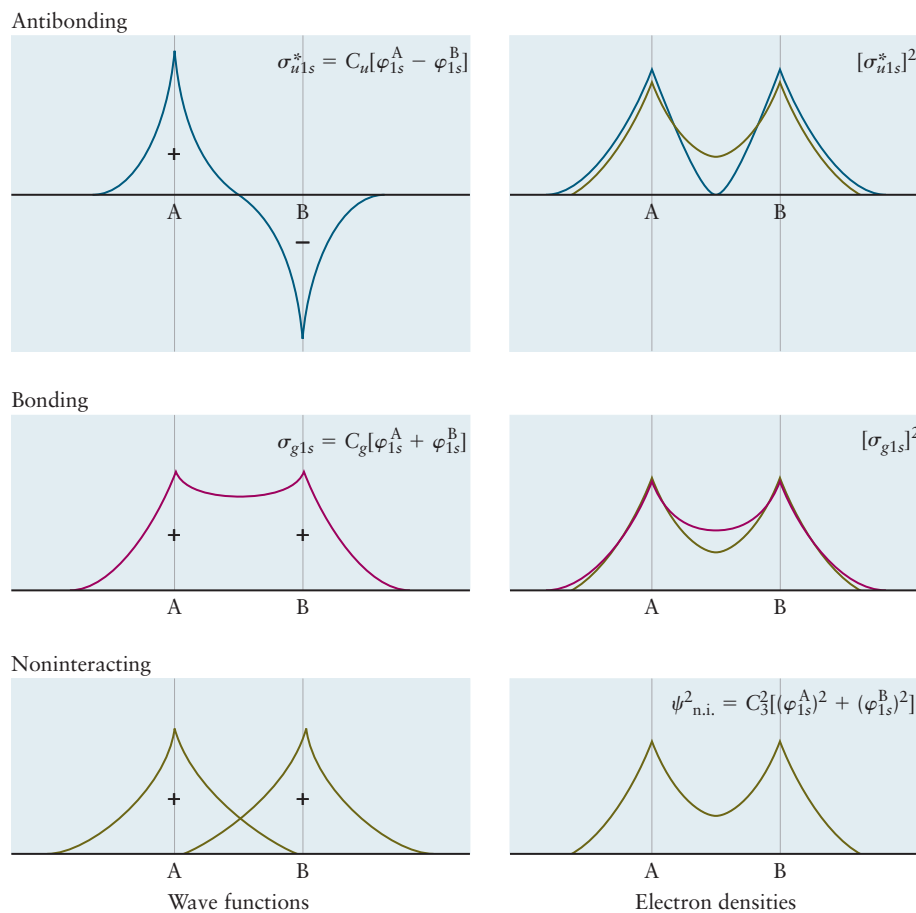

These can be compared with the electron probability distribution for a noninteracting (n.i.) system (obtained by averaging the probabilities for  $\text{H}_A + \text{H}_B^+$  and  $\text{H}_A^+ + \text{H}_B$ ), which is

$$\psi_{\text{n.i.}}^2 = C_3^2[(\varphi_{1s}^A)^2 + (\varphi_{1s}^B)^2] \quad [6.4]$$

To describe the noninteracting system as one electron distributed over two possible sites, we set  $C_3^2 = 0.5$ . The interpretation of these approximate MOs in relation to the noninteracting system is best explained graphically. Figure 6.7 shows plots of these various wave functions (left side) and their squares (right side). Compared with the noninteracting pair of atoms, the system described by the approximate MO  $\sigma_{g1s}$  shows increased electron density between the nuclei and is therefore a bonding orbital as defined in Section 6.2. By contrast, the approximate MO  $\sigma_{u1s}^*$  shows reduced probability for finding an electron between the nuclei and so is an antibonding orbital. Note in Figure 6.7 that  $\sigma_{u1s}^*$  has a node between the nuclei and is antisymmetric with respect to inversion through the molecular center (see Section 6.2). Comparing Figure 6.7 with Figure 6.5 shows that the LCAO method has reproduced qualitatively the probability density in the first two exact wave functions for  $\text{H}_2^+$ .

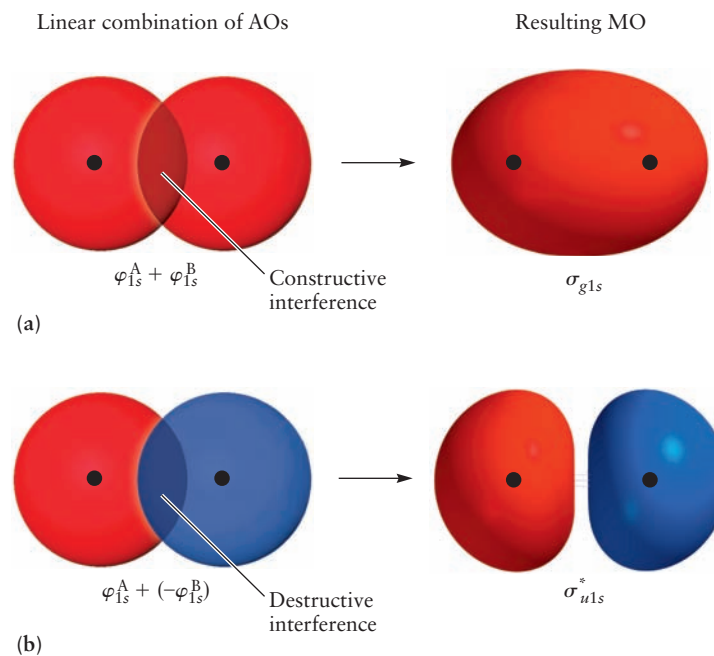

A simple way to understand why a particular linear combination of atomic orbitals results in increasing or decreasing electron density between the nuclei is shown graphically in Figure 6.8. In the linear combination of atomic orbitals for the  $\sigma_{g1s}$  orbital in Figure 6.8a, the two atomic orbitals have the same sign (both positive) where they overlap between the nuclei. Thus, the electron waves

**FIGURE 6.7** Antibonding and bonding molecular orbitals of  $H_2^+$  along the internuclear axis in the linear combination of atomic orbitals (LCAO) approximation. For comparison, the green lines show the independent atomic orbitals and the electron probability distribution  $\psi^2(\text{n.i.})$  for a noninteracting system. Compared with this reference system, the bonding orbital shows *increased* probability density between the nuclei, but the antibonding orbital shows *decreased* probability density in this region.

constructively interfere, giving more electron density in that region. The linear combination for the  $\sigma_{u1s}^*$  molecular orbital is  $C_u[\varphi_{1s}^A + (-\varphi_{1s}^B)]$ , so a wave function with positive sign is added to a wave function of negative sign,  $(-\varphi_{1s}^B)$ . Thus, as shown in Figure 6.8b, the waves destructively interfere where they

**FIGURE 6.8** Graphical representation of the linear combination of atomic orbitals (AOs) resulting in a bonding molecular orbital, shown in (a), and an antibonding molecular orbital, shown in (b). The black dots show the approximate positions of the nuclei.

**FIGURE 6.9** Effective potential energy of the protons in  $\text{H}_2^+$  when the electron is in a  $\sigma_{g1s}$  (bonding) and  $\sigma_{u1s}^*$  (antibonding) molecular orbital, shown as a function of internuclear separation  $R_{AB}$  in the LCAO approximation.

overlap between the nuclei, giving an anti-bonding molecular orbital. In the figure, red indicates a wave function with positive sign and blue indicates a wave function with negative sign. Note that  $\varphi_{1s}^B$  is positive everywhere (see Table 5.2), so  $(-\varphi_{1s}^B)$  is negative everywhere; thus  $(-\varphi_{1s}^B)$  is shown in blue for the linear combination that gives the  $\sigma_{u1s}^*$  molecular orbital.

### 6.3.2 Energy of $\text{H}_2^+$ in the LCAO Approximation

To complete the demonstration that  $\sigma_{g1s}$  and  $\sigma_{u1s}^*$  are bonding and antibonding MOs respectively, we examine the effective potential energy curve for the  $\text{H}_2^+$  ion with its electron in each of these approximate MOs. Figure 6.9 shows the effective potential energy of the  $\text{H}_2^+$  ion in the LCAO approximation for the  $\sigma_{g1s}$  and  $\sigma_{u1s}^*$  MOs. In the ground electronic state shown in red, resulting from the  $\sigma_{g1s}$  electron probability density, the  $\text{H}_2^+$  ion has a bound region of the potential, with the equilibrium internuclear distance  $R_e$  shown. In the excited electronic state shown in blue, there is no bound potential well, and a repulsive force acts to separate the transient molecular ion into  $\text{H} + \text{H}^+$ .

How well does the LCAO approximation describe the effective potential energy curve in  $\text{H}_2^+$ ? We compare the exact and LCAO results in Figure 6.10, where the zero of energy at infinite separation is again taken to be the separated species  $\text{H}$  and  $\text{H}^+$ . The energy in  $\sigma_{g1s}$  has a minimum at  $R_{AB} = 1.32 \text{ \AA}$ , and the predicted energy to dissociate the ion to  $\text{H}$  and  $\text{H}^+$  is  $D_e = 1.76 \text{ eV}$ . These results compare reasonably well to the exact theoretical values  $R_{AB} = 1.06 \text{ \AA}$  and  $D_e = 2.79 \text{ eV}$ , (see Section 6.2) and to the experimentally measured bond energy  $D_0$  (after correcting for zero-point energy).

**FIGURE 6.10** Comparison of the effective potential energy for the  $\sigma_{g1s}$  and  $\sigma_{u1s}^*$  orbitals of  $\text{H}_2^+$  in the LCAO approximation (dashed lines) with the exact results (solid lines). The internuclear separation is plotted in units of the Bohr radius. (Adapted from R. S. Berry, S. A. Rice, and J. Ross, *Physical Chemistry*, 2nd ed., New York: Oxford, 2000, Figure 6.6.)

**FIGURE 6.11** Correlation diagram for  $\text{H}_2^+$  in the linear combination of atomic orbitals (LCAO) approximation. The bonding orbital is stabilized relative to the noninteracting system.  $E_{1s} + (-\Delta E) = E_{\sigma_{g1s}}$ , so  $\Delta E$  is a positive number.

Let's put these results of the LCAO approximation in perspective. The results in Figure 6.7 and Figure 6.9 were obtained by working out the details of the approximation expressed in Equation 6.2ab. These LCAO results have captured qualitatively the results of the exact calculation. Therefore we can apply the LCAO method in other more complex cases and be confident we have included the qualitative essential features of bond formation. And, we can always improve the results by following up with a self-consistent computer calculation that produces optimized MOs. We will give some examples later in the chapter to illustrate how advanced calculations flow very easily from the simple LCAO theory introduced here.

The energy-level diagram within the LCAO approximation is given by a **correlation diagram** (Fig. 6.11), which shows that two  $1s$  atomic orbitals have been combined to give a  $\sigma_{g1s}$  MO with energy lower than the atomic orbitals and a  $\sigma_{u1s}^*$  MO with higher energy than the atomic orbitals. This diagram is a purely qualitative representation of the same information contained in Figure 6.9. The actual energy level values will depend on the distance between the fixed nuclei (as shown in Figure 6.9) and must be determined from calculations. Even without the results shown in Figure 6.9, we would know that an electron in an antibonding orbital has higher energy than one in a bonding orbital because the antibonding orbital has a node. Consequently, in the ground state of  $\text{H}_2^+$ , the electron occupies the  $\sigma_{g1s}$  molecular orbital. By forming the bond in the molecular ion, the total system of two hydrogen nuclei and one electron becomes more stable than the separated atoms, where  $E_{\sigma_{g1s}} = E_{1s} + (-\Delta E)$  and  $\Delta E$  is positive (see Figure 6.11).

## 6.4 Homonuclear Diatomic Molecules: First-Period Atoms

We can combine the LCAO method for  $\text{H}_2^+$  with an aufbau principle, analogous to that developed for atoms, to describe the electron configurations of more complex molecules. Electrons available from the two atoms are “fed” into the molecular orbitals, starting with the MO of lowest energy. At most, two electrons can occupy each molecular orbital. The ground-state  $\text{H}_2$  molecule, therefore, accommodates two electrons with opposite spins in a  $\sigma_{g1s}$  bonding molecular orbital, as shown in Figure 6.12. The diatomic molecule is more stable than the isolated atoms by the energy difference  $-2\Delta E$ . The value of  $-\Delta E$  here is different from that in Figure 6.11 because the present case involves the effects of electron–electron repulsion.

The LCAO approximation can be applied in this same way to  $\text{He}_2^+$  and  $\text{He}_2$ , with one change. The MOs must be generated as linear combinations of He  $1s$  atomic orbitals, not H  $1s$  orbitals. The reason is that when the electrons in  $\text{He}_2^+$  and  $\text{He}_2$  approach close to one of the nuclei, they experience a potential much closer to that in a He atom than in a H atom. Therefore, the equations for the MOs are

$$\sigma_{g1s} = C_g[\varphi_{\text{He}1s}^{\text{A}} + \varphi_{\text{He}1s}^{\text{B}}] \quad [6.5\text{a}]$$

$$\sigma_{u1s}^* = C_u[\varphi_{\text{He}1s}^{\text{A}} - \varphi_{\text{He}1s}^{\text{B}}] \quad [6.5\text{b}]$$

We rewrite Equations 6.5a and 6.5b using a simpler notation, which we adopt for the remainder of the text.

$$\sigma_{g1s} = C_g[1s^{\text{A}} + 1s^{\text{B}}] \quad [6.6\text{a}]$$

$$\sigma_{u1s}^* = C_u[1s^{\text{A}} - 1s^{\text{B}}] = C_u[1s^{\text{A}} + (-1s^{\text{B}})] \quad [6.6\text{b}]$$

**FIGURE 6.12** Correlation diagram for first-period diatomic molecules. Blue arrows indicate the electron filling for the  $\text{H}_2$  molecule. All of the atomic electrons are pooled and used to fill the molecular orbitals following the aufbau principle. In the molecules, electrons are no longer connected to any particular atom.

The second equality shown in Equation 6.6b emphasizes that the minus sign changes the sign of the 1s wave function, from positive (red) to negative (blue), to help you understand the graphical representation of these linear combinations in Figure 6.8 and the other figures in this chapter.

In these equations the symbol for the atomic wave function  $\varphi$  has been dropped and the atomic orbitals are identified by their hydrogenic labels  $1s$ ,  $2s$ ,  $2p$ , etc. The superscripts A and B will be used to identify particular atoms of the same element in bonds formed from the same element in homonuclear diatomics. These helium MOs have the same general shapes as those shown in Figure 6.7 for the MOs constructed from H  $1s$ . They lead to potential energy curves as shown in Figure 6.9 and a correlation diagram similar to Figure 6.12. Quantitative calculations of electron density and energy (these calculations are not performed in this book) would produce different values for the two sets of MOs in Equations 6.2a and 6.2b and Equations 6.5a and 6.5b. Keep in mind that we construct the MOs as combinations of all the atomic orbitals required to accommodate the electrons in the ground states of the atoms forming the molecule. This set of atomic orbitals is called the *minimum basis set* for that specific molecule. Therefore, quantitative calculations for each molecule are influenced by the detailed properties of the atoms in the molecule.

Because  $\text{He}_2^+$  and  $\text{He}_2$  have more than two electrons, the aufbau principle requires them to have one or two electrons, respectively, in the  $\sigma_{u1s}^*$  antibonding orbital. The electrons in the antibonding orbital contribute a destabilization energy in the amount  $+\Delta E$  relative to the separated He atoms, as shown in Figure 6.13. This effect competes with the stabilization energy of  $-\Delta E$  that arises from the electrons in the  $\sigma_{g1s}$  bonding orbital, giving a weak bond in  $\text{He}_2^+$  and no stable bond in  $\text{He}_2$ .

The general features of covalent bonding in the LCAO picture can be summarized as follows. Covalent bond formation arises from the presence of electrons (most often electron pairs with opposite spins) in *bonding* MOs. The average electron density between the nuclei is greater than between the non-interacting atoms, and tends to pull them together. Electrons in an *antibonding* MO tend to force the nuclei apart, reducing the bond strength. This competition is described by the **bond order**, defined as follows:

$$\text{bond order} = \frac{1}{2} (\text{number of electrons in bonding molecular orbitals} - \text{number of electrons in antibonding molecular orbitals})$$

In the LCAO molecular orbital description, the  $\text{H}_2$  molecule in its ground state has a pair of electrons in a bonding molecular orbital and thus a single bond (that is, its bond order is one). Later on, as we describe more complex diatomic molecules in the LCAO approximation, we will see bond orders greater than one. This quantum mechanical definition of bond order generalizes the concept first developed in the Lewis theory of chemical bonding, that a shared pair of electrons corresponds to a single bond, two shared pairs to a double bond, and so forth.

### EXAMPLE 6.2

Give the ground-state electron configuration and the bond order of the  $\text{He}_2^+$  molecular ion.

#### Solution

The  $\text{He}_2^+$  ion has three electrons, which are placed in molecular orbitals to give the ground-state configuration  $(\sigma_{g1s})^2(\sigma_{u1s}^*)^1$ , indicating that the ion has a doubly

(Continued)

**FIGURE 6.13** Correlation diagram for first-period diatomic molecules. Blue arrows indicate the electron filling for the  $\text{He}_2^+$  molecule. The aufbau principle fills the bonding orbital with two electrons, so the third electron must go into the antibonding orbital, thus reducing the bond order compared with that in  $\text{H}_2$ .

occupied  $\sigma_{g1s}$  orbital (bonding) and a singly occupied  $\sigma_{u1s}^*$  orbital (antibonding). The bond order is

$$\text{bond order} = \frac{1}{2} (2 \text{ electrons in } \sigma_{g1s} - 1 \text{ electron in } \sigma_{u1s}^*) = \frac{1}{2}$$

This should be a weaker bond than that in  $\text{H}_2$ .

**Related Problems: 7, 8, 9, 10, 11, 12, 13, 14, 15, 16**

**TABLE 6.2**

Electron Configurations and Bond Orders for First-Row Diatomic Molecules

Species	Electron Configuration	Bond Order	Bond Energy (kJ mol <sup>-1</sup> )	Bond Length (Å)
$\text{H}_2^+$	$(\sigma_{g1s})^1$	$\frac{1}{2}$	255	1.06
$\text{H}_2$	$(\sigma_{g1s})^2$	1	431	0.74
$\text{He}_2^+$	$(\sigma_{g1s})^2(\sigma_{u1s}^*)^1$	$\frac{1}{2}$	251	1.08
$\text{He}_2$	$(\sigma_{g1s})^2(\sigma_{u1s}^*)^2$	0	~0	Large

Table 6.2 lists the molecular orbital configurations of **homonuclear diatomic molecules** and molecular ions made from first-period elements. These configurations are simply the occupied molecular orbitals in order of increasing energy, together with the number of electrons in each orbital. Higher bond order corresponds to greater bond dissociation energies and shorter bond lengths. The species  $\text{He}_2$  has bond order 0 and does not form a true chemical bond.

The preceding paragraphs have illustrated the LCAO approximation with specific examples and shown how the character of the chemical bond is determined by the difference in the number of electrons in bonding and antibonding MOs. The systematic procedure for applying the LCAO approximation to define the MOs for any diatomic molecule consists of three steps:

1. Form linear combinations of the minimum basis set of AOs (all of the AOs in the valence shell of each atom, whether or not these AOs are occupied in the ground state of each atom) to generate MOs. The total number of MOs formed in this way must equal the number of AOs used.
2. Arrange the MOs in order from lowest to highest energy.
3. Put in electrons (at most two electrons per MO), starting from the orbital of lowest energy. Apply Hund's rules when appropriate.

## 6.5 Homonuclear Diatomic Molecules: Second-Period Atoms

Now that we have some experience with the LCAO method, it is useful to collect several important insights before we proceed to more complicated molecular examples. The LCAO method extends to molecules the description developed for many-electron atoms in Section 5.2. We wrote the electron configuration for a many-electron atom by placing electrons in a set of single-particle AOs according to the Pauli exclusion principle. Here we will see how to write the

electron configuration for a molecule by placing electrons in a set of single-particle MOs, guided by the Pauli exclusion principle.

How do we obtain the single-electron molecular orbitals? The LCAO method was invented to construct *approximate molecular orbitals* directly from the Hartree atomic orbitals for the specific atoms in the molecule, guided by molecular symmetry and chemical intuition. We start with the Hartree AOs (see Section 5.2) because they already include the effects of the atomic number  $Z$  and of shielding on the size and energy of the AOs in each atom. We thus have a quick check on, for example, the relative energies of the  $2s$  and  $2p$  AOs in a pair of different atoms, and from this we can quickly see the extent to which electrons in these AOs interact or compete to determine the size and energy of the resulting MO.

The essential new feature compared to the atomic case is that the (multi-center) approximate MOs are spread around all the nuclei in the molecule, so the electron density is *delocalized* over the entire molecule. The approximate MOs therefore differ considerably from the (single-center) atomic orbitals used in Section 5.2. Constructing the approximate MOs and recognizing how their electron density is distributed over the entire network of fixed nuclei are the key tools for describing molecular structure and bonding. Mastering these tools for progressively more complicated molecules is our objective in this Section and the next three after it.

In order to discuss bonding with atoms in the second period and beyond, we must generate approximate MOs to accommodate electrons from AOs higher than the  $1s$  orbitals. Let's try to motivate these combinations by physical reasoning, as we did at the beginning of Section 6.3. Imagine that two Li atoms in their ground-state electronic configurations  $(1s)^2(2s)^1$  approach each other. It is reasonable to expect that their  $2s$  AOs will interact to produce MOs very similar in shape to the  $\sigma_{1s}$  bonding and anti-bonding MOs but larger in size, and that two electrons will go into this new bonding MO which we temporarily name  $\sigma_{2s}$ . What happens to the  $1s$  electrons? We can use Figure 5.26 to estimate that the energy of the Li( $1s$ ) AO is about 3.8 Ry (or 52 eV) below that of the Li( $2s$ ) AO. Because this is a very significant difference, it is unlikely that the  $1s$  and  $2s$  electrons will interact, and it is reasonable to suppose the  $1s$  orbitals will combine to form  $\sigma_{1s}$  bonding and anti-bonding MOs as described in the previous section, independent of the  $2s$  electrons. If our thinking is correct, then the  $\text{Li}_2$  molecule would have the electron configuration  $(\sigma_{g1s})^2(\sigma_{u1s}^*)^2(\sigma_{g2s})^2$ . In a similar way we would expect  $\text{Be}_2$  to have the configuration  $(\sigma_{g1s})^2(\sigma_{u1s}^*)^2(\sigma_{g2s})^2(\sigma_{u2s}^*)^2$ . Because of the very poor spatial overlap of the  $1s$  AOs, however, it is typical to see those electrons listed as simply remaining in the two  $1s$  AOs. They are often omitted from the LCAO-MO correlation diagram. In this case one should specify that you are constructing the MOs that result from the valence AOs only, and don't forget to subtract off the core electrons (two  $1s$  electrons on each Li atom) from the total number of electrons to calculate the number of electrons to put in your LCAO-MO correlation diagram.

In the remainder of Period 2 from B to Ne we must consider the possibility that the  $2p$  AOs will interact with each other and also with the  $2s$  AOs. Because the  $2p$  AOs are not spherical, we expect the relative orientation of the two orbitals will strongly influence the formation of MOs. Qualitatively, we expect that two dumbbell shapes interacting end-to-end will produce a different result than side-to-side or end-to-side. Moreover, the difference in phase (the sign of the wave function) of the two lobes will strongly influence the result. Careful geometrical analysis is required to identify the MOs formed from the  $2p$  AOs.

Two conclusions from more advanced discussions of quantum theory justify the results of our physical reasoning and tell us how to construct the MOs for second-period atoms in a systematic way.

1. *Two atomic orbitals contribute significantly to bond formation only if their atomic energy levels are very close to one another.*

Consequently, we can ignore mixing between the core-shell  $1s$  orbitals and the valence-shell  $2s$  and  $2p$  orbitals. Similarly, we can ignore mixing between the  $2s$  and  $2p$  orbitals except in special cases to be described below.

2. *Two atomic orbitals on different atoms contribute significantly to bond formation only if they overlap significantly.*

The term *overlap* is used in bonding theory to describe the extent to which orbitals on separate atoms “interact” or “inter-penetrate” as two atoms approach one another at close distance. Two orbitals overlap significantly if both have appreciable amplitudes over the same region of space. The net overlap may be positive, negative, or zero, depending on the relative amplitudes and phases of orbitals involved in the overlap region. Formally, one calculates an overlap integral, the integral of the product of  $\varphi^A$  with  $\varphi^B$  over all space. If this is zero, the two orbitals are said to have zero overlap. Thus, though they appear to have overlapping regions, the  $2s$  orbital on atom A has zero overlap with the  $2p_x$  or the  $2p_y$  orbital on atom B (defining the  $z$  axis as the internuclear axis). Bonding molecular orbitals arise from positive net overlap (constructive interference between the wave functions for atomic orbitals), antibonding molecular orbitals result from negative net overlap (destructive interference between the wave functions for atomic orbitals). Nonbonding molecular orbitals can arise in two ways: a) there may be negligible overlap of the atomic orbitals because the separation between the nuclei is greater than the spatial extent of the orbitals or b) regions of positive overlap cancel regions of negative overlap to give zero net overlap. We give specific examples in the following paragraphs.

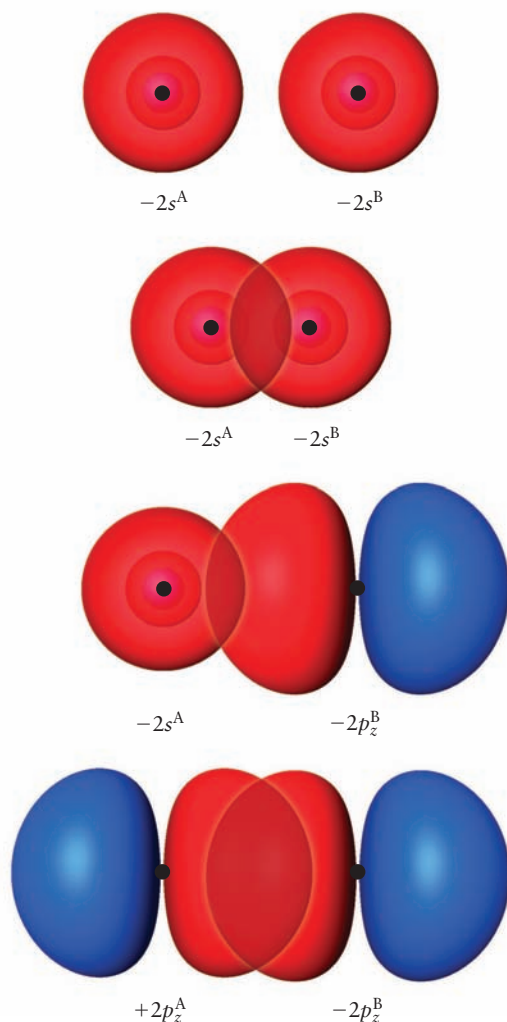

For  $s$  orbitals it is rather easy to guess the degree of overlap; the closer the nuclei, the greater the overlap. If the wave functions have the same phase, the overlap is positive; if they have opposite phases, the overlap is negative. For more complex cases, the overlap between participating atomic orbitals depends strongly on both the symmetry of the arrangement of the nuclei and on the phases of the orbitals. If the two orbitals are shaped so that neither has substantial amplitude in the region of interest, then their overlap is negligible. However, if they both have significant magnitude in the region of interest, it is important to know whether regions of positive overlap (where the two orbitals have the same phase) are canceled by regions of negative overlap (where the two orbitals have opposite phases). Such cancellation leads to negligible or zero overlap between the orbitals. Qualitative sketches that illustrate significant or negligible overlap in several common cases are shown in Figure 6.14. In particular, constructive interference and overlap between  $s$  and  $p$  orbitals is significant only in the case where an  $s$  orbital approaches a  $p$  orbital “end-on.” The phase of the  $p$  orbital lobe pointing toward the  $s$  orbital must be the same as that of the  $s$  orbital. You should review the “sizes and shapes” of hydrogenic orbitals discussed in Section 5.1 and depicted in Figure 5.4. A great deal of qualitative insight into the construction of molecular orbitals can be gleaned from these considerations.

The two conclusions stated above justify the following approximate LCAO MOs for the second-period homonuclear diatomic molecules. As with the first-period atoms, we use the new labels in Table 6.1 to distinguish the approximate MOs from the exact  $H_2^+$  MOs in Figure 6.5 and to indicate their atomic parentage.

We combine the  $2s$  atomic orbitals of the two atoms in the same fashion as  $1s$  orbitals, giving a  $\sigma_{g2s}$  bonding orbital and a  $\sigma_{u2s}^*$  antibonding orbital. The

**FIGURE 6.14** Overlap of orbitals in several common combinations. The magnitude of overlap can be estimated qualitatively from the relative size and symmetry of the two orbitals involved. (Note the radial nodes in the  $2s$  orbitals, clearly visible in these images, and the minus sign in front of each. Table 5.2 and Figure 5.7 show the sign of the  $2s$  wave function far from the nucleus is negative, but we are depicting the orbitals in these linear combinations as red. The red spherical orbital depicted is the  $2s$  function in Table 5.2 multiplied by a  $-1$ , so the resulting  $-2s$  wave function is positive far from the nucleus.) For the  $2p_z$  orbitals, the  $z$ -axis points from left to right along the internuclear axis. (Courtesy of Mr. Hatem Helal and Professor William A. Goddard III, California Institute of Technology, and Dr. Kelly P. Gaither, University of Texas at Austin.)

particular linear combinations that give the molecular orbitals depicted in Figure 6.18 are

$$\sigma_{g2s} = C_g[-2s^A - 2s^B] \quad [6.7a]$$

$$\sigma_{u2s}^* = C_u[-2s^A + 2s^B] \quad [6.7b]$$

(Note that after the wave function is squared to obtain the MO's electron density, the linear combination calculated by writing  $\sigma_{g2s}$  as either  $2s^A + 2s^B$  or as  $-2s^A - 2s^B$ , give the same electron density, so correspond to the same molecular orbital. We are only being specific about the signs so that it is easy to match the linear combination with the graphical representations in Figures 6.14 and 6.18.)

The choice of appropriate combinations of the  $2p$  orbitals is guided by the overlap arguments and by recalling that the bond axis is the  $z$ -axis. The  $2p$  orbitals form different MOs depending on whether they are parallel or perpendicular to the internuclear (bond) axis. Consider first the  $2p_z$  orbitals, which can be used to form two different kinds of  $\sigma$  orbitals. If the phase of the  $2p_z$  orbital on atom B is reversed by multiplying it by a  $-1$  (see Equation 6.8a), it then has the same phase in the internuclear region as the  $2p_z$  orbital on atom A (see Figure 6.15a). They thus interfere constructively in the internuclear region, and a bonding  $\sigma_{g2p_z}$  orbital is formed. Conversely, if lobes of opposite phase

overlap, they form an antibonding MO labeled  $\sigma_{u2p_z}^*$  (see Figure 6.15b, corresponding to the linear combination shown in Equation 6.8b).

$$\sigma_{g2p_z} = C_g[2p_z^A - 2p_z^B] \quad [6.8a]$$

$$\sigma_{u2p_z}^* = C_u[2p_z^A + 2p_z^B] \quad [6.8b]$$

The bonding MO shows increased electron density between the nuclei, whereas the antibonding MO has a node.

The two  $2p_x$  orbitals, whose lobes are perpendicular to the bond axis, can overlap “side by side” to form a bonding MO denoted  $\pi_{u2p_x}$  and an antibonding MO denoted  $\pi_{g2p_x}^*$ . The overlap leading to these MOs is shown in Fig. 6.16.

$$\pi_{u2p_x} = C_u[2p_x^A + 2p_x^B] \quad [6.9a]$$

$$\pi_{g2p_x}^* = C_g[2p_x^A - 2p_x^B] \quad [6.9b]$$

These orbitals have a nodal plane that contains the internuclear axis (in this case, the  $y$ - $z$  plane perpendicular to the page). They are designated by  $\pi$  to signify their origin in AOs that have one unit of angular momentum along the internuclear axis. The  $\pi$  MOs do not have cylindrical symmetry about the internuclear axis. In the same way,  $\pi_{u2p_y}$  and  $\pi_{g2p_y}^*$  orbitals can be formed from the  $2p_y$  atomic orbitals. Their lobes project above and below the  $x$ - $z$  nodal plane, which is the plane of the page, so they are shown in perspective in Figure 6.18.

$$\pi_{u2p_y} = C_u[2p_y^A + 2p_y^B] \quad [6.10a]$$

$$\pi_{g2p_y}^* = C_g[2p_y^A - 2p_y^B] \quad [6.10b]$$

**FIGURE 6.15** Formation of (a)  $\sigma_{g2p_z}$  bonding and (b)  $\sigma_{u2p_z}^*$  antibonding molecular orbitals from  $2p_z$  orbitals on atoms A and B. Regions where the wave function has positive sign are shown in red, and those with negative sign are shown in blue.

**FIGURE 6.16** Formation of (a)  $\pi_{u2p_x}$  bonding and (b)  $\pi_{g2p_x}^*$  antibonding molecular orbitals from  $2p_x$  orbitals on atoms A and B. (Courtesy of Mr. Hatem Helal and Professor William A. Goddard III, California Institute of Technology, and Dr. Kelly P. Gaither, University of Texas at Austin.)

Like the  $2p$  AOs from which they are constructed, the  $\pi_{2p}$  MOs are degenerate:  $\pi_{u2p_x}$  and  $\pi_{u2p_y}$  have the same energy, and  $\pi_{g2p_x}^*$  and  $\pi_{g2p_y}^*$  have the same energy. We expect  $\pi_{u2p_x}$  and  $\pi_{u2p_y}$  to be less effective than  $\sigma_{g2p_z}$  as bonding orbitals, because the overlap in the  $\pi$  orbitals is smaller and because it occurs off the internuclear axis and therefore has less tendency to increase the electron density between the nuclei and to pull them closer together.

The most important point to understand in constructing MOs and predicting their behavior by the overlap argument is that the relative phases of the two AOs determine whether the resulting MO is bonding or antibonding. Bonding orbitals form through the overlap of wave functions with the same phase, by constructive interference of “electron waves”; antibonding orbitals form through the overlap of wave functions with opposite phase, by destructive interference of “electron waves.”

By considering the symmetry and relative energies of the participating AOs, we have generated a total of 8 approximate LCAO MOs to accommodate the electrons in the  $2s$  and  $2p$  AOs. Including the two MOs originating from the  $1s$  AOs, we now have a total of 10 approximate MOs which can describe diatomic molecules containing up to 20 electrons, from  $H_2$  to  $Ne_2$ . Each of these is a simple sum or difference of two AOs.

The next step is to determine the energy ordering of the MOs. In general, that step requires a calculation, as we did for the first-period diatomics in Figure 6.11 and Figure 6.12. The results for  $Li_2$  through  $F_2$  are shown in Figure 6.17. The electrons for each molecule have been placed in MOs according to the aufbau principle. We show only the MOs formed from the  $2s$  and  $2p$  orbitals. In second-period diatomic molecules, the  $1s$  orbitals of the two atoms barely overlap. Because the  $\sigma_{g1s}$  bonding and  $\sigma_{u1s}^*$  antibonding orbitals are both doubly occupied, they have little net effect on bonding properties and need not be considered. Thus in Figure 6.18 we only show the MOs from the valence AOs, and we leave the electrons in the core  $1s$  orbitals out of the diagram, filling the MOs generated from valence AOs with the valence electrons only.

There are two different energy orderings for diatomic molecules formed from second-period elements. The first (Fig. 6.18a) applies to the molecules with atoms Li through N (that is, the first part of the period) and their positive and negative ions. The second (Fig. 6.18b) applies to the later elements, O, F, and Ne, and their positive and negative ions. This difference is based on experimental measurements of molecular orbital energies by photoelectron spectroscopy (see Section 6.7) summarized in Figure 6.17. While the energy of the  $\pi_{u2p_{x(y)}}$  molecular orbital remains nearly constant as we move across Period 2, the energy of the  $\sigma_{g2p_z}$  molecular orbital lies above  $\pi_{u2p_{x(y)}}$  in the first part of the period and falls below it for the later elements O, F, and Ne. This behavior is borne out by advanced calculations of the energies for these two molecular orbitals. A simplified physical interpretation relates this result to the extent to which the  $2s$  and  $2p_z$  atomic orbitals can mix while contributing to the molecular orbital. The  $2s$  AOs have the right symmetry to mix with  $2p_z$  AOs to form a  $\sigma$  molecular orbital directed along the  $z$ -axis. In the first part of Period 2 the  $2s$  and  $2p$  are sufficiently close in energy that mixing occurs and increases the energy of the nominal  $\sigma_{g2p_z}$  orbital while decreasing the energy of the nominal  $\sigma_{g2s}$  orbital. In the latter part the energy separation of  $2p$  and  $2s$  AOs is too great for mixing to occur. Because the  $2s$  and  $2p_x$  and  $2p_y$  AOs do not have the right symmetry to mix and form a  $\pi$  molecular orbital, the energy of the  $\pi_{u2p_{x(y)}}$  MO remains nearly constant across the period even when the  $2s$  and  $2p$  AOs are close together in energy.

An important prediction comes from the molecular orbital energy levels in Figure 6.17. Hund's rules require that, in the ground state, the electrons occupy different orbitals and have parallel spins, so  $B_2$  and  $O_2$  are predicted to be paramagnetic. This paramagnetism is exactly what is found experimentally (Fig. 6.19). In contrast, in the Lewis electron dot diagram for  $O_2$ ,

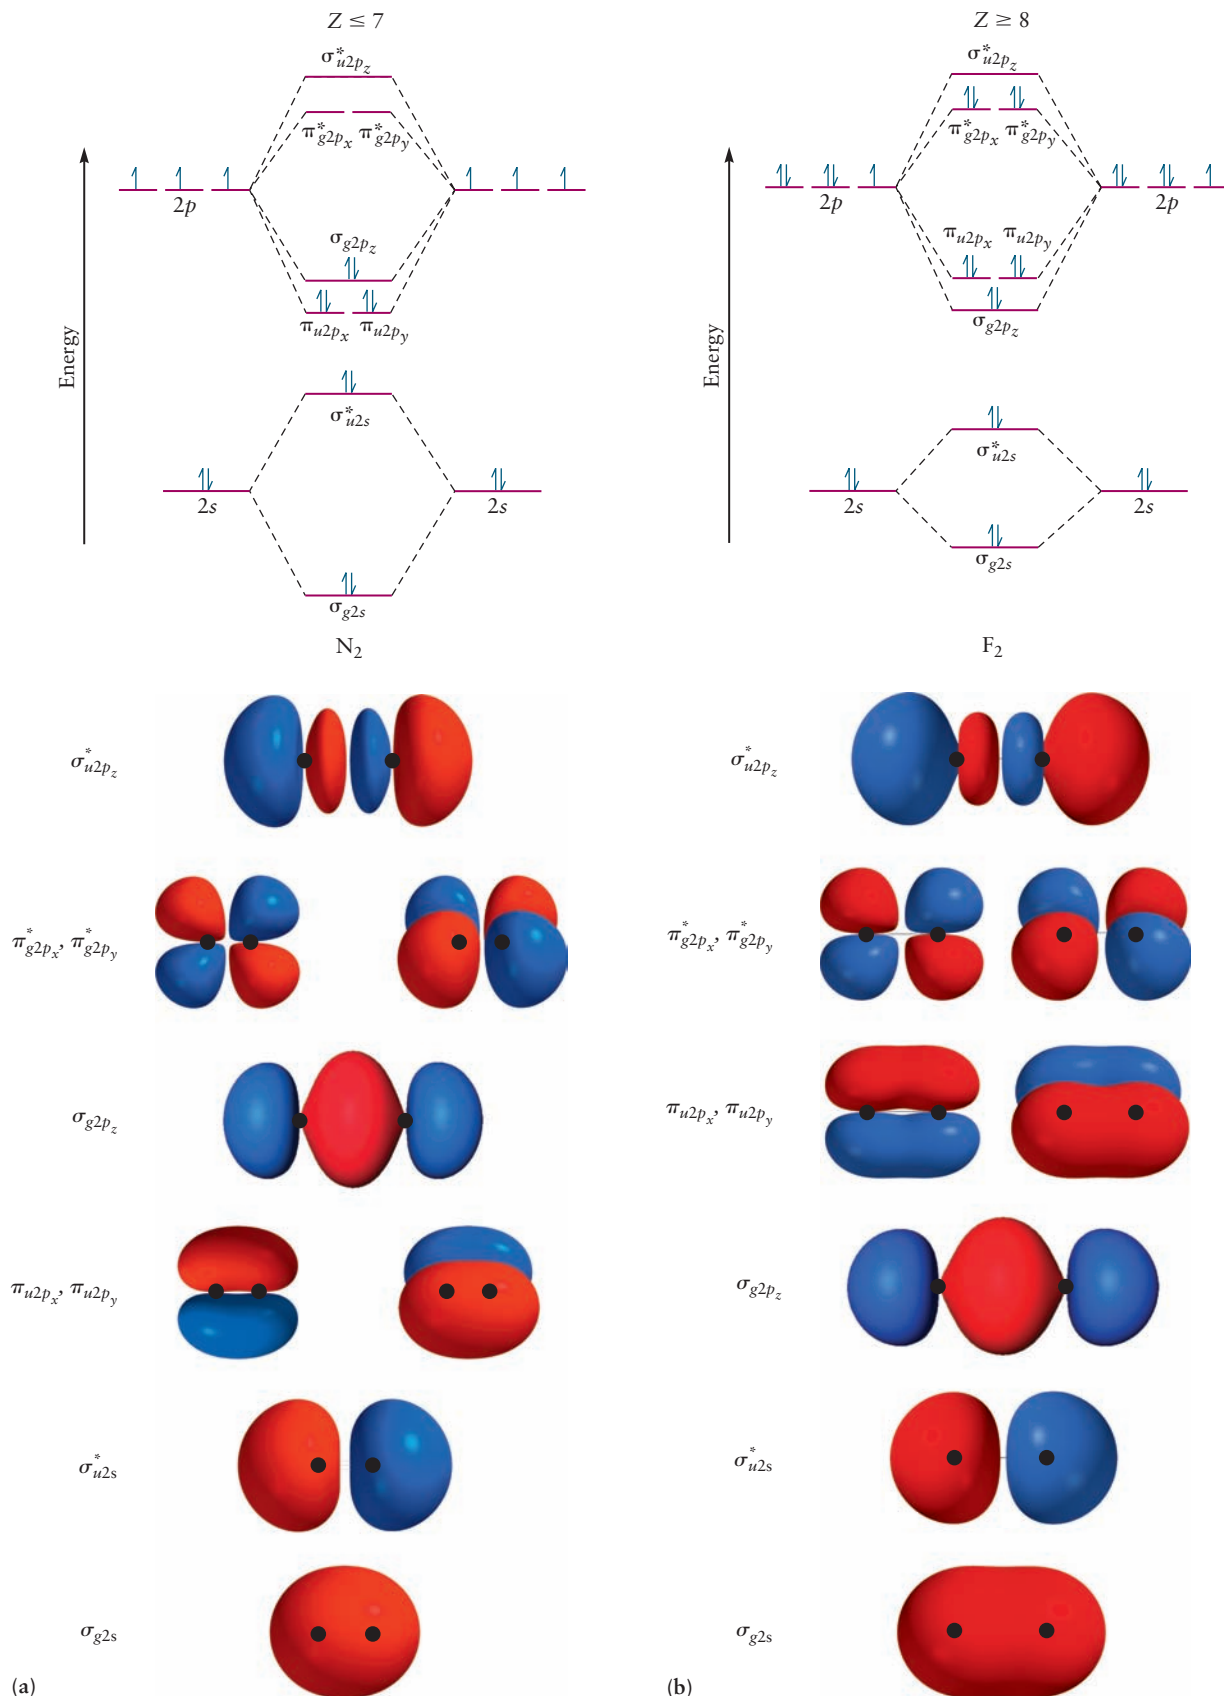

all the electrons appear to be paired. The highly reactive nature of molecular oxygen as compared to  $N_2$  can be rationalized as resulting from the readiness of the two  $\pi^*$  electrons, unpaired and in different regions of space, to find additional bonding partners in other molecules.

The electron configurations in Figure 6.17 allow us to calculate the bond order for each molecule and correlate it with other properties of the molecules.

**FIGURE 6.17** Energy levels for the homonuclear diatomics  $Li_2$  through  $F_2$ . Notice how the highest occupied level changes with the number of valence electrons. Notice especially the change between  $N_2$  and  $O_2$ .

**FIGURE 6.18** Correlation diagrams and molecular orbitals for second-period diatomic molecules. The black dots represent the positions of the nuclei in the  $x$ - $z$  plane. The isosurfaces shown enclose the nuclei in some cases and it may be difficult to visualize the curved nodal surfaces that surround the nuclei in these cases, such as the  $\sigma_{u2p_z}^*$  orbitals. (a) Correlation diagram and molecular orbitals calculated for  $N_2$ . (b) Correlation diagram and molecular orbitals calculated for  $F_2$ . (Courtesy of Mr. Hatem Helal and Professor William A. Goddard III, California Institute of Technology, and Dr. Kelly P. Gaither, University of Texas at Austin.)

**FIGURE 6.19** (a) Oxygen is paramagnetic; liquid oxygen ( $O_2$ ) poured between the pole faces of a magnet is attracted and held there. (b) When the experiment is repeated with liquid nitrogen ( $N_2$ ), which is diamagnetic, the liquid pours straight through.

### EXAMPLE 6.3

Determine the ground-state electron configuration and bond order of the  $F_2$  molecule.

#### Solution

Each atom of fluorine has 7 valence electrons, so 14 electrons are placed in the molecular orbitals constructed from the valence atomic orbitals (occupied and unoccupied) to represent bonding in the  $F_2$  molecule. The correlation diagram of Figure 6.18 gives the electron configuration

$$(\sigma_{g2s})^2(\sigma_{u2s}^*)^2(\sigma_{g2p_z})^2(\pi_{u2p_x}, \pi_{u2p_y})^4(\pi_{g2p_x}^*, \pi_{g2p_y}^*)^4$$

Because there are 8 valence electrons in bonding orbitals and 6 in antibonding orbitals, the bond order is

$$\text{bond order} = \frac{1}{2}(8 - 6) = 1$$

and the  $F_2$  molecule has a single bond.

**Related Problems:** 17, 18, 19, 20, 21, 22, 23, 24

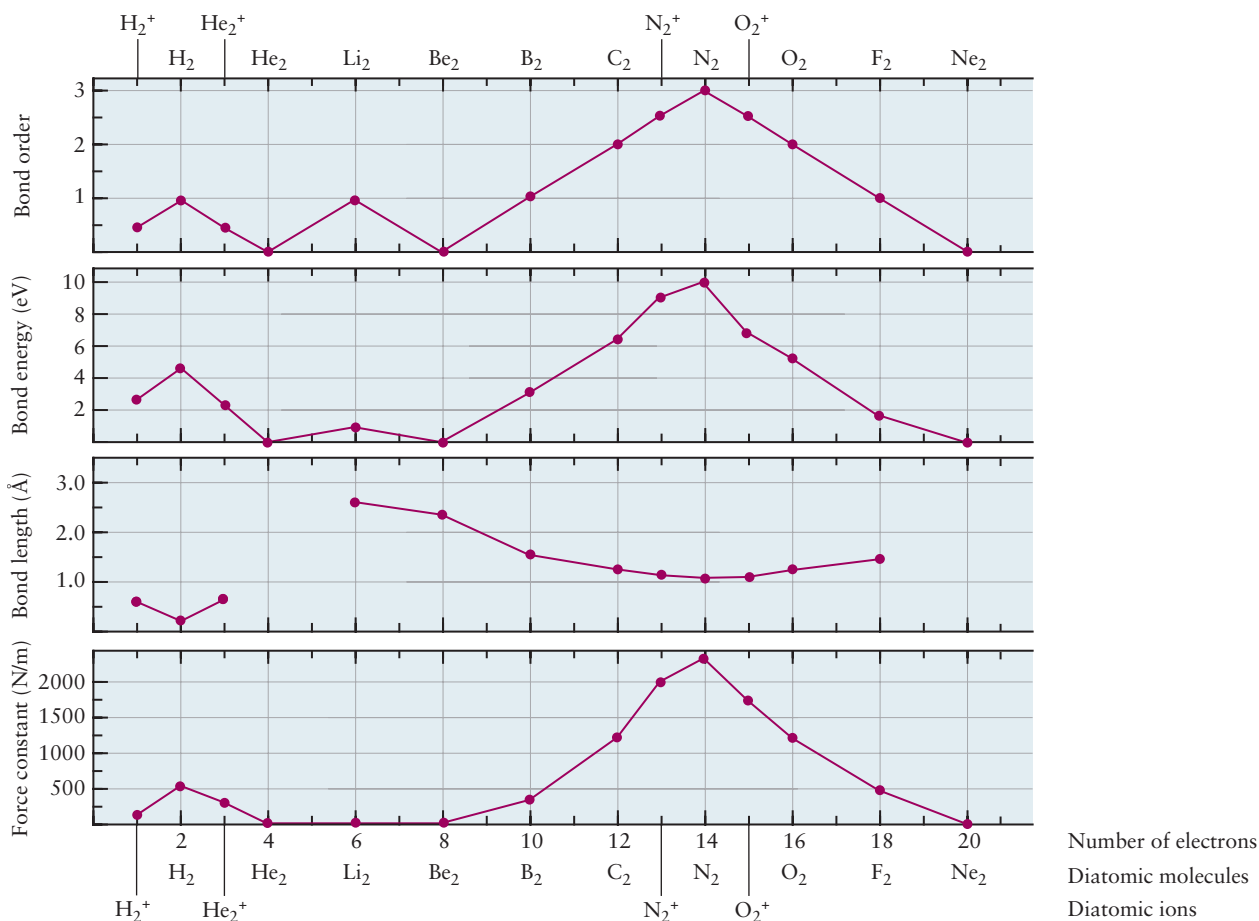

Table 6.3 summarizes the properties of second-period homonuclear diatomic molecules. Note the close relationship among bond order, bond length, and bond energy and the fact that the bond orders calculated from the MOs agree completely with the results of the Lewis electron dot model. How these properties depend upon the number of electrons in the molecules is shown in Figure 6.20. The bond orders simply follow the filling of MOs in a given subshell, rising from

**TABLE 6.3**

Molecular Orbitals of Homonuclear Diatomic Molecules

Species	Number of Valence Electrons	Valence Electron Configuration	Bond Order	Bond Length (Å)	Bond Energy ( $\text{kJ mol}^{-1}$ )
$H_2$	2	$(\sigma_{g1s})^2$	1	0.74	431
$He_2$	4	$(\sigma_{g1s})^2(\sigma_{u1s}^*)^2$	0		
$Li_2$	2	$(\sigma_{g2s})^2$	1	2.67	105
$Be_2$	4	$(\sigma_{g2s})^2(\sigma_{u2s}^*)^2$	0	2.45	9
$B_2$	6	$(\sigma_{g2s})^2(\sigma_{u2s}^*)^2(\pi_{u2p})^2$	1	1.59	289
$C_2$	8	$(\sigma_{g2s})^2(\sigma_{u2s}^*)^2(\pi_{u2p})^4$	2	1.24	599
$N_2$	10	$(\sigma_{g2s})^2(\sigma_{u2s}^*)^2(\pi_{u2p})^4(\sigma_{g2p_z})^2$	3	1.10	942
$O_2$	12	$(\sigma_{g2s})^2(\sigma_{u2s}^*)^2(\sigma_{g2p_z})^2(\pi_{u2p})^4(\pi_{g2p}^*)^2$	2	1.21	494
$F_2$	14	$(\sigma_{g2s})^2(\sigma_{u2s}^*)^2(\sigma_{g2p_z})^2(\pi_{u2p})^4(\pi_{g2p}^*)^4$	1	1.41	154
$Ne_2$	16	$(\sigma_{g2s})^2(\sigma_{u2s}^*)^2(\sigma_{g2p_z})^2(\pi_{u2p})^4(\pi_{g2p}^*)^4(\sigma_{u2p_z}^*)^2$	0		

$\pi_{u2p}$  refers to the  $\pi$  orbitals constructed from the  $2p_x$  and/or the  $2p_y$  orbitals.

**FIGURE 6.20** Trends in bond order, bond length, bond energy, and force constant with the number of valence electrons in the second-row diatomic molecules.

zero to one and then falling back to zero for the first-period diatomics and also for Li<sub>2</sub>, Be<sub>2</sub>, and their ions. The bond orders move in half-integral steps if we include the molecular ions; they increase as the  $\sigma$  orbitals are filled and decrease as the  $\sigma^*$  orbitals begin to fill. These MOs are all constructed from  $s$  orbitals and so there is no possibility for multiple bonds. Moving from Be<sub>2</sub> through Ne<sub>2</sub>, the bond orders move again in half-integer increments from zero to three and back to zero as the  $\pi$  orbitals and then the  $\pi^*$  orbitals are filled. Both bond energies and force constants are directly correlated with the bond order, whereas the bond length varies in the opposite direction. This makes perfect sense; multiple bonds between atoms should be stronger and shorter than single bonds.

In summary, the simple LCAO method provides a great deal of insight into the nature of chemical bonding in homonuclear diatomic molecules and the trends in their properties that result. It is consistent with the predictions of simpler theories, like that of G. N. Lewis; but clearly more powerful and more easily generalized to problems of greater complexity.

## 6.6 Heteronuclear Diatomic Molecules

A diatomic molecule formed from atoms of two different elements (such as CO and NO) is called a **heteronuclear diatomic molecule**. We construct molecular orbitals for such molecules by following the procedure described earlier, with two changes. First, we use a different set of labels because heteronuclear

diatomic molecules lack the inversion symmetry of homonuclear diatomic molecules. We therefore drop the  $g$  and  $u$  subscripts on the MO labels. Second, we recognize that the AOs on the participating atoms now correspond to different energies. For example, we combine the  $2s$  atomic orbital of carbon and the  $2s$  atomic orbital of oxygen to produce a bonding MO (without a node)

$$\sigma_{2s} = C_A(-2s^A) + C_B(-2s^B) \quad [6.11a]$$

and an antibonding MO (with a node)

$$\sigma_{2s}^* = C'_A(-2s^A) + C_B(2s^B) \quad [6.11b]$$

where A and B refer to the two different atoms in the molecule. In the homonuclear case we argued that  $C_A = C_B$  and  $C'_A = C'_B$  because the electron must have equal probability of being near each nucleus, as required by symmetry. When the two nuclei are different, this reasoning does not apply. If atom B is more electronegative than atom A, then  $|C_B| > |C_A|$  for the bonding  $\sigma$  MO (and the electron spends more time on the electronegative atom);  $|C'_A| > |C'_B|$  for the higher energy  $\sigma^*$  MO and it more closely resembles a  $2s^A$  AO.

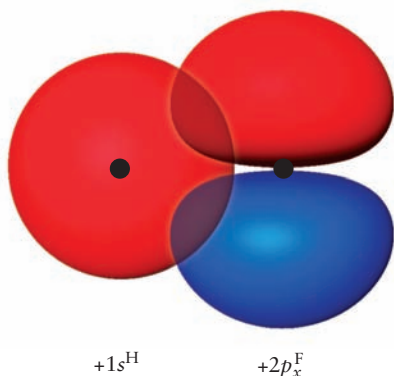

Molecular orbital correlation diagrams for heteronuclear diatomics start with the energy levels of the more electronegative atom displaced *downward* because that atom attracts valence electrons more strongly than does the less electronegative atom. Figure 6.21 shows the diagram appropriate for many heteronuclear diatomic molecules of second-period elements (where the electronegativity difference is not too great). This diagram has been filled with the valence electrons for the ground state of the molecule BO. Another example, NO, with 11 valence electrons (5 from N, 6 from O), has the ground-state configuration

$$(\sigma_{2s})^2(\sigma_{2s}^*)^2(\pi_{2p_x}, \pi_{2p_y})^4(\sigma_{2p_z})^2(\pi_{2p_x}^*, \pi_{2p_y}^*)^1$$

**FIGURE 6.21** Correlation diagram for heteronuclear diatomic molecules, AB. The atomic orbitals for the more electronegative atom (B) are displaced downward because they have lower energies than those for A. The orbital filling shown is that for (boron monoxide) BO.

**FIGURE 6.22** The H  $1s$  and F  $2p_x$  (or  $2p_y$ ) orbitals have no net overlap in HF.

With eight electrons in bonding orbitals and three in antibonding orbitals, the bond order of NO is  $\frac{1}{2}(8 - 3) = 2\frac{1}{2}$  and it is paramagnetic. The bond energy of NO should be smaller than that of CO, which has one fewer electron but a bond order of three; experiment agrees with this prediction.

We explained earlier that in homonuclear diatomics, atomic orbitals mix significantly to form molecular orbitals only if they are fairly close in energy (within 1 Ry or so) and have similar symmetries. The same reasoning is very helpful in constructing MOs for heteronuclear diatomics. For example, in the HF molecule, both the  $1s$  and  $2s$  orbitals of the F atom are far too low in energy to mix with the H  $1s$  orbital. Moreover, the overlap between the H  $1s$  and F  $2s$  is negligible (Fig. 6.23a). The net overlap of the H  $1s$  orbital with the  $2p_x$  or  $2p_y$  F orbital is zero (Fig. 6.22) because the regions of positive and

**FIGURE 6.23** Overlap of atomic orbitals in HF. (**Note:** in the correlation diagram in Figure 6.24 it is assumed that lowest energy orbital is a non-bonding one that looks identical to a  $2s$  orbital on the F atom, with no contribution from the H  $1s$  orbital. In the graphical depiction of this orbital in (a) in this figure, a small coefficient multiplies the H  $1s$  orbital in this linear combination; the overlap is negligible.) (Courtesy of Mr. Hatem Helal and Professor William A. Goddard III, California Institute of Technology, and Dr. Kelly P. Gaither, University of Texas at Austin.)

negative overlap sum to zero. This leaves only the  $2p_z$  orbital of F to mix with the H  $1s$  orbital to give both  $\sigma$  bonding and  $\sigma^*$  anti-bonding orbitals (see Figs. 6.23b and d). The correlation diagram for HF is shown in Figure 6.24. The  $2s$ ,  $2p_x$ , and  $2p_y$  orbitals of fluorine do not mix with the  $1s$  of hydrogen and therefore remain as atomic (nonbonding) orbitals denoted by  $\sigma^{\text{nb}}$  and  $\pi^{\text{nb}}$ . Electrons in these orbitals do not contribute significantly to chemical bonding. Because fluorine is more electronegative than hydrogen, its  $2p$  orbitals lie below the  $1s$  hydrogen orbital in energy. The  $\sigma$  orbital then contains more fluorine  $2p_z$  character, and the  $\sigma^*$  orbital more closely resembles a hydrogen  $1s$  AO. When the eight valence electrons are put in for HF, the result is the electron configuration:

The net bond order is 1 because electrons in **nonbonding atomic orbitals** do not affect bond order. The electrons in the  $\sigma$  orbital are more likely to be found near the fluorine atom than near the hydrogen, so HF has the dipole moment  $\text{H}^{\delta+}\text{F}^{\delta-}$ .

If a more electropositive atom (such as Na or K) is substituted for H, the energy of its outermost  $s$  orbital will be higher than that of the H atom, because its ionization energy is lower. In this case, the  $\sigma$  orbital will resemble a fluorine  $2p_z$  orbital even more (that is, the coefficient  $C_F$  of the fluorine wave function will be close to 1, and  $C_A$  for the alkali atom will be very small). In this limit the molecule can be described as having the valence electron configuration  $(\sigma^{\text{nb}})^2(\sigma)^2(\pi_x^{\text{nb}}, \pi_y^{\text{nb}})^4$ , which corresponds to the ionic species  $\text{Na}^+\text{F}^-$  or  $\text{K}^+\text{F}^-$ . The magnitudes of the coefficients in the molecular orbital wave function are thus closely related to the ionic-covalent character of the bonding and to the dipole moment.

**FIGURE 6.24** Correlation diagram for HF. The  $2s$ ,  $2p_x$ , and  $2p_y$  atomic orbitals of fluorine do not mix with the  $1s$  atomic orbital of hydrogen, and therefore remain nonbonding.

## CONNECTION TO INSTRUMENTAL ANALYSIS

## Photoelectron Spectroscopy

In photoelectron spectroscopy (PES), we illuminate a sample with high-frequency radiation (ultraviolet or X-ray) and measure the kinetic energy of the photoelectrons emitted from the sample (see Figs. 5.22 and 5.23). We used PES in Section 5.4 to confirm the shell structure of the atom predicted by quantum mechanics (see Fig. 5.26). For molecules, PES confirms the MO description of bonding and measures the energy,  $\varepsilon$ , for individual MOs. The bridge between PES results and MO theory is Koopmans's approximation (stated in Section 5.4). These three tools are used together to study the electronic structure of molecules in all branches of chemistry.

As a concrete example, suppose we illuminate a diatomic gaseous sample with He(I) radiation, which has energy of 21.22 eV and a wavelength of 58.43 nm, and we measure the kinetic energy of the emitted photoelectrons with an energy analyzer. The resulting PES spectrum shows a series of peaks, each of which we label with an index  $i$ . We subtract the measured kinetic energy from the photon energy, which is fixed in our experiment. Thus, by conservation of energy, we are measuring the *ionization energy*,  $IE_i$ , required to liberate those electrons that contribute to peak  $i$ . Koopmans's theorem states that the measured ionization energy is the negative of the energy of the orbital from which the photoelectrons were emitted:  $IE_i = -\varepsilon_i$ . (Recall that  $IE_i$  is positive because it must be provided to the system, and that  $\varepsilon_i$  is negative because it measures the amount by which the molecular orbital is stabilized relative to the cation plus a free electron.) Koopmans's theorem is only an approximation, because it assumes that the ion produced during photoemission has the same orbital energies as the parent neutral molecule. In addition to the relaxation of the resulting ion as observed for atoms (see discussion in Section 5.4), some of the energy provided by the photon can be used to excite vibrational states in the molecular ion, which requires an amount of energy,  $E_i^{(\text{vib})}$ . Now the energy conservation equation is

$$h\nu_{\text{photon}} - \frac{1}{2}m_e v^2 = -\varepsilon_i + E_i^{(\text{vib})} = IE_i$$

As a result of the vibrational excitation, the peak  $i$  in the spectrum is actually a series of narrower peaks; the separation between adjacent peaks depends on the vibrational frequency of the diatomic ion. The result illustrated in Figure C6.1 shows the PES of hydrogen. The peak near 15.5 eV corresponds to the ionization energy

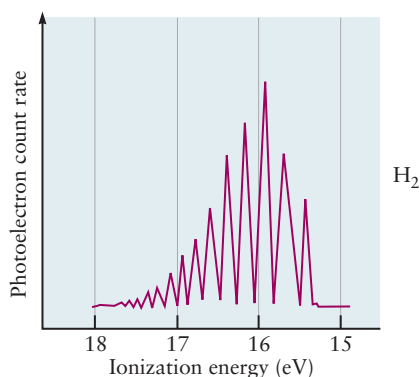

for removing electrons with no vibrational excitation of the resulting molecular ion. As the energy increases along the axis toward 18 eV, the amount of vibrational excitation of the  $\text{H}_2^+$  ion increases, and the spacing between vibrational levels becomes smaller. The  $\text{H}_2^+$  ion is approaching its dissociation limit.

These vibrational “fine-structure” peaks on the PES data at first appear to be a nuisance, but in fact, they greatly aid in relating experimental data to particular MOs. The connection is made through the concept of bond order introduced in Section 6.4.

Case A: If the photoelectron is removed from a bonding MO, the bond order of the positive ion will be smaller than the bond order of the parent molecule. Consequently, the bond in the molecular ion will be less stiff, and its vibrational frequency (determined directly from the PES fine structure) will be lower than that of the parent molecule (determined by vibrational spectroscopy).

Case B: If the photoelectron is emitted from an antibonding orbital, the bond order of the positive ion will be larger than the bond order of the parent molecule. The bond in the diatomic molecular ion will be stiffer and will show a higher vibrational frequency.

Case C: If the photoelectron is emitted from a nonbonding orbital, there is no change in the bond order, and consequently little or no change in the vibrational frequency. The PES spectrum for the orbital will show few vibrational peaks, because the disturbance to the bond during photoemission is quite small. By contrast, the spectrum in Case A will show several vibrational fine structure peaks because removal of a bonding electron is a major disturbance that starts many vibrations of the bond. Case B is intermediate, with fewer vibrational

**FIGURE C6.1** The photoelectron spectrum of  $\text{H}_2$  shows a series of peaks corresponding to vibrational excitation of  $\text{H}_2^+$ .

subpeaks, because removing an antibonding electron disturbs the bond, but less so than in Case A.

The photoelectron spectra for  $\text{N}_2$  and  $\text{O}_2$  are shown in Figures C6.2 and C6.3. The experimental peaks have been assigned to orbitals by slightly more complex versions of the arguments used previously. Note that for  $\text{N}_2$ , the energy for the  $\sigma_{g2p_z}$  MO is lower than that for  $\pi_{u2p_x}$  and  $\pi_{u2p_y}$ , whereas the order is switched for  $\text{O}_2$ , as indicated in Figure 6.17, Table 6.3, and the related text. This switch is due to interaction between the  $2s$  and  $2p$  AOs.

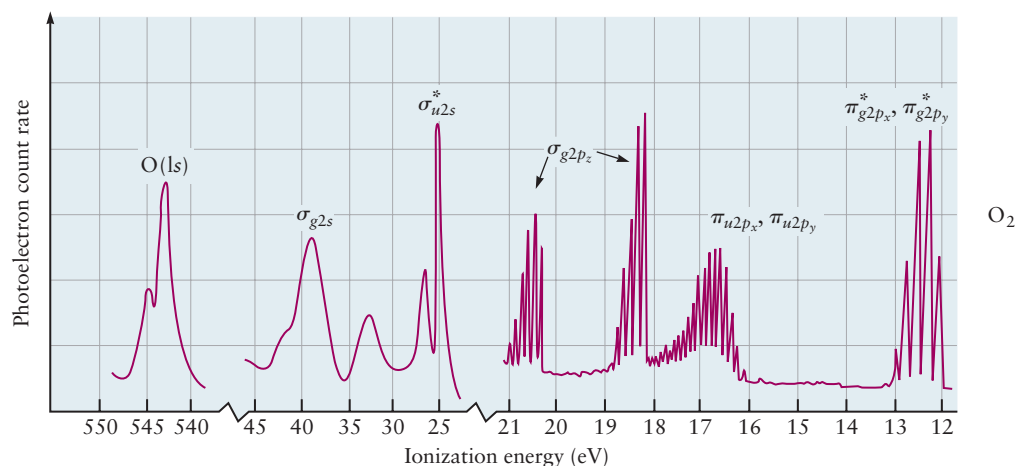

The photoelectron spectrum for NO is shown in Figure C6.4. The orbital assignments are based on the arguments summarized above. Note that the  $1s$  core levels

for both N and O appear at the same orbital energies as they do in their respective elemental gases,  $\text{N}_2$  and  $\text{O}_2$ . This experimental result demonstrates clearly that the core levels do not participate in chemical bond formation and can be neglected in the MO analysis of bond formation.

These examples show that photoelectron spectroscopy is useful in testing theoretical models for bonding because it directly measures ionization energies that can be correlated with theoretical orbital energies through Koopmans's theorem. These methods are readily extended to polyatomic molecules (see Section 20.5).

**FIGURE C6.2** The photoelectron spectrum for  $\text{N}_2$  shows the valence electrons in the occupied molecular orbitals and the  $\text{N}(1s)$  core electrons.

**FIGURE C6.3** The photoelectron spectrum for  $\text{O}_2$  shows valence electrons in the occupied molecular orbitals and the  $\text{O}(1s)$  core electrons.

FIGURE C6.4 The photoelectron spectrum for NO.

## 6.7 Summary Comments for the LCAO Method and Diatomic Molecules

The qualitative LCAO method presented in Sections 6.4–6.6 can rationalize experimentally observed trends in bond length and bond energy in a group of molecules by relating both these properties to bond order, but it cannot predict the values of bond energy or molecular geometry for any specific molecule. Predicting these properties requires calculations of the electronic energy as a function of the internuclear separation to determine the effective potential energy curve, as shown in Figure 6.6 for  $\text{H}_2^+$ . The minimum value of this curve defines the bond energy. The equilibrium bond length is then identified as the internuclear separation at which the minimum of the effective potential energy curve appears. The LCAO method can achieve quantitative results for molecular properties using modern computer programs to calculate the effective potential energy curve, once the basis set of AOs has been chosen for a specific molecule.

The qualitative LCAO method easily identifies the sequence of energy levels for a molecule, but does not give their specific values. The qualitative energy level diagram is very useful for interpreting experiments that involve adsorption and emission of energy such as spectroscopy, ionization by electron removal, and electron attachment. Trends in such results for a group of molecules can be easily rationalized, but predicting specific results requires the quantitative calculations described in the preceding paragraph.

## 6.8 Valence Bond Theory and the Electron Pair Bond

The characteristics (bond length, bond energy, polarity, etc.) of specific chemical bonds such as O—H, C—C, and C—H do not differ much from molecule to molecule (see Section 3.9, especially Table 3.4). If the bonding electrons are spread out over the entire molecule, as described by the LCAO model, then why should the properties of a bond be nearly independent of the nature of the rest of the molecule? Would some other model that associates electrons directly with the bond provide a better description of chemical bonds?

The **valence bond (VB) theory** was developed to provide a quantum explanation and justification for the Lewis electron pair model in which the chemical bond is described as a pair of electrons localized between two atoms. The valence bond theory constructs a wave function for each individual chemical bond by assuming that each participating atom arrives with at least one unpaired electron in an AO. The VB wave function for the bond is a *product* of two one-electron AO wave functions, each describing an electron localized on one of the atoms. The spins of the electrons must be paired to satisfy the Pauli exclusion principle.

The VB description for  $H_2$  was developed by the German physicists Walter Heitler and Fritz London in 1927, just one year after Schrödinger introduced wave mechanics to explain the structure of the H atom. The American physicist John C. Slater also made important contributions to developing the VB method. Establishing the VB method as one of the cornerstones of modern structural chemistry awaited the pioneering work of the American chemist Linus Pauling, who used it to describe structure and bonding in polyatomic molecules, starting in 1931. VB theory predates LCAO theory, and until modern computer calculations became available in the 1960s, VB theory was more widely used than LCAO because it could describe molecular structure without performing detailed calculations. VB theory is still very popular today for the same reason.

This section presents a qualitative version of VB theory, which easily describes the structure and geometry of bonds in polyatomic molecules by hand-drawn sketches. Because of this ease, qualitative VB theory is a very useful complement to qualitative LCAO theory. It is widely used in organic and inorganic chemistry and in biochemistry. Later in this chapter we compare VB and LCAO methods and see when one is preferable to the other. In some cases we see it is beneficial to use the two methods together.

**FIGURE 6.25** Two hydrogen atoms approach one another. The protons are separated by the distance  $R_{AB}$ . (a) At large values of  $R_{AB}$  each electron interacts only with the proton to which it is bound. (b) As the atoms approach closer, both electrons interact with both protons. The distance of electron 1 from nuclei A and B is given by  $r_{1A}$ ,  $r_{1B}$ ; the distance of electron 2 from nuclei A and B is given by  $r_{2A}$ ,  $r_{2B}$ ; the distance between the electrons is given by  $r_{12}$ .

### 6.8.1 Single Bonds

Consider that the hydrogen molecule, described by the Lewis structure H:H, is formed by combining two hydrogen atoms each with the electron configuration H:  $(1s)^1$ . The two atoms approach one another and begin to interact as shown in Figure 6.1, and in more detail in Figure 6.25. The protons are separated by the distance  $R_{AB}$ . At very large separations, each electron is bound to its own proton, and is located by coordinate  $r_{1A}$  or  $r_{2B}$ . At very large distances, the atoms are independent of each other, and the wave function describing the pair of them is  $\varphi^A(r_{1A})\varphi^B(r_{2B})$ . This result is a consequence of the form of the Schrödinger equation. If two objects are independent, their total energy is the sum of the individual energies, and the wave function for the two of them is the product of the individual wave functions. As the atoms approach closer together so that

bond formation is a possibility, it is reasonable to propose an approximate wave function for the two of them would take the form

$$\psi^{\text{el}}(r_{1A}, r_{2B}; R_{AB}) = c(R_{AB})\varphi^A(r_{1A})\varphi^B(r_{2B}) \quad [6.12]$$

in which the coefficient  $c(R_{AB})$  compensates for the fact that the product form is strictly valid only at very large values of  $R_{AB}$ .

As the atoms begin to interact strongly, we cannot determine whether electron 1 arrived with proton A and electron 2 with proton B, or vice versa, because the electrons are indistinguishable. To allow for both possibilities we propose a wave function that is a sum of two of the product forms just discussed. We assign electron 1 to proton A and electron 2 to proton B in the first product form, and in the second product we switch each electron to the other proton. The result is

$$\psi^{\text{el}}(r_{1A}, r_{2B}; R_{AB}) = c_1(R_{AB})\varphi^A(r_{1A})\varphi^B(r_{2B}) + c_2(R_{AB})\varphi^A(r_{2A})\varphi^B(r_{1B}) \quad [6.13]$$

Symmetry requires that  $c_1 = c_2$  and  $c_1 = -c_2$  be equally valid choices. We label these combinations *gerade* (*g*) and *ungerade* (*u*) respectively to show how each behaves under inversion symmetry, as in Sections 6.2 and 6.3. We must check both cases to determine whether they describe bond formation, using our familiar criteria of increased electron density between the nuclei and energy reduced below that of the separated atoms.

It requires some care to calculate the electron density for  $\psi_g^{\text{el}}$  and  $\psi_u^{\text{el}}$ . Unlike the one-electron wave functions we have seen earlier, these are examples of *two-electron functions*, which depend explicitly on the positions of both electrons. Their squares give the probability density for finding electron 1 at  $r_1$  and electron 2 at  $r_2$ . To calculate the probability density for finding electron 1 at  $r_1$ , no matter where electron 2 is located, we must square the function and then average over all possible locations for electron 2. Similarly, we calculate the probability density for finding electron 2 at  $r_2$  regardless of the location of electron 1. Adding these results together gives the total electron density at each point in space, as a function of the internuclear distance  $R_{AB}$ . The results for  $\psi_g^{\text{el}}$  and  $\psi_u^{\text{el}}$  are shown in Figure 6.26a. The wave function  $\psi_g^{\text{el}}$  shows increased electron density between the nuclei, whereas  $\psi_u^{\text{el}}$  shows reduced electron density between the nuclei. The shape of the electron density in three dimensions is more conveniently obtained from computer calculations using a quantitative version of the VB method which will be described later. Figure 6.26b shows a three-dimensional isosurface of the electron density for  $\text{H}_2$  calculated from  $\psi_g^{\text{el}}$ .

It is a straightforward exercise in quantum mechanics—although beyond the scope of this book—to calculate the energy of the hydrogen molecule as a function of  $R_{AB}$  when the electrons are described by  $\psi_g^{\text{el}}$  and by  $\psi_u^{\text{el}}$ . The results give the effective potential energy curve for each value of  $R_{AB}$ . The two calculated effective potential energy curves (not shown here) are qualitatively similar to those in Figure 6.9. They show that  $\psi_g^{\text{el}}$  describes a state with lower energy than that of the separated atoms, whereas  $\psi_u^{\text{el}}$  describes a state whose energy is higher than that of the separated atoms for all values of  $R_{AB}$ .

Taken together, the reduced effective potential energy and increased electron density between the nuclei demonstrate that  $\psi_g^{\text{el}}$  describes a stable chemical bond, while  $\psi_u^{\text{el}}$  describes a state that is strictly repulsive everywhere and does not lead to bond formation. Therefore, we conclude that the correct wave function to describe an electron pair bond in the VB method is

$$\psi_g^{\text{el}} = C_1[1s^A(1)1s^B(2) + 1s^A(2)1s^B(1)] \quad [6.14]$$

**FIGURE 6.26** The electron density for the  $\psi_g^{\text{el}}$  and  $\psi_u^{\text{el}}$  wave functions in the simple valence bond model for  $\text{H}_2$ . (a) The electron density  $\rho_g$  for  $\psi_g^{\text{el}}$  and  $\rho_u$  for  $\psi_u^{\text{el}}$  calculated analytically as described in the text. (b) Three-dimensional isosurface of the electron density for the  $\psi_g^{\text{el}}$  wave function obtained by computer calculations. (Courtesy of Mr. Hatem Helal and Professor William A. Goddard III, California Institute of Technology, and Dr. Kelly P. Gaither, University of Texas at Austin.)

In this and the following equations we use the simplified notation for atomic orbitals introduced earlier in our discussion of the LCAO approximation in Section 6.3. In addition, we use “1” and “2” as shorthand notation for the coordinates locating electron 1 and electron 2, and  $C_1$  is a normalization constant.

Equations 6.13 and 6.14 are the basic descriptions of the electron pair bond in VB theory. At first glance they may seem a bit daunting with the numerous subscripts and superscripts, but they provide a concise summary of a great deal of important information. They symbolically represent the elaborate verbal description of what happens when the electron densities of two H atoms begin to interpenetrate and form a new density characteristic of the  $\text{H}_2$  molecule: “The wave function for the electron pair bond in a hydrogen molecule is constructed by multiplying a 1s orbital for electron 1 on atom A by a 1s orbital for electron 2 on atom B and adding the product to the result of multiplying a 1s orbital for electron 2 on atom A by a 1s orbital for electron 1 on atom B and finally normalizing the resulting sum.” There is a beautiful and satisfying interplay between visualizing the physical events, describing them verbally, and describing them in simple equations. We use these equations repeatedly to describe several different types of electron pair bonds in VB theory. The atoms and the orbitals involved change from one case to another, but the verbal description of the process and the equations are always the same.

Now let’s consider the formation of  $\text{F}_2$ , represented by its Lewis diagram, from two F atoms each with electron configuration F:  $(1s)^2(2s)^2(2p_x)^2(2p_y)^2(2p_z)^1$ . Suppose the two atoms labeled A and B approach each other along the  $z$ -axis so that their  $2p_z$  orbitals with the same phase point toward each other. As the atoms draw close, these two orbitals can overlap to form a single bond with two

**FIGURE 6.27** Isosurface representation of the electron density in the  $F_2$   $\sigma$  bond formed from a pair of electrons initially localized in a  $2p_z$  orbital on each F atom. **FIGURE 6.30** Lewis diagram for  $N_2$ .

electrons. Reasoning as we did above for  $H_2$ , we write the VB wave function for the electron pair bond in  $F_2$  as

$$\psi_g^{\text{bond}} = C_1[2p_z^A(1)2p_z^B(2) + 2p_z^A(2)2p_z^B(1)] \quad [6.15]$$

The electron density obtained from this wave function is represented by the three-dimensional isosurface shown in Figure 6.27. It gives the probability density for locating two electrons in the  $F_2$  molecule with internuclear separation  $R_{AB}$ . Comparing this surface with the one shown in Figure 6.26b clearly reveals the influence of its parentage in  $2p$  AOs. This wave function gives no information on the eight pairs of electrons remaining in their atomic orbitals on atoms A and B, six pairs of which are shown as unshared pairs in the Lewis diagram for  $F_2$  (Fig. 6.28).

The VB model also describes bond formation in heteronuclear diatomics. We can combine the features of the two preceding examples to describe HF, which has one shared pair in a single bond produced by overlap of H  $1s$  and F  $2p_z$ . To write a wave function for the electron pair bond, one might begin with

$$\psi^{\text{bond}} = C_1[2p_z^F(1)1s^H(2)] + C_2[2p_z^F(2)1s^H(1)] \quad [6.16]$$

However,  $C_1$  and  $C_2$  are equal and should be omitted. The electron density isosurface is depicted in Figure 6.29. Because the wave function for the bond pair is symmetric (does not change sign) upon interchanging the spatial positions of the two electrons, the Pauli principle tells us that the spin part of the wave function should be antisymmetric (i.e.  $\alpha(1)\beta(2) - \alpha(2)\beta(1)$ , where  $\alpha$  indicates  $m_s = 1/2$  and  $\beta$  indicates  $m_s = -1/2$ ).

The bond pair wave functions in Equations 6.14, 6.15, and 6.16 were specially constructed to describe two electrons localized between two atoms as a single chemical bond between the atoms. These wave functions should not be called MOs, because they are not single-electron functions and they are not delocalized over the entire molecule. The corresponding single bonds, shown in Figures 6.26, 6.27, and 6.29 are examples of a **sigma ( $\sigma$ ) bond**, because their electron density is cylindrically symmetric about the bond axis. Because of this symmetry it is said to have zero angular momentum about the bond axis. Finally, electrons are not placed in these bonds by the aufbau principle. Rather, each bond is formed by overlap of two AOs, each of which is already half-filled with one electron. The electrons in the two participating AOs must have opposite spin, so the bond corresponds to an electron pair with opposite, or “paired” spins.

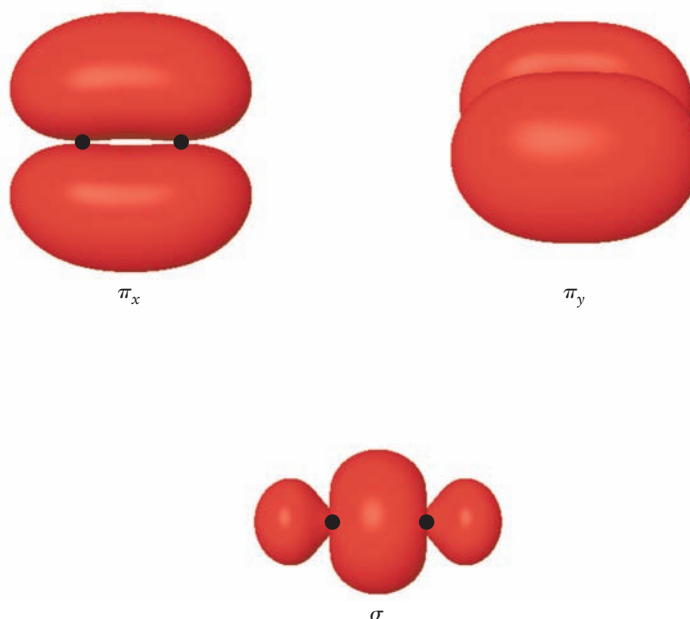

## 6.8.2 Multiple Bonds

To see how the VB method describes multiple bonds, let's examine  $N_2$  (Fig. 6.30). Suppose two nitrogen atoms with electron configuration N:  $(1s)^2(2s)^2(2p_x)^1(2p_y)^1(2p_z)^1$  approach one another along the  $z$ -axis. The two  $2p_z$  orbitals can overlap and form a  $\sigma$  bond whose wave function is

$$\psi_\sigma^{\text{bond}} = C_1[2p_z^A(1)2p_z^B(2) + 2p_z^A(2)2p_z^B(1)] \quad [6.17]$$

The  $2p_x$  orbitals and the  $2p_y$  orbitals on the two atoms do not approach head-on in this configuration, but rather side-to-side. Therefore, the positive lobes of the  $2p_x$  orbitals can overlap laterally, as can the negative lobes. Together they form a **pi ( $\pi$ ) bond**, which has a node through the plane containing the

**FIGURE 6.31** Isosurface representation of the electron densities in the  $\sigma$  bond and the two  $\pi$  bonds for nitrogen obtained by computer calculations. (Courtesy of Mr. Hatem Helal and Professor William A. Goddard III, California Institute of Technology, and Dr. Kelly P. Gaither, University of Texas at Austin.)

bond axis with amplitude above and below the plane. The wave function for the  $\pi_x$  bond is

$$\psi_{\pi_x}^{\text{bond}}(1, 2) = C_1[2p_x^{\text{A}}(1)2p_x^{\text{B}}(2)] + C_1[2p_x^{\text{A}}(2)2p_x^{\text{B}}(1)] \quad [6.18]$$

Similarly, the  $2p_y$  orbitals on the two atoms can overlap to form a second  $\pi$  bond, the  $\pi_y$  bond in the  $y$ - $z$  plane, for which the wave function is

$$\psi_{\pi_y}^{\text{bond}}(1, 2) = C_1[2p_y^{\text{A}}(1)2p_y^{\text{B}}(2) + 2p_y^{\text{A}}(2)2p_y^{\text{B}}(1)] \quad [6.19]$$

Again the two spins in each bond are opposite. The three bonds in  $\text{N}_2$  are shown as isosurfaces of electron density in Figure 6.31.

The problems for Section 6.8 at the end of the chapter give practice in writing out the wave functions for electron pair bonds in several other diatomic molecules, and identifying the bond order in each molecule. You should prepare hand sketches of the electron density isosurfaces for each bond you describe.

### 6.8.3 Polyatomic Molecules

Describing the three-dimensional structure of polyatomic molecules requires that we include bond angles as well as bond lengths. Let's test the VB approximation on the second-period hydrides, whose structures we have already examined using VSEPR theory in Chapter 3, to see how well it describes bond angles and molecular shapes.

Beryllium hydride,  $\text{BeH}_2$ , has four valence electrons, two from Be and one each from the two H atoms, all of which appear in the Lewis diagram in Figure 6.32. In VSEPR theory, the steric number is 2, so the molecule is predicted to be linear, and this prediction is verified by experiment. The electron configuration of the central atom is Be:  $(1s)^2(2s)^2$ . There are no unpaired electrons to overlap with H(1s) orbitals, so the VB model fails to predict the formation of  $\text{BeH}_2$ .

Boron hydride,  $\text{BH}_3$  (Fig. 6.33), has six valence electrons corresponding to steric number 3 and a trigonal planar structure. With the electron configuration

**FIGURE 6.32** Lewis diagram for  $\text{BeH}_2$ .

**FIGURE 6.33** Lewis diagram for  $\text{BH}_3$ .

FIGURE 6.34 Lewis diagram for CH<sub>4</sub>.FIGURE 6.35 Lewis diagram for NH<sub>3</sub>.FIGURE 6.36 Lewis diagram for H<sub>2</sub>O.

B:  $(1s)^2(2s)^2(2p)^1$  on the central atom, the VB model cannot account for the formation of BH<sub>3</sub> and, in fact, predicts that BH is the stable molecule, which does not agree with experiment.

Methane, CH<sub>4</sub> (Fig. 6.34), has steric number 4, and VSEPR predicts a tetrahedral structure, which is confirmed by experiment. Starting with the electron configuration C:  $(1s)^2(2s)^2(2p)^2$ , the VB model cannot account for the formation of CH<sub>4</sub> and predicts that CH<sub>2</sub> would be the stable hydride, which is again contrary to the experimental results.

Ammonia, NH<sub>3</sub> (Fig. 6.35), has steric number 4 with three shared pairs and one unshared pair on the N atom. VSEPR predicts a trigonal pyramid structure, as a subcase of tetrahedral structure, with angles slightly less than 109.5° due to repulsion between the unshared pair and the three bonding pairs. Experiment verifies this structure with angles of 107°. The electron configuration N:  $(1s)^2(2s)^2(2p_x)^1(2p_y)^1(2p_z)^1$  would permit the formation of three  $\sigma$  bonds by overlap of H(1s) orbitals with each of the 2p orbitals on N. Because these 2p orbitals are all mutually perpendicular, VB predicts a trigonal pyramid but one with bond angles of 90°.

Finally, water, H<sub>2</sub>O (Fig. 6.36), has steric number 4 with two shared pairs and two unshared pairs on the O atom. VSEPR predicts a bent structure, as a subcase of tetrahedral structure, with angles significantly less than the tetrahedral value of 109° due to repulsion between the two unshared pairs and the bonding pairs. Experiment verifies this prediction with a bond angle of 104.5°. The electron configuration O:  $(1s)^2(2s)^2(2p_x)^2(2p_y)^1(2p_z)^1$  would permit formation of two  $\sigma$  bonds by overlap of H(1s) orbitals with each of the 2p orbitals on O. VB predicts a bent structure for H<sub>2</sub>O, but with bond angle of 90°.

These examples show that the VB model does not accurately describe bonding in the second-period hydrides. It predicts the wrong valence for atoms in Groups IIA through IVA, and the wrong structure for atoms in Groups VA and VIA. Clearly, the model had to be improved. Linus Pauling gave the answer in 1931 by introducing the concepts of *promotion* and *hybridization*.

Atoms such as Be, B, and C can have the correct valence for bonding by **promotion** of valence electrons from the ground state to excited states at higher energy. For example,

and

are ready to form BeH<sub>2</sub> and CH<sub>4</sub>, respectively. These excited states are known from spectroscopy. The C excited state lies about 8.26 eV (190 kcal mol<sup>-1</sup>) above the ground state; promoting an electron to create the excited state clearly requires energy. Pauling argued that this investment would be repaid by the energy released when the C–H bonds of methane form (about 100 kcal mol<sup>-1</sup> for each bond).

Even though the valence is correct after promotion, the structure would still be wrong. Beryllium hydride would have two different kinds of bonds, and methane would have three identical bonds formed by overlap of H(1s) with the C(2p) orbitals and a different bond formed by H(1s) and C(2s). Pauling proposed that new atomic orbitals with the proper symmetry for bond formation could be formed by **hybridization** of 2s and 2p orbitals after promotion. The Be(2s) and Be(2p<sub>z</sub>) orbitals would combine to form two equivalent hybrid atomic orbitals oriented 180° apart. The C(2s) would hybridize with the three C(2p) orbitals to give four equivalent new atomic orbitals arranged as a tetrahedron around the C atom.

Pauling's achievements made it possible to describe polyatomic molecules by VB theory, and hybridization has provided the vocabulary and structural

concepts for much of the fields of inorganic chemistry, organic chemistry, and biochemistry.

## 6.9 Orbital Hybridization for Polyatomic Molecules

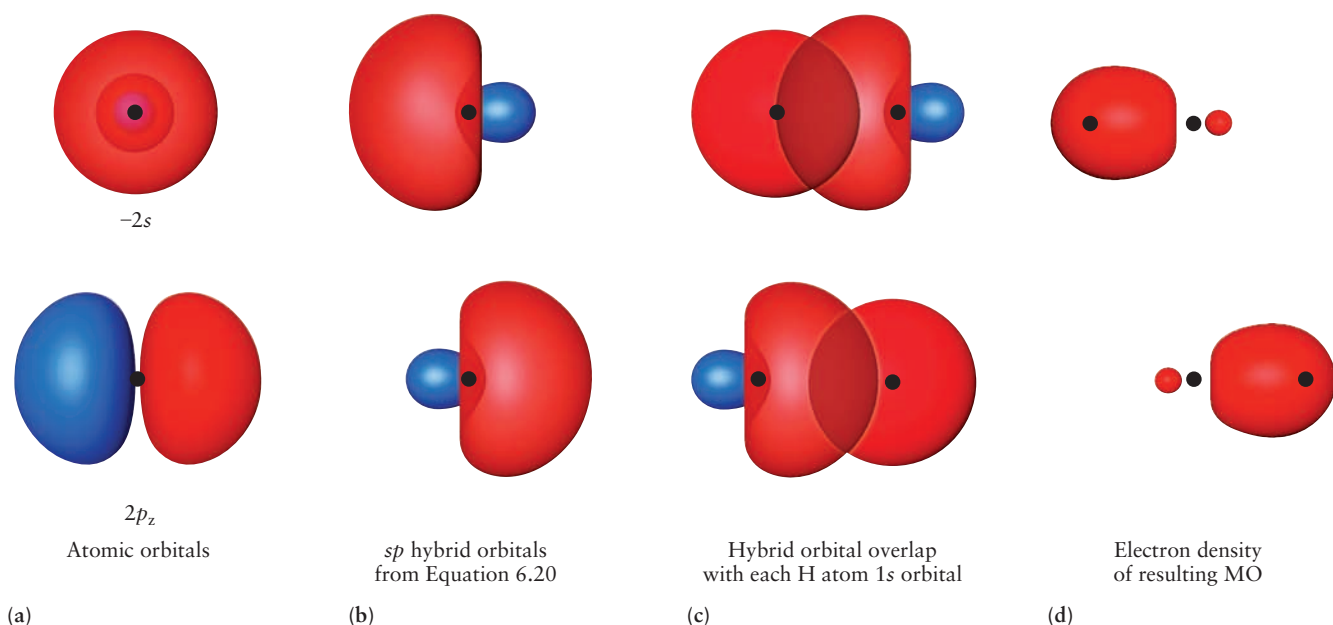

Pauling developed the method of hybrid orbitals to describe the bonding in molecules containing second-period atoms with steric numbers 2, 3, and 4. Let's discuss these hybridization schemes in sequence, starting with  $\text{BeH}_2$ . In each case we will learn how to construct the hybrid orbitals and how to use them to describe the bonds and the three-dimensional structure of polyatomic molecules. We will use the lower case Greek letter "chi"  $\chi$  to represent hybrid orbitals.

### 6.9.1 $sp$ Hybridization

Because the  $\text{BeH}_2$  molecule is known to be linear, we need two new atomic orbitals oriented  $180^\circ$  apart on the Be atom, each of which can overlap with one H atom. We can generate these new atomic orbitals in the following way. Let's define the  $z$ -axis of the coordinate system to lie along the  $\text{H}-\text{Be}-\text{H}$  bonds, and place the Be nucleus at the origin. We mix the  $2s$  and  $2p_z$  orbitals of Be to form two new orbitals on the Be atom. The linear combinations that correspond to Figure 6.37b (with the  $z$ -axis pointing to the right), are

$$\chi_1(r) = \frac{1}{\sqrt{2}}[-2s - 2p_z] \quad [6.20a]$$

$$\chi_2(r) = \frac{1}{\sqrt{2}}[-2s + 2p_z] \quad [6.20b]$$

**FIGURE 6.37** Formation, shapes, and bonding of the  $sp$  hybrid orbitals in the  $\text{BeH}_2$  molecule. (a) The  $-2s$  and  $2p_z$  orbitals of the Be atom. (b) The two  $sp$  hybrid orbitals formed from the  $2s$  and  $2p_z$  orbitals on the beryllium atom. (c) The two  $\sigma$  bonds that form from the overlap of the  $sp$  hybrid orbitals with the hydrogen  $1s$  orbitals, making two single bonds in the  $\text{BeH}_2$  molecule. (d) Electron density in the two  $\sigma$  bonds obtained by computer calculations.

(Courtesy of Mr. Hatem Helal and Professor William A. Goddard III, California Institute of Technology, and Dr. Kelly P. Gaither, University of Texas at Austin.)

The coefficient  $1/\sqrt{2}$  is a normalization constant. We call these ***sp* hybrid atomic orbitals** because they are formed as the sum or difference of one *s* orbital and one *p* orbital. Like the familiar *s* and *p* orbitals, a hybrid atomic orbital is a one-electron wave function that is defined at every point in space. The value of the wave function at each point is the sum or difference of the original AOs combined to form the hybrid. Its square at each point in three-dimensional space gives the probability density for finding the electron at that point, when the electron is in the hybrid orbital.

The formation, shapes, and orientation of the *sp* hybrid orbitals—and their participation in chemical bonds—are shown in Figure 6.37. The first column shows the standard orbitals on the Be atom before hybridization, and the second shows the hybrid atomic orbitals on Be resulting from the linear combination of the Be  $2s$  and  $2p_z$  atomic orbitals given in Equation 6.20. The hybrid atomic orbital shown on the top of the second column is the one with large electron density pointing in the negative *z* direction, from Equation 6.20a. It is the one that will have substantial overlap with the H atom coming in from the left as you form H-Be-H. As the two hydrogen atoms approach the Be atom from opposite directions along the *z*-axis, each shares its electron with the nearest hybrid orbital to form a localized  $\sigma$  bond (see Fig. 6.37c). The result is a pair of localized  $\sigma$  bonds, one on each side of the Be atom. The third column in Figure 6.37 illustrates these two  $\sigma$  bonds by locating the Be and H nuclei at distances apart equal to the experimental bond length of  $\text{BeH}_2$ , and placing an *sp* hybrid on the Be atom and a  $1s$  AO on the H atom in order to show where these orbitals overlap. Since the advent of the VB method, chemists have used qualitative sketches similar to this third column to show the location, shape, and orientation of the  $\sigma$  bonds. With modern computational methods, detailed representations of the electron density can be obtained from the wave functions for the two bonding pairs. The fourth column in Figure 6.37 shows the electron density in the  $\sigma$  bonds of  $\text{BeH}_2$  calculated in this way.

*sp* hybridization explains how an atom can have a pair of  $\sigma$  bonds at an angle of  $180^\circ$  apart and therefore be part of a linear molecule. This result is broadly applicable and can be combined with other aspects of molecular structure. Later in this section we shall see that atoms having more than two valence electrons can form linear molecules through *sp* hybridization and at the same time can also form multiple bonds through linear combinations of the two *p* orbitals not used in making the *sp* hybrid AOs with orbitals on other atoms.

## 6.9.2 *sp*<sup>2</sup> Hybridization

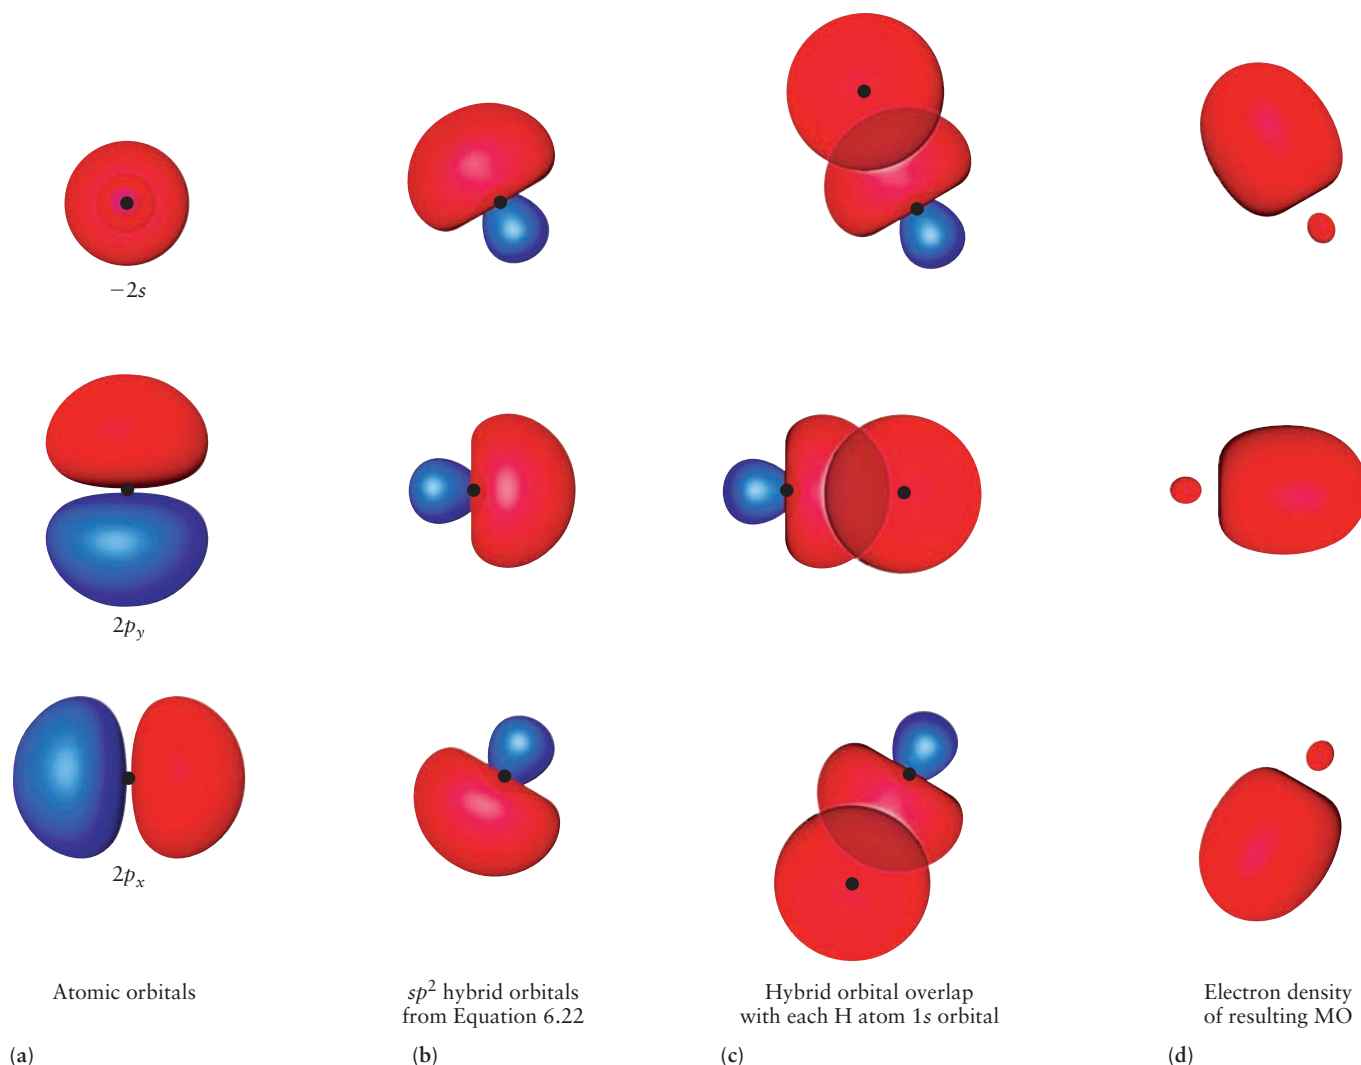

Experimental data suggest that the  $\text{BH}_3$  molecule has a trigonal planar structure with three equivalent bonds, as predicted by VSEPR theory. To explain this structure, we need three new orbitals oriented  $120^\circ$  apart in a plane containing the B atom, each of which can overlap with one H atom. We can generate these new orbitals in the following way. Let's choose coordinates so that the structure lies in the *x*-*y* plane with the B atom at the origin. Promotion of one of the  $2s$  electrons creates the excited-state configuration B:  $2s^1 2p_x^1 2p_y^1$ . The two occupied  $2p$  AOs already lie in the desired plane. Geometry shows they can be mixed with the  $2s$  AO to form three equivalent new orbitals separated by  $120^\circ$ . To calculate the *sp*<sup>2</sup> hybrid orbitals depicted in Figure 6.29b, if the *y*-axis is pointing vertically on the page while the *x*-axis points to the right, the necessary linear combinations of boron's AOs, for the top, middle and bottom *sp*<sup>2</sup> hybrid AOs, respectively, are

$$\chi_1(r) = (1/3)^{1/2}(-2s) - (1/6)^{1/2}(2p_x) + (1/2)^{1/2}(2p_y) \quad [6.22a]$$

$$\chi_2(r) = (1/3)^{1/2}(-2s) + 2(1/6)^{1/2}(2p_x) \quad [6.22b]$$

$$\chi_3(r) = (1/3)^{1/2}(-2s) - (1/6)^{1/2}(2p_x) - (1/2)^{1/2}(2p_y) \quad [6.22c]$$

These are called  **$sp^2$  hybrid atomic orbitals** because they are generated from one  $s$  and two  $p$  orbitals. The formation, shape, and orientation of the  $sp^2$  hybrids are shown in Figure 6.38. They lie in the  $x$ - $y$  plane with an angle of  $120^\circ$  between them. After hybridization, the electron configuration of the atom is B:  $(1s)^2(\chi_1)^1(\chi_2)^1(\chi_3)^1$ . Each of the  $sp^2$  hybrids can overlap with an H( $1s$ ) orbital to produce a  $\sigma$  bond. The third column shows the traditional sketches of the orbital overlap leading to each of these  $\sigma$  bonds in  $BH_3$ , and the fourth column shows the electron density in the resulting bonding MOs. Experimentally,  $BH_3$  molecules turn out to be unstable and react rapidly to form  $B_2H_6$  or other higher compounds called *boranes*, but  $BH_3$  can be detected in a mass spectrometer as a fragment of the higher compounds. The closely related  $BF_3$  molecule is stable, and experiments have shown its structure to be the trigonal planar geometry

**FIGURE 6.38** Formation, shapes, relative orientation, and bonding of the three  $sp^2$  hybrid orbitals in the  $BH_3$  molecule. Goddard III, California Institute of Technology, and Dr. Kelly P. Gaither, University of Texas at Austin.)

**FIGURE 6.39** Shapes and relative orientations of the four  $sp^3$  hybrid orbitals in  $\text{CH}_4$  pointing at the corners of a tetrahedron with the carbon atom at its center. The “exploded view” at the bottom shows the tetrahedral

geometry. (Courtesy of Mr. Hatem Helal and Professor William A. Goddard III, California Institute of Technology, and Dr. Kelly P. Gaither, University of Texas at Austin.)

characteristic of  $sp^2$  hybridization. It forms three  $\sigma$  bonds by overlap of a  $B(sp^2)$  hybrid with an  $F(2p)$  orbital directed along each B-F bond in the  $x$ - $y$  plane.

$sp^2$  hybridization explains how an atom can form three  $\sigma$  bonds at an angle of  $120^\circ$  in a plane and therefore be part of a trigonal planar molecule. This is a general result, which can be combined with other aspects of molecular structure. Later in this section we shall see that atoms having more than three valence electrons can form trigonal structures through  $sp^2$  hybridization and at the same time can also form multiple bonds through linear combinations of each  $p$  orbital not used in making the three  $sp^2$  hybrid AOs with orbitals on neighboring atoms.

### 6.9.3 $sp^3$ Hybridization

The structure of methane  $\text{CH}_4$  has been shown by numerous experimental measurements to be tetrahedral with H—C—H bond angles of  $109.5^\circ$  and C—H bond length of  $1.093 \text{ \AA}$ . To describe this structure for  $\text{CH}_4$ , we need four new equivalent orbitals on C oriented as a tetrahedron about the C atom. To construct these orbitals, we first promote C from C:  $(1s)^2(2s)^2(2p_x)^1(2p_y)^1$  to C:  $(1s)^2(2s)^1(2p_x)^1(2p_y)^1(2p_z)^1$ . Then we combine the  $2s$  and three  $2p$  orbitals of the central carbon atom to form four equivalent  **$sp^3$  hybrid atomic orbitals**, which point toward the vertices of a tetrahedron:

$$\chi_1(r) = -\frac{1}{2} [2s + 2p_x + 2p_y + 2p_z] \quad [6.23a]$$

$$\chi_2(r) = -\frac{1}{2} [2s - 2p_x - 2p_y + 2p_z] \quad [6.23b]$$

$$\chi_3(r) = -\frac{1}{2} [2s + 2p_x - 2p_y - 2p_z] \quad [6.23c]$$

$$\chi_4(r) = -\frac{1}{2} [2s - 2p_x + 2p_y - 2p_z] \quad [6.23d]$$

Figure 6.39 shows the shape and orientation of these four hybrid AOs, pointing toward the vertices of a tetrahedron, which has the C atom at its center. The bottom image in Figure 6.39 shows an “exploded view” in which the hybrid AOs have been displaced from one another to clearly reveal the tetrahedral geometry. Each hybrid AO can overlap a  $1s$  orbital of one of the hydrogen atoms to give an overall tetrahedral structure for  $\text{CH}_4$ .

The key result of  $sp^3$  hybridization is to explain how an atom can form four  $\sigma$  bonds at an angle of  $109.5^\circ$  and thereby generate tetrahedral geometry. This structural unit is a major building block in organic chemistry and polymeric materials based on C, and in semiconductor materials based on Si and Ge.

### 6.9.4 Summary of Hybridization Results

Table 6.4 summarizes the three types of hybrid orbitals and the molecular geometry they produce when there are no nonbonding electron pairs on atom A.

**TABLE 6.4**

Orbital Hybridization and Molecular Geometry

Molecule	Hybrid Orbitals on Central Atom	Molecular Geometry	Example
$\text{AX}_2$	$sp$	Linear	$\text{BeH}_2$
$\text{AX}_3$	$sp^2$	Trigonal planar	$\text{BH}_3$
$\text{AX}_4$	$sp^3$	Tetrahedral	$\text{CH}_4$

**FIGURE 6.40** Exact and approximate representations of the hybrid orbital shapes. For each type of hybrid orbital shown, the left column shows typical chemists' sketches, the center column shows isosurfaces, and the right column shows contour plots. The top row is the  $sp$  hybrid orbitals, the middle row is the  $sp^2$  hybrid orbitals, and the bottom row is the  $sp^3$  hybrid orbitals. (Courtesy of Mr. Hatem Helal and Professor William A. Goddard III, California Institute of Technology, and Dr. Kelly P. Gaither, University of Texas at Austin.)

Because of their widespread use in chemistry, it is important to have a good sense of the sizes and shapes of hybrid orbitals. The shapes of the  $sp$  hybrid orbitals in Figure 6.37 are quantitatively correct and properly scaled in size relative to the other orbitals shown. Chemists tend to sketch these orbitals by hand like those shown in Figure 6.40, which gives the misleading impression that the  $sp$  hybrids are thin, cigar-like shapes with highly directional electron density concentrated right along the direction of the bonds. A contour map of  $\chi_1$  (from Equation 6.20b) shows that the orbital is rather diffuse and broadly spread out, despite its directional concentration (see Fig. 6.40). Because this plot is symmetrical about the  $z$ -axis, each of these contours can be rotated about the  $z$ -axis to produce a three-dimensional isosurface at a specified fraction of the total amplitude; the isosurfaces in Figure 6.37 were generated in just that way. These isosurfaces show the real effect of  $sp$  hybridization: The amplitudes of the Be AOs are now “pooched out” a bit in the  $+z$  and  $-z$  directions, but it has not been squeezed down into a thin tube. The  $2p_x$  and  $2p_y$  orbitals remain unchanged, oriented perpendicular to each other and to the  $sp$  hybrid orbitals.

The chemist's sketches typically drawn to emphasize directionality of the  $sp^2$  orbitals and a contour plot of the actual shape are shown in the second row of Figure 6.40. Each of these contours can be rotated about the  $x$ - $y$  plane to produce a three-dimensional isosurface at a value (+ or -) chosen to be a specific fraction of the maximum value of the wave function. These isosurfaces demonstrate that  $sp^2$  hybridization give a hybrid AO wave function of the B atom that is “pooched out” at three equally spaced locations around the “equator” of the atom (see Fig. 6.38). The  $2p_z$  orbital is not involved and remains perpendicular to the plane of the  $sp^2$  hybrids. The electron density in each hybrid AO is more directional (as it is the square of the wave function).

The standard chemist's sketches of the  $sp^3$  orbitals and a contour plot that shows the exact shape and directionality of each orbital are shown in the third row of Figure 6.40. The isosurfaces shown in Figure 6.39 were generated from these contour plots.

### 6.9.5 Hybridization and Lone Pairs

Let's return to our systematic study of bonding in hydrides of second-period atoms and see how hybridization can correctly explain the structure of the ammonia and water molecules. The Lewis diagram for ammonia shows the N atom has one unshared pair, giving steric number 4. Let's use  $sp^3$  hybridization to describe the bonding of this atom. Of the eight valence electrons in  $\text{NH}_3$ , six are involved in  $\sigma$  bonds between nitrogen and hydrogen; the other two occupy the fourth  $sp^3$  hybrid orbital as a lone pair (see Fig. 6.41a). This model predicts a trigonal pyramid with three equivalent bonds, in accordance with VSEPR theory. Placing the unshared pair in an  $sp^3$  hybrid orbital predicts bond angles of  $109.5^\circ$ , reasonably close to the measured values of  $107^\circ$  for  $\text{NH}_3$ . The general conclusion is that  $sp^3$  hybridization with a lone pair in one of the hybrid AOs explains the trigonal pyramid structure for  $\text{AX}_3$  molecules, as a subcase of tetrahedral structure. Examples include the hydrides and halides of the Group V elements N, P, As, Sb, and Bi, all of which have the trigonal pyramid structure with bond angles ranging from  $92^\circ$  to  $107^\circ$ . Additional effects must be considered to explain the range of bond angle values in this group of molecules.

Oxygen in  $\text{H}_2\text{O}$  likewise has steric number 4 and can be described with  $sp^3$  hybridization, with two lone pairs in  $sp^3$  orbitals (see Figure 6.41b). Placing the unshared pairs in an  $sp^3$  hybrid orbital predicts bond angles of  $109.5^\circ$ , reasonably close to the measured values of  $104.5^\circ$  for  $\text{H}_2\text{O}$ . The general conclusion is that  $sp^3$  hybridization with lone pairs in two of the hybrid AOs explains the bent or angular structure for  $\text{AX}_2$  molecules, as a subcase of tetrahedral structure. Other examples besides water are  $\text{H}_2\text{S}$ ,  $\text{OF}_2$ , and  $\text{SF}_2$ . Again, additional

**FIGURE 6.41** (a) Ammonia ( $\text{NH}_3$ ) has a pyramidal structure in which the bond angles are less than  $109.5^\circ$ . (b) Water ( $\text{H}_2\text{O}$ ) has a bent structure, with a bond angle less than  $109.5^\circ$  and smaller than that of  $\text{NH}_3$ .

effects must be considered to explain the range of bond angle values in this group of molecules.

### 6.9.6 Hybridization and Multiple Bonds in Organic Carbon Compounds

Carbon (C) is unique among all the elements in its ability to form large numbers of molecules with great variety in their structures. Different hydrocarbons (molecules consisting of H and C atoms) have structures with single, double, and triple carbon–carbon bonds. This variety traces to the location of carbon in the periodic table. As a Group IV element, carbon can form four bonds, which we have already seen is more than the other elements in the second period. Because of its small size, carbon can form double and triple bonds, which are rare in the larger atoms (Ge, Si) in Group IV. With intermediate value of electronegativity, carbon forms covalent compounds with more electronegative elements such as nitrogen, oxygen, and the halogens and also with more electropositive elements such as hydrogen, mercury, and lead.

The chemistry of carbon constitutes the field of organic chemistry, to which Chapter 7 provides a brief systematic introduction organized around the bonding in organic molecules. Orbital hybridization plays a key role in explaining bonding and structure of organic molecules. The methane molecule  $\text{CH}_4$  explained by  $sp^3$  hybrid bonding is the simplest example of single bonds in organic chemistry. Here we give a brief introduction to double and triple bonds in organic chemistry based on  $sp^2$  and  $sp$  hybridization, respectively. More extensive discussions of these multiple bonds and their implications for organic reactions are in Chapter 7.

We begin with the compound ethene  $\text{C}_2\text{H}_4$  for which the Lewis diagram indicates a double bond between the C atoms and a single bond between each H and the adjacent C. Experiments show that ethene is a planar molecule with  $\text{H}-\text{C}-\text{H}$  bond angles of  $117^\circ$  and  $\text{H}-\text{C}-\text{C}$  bond angles of  $120^\circ$ . This structure can be explained with  $sp^2$  hybrid orbitals on each carbon atom. To construct these orbitals, we first promote C from C:  $(1s)^2(2s)^2(2p_x)^1(2p_y)^1$  to C:  $(1s)^2(2s)^1(2p_x)^1(2p_y)^1(2p_z)^1$ . Then we combine the  $2s$  and two of the  $2p$  orbitals to form three equivalent  $sp^2$  hybrid atomic orbitals which lie  $120^\circ$  apart in a plane. After hybridization, each C atom has the electron configuration C:  $(1s)^2(\chi_1)^1(\chi_2)^1(\chi_3)^1(2p_z)^1$ . The new feature compared to hybridization in boron discussed earlier is that the nonhybridized  $2p_z$  has one electron, and this orbital has its original orientation perpendicular to the plane containing the hybrids. Figure 6.42a shows the three  $sp^2$  hybrid orbitals, and the nonhybridized

**FIGURE 6.42** Formation of  $\sigma$  bonds in ethene. (a) The three  $sp^2$  hybridized orbitals are oriented in a plane with their axes at angles of  $120^\circ$ . The non-hybridized  $2p$  orbital is perpendicular to the plane containing the three  $sp^2$  hybrid orbitals. (b) Top view showing formation of a C–C  $\sigma$  bond by overlap of two  $sp^2$  hybrid orbitals and formation of four C–H  $\sigma$  bonds by overlap between four C  $sp^2$  hybrid orbitals and four H  $1s$  orbitals.

**FIGURE 6.43** Formation of  $\pi$  bonds in ethene. (a) Overlap of parallel  $2p$  orbitals forms a  $\pi$  bond. (b) The complete bonding scheme for ethene includes a C=C double bond and four C—H single bonds.

$2p_z$  orbital. A  $\sigma$  bond is formed by overlap of the  $sp^2$  orbitals on each carbon atom, and the remaining four  $sp^2$  orbitals form  $\sigma$  bonds with the four hydrogen atoms. Each carbon forms  $\sigma$  bonds with two hydrogen atoms (Fig. 6.42b). The nonhybridized  $2p_z$  orbitals on the two carbon atoms are parallel to each other and overlap to form a  $\pi$  bond (see Fig. 6.43a), just as illustrated in Figure 6.31. The result is a double bond between the two carbon atoms (Fig. 6.43b). This description of double bonds is used for a large class of organic molecules called *alkenes*.

**FIGURE 6.44** Lewis diagram for  $C_2H_2$ .

Now we turn to acetylene (also called ethyne, the IUPAC name),  $C_2H_2$ , the Lewis diagram for which (Fig. 6.44) shows a triple bond between the carbon atoms. Acetylene is known to be a linear molecule. This structure can be explained by  $sp$  hybridization on each of the carbon atoms. To construct these orbitals, we define the  $z$ -axis to lie along the bond, and we promote each carbon atom from C:  $(1s)^2(2s)^2(2p_x)^1(2p_y)^1$  to C:  $(1s)^2(2s)^1(2p_x)^1(2p_y)^1(2p_z)^1$ . On each carbon atom we form a pair of  $sp$  hybrid orbitals oriented  $180^\circ$  apart along the  $z$ -axis. After hybridization each carbon atom has the electron configuration C:  $(1s)^2(\chi_1)^1(\chi_2)^1(2p_x)^1(2p_y)^1$ . Figure 6.45a sketches the formation of the  $sp$  hybrid orbitals and shows these along with the  $2p_x$  and  $2p_y$  nonhybridized atomic orbitals. Sigma bond formation in acetylene is shown in Figure 6.45b. A  $\sigma$  bond between the two carbon atoms is formed by overlap of  $sp$  hybrids on each carbon, and each carbon forms a  $\sigma$  bond with one hydrogen atom using its other  $sp$  hybrid. The  $2p_x$  and  $2p_y$  non-hybridized atomic orbitals are parallel pairs on the two carbon atoms. Each pair overlaps to form a  $\pi$  bond, as shown in Figure 6.46a. The result is a triple bond in acetylene (see Fig. 6.46b), analogous to the triple bond in  $N_2$  shown in Figure 6.31. This description of triple bonds is used for a large class of organic molecules called *alkynes*.

Finally, the concept of orbital hybridization has played a key role in leading us to the modern theory of the chemical bond, and the tools of hybridization are used to this day in every branch of chemistry. Hybridization has inspired a great deal of discussion over the years, some of it impassioned, on the meaning and significance of “promotion” and “return on the energy investment.” Where

**FIGURE 6.45** Formation of sigma bonds in acetylene. (a) The two  $sp$  hybridized orbitals are oriented in a plane with their axes at angles of  $180^\circ$ . Two nonhybridized  $2p$  orbitals are oriented perpendicular to the plane of the two  $sp$  hybrid orbitals. (b) Top view showing formation of a C—C  $\sigma$  bond by overlap of two  $sp$  hybrid orbitals. The other two  $sp$  hybrid orbitals shown in (b) are available to form  $\sigma$  C—H bonds with each H atom to form HCCH.

**FIGURE 6.46** Formation of  $\pi$  bonds in acetylene. (a) Overlap of two sets of  $2p$  orbitals forms two  $\pi$  bonds. (b) The complete bonding scheme for acetylene includes a C=C double bond and two C-H single bonds.

does the energy input for promotion come from? How is the bond formed? How does the energy released on bond formation compensate for promotion? Do these concerns cast doubt on the validity and usefulness of the hybrid orbital representations of the chemical bond? These may be legitimate concerns if one is trying to describe the dynamic events by which the bond is actually formed. However, these concerns are largely side issues for our main question: is hybridization a useful way to describe the *structure* of a chemical bond after it has been formed? Quantum mechanics with exact molecular orbital theory offers accurate predictions for molecular shapes without any assumptions inherent in VSEPR theory, but bonding by first constructing hybrid AOs continues to give a good qualitative picture for many organic molecules.

## 6.10 Predicting Molecular Structures and Shapes

The three-dimensional shape of a molecule strongly influences how a pair of molecules approach one another, and whether this pair will successfully encounter for a chemical reaction or join together in a “guest-host” arrangement. Molecular shape has enormous influence over the function of molecules to determine the properties of a material or to achieve specific biological activity. The “shape of a molecule” is a descriptive term such as “square planar” or “tetrahedral” that we apply once we know the detailed molecular structure, specified by the bond lengths and bond angles in the molecule. The term “shape” connotes a specific geometrical relationship between bonds, but does not imply specific quantitative dimensions. If we know the detailed molecular structure, we can determine the shape by inspection.

To what extent can we predict the shape of a particular molecule based on the information we have developed so far? The VSEPR theory in Section 3.11 can predict the idealized shape by counting up the total number of bonding and unshared electron pairs in the valence shell and finding the spatial arrangement of all the pairs that minimizes the potential energy. The location of the bonding pairs within this optimum arrangement determines the location of the bonds in the molecule. From this, the theory assigns the shape of the molecule to a particular geometrical label. The results are summarized in Table 3.8. Deviations from these perfect shapes are rationalized by ranking the importance of repulsions between bonding pairs and unshared pairs. Note, however, that orbital hybridization as described in this book has no predictive capabilities at all. Recall that we had to specify the bond angles that we wanted to achieve before starting each type of hybridization. Orbital hybridization provides a quantum justification or interpretation for a molecular shape that we already know or assume, but it does not predict the shape or the geometrical structure.

At this point, the best method we can provide to describe the structure and shape of a molecule is summarized by the following steps:

1. Determine the empirical formula for the substance from an elemental analysis based on combustion (see Section 2.2.3).
2. Determine the molecular formula for the substance by its behavior as a gas (see Section 2.2.4) or by mass spectrometry (see the *Connection* in Chapter 3).
3. Determine the structural formula for the molecule by writing a Lewis diagram based on the molecular formula (see Section 3.10).
4. Determine the molecular shape experimentally, e.g., by X-ray scattering, or predict the shape by using VSEPR theory (see Section 3.11).
5. Identify the hybridization scheme that best explains the shape predicted by VSEPR (see Section 6.9).

This method is illustrated in Example 6.4 for the compound hydrazine, which is used as a fuel in rocket propulsion.

### EXAMPLE 6.4

Hydrazine is a potentially explosive gas used in rocket fuels. Elemental analysis shows its mass percent composition to be 87.419% nitrogen and 12.581% hydrogen. The density of hydrazine at 1 atm pressure and 25°C is 1.31 g L<sup>-1</sup>. Determine the molecular formula for hydrazine. Predict the structure of hydrazine by writing down its Lewis diagram and using VSEPR theory. What is the hybridization of the nitrogen atoms?

#### Solution

The background for the first part of this example is described in Section 2.2 and Examples 2.1 and 2.2. The number of moles of nitrogen and hydrogen in a sample of 100.00 g of hydrazine are

$$\text{nitrogen} : \frac{87.42 \text{ g N}}{14.9967 \text{ g mol}^{-1}} = 6.2413 \text{ mol N}$$

$$\text{hydrogen} : \frac{12.58 \text{ g H}}{1.0079 \text{ g mol}^{-1}} = 12.4814 \text{ mol H}$$

$$\text{ratio} : \frac{\text{moles H}}{\text{moles N}} = \frac{12.4814}{6.2413} = 1.9998$$

The empirical formula is therefore close to NH<sub>2</sub>. To determine the true molecular formula we estimate the molar mass of hydrazine using the ideal gas law (see Sec. 9.3). If  $m$  is the mass of the sample in grams and  $\mathcal{M}$  is the molar mass in grams mol<sup>-1</sup>, the molar mass  $\mathcal{M}$  is determined from the density  $\rho$  and the gas properties as follows:

$$PV = nRT = \frac{m}{\mathcal{M}} RT$$

$$\mathcal{M} = \frac{mRT}{PV} = \left(\frac{m}{V}\right) \frac{RT}{P} = \rho \frac{RT}{P}$$

$$\mathcal{M} = \frac{(1.31 \text{ g L}^{-1})(0.0821 \text{ L atm mol}^{-1} \text{ K}^{-1})(298.15 \text{ K})}{1 \text{ atm}}$$

$$\mathcal{M} = 32.066 \text{ g mol}^{-1}$$

FIGURE 6.47 The structure of hydrazine, N<sub>2</sub>H<sub>4</sub>.

The molar mass corresponding to the empirical formula NH<sub>2</sub> is 16.0125 g mol<sup>-1</sup>. Because the true molar mass is approximately twice this value the molecular formula for hydrazine is N<sub>2</sub>H<sub>4</sub>, which is frequently written as H<sub>2</sub>NNH<sub>2</sub>. The Lewis diagram is

Lewis diagram for N<sub>2</sub>NNH<sub>2</sub>.

Both nitrogen atoms have steric number 4 and are  $sp^3$  hybridized, with H—N—H and H—N—N angles of approximately 109.5°. The extent of rotation about the N—N bond cannot be predicted from the VSEPR theory or the hybrid orbital model. Figure 6.47 shows the full three-dimensional structure of hydrazine.

TABLE 6.5

Molecular Shapes Predicted by the Valence Shell Electron-Pair Repulsion Theory and Rationalized by Orbital Hybridization

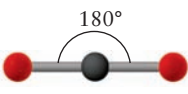

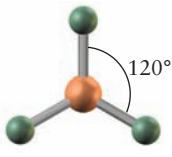

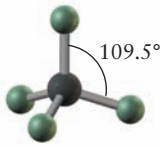

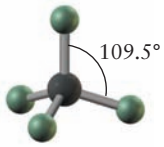

Molecule	Steric Number	Number of Lone Pairs	Orbital Hybridization	Predicted Geometry	Image	Example
$AX_2$	2	0	$sp$	Linear		$BeH_2, CO_2$
$AX_3$	3	0	$sp^2$	Trigonal planar		$BF_3, SO_3$
$AX_2$	3	1	$sp^2$	Bent		$SO_2$
$AX_4$	4	0	$sp^3$	Tetrahedral		$CF_4, SO_4^{2-}$
$AX_3$	4	1	$sp^3$	Trigonal pyramidal		$NH_3, PF_3, AsCl_3$
$AX_2$	4	2	$sp^3$	Bent		$H_2O, H_2S, SF_2$

Table 6.5 summarizes the results of this procedure for molecules with steric numbers 2–4 and gives several examples of each type.

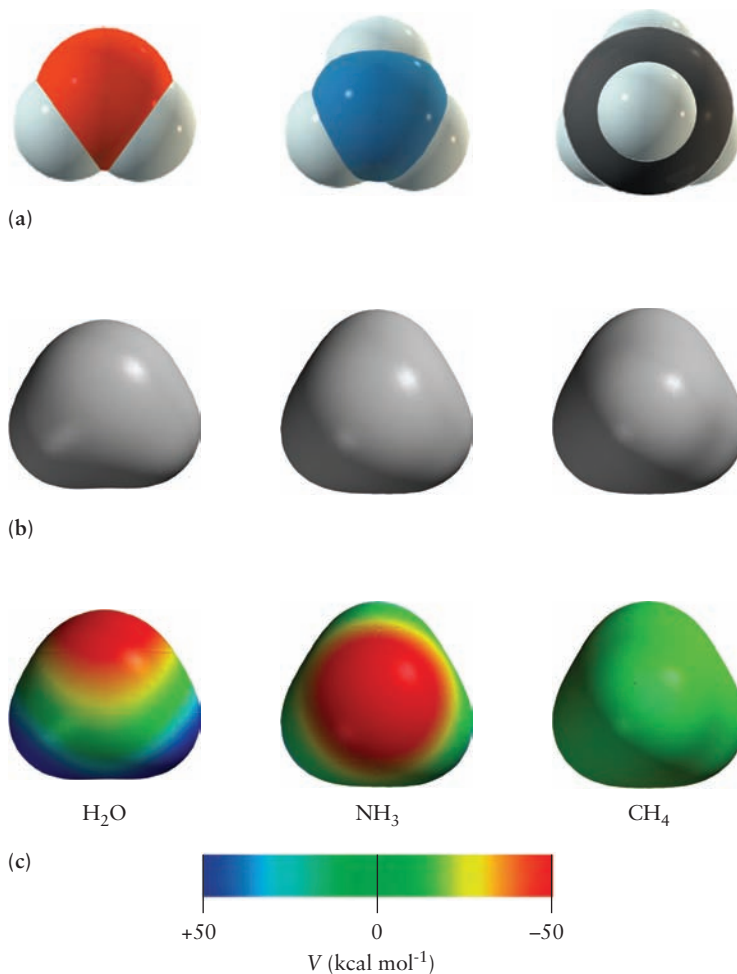

### 6.10.1 The Shapes of Molecules and Electrostatic Forces

The **electrostatic potential energy map** for a molecule combines information from two different sources into one representation. The size and shape of the molecule come from the spatial distribution of the electron density (from high-level electronic structure calculations) represented as an isosurface. The electrostatic potential energy that a positive test charge would experience is indicated at each point on that isosurface. Let's construct each of these pieces in turn.

Isosurfaces of electron density are obtained from the probability density isosurfaces for molecules described in Sections 6.4–6.9. These are surfaces in three-dimensional space that include all the points at which  $\psi^2$  has a particular value. The value of electron density chosen to define the isosurface is selected by some definite, though arbitrary, criterion. There is broad acceptance of a standard density of  $0.002 e/(a_0)^3$ , where  $a_0$  is the Bohr radius. This value is thought to best represent the “sizes” and shapes of molecules because it corresponds to the van der Waals atomic radii discussed earlier in the context of atomic size. These are the same dimensions depicted in space-filling models of molecules. Figures 6.48a and 6.48b show, respectively, space-filling models and electron density isosurfaces plotted at  $0.002 e/(a_0)^3$  for water, ammonia, and methane. The electron densities plotted here include all of the electrons in the molecule. They are calculated using state-of-the-art quantum chemical methods.

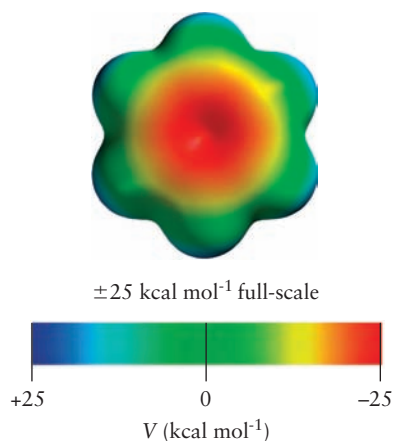

To understand how a value of the electrostatic potential energy can be associated with each point on the electron density isosurface, we imagine a thought experiment in which a positive unit test charge moves over this isosurface, interacting with all of the electrons and the nuclei of the molecule as it visits every position on the isosurface. The magnitude of the test charge must be extremely small to avoid distorting and polarizing the electron density of the

**FIGURE 6.48** Representations of the shape, size, and electrostatic potential of molecules. (a) Space-filling models, (b)  $0.002 e/(a_0)^3$  electron density isosurfaces, and (c) electrostatic potential energy surfaces for water, ammonia, and methane. Note that the energy units are  $\text{kcal mol}^{-1}$ , which are still in common use in organic chemistry.

molecule. The test particle is attracted to the molecule at those points where it experiences negative electrostatic potential energy, and it is repelled away from the molecule at points where it experiences positive electrostatic potential energy. It is convenient to summarize these explorations by assigning color to each location on the isosurface on the basis of the sign and magnitude of the electrostatic potential energy experienced by the test charge. The conventional choice for the color map is based on the visible spectrum, in which the most negative potential is represented by red and the most positive potential is represented by blue. The colors assigned to each point on the electron density isosurface vary continuously between these extremes on the basis of the sign and magnitude of the electrostatic potential energy. The potential energy values near zero are represented by green.

This thought experiment is carried out as follows to obtain actual values of electrostatic potential energy through computer calculations. After the electron density isosurface has been calculated by quantum mechanics, a unit (elementary) positive test charge is moved around the molecule at locations corresponding to points on the isosurface. At each location the electrostatic potential energy is calculated using Coulomb's law to describe the interaction of the test charge with each nucleus and the distributed electron density in the molecule (with the total charge on the electrons equal to the number of electrons multiplied by  $-e$ ). At each location, the value of the electrostatic potential energy represents the balance between attraction of the test charge by electrons and repulsion by the nuclei in the molecule. The value obtained at each location of the test particle is then mapped onto the corresponding point on the electron

**FIGURE 6.49** Electrostatic potential energy surface for benzene plotted at  $\pm 25 \text{ kcal mol}^{-1}$  full-scale.

density isosurface for the molecule by assigning color according to the color map. The electrostatic potential energy maps calculated for the molecules shown in Figures 6.48a and 6.48b are shown in Figure 6.48c.

The electrostatic potential energy map for a given molecule can be used to predict how the target molecule influences the motion of charged particles as they approach it. The images show at a glance which portions of the molecule are most likely to attract or repel a proton. For example, in Figure 6.48c the red region shows a region of low electrostatic potential energy, to which a proton will be attracted. Thus, positive ions will be attracted to the oxygen end of the water molecule and to the nitrogen end of the ammonia molecule; the opposite is true for negative ions. The interaction of a positive or a negative ion with methane is weak and shows no pronounced directionality. Comparing Figure 6.48c with Figure 6.49 shows that a positive ion experiences greater attraction to the oxygen end of a water molecule than to the center of a benzene molecule.

Electrostatic potential energy maps can be used to identify reactive sites on molecules. Locations with large negative values of the electrostatic potential are relatively rich in electron density, and those with large positive values are relatively depleted in electron density. These maps are now widely used in organic chemistry to predict patterns of reactivity for electrophilic (electron-loving) and nucleophilic (proton-loving) molecules and to explain how the presence of different functional groups in the molecule can affect these patterns. These methods are effective aids in identifying sites for chemical reactivity in more complicated molecules, including those of biological interest. They are widely used in molecular modeling simulations of drug design.

## 6.11 Using the LCAO and Valence Bond Methods Together

The LCAO and VB approaches are both good starting points for describing bonding and reactivity. You can apply either one to set up a purely qualitative description of the problem of interest, confident that you can move on to a high-level quantitative calculation as your needs demand. Which method you choose at the beginning depends primarily on the area of chemistry in which you are working and the broad class of problems you are investigating. LCAO theory is most often used to describe the electronic states of molecules in contexts that require knowledge of energy levels. Examples include molecular spectroscopy, photochemistry, and phenomena that involve ionization (such as electron-induced reactions and photoelectron spectroscopy). VB theory is more widely used to describe molecular structure, especially in pictorial ways.

Many chemists use a mixture of the two methods, where localized VB  $\sigma$  bonds describe the network holding the molecule together and de-localized LCAO  $\pi$  bonds describe the spread of electron density over the molecule. We will illustrate this combination for the case of linear and also bent triatomic molecules here, then discuss two cases that illustrate delocalized  $\pi$  bonding in polyatomic molecules, 1,3-butadiene and benzene.

### 6.11.1 Triatomic Nonhydrides

Many triatomic molecules and molecular ions can be formed from atoms of elements in the second and third periods. Some are linear (examples are  $\text{CO}_2$ ,  $\text{N}_2\text{O}$ ,  $\text{OCS}$ , and  $\text{NO}_2^+$ ), and others are bent (examples include  $\text{NO}_2$ ,  $\text{O}_3$ ,  $\text{NF}_2$ , and  $\text{NO}_2^-$ ).

Experiments show that triatomic nonhydrides with 16 or fewer valence electrons generally are linear, whereas those with 17 to 20 valence electrons

generally are bent. This is consistent with the VSEPR theory, because the former have steric number 2 (giving linear molecules), whereas the latter have steric number 3 or 4 (giving bent molecules with one or two lone-pair orbitals on the central atom). These experimental results can be explained by the combined approach in which we use localized orbitals for the  $\sigma$  bonds and delocalized orbitals for the  $\pi$  bonds of these molecules.

### 6.11.2 Linear Triatomic Nonhydrides

For linear molecules (examples are  $\text{CO}_2$ ,  $\text{N}_2\text{O}$ ,  $\text{OCS}$ , and  $\text{NO}_2^+$ ), it is logical to use  $sp$  hybridization to describe the central atom. This leaves two  $p$  orbitals ( $p_x$  and  $p_y$ ) perpendicular to the bond axis. Hybridization of the outer atoms is not necessary to treat such molecules; the outer atoms are most simply described as having fully occupied  $s$  orbitals not involved in bonding, a  $p_z$  orbital that takes part in  $\sigma$  bonding, and  $p_x$  and  $p_y$  orbitals that form delocalized  $\pi$  bonds with the other atoms. The  $\sigma$  bonds (which extend along the bond axes) can be obtained by combining the  $p_z$  orbital of each of the outer atoms with the  $sp$  hybrid orbital of the central atom that points toward it to form a localized bonding orbital. These two localized  $\sigma$  bonds are filled by two pairs of electrons.

Linear combinations of the  $p_x$  and  $p_y$  orbitals of all three atoms make up the delocalized molecular orbitals involved in  $\pi$  bonding. How do three  $p_x$  orbitals combine to form three molecular orbitals? Two of the combinations are obvious. The lowest in energy of the three, the  $\pi_x$  molecular orbital (Fig. 6.50a) is fully bonding, with no nodes, and the highest in energy of the three, the  $\pi_x^*$  molecular orbital (Fig. 6.50c) is fully antibonding, with two nodes, one between each pair of atoms. The third linear combination is less obvious. Intermediate

**FIGURE 6.50**  $\pi$  bonding in linear triatomic molecules. From three  $p$  orbitals lying perpendicular to the bond axis, one bonding, one antibonding, and one nonbonding molecular orbital can be constructed. A second group of molecular orbitals can be constructed from the  $p$  orbitals that lie perpendicular to the plane of the page.

**FIGURE 6.51** Correlation diagram for  $\pi$  electrons in linear triatomic molecules. The orbital filling shown is that for  $\text{CO}_2$ .

in energy, the  $\pi_x^{\text{nb}}$  orbital has the form of Figure 6.50b, with a single node and with the coefficient of the wave function on the central atom being zero. Because there is only one molecular orbital at this energy formed from  $2p_x$  AOs, the electron density corresponding to this orbital must be evenly distributed, so an orbital with a node between the left and center atoms would not reflect the correct symmetry of the molecule. This orbital is nonbonding ( $\pi_x^{\text{nb}}$ ) because there is neither a node nor a region of increased electron density between the central atom and its neighbors. The three  $p_y$  orbitals can be combined to give the same types of molecular orbitals as the  $p_x$ . Figure 6.51 is the resulting correlation diagram for the  $\pi$  levels only, with the nonbonding orbitals lying between the bonding and the antibonding orbitals in energy. As before, the energy increases with the number of nodes.

Consider the  $\text{CO}_2$  molecule. It has 16 valence electrons (4 from the carbon and 6 from each oxygen). Two electrons on each oxygen atom are nonbonding electrons in  $2s$  atomic orbitals. Of the remaining 12 electrons, 4 take part in localized  $\sigma$  bonds, 2 between each oxygen and the carbon. This leaves 8 electrons for the  $\pi$  system. Placing them in the correlation diagram of Figure 6.51 gives two electron pairs in  $\pi$  orbitals and two pairs in  $\pi^{\text{nb}}$  orbitals. The total bond order for the molecule is 4, because there are two pairs of electrons in  $\sigma$  bonding orbitals (from the  $sp$  hybrids) and two pairs in  $\pi$  bonding orbitals (the nonbonding  $\pi^{\text{nb}}$  and atomic oxygen  $2s$  orbitals neither increase nor decrease the bond order). Each bond is then of order 2, in agreement with the Lewis diagram result for  $\text{CO}_2$ . The meaning is slightly different here, however, in that some of the bonding electrons (those in the  $\pi$  orbital system) are delocalized over the full molecule rather than shared by only two of the atoms.

### 6.11.3 Nonlinear Triatomic Molecules

Nonlinear triatomic molecules (examples include  $\text{NO}_2$ ,  $\text{O}_3$ ,  $\text{NF}_2$ , and  $\text{NO}_2^-$ ) can be described through  $sp^2$  hybridization of the central atom. If the molecule lies in the  $x$ - $y$  plane, then the valence  $s$ ,  $p_x$ , and  $p_y$  orbitals of the central atom can be combined to form three  $sp^2$  hybrid orbitals with an angle close to  $120^\circ$  between each pair. One of these orbitals holds a lone pair of electrons, and the other two take part in  $\sigma$  bonds with the outer atoms. The fourth orbital, a  $p_z$  orbital, takes part in delocalized  $\pi$  bonding (Fig. 6.52a). On the outer atoms, the  $p$  orbital pointing toward the central atom takes part in a localized  $\sigma$  bond, and the  $p_z$  orbital takes part in  $\pi$  bonding; the third  $p$  orbital and the  $s$  orbital are AOs that do not participate in bonding; in the molecular orbital correlation diagram these would be represented by nonbonding molecular orbitals localized on each respective atom (with the same energy as they had in the atom). Finally, the three  $p_z$  AOs can be combined into bonding, nonbonding, and antibonding  $\pi$  orbitals (Fig. 6.52a) much as in the linear molecule case. Here

**FIGURE 6.52** (a) Ball-and-stick model (bottom) and molecular orbitals for bent triatomic molecules. The central atom has three  $sp^2$  hybrid orbitals (not shown) that would lie in the plane of the molecule. From the three  $p_z$  orbitals perpendicular to this plane, three  $\pi$  orbitals can be constructed. (b) Correlation diagram for the  $\pi$  orbitals.

there is only one of each type of orbital ( $\pi$ ,  $\pi^{\text{nb}}$ ,  $\pi^*$ ) rather than two as for linear molecules.

Consider a specific example,  $\text{NO}_2^-$ , with 18 electrons. Two electrons are placed in each oxygen  $2s$  orbital and 2 more in each nonbonding oxygen  $2p$  orbital, so that a total of 8 electrons are localized on oxygen atoms. Two electrons also are placed as a lone pair in the third  $sp^2$  orbital of the nitrogen atom. Of the remaining 8 electrons, 4 are involved in the two  $\sigma$  bonds between nitrogen and the oxygen atoms. The last 4 are placed into the  $\pi$  electron system: 2 into the bonding  $\pi$  orbital and 2 into the nonbonding  $\pi^{\text{nb}}$  orbital. Because a total of 6 electrons are in bonding orbitals and none are in antibonding, the net bond order for the molecule is 3, or  $1\frac{1}{2}$  per bond. In the Lewis model, 2 resonance forms are needed to represent  $\text{NO}_2^-$ . The awkwardness of the multiple resonance forms required by the Lewis model is avoided by treating the electrons in the bonding  $\pi$  molecular orbital as delocalized over the three atoms in the molecule.

#### 6.11.4 Organic Molecules with Delocalized Electrons

Organic chemists make extensive use of the combined approach, where localized VB  $\sigma$  bonds describe the network holding the molecule together and de-localized LCAO  $\pi$  bonds describe the spread of electron density over the molecule. In Chapter 7 we illustrate this approach in some detail for several molecules that belong to the classes substituted alkenes and alkynes (Section 7.3, Example 7.2). Here in this chapter, we now describe the delocalized  $\pi$  bonding in a polyene, 1,3-butadiene, and in benzene, a cyclic hydrocarbon with two resonance Lewis structures.

De-localized  $\pi$  bonding is important in many polyenes, the simplest of which is 1,3-butadiene ( $\text{CH}_2\text{CHCHCH}_2$ ). Its Lewis dot structure, seen below, does not

show resonance, yet the  $\pi$  molecular orbitals in 1,3-butadiene are de-localized over all four carbon atoms.

All four carbon atoms have steric number 3, so all are  $sp^2$  hybridized. The remaining  $p_z$  orbitals have maximum overlap when the four carbon atoms lie in the same plane, so this molecule is predicted to be planar. From these four  $p_z$  atomic orbitals, four MOs can be constructed by combining their phases, as shown in Figure 6.53. The four electrons that remain after the  $\sigma$  orbitals are filled are placed in the two lowest  $\pi$  orbitals. The first of these is bonding among all four carbon atoms; the second is bonding between the outer carbon atom pairs, but antibonding between the central pair. Therefore, 1,3-butadiene has stronger and shorter bonds between the outer carbon pairs than between the two central carbon atoms. It is an example of a **conjugated  $\pi$  electron system**, in which two or more double or triple bonds alternate with single bonds. Such conjugated systems have lower energies than would be predicted from localized bond models and are best described with delocalized MOs extending over the entire  $\pi$  electron system. The optical absorption spectrum of 1,3-butadiene evidences a transition from the highest occupied  $\pi$  orbital to the lowest unoccupied  $\pi^*$  orbital. This requires a much smaller photon energy than in ethene, as the energies of the two middle orbitals in Figure 6.53 are much closer together than are the  $\pi$  and  $\pi^*$  orbitals of ethene.

Finally, we show the de-localized  $\pi$  orbitals of benzene in Figure 6.54. You can easily tell from the perspective view in Figure 6.54(b) what particular linear

**FIGURE 6.53** The four  $\pi$  molecular orbitals formed from four  $2p_z$  atomic orbitals in 1,3-butadiene, viewed from the side. In all but the lowest energy orbital there are  $y$ - $z$  nodal planes between some of the carbon atoms. The horizontal black line represents the  $x$ - $y$  nodal plane of the  $\pi$  orbitals; it is also the molecular plane. Note the similarity in the  $y$ - $z$  nodal patterns to those of the first four modes of a vibrating string or the first four wave functions of the one-dimensional particle in a box (right). Only the two lowest energy  $\pi$  orbitals are occupied in the ground state of 1,3-butadiene.

**FIGURE 6.54** The six  $\pi$  molecular orbitals for benzene. In the view from the top in (a) you can more easily see the nodal planes indicated in dashed lines. In the view from the side in (b), you can see how each molecular orbital results from a linear combination of six  $2p_z$  atomic orbitals oriented perpendicular to the plane of the molecule. Only the three lowest energy orbitals are occupied in molecules of benzene in the ground state.

combination of the six  $2p$  orbitals perpendicular to the plane of the molecule were used to make each de-localized  $\pi$  orbital. The six  $\pi$  MOs are characterized by their energies and by the number of nodal planes perpendicular to the molecular plane. The lowest energy MO has no such nodal planes, the next highest energy orbitals are a degenerate pair with one nodal plane, the next highest in energy are also degenerate with two nodal planes, and the highest energy orbital has three nodal planes. The  $C_6H_6$  molecule has 30 valence electrons, of which 24 occupy  $\sigma$  bonding orbitals formed from a linear combination of two  $sp^2$  hybrids (for each C—C bond) or a linear combination of an  $sp^2$  hybrid with an H  $1s$  AO (for each C—H bond). When the six remaining valence electrons are placed in the three lowest energy  $\pi$  orbitals, the resulting electron distribution is the same in all six carbon–carbon bonds. As a result, benzene has six carbon–carbon bonds of equal length whose properties are intermediate between those of single and double bonds.

## 6.12 Summary and Comparison of the LCAO and Valence Bond Methods

Most of our understanding of chemical bonding, structure, and reactivity is based on the simple approaches to MO and VB theory presented in this chapter. They provide the foundation upon which our chemical intuition has been built. The concepts in these simple theories are central to all areas of modern

chemistry. The LCAO and VB methods start with very different quantum mechanical approaches to describe chemical bonding. Each originated as an approximation method for constructing approximate wave functions for molecules, using very different initial models of the chemical bond. The two methods look very different at the beginning, and their results presented in this book look very different. Are the two methods equally valid? Are they equally applicable to a broad range of molecules? Can they both be used for quantitative calculations on large molecules? The answer is *yes* for each of these questions. This section compares the two methods to give deeper insight into their conceptual meanings and to provide a basis for choosing to use one over the other in a particular chemical investigation.

### 6.12.1 Conceptual Comparison of LCAO and VB

The accuracy of any quantum chemical method is judged by how well its predictions agree with the results of experiment. Predicting measurable values of molecular properties requires that we know the molecular electronic wave function for the molecule. Therefore, the best way to compare the LCAO and VB methods is to compare the molecular electronic wave functions generated by each. We illustrate this comparison using the molecular electronic wave functions for H<sub>2</sub> constructed using both methods.

The LCAO method for H<sub>2</sub> constructs a  $\sigma$  bonding MO as a linear combination of H 1s AOs centered on the two hydrogen atoms. This MO, delocalized over the entire molecule, is given by the equation

$$\sigma_{g1s} = C_g[\varphi_{1s}^A + \varphi_{1s}^B] \quad [6.24]$$

Neglecting the normalization constant and using the simplified notation from Section 6.3 gives the form

$$\sigma_{g1s} = [1s^A + 1s^B] \quad [6.25]$$

Both electrons occupy this bonding orbital, satisfying the condition of indistinguishability and the Pauli principle. Recall from Section 6.4 that the molecular electronic wave function in the LCAO approximation is the *product* of all of the occupied MOs, just as the wave function for an atom is the product of all the occupied Hartree orbitals. Thus we have the molecular wave function

$$\psi_{\text{MO}}^{\text{el}} = \sigma_{g1s}(1)\sigma_{g1s}(2) = [1s^A(1) + 1s^B(1)][1s^A(2) + 1s^B(2)] \quad [6.26]$$

The VB model, in contrast, starts by assuming that a good approximation to the molecular electronic wave function for H<sub>2</sub> is the product of an H 1s orbital centered on atom A, occupied by electron 1, and another H 1s orbital centered on atom B, occupied by electron 2. As shown in Section 6.8, this molecular electronic wave function is given by

$$\psi_{\text{VB}}^{\text{el}}(r_{1A}, r_{2B}) = c_1\varphi_A(r_{1A})\varphi_B(r_{2B}) + c_2\varphi_A(r_{2A})\varphi_B(r_{1B}) \quad [6.27]$$

which upon dropping the normalization factors and using the simplified notation introduced in Section 6.4 becomes

$$\psi_{\text{VB}}^{\text{el}} = 1s^A(1)1s^B(2) + 1s^A(2)1s^B(1) \quad [6.28]$$

Now we can compare the LCAO and VB molecular electronic wave functions directly by multiplying out  $\psi_{\text{MO}}^{\text{el}}$  and rearranging terms to obtain

$$\psi_{\text{MO}}^{\text{el}} = [1s^A(1)1s^B(2) + 1s^A(2)1s^B(1)] + [1s^A(1)1s^A(2) + 1s^B(1)1s^B(2)] \quad [6.29]$$

The first bracketed term in  $\psi_{\text{MO}}^{\text{el}}$  is identical to  $\psi_{\text{VB}}^{\text{el}}$ . It represents the purely covalent structure H–H because the two electrons are shared equally between atoms A and B. The second term may be labeled  $\psi_{\text{ionic}}$  because it is a mixture of the ionic states  $\text{H}_\text{A}^- \text{H}_\text{B}^+$  and  $\text{H}_\text{A}^+ \text{H}_\text{B}^-$ , respectively. This can be seen by looking at the two terms in the second set of brackets; the first term puts both electrons on nucleus A (making it  $\text{H}^-$ ) and the second term puts both electrons on nucleus B (making it  $\text{H}^-$ ).

Thus, our comparison shows that the LCAO method includes an ionic contribution to the bond but the VB method does not. In fact, the simple MO approach suggests that the bond in  $\text{H}_2$  is 50% covalent and 50% ionic, which is contrary both to experience and intuition. Because the electronegativities of the two atoms in a homonuclear diatomic molecule are the same, there is no reason to expect any ionic contribution to the bond, much less such a large one. The complete absence of ionic contributions in the VB molecular wave function suggests this method is not well suited for polar molecules like HF. Thus, the truth in describing the chemical bond and molecular structure appears to lie somewhere between the LCAO and VB methods.

It is also informative to compare how these methods describe chemical reactivity, which requires bonds to be broken. We already know that the VB wave function for  $\text{H}_2$  correctly describes the long-distance limit as two separate H atoms. But, the LCAO wave function predicts that in the long-distance limit  $\text{H}_2$  dissociates into ionic species as well as H atoms. Ionic products are not usually produced by dissociation under ordinary thermal conditions. Again, the best description must lie between the extremes defined by the simple LCAO and VB methods.

The simple form of LCAO and VB methods, as presented here, can be refined to provide more accurate wave functions for molecules and solids from which measurable properties can be calculated. Both methods have been improved significantly in a number of ways. We illustrate one approach for improving  $\psi_{\text{VB}}$ , not only because it is easy to understand but also because the method is generally applicable in many areas of quantum chemistry. The simple VB wave function can be improved by adding in (mixing) some ionic character. We write

$$\psi_{\text{improved}} = \psi_{\text{VB}} + \lambda \psi_{\text{ionic}} \quad [6.30]$$

and then choose  $\lambda$  on the basis of some criterion (see discussion later). For example, the purely covalent description of the HF molecule in Equation 6.16 could be improved in this way to describe the bond polarity and the percent ionic character determined from measurements of the dipole moment (see Sec. 3.9 and Eq. 3.24). The most common way to do this is to adjust  $\lambda$  to minimize the energy. We calculate the energy, using the methods developed in Chapter 5, with  $\lambda$  as a parameter, and then differentiate the result with respect to  $\lambda$  to find the value of  $\lambda$  that minimizes the energy, just as in ordinary calculus. Using that special value of  $\lambda$  in Equation 6.30 gives a wave function that is a better approximation to the true wave function than the simple VB wave function. Moreover, the energy calculated for the ground state of the system using the “improved” wave function is guaranteed never to be lower than the true ground-state energy. These results are consequences of the **variational principle** in quantum mechanics, which gives a guideline for improving the accuracy of various approximations; lower energy is always better. The variational principle is also routinely used to improve predictions from modern versions of LCAO theory.

### 6.12.1 Elementary LCAO and VB Theories as Qualitative Predictive Tools

The introductory levels of the LCAO and VB methods presented in this chapter are appropriate for the hand-drawn sketches and “back of the envelope”

calculations that occur in the early stages of any project in basic or applied chemistry. Depending on the molecules under investigation and the kinds of questions being asked, one method may be more useful than the other at this early stage. Either one can serve as the starting point for a later calculation.

Elementary LCAO theory offers qualitative predictions for processes in diatomic and polyatomic molecules that involve promoting a molecule to an excited electronic state. Using diagrams like that in Figure 6.18 and Figure 6.53, one can determine the relative energy ordering of occupied and unoccupied orbitals in a molecule. We can immediately use these diagrams to describe the absorption and emission of light, formation of cations by electron removal, formation of anions by electron attachment, and other processes that involve loss or gain of electronic energy.

These results are quite hard to achieve with elementary VB. Bond formation pairs up two electrons in half-filled AOs on two separate atoms, and ignores all the other electrons on both atoms. The model predicts the energy in the bonding and the antibonding states of this particular bond, and thereby guarantees that the bond has a stable ground state lower than the energy of the separated atoms. The model gives no additional information about energy levels.

Most of our understanding of chemical bonding, structure, and reactivity is based on the elementary approaches to MO and VB theory presented in this chapter. They provide the foundation upon which our chemical intuition has been built; the concepts introduced in this chapter are central to all areas of modern chemistry. Publicly available software packages enable computer-based calculations that remove the limitations on the elementary approaches. You will likely begin to use computational chemistry software in your second-year courses in college-level chemistry. Both the MO and VB elementary approaches serve as the starting point for such calculations, and the elementary concepts are essential for interpreting the results of the computational chemistry tools.

## 6.13 A DEEPER LOOK Properties of the Exact Molecular Orbitals for $\text{H}_2^+$

Here we give a more detailed analysis of the exact wave functions for  $\text{H}_2^+$  presented in Section 6.2 and Figure 6.5, and for the associated electron density functions.

### 6.13.1 Wave Functions

The first eight wave functions, starting with the ground state, are shown in Figure 6.55 using representations that give additional insight into their structure beyond Figure 6.5. These are plotted using the same coordinates as in Figure 6.4, where the two protons lie on the  $z$ -axis and the value of  $R_{AB}$  is the experimental bond length for  $\text{H}_2^+$ , which is 1.06 Å. Each wave function is shown in three different representations: (a) an isosurface comprising all those points in three-dimensional space where the wave function has a value equal to 0.1 of its maximum value; (b) a contour plot in a plane containing the internuclear axis with contours shown for  $\pm 0.1$ ,  $\pm 0.3$ ,  $\pm 0.5$ ,  $\pm 0.7$ , and  $\pm 0.9$  of the maximum value; (c) a plot of the amplitude along the internuclear axis, which amounts to a “line scan” across the contour plot. Part (a) is the same as Figure 6.5, with red isosurfaces representing positive values of the wave function representing negative values. In part (b) the contours have the same color coding, with nodal contours represented as dashed black lines. We encourage you to compare these representations to develop intuition for the shape and symmetry of each wave function and its corresponding probability density for locating the electron. It is important to develop a very quick feel for “How many nodes and where are they?” for each wave function. In

developing these insights you will be guided by the four labels on each wave function; their meanings are explained in Section 6.2.

Here we give deeper insight into the meaning of the Greek letter in each label. The position of the electron in H<sub>2</sub><sup>+</sup> around the internuclear axis is given by the angle  $\phi$  (see Fig. 6.4). Because the potential energy of H<sub>2</sub><sup>+</sup> is the same at all values of  $\phi$  (see Eq. 6.1), the angular coordinate will influence the shape of the molecular orbital, but not the energy levels, just as the angles  $(\theta, \phi)$  in Figure 5.1 influence the shape of the atomic orbitals for hydrogen, but not the energy levels. The component of the electron's angular momentum along the internuclear axis in H<sub>2</sub><sup>+</sup> is quantized exactly the same as the component of angular momentum along the  $z$ -axis in the hydrogen atom (see Eq. 5.2b). This quantization condition is given by the expression,

$$\text{Allowed value of } L_z = m \frac{h}{2\pi} \quad m = 0, \pm 1, \pm 2, \pm 3, \dots$$

Because the total angular momentum of the electron in H<sub>2</sub><sup>+</sup> is not quantized, there is no analog of the atomic quantum number  $\ell$  to define an upper limit to the allowed values of  $m$ . Greek letters are used to identify the component of angular momentum along the internuclear axis as follows:

- $\sigma$  ————— angular momentum component = 0
- $\pi$  ————— momentum component =  $\pm h/2\pi$
- $\delta$  ————— angular momentum component =  $\pm 2h/2\pi$
- $\phi$  ————— angular momentum component =  $\pm 3h/2\pi$

The Greek letter tells us how the electron probability density is distributed around the internuclear axis, as viewed in a plane perpendicular to the axis. The  $\sigma$  wave functions have finite amplitudes on the internuclear axis, and the probability of finding the electron on that axis is therefore finite. As you can deduce from Figure 6.55, in a cross-section perpendicular to the internuclear axis the  $\sigma$  wave functions are cylindrically symmetric. The  $\pi$  wave functions, in contrast, describe electron motion about the internuclear axis with angular momentum  $+h/2\pi$  or  $-h/2\pi$ . Physically, these two cases correspond to clockwise and counter-clockwise motion of the electron around the internuclear axis. These two molecular orbitals do not have a simple geometrical representation, but we can form linear combinations of them just as we did to define the  $p_x$  and  $p_y$  atomic orbitals (see Eq. 5.6). This leads to two wave functions— $\pi_{u2p_x}$  and  $\pi_{u2p_y}$ —with the same energy, one of which lies along the  $x$ -axis and the other along the  $y$ -axis (the internuclear axis is chosen to be the  $z$ -axis). Because the  $\pi_{u2p_x}$  and  $\pi_{u2p_y}$  wave functions have nodal planes that include the internuclear axis, there is zero probability of finding the electron anywhere along the  $z$ -axis just as there is zero probability of finding the electron at the nucleus in an atomic  $p$  orbital. Viewed perpendicular to the internuclear axis, the  $\pi_{u2p_x}$  and  $\pi_{u2p_y}$  wave functions do not have cylindrical symmetry about the axis. These results remind us of the  $s$ ,  $p$ ,  $d$ ,  $f$  progression for angular momentum of the electron about the nucleus in the hydrogen atom and the fact that  $s$  orbitals have amplitude at the nucleus, whereas  $p$  orbitals have nodes at the nucleus.

### 6.13.2 Electron Probability Density Functions

To understand the nature of the chemical bond in H<sub>2</sub><sup>+</sup>, we must calculate the electron density around the nuclei, which are assumed to be fixed at their equilibrium positions. In quantum mechanics, the electron probability density in a region of space is simply proportional to the probability density for an electron to be in that region. The probability density functions for locating the electron at each point in space are shown in Figure 6.56; they were calculated by

**FIGURE 6.55** Wave functions for the first eight energy levels of the  $\text{H}_2^+$  molecular ion, calculated exactly by quantum mechanics. The ground-state wave function is at the bottom of the figure; the others are arranged above it in order of increasing energy. The two nuclei lie along the  $z$ -axis, which is in the plane of the paper. Regions of positive and negative amplitude are shown in red and blue, respectively. The labels for each orbital are explained in the text. (a) Isosurfaces corresponding to contours at  $\pm 0.1$  of the maximum amplitude. (Courtesy of Mr. Hatem Helal and Professor William A. Goddard III, California Institute of Technology, and Dr. Kelly P. Gaither, University of Texas at Austin.)

**FIGURE 6.55 cont'd** (b) Contours of constant amplitude in the x-z plane, at values  $\pm 0.1$ ,  $\pm 0.3$ ,  $\pm 0.5$ ,  $\pm 0.7$ , and  $\pm 0.9$  of the maximum amplitude. Nodes are represented by black dashed lines. (c) The amplitude along the z-axis, obtained as a "line scan" across the contour plot, along the direction indicated by the green arrow in (b).

(Courtesy of Mr. Hatem Helal and Professor William A. Goddard III, California Institute of Technology, and Dr. Kelly P. Gaither, University of Texas at Austin.)

**FIGURE 6.56** Probability density distributions for the first eight energy levels of the  $H_2^+$  molecular ion, calculated exactly by quantum mechanics. (a) Isosurfaces comprising all points at which the probability density is 0.01 of its maximum value. (b) Contour plots in the  $x-z$  plane with contours at 0.01, 0.1, 0.3, 0.5, 0.7, and 0.9 of the maximum value. (Courtesy of Mr. Hatem Helal and Professor William A. Goddard III, California Institute of Technology, and Dr. Kelly P. Gaither, University of Texas at Austin.)

**FIGURE 6.56 cont'd** (c) Line scans across the contour plot, along the direction indicated by the green arrow in (b), showing the variation in probability density along the internuclear axis.

(Courtesy of Mr. Hatem Helal and Professor William A. Goddard III, California Institute of Technology, and Dr. Kelly P. Gaither, University of Texas at Austin.)

squaring each MO wave function shown in Figure 6.55. The probability density functions are shown in three views: (a) isosurfaces comprising all points at which the probability density is 0.01 of its maximum value; (b) contour plots in a plane containing the internuclear axis with contours at 0.05, 0.01, 0.3, 0.5, 0.7, and 0.9 of the maximum value; (c) line scans across the contour plot showing variation in probability density along the internuclear axis. We encourage you to compare these representations to develop intuition for the shape and symmetry of each probability density for locating the electron.

The ground-state wave function  $1\sigma_g$  has much greater electron density in the region between the nuclei than at the extreme ends of the molecule. In Section 6.2 we show that when the electron is in the  $1\sigma_g$  MO, the  $H_2^+$  ion has energy lower than that of the separated atoms. These two effects together are consistent with our expectations about chemical bonding, and so  $1\sigma_g$  is labeled a bonding MO. But, the first excited state wave function  $1\sigma_u^*$  has a node halfway between the nuclei. In Section 6.2 we show that when the electron is in the  $1\sigma_u^*$  MO, the  $H_2^+$  ion has energy higher than that of the separated atoms, and so  $1\sigma_u^*$  is labeled an antibonding MO.

## CHAPTER SUMMARY

The Born–Oppenheimer approximation is the starting point for all of molecular quantum mechanics. The fact that electrons move so much faster than nuclei allows us to treat electronic motion independently of nuclear motion by solving an electronic Schrödinger equation for each value of the internuclear separation. The resulting MOs provide all of the information of interest, the probability density distributions and the electronic energies being the most important. With the repulsive Coulomb potential included in the electronic Hamiltonian at a fixed internuclear separation, the lowest energy solution to  $\mathcal{H}_{el}\psi_{el} = E_{el}\psi_{el}$  as a function of geometry becomes the ground-state potential energy curve  $V(R)$  that governs the nuclear motion.

The MOs for the simplest molecule,  $H_2^+$ , can be calculated exactly within the Born–Oppenheimer approximation. The results illustrate the general features of molecular quantum mechanics that form the basis for our understanding of structure and bonding in more complicated molecules. The orbitals are characterized by their symmetry, the number and nature of their nodes, and their energies. Orbitals in which the electron density increases between the nuclei lead to energies lower than that of separated H and  $H^+$ ; these are called bonding MOs. Orbitals in which there is a node in the wave function and the electron density goes to zero midway between the nuclei are called antibonding orbitals. States of  $H_2^+$  in which the electron resides in an antibonding orbital are unstable with respect to dissociation to H and  $H^+$ .

Additional approximations must be made to calculate the MOs for many-electron molecules. The most important approximation procedures are the LCAO method and the VB model. The LCAO method constructs de-localized one-electron MOs by taking linear combinations of AOs centered on different atoms and generates electron configurations by placing electrons in these MOs using an aufbau principle and invoking Hund’s rules for the ground-state configuration. The VB model constructs a wave function for a localized pair bond starting with an “occupied” AO on each of the two atoms that form the bond. These two procedures provide the conceptual foundation and vocabulary for qualitative and even semiquantitative understanding of chemical bonding and molecular structure in contemporary chemistry. A variety of sophisticated computational methods have been developed using these procedures as starting points, and the results of these calculations are now sufficiently accurate to have both analytical and predictive value. Our goal has been to give you a

comprehensive introduction to molecular quantum mechanics so that you can easily read more advanced treatments and begin to use commercially available software with intelligence and confidence.

## CONCEPTS AND SKILLS

### Section 6.1 – Quantum Picture of the Chemical Bond

*Give a general description of the Born–Oppenheimer approximation and explain why it is the foundation for all molecular quantum mechanics. Describe the key features of the Born–Oppenheimer approximation (Section 6.1).*

- Nuclei are so much heavier than electrons that they may be considered fixed in space while the electrons move rapidly around them.
- The Born–Oppenheimer approximation allows us to solve the electronic Schrödinger equation for  $\text{H}_2^+$  for a fixed internuclear separation  $R_{\text{AB}}$ . The result is a one-electron MO, which is analogous to the one-electron hydrogen AO.
- With the repulsive Coulomb potential included in the electronic Hamiltonian at a fixed internuclear separation, the lowest energy solution to  $\mathcal{H}_{\text{el}}\psi_{\text{el}} = E_{\text{el}}\psi_{\text{el}}$  as a function of the relative positions of the nuclei,  $R_{\text{AB}}$  for a diatomic molecule, is the ground-state potential energy curve  $V(R_{\text{AB}})$  that governs the nuclear motion. Excited states are obtained from higher energy solutions.
- We write Schrödinger’s equation with the kinetic energy of the nuclei and the potential energy described earlier to find the quantized ground-state energy of the molecule. The nuclei vibrate about the equilibrium bond length—this is the zero point motion required by the uncertainty principle. The energy required to dissociate the molecular ion from the ground state into a separated proton and hydrogen atom is the bond dissociation energy.

### Section 6.2 – Exact Molecular Orbitals for the Simplest Molecule: $\text{H}_2^+$

*Give a general description of the quantum picture of the chemical bond and how it differs from the classical picture. Describe the key features of the quantum picture, including the nature of bonding and antibonding MOs, symmetry of MOs, and the energy sequence of MOs (Problems 1–8).*

- We illustrate graphically the first eight MOs for  $\text{H}_2^+$  to show their shapes and to characterize them by their energies and symmetry, just as we characterized the atomic orbitals for the hydrogen atom. The MOs are characterized by the component of the angular momentum along the internuclear axis: by analogy to the hydrogen atom, these are called  $\sigma$  for orbitals with cylindrical symmetry and  $\pi$  for MOs with one nodal plane that contains the internuclear axis.

### Sections 6.3–6.6 – Delocalized Bonds: Molecular Orbital Theory and the LCAO

*Show how MOs can be constructed from the AOs of two atoms that form a chemical bond, and explain how the electron density between the atoms is related to the MO (Problems 9–16).*

- A good approximation to the one-electron MOs for a diatomic molecule is the weighted sum or difference of AOs of the atoms of the molecule. The linear combination for which the contributing AOs overlap with the same phase (either both positive or both negative) leads to increased electron density between the nuclei and bonding; the linear combination for which the contributing AOs overlap with the opposite phase (one positive and the other negative) leads to a node between the nuclei and decreased electron density, and it is antibonding.

- Correlation diagrams show how pairs of AOs lead to bonding and antibonding pairs of MOs. An aufbau principle is used to build up electron configurations, just like for atoms. Hund's rules predict the lowest energy electron configurations and either paramagnetic or diamagnetic behavior.
- The bond order is found by counting the number of electrons in bonding orbitals, subtracting the number in antibonding orbitals, and dividing the result by 2. Electrons in antibonding orbitals effectively cancel the bonding capacity of those in bonding orbitals. This scheme explains the trends in bond length, bond stiffness, and bond dissociation energy of the first- and second-row diatomic molecules.
- The energy sequence of the MOs is slightly more complicated in second-row homonuclear diatomic molecules, because the  $p$  orbitals can overlap in two different ways. Moving from left to right across the row, the energy-level ordering changes at  $N_2$  because the energy of the  $\pi$  orbital remains nearly constant, whereas that of the  $\sigma$  orbital drops rapidly (see Fig. 6.16). Therefore, two energy level diagrams are required to explain the bonding in the second-period diatomic molecules.
- The MOs for heteronuclear diatomic molecules are obtained by the same approach, with the AO energies of the more electronegative element placed lower (more stable) than those of the other element. If the difference in AO energies is small, the MO energy sequence is that given in Figure 6.21; for larger AO energy differences, the MOs are those described in Figure 6.24.

### Connection to Instrumental Analysis: Photoelectron Spectroscopy

#### Section 6.7 – Summary Comments for the LCAO Method and Diatomic Molecules

*Relate photoelectron spectra to correlation diagrams for MOs (Problems 35–40).*

- Photoelectron spectroscopy confirms the validity of the orbital approximation by measuring the ionization energies of the MOs directly. The ionization energy of the orbital is obtained as the difference in the energy of the photon used to ionize the molecule and the measured kinetic energy of the emitted electrons. Koopmans's approximation states that the orbital energy  $\varepsilon$  in the LCAO method is the negative of the ionization energy.
- In addition to the orbital energies, PES provides a great deal of information about the nature of the orbital (bonding, nonbonding, or antibonding) from the vibrational fine structure observed in the spectra.

#### Sections 6.8–6.10 – Localized Bonds: The Valence Bond Model

*Use the VB method to construct wave functions for localized electron pair bonds, including multiple bonds, and predict the molecular geometry from these bonds (Problems 41–48).*

- The VB model constructs wave functions to describe localized electron-pair bonds. The model describes bonding in diatomic molecules, including the formation of multiple ( $\sigma$  and  $\pi$ ) bonds. It is most frequently applied to organize and correlate data on molecular structures, especially for molecules of the type  $AB_x$ , the geometries of which are described by VSEPR theory.
- The simple VB model is augmented with the concept of orbital hybridization to account for the valence of second-row atoms and the structures of their compounds. Hybrid orbitals are constructed by adding  $s$  and  $p$  orbitals with different coefficients (weights or percentage contributions) and phases. The number of hybrid orbitals produced equals the number of starting AOs; there are two  $sp$  hybrid orbitals, three  $sp^2$  hybrid orbitals, and four  $sp^3$  hybrid orbitals.

### Sections 6.11–6.12 – Comparison of LCAO and Valence Bond Methods and Using Them Together

Compare the LCAO and VB approaches, and combine them to describe the molecular network and delocalized bonds in certain classes of molecules (Problems 57–62).

- Comparing the LCAO and VB treatments for the hydrogen molecule at the level of the *electronic wave function for the molecule* gives considerable insight into the differences between the methods and also suggests ways to improve each. The VB wave function predicts a purely covalent bond, whereas the LCAO wave function predicts a bond with an equal mixture of covalent and ionic character. Neither of these is the best representation of bonding in most diatomics so refinements of both approaches are necessary to produce results that are in better agreement with experiment.
- Many methods have been developed to improve both the simple LCAO and VB models; it is easiest to illustrate one approach for improving the VB model. Let  $\psi_{\text{improved}} = \psi_{\text{VB}} + \lambda\psi_{\text{MO}}$ , where  $\lambda$  is chosen so that the energy of the electronic state  $\psi$  for the energy of the ground electronic state is minimized. The variational principle ensures that the true energy is always lower than the energy calculated using an approximate wave function. This provides a well-defined criterion to judge improvement—lower energy is always better.
- Many chemists combine the LCAO and VB methods to describe bonding in polyatomic molecules. They use the VB model to describe the localized  $\sigma$  bonds that provide “connectivity” for the molecule structure and use the LCAO method to describe the de-localized  $\pi$  bonds that distribute electrons over the entire structure.
- In hydrocarbon molecules with alternating single and double bonds along a carbon backbone, such as 1,3-butadiene, the electron density distribution and energy levels of the delocalized  $\pi$  orbitals can be understood using particle-in-a-box models. The energies of a set of levels increases with the number of nodes in the wave function.

## CUMULATIVE EXERCISE

### Iodine in the Human Diet

The shiny purple-black crystals of elemental iodine (Fig. 6.57) were first prepared in 1811 from the ashes of seaweed. Several species of seaweed concentrate the iodine that is present in low proportions in seawater, and for many years, seaweed was the major practical source of this element. Most iodine is now produced from natural brines via oxidation of iodide ion with chlorine.

- Iodine is an essential trace element in the human diet, and iodine deficiency causes goiter, the enlargement of the thyroid gland. Much of the salt intended for human consumption is “iodized” by the addition of small quantities of sodium iodide to prevent goiter. Calculate the electronegativity difference between sodium and iodine. Is sodium iodide an ionic or a covalent compound? What is its chemical formula?
- Iodine is an important reagent in synthetic organic chemistry because bonds between carbon and iodine form readily. Use electronegativities to determine whether the C–I bond is ionic, purely covalent, or polar covalent in character.
- Give the steric numbers for the iodine atom and identify the geometries of the following ions containing iodine and oxygen:  $\text{IO}_3^-$ ,  $\text{IO}_6^{5-}$ , and  $\text{IO}_4^-$ .

- (d) What is the ground-state electron configuration of the valence electrons of iodine molecules ( $I_2$ )? Is iodine paramagnetic or diamagnetic?
- (e) What is the electron configuration of the  $I_2^+$  molecular ion? Is its bond stronger or weaker than that in  $I_2$ ? What is its bond order?

### Answers

- (a) The electronegativity difference is 1.73; thus, the compound is largely ionic, with formula NaI.
- (b) The electronegativity difference is 0.11; thus, the C—I bond is largely covalent, with nearly equal sharing of electrons between the atoms.
- (c)  $IO_3^-$ :  $SN = 4$ , structure is pyramidal;  $IO_6^{5-}$ :  $SN = 6$ , structure is octahedral;  $IO_4^-$ :  $SN = 4$ , structure is tetrahedral.
- (d)  $(\sigma_{g5s})^2(\sigma_{u5s})^2(\sigma_{g5p_z})^2(\pi_{u5p_x}\pi_{u5p_y})^4(\pi_{g5p_x}^*\pi_{g5p_y}^*)^4$ ; iodine is diamagnetic.
- (e)  $(\sigma_{g5s})^2(\sigma_{u5s})^2(\sigma_{g5p_z})^2(\pi_{u5p_x}\pi_{u5p_y})^4(\pi_{g5p_x}^*\pi_{g5p_y}^*)^3$ ; the bond is stronger; bond order is  $3/2$  versus 1.

## PROBLEMS

Answers to problems whose numbers are red appear in Appendix G. Problems that are more challenging are indicated with asterisks.

### 6.1 Quantum Picture of the Chemical Bond

- Determine the number of nodes along the internuclear axis for each of the  $\sigma$  molecular orbitals for  $H_2^+$  shown in Figure 6.5.
- Determine the number of nodes along the internuclear axis and the number of nodal planes for each of the  $\pi$  molecular orbitals for  $H_2^+$  shown in Figure 6.5.
- Sketch the shape of each of the  $\sigma$  molecular orbitals for  $H_2^+$  shown in Figure 6.5 in a plane perpendicular to the internuclear axis located at the midpoint between the two nuclei. Repeat the sketches for a plane perpendicular to the internuclear axis located at a point one quarter of the distance between the two nuclei.
- Sketch the shape of each of the  $\pi$  molecular orbitals for  $H_2^+$  shown in Figure 6.5 in a plane perpendicular to the internuclear axis located at the midpoint between the two nuclei. Repeat the sketches for a plane perpendicular to the internuclear axis located at a point one quarter of the distance between the two nuclei.
- Compare the electron density in the  $1\sigma_g$  and  $1\sigma_u^*$  molecular orbitals for  $H_2^+$  shown in Figure 6.5 with the classical model for bonding for  $H_2^+$  summarized in Figure 3.22b. Which of these molecular orbitals describes the bond in  $H_2^+$ ?
- Explain why  $1\sigma_g$  is the ground state for  $H_2^+$ . By combining your answer with the answer to Problem 5, what conclusions can you draw about the molecular orbital description of the bond in  $H_2^+$ ?

### 6.3 Molecular Orbital Theory and the Linear Combination of Atomic Orbitals Approximation for $H_2^+$

### 6.4 Homonuclear Diatomic Molecules: First-Period Atoms

- The ground state of  $H_2$  has the electron configuration  $(\sigma_{g1s})^2$ . There are excited states that have the following configurations
  - $(\sigma_{g1s})^1(\sigma_{u1s})^1$
  - $(\sigma_{g1s})(\sigma_{u1s})^2$
 Which state do you predict to have higher energy?
- Predict the ground electronic state of the  $He_2^{2+}$  ion. What is the bond order? Will it be stable in the ground state?
- Without consulting tables of data, predict which species has the larger bond energy,  $H_2$  or  $He_2^+$ .
- Without consulting tables of data, predict which species has the larger bond energy,  $H_2^+$  or  $H_2$ .
- Without consulting tables of data, predict which species has the greater bond length,  $H_2$  or  $He_2^+$ .
- Without consulting tables of data, predict which species has the greater bond length,  $H_2^+$  or  $H_2$ .
- Without consulting tables of data, on the same graph sketch the effective potential energy curves for  $H_2$  and  $He_2^+$ .
- Without consulting tables of data, on the same graph sketch the effective potential energy curves for  $H_2^+$  and  $H_2$ .
- Suppose we supply enough energy to  $H_2$  to remove one of its electrons. Is the bond energy of the resulting ion larger or smaller than that of  $H_2$ ? Is the bond length of the resulting ion larger or smaller than that of  $H_2$ ?

16. Suppose we supply enough energy to  $\text{He}_2^+$  to remove its most weakly bound electron. Is the bond energy of the resulting ion larger or smaller than that of  $\text{He}_2^+$ ? Is the bond length of the resulting ion larger or smaller than that of  $\text{He}_2$ ?

### 6.5 Homonuclear Diatomic Molecules: Second-Period Atoms

17. If an electron is removed from a fluorine molecule, an  $\text{F}_2^+$  molecular ion forms.
- Give the molecular electron configurations for  $\text{F}_2$  and  $\text{F}_2^+$  (for the MOs constructed from valence AOs).
  - Give the bond order of each species.
  - Predict which species should be paramagnetic.
  - Predict which species has the greater bond dissociation energy.
18. When one electron is added to an oxygen molecule, a superoxide ion ( $\text{O}_2^-$ ) is formed. The addition of two electrons gives a peroxide ion ( $\text{O}_2^{2-}$ ). Removal of an electron from  $\text{O}_2$  leads to  $\text{O}_2^+$ .
- Construct the correlation diagram for  $\text{O}_2^-$ .
  - Give the valence electron configuration for each of the following species:  $\text{O}_2^+$ ,  $\text{O}_2$ ,  $\text{O}_2^-$ ,  $\text{O}_2^{2-}$ .
  - Give the bond order of each species.
  - Predict which species are paramagnetic.
  - Predict the order of increasing bond dissociation energy among the species.
19. Predict the valence electron configuration and the total bond order for the molecule  $\text{S}_2$ , which forms in the gas phase when sulfur is heated to a high temperature. Will  $\text{S}_2$  be paramagnetic or diamagnetic?
20. Predict the valence electron configuration and the total bond order for the molecule  $\text{I}_2$ . Will  $\text{I}_2$  be paramagnetic or diamagnetic?
21. For each of the following valence electron configurations of a homonuclear diatomic molecule or molecular ion, identify the element X, Q, or Z and determine the total bond order.
- $\text{X}_2: (\sigma_{g2s})^2 (\sigma_{u2s})^2 (\sigma_{g2p_z})^2 (\pi_{u2p})^4 (\pi_{g2p}^*)^4$
  - $\text{Q}_2^+: (\sigma_{g2s})^2 (\sigma_{u2s})^2 (\pi_{u2p})^4 (\sigma_{g2p_z})^1$
  - $\text{Z}_2^-: (\sigma_{g2s})^2 (\sigma_{u2s})^2 (\sigma_{g2p_z})^2 (\pi_{u2p})^4 (\pi_{g2p}^*)^3$
22. For each of the following valence electron configurations of a homonuclear diatomic molecule or molecular ion, identify the element X, Q, or Z and determine the total bond order.
- $\text{X}_2: (\sigma_{g2s})^2 (\sigma_{u2s})^2 (\sigma_{g2p_z})^2 (\pi_{u2p})^4 (\pi_{g2p}^*)^2$
  - $\text{Q}_2^-: (\sigma_{g2s})^2 (\sigma_{u2s})^2 (\pi_{u2p})^3$
  - $\text{Z}_2^+: (\sigma_{g2s})^2 (\sigma_{u2s})^2 (\sigma_{g2p_z})^2 (\pi_{u2p})^4 (\pi_{g2p}^*)^2$
23. For each of the electron configurations in Problem 21, determine whether the molecule or molecular ion is paramagnetic or diamagnetic.
24. For each of the electron configurations in Problem 22, determine whether the molecule or molecular ion is paramagnetic or diamagnetic.

### 6.6 Heteronuclear Diatomic Molecules

25. Following the pattern of Figure 6.21, work out the correlation diagram for the CN molecule, showing the relative energy levels of the atoms and the bonding and antibonding orbitals of the molecule. Indicate the occupation of the MOs with arrows. State the order of the bond and comment on the magnetic properties of CN.
26. Following the pattern of Figure 6.21, work out the correlation diagram for the BeN molecule, showing the relative energy levels of the atoms and the bonding and antibonding orbitals of the molecule. Indicate the occupation of the MOs with arrows. State the order of the bond and comment on the magnetic properties of BeN.
27. The bond length of the transient diatomic molecule CF is 1.291 Å; that of the molecular ion  $\text{CF}^+$  is 1.173 Å. Explain why the CF bond shortens with the loss of an electron. Refer to the proper MO correlation diagram.
28. The compound nitrogen oxide (NO) forms when the nitrogen and oxygen in air are heated. Predict whether the nitrosyl ion ( $\text{NO}^+$ ) will have a shorter or a longer bond than the NO molecule. Will  $\text{NO}^+$  be paramagnetic like NO or diamagnetic?
29. What would be the electron configuration for a  $\text{HeH}^-$  molecular ion? What bond order would you predict? How stable should such a species be?
30. The molecular ion  $\text{HeH}^+$  has an equilibrium bond length of 0.774 Å. Draw an electron correlation diagram for this ion, indicating the occupied MOs. Is  $\text{HeH}^+$  paramagnetic? When  $\text{HeH}^+$  dissociates, is a lower energy state reached by forming  $\text{He} + \text{H}^+$  or  $\text{He}^+ + \text{H}$ ?
31. Predict the ground state electronic configurations of CF, CH,  $\text{CH}^+$ , and  $\text{CN}^-$ . Do any of them have unpaired electrons?
32. Predict the ground state electronic configuration of HeBe. What is the bond order?
33. The bond dissociation energies for the species NO,  $\text{CF}^-$ , and  $\text{CF}^+$  are ordered as  $\text{CF}^+ > \text{NO} > \text{CF}^-$ . Use MO theory to explain this ordering.
34. The ionization energy of CO is greater than that of NO. Explain this difference based on the electron configurations of these two molecules.

### Connection to Instrumental Analysis: Photoelectron Spectroscopy

35. Photoelectron spectra were acquired from a sample of gaseous  $\text{N}_2$  using He(I) light with energy 21.22 eV as the ionization source. Photoelectrons were detected with kinetic energy values 5.63 eV and also with 4.53 eV. Calculate the ionization energy for each group of electrons. Identify the MOs that were most likely the sources of these two groups of electrons.

36. Photoelectron spectra were acquired from a sample of gaseous  $O_2$  using X-ray radiation with wavelength 0.99 nm and energy 1253.6 eV. The spectrum contained a large peak for photoelectrons with speed of  $1.57 \times 10^7 \text{ m s}^{-1}$ . Calculate the ionization energy of these electrons. Identify the orbital from which they were most likely emitted.
37. From the  $n = 0$  peaks in the photoelectron spectrum for  $N_2$  shown in the figure in *Connections* box, prepare a quantitative energy level diagram for the molecular orbitals of  $N_2$ .
38. From the  $n = 0$  peaks in the photoelectron spectrum for  $O_2$  shown in the figure in *Connections* box, prepare a quantitative energy level diagram for the molecular orbitals of  $O_2$ .
39. The photoelectron spectrum of HBr has two main groups of peaks. The first has ionization energy 11.88 eV. The next peak has ionization energy 15.2 eV, and it is followed by a long progression of peaks with higher ionization energies. Identify the molecular orbitals corresponding to these two groups of peaks.
40. The photoelectron spectrum of CO has four major peaks with ionization energies of 14.5, 17.2, 20.1, and 38.3 eV. Assign these peaks of molecular orbitals of CO, and prepare a quantitative energy level correlation diagram for CO. The ionization energy of carbon atoms is 11.26 eV, and the ionization energy of oxygen atoms is 13.62 eV.

### 6.8 Valence Bond Theory and Electron Pair Bond

41. Write simple valence bond wave functions for the diatomic molecules  $Li_2$  and  $C_2$ . State the bond order predicted by the simple VB model and compare with the LCAO predictions in Table 6.3.
42. Write simple valence bond wave functions for the diatomic molecules  $B_2$  and  $O_2$ . State the bond order predicted by the simple VB model and compare with the LCAO predictions in Table 6.3.
43. Both the simple VB model and the LCAO method predict that the bond order of  $Be_2$  is 0. Explain how each arrives at that conclusion.
44. Both the simple VB model and the LCAO method predict that the bond order of  $Ne_2$  is 0. Explain how each arrives at that conclusion.
45. Write simple valence bond wave functions for formation of bonds between B atoms and H atoms. What B—H compound does the VB model predict? What geometry does it predict for the molecules?
46. Write simple valence bond wave functions for formation of bonds between C and H atoms. What C—H compound does the VB model predict? What geometry does it predict for the molecules?
47. Write simple valence bond wave functions for the bonds in  $NH_3$ . What geometry does the VB model predict for  $NH_3$ ?
48. Write simple valence bond wave functions for the bonds in  $H_2O$ . What geometry does the VB model predict for  $H_2O$ ?

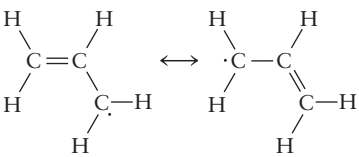

### 6.9 Orbital Hybridization for Polyatomic Molecules

#### 6.10 Predicting Molecular Structures and Shapes

49. Formulate a localized bond picture for the amide ion ( $NH_2^-$ ). What hybridization do you expect the central nitrogen atom to have, and what geometry do you predict for the molecular ion?
50. Formulate a localized bond picture for the hydronium ion ( $H_3O^+$ ). What hybridization do you expect the central oxygen atom to have, and what geometry do you predict for the molecular ion?
51. Draw a Lewis electron dot diagram for each of the following molecules and ions. Formulate the hybridization for the central atom in each case and give the molecular geometry.
- $CCl_4$
  - $CO_2$
  - $OF_2$
  - $CH_3^-$
  - $BeH_2$
52. Draw a Lewis electron dot diagram for each of the following molecules and ions. Formulate the hybridization for the central atom in each case and give the molecular geometry.
- $BF_3$
  - $BH_4^-$
  - $PH_3$
  - $CS_2$
  - $CH_3^+$
53. Describe the hybrid orbitals on the chlorine atom in the  $ClO_3^+$  and  $ClO_2^+$  molecular ions. Sketch the expected geometries of these ions.
54. Describe the hybrid orbitals on the chlorine atom in the  $ClO_4^-$  and  $ClO_3^-$  molecular ions. Sketch the expected geometries of these ions.
55. The sodium salt of the unfamiliar orthonitrate ion ( $NO_4^{3-}$ ) has been prepared. What hybridization is expected on the nitrogen atom at the center of this ion? Predict the geometry of the  $NO_4^{3-}$  ion.
56. Describe the hybrid orbitals used by the carbon atom in  $N \equiv C - Cl$ . Predict the geometry of the molecule.

### 6.11 Using the LCAO and Valence Bond Methods Together

57. Describe the bonding in the bent molecule  $NF_2$ . Predict its energy level diagram and electron configuration.
58. Describe the bonding in the bent molecule  $OF_2$ . Predict its energy level diagram and electron configuration.

59. The azide ion ( $\text{N}_3^-$ ) is a weakly bound molecular ion. Formulate its MO structure for localized  $\sigma$  bonds and de-localized  $\pi$  bonds. Do you expect  $\text{N}_3$  and  $\text{N}_3^+$  to be bound as well? Which of the three species do you expect to be paramagnetic?
60. Formulate the MO structure of ( $\text{NO}_2^+$ ) for localized  $\sigma$  bonds and de-localized  $\pi$  bonds. Is it linear or nonlinear? Do you expect it to be paramagnetic? Repeat the analysis for  $\text{NO}_2$  and for  $\text{NO}_2^-$ .
61. Discuss the nature of the bonding in the nitrite ion ( $\text{NO}_2^-$ ). Draw the possible Lewis resonance diagrams for this ion. Use the VSEPR theory to determine the steric number, the hybridization of the central nitrogen atom, and the geometry of the ion. Show how the use of resonance structures can be avoided by introducing a de-localized  $\pi$  MO. What bond order does the MO model predict for the N—O bonds in the nitrite ion?
62. Discuss the nature of the bonding in the nitrate ion ( $\text{NO}_3^-$ ). Draw the possible Lewis resonance diagrams for this ion. Use the VSEPR theory to determine the steric number, the hybridization of the central N atom, and the geometry of the ion. Show how the use of resonance structures can be avoided by introducing a de-localized  $\pi$  MO. What bond order is predicted by the MO model for the N—O bonds in the nitrate ion?
- \*63. The pyridine molecule ( $\text{C}_5\text{H}_5\text{N}$ ) is obtained by replacing one C—H group in benzene with a nitrogen atom. Because nitrogen is more electronegative than the C—H group, orbitals with electron density on nitrogen are lower in energy. How do you expect the  $\pi$  MOs and energy levels of pyridine to differ from those of benzene?
64. For each of the following molecules, construct the  $\pi$  MOs from the  $2p_z$  atomic orbitals perpendicular to the plane of the carbon atoms.
- (a) Cyclobutadiene 
- (b) Allyl radical 

Indicate which, if any, of these orbitals have identical energies from symmetry considerations. Show the number of electrons occupying each  $\pi$  MO in the ground state, and indicate whether either or both of the molecules are paramagnetic. Assume that the C atoms in the allyl radical are all  $sp^2$  hybridized.

## ADDITIONAL PROBLEMS

65. (a) Sketch the occupied MOs of the valence shell for the  $\text{N}_2$  molecule. Label the orbitals as  $\sigma$  or  $\pi$  orbitals, and specify which are bonding and which are antibonding.  
 (b) If one electron is removed from the highest occupied orbital of  $\text{N}_2$ , will the equilibrium N—N distance become longer or shorter? Explain briefly.
66. Calcium carbide ( $\text{CaC}_2$ ) is an intermediate in the manufacturing of acetylene ( $\text{C}_2\text{H}_2$ ). It is the calcium salt of the carbide (also called acetylide) ion ( $\text{C}_2^{2-}$ ). What is the electron configuration of this molecular ion? What is its bond order?
67. The  $\text{B}_2$  molecule is paramagnetic; show how this indicates that the energy ordering of the orbitals in this molecule is given by Figure 6.18a rather than 6.18b.
68. The  $\text{Be}_2$  molecule has been detected experimentally. It has a bond length of 2.45 Å and a bond dissociation energy of 9.46 kJ mol<sup>-1</sup>. Write the ground-state electron configuration of  $\text{Be}_2$  and predict its bond order using the theory developed in the text. Compare the experimental bonding data on  $\text{Be}_2$  with those recorded for  $\text{B}_2$ ,  $\text{C}_2$ ,  $\text{N}_2$ , and  $\text{O}_2$  in Table 6.3. Is the prediction that stems from the simple theory significantly incorrect?
- \*69. (a) The ionization energy of molecular hydrogen ( $\text{H}_2$ ) is *greater* than that of atomic hydrogen (H), but that of molecular oxygen ( $\text{O}_2$ ) is *lower* than that of atomic oxygen (O). Explain. (*Hint*: Think about the stability of the molecular ion that forms in relation to bonding and antibonding electrons.)  
 (b) What prediction would you make for the relative ionization energies of atomic and molecular fluorine (F and  $\text{F}_2$ )?
70. The molecular ion  $\text{HeH}^+$  has an equilibrium bond length of 0.774 Å. Draw an electron correlation diagram for this molecule, indicating the occupied MOs. If the lowest energy MO has the form  $C_1\psi_{1s}^{\text{H}} + C_2\psi_{1s}^{\text{He}}$ , do you expect  $C_2$  to be larger or smaller than  $C_1$ ?
- \*71. The MO of the ground state of a heteronuclear diatomic molecule AB is
- $$\psi_{\text{mol}} = C_A\varphi^A + C_B\varphi^B$$
- If a bonding electron spends 90% of its time in an orbital  $\varphi^A$  on atom A and 10% of its time in  $\varphi^B$  on atom B, what are the values of  $C_A$  and  $C_B$ ? (Neglect the overlap of the two orbitals.)

72. The stable molecular ion  $\text{H}_3^+$  is triangular, with H—H distances of  $0.87 \text{ \AA}$ . Sketch the molecule and indicate the region of greatest electron density of the lowest energy MO.

\*73. According to recent spectroscopic results, nitramide

is a nonplanar molecule. It was previously thought to be planar.

- (a) Predict the bond order of the N—N bond in the nonplanar structure.  
 (b) If the molecule really were planar after all, what would be the bond order of the N—N bond?

74. *trans*-tetrazene ( $\text{N}_4\text{H}_4$ ) consists of a chain of four nitrogen atoms with each of the two end atoms bonded to two hydrogen atoms. Use the concepts of steric number and hybridization to predict the overall geometry of the molecule. Give the expected structure of *cis*-tetrazene.

Carbon (C) is unique among the elements in the large number of compounds it forms and in the variety of their structures. There are thousands of hydrocarbons (compounds that contain only hydrogen and carbon) that contain single, double, and triple bonds arranged as chains, rings, branched structures, and cages (Fig. 7.1). Hydrogen and oxygen, in contrast, form only two stable neutral compounds, water and hydrogen peroxide, and there are only six stable compounds that contain only nitrogen and oxygen.

The unique properties of carbon relate to its position in the periodic table. As a second-period element, carbon atoms are relatively small. Therefore, carbon can easily form the double and triple bonds that are rare in the compounds of related elements, such as silicon. Carbon can make four bonds, as a group IV element, which is more than the other second-period elements; the number of possible bonds plus the variety in their geometries (linear, trigonal planar, and

**FIGURE 7.1** One simple and unusual hydrocarbon is cubane ( $C_8H_8$ ), in which the eight carbon atoms are arranged at the corners of a cube. Recently, a derivative was made in which all eight hydrogen atoms were replaced by  $-NO_2$  groups.

tetrahedral) means an enormous variety of possible structures. Finally, as an element of intermediate electronegativity, carbon forms covalent compounds both with relatively electronegative elements, such as oxygen, nitrogen, and the halogens, and with relatively electropositive elements, such as hydrogen and the heavy metals mercury and lead.

The study of the compounds of carbon is the discipline traditionally called **organic chemistry**, although the chemistry of carbon is intimately connected to that of the inorganic elements and to biochemistry. This chapter builds on the general principles of covalent bonding in carbon compounds presented in Chapter 6. The relationship between molecular structure and the properties of organic substances is illustrated by examining the composition, refining, and chemical processing of petroleum, the primary starting material for the production of hydrocarbons and their derivatives. The chapter continues with an introduction to the types of compounds produced when elements such as chlorine, oxygen, and nitrogen combine with carbon and hydrogen. It concludes with a brief introduction to some organic molecules important to agriculture and to medicine.

## 7.1 Petroleum Refining and the Hydrocarbons

The effects of petroleum on everyday life could not have been anticipated when the first oil well was drilled in 1859 near Titusville, Pennsylvania. Today, the petroleum and petrochemical industries span the world and influence nearly every aspect of our daily lives. In the early years of the 20th century, the development of the automobile, fueled by low-cost gasoline derived from petroleum, dramatically changed many people's lifestyles. The subsequent use of gasoline and oil to power trains and planes, tractors and harvesters, and pumps and coolers transformed travel, agriculture, and industry. Natural gas and heating oil warm most homes in the United States. Finally, the spectacular growth of the petrochemical industry since 1945 has led to the introduction of innumerable new products, ranging from pharmaceuticals to plastics and synthetic fibers. More than half of the chemical compounds produced in greatest volumes are synthesized from petroleum feedstocks.

Prospects for the continued availability of cheap petroleum and petrochemicals are clouded for the 21st century and beyond. Many wells have been drained, and the remaining petroleum is relatively difficult and costly to extract. Petroleum is not easy to make. It originated from the deposition and decay of organic

matter (of animal or vegetable origin) in oxygen-poor marine sediments. Petroleum subsequently migrated to the porous sandstone rocks from which it is extracted today. Over the past 100 years, we have consumed a significant fraction of the petroleum accumulated in the earth over many millions of years. The imperative for the future is to save the remaining reserves for uses for which few substitutes are available (such as the manufacture of specialty chemicals) while finding other sources of heat and energy.

Although crude petroleum contains small amounts of oxygen, nitrogen, and sulfur, its major constituents are **hydrocarbons**—compounds of carbon and hydrogen. Isolating individual hydrocarbon substances from petroleum mixtures is an industrial process of central importance. Moreover, it provides a fascinating story that illustrates how the structures of molecules determine the properties of substances and the behavior of those substances in particular processes. The next three sections present a brief introduction to this story, emphasizing the structure–property correlations.

**FIGURE 7.2** Bonding in the alkanes involves  $sp^3$  hybridized orbitals on carbon. (a) Methane. (b) Ethane. The orbitals shown here are typical sketches used by organic chemists to describe bonding in organic molecules. Figure 6.40 compares these shapes to the actual shapes of the hybrid orbitals. (For clarity, the minor negative (blue) lobe of each hybrid orbital is not shown.)

### 7.2.1 Normal Alkanes

The most prevalent hydrocarbons in petroleum are the **straight-chain alkanes** (also called normal alkanes, or *n*-alkanes), which consist of chains of carbon atoms bonded to one another by single bonds, with enough hydrogen atoms on each carbon atom to bring it to the maximum bonding capacity of four. These alkanes have the generic formula  $C_nH_{2n+2}$ ; Table 7.1 lists the names and formulas of the first few alkanes. The ends of the molecules are methyl ( $-CH_3$ ) groups, with methylene ( $-CH_2-$ ) groups between them. We could write pentane ( $C_5H_{12}$ ) as  $CH_3CH_2CH_2CH_2CH_3$  to indicate the structure more explicitly or, in abbreviated fashion, as  $CH_3(CH_2)_3CH_3$ .

Bonding in the normal alkanes is explained by the valence bond (VB) model with orbital hybridization described in Section 6.8. The carbon atom in methane has four  $sp^3$  hybridized orbitals, which overlap with hydrogen 1s orbitals to form four  $\sigma$  bonds pointing toward the vertices of a tetrahedron with the carbon atom at its center. These orbitals are represented in Figures 6.39 and 6.40; the methane molecule is shown in Figure 7.2a. The bonds in ethane are also described by  $sp^3$  hybridization. One hybrid orbital on each carbon atom overlaps another hybrid orbital to form the C–C  $\sigma$  bond. The remaining three hybrids on each carbon overlap with hydrogen 1s orbitals to form  $\sigma$  bonds. The ethane molecule is shown in Figure 7.2b.

**FIGURE 7.3** The two  $\text{—CH}_3$  groups in ethane rotate easily about the bond that joins them.

**FIGURE 7.4** Two of the many possible conformations of the alkane  $\text{C}_{16}\text{H}_{34}$ . The carbon atoms are not shown explicitly, but they lie at the black intersections. Hydrogen atoms are at the white ends. Eliminating the spheres representing atoms in these tube (or Dreiding) models reveals the conformations more clearly.

The same bonding scheme applies to the larger straight-chain alkanes. Alkanes with all their carbon atoms in a straight chain are called normal alkanes or *n*-alkanes. Two of the  $sp^3$  hybrid orbitals on each carbon atom overlap those of adjacent atoms to form the backbone of the chain, and the remaining two bond to hydrogen atoms. Although molecular vibrations do not change bond lengths very much, internal rotation about C—C single bonds is quite easy (Fig. 7.3). Thus, a hydrocarbon molecule in a gas or liquid is constantly changing conformations which, for long chain hydrocarbons, can range from rather linear molecules like strands of spaghetti to more compact forms like balls of yarn. The term *straight chain* refers only to the bonding pattern in which each carbon atom is bonded to the next one in a sequence; it does not mean that the carbon atoms are positioned along a straight line. An alkane molecule with 10 to 20 carbon atoms looks quite different when “balled up” than when its bonds are extended to give a “stretched” molecule (Fig. 7.4). These two extreme conformations and many others interconvert rapidly at room temperature.

Figure 7.5 shows the melting and boiling points of the straight-chain alkanes, which both increase with the number of carbon atoms and thus with molecular mass. This is a consequence of the increasing strength of *dispersion forces* between these molecules (see discussion in Section 10.2). Methane, ethane, propane, and butane are all gases at room temperature, but the hydrocarbons that follow them in the alkane series are liquids. Alkanes beyond about  $\text{C}_{17}\text{H}_{36}$  are waxy solids at  $20^\circ\text{C}$ , whose melting points increase with the number of carbon atoms present. Paraffin wax, a low-melting solid, is a mixture of alkanes with 20 to 30 carbon atoms per molecule. Petrolatum (petroleum jelly, or Vaseline) is a different mixture that is semisolid at room temperature.

Mixtures of hydrocarbons such as petroleum do not boil at single, sharply defined temperatures. Instead, as such a mixture is heated, the compounds with lower boiling points (the most volatile) boil off first, and as the temperature increases, more and more of the material vaporizes. The existence of a boiling-point range permits components of a mixture to be separated by distillation (see discussion in Section 11.6). The earliest petroleum distillation was a simple

**FIGURE 7.5** The melting and boiling points of the straight-chain alkanes increase with chain length  $n$ . Note the alternation in the melting points: Alkanes with  $n$  odd tend to have lower melting points because they are more difficult to pack into a crystal lattice.

**FIGURE 7.6** In the distillation of petroleum, the lighter, more volatile hydrocarbon fractions are removed from higher up the column and the heavier fractions from lower down.

batch process: The crude oil was heated in a still, the volatile fractions were removed at the top and condensed to gasoline, and the still was cleaned for another batch. Modern petroleum refineries use much more sophisticated and efficient distillation methods, in which crude oil is added continuously and fractions of different volatility (vapor pressure) are tapped off at various points up and down the distillation column (Fig. 7.6). Heat exchangers capture the heat liberated from condensation of the liquid products to save on energy costs.

Distillation separates hydrocarbons by their boiling points, and thus by molecular mass. A mixture of gases emerges from the top of the column, resembling the natural gas that collects in rock cavities above petroleum deposits. These gas mixtures contain ethane, propane, and butane, which can be separated further by redissolving them in a liquid solvent such as hexane. The methane-rich mixture of gases that remains is used for chemical synthesis or is shipped by pipeline to heat homes. The gases dissolved in hexane can be separated by redistilling, after which they can be used as starting materials in chemical processes. Propane and butane are also bottled under pressure and sold as liquefied petroleum gas, which is used for fuel in areas where natural gas is not available from pipelines. The next fraction to emerge from the petroleum distillation column after the gases is naphtha, which is used primarily to manufacture gasoline. Subsequent fractions of successively higher molecular mass are used for jet and diesel fuel, heating oil, and machine lubricating oil. The heavy, non-volatile sludge that remains at the bottom of the distillation unit is pitch or asphalt, which is used for roofing and paving.

## 7.2.2 Cyclic Alkanes

In addition to the straight-chain alkanes, the cyclic alkanes also appear in petroleum. A **cycloalkane** consists of at least one chain of carbon atoms attached at the ends to form a closed loop. Two hydrogen atoms must be eliminated to form this additional C—C bond; thus, the general formula for cycloalkanes having one ring is C<sub>n</sub>H<sub>2n</sub> (Fig. 7.7). The cycloalkanes are named by adding the prefix *cyclo-* to the name of the straight-chain alkane that has the same number of

**FIGURE 7.7** Three cyclic hydrocarbons. (a) Cyclopropane,  $C_3H_6$ . (b) Cyclobutane,  $C_4H_8$ . (c) Cyclohexane,  $C_6H_{12}$ .

carbon atoms as the ring compound. Bonding in the cycloalkanes involves  $sp^3$  hybridization of the carbon atoms, just as in the straight-chain alkanes. But, coupling the tetrahedral angle of  $109.5^\circ$  with the restriction of a cyclic structure leads to two new interesting structural features that introduce *strain energy* in the cycloalkanes and influence the stability of their conformations.

It is easy to see from inspection of molecular models that two distinct conformations of cyclohexane can be formed when the tetrahedral angle is maintained at each carbon atom. These are called either the **boat conformation** or the **chair conformation** because of their resemblance to these objects (Fig. 7.8). The chair conformation has four carbon atoms in a plane with one carbon atom above and one carbon atom below that plane, located on opposite sides of the molecule. The boat conformation also has four carbon atoms in a plane, but both of the remaining atoms are located above this plane. Both conformations exist and appear to interconvert rapidly at room temperature through a sequence of rotations about single bonds (see Fig. 7.3). The chair conformation is significantly more stable than the boat configuration, because the hydrogen atoms can become quite close and interfere with one another in the boat conformation. When atoms that are not bonded to each other come sufficiently close in space to experience a repulsive interaction, this increase in potential energy reduces the stability of the molecule. Such interactions are called *steric strain*, and they play a significant role in determining the structure of polyatomic molecules. When the hydrogen atoms on cyclohexane are replaced with larger substituents, these effects can prevent interconversion between the boat and chair conformations. This effect is seen in many large molecules of biological significance, where the cyclohexane ring is an important structural unit, locked into one of its conformations.

**FIGURE 7.8** The conformations of cyclohexane. (a) Chair. (b) Boat.

Consider the possibility that cyclohexane could have a planar hexagonal structure. Then each C—C—C bond angle would be  $120^\circ$  resulting in angle strain of  $10.5^\circ$ . This distortion of the bond angle from the tetrahedral value increases the potential energy of the bond above its equilibrium value (which can be understood qualitatively using VSEPR; see Section 3.11), and the resulting **angle strain** energy reduces the stability of the molecule. Cyclohexane minimizes this effect through rotation about single bonds. The geometries of organic molecules are those that minimize the total strain, balancing the opposing contributions from angle and steric strain. The smallest cycloalkanes, namely, cyclopropane and cyclobutane, have much less freedom to rotate about single bonds. Consequently, they are strained compounds because the C—C—C bond angle is  $60^\circ$  (in  $C_3H_6$ ) or  $90^\circ$  (in  $C_4H_8$ ), which is far less than the normal tetrahedral angle of  $109.5^\circ$ . As a result, these compounds are more reactive than the heavier cycloalkanes or their straight-chain analogs, propane and butane.

### 7.2.3 Branched-Chain Alkanes and Isomerism

A **branched-chain alkane** is a hydrocarbon that contains only C—C and C—H single bonds, but in which the carbon atoms are no longer arranged in a

(a)

(b)

**FIGURE 7.9** Two isomeric hydrocarbons with the molecular formula  $C_4H_{10}$ . (a) Butane. (b) 2-Methylpropane.

**TABLE 7.2**

Alkyl Side Groups

Name	Formula
Methyl	$-CH_3$
Ethyl	$-CH_2CH_3$
Propyl	$-CH_2CH_2CH_3$
Isopropyl	$-CH(CH_3)_2$
Butyl	$-CH_2CH_2CH_2CH_3$

straight chain. One or more carbon atoms in each molecule is bonded to three or four other carbon atoms, rather than to only one or two as in the normal alkanes (*n*-alkanes) or cycloalkanes. The simplest branched-chain molecule (Fig. 7.9) is 2-methylpropane, sometimes referred to as isobutane. This molecule has the same molecular formula as butane ( $C_4H_{10}$ ) but a different bonding structure in which the central carbon atom is bonded to three  $-CH_3$  groups and only one hydrogen atom. The compounds butane and 2-methylpropane are each called a **geometrical isomer** of the other. The molecules have the same formula but different three-dimensional structures that can be interconverted only by breaking and re-forming chemical bonds.

The number of possible geometrical isomers increases rapidly with increasing numbers of carbon atoms. Butane and 2-methylpropane are the only two isomers with the chemical formula  $C_4H_{10}$ , but there are three isomers of  $C_5H_{12}$ , five isomers of  $C_6H_{14}$ , nine isomers of  $C_7H_{16}$ , and millions of isomers of  $C_{30}H_{62}$ . A systematic procedure for naming these isomers has been codified by the International Union of Pure and Applied Chemistry (IUPAC). The following set of rules is a part of that procedure:

1. Find the longest continuous chain of carbon atoms in the molecule. The molecule is named as a derivative of this alkane. In Figure 7.9b, a chain of three carbon atoms can be found; thus, the molecule is a derivative of propane.
2. The hydrocarbon groups attached to the chain are called alkyl groups. Their names are obtained by dropping the ending *-ane* from the corresponding alkane and replacing it with *-yl* (Table 7.2). The methyl group,  $CH_3$ , is derived from methane ( $CH_4$ ), for example. Note that the isopropyl group attaches by its middle carbon atom. Alkyl side groups not bonded to a hydrocarbon chain, as represented in Table 7.2, are free radicals, neutral species with a single unpaired electron.
3. Number the carbon atoms along the chain identified in rule 1. Identify each alkyl group by the number of the carbon atom at which it is attached to the chain. The methyl group in the molecule in Figure 7.9b is attached to the second of the three carbon atoms in the propane chain; therefore, the molecule is called 2-methylpropane. The carbon chain is numbered from the end that gives the lowest number for the position of the first attached group.
4. If more than one alkyl group of the same type is attached to the chain, use the prefixes *di-* (two), *tri-* (three), *tetra-* (four), *penta-* (five), and so forth to specify the total number of such attached groups in the molecule. Thus, 2,2,3-trimethylbutane has two methyl groups attached to the second carbon atom and one to the third carbon atom of the four-atom butane chain. It is an isomer of heptane ( $C_7H_{16}$ ).
5. If several types of alkyl groups appear, name them in alphabetical order. Ethyl is listed before methyl, which appears before propyl.

**EXAMPLE 7.1**

Name the following branched-chain alkane:

**Solution**

The longest continuous chain of carbon atoms is six, so this is a derivative of hexane. Number the carbon atoms starting from the left.

(Continued)

Methyl groups are attached to carbon atoms 2 and 4, and an ethyl group is attached to atom 4. The name is thus 4-ethyl-2,4-dimethylhexane. Note that if we had started numbering from the right, the higher number 3 would have appeared for

the position of the first methyl group; therefore, the numbering from the left is preferred.

**Related Problems: 7, 8, 9, 10, 11, 12**

**Optical isomerism, or chirality,** is a second type of isomerism that is characteristic of organic molecules. A carbon atom that makes single bonds to four different atoms or groups of atoms can exist in two forms that are mirror images of each other but that cannot be interconverted without breaking and re-forming bonds (Fig. 7.10). If a mixture of the two forms is resolved into its optical isomers, the two forms rotate the plane of polarized light in different directions; therefore, such molecules are said to be “optically active.” Although paired optical isomers have identical physical properties, their chemical properties can differ when they interact with other optically active molecules. As discussed in Section 23.4, proteins and other biomolecules are optically active. One goal of pharmaceutical research is to prepare particular optical isomers of carbon compounds for medicinal use. In many cases, one optical isomer is beneficial and the other is useless or even harmful.

The fraction of branched-chain alkanes in gasoline affects how it burns in an engine. Gasoline consisting entirely of straight-chain alkanes burns unevenly, causing “knocking” that can damage the engine. Blends that are richer in branched-chain and cyclic alkanes burn with much less knocking. Smoothness of combustion is rated quantitatively via the **octane number** of the gasoline, which was defined in 1927 by selecting as references one compound that causes large amounts of knocking and another that causes little to no knocking. Pure 2,2,4-trimethylpentane (commonly known as isooctane) burns smoothly and was assigned an octane number of 100. Of the compounds examined at the time, pure heptane caused the most knocking and was assigned octane number 0. Mixtures of heptane and isooctane cause intermediate amounts of knocking. Standard mixtures of these two compounds define a scale for evaluating the knocking caused by real gasolines, which are complex mixtures of branched- and straight-chain hydrocarbons. If a gasoline sample produces the same amount of knocking in a test engine as a mixture of 90% (by volume) 2,2,4-trimethylpentane and 10% heptane, it is assigned the octane number 90.

Certain additives increase the octane rating of gasoline. The least expensive of these is tetraethyllead,  $\text{Pb}(\text{C}_2\text{H}_5)_4$ , a compound that has weak bonds between the central lead atom and the ethyl carbon atoms. It readily releases ethyl radicals ( $\cdot\text{C}_2\text{H}_5$ ) into the gasoline during combustion; these reactive species speed and smooth the combustion process, reducing knocking and giving better fuel performance. A **radical** is an atom or molecule that has one or more unpaired electrons; a radical that is electrically neutral is called a **free radical**. Chlorine atoms and oxygen molecules are both free radicals, for example, with one and

**FIGURE 7.10** A molecule such as  $\text{CHBrClF}$ , which has four different atoms or groups of atoms bonded to a single carbon atom, exists in two mirror-image forms that cannot be superimposed by rotation of the molecule in space. Such pairs of molecules are optical isomers; the carbon atom is called a chiral center.

two unpaired electrons, respectively. The lead released into the atmosphere is a long-term health hazard and poisons catalytic converters (Section 18.8), rendering them ineffective. Leaded gasoline has been phased out and other low-cost additives have been developed to increase octane numbers. Chemical processing to make branched-chain compounds from straight-chain compounds is also used to control the octane number of gasoline.

## 7.3 The Alkenes and Alkynes

The hydrocarbons discussed so far in this chapter are referred to as **saturated**, because all the carbon–carbon bonds are single bonds. Any hydrocarbon that has double and triple carbon–carbon bonds is referred to as an **unsaturated hydrocarbon** (Fig. 7.11). Ethene ( $C_2H_4$ ) has a double bond between its carbon atoms and is called an **alkene**. The simplest **alkyne** is acetylene ( $C_2H_2$ ), which has a triple bond between its carbon atoms. In naming these compounds, the *-ane* ending of the corresponding alkane is replaced by *-ene* when a double bond is present and by *-yne* when a triple bond is present. Ethyne is thus the systematic name for acetylene, although we will continue to use its more common name. For any compound with a carbon backbone of four or more carbon atoms, it is necessary to specify the location of the double or triple bond. This is done by numbering the carbon–carbon bonds and putting the number of the lower numbered carbon involved in the multiple bond before the name of the alkene or alkyne. Thus, the two different isomeric alkynes with the formula  $C_4H_6$  are

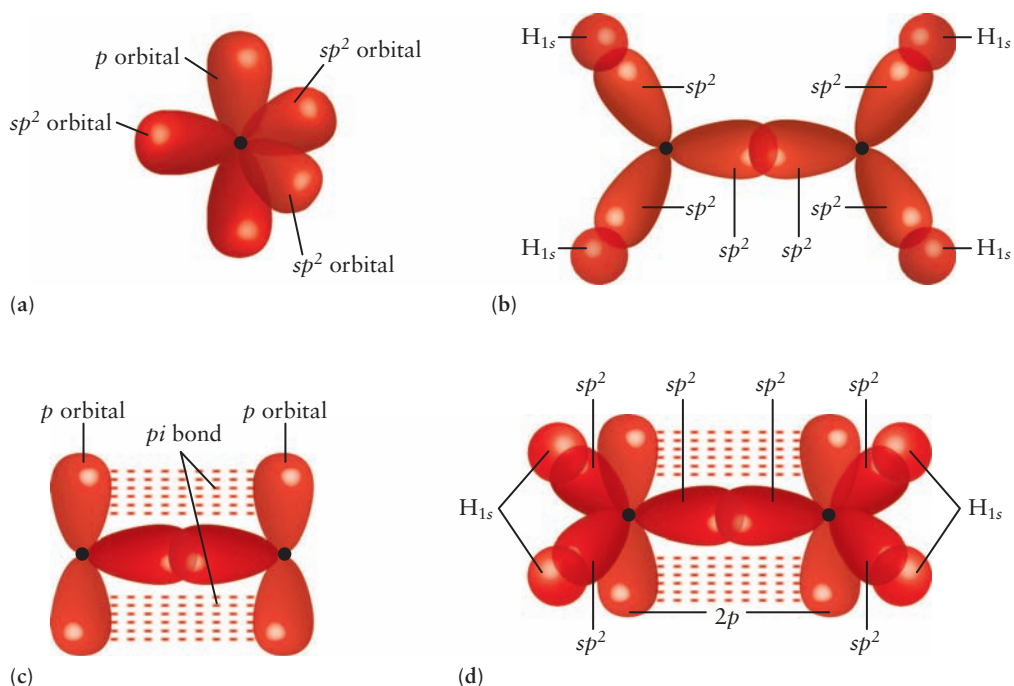

Bonding in alkenes is described by the VB method with  $sp^2$  hybrid orbitals on each carbon atom. (This method is described in Section 6.8 and shown in Figures 6.42 and 6.43. You should review that material before proceeding.) Figure 7.12a shows the three  $sp^2$  hybrid orbitals and the nonhybridized  $2p_z$  orbital. A  $\sigma$  bond is formed between the carbon atoms by overlap of one  $sp^2$  orbital on each carbon atom, and the remaining four  $sp^2$  orbitals form  $\sigma$  bonds with the four hydrogen atoms, as shown in Figure 7.12b. The nonhybridized  $2p_z$  orbitals on the two carbon atoms are oriented parallel to one other and overlap to form a  $\pi$  bond (Fig. 7.12c). The overall result is the formation of a double bond between the two carbon atoms (Fig. 7.12d).

Bonding in alkynes is explained by  $sp$  hybridization (see description in Section 6.8 and illustrations in Figs. 6.44 and 6.45). Figure 7.13a shows two

**FIGURE 7.11** One way to distinguish alkanes from alkenes is by their reactions with aqueous  $KMnO_4$ . This strong oxidizing agent does not react with hexane and retains its purple color (left). But, when  $KMnO_4$  is placed in contact with 1-hexene, a redox reaction occurs in which the brown solid  $MnO_2$  forms (right) and  $-OH$  groups are added to both sides of the double bond in the 1-hexene, giving a compound with the formula  $CH_3(CH_2)_3CH(OH)CH_2OH$ .

(c) Overlap of two mutually perpendicular pairs of nonhybridized  $p$  orbitals to form two perpendicular  $\pi$  bonds. (d) The complete bonding scheme includes a C≡C triple bond and two C–H single bonds.

Figure 7.13d shows the complete bonding scheme with the formation of two C–H bonds formed by overlap of two carbon  $sp$  orbitals with two H  $1s$  orbitals.

As explained later in this chapter, bond rotation does not occur readily about a carbon–carbon double bond. Many alkenes therefore exist in contrasting isomeric forms, depending on whether bonding groups are on the same (*cis*) or opposite (*trans*) sides of the double bond. There is only a single isomer of 1-butene but two of 2-butene, distinguished by the two possible placements for the outer  $\text{CH}_3$  groups relative to the double bond:

**FIGURE 7.14** The overlap between the two  $p$  orbitals decreases when the 2-butene molecule is twisted about the C–C bond. The bonding MO becomes a nonbonding MO, and the energy of the molecule increases.

These compounds differ in melting and boiling points, density, and other physical and chemical properties.

The structures and bonding in substituted alkenes and alkynes can be described through the combined molecular orbital (MO) and VB picture presented in Section 6.11, which uses localized VB bonds to describe the molecular framework and delocalized MOs to describe the  $\pi$  electrons. Let's apply this method to 2-butene ( $\text{CH}_3\text{CHCHCH}_3$ ) and gain deeper understanding of the isomers discussed earlier. The Lewis diagram for 2-butene is

From the valence shell electron-pair repulsion (VSEPR) theory, the steric number of the two outer carbon atoms is 4 (so they are  $sp^3$  hybridized), and that of the two central carbon atoms is 3 ( $sp^2$  hybridized). The bonding around the outer carbon atoms is tetrahedral, and that about the central ones is trigonal planar. Each localized  $\sigma$  bond uses two electrons, resulting in a single bond between each pair of bonding atoms. In the case of 2-butene, these placements use 22 of the 24 available valence electrons, forming a total of 11 sigma bonds.

Next, the remaining  $p$  orbitals that were not involved in hybridization are combined to form  $\pi$  MOs. The  $p_z$  orbitals from the two central carbon atoms can be mixed to form a  $\pi$  (bonding) MO and a  $\pi^*$  (antibonding) MO. The remaining two valence electrons are placed into the  $\pi$  orbital, resulting in a double bond between the central carbon atoms. If the  $p_z$  orbital of one of these atoms is rotated about the central C–C axis, its overlap with the  $p_z$  orbital of the other carbon atom changes (Fig. 7.14). The overlap is greatest and the energy lowest when the two  $p_z$  orbitals are parallel to each other. In the most stable molecular geometry, the hydrogen atoms on the central carbon atoms lie in the same plane as the C–C–C–C carbon skeleton. This prediction is verified by experiment.

Figure 7.15 shows the structures of the isomers *cis*-2-butene and *trans*-2-butene. Converting one form to the other requires breaking the central  $\pi$  bond (by rotating the two  $p_z$  orbitals  $180^\circ$  with respect to each other as in Fig. 7.14), then re-forming it in the other configuration. Because breaking a  $\pi$  bond costs a significant amount of energy, both *cis* and *trans* forms are stable at room temperature, and interconversion between the two is slow. *Cis-trans* isomerization can be induced in photochemical reactions, however (see Section 20.6). Molecules such as *trans*-2-butene can absorb ultraviolet light, which excites an electron from a  $\pi$  to a  $\pi^*$  MO. In the excited electronic state of *trans*-2-butene, the carbon–carbon double bond is effectively reduced to a single bond, and one  $\text{CH}_3$  group can rotate relative to the other to form *cis*-2-butene.

**FIGURE 7.15** The two *cis-trans* isomers of 2-butene.

## EXAMPLE 7.2

The Lewis diagram for propyne ( $\text{CH}_3\text{CCH}$ ) is

Discuss its bonding and predict its geometry.

**Solution**

The leftmost carbon atom in the structure is  $sp^3$  hybridized, and the other two carbon atoms are  $sp$  hybridized. The atoms in the

molecule are located on a single straight line, with the exception of the three hydrogen atoms on the leftmost carbon atom, which point outward toward three of the vertices of a tetrahedron. There is a  $\sigma$  bond between each pair of bonded atoms. The  $p_x$  and  $p_y$  orbitals on carbon atoms 2 and 3 combine to form two  $\pi$  orbitals and two  $\pi^*$  orbitals; only the former are occupied in the ground-state electron configuration.

**Related Problems:** 13, 14

Compounds with two double bonds are called *dienes*, those with three double bonds are called *trienes*, and so forth. The compound 1,3-pentadiene, for example, is a derivative of pentane with two double bonds:

Each double bond in **polyenes** may lead to *cis* and *trans* conformations, depending on its neighboring groups; therefore, several isomers may have the same bonding patterns but different molecular geometries and physical properties.

When two or more double or triple bonds occur close to each other in a molecule, delocalized  $\pi$  bonding may best describe the bonding. See Section 6.11.4 for a detailed description of the delocalized  $\pi$  orbitals of 1,3-butadiene ( $\text{CH}_2\text{CHCHCH}_2$ ).

Alkenes are not present to a significant extent in crude petroleum. They are essential starting compounds for the synthesis of organic chemicals and polymers, however, so their production from alkanes is of great importance. One way to produce alkenes is by **cracking** the petroleum using heat or catalysts. In **catalytic cracking**, the heavier fractions from the distillation column (compounds of  $\text{C}_{12}$  or higher) are passed over a silica–alumina catalyst at temperatures of  $450^\circ\text{C}$  to  $550^\circ\text{C}$ . Catalysts increase reaction rates without being consumed or produced by the reaction (see Section 18.8). Reactions such as

occur to break the long chain into fragments. This type of reaction accomplishes two purposes. First, the shorter chain hydrocarbons have lower boiling points and can be added to gasoline. Second, the alkenes that result have higher octane numbers than the corresponding alkanes and perform better in the engine. Moreover, these alkenes can react with alkanes to give the more highly branched alkanes that are desirable in gasoline. **Thermal cracking** uses higher temperatures of  $850^\circ\text{C}$  to  $900^\circ\text{C}$  and no catalyst. It produces shorter chain alkenes, such as ethene and propene, through reactions such as

The short-chain alkenes are too volatile to be good components of gasoline, but they are among the most important starting materials for chemical synthesis.

## 7.4 Aromatic Hydrocarbons

Our final example of a group of hydrocarbons found in crude petroleum is the **aromatic hydrocarbon**, of which benzene is the simplest example. Benzene is a

cyclic molecule with the formula  $C_6H_6$ . In the language of Chapter 3, benzene is represented as a resonance hybrid of two Lewis diagrams:

The modern view of resonant structures is that the molecule does not jump between two structures, but rather has a single, time-independent electron distribution in which the  $\pi$  bonding is described by delocalized MOs. Each carbon atom is  $sp^2$  hybridized, and the remaining six  $p_z$  orbitals combine to give six MOs delocalized over the entire molecule. The  $\pi$  MOs are described in Section 6.11, and depicted in Figure 6.54 with their energy level diagram. In the ground electronic state of benzene, the three bonding  $\pi$  orbitals are occupied. As a result, benzene has six carbon-carbon bonds of equal length whose properties are intermediate between those of single and double bonds.

Benzene is sometimes represented by its chemical formula  $C_6H_6$  and sometimes (to show structure) by a hexagon with a circle inside it:

The six points of the hexagon represent the six carbon atoms, with the hydrogen atoms omitted for simplicity. The circle represents the de-localized  $\pi$  electrons, which are spread out evenly over the ring. The molecules of other aromatic compounds contain benzene rings with various side groups or two (or more) benzene rings linked by alkyl chains or fused side by side, as in naphthalene ( $C_{10}H_8$ ):

The most prevalent aromatic compounds in petroleum, other than benzene, are toluene, in which one hydrogen atom on the benzene ring is replaced by a methyl group, and the xylenes, in which two such replacements are made:

This set of compounds is referred to as BTX (for *benzene-toluene-xylene*). The BTX in petroleum is important to polymer synthesis (see Section 23.1). These components also significantly increase octane numbers and are used to make high-performance fuels with octane numbers above 100, as are required in modern aviation. There are ring compounds that contain alternating single and double bonds that are not aromatic. Only those ring compounds with  $4n + 2$   $\pi$  electrons

**FIGURE 7.16** The reforming reaction that produces benzene from hexane uses a bifunctional catalyst of platinum metal supported on alumina. Platinum catalyzes hydrogenation/dehydrogenation reactions (blue arrows) while the alumina catalyzes ring opening and closing reactions (red arrows). It is common in reaction schemes of this type to omit most of the hydrogen atoms. The carbon atom at each vertex is assumed to have enough hydrogen atoms to satisfy the octet rule.

are considered to be aromatic, on the basis of an additional stability conferred by that electronic configuration.

A major advance in petroleum refining has been the development of **reforming reactions**, which produce BTX aromatics from straight-chain alkanes that contain the same numbers of carbon atoms. A fairly narrow distillation fraction that contains only  $\text{C}_6$  to  $\text{C}_8$  alkanes is taken as the starting material. The reactions use high temperatures and transition-metal catalysts such as platinum or rhenium on alumina supports, and their detailed mechanisms are not fully understood. Apparently, a normal alkane such as hexane is cyclized and dehydrogenated to give benzene as the primary product (Fig. 7.16). Heptane yields mostly toluene, and octane yields a mixture of xylenes. Toluene is replacing benzene as a solvent in industrial applications because tests on laboratory animals show it to be far less carcinogenic (cancer-causing) than benzene. Benzene is more important than toluene as a starting material for chemical synthesis; so a large fraction of the toluene produced is converted to benzene by **hydrodealkylation**:

This reaction is conducted at high temperatures ( $550\text{--}650^\circ\text{C}$ ) and pressures of 40 to 80 atm.

## 7.5 Fullerenes

Among the most interesting conjugated  $\pi$  electron systems is a molecule discovered in 1985: buckminsterfullerene,  $C_{60}$ . Previously, only two forms of pure carbon (diamond and graphite) were known. In 1985, Harold Kroto, Robert Curl, and Richard Smalley were studying certain long-chain carbon molecules that had been discovered in the vicinity of red giant stars by radioastronomers using spectroscopy. They sought to duplicate the conditions near those stars by vaporizing a graphite target with a laser beam. Analysis of the products by mass spectrometry demonstrated not only the hoped-for molecules but a large proportion of molecules of molar mass  $720 \text{ g mol}^{-1}$ , which corresponds to the molecular formula  $C_{60}$ . Although the amounts of  $C_{60}$  present were far too small to isolate for direct determination of molecular structure, Kroto, Curl, and Smalley correctly suggested the cage structure shown in Figure 7.17a and named the molecule *buckminsterfullerene* after the architect Buckminster Fuller, the inventor of the geodesic dome, which the molecular structure of  $C_{60}$  resembles.

Molecules of  $C_{60}$  have a highly symmetric structure: 60 carbon atoms are arranged in a closed net with 20 hexagonal faces and 12 pentagonal faces. The pattern is exactly the design on the surface of a soccer ball (see Fig. 7.17b). Every carbon atom has a steric number of 3; all 60 atoms are  $sp^2$  hybridized accordingly, although 1 of the 3 bond angles at each carbon atom must be distorted from the usual  $120^\circ$   $sp^2$  bond angle down to  $108^\circ$ . The  $\pi$  electrons of the double bonds are de-localized: The 60  $p$  orbitals (1 from each carbon atom) mix to give 60 MOs with amplitude spread over both the inner and outer surfaces of the molecule. The lowest 30 of these MOs are occupied by the 60  $\pi$  electrons.

Scientists succeeded in synthesizing  $C_{60}$  in gram quantities, in 1990, by striking an electric arc between two carbon rods held under an inert atmosphere. The carbon vapors condensed to form soot, which was extracted with an organic solvent. Using chromatography, the scientists could separate the  $C_{60}$ —first as a solution of a delicate magenta hue and, finally, as a crystalline solid—from the various impurities in the growth batch.  $C_{60}$  has subsequently been found in soot-forming flames when hydrocarbons are burned. Thus, the newest form of carbon has been (in the words of one of its discoverers) “under our noses since time immemorial.” In 1994, the first buckminsterfullerene molecules were brought back from outer space in the form of the impact crater from a tiny meteorite colliding with an orbiting spacecraft.

Buckminsterfullerene is not the only new form of carbon to emerge from the chaos of carbon vapor condensing at high temperature. Synthesis of  $C_{60}$

**FIGURE 7.17** (a) The structure of  $C_{60}$ , buckminsterfullerene. Note the pattern of hexagons and pentagons. (b) The design on the surface of a soccer ball has the same pattern as the structure of  $C_{60}$ .

**FIGURE 7.18** A bundle of carbon nanotubes, each about 1.4 nm in diameter. The bundle is 10 to 20 nm in thickness.

simultaneously produces a whole family of closed-cage carbon molecules called **fullerenes**. All the fullerenes have even numbers of atoms, with formulas ranging up to  $C_{400}$  and even higher. These materials offer exciting prospects for technical applications. For example, because  $C_{60}$  readily accepts and donates electrons to or from its  $\pi$  MOs, it has possible applications in batteries. It forms compounds (such as  $Rb_3C_{60}$ ) that are superconducting (have zero resistance to the passage of an electric current) up to 30 K. Fullerenes also can encapsulate foreign atoms present during synthesis. If a graphite disk is soaked with a solution of  $LaCl_3$ , dried, and used as a laser target, the substance  $La@C_{60}$  forms, where the symbol @ means that the lanthanum atom is trapped within the 60-atom carbon cage.

Condensation of the carbon vapor under certain conditions favors the formation of *nanotubes*, which consist of seamless, cylindrical shells of thousands of  $sp^2$  hybridized carbon atoms arranged in hexagons. The ends of the tubes are capped by pentagons inserted into the hexagonal network. These structures all have a de-localized  $\pi$ -electron system that covers the inner and outer surfaces of the cage or cylinder. Nanotubes also offer exciting prospects for material science and technological applications. For example, the mechanical properties of nanotubes suggest applications as high-strength fibers (Fig. 7.18).

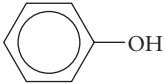

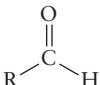

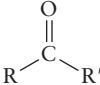

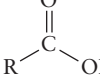

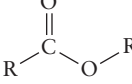

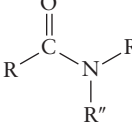

## 7.6 Functional Groups and Organic Reactions

We discussed petroleum refining and the various classes of hydrocarbons produced in Sections 7.1–7.4. We now consider the structures, properties, and reactions of molecules formed by adding substituent atoms such as oxygen, nitrogen, and the halogens to the hydrocarbon backbone. In doing so, we shift our attention from the structures of entire molecules to the properties of **functional groups**, which are atoms or groups of atoms within molecules, with characteristic physical and chemical properties that are largely independent of the molecules of which they are a part. Organic chemists have identified functional groups on the basis of patterns of chemical reactivity. This fact permits us to regard an organic molecule as a hydrocarbon frame, which mainly governs size and shape, to which are attached functional groups that mainly determine the chemistry of the molecule. Table 7.3 shows some of the most important functional groups.

A few small molecules (methane, ethene, propene, benzene, and xylene) derived from petroleum or natural gas and their derivatives are the starting materials for chemicals produced in high-volume industrial processes. This section introduces the common functional groups, describes their bonding, and illustrates typical reactions in their synthesis or applications.

TABLE 7.3

## Common Functional Groups

Functional Group†	Type of Compound	Examples
R-F, -Cl, -Br, -I	Alkyl or aryl halide	CH <sub>3</sub> CH <sub>2</sub> Br (bromoethane)
R-OH	Alcohol	CH <sub>3</sub> CH <sub>2</sub> OH (ethanol)
	Phenol	C <sub>6</sub> H <sub>5</sub> -OH (phenol)
R-O-R'	Ether	H <sub>3</sub> C-O-CH <sub>3</sub> (dimethyl ether)
	Aldehyde	CH <sub>3</sub> CH <sub>2</sub> CH <sub>2</sub> -C(=O)-H (butyraldehyde, or butanal)
	Ketone	H <sub>3</sub> C-C(=O)-CH <sub>3</sub> (propanone, or acetone)
	Carboxylic acid	CH <sub>3</sub> COOH (acetic acid)
	Ester	H <sub>3</sub> C-C(=O)-O-CH <sub>3</sub> (methyl acetate)
R-NH <sub>2</sub>	Amine	CH <sub>3</sub> NH <sub>2</sub> (methylamine)
	Amide	H <sub>3</sub> C-C(=O)-NH <sub>2</sub> (acetamide)

†The symbols R, R', and R'' stand for alkyl groups such as CH<sub>3</sub> or C<sub>2</sub>H<sub>5</sub>. In some cases, they may represent an H atom.

### 7.6.1 Halides

One of the simplest functional groups consists of a single halogen atom, which we take to be chlorine for illustrative purposes. The chlorine atom forms a  $\sigma$  bond to a carbon atom by overlap of its  $3p_z$  orbital with a hybridized orbital on the carbon. The hybridized orbital may be  $sp^3$ ,  $sp^2$ , or  $sp$  depending on the bonding in the hydrocarbon frame. An **alkyl halide** forms when mixtures of alkanes and halogens (except iodine) are heated or exposed to light.

The mechanism is a free radical chain reaction (see Section 18.4). Ultraviolet light initiates the reaction by dissociating a small number of chlorine molecules into highly reactive chlorine radicals. The chlorine radical abstracts a hydrogen atom from methane to form HCl and a methyl radical. Chlorine atoms and methyl radicals are both free radicals, which means that they are neutral species with one unpaired electron. Free radicals are often very reactive because they

have incomplete octets and because the products formed by abstraction reactions are often very stable:

The chlorine atoms and the methyl species are called free radicals, and are denoted by the dots next to the chemical symbols. A **free radical** is a chemical species that contains an odd (unpaired) electron; it is usually formed by breaking a covalent bond to form a pair of such species. They often appear as intermediates in reactions. Chloromethane (also called methyl chloride) is used in synthesis to add methyl groups to organic molecules. If sufficient chlorine is present, more highly chlorinated methanes form, providing a route for the industrial synthesis of dichloromethane ( $\text{CH}_2\text{Cl}_2$ , also called methylene chloride), trichloromethane ( $\text{CHCl}_3$ , chloroform), and tetrachloromethane ( $\text{CCl}_4$ , carbon tetrachloride). All three chloromethanes are used as solvents and their vapors have anesthetic or narcotic effects; environmental and health concerns have led to their production and use being highly regulated.

Adding chlorine to  $\text{C}=\text{C}$  bonds is a more important industrial route to alkyl halides than the free-radical reactions just described. Billions of kilograms of 1,2-dichloroethane (sometimes called by its old, now incorrect, name of ethylene dichloride) are manufactured each year, making this compound the largest organic chemical produced by volume. It is made by adding chlorine to ethene over an iron(III) oxide catalyst at moderate temperatures ( $40\text{--}50^\circ\text{C}$ ), either in the vapor phase or in a solution of 1,2-dibromoethane:

Almost all of the 1,2-dichloroethane produced is used to make chloroethene (vinyl chloride,  $\text{CH}_2=\text{CHCl}$ ). This is accomplished by heating the 1,2-dichloroethane to  $500^\circ\text{C}$  over a charcoal catalyst to abstract HCl:

The HCl can be recovered and converted to  $\text{Cl}_2$  for further production of 1,2-dichloroethane from ethene. Vinyl chloride has a much lower boiling point than 1,2-dichloroethane ( $-13^\circ\text{C}$  compared with  $84^\circ\text{C}$ ), so the two are easily separated by fractional distillation. Vinyl chloride is used in the production of polyvinyl chloride plastic (see Section 23.1).

## 7.6.2 Alcohols and Phenols

**Alcohols** have the  $-\text{OH}$  functional group attached to a tetrahedral carbon atom, that is, a carbon atom with single bonds to four other atoms. The carbon atom in the functional group is  $sp^3$  hybridized. The oxygen atom is likewise  $sp^3$  hybridized; two of the hybrid orbitals form  $\sigma$  bonds, whereas the other two hold lone pairs of electrons.

The simplest alcohol is methanol ( $\text{CH}_3\text{OH}$ ), which is made from methane in a two-step process. The first is the **reforming reaction**

conducted at high temperatures ( $750\text{--}1000^\circ\text{C}$ ) with a nickel catalyst. The gas mixture that results, called **synthesis gas**, reacts directly to form methanol at  $300^\circ\text{C}$ .

The next higher alcohol, ethanol ( $\text{CH}_3\text{CH}_2\text{OH}$ ) (Fig. 7.19), can be produced from the fermentation of sugars. Although fermentation is the major source of

FIGURE 7.19 Ethanol (an alcohol).

ethanol for alcoholic beverages and for gasoline additives (like E10 or E85, where the number is the percent alcohol by volume), it is not significant for industrial production, which relies on the direct hydration of ethene:

Temperatures of 300°C to 400°C and pressures of 60 to 70 atm are used with a phosphoric acid catalyst. Both methanol and ethanol are used widely as solvents and as intermediates for further chemical synthesis.

Two three-carbon alcohols exist, depending on whether the —OH group is attached to a terminal carbon atom or the central carbon atom. They are named 1-propanol and 2-propanol:

1-Propanol and 2-propanol are commonly referred to as *n*-propyl alcohol and isopropyl alcohol, respectively. The systematic names of alcohols are obtained by replacing the *-ane* ending of the corresponding alkane with *-anol* and using a numeric prefix, when necessary, to identify the carbon atom to which the —OH group is attached.<sup>1</sup> Isopropanol is manufactured by the acid-catalyzed direct hydration of propene, the first step of which is

producing a transient charged species in which the positive charge is centered on the central carbon atom. Water reacts at this positive site to give the following intermediate:

which loses a proton (the catalyst) and produces 2-propanol as follows:

2-propanol is produced preferentially because secondary carbon cations (with the positive charge localized on the carbon atom bonded to two carbon atoms) are more stable than primary carbon cations.

The compound 1-propanol is a *primary alcohol*: The carbon atom to which the —OH group is bonded has exactly one other carbon atom attached to it. The isomeric compound 2-propanol is a *secondary alcohol* because the carbon atom to which the —OH group is attached has two carbon atoms (in the two methyl groups) attached to it. The simplest *tertiary alcohol* (in which the carbon atom attached to the —OH group is also bonded to three other carbon atoms) is 2-methyl-2-propanol:

Primary, secondary, and tertiary alcohols differ in chemical properties.

<sup>1</sup>Compare the names of alcohols with the corresponding names of alkyl halides. If the —OH group were replaced by a chlorine atom, the names of these compounds would be 1-chloropropane and 2-chloropropane.

FIGURE 7.20 The structure of phenol,  $C_6H_5OH$ .

A **phenol** is a compound in which an  $-OH$  group is attached directly to an aromatic ring. The simplest example is phenol itself ( $C_6H_5OH$ , Fig. 7.20). As in the alcohols, the oxygen atom is  $sp^3$  hybridized with two unshared pairs. The carbon atom, which is part of the aromatic ring, is  $sp^2$  hybridized (see Section 7.4).

The manufacture of phenols uses quite different types of reactions from those used to make alcohols. One method, introduced in 1924 and still used to a small extent today, involves the chlorination of the benzene ring followed by reaction with sodium hydroxide:

This approach illustrates a characteristic difference between the reactions of aromatics and alkenes. When chlorine reacts with an alkene, it *adds* across the double bond (as shown in the production of 1,2-dichloroethane). When an aromatic ring is involved, substitution of chlorine for hydrogen occurs instead and the aromatic  $\pi$ -bonding structure is preserved.

A different approach is used to make almost all phenol today. It involves, first, the acid-catalyzed reaction of benzene with propene to give cumene, or isopropyl benzene:

As in the production of 2-propanol, the first step is the addition of  $H^+$  to propene to give  $CH_3-CH^+-CH_3$  (see earlier in this section). This ion then attaches to the benzene ring through its central carbon atom to give the cumene and regenerate  $H^+$ . Subsequent reaction of cumene with oxygen (Fig. 7.21) gives phenol and acetone, an important compound that is discussed later in this section. The main use of phenol is in the manufacturing of polymers and aspirin.

### 7.6.3 Ethers

An **ether** is characterized by the  $-O-$  functional group, in which an oxygen atom provides a link between two separate alkyl or aromatic groups. Figure 7.22

FIGURE 7.21 The synthesis of phenol and acetone from cumene is a two-step process that involves insertion of  $O_2$  into a  $C-H$  bond to make a peroxide ( $R-O-O-R'$ ), followed by acid-catalyzed migration of the  $-OH$  group to form the products.

**FIGURE 7.22** Structure of dimethyl ether. (a) Lewis diagram. (b) Ball-and-stick model.

shows the simplest ether, dimethyl ether. The oxygen atom is  $sp^3$  hybridized. Two of these hybrid orbitals form  $\sigma$  bonds to the carbon atoms, whereas each of the other two holds an unshared pair. The C—O—C bond angle is  $110.3^\circ$ , which is close to the tetrahedral value  $109.5^\circ$  predicted by  $sp^3$  hybridization.

One important ether is diethyl ether, often called simply ether, in which two ethyl groups are linked to the same oxygen atom:

Diethyl ether is a useful solvent for organic reactions, and was formerly used as an anesthetic. It can be produced by a **condensation reaction** (a reaction in which a small molecule such as water is eliminated to join [condense] two species) between two molecules of ethanol in the presence of concentrated sulfuric acid as a dehydrating agent:

Another ether of considerable importance is methyl *t*-butyl ether (MTBE):

This compound appeared to be a successful replacement for tetraethyllead as an additive to increase the octane ratings of gasolines. The bond between the oxygen and the *t*-butyl group is weak, and it breaks to form radicals that assist the smooth combustion of gasoline. MTBE is readily soluble in water, however, and it has appeared in drinking water supplies through leaks from underground storage tanks for gasoline. Concern over possible health risks has caused MTBE to be phased out in various regions of the United States.

In a cyclic ether, oxygen forms part of a ring with carbon atoms, as in the common solvent tetrahydrofuran (Fig. 7.23). The smallest such ring has two carbon atoms bonded to each other and to the oxygen atom; it occurs in oxirane, commonly called ethylene oxide,

**FIGURE 7.23** The structure of tetrahydrofuran,  $\text{C}_4\text{H}_8\text{O}$ .

which is made by direct oxidation of ethene over a silver catalyst:

Any ether with three-membered rings is called an **epoxide**. The major use of oxirane is in the preparation of 1,2-dihydroxyethane (commonly called ethylene glycol):

This reaction is conducted either at  $195^\circ\text{C}$  under pressure or at lower temperatures ( $50\text{--}70^\circ\text{C}$ ) with sulfuric acid as a catalyst. 1,2-dihydroxyethane is a di-alcohol, or **diol**, in which two  $-\text{OH}$  groups are attached to adjacent carbon atoms. Its primary use is as a component in antifreeze to decrease the freezing point of water in automobile radiators (see the discussion of colligative properties in Section 11.5).

FIGURE 7.24 Acetaldehyde (an aldehyde).

### 7.6.4 Aldehydes and Ketones

An **aldehyde** contains the characteristic  $\text{—}\overset{\text{O}}{\parallel}{\text{C}}\text{—H}$  functional group (Fig. 7.24). Figure 7.26 shows the bonding in formaldehyde, which is the simplest organic molecule with a double bond between carbon and oxygen. The carbon is  $sp^2$  hybridized and forms  $\sigma$  bonds to two hydrogen atoms. The oxygen is also  $sp^2$  hybridized. Carbon and oxygen form one  $\sigma$  bond by overlap of  $sp^2$  orbitals and one  $\pi$  bond by overlap of parallel nonhybridized  $2p$  orbitals. This is the same bonding model used to describe  $\text{C}=\text{C}$  double bonds in Figure 7.12c.

Aldehydes can be prepared by the dehydrogenation of primary alcohols. Formaldehyde results from the dehydrogenation of methanol at high temperatures using an iron oxide–molybdenum oxide catalyst:

Another reaction that gives the same primary product is the oxidation reaction

Formaldehyde is readily soluble in water, and a 40% aqueous solution of formaldehyde called *formalin* is used to preserve biological specimens. It is a component of wood smoke and helps to preserve smoked meat and fish, probably by reacting with nitrogen-containing groups in the proteins of attacking bacteria. Its major use is in making polymer adhesives and insulating foam.

The next aldehyde in the series is acetaldehyde, the structure of which is shown above. Industrially, acetaldehyde is produced not from ethanol but by the oxidation of ethene, using a  $\text{PdCl}_2$  catalyst.

FIGURE 7.25 Acetone (a ketone).

A **ketone** has the  $\text{—}\overset{\text{O}}{\parallel}{\text{C}}\text{—}$  functional group in which a carbon atom forms a double bond to an oxygen atom and single bonds to two separate alkyl or aromatic groups. The simplest ketone is acetone (Fig. 7.25), in which two methyl groups are bonded to the central carbon. The bonding scheme is the same as that shown in Figure 7.26, with alkyl or aromatic groups replacing hydrogen atoms in the two single bonds. Such compounds can be prepared by dehydrogenation or oxidation of secondary alcohols, just as aldehydes come from primary alcohols. Acetone is made by the dehydrogenation of 2-propanol over a copper oxide or zinc oxide catalyst at  $500^\circ\text{C}$ :

FIGURE 7.26 Bonding in formaldehyde involves  $sp^2$  hybrid orbitals of both the carbon (C) and oxygen (O) atoms. The  $\text{C—O}$   $\sigma$  bond is constructed by overlap of C and O  $sp^2$  hybrid orbitals and the  $\text{C—H}$  bonds from overlap of C  $sp^2$  orbitals with H  $1s$  orbitals. Two lone pairs occupy the other O  $sp^2$  hybrid orbitals. The  $\pi$  bond is formed by overlap of the parallel unhybridized  $2p$  orbitals.

Acetone is also produced (in greater volume) as the coproduct with phenol of the oxidation of cumene (see earlier). It is a widely used solvent and is the starting material for the synthesis of a number of polymers.

**FIGURE 7.27** Acetic acid (a carboxylic acid).

### 7.6.5 Carboxylic Acids and Esters

A **carboxylic acid** contains the  $\text{—}\overset{\text{O}}{\parallel}{\text{C}}\text{—OH}$  functional group (also written as  $\text{—COOH}$ ). The bonding scheme is a variation of that shown in Figure 7.26, in which the doubly bonded oxygen atom is  $sp^2$  hybridized and the singly bonded oxygen is  $sp^3$  hybridized with unshared pairs in two of the hybrid orbitals. Carboxylic acids are the products of the oxidation of aldehydes, just as aldehydes are the products of the oxidation of primary alcohols. (The turning of wine to vinegar is a two-step oxidation leading from ethanol through acetaldehyde to acetic acid.) Acetic acid (Fig. 7.27) can be produced industrially by the air oxidation of acetaldehyde over a manganese acetate catalyst at  $55^\circ\text{C}$  to  $80^\circ\text{C}$ :

The reaction now preferred on economic grounds for acetic acid production is the combination of methanol with carbon monoxide (both derived from natural gas) over a catalyst that contains rhodium and iodine. The overall reaction is

and can be described as a **carbonylation**, or the insertion of CO into the methanol C—O bond.

Acetic acid is a member of a series of carboxylic acids with formulas  $\text{H}-(\text{CH}_2)_n-\text{COOH}$ . The simplest carboxylic acid is formic acid ( $\text{HCOOH}$ ), with  $n = 0$ . This compound was first isolated from extracts of the crushed bodies of ants, and its name stems from the Latin word *formica*, meaning “ant.” Formic acid is the strongest acid of the series, and acid strength decreases with increasing length of the hydrocarbon chain. (See Section 15.8.) Long chain carboxylic acids are called fatty acids. Sodium stearate, the sodium salt of stearic acid,  $\text{CH}_3(\text{CH}_2)_{16}\text{COOH}$ , is a typical component of soap. It cuts grime by simultaneously interacting with grease particles along its hydrocarbon tail and with water molecules at its carboxylate ion end group to make the grease soluble in water.

**FIGURE 7.28** Methyl acetate (an ester).

An **ester** is created when a carboxylic acid reacts with an alcohol or a phenol, with water forming as the coproduct in a condensation reaction. The bonding scheme in esters is a variation of that shown in Figure 7.26, in which the singly bonded oxygen is  $sp^3$  hybridized, with unshared pairs occupying two of the hybrid orbitals. An example is the condensation of acetic acid with methanol to give methyl acetate (Fig. 7.28):

Esters are named by stating the name of the alkyl group of the alcohol (the methyl group in this case), followed by the name of the carboxylic acid with the ending *-ate* (acetate). One of the most important esters in commercial production is vinyl acetate, with the structure

## CONNECTION TO BIOLOGY

## Functional Groups in Proteins

Proteins are natural polymers of amino acids linked by amide bonds to form long polyamide chains. Amides are functional groups produced by condensation reactions of amines with carboxylic acids, reactions that are analogous to those that form esters (see p. 315 for an introduction to amines and amides). The amide bond is generally referred to as a peptide bond in biochemistry and the polyamide chains are generally called polypeptides. Proteins serve a variety of biological functions: structural proteins are long fibers that make up the basic structures of hair, skin, and nails; enzymes are exquisitely selective catalysts for biochemical reactions, and hormones are chemical messengers that send signals to trigger specific biological responses. The structures and functions of proteins are, in large part, determined by the nature of the functional groups of the amino acids from which they are constructed and by the sequences in which they are assembled. An introduction to the structure and function of proteins provides an excellent opportunity to illustrate the utility of the functional group concept in chemistry and biology.

The general structures of the biologically important  $\alpha$ -amino acids are represented by the reactants in the condensation reaction shown below.

There are four different functional groups bonded to the central ( $\alpha$ ) carbon atom: a carboxylic acid group, an amine group, a hydrogen atom, and an R group, which is generally referred to as a side chain in biochemistry. Amino acids are bifunctional molecules, which allows them to form proteins via condensation reactions as shown. The dipeptide, whose structure is not shown, has a free amine group on the left side and a free carboxylic acid group on the right side, which are available to react with the complementary functional groups of other amino acids to form polypeptides of increasing size through condensation polymerization reactions of this

type. The reverse hydrolysis reactions break up proteins into smaller polypeptides and even down to their constituent amino acids.

The 20 common amino acids differ only in the nature of the R groups attached to the  $\alpha$  carbon atom, but those differences lead to a great diversity in the properties of proteins from which they are constructed. The side chains fall into several classes (see Table 23.2) that are defined primarily by their polarity but also by their acid/base character. The nonpolar alkane and aromatic hydrocarbon side chains are called hydrophobic (water avoiding) whereas the water-soluble side chains like alcohols, carboxylic acids, and amines are called hydrophilic (water seeking).

Proteins that consist of a single polypeptide chain are characterized by three levels of structure, whereas those that contain two or more polypeptide subunits, like hemoglobin (see the *Connection to Biology* in Chapter 14) have an additional level of organization. The primary structure is simply the protein's amino acid sequence. The three-dimensional structure of the enzyme chymotrypsin (Fig. C7.1) provides an excellent example of secondary and tertiary protein structures.

Secondary structures are determined primarily by the extent of inter-chain hydrogen bonding; the  $\alpha$ -helix and  $\beta$ -pleated sheets (see Figs. 23.19 and 23.20) are examples of highly organized secondary structures that contrast with less highly organized structures called random coils. Chymotrypsin's  $\alpha$ -helical regions are represented by the coiled ribbons,  $\beta$ -pleated sheets by the broad

**FIGURE C7.1** Three-dimensional structure of the enzyme chymotrypsin. (Adapted from Garrett/Grisham, *Biochemistry*, 4e, Figure 4.17, p. 438, Cengage Learning, 2009, © Cengage Learning)

arrows, and random coils by the thin tubes. Proteins fold to form a variety of global three-dimensional (tertiary) structures that are determined, to a large degree, by the locations of their hydrophobic and hydrophilic regions in the sequence. The hydrophobic regions of proteins tend to be located in the interior of folded proteins, whereas the hydrophilic regions tend to be found on the exterior, where they can interact favorably with water and solvated ions. The folded tertiary structure of chymotrypsin shown is the result of these interactions.

The active site of an enzyme is the site at which catalysis occurs. The active site in chymotrypsin comprises three polar amino acids (the catalytic triad) located in a hydrophobic pocket of the enzyme as shown by the colored space-filling models in the center of the enzyme structure in Fig. C7.1 and in the ball-and-stick models in the expanded view in Figure C7.2 below. Acidic and basic side chains, such as serine (Ser) and aspartic acid (Asp) help catalyze biochemical reactions by transferring protons, as exemplified by the hydrolysis reaction catalyzed by chymotrypsin.

Chymotrypsin is a digestive enzyme that catalyzes the hydrolysis of peptide bonds in proteins; it is a member of a class of proteins called serine proteases because the amino acid serine present in the active site plays a critical role in the reaction mechanism. The selectivity of different serine proteases for specific side chains is remarkable: the hydrophobic pocket in chymotrypsin can accommodate aromatic amino acids, as shown,

**FIGURE C7.2** Expanded view of the active site in chymotrypsin. (The ball-and-stick models omit H atoms except those in the hydrogen bonds between the three amino acids.)

**FIGURE C7.3** Binding of the amino acid phenylalanine in the active site of chymotrypsin. (Adapted from Garrett/Grisham, *Biochemistry*, 4e, Figure 4.18, p. 438, Cengage Learning, 2009, © Cengage Learning.)

whereas a negatively charged amino acid in the active site of the closely related enzyme trypsin binds positively charged amino acids such as arginine and histidine. Binding of the amino acid phenylalanine (the substrate) in the active site is illustrated in Figure C7.3.

The mechanism by which chymotrypsin hydrolyzes peptide bonds is described by the following abbreviated reaction sequence: 1) The aromatic amino acids phenylalanine (shown in the figure) or tyrosine bind in the active site with their aromatic side chains in the hydrophobic pocket. 2) A proton is transferred from the serine  $\text{—OH}$  group to a nitrogen atom of the nearby histidine residue, releasing a pair of electrons to form a covalent anionic intermediate. 3) Proton transfer from the histidine residue to the amino group of the substrate induces electron transfer from the oxygen lone pair on the anion to the amide  $\text{C—N}$  bond, cleaving that bond and releasing the amino-terminated fragment. 4) The carboxyl-terminated fragment covalently binds as an ester to serine. 5) Water finally hydrolyzes the ester bond, releasing the carboxylic acid product. This mechanism, one of the most well established in all of enzyme catalysis, shows the importance of: 1) hydrophobic interactions that allow the active site to selectively bind aromatic amino acids, and 2) spatial organization of the three amino acids in the active site that facilitates bond cleavage by proton transfer among both acidic and basic functional groups. Many enzyme-catalyzed reactions use acidic functional groups in this way to shuttle protons and catalyze the hydrolysis of amide and ester bonds in natural biopolymers.

Despite its name, vinyl acetate is not prepared by the reaction of acetic acid with an alcohol but rather with ethene and oxygen over a catalyst such as  $\text{CuCl}_2$  and  $\text{PdCl}_2$ :

Esters are colorless, volatile liquids that often have pleasant odors. Many esters occur naturally in flowers and fruits. Isoamyl acetate (Fig. 7.29a) is generated in apples as they ripen and contributes to the flavor and odor of the fruit. Benzyl acetate, the ester formed from acetic acid and benzyl alcohol (see Fig. 7.29b), is a major component of oil of jasmine and is used in the preparation of perfumes.

Animal fats and vegetable oils are triesters of long-chain carboxylic acids with glycerol,  $\text{HOCH}_2\text{CH}(\text{OH})\text{CH}_2\text{OH}$ , a trialcohol; they are referred to as **triglycerides**. These are energy-storage molecules of biological origin. A large proportion of sunflower oil is an oily liquid composed of molecules with the structural formula

Molecules of this type are called polyunsaturated because they have more than one double bond. Butter is a mixture of triglycerides, many of which are **saturated** because their hydrocarbon chains contain no double bonds. Hydrogen is used in food processing to convert unsaturated liquid vegetable oils to saturated solids. **Hydrogenation** of sunflower oil with 6 mol  $\text{H}_2$  in the presence of a catalyst saturates it, and the product has a high enough melting point to make it a solid at room conditions. The use of solid fats (or solidified oils) has advantages in food processing and preservation; therefore, “hydrogenated vegetable oil” is an ingredient in many foodstuffs. The distinction between fats and oils is a practical one: fats are solid at room temperature, and oils are liquids. Heavy consumption of saturated fats has been linked to diseases of the heart and circulatory system, and the presence of *unhydrogenated* (polyunsaturated) oils in foods is now extensively advertised. *Trans* fats, which have only one double

**FIGURE 7.29** The structures of (a) isoamyl acetate,  $\text{CH}_3\text{COO}(\text{CH}_2)_2\text{CH}(\text{CH}_3)_2$ , and (b) benzyl acetate,  $\text{CH}_3\text{COOCH}_2\text{C}_6\text{H}_5$ .

bond with hydrocarbon chains in the *trans* configuration, have recently been implicated in heart disease, and a ban on their use in food preparation is under consideration. When a triglyceride is hydrolyzed (by adding water to break bonds, the reverse of condensation) through addition of sodium hydroxide, the ester bonds are broken and glycerol and sodium salts of long-chain carboxylic acids are produced. This reaction is the basis for traditional soap making through the addition of lye (sodium hydroxide) to animal fats.

### 7.6.6 Amines and Amides

Amines are derivatives of ammonia with the general formula  $R_3N$ , where R can represent a hydrocarbon group or a hydrogen atom. If only one hydrogen atom of ammonia is replaced by a hydrocarbon group, the result is a *primary amine*. Examples include ethylamine and aniline:

If two hydrocarbon groups replace hydrogen atoms in the ammonia molecule, the compound is called a *secondary amine* (such as dimethylamine), and three replacements make a *tertiary amine* (trimethylamine). You should draw Lewis dot diagrams for several amines and recognize that the nitrogen atom is  $sp^3$  hybridized and forms three  $\sigma$  bonds with one unshared pair occupying the fourth hybrid orbital. Amines are bases, like ammonia, because the lone pair on the nitrogen atom can act either as a hydrogen ion acceptor or as an electron pair donor (see Section 15.1).

Primary or secondary amines (or ammonia itself) can react with carboxylic acids to form amides, in condensation reactions that are analogous to the formation of esters from alcohols and carboxylic acids. An example of amide formation is

If ammonia is the reactant, an  $-\text{NH}_2$  group replaces the  $-\text{OH}$  group in the carboxylic acid as the amide is formed:

**FIGURE 7.30** Bonding in dimethyl acetamide, an amide. The amide linkage is planar, in agreement with the expectation of delocalized  $\pi$  bonding.

Amide linkages are present in the backbone of every protein molecule and are very important in biochemistry, where the structure of the molecule strongly influences its function (see Section 23.4). The bonding scheme in amides has two resonance structures; both are shown in Figure 7.30. In one resonance structure the doubly bonded carbon and oxygen atoms are  $sp^2$  hybridized and the singly bonded nitrogen atom is  $sp^3$  hybridized with an unshared pair occupying one of the hybrid orbitals. In the other, the N atom is double bonded to the C atom, and has no lone pair, so is  $sp^2$  hybridized, while the CO bond is a single one. The resulting  $\pi$  bonding is delocalized, much like that in  $\text{NO}_2^-$  in Figure 6.52. The four bonds of the amide group lie in the same plane, as shown in Figure 7.30, a fact that has important consequences for the structures of proteins.

## 7.7 Pesticides and Pharmaceuticals

Most of the organic compounds discussed so far in this chapter are relatively small molecules that are produced in large volume. Molecules like these are starting materials for the synthesis of numerous structurally more complex organic compounds with applications in agriculture, medicine, and consumer products. This section discusses a selection of these compounds, all of which are used in agriculture or as pharmaceuticals. Some of the structures and syntheses of these compounds are intricate; do not try to memorize them. Your goals, instead, should be to recognize the hydrocarbon frameworks of the molecules, to recognize functional groups, and to begin to appreciate the extremely diverse structures and properties of organic compounds.

Chemists have developed a shorthand notation to represent the structures of complex organic molecules. These line structures which focus attention to the most important structural elements, are illustrated in Figure 7.31. In this notation, the symbol “C” for a carbon atom is omitted, and only the C—C bonds are shown. A carbon atom is assumed to lie at each end of the line segments that represent bonds. In addition, symbols for the hydrogen atoms attached to carbon atoms are omitted. Terminal carbon atoms (those at the end of chains) and their associated hydrogen atoms are shown explicitly. To generate the full structure (and the molecular formula) from line structures, carbon atoms must be inserted at the end of each bond, and enough hydrogen atoms must be attached to each carbon atom to satisfy its valence of four.

### 7.7.1 Insecticides

The chemical control of insect pests dates back thousands of years. The earliest insecticides were inorganic compounds of copper, lead, and arsenic, as well as some naturally occurring organic compounds such as nicotine (Fig. 7.32a). Few of these “first-generation” insecticides are in use today because of their adverse side effects on plants, animals, and humans.

Controlled organic syntheses developed after World War II gave rise to a second generation of insecticides. The success of these agents led to rapid growth in the use of chemicals for insect control. The leading insecticide of the 1950s and 1960s was DDT (an abbreviation for dichlorodiphenyltrichloroethane; see Fig. 7.32b). DDT was extremely important worldwide in slowing the spread of typhus (transmitted by body lice) and malaria (transmitted by

**FIGURE 7.31** Extended molecular structures for two esters are shown on the left side of the figure with their associated line structures shown on the right. Carbon atoms are assumed to lie at the intersections of the lines representing bonds, and there are enough hydrogen atoms attached to each carbon atom to satisfy its valence. It is customary to show the carbon and hydrogen atoms of terminal methyl groups, however.

**FIGURE 7.32** Structures of several insecticides: (a) nicotine; (b) dichlorodiphenyltrichloroethane (DDT); (c) malathion; and (d) methoprene.

mosquitoes). But mosquitoes developed strong resistance to DDT, and its use was banned in the United States in 1972 because of its adverse effects on birds, fish, and other life-forms that can accumulate DDT to high concentrations. Many other chlorine-substituted hydrocarbons are no longer used as insecticides for the same reason and organophosphorus compounds are used widely instead. The structure of the insecticide malathion, in which phosphorus appears with organic functional groups, is shown in Figure 7.32c. Note the two ester groups, the two kinds of sulfur atoms, and the “expanded octet” (see valence shell expansion in Section 3.10) on the central phosphorus atom that lets it form five bonds.

Second-generation insecticides frequently kill beneficial insects along with the pests unless they are applied at the right times and in properly controlled doses. Third-generation insecticides are more subtle. Many of these are based on sex attractants (to collect insects together in one place before exterminating them or to lead them to mate with sterile partners) or juvenile hormones (to prevent insects from maturing and reproducing). These compounds have the advantages of being specific against the pests and doing little or no harm to other organisms. Moreover, they can be used in small quantities, and they degrade rapidly in the environment. An example is the juvenile hormone methoprene (see Fig. 7.32d), which is used in controlling mosquitoes. It consists of a branched dialkene chain with a methyl ether (methoxy) and an isopropyl-ester functional group.

## 7.7.2 Herbicides

Chemical control of weeds, together with use of fertilizers, has contributed to the “green revolution” that began in the 1940s and during which agricultural productivity has increased dramatically throughout the world. The first herbicide of major importance, introduced in 1945 and still in use today, was 2,4-D

**FIGURE 7.33** Structures of some herbicides. (a) 2,4-D (2,4-dichlorophenoxyacetic acid); (b) TCDD (“dioxin,” or 2,3,7,8-tetrachlorodibenzo-*p*-dioxin); and (c) atrazine.

(2,4-dichlorophenoxyacetic acid; Fig. 7.33a), a derivative of phenol with chlorine and carboxylic acid functional groups. 2,4-D kills broadleaf weeds in wheat, corn, and cotton without unduly persisting in the environment, as the chlorinated insecticides discussed earlier do. A related compound is 2,4,5-T (2,4,5-trichlorophenoxyacetic acid), in which a hydrogen atom in 2,4-D is replaced by a chlorine atom. Much attention has been given recently to TCDD (“dioxin,” or 2,3,7,8-tetrachlorodibenzo-*p*-dioxin; see Fig. 7.33b), which occurs as a trace impurity (10–20 ppb by mass) in 2,4,5-T and which, in animal tests, is the most toxic compound of low-to-moderate molar mass currently known. The use of 2,4,5-T as a defoliant (Agent Orange) during the Vietnam War led to a lawsuit by veterans who claimed that health problems arose from contact with the traces of TCDD present in the 2,4,5-T. Although such a direct connection has never been proved, the use of chlorinated phenoxy herbicides has decreased, and that of other herbicides, such as atrazine (see Fig. 7.33c), has grown.

### 7.7.3 Analgesics

Drugs that relieve pain are called analgesics, the oldest of which was probably a tea brewed from the bark of a willow tree and “prescribed” by the physician Hippocrates in the fourth century BC. The active ingredient in willow bark tea is salicylic acid, which is an effective analgesic but can cause severe intestinal bleeding, so chemists in the late 1800s sought to modify salicylic acid to preserve its desirable properties while minimizing its undesirable side effects. The German chemist, Fritz Hoffman, working for the Bayer chemical company, succeeded in making an ester of salicylic acid by reacting its alcohol functional group with acetic acid to make acetylsalicylic acid, the structure of which is shown in Figure 7.34a. You probably know this molecule by its generic name, aspirin, or by its trade name Bayer Aspirin.

Aspirin is not only an analgesic but also reduces fever (an antipyretic) and inflammation (an anti-inflammatory). Two related drugs, acetaminophen and ibuprofen, are shown in Figures 7.34b and 7.34c. This family of drugs provides an excellent example of structure-property relationships in organic chemistry and how subtle changes in the functional groups arranged around the hydrocarbon framework can dramatically alter biological function. All three of these molecules (called nonsteroidal anti-inflammatories or NSAIDs) work by binding to a site in a family of enzymes called cyclooxygenases (COX) that catalyze the synthesis of an important family of hormones called prostaglandins. Hormones

**FIGURE 7.34** The molecular structures of some analgesics: (a) aspirin; (b) acetaminophen; and (c) ibuprofen.

are chemical messengers that instruct cells to carry out specific functions, for instance, to suppress inflammation or block the transmission of pain signals. These so-called COX inhibitors block prostaglandin synthesis by occupying the active site of these enzymes, inhibition being an important mode mechanism of drug action. Note the similarity of the hydrocarbon frameworks in these molecules; they contain the phenyl structural group, which is a hydrocarbon that is soluble in fatty cell membranes where the COX enzymes reside. The frameworks all have approximately the same three-dimensional geometries that allow them to fit in the binding site like a hand in a glove. As stated earlier, it is the framework that determines the three-dimensional structure of organic molecules but the functional groups that determine the chemistry. Ibuprofen is the best anti-inflammatory of the three drugs, with acetaminophen showing almost no anti-inflammatory activity at all. Acetaminophen (Fig. 7.35), however, does not inhibit clotting to the extent that aspirin does, which is why “more hospitals use Tylenol.”

A much more powerful pain reliever, which is available only by prescription because of its addictive properties, is morphine, which acts on the central nervous system, apparently because its shape fits a receptor site on the nerve cell, and blocks the transmission of pain signals to the brain. Its structure contains five interconnected rings. A small change (the replacement of one  $\text{—OH}$  group by an  $\text{—OCH}_3$  group, giving a methyl ether) converts morphine into codeine, a prescription drug used as a cough suppressant. Replacing *both*  $\text{—OH}$  groups by

**FIGURE 7.35** Crystals of 4-acetaminophenol (Tylenol) viewed under polarized light.

Michael W. Davidson/Photo Researchers, Inc.

**FIGURE 7.36** Codeine and heroin are derivatives of morphine, which is a natural product found in the common poppy. Subtle variations in molecular structure produce significant differences in biological function.

acetyl groups ( $-\text{COCH}_3$ ) generates the notoriously addictive substance heroin (Fig. 7.36).

### 7.7.4 Antibacterial Agents

The advent of antibacterial agents changed the treatment of bacterial diseases such as tuberculosis and pneumonia dramatically beginning in the 1930s. The first “wonder drug” was sulfanilamide (Fig. 7.37a), a derivative of aniline. Other “sulfa drugs” are obtained by replacing one of the hydrogen atoms on the sulfonamide group by other functional groups. Bacteria mistake sulfanilamide for *p*-aminobenzoic acid, a molecule with a very similar shape but a carboxylic acid ( $-\text{COOH}$ ) group in place of the  $-\text{SO}_2\text{NH}_2$  group. The drug then interferes with the bacterium’s synthesis of folic acid, an essential biochemical, so the organism dies. Mammals do not synthesize folic acid (they obtain it from their diet), so they are not affected by sulfanilamide.

The penicillin molecule (see Fig. 7.37b) contains an amide linkage that connects a substituted double ring (including sulfur and nitrogen atoms) to a benzyl (phenylmethyl) group. It is a natural product formed by certain molds. Although the total synthesis of penicillin was achieved in 1957, that chemical route is not competitive economically with biosynthesis via fermentation. The mold grows

**FIGURE 7.37** Molecular structures of some antibiotics: (a) sulfanilamide; (b) penicillin G; and (c) tetracycline.

**FIGURE 7.38** Fermentation tanks used in modern penicillin production.

for several days in tanks that may hold up to 100,000 L of a fermentation broth (Fig. 7.38). The penicillin is later separated by solvent extraction. Penicillin functions by deactivating enzymes responsible for building cell walls in the bacteria. Derivatives of natural penicillin have been developed and are commercially available.

Finally we mention the tetracyclines, which are derivatives of the four-ring aromatic compound represented in Figure 7.37c. These drugs have the broadest spectrum of antibacterial activity found to date.

### 7.7.5 Steroids

The **steroids** are a family of naturally occurring compounds with a wide variety of functions. Most of them are synthesized from cholesterol. The structure of cholesterol (Fig. 7.39a) contains a group of four fused hydrocarbon rings (3 six-atom rings and 1 five-atom ring). All steroids possess this “steroid nucleus.” Cholesterol itself is present in all tissues of the human body. When present in excess in the bloodstream, it can accumulate in the arteries, restricting the flow of blood and leading to heart attacks. Its derivatives have widely different functions. The hormone cortisone (see Fig. 7.39b), which is secreted by the adrenal glands, regulates the metabolism of sugars, fats, and proteins in all body cells. As a drug, cortisone reduces inflammation and moderates allergic responses. It often is prescribed to combat arthritic inflammation of the joints.

The human sex hormones are also derivatives of cholesterol. Here the resourcefulness of nature for building compounds with quite different functions from the same starting material is particularly evident. The female sex hormone progesterone (see Fig. 7.39c) differs from the male sex hormone testosterone only by replacing an acetyl ( $-\text{C}(\text{O})\text{CH}_3$ ) group by a hydroxyl ( $-\text{OH}$ ) group. Oral contraceptives are synthetic compounds with structures that are closely related to progesterone.

**FIGURE 7.39** Molecular structures of some steroids: (a) cholesterol; (b) cortisone; and (c) progesterone and testosterone.

## CHAPTER SUMMARY

---

The element carbon has a rich and varied chemistry because of its location in the periodic table. As a Group IV element, each carbon atom forms four covalent bonds, more than any other second-period element. In consequence of its intermediate value of electronegativity, carbon can bond with the more electronegative elements, such as oxygen, nitrogen, and the halogens, as well as the more electropositive elements such as hydrogen and some of the heavy metals, by virtue of its intermediate electronegativity. Carbon atoms also bond with other carbon atoms, forming single, double, and triple bonds.

The hydrocarbons—molecules that contain only carbon and hydrogen—are fundamental to organic chemistry because they provide the archetypes for models of bond formation and the starting point for synthesis of other organic molecules. The hydrocarbons fall naturally into three families, based on their chemical properties and types of bonds.

The alkanes, also called saturated hydrocarbons, have only single bonds. The bonds are described by  $sp^3$  hybridization of the carbon atoms. When the carbon atoms are not bonded in a linear sequence, cases can occur in which two molecules with the same formula can have different structures, called geometrical isomers, with quite distinct properties.

Unsaturated hydrocarbons have double or triple bonds between carbon atoms. The alkenes have C=C double bonds, described by  $sp^2$  hybridization of the carbon atoms. The alkynes have C≡C triple bonds, described by  $sp$  hybridization of the carbon atoms. Because bond rotation does not occur readily about a carbon-carbon double bond, many alkenes exist in contrasting isomeric forms, depending on whether bonding groups are on the same (*cis*) or opposite (*trans*) sides of the double bond. When two or more double or triple bonds are separated by one single bond, the  $p$  orbitals form a conjugated system, in which the de-localized  $\pi$  orbitals are best described by MO theory.

The aromatic hydrocarbons are conjugated cyclic structures in which the  $\pi$  bonding is described through de-localized MOs formed at carbon atoms that have  $sp^2$  hybridization.

The fullerenes, which contain only carbon, are allotropic forms of carbon discovered in 1985. All the fullerenes have even numbers of atoms, with formulas ranging up to  $C_{400}$  and higher. Their  $\pi$  bonds form conjugated  $\pi$  electron systems.

Functional groups are sites of specific, heightened reactivity caused by insertion of atoms other than carbon into hydrocarbon structures or by attachment to a hydrocarbon chain. Thus, organic molecules are conveniently viewed as carbon skeletal templates on which these highly reactive sites are located. Because of their reactivity, functional groups are key elements in strategies for synthesizing more complex organic structures.

The hydrocarbons recovered from petroleum, and their derivatives containing functional groups, are relatively small molecules with simple structures. Substances such as these provide starting materials for the synthesis of numerous structurally more complex organic compounds with applications in agriculture, medicine, and consumer products. These compounds include insecticides and herbicides for pest control and analgesics for controlling pain. Antibacterial agents fight disease. Steroids are naturally occurring compounds that derive from cholesterol. Hormones, including the human sex hormones, are derivatives of cholesterol. The bonding in these more elaborate structures is explained in the same way as the hydrocarbon skeletons and functional groups that comprise the structures.

## CONCEPTS AND SKILLS

### Sections 7.1–7.4 – Petroleum Refining and the Hydrocarbons, Alkanes, Alkenes, Alkynes, and Aromatic Hydrocarbons

Identify important classes of hydrocarbons found in crude oil and natural gas, and describe their behavior in combustion reactions (Problems 1–4).

- Hydrocarbons are the principal components of crude oil and natural gas; they are used as fuels and as building blocks for the synthesis of organic molecules of industrial and commercial importance, such as polymers and pharmaceuticals.
- Alkanes are saturated hydrocarbons with the general formula  $C_nH_{2n+2}$ , in which every carbon atom makes four bonds either to other carbon atoms or to hydrogen.
- Alkenes have one or more  $C=C$  double bonds.
- Alkynes have one or more  $C\equiv C$  triple bonds.
- Aromatic hydrocarbons are planar ring structures with  $4n + 2$  delocalized  $\pi$  electrons, with  $n$  being an integer.

Write names and structural formulas for hydrocarbons (Problems 5–12).

- Hydrocarbons are named using a combination of prefixes, which depend on the number of carbon atoms in a molecule, and suffixes that identify the hydrocarbon class to which it belongs. The molecule is named after its longest chain using the following rules:
- Hydrocarbons that contain 1–4 carbon atoms in a chain are named after the hydrocarbons from which they are derived: methane, ethane, propane, and butane, respectively.
- Hydrocarbons that contain five or more carbon atoms are named using the Greek prefixes *penta-*, *hexa-*, *hepta-*, etc., in which the Greek prefix identifies the number of carbon atoms in the molecule.
- The ending *-ane* is replaced by *-ene* for alkenes and *-yne* for alkynes.
- Branches are named by identifying the radical and the position at which it is located along the main chain: 2-methylpentane, for example, has a methyl group attached to the second carbon atom in the pentane chain.

Describe the bonding in hydrocarbons using the VB model with hybrid orbitals on the carbon atoms (Problems 13–14).

- Bonding in alkanes is described using  $sp^3$  hybrid orbitals on each carbon atom to make four  $\sigma$  bonds either to other carbon atoms or to hydrogen.
- Bonding in alkenes is described using  $sp^2$  hybrid orbitals on each carbon atom to make three  $\sigma$  bonds either to other carbon atoms or to hydrogen and one  $\pi$  bond to an adjacent carbon atom. There is no rotation about the double bonds in alkenes, which makes it possible to have geometric isomers.
- Bonding in alkynes is described using  $sp$  hybrid orbitals on each carbon atom to make two  $\sigma$  bonds either to other carbon atoms or to hydrogen and two  $\pi$  bonds to an adjacent carbon atom.

### Sections 7.3–7.5 – Alkenes, Alkynes, Aromatic Hydrocarbons, and Fullerenes

*Discuss the delocalization of the  $\pi$  electrons in organic molecules and fullerenes (Problems 15–16).*

- Alternating single and double bonds in linear or cyclic alkenes can be described using resonance structures in which the electron density is delocalized over the entire molecule.

### Section 7.6 – Functional Groups and Organic Reactions

*Identify important functional groups and outline chemical processes by which important chemical compounds are synthesized (Problems 17–26).*

- Functional groups are atoms or groups of atoms with similar physical and chemical properties that are largely independent of the molecules of which they are a part.
- Important organic functional groups include carboxylic acids (weak acids), amines (weak bases), alcohols, esters (produced by reactions between carboxylic acids and alcohols), amides (produced by reactions between carboxylic acids and amines) and ethers, which are not particularly reactive species.

*Describe the bonding in important functional groups using the VB model with hybrid orbitals on carbon, oxygen, and nitrogen atoms (Problems 27–30).*

- The bonding in alkyl functional groups is described using  $sp^3$  hybridization on each carbon, as is the bonding for all functional groups that involve only single bonds, for example, alcohols, ethers, and amines. The bonding in all functional groups that contain double bonds is described using  $sp^2$  hybridization on the two atoms connected by the double bond; examples include aldehydes, ketones, carboxylic acids, esters, and amides.

### Section 7.7 – Pesticides and Pharmaceuticals

*Recognize and describe the shapes and functional groups for molecules used as pesticides and pharmaceuticals (Problems 31–36).*

- Pesticides and pharmaceuticals are molecules that include functional groups such as phenyl groups, alcohols, ethers, aldehydes, ketones, carboxylic acids, amines, and amides. Many of these structures have more than one ring, which gives them characteristic three-dimensional shapes that are important for their biological functions.

## PROBLEMS

Answers to problems whose numbers are red appear in Appendix G. Problems that are more challenging are indicated with asterisks.

### 7.1 Petroleum Refining and the Hydrocarbons

- Is it possible for a gasoline to have an octane number exceeding 100? Explain.
- Is it possible for a motor fuel to have a negative octane rating? Explain.
- A gaseous alkane is burned completely in oxygen. The volume of the carbon dioxide that forms equals twice the volume of the alkane burned (the volumes are measured at the same temperature and pressure). Name the alkane and write a balanced equation for its combustion.
- A gaseous alkyne is burned completely in oxygen. The volume of the water vapor that forms equals the volume of the alkyne burned (the volumes are measured at the same temperature and pressure). Name the alkyne and write a balanced equation for its combustion.
- Write a chemical equation involving structural formulas for the catalytic cracking of decane into an alkane and an alkene that contain equal numbers of carbon atoms. Assume that both products have straight chains of carbon atoms.
  - Draw and name one other isomer of the alkene.
- Write an equation involving structural formulas for the catalytic cracking of 2,2,3,4,5,5-hexamethylhexane. Assume that the cracking occurs between carbon atoms 3 and 4.
  - Draw and name one other isomer of the alkene.
- Write structural formulas for the following:
  - 2,3-Dimethylpentane
  - 3-Ethyl-2-pentene
  - Methylcyclopropane
  - 2,2-Dimethylbutane
  - 3-Propyl-2-hexene
  - 3-Methyl-1-hexene
  - 4-Ethyl-2-methylheptane
  - 4-Ethyl-2-heptyne
- Write structural formulas for the following:
  - 2,3-Dimethyl-1-cyclobutene
  - 2-Methyl-2-butene
  - 2-Methyl-1,3-butadiene
  - 2,3-Dimethyl-3-ethylhexane
  - 4,5-Diethyloctane
  - Cyclooctene
  - Propadiene
  - 2-pentyne
- Write structural formulas for *trans*-3-heptene and *cis*-3-heptene.

10. Write structural formulas for *cis*-4-octene and *trans*-4-octene.

11. Name the following hydrocarbons:

12. Name the following hydrocarbons:

13. State the hybridization of each of the carbon atoms in the hydrocarbon structures in Problem 11.

14. State the hybridization of each of the carbon atoms in the hydrocarbon structures in Problem 12.

### 7.5 Fullerenes

15. To satisfy the octet rule, fullerenes must have double bonds. How many? Give a simple rule for one way of placing them in the structure shown in Figure 7.17a.

16. It has been suggested that a compound of formula  $\text{C}_{12}\text{B}_{24}\text{N}_{24}$  might exist and have a structure similar to that of  $\text{C}_{60}$  (buckminsterfullerene).

(a) Explain the logic of this suggestion by comparing the number of valence electrons in  $\text{C}_{60}$  and  $\text{C}_{12}\text{B}_{24}\text{N}_{24}$ .

(b) Propose the most symmetric pattern of carbon, boron, and nitrogen atoms in  $\text{C}_{12}\text{B}_{24}\text{N}_{24}$  to occupy the 60 atom sites in the buckminsterfullerene structure. Where could the double bonds be placed in such a structure?

## 7.6 Functional Groups and Organic Reactions

17. In a recent year, the United States produced  $6.26 \times 10^9$  kg of 1,2-dichloroethane (sometimes still called by its old name of ethylene dichloride) and  $15.87 \times 10^9$  kg ethene. Assuming that all significant quantities of 1,2-dichloroethane were produced from ethene, what fraction of the ethene production went into making 1,2-dichloroethane? What mass of chlorine was required for this conversion?
18. In a recent year, the United States produced  $6.26 \times 10^9$  kg 1,2-dichloroethane and  $3.73 \times 10^9$  kg vinyl chloride. Assuming that all significant quantities of vinyl chloride were produced from 1,2-dichloroethane, what fraction of the 1,2-dichloroethane production went into making vinyl chloride? What mass of hydrogen chloride was generated as a by-product?
19. Write balanced equations for the following reactions. Use structural formulas to represent the organic compounds.
- The production of butyl acetate from butanol and acetic acid
  - The conversion of ammonium acetate to acetamide and water
  - The dehydrogenation of 1-propanol
  - The complete combustion (to  $\text{CO}_2$  and  $\text{H}_2\text{O}$ ) of heptane
20. Write balanced equations for the following reactions. Use structural formulas to represent the organic compounds.
- The complete combustion (to  $\text{CO}_2$  and  $\text{H}_2\text{O}$ ) of cyclopropanol
  - The reaction of isopropyl acetate with water to give acetic acid and isopropanol
  - The dehydration of ethanol to give ethene
  - The reaction of 1-iodobutane with water to give 1-butanol
21. Outline, using chemical equations, the synthesis of the following from easily available petrochemicals and inorganic starting materials.
- Vinyl bromide ( $\text{CH}_2=\text{CHBr}$ )
  - 2-Butanol
  - Acetone ( $\text{CH}_3\text{COCH}_3$ )
22. Outline, using chemical equations, the synthesis of the following from easily available petrochemicals and inorganic starting materials.
- Vinyl acetate ( $\text{CH}_3\text{COOCH}=\text{CH}_2$ )
  - Formamide ( $\text{HCONH}_2$ )
  - 1,2-Difluoroethane
23. Write a general equation (using R to represent a general alkyl group) for the formation of an ester by the condensation of a tertiary alcohol with a carboxylic acid.
24. Explain why it is impossible to form an amide by the condensation of a tertiary amine with a carboxylic acid.
25. Calculate the volume of hydrogen at  $0^\circ\text{C}$  and 1.00 atm that is required to convert 500.0 g linoleic acid ( $\text{C}_{18}\text{H}_{32}\text{O}_2$ ) to stearic acid ( $\text{C}_{18}\text{H}_{36}\text{O}_2$ ). (See Sec. 9.1.)
26. A chemist determines that 4.20 L hydrogen at 298 K and a pressure of 1.00 atm is required to completely hydrogenate 48.5 g of the unsaturated compound oleic acid to stearic acid ( $\text{C}_{18}\text{H}_{36}\text{O}_2$ ). How many units of unsaturation (where a unit of unsaturation is one double bond) are in a molecule of oleic acid? (See Sec. 9.1.)
27. Acetic acid can be made by the oxidation of acetaldehyde ( $\text{CH}_3\text{CHO}$ ). Molecules of acetaldehyde have a  $-\text{CH}_3$  group, an oxygen atom, and a hydrogen atom attached to a carbon atom. Draw the Lewis diagram for this molecule, give the hybridization of each carbon atom, and describe the  $\pi$  orbitals and the number of electrons that occupy each one. Draw the three-dimensional structure of the molecule, showing all angles.
28. Acrylic fibers are polymers made from a starting material called acrylonitrile,  $\text{H}_2\text{C}(\text{CH})\text{CN}$ . In acrylonitrile, a  $-\text{C}\equiv\text{N}$  group replaces a hydrogen atom on ethene. Draw the Lewis diagram for this molecule, give the hybridization of each carbon atom, and describe the  $\pi$  orbitals and the number of electrons that occupy each one. Draw the three-dimensional structure of the molecule, showing all angles.
29. Compare the bonding in formic acid ( $\text{HCOOH}$ ) with that in its conjugate base formate ion ( $\text{HCOO}^-$ ). Each molecule has a central carbon atom bonded to the two oxygen atoms and to a hydrogen atom. Draw Lewis diagrams, determine the steric numbers and hybridization of the central carbon atom, and give the molecular geometries. How do the  $\pi$  orbitals differ in formic acid and the formate molecular ion? The bond lengths of the C—O bonds in  $\text{HCOOH}$  are 1.23 (for the bond to the lone oxygen) and 1.36 Å (for the bond to the oxygen with a hydrogen atom attached). In what range of lengths do you predict the C—O bond length in the formate ion to lie?
30. Section 7.3 shows that the compound 2-butene exists in two isomeric forms, which can be interconverted only by breaking a bond (in that case, the central double bond). How many possible isomers correspond to each of the following chemical formulas? Remember that a simple rotation of an entire molecule does not give a different isomer. Each molecule contains a central C=C bond.
- $\text{C}_2\text{H}_2\text{Br}_2$
  - $\text{C}_2\text{H}_2\text{BrCl}$
  - $\text{C}_2\text{HBrClF}$

## 7.7 Pesticides and Pharmaceuticals

31. (a) The insecticide methoprene (see Fig. 7.32d) is an ester. Write the structural formulas for the alcohol and the carboxylic acid that react to form it. Name the alcohol.
- (b) Suppose that the carboxylic acid from part (a) is changed chemically so that the  $\text{OCH}_3$  group is replaced by a hydrogen atom and the  $\text{COOH}$  group is replaced by a  $\text{CH}_3$  group. Name the hydrocarbon that would result.

32. (a) The herbicide 2,4-D (see Fig. 7.33a) is an ether. Write the structural formulas of the two alcohol or phenol compounds that, on condensation, would form this ether. (The usual method of synthesis does not follow this plan.)
- (b) Suppose that hydrogen atoms replace the chlorine atoms and a  $-\text{CH}_3$  group replaces the carboxylic acid group in the two compounds in part (a). Name the resulting compounds.
33. (a) Write the molecular formula of acetylsalicylic acid (see Fig. 7.34a).
- (b) An aspirin tablet contains 325 mg acetylsalicylic acid. Calculate the number of moles of that compound in the tablet.
34. (a) Write the molecular formula of acetaminophen (see Fig. 7.34b).
- (b) A tablet of Extra Strength Tylenol contains 500 mg acetaminophen. Calculate the chemical amount (in moles) of that compound in the tablet.
35. Describe the changes in hydrocarbon structure and functional groups that are needed to make cortisone from cholesterol (see Fig. 7.39).
36. Describe the changes in hydrocarbon structure and functional groups that are needed to make testosterone from cortisone (see Fig. 7.39).

## ADDITIONAL PROBLEMS

37. *trans*-Cyclodecene boils at  $193^\circ\text{C}$ , but *cis*-cyclodecene boils at  $195.6^\circ\text{C}$ . Write structural formulas for these two compounds.
38. A compound  $\text{C}_4\text{H}_{11}\text{N}$  is known from its reactivity and spectroscopic properties to have no hydrogen atoms attached directly to the nitrogen atom. Write all structural formulas consistent with this information.
39. A compound  $\text{C}_3\text{H}_6\text{O}$  has a hydroxyl group but no double bonds. Write a structural formula consistent with this information.
40. Consider the following proposed structures for benzene, each of which is consistent with the molecular formula  $\text{C}_6\text{H}_6$ .
- (i)
- (ii)
- (iii)
- (iv)  $\text{CH}_3-\text{C}=\text{C}-\text{C}\equiv\text{C}-\text{CH}_3$
- (v)  $\text{CH}_2=\text{CH}-\text{C}\equiv\text{C}-\text{CH}=\text{CH}_2$
- (a) When benzene reacts with chlorine to give  $\text{C}_6\text{H}_5\text{Cl}$ , only one isomer of that compound forms. Which of the five proposed structures for benzene are consistent with this observation?
- (b) When  $\text{C}_6\text{H}_5\text{Cl}$  reacts further with chlorine to give  $\text{C}_6\text{H}_4\text{Cl}_2$ , exactly three isomers of the latter compound form. Which of the five proposed structures for benzene are consistent with this observation?
41. Acetyl chloride,  $\text{CH}_3\text{COCl}$ , reacts with the hydroxyl groups of alcohols to form ester groups with the elimination of  $\text{HCl}$ . When an unknown compound X with formula  $\text{C}_4\text{H}_8\text{O}_3$  reacted with acetyl chloride, a new compound Y with formula  $\text{C}_8\text{H}_{12}\text{O}_5$  was formed.
- (a) How many hydroxyl groups were there in X?
- (b) Assume that X is an aldehyde. Write a possible structure for X and a possible structure for Y consistent with your structure for X.
42. When an ester forms from an alcohol and a carboxylic acid, an oxygen atom links the two parts of each ester molecule. This atom could have come originally from the alcohol, from the carboxylic acid, or randomly from either. Propose an experiment using isotopes to determine which is the case.
43. Hydrogen can be added to a certain unsaturated hydrocarbon in the presence of a platinum catalyst to form hexane. When the same hydrocarbon is oxidized with  $\text{KMnO}_4$ , it yields acetic acid and butanoic acid. Identify the hydrocarbon and write balanced chemical equations for the reactions.
44. (a) It is reported that ethene is released when pure ethanol is passed over alumina ( $\text{Al}_2\text{O}_3$ ) that is heated to  $400^\circ\text{C}$ , but diethyl ether is obtained at a temperature of  $230^\circ\text{C}$ . Write balanced equations for both of these dehydration reactions.
- (b) If the temperature is increased well above  $400^\circ\text{C}$ , an aldehyde forms. Write a chemical equation for this reaction.
45. In what ways do the systematic developments of pesticides and of pharmaceuticals resemble each other, and in what ways do they differ? Consider such aspects as “deceptor” molecules, which are mistaken by living organisms for other molecules; side effects; and the relative advantages of a broad versus a narrow spectrum of activity.

46. The steroid stanolone is an androgenic steroid (a steroid that develops or maintains certain male sexual characteristics). It is derived from testosterone by adding a molecule of hydrogen across the C=C bond in testosterone.
- (a) Using Figure 7.39c as a guide, draw the molecular structure of stanolone.  
(b) What is the molecular formula of stanolone?

## CUMULATIVE PROBLEMS

---

47. The structure of the molecule cyclohexene is

Does the absorption of ultraviolet light by cyclohexene occur at longer or at shorter wavelengths than the absorption by benzene? Explain.

48. The naphthalene molecule has a structure that corresponds to two benzene molecules fused together:

The  $\pi$  electrons in this molecule are delocalized over the entire molecule. The wavelength of maximum absorption in benzene is 255 nm. Will the corresponding wavelength in naphthalene be shorter or longer than 255 nm?

The colors of gemstones originate with transition-metal ions. Emerald is the mineral beryl (beryllium aluminum silicate  $3\text{BeO} \cdot \text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2$ ), in which some of the  $\text{Al}^{3+}$  ions have been replaced by  $\text{Cr}^{3+}$  ions. The spatial arrangement of the oxide ions around each  $\text{Cr}^{3+}$  ion breaks the degeneracy of the  $3d$  orbitals into two sets of orbitals at different energies; the absorption of red and yellow light causes transitions between these levels. There is also another absorption band in the blue-violet region of the spectrum, and the color of emeralds is due to the transmission of the green light.

The partially filled  $d$ -electron shells of the transition-metal elements are responsible for a range of physical properties and chemical reactions quite different from those of the main-group elements. The presence of unpaired electrons in the transition-metal elements and their compounds, the availability of low-energy unoccupied orbitals, and the facility with which transition-metal oxidation states change are important factors that determine their rich and fascinating chemistry. Transition-metal complexes are characterized by a wide variety of geometric structures, variable and striking colors, and magnetic properties that depend on subtle details of their structure and bonding. This chapter begins

with a descriptive overview of the systematic trends in the properties of these metals, and then presents a comprehensive introduction to the classical and quantum mechanical models that describe bond formation in their compounds.

## 8.1 Chemistry of the Transition Metals

Let's begin by surveying some of the most important physical and chemical properties of the transition-metal elements and interpreting the trends observed in those properties using the quantum theory of atomic structure developed in Chapter 5. We focus initially on the fourth-period elements, also called the first transition series (those from scandium through zinc in which the  $3d$  shell is progressively filled). We then discuss the periodic trends in the melting points and atomic radii of the second and third transition series elements.

### 8.1.1 Physical Properties

Table 8.1 lists some of the most important physical properties of the elements of the first transition series, which were obtained primarily from Appendix F. The general trends in all of these properties can be understood by recalling that both the number of protons and the number of electrons increase as we move from left to right along a period. We showed in Chapter 5 that the trends in ionization energies for the main group elements could be explained by the shell model of the atom, in which electrons are added to the same shell, each being located at about the same distance from the nucleus. Increasing effective nuclear charge leads to rather smooth increases in the ionization energies as we move across each of the first three periods. First and second ionization energies generally increase as we move across the first transition series but the trend is not smooth. The energies of the  $4s$  and  $3d$  orbitals are so close to one another that the electron configurations of the neutral atoms and their ions are not easily predicted from the simplest model of atomic structure.

The increase in electron–nuclear attraction that results from increasing  $Z_{\text{eff}}$  causes atomic and ionic radii initially to decrease from left to right along each period, as shown in Table 8.1 and Figure 8.1, but then to increase toward the end of each series as electron–electron repulsion begins to dominate. Atoms of the second transition series (from yttrium to cadmium) are larger than those of the first transition series, as expected from the fact that the  $4d$  orbitals are larger than the  $3d$  orbitals. However, the atomic radii of the third transition series are not that much different from those of the second (see Fig. 8.1). This

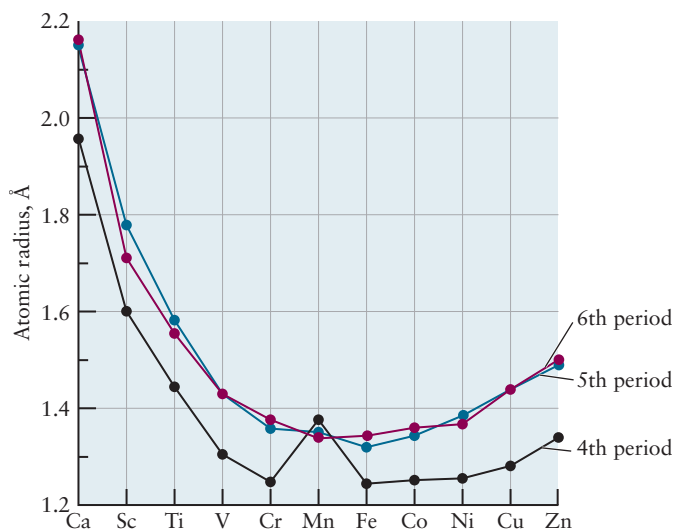

TABLE 8.1

Properties of the Fourth-Period Transition Elements

Element	Sc	Ti	V	Cr	Mn	Fe	Co	Ni	Cu	Zn
$IE_1$ (kJ mol <sup>-1</sup> )	631	658	650	653	717	759	758	737	745	906
$IE_2$ (kJ mol <sup>-1</sup> )	1235	1310	1414	1592	1509	1562	1648	1753	1958	1733
Boiling point (°C)	2831	3287	3380	2672	1962	2750	2870	2732	2567	907
Melting point (°C)	1541	1660	1890	1857	1244	1535	1495	1453	1083	420
Atomic radius (Å)	1.61	1.45	1.31	1.25	1.37	1.24	1.25	1.25	1.28	1.34
$M^{2+}$ ionic radius (Å)	0.81	0.68	0.88	0.89	0.80	0.72	0.72	0.69	0.72	0.74
$M^{2+}$ configuration	$d^1$	$d^2$	$d^3$	$d^4$	$d^5$	$d^6$	$d^7$	$d^8$	$d^9$	$d^{10}$
$\Delta H_{\text{hyd}}(M^{2+})$ (kJ mol <sup>-1</sup> )				-2799	-2740	-2839	-2902	-2985	-2989	-2937

<sup>†</sup>Defined as  $\Delta H_f^\circ(M^{2+}(aq)) - \Delta H_f^\circ(M^{2+}(g))$ .

**FIGURE 8.1** Variation of atomic radii through the fourth-, fifth-, and sixth-period transition-metal elements. The chemical symbols shown at the bottom of the graph refer to the fourth-period elements.

experimental fact is explained by the **lanthanide contraction**. The first and second transition series are separated by 18 elements, whereas the second and third are separated by 32 elements. The lanthanides have intervened, but their presence is not so obvious from the modern periodic table. Both the nuclear charge and the electron count have increased between the fifth and sixth period elements in a given group, but the *f* orbitals are much more diffuse than the *d* orbitals and much less effective in screening the nuclear charge. Elements in the sixth period experience much greater effective nuclear charges than expected and are therefore smaller. The atomic and ionic radii of hafnium, in the sixth period, are essentially the same as those of zirconium, in the fifth period. These two elements are difficult to separate from one another because they have the same valence, similar size, and, therefore, similar properties. (A similar effect, shown in Fig. 5.27 and discussed in Section 5.5 for main-group atoms and ions, arises from the filling of the 3*d* shell.)

The term *lanthanide contraction* is also used to identify another trend—the decrease in the atomic and ionic radii of the lanthanides from left to right along the sixth period. This trend has the same physical origin as that discussed previously in Chapter 5 for the second- and third-period elements and repeated earlier here: Nuclear charge is increasing while electrons are being added to the same subshell, in this case, the *f* shell. Using the same term to identify two different phenomena can cause confusion; therefore, we suggest you pay careful attention to the context when you see the term *lanthanide contraction*.

Metal–metal bond strengths first increase and then decrease going across each period, reaching a maximum in the middle. Evidence supporting this conclusion comes from the periodic variation in the melting and boiling points of the fourth-period elements shown in Table 8.1 and the corresponding trends in melting points for the three periods shown in Figure 8.2. The melting and boiling points are functions of the bond strengths between the atoms or ions in solids. Both of these properties correlate roughly with the number of unpaired electrons in the elements involved, which reaches a maximum in the middle of the corresponding series. We can rationalize this correlation by thinking about the number of covalent bonds a given metal atom can form with its neighbors; the larger the number of unpaired electrons available for bonding, the greater the number of potential bonds. Another way to understand this trend is to think about bonding in terms of the formation of molecular orbitals that are delocalized over the entire solid (see Section 21.3). These molecular orbitals are constructed from the outermost *d* orbitals on the metal atoms, and each of them can accommodate two electrons. Lower energy orbitals in the solid are

**FIGURE 8.2** Variation in the melting points of the transition metals across three periods with the alkaline earth metals included for reference.

primarily bonding. As they are progressively filled through the first half of each transition series, the overall metal–metal bond strength increases. In the second half of each transition series, the higher energy antibonding orbitals become filled, and the bond strength decreases. Tungsten, near the middle of the sixth period, has a very high melting point (3410°C), which makes it useful in light-bulb filaments; mercury, at the end of the same period, has a melting point well below room temperature (−39°C).

Most reactions involving transition metal ions have historically been carried out in aqueous solution; it is important, therefore, to understand the enthalpy changes that occur when metal ions are hydrated. The enthalpy of reaction,  $\Delta H_{\text{rxn}} = \Delta E + \Delta(PV)$ , is close to the energy change for the reaction  $\Delta E$  (for small  $\Delta(PV)$ ). Thus the enthalpy of hydration is roughly equal to the energy change associated with the hydration of the gas phase ion

Equivalently, if six water molecules comprise the solvation sphere around the aqueous metal ion, you might write

Enthalpies of hydration for the  $\text{M}^{2+}$  ions of the first transition series show an interesting trend (see Table 8.1 and Fig. 8.3). Although we have not yet discussed how ions interact with water in aqueous solutions (see Section 10.2), we might expect the strength of the interactions to increase as the ionic radii decrease, allowing the water molecules to approach the ions more closely. A roughly linear trend that might be expected using this reasoning is shown as the red line in Figure 8.3. The experimental results shown as the black points connected by the blue line follow the same general trend, but clear deviations from linearity suggest that factors other than ionic radii are important. In particular, the experimental results show that ions with filled shells ( $\text{Ca}^{2+}[\text{Ar}]$  and  $\text{Zn}^{2+}[\text{d}^{10}]$ ) or half-filled shells ( $\text{Mn}^{2+}[\text{d}^5]$ ) follow the simple linear trend quite

**FIGURE 8.3** Enthalpies of hydration of  $M^{2+}$  ions, defined as  $\Delta H_f^\circ(M^{2+}(aq)) - \Delta H_f^\circ(M^{2+}(g))$ . The crystal field stabilization energy (discussed in Section 8.4) preferentially stabilizes certain ions, lowering  $\Delta H_{\text{hyd}}$  from a line representing a roughly linear change with increasing atomic number (red line) to the experimental results (blue line).

closely. We connect this behavior to the electron configurations of the elements in Section 8.4. The anomalously low melting and boiling points and larger atomic radius of manganese, relative to its neighbors, as shown in Figures 8.1 and 8.2, also arises from its half-filled  $d$  shell.

### 8.1.2 Oxidation States of the Transition-Metal Elements

Figure 8.4 shows the characteristic oxidation states of the transition metals in common compounds, which you should compare with those of the main group elements shown in Figure 3.41. The maximum oxidation states of the early members of each period reflect, in a formal sense, the participation of all the outer  $s$  and  $d$  electrons in ionic or covalent bonding. The maximum oxidation state increases from +3 for Sc to +7 for Mn and then decreases as we continue to

**FIGURE 8.4** Some of the oxidation states found in compounds of the transition-metal elements. The more common oxidation states are represented by solid circles, and the less common ones are represented by open circles.

move to the right along the period. The electronic configuration of  $\text{Sc}^{3+}$  is the same as that of Ar and it forms ionic compounds with halogens like  $\text{ScF}_3$ , for example. The nature of the chemical bond varies with the oxidation state of a particular metal; the higher oxidation states form more covalent bonds, whereas the lower oxidation states form more ionic bonds. Oxides are good examples:  $\text{Mn}_2\text{O}_7$  is a covalent compound that is a liquid at room temperature (crystallizing only at  $6^\circ\text{C}$ ), but  $\text{Mn}_3\text{O}_4$  is an ionic compound, containing both  $\text{Mn}^{2+}$  and  $\text{Mn}^{3+}$ , that melts at  $1564^\circ\text{C}$ . Metal oxides can be classified as acids or bases (see following discussion) by the size and oxidation state of the metal cation. Cations in high oxidation states, for example  $\text{Ti}^{4+}$ , attract electrons from the oxygen atom in water quite strongly, forming more covalent bonds, making it relatively easy for the compounds to act as proton donors. Compounds that readily accept protons are characterized as bases. Compounds whose behavior is intermediate between these limits are called **amphoteric**, which means that they can act either as acids or bases, depending on the circumstances.

Inorganic chemists often refer to higher oxidation states being “stabilized” when bonded to certain **ligands** (bonding partners). This generally means that ligands such as  $\text{O}^{2-}$  and  $\text{F}^-$  donate electrons to the metal cation in order to achieve a more neutral configuration overall. This tendency to transfer charge is an example of Pauling’s principle of *electroneutrality*, which we used in Section 3.10 (without naming it as such) to help choose among different possible Lewis diagrams by minimizing the degree of charge separation. A covalent bond that results from electron pair donation is called a **dative bond**, and these are extremely important in the chemistry of the transition metals.

Higher oxidation states for metals in a given group are more commonly found for the heavier members of the group because the valence electrons are in the  $5s4d$  and  $6s5d$  shells, which are much further from the nucleus than those of the first transition series. The chemistry of iron is dominated by the +2 and +3 oxidation states, as found in the common oxides  $\text{FeO}$  and  $\text{Fe}_2\text{O}_3$ , but the +8 state, which is nonexistent for iron, has been observed for the heavier members of the iron group, ruthenium and osmium. The oxide  $\text{OsO}_4$ , for example, is a volatile yellow solid that melts at  $41^\circ\text{C}$  and boils at  $131^\circ\text{C}$ . It selectively oxidizes  $\text{C}=\text{C}$  double bonds to *cis* diols, which makes it useful in organic synthesis (a similar reaction is shown in Fig. 7.11) and as a biological stain, where it precipitates out as black osmium metal that is easily seen. The chemistry of nickel is almost entirely that of the +2 oxidation state, but the chemistry of the heavier elements in the nickel group, palladium and platinum, is dominated by the +4 state. For example,  $\text{NiF}_2$  is the only stable fluoride of nickel, but both  $\text{PdF}_2$  and  $\text{PdF}_4$  exist.  $\text{PtF}_2$  is not known, but both  $\text{PtF}_4$  and  $\text{PtF}_6$  have been prepared.

Transition metals exist in a wide range of oxidation states because their partially filled *d* orbitals can either accept or donate electrons to form chemical bonds, and many of their compounds are effective homogeneous and heterogeneous catalysts for this very reason (see Sec. 18.8). An element like iron can exist either as  $\text{Fe}^{2+}$  or  $\text{Fe}^{3+}$  in solution, where it can catalyze electron-transfer reactions by easily shuttling back and forth between its oxidized and reduced forms while remaining in solution, unlike ions such as  $\text{K}^+$ , which have only one oxidation state in solution. Iron oxides are used as heterogeneous catalysts for the production of ammonia from the elements, and solid  $\text{V}_2\text{O}_5$  catalyzes the oxidation of  $\text{SO}_2$  to  $\text{SO}_3$ , an important step in the commercial synthesis of sulfuric acid (see *Connection to Chemical Engineering* in Section 2.3). The active sites of many enzymes (biological catalysts) include transition-metal ions that catalyze a variety of important redox reactions such as the reduction of  $\text{O}_2$  to  $\text{H}_2\text{O}$  during respiration. General mechanisms of enzyme catalysis are discussed in Section 18.8.

**EXAMPLE 8.1**

Assign oxidation states to the transition-metal ions in the following compounds:  $\text{TiO}_2$ ,  $\text{ZrCl}_4$ ,  $\text{VCl}_3$ ,  $\text{CrF}_6$ ,  $\text{Mo}_2\text{S}_3$ ,  $\text{FeO}$ ,  $\text{AuCl}_3$ . Explain, where appropriate, which ligands stabilize the higher oxidation states and why.

**Solution**

Recall from Section 3.12 that the most important oxidation states of the halogens and the chalcogenides (Group VI) are  $-1$  and  $-2$ , respectively. In this chapter we assume that these are the only oxidation states of these elements, unless otherwise stated. The sum of the oxidation numbers for neutral

species must equal zero so the oxidation states of the metal cations must be equal in magnitude but opposite in sign to the sum of the oxidation states of the halogens or the chalcogenides. These may be determined by inspection: Ti(IV) in  $\text{TiO}_2$ ; Zr(IV) in  $\text{ZrCl}_4$ ; V(III) in  $\text{VCl}_3$ ; Cr(VI) in  $\text{CrF}_6$ ; Mo(III) in  $\text{Mo}_2\text{S}_3$ ; Fe(II) in  $\text{FeO}$ ; Au(III) in  $\text{AuCl}_3$ . V(IV) and Cr(VI) are the highest oxidation states of those two elements; they are stabilized only by small ligands with high charge densities,  $\text{O}^{2-}$  and  $\text{F}^-$ .

**Related Problems: 1, 2, 3, 4**

**8.1.3 Hard and Soft Acids and Bases**

Inorganic compounds can be broadly characterized as acids or bases using the Lewis model (see Section 15.1), in which bases are defined as electron pair donors and acids are defined as electron pair acceptors. The American inorganic chemist Ralph Pearson extended this model by developing the additional categories “hard” and “soft,” which has enabled chemists to organize the physical and chemical properties of these compounds in a simple way and to make predictions about their reactions. We introduce you to the Lewis model to provide the background necessary to develop the hard and soft acid–base concept.

You are probably familiar with the Brønsted-Lowry definition of acids and bases in which acids are defined as proton donors and bases are defined as proton acceptors, as illustrated by the following reaction:

A proton has been transferred from  $\text{HCl}(g)$  (the acid) to  $\text{OH}^-(aq)$  (the base) to form the water  $\text{H}_2\text{O}(\ell)$ . This reaction can be interpreted equally well using the Lewis model by focusing on the sharing of one of the oxygen lone pairs with the proton to form a new OH bond. (In the Lewis jargon, one would say the lone pair on the O atom is *donated to* the proton, so the  $\text{OH}^-(aq)$  is an electron pair donor, or a Lewis base.) The Lewis concept is more general than the Brønsted-Lowry concept because it allows us to treat systems that don't involve protons at all. For example, the reaction

can be considered to be an acid–base reaction in which a lone pair of electrons in  $\text{Cl}^-(aq)$  (the Lewis base) is donated to  $\text{Ag}^+(aq)$  (the Lewis acid) to form the solid precipitate  $\text{AgCl}$ . Most, if not all, of the compounds we discuss in this chapter can be identified either as Lewis acids or Lewis bases, and we can predict their most likely reactions using this concept. Bonding in inorganic compounds, and especially the coordination complexes discussed in Section 8.6, is also described largely in terms of the transfer of one or more pairs of electrons from electron donors (Lewis bases) to electron acceptors (Lewis acids).

Most of the elements in the periodic table are metals that tend to form positive ions because of their relatively low ionization energies and low electron affinities (or, equivalently, their low electronegativities). These metal cations are electron pair acceptors and are classified as Lewis acids. They may be classified as hard, soft, or borderline. Most metal ions are *hard acids* because of their low electronegativities and their propensity to accept electrons. Charge density is also a good measure of hardness; small, multiply charged ions like  $\text{Be}^{2+}$  and

$\text{Mg}^{2+}$  are hard acids, for example, and the hardness of a given transition metal increases with the increasing oxidation number as the charge density of the cation increases. The *soft acids* are found in the lower-right region of the metallic elements in the periodic table; they have high electronegativities and relatively low charge densities because of their large size and generally low oxidation states. Finally, a few elements form borderline acids because their physical properties are intermediate between those of the hard and soft acids. We may discuss some examples in passing, but note that the classification of several of these ions changes with oxidation state.  $\text{Cu}^+$ , with its relatively low charge density, is a soft acid, whereas  $\text{Cu}^{2+}$ , with a somewhat higher charge density due to its 2+ charge, is a borderline acid. Representative examples are shown in Table 8.2.

There are significantly fewer bases than acids. The hard bases include  $\text{F}^-$ , polyatomic anions that bond to metals through oxygen, such as sulfate and nitrate, and the neutral Lewis bases, water and ammonia, which are lone pair donors. The soft bases include the large, less electronegative anions such as  $\text{I}^-$  and  $\text{S}^{2-}$ , as well as a few polyatomic species that may either be neutral (CO) or anionic ( $\text{CN}^-$ ,  $\text{SCN}^-$ ).  $\text{Cl}^-$  and  $\text{Br}^-$  are the most important of the very few borderline bases. These examples are also shown in Table 8.2.

Let's illustrate the utility of the hard/soft acid/base concept in understanding chemical reactivity before discussing how the model also provides insight into the nature of the bonding in these species. Predicting reactivity follows one simple rule: Hard acids tend to pair with hard bases, whereas soft acids tend to pair with soft bases. The outcomes of many possible reactions can be predicted by simply looking at the character of the species involved. For example, the outcome of the following gas phase reaction can be predicted using this concept.

The reactants include a soft acid paired with a hard base, and a hard acid paired with a soft base; they exchange partners to pair the hard acid with the hard base and vice versa, as predicted. The concept can also be used to predict the course of displacement reactions as illustrated by the reaction

because the soft acid  $\text{Ag}^+$  prefers to bond with the softer of the two bases, which is  $\text{I}^-(aq)$ . The concept can be used to quickly assess the outcomes of possible reactions as well as to predict trends in the solubility of inorganic compounds in aqueous solutions. For example, the solubilities of the sodium halides

TABLE 8.2

Classification of Lewis Acids and Bases<sup>†</sup>

	Hard	Borderline	Soft
<b>Acids</b>	$\text{H}^+$ , $\text{Li}^+$ , $\text{Na}^+$ , $\text{K}^+$ , $\text{Be}^{2+}$ , $\text{Mg}^{2+}$ , $\text{Ca}^{2+}$ , $\text{Cr}^{2+}$ , $\text{Cr}^{3+}$ , $\text{Al}^{3+}$ , $\text{SO}_3$ , $\text{BF}_3$	$\text{Fe}^{2+}$ , $\text{Co}^{2+}$ , $\text{Ni}^{2+}$ , $\text{Cu}^{2+}$ , $\text{Zn}^{2+}$ , $\text{Pb}^{2+}$ , $\text{SO}_2$ , $\text{BBr}_3$	$\text{Cu}^+$ , $\text{Ag}^+$ , $\text{Au}^+$ , $\text{Tl}^+$ , $\text{Hg}^+$ , $\text{Pd}^{2+}$ , $\text{Cd}^{2+}$ , $\text{Pt}^{2+}$ , $\text{Hg}^{2+}$ , $\text{BH}_3$
<b>Bases</b>	$\text{F}^-$ , $\text{OH}^-$ , $\text{H}_2\text{O}$ , $\text{NH}_3$ , $\text{CO}_3^{2-}$ , $\text{NO}_3^-$ , $\text{O}^{2-}$ , $\text{SO}_4^{2-}$ , $\text{PO}_4^{3-}$ , $\text{ClO}_4^-$	$\text{NO}_2^-$ , $\text{SO}_3^{2-}$ , $\text{Br}^-$ , $\text{N}_3^-$ , $\text{N}_2$ , $\text{C}_6\text{H}_5\text{N}$ , $\text{SCN}^-$	$\text{H}^-$ , $\text{R}^-$ , $\text{CN}^-$ , $\text{CO}$ , $\text{I}^-$ , $\text{CN}^-$ , $\text{R}_3\text{P}$ , $\text{C}_6\text{H}_6$ , $\text{R}_2\text{S}$

<sup>†</sup>The underlined element identifies the electron pair donor if there is more than one possible choice. (R indicates an alkyl group, such as  $\text{CH}_3$ .)

increase in the order  $F^- < Cl^- < Br^- < I^-$ , whereas the solubilities of the silver halides increase in the inverse order, reflecting the preference of the hard acid  $Na^+$  to bond with the hard bases and the preference of the soft acid  $Ag^+$  to bond with the soft bases. These preferences also tell us something about the nature of the bonding involved. Hard acid/hard base interactions are primarily ionic in nature, whereas soft acid/soft base interactions are primarily covalent.

### EXAMPLE 8.2

Use the hard/soft acid/base concept to predict whether the following reactions will occur.

#### Solution

(a) No. Calcium is a hard acid that prefers to bond to the hard base  $F^-$ .

(b) Yes. Chromium is a hard acid that prefers to bond to the hard base  $OH^-$ .

**Related Problems: 5, 6**

## 8.2 Introduction to Coordination Chemistry

### 8.2.1 Formation of Coordination Complexes

The Alsatian-Swiss chemist Alfred Werner pioneered the field of coordination chemistry in the late 19th century. At that time, a number of compounds of cobalt(III) chloride with ammonia were known. They had the following chemical formulas and colors:

Compound 1: $CoCl_3 \cdot 6NH_3$	Orange-yellow
Compound 2: $CoCl_3 \cdot 5NH_3$	Purple
Compound 3: $CoCl_3 \cdot 4NH_3$	Green
Compound 4: $CoCl_3 \cdot 3NH_3$	Green

Treatment of these compounds with aqueous hydrochloric acid did not remove the ammonia, which suggested that it was somehow closely bound with the cobalt ions. Treatment with aqueous silver nitrate at  $0^\circ C$ , however, gave interesting results. With compound 1, all of the chloride present precipitated as solid  $AgCl$ . With compound 2, only two thirds of the chloride precipitated, and with compound 3, only one third precipitated. Compound 4 did not react at all with the silver nitrate. These results suggested that there were two different kinds of species associated with the cobalt ions, which Werner called *valences* (recall that the electron, the key player in the formation of the chemical bond, was just being characterized by J. J. Thomson). The primary, or ionizable, valences were anions like  $Cl^-$  in simple salts such as  $CoCl_3$ , whereas the secondary valences could be either simple anions or neutral molecules such as  $NH_3$ . Werner assumed that the primary valences were nondirectional, whereas the secondary valences were oriented along well-defined directions in space. The picture that emerged was that of a metal atom coordinated to the secondary valences (ligands) in the **inner coordination sphere** surrounded by the primary valences and solvent in the **outer coordination sphere**. The primary valences neutralize the positive charge on the complex ion. Werner accounted for experimental results described earlier by positing the existence of **coordination complexes** with six

ligands (either chloride ions or ammonia molecules) attached to each  $\text{Co}^{3+}$  ion. Specifically, he wrote the formulas for compounds 1 through 4 as

with the charge on each complex ion being balanced by an equal number of  $\text{Cl}^-$  ions in the outer coordination sphere. Only these chloride ions, which were *not* bonded directly to cobalt, could react with the silver ions in cold aqueous silver nitrate to form the  $\text{AgCl}$  precipitate.

Werner realized that he could test his hypothesis by measuring the electrical conductivity of aqueous solutions of the salts of these complex ions. Ions are the electrical conductors in aqueous solutions, and the conductivity is proportional to the ion concentration. If Werner's proposal was correct, then an aqueous solution of Compound 1, for example, should have a molar conductivity close to that of an aqueous solution of  $\text{Al}(\text{NO}_3)_3$ , which also forms four ions per formula unit when it dissociates completely in water (one  $3+$  ion and three  $1-$  ions). His experiments confirmed that the conductivities of these two solutions were, indeed, similar. Furthermore the conductivity of aqueous solutions of compound 2 was close to those of  $\text{Mg}(\text{NO}_3)_2$ , and solutions of compound 3 conducted electricity about as well as those containing  $\text{NaNO}_3$ . Compound 4, in contrast, did not dissociate into ions when dissolved in water, producing a solution of very low electrical conductivity.

Werner and other chemists studied a variety of other coordination complexes, using both physical and chemical techniques. Their research showed that 6 is the most common coordination number by far, as in the cobalt complexes discussed earlier. Coordination numbers ranging from 1 to 16 have subsequently been discovered, however. The most common of these include coordination numbers 2 (as in  $[\text{Ag}(\text{NH}_2)_2]^-$ ), 4 (as in  $[\text{PtCl}_4]^{2-}$ ), and 5 (as in  $[\text{Ni}(\text{CN})_5]^{3-}$ ).

A second example illustrates the ability of transition metals to form complexes with small molecules and ions. Copper metal and hot concentrated sulfuric acid ("oil of vitriol") react to form solid copper(II) sulfate, commonly called "blue vitriol" by virtue of its deep blue color. There is more to this compound than copper and sulfate, however; it contains water as well. When the water is driven away by heating, the blue color vanishes, leaving greenish white anhydrous copper(II) sulfate (Fig. 8.5). The blue color of blue vitriol comes from a **coordination complex** in which  $\text{H}_2\text{O}$  molecules bond directly to  $\text{Cu}^{2+}$  ions to form coordination complexes with the formula  $[\text{Cu}(\text{OH}_2)_4]^{2+}$ . Bonding in this complex ion can be described qualitatively using the Lewis theory of acids and bases (discussed previously and in more detail in Section 15.1). The transfer of a pair of electrons from water to  $\text{Cu}^{2+}$  to form a dative bond can be thought of as an acid–base reaction. As a Lewis acid, the  $\text{Cu}^{2+}$  ion *coordinates* four water molecules into a group by accepting electron density from a lone pair on each. By acting as electron-pair donors and sharing electron density with the  $\text{Cu}^{2+}$  ion, the four water molecules are the ligands, occupying the inner coordination sphere of the ion. The chemical formula of blue vitriol is  $[\text{Cu}(\text{OH}_2)_4]\text{SO}_4 \cdot \text{H}_2\text{O}$ ; the fifth water molecule is not coordinated directly to copper. Coordination complexes are those in which a central metal atom or ion is surrounded by a set of ligands. (Some textbooks use the term *coordination compound* to refer to a neutral coordination complex or to an ionic compound in which at least one of the ions is a coordination complex. The ion  $[\text{Cu}(\text{OH}_2)_4]^{2+}$  would be referred to as a coordination complex, whereas blue vitriol would be referred to as a coordination compound. We often use the terms interchangeably.)

**FIGURE 8.5** Hydrated copper(II) sulfate,  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ , is blue (left), but the anhydrous compound,  $\text{CuSO}_4$ , is greenish white (right). A structural study of the solid compound demonstrates that four of the water molecules are closely associated with the copper and the fifth is not. Thus, a better representation of the hydrated compound is  $[\text{Cu}(\text{OH}_2)_4]\text{SO}_4 \cdot \text{H}_2\text{O}$ .

© Cengage Learning/Charles D. Winters

The positive ions of every metal in the periodic table accept electron density to some degree and can therefore coordinate surrounding electron donors, even if only weakly. The solvation of  $\text{Na}^+$  by  $\text{H}_2\text{O}$  molecules in aqueous solution (see Fig. 10.6) is an example of weak coordination. The ability to make fairly strong, *directional* bonds by accepting electron pairs from neighboring molecules or ions is characteristic of the transition-metal elements. Coordination occupies a middle place energetically between the weak intermolecular attractions in molecular solids and liquids (see Chapter 10) and the stronger covalent and ionic bonding (see Chapters 3 and 6). Thus, heating blue vitriol disrupts the  $\text{Cu}-\text{OH}_2$  bonds at temperatures well below those required to break the covalent bonds in the  $\text{SO}_4^{2-}$  group (here  $M$  represents a metallic element such as  $\text{Cu}$ ). The energy (more precisely, the enthalpy) required to break a  $M^{2+}-\text{OH}_2$  bond in a transition metal coordination complex falls in the range between 170 and 210  $\text{kJ mol}^{-1}$ . This bond dissociation energy is far less than the bond energies of the strongest chemical bonds (e.g., 942  $\text{kJ mol}^{-1}$  for  $\text{N}_2$ ), but it is by no means small. The bond dissociation enthalpy increases as the charge density on the metal atom increases;  $\text{Cu}^{3+}$  binds water more strongly than  $\text{Cu}^{2+}$ , for example.

A wide variety of molecules and ions bond to metals as ligands; common ones include the halide ions ( $\text{F}^-$ ,  $\text{Cl}^-$ ,  $\text{Br}^-$ ,  $\text{I}^-$ ), ammonia ( $\text{NH}_3$ ), carbon monoxide ( $\text{CO}$ ), water, and a few other simple ligands listed in Table 8.3. Ligands that bond to a metal atom through a single point of attachment are called *monodentate* (derived from Latin *mono*, meaning “one,” plus *dens*, meaning “tooth,” indicating that they bind at only one point). More complex ligands can bond through two or more attachment points; they are referred to as *bidentate*, *tridentate*, and so forth. Ethylenediamine ( $\text{NH}_2\text{CH}_2\text{CH}_2\text{NH}_2$ ) (abbreviated as “en” in chemical formulas), in which two  $\text{NH}_2$  groups are connected by a hydrocarbon chain, is a particularly important bidentate ligand. Both nitrogen atoms in ethylenediamine have lone electron pairs to share. If all the nitrogen atoms in three ethylenediamine molecules bind to a single  $\text{Co}^{3+}$  ion, then that ion has a coordination number of 6 and the formula of the resulting complex is  $[\text{Co}(\text{en})_3]^{3+}$ . Complexes in which a ligand coordinates via two or more donors to the same central atom are called **chelates** (derived from Greek *chele*, meaning “claw,” because the ligand grabs onto the central atom like a pair of pincers). Figure 8.6 shows the structures of some important chelating ligands.

**TABLE 8.3**

Common Ligands and Their Names

Ligand <sup>†</sup>	Name
: $\text{NO}_2^-$	Nitro
: $\text{OCO}_3^{2-}$	Carbonato
: $\text{ONO}^-$	Nitrito
: $\text{CN}^-$	Cyano
: $\text{SCN}^-$	Thiocyanato
: $\text{NCS}^-$	Isothiocyanato
: $\text{OH}^-$	Hydroxo
: $\text{OH}_2$	Aqua
: $\text{NH}_3$	Ammine
: $\text{CO}$	Carbonyl
: $\text{NO}^+$	Nitrosyl

<sup>†</sup>The ligating atom is indicated by a pair of dots (: ) to show a lone pair of electrons. In the  $\text{CO}_3^{2-}$  ligand, either one or both of the O atoms can donate a lone pair to a metal.

**FIGURE 8.6** Three bidentate ligands, each capable of donating two pairs of electrons.

Brackets are used to identify complex ions in modern notation. The charge of the ion in a coordination compound is not written explicitly but inferred from the charges of the counterions. In the formula  $[\text{Pt}(\text{NH}_3)_6]\text{Cl}_4$ , the portion in brackets represents a coordination complex in which Pt coordinates six  $\text{NH}_3$  ligands. Four  $\text{Cl}^-$  ions surround it so the charge of the complex ion in brackets is +4. The brackets emphasize that a complex is a distinct chemical entity and within the brackets, the symbol of the central atom comes first. The electric charge on a coordination complex is the sum of the oxidation number of the metal ion and the charges of the ligands that surround it. Thus, the complex of copper(II) ( $\text{Cu}^{2+}$ ) with four  $\text{Br}^-$  ions is an anion with a  $-2$  charge,  $[\text{CuBr}_4]^{2-}$  and the Pt in the above complex is in a +4 oxidation state.

### EXAMPLE 8.3

Determine the oxidation state of the coordinated metal atom in each of the following compounds:

- (a)  $\text{K}[\text{Co}(\text{NH}_3)_2(\text{CN})_4]$ ; (b)  $\text{Os}(\text{CO})_5$ ;  
 (c)  $\text{Na}[\text{Co}(\text{OH}_2)_3(\text{OH})_3]$ .

#### Solution

- (a) The oxidation state of K is known to be +1, so the complex in brackets is an anion with a  $-1$  charge,  $[\text{Co}(\text{NH}_3)_2(\text{CN})_4]^-$ . The charge on the two  $\text{NH}_3$  ligands is 0, and the charge on each of the four  $\text{CN}^-$  ligands is  $-1$ . The oxidation state of the Co must then be +3, because

$4 \times -1$  (for the  $\text{CN}^-$ ) +  $2 \times 0$  (for the  $\text{NH}_3$ ) + 3 (for Co) equals the required  $-1$ .

- (b) The ligand CO has zero charge, and the complex has zero charge as well. Therefore, the oxidation state of the osmium is 0.  
 (c) There are three neutral ligands (the water molecules) and three ligands with  $-1$  charges (the hydroxide ions). The  $\text{Na}^+$  ion contributes only +1; thus, the oxidation state of the cobalt must be +2.

**Related Problems: 9, 10**

Coordination modifies the chemical and physical properties of both the central atom and the ligands. Consider the chemistry of aqueous cyanide ( $\text{CN}^-$ ) and iron(II) ( $\text{Fe}^{2+}$ ) ions. The  $\text{CN}^-$  ion reacts immediately with acid to generate gaseous HCN, a deadly poison, and  $\text{Fe}^{2+}$ , when mixed with aqueous base, instantly precipitates a gelatinous hydroxide. The reaction between  $\text{Fe}^{2+}$  and  $\text{CN}^-$  produces the complex ion  $[\text{Fe}(\text{CN})_6]^{4-}(\text{aq})$ , which undergoes neither of the two reactions just described nor any others considered characteristic of  $\text{CN}^-$  or  $\text{Fe}^{2+}$ . Ions or molecules may be present in multiple forms in the same compound. The two  $\text{Cl}^-$  ions in  $[\text{Pt}(\text{NH}_3)_3\text{Cl}]\text{Cl}$  are chemically different, because one is coordinated and the other is not. Treatment of an aqueous solution of this substance with  $\text{Ag}^+$  immediately precipitates the uncoordinated  $\text{Cl}^-$  as  $\text{AgCl}(\text{s})$ , but *not* the coordinated  $\text{Cl}^-$ , just as it did for Werner's complexes discussed earlier.

Ionic coordination complexes of opposite charges can combine with each other—just as any positive ion can combine with a negative ion—to form salts. For example, the cation  $[\text{Pt}(\text{NH}_3)_4]^{2+}$  and the anion  $[\text{PtCl}_4]^{2-}$  form an ionic compound with the formula  $[\text{Pt}(\text{NH}_3)_4][\text{PtCl}_4]$ . This compound and the following four compounds,

all contain Pt,  $\text{NH}_3$ , and Cl in the ratio of 1:2:2; that is, they have the same percentage composition. Two pairs even have the same molar mass. Yet, the five

compounds differ in structure and in physical and chemical properties. The concept of coordination organizes an immense number of chemical compositions and patterns of reactivity by considering combinations of ligands linked in varied ratios with central metal atoms or ions.

## 8.2.2 Naming Coordination Compounds

So far, we have identified coordination compounds only by their chemical formulas, but names are also useful for many purposes. Some substances were named before their structures were known. Thus,  $K_3[Fe(CN)_6]$  was called potassium ferricyanide, and  $K_4[Fe(CN)_6]$  was called potassium ferrocyanide [these are complexes of  $Fe^{3+}$  (ferric) and  $Fe^{2+}$  (ferrous) ions, respectively]. These older names are still used conversationally, but systematic names are preferred to avoid ambiguity. The definitive source for the naming of inorganic compounds is *Nomenclature of Inorganic Chemistry: IUPAC Recommendations 2005* (N. G. Connelly and T. Damhus, Sr., Eds. Royal Society of Chemistry, 2005).

1. The name of a coordination complex is written as a single word built from the names of the ligands, a prefix before each ligand to indicate how many ligands of that kind are present in the complex, and the name of the central metal atom.
2. Compounds containing coordination complexes are named following the same rules as those for simple ionic compounds: The positive ion is named first, followed (after a space) by the name of the negative ion.
3. Anionic ligands are named by replacing the usual ending with the suffix *-o*. The names of neutral ligands are unchanged. Exceptions to the latter rule are aqua (for water), ammine (for  $NH_3$ ), and carbonyl (for CO) (see Table 8.3).
4. Greek prefixes (*di-*, *tri-*, *tetra-*, *penta-*, *hexa-*) are used to specify the number of ligands of a given type attached to the central ion, if there is more than one. The prefix *mono-* (for one) is not used. If the name of the ligand itself contains a term such as *mono-* or *di-* (as in ethylenediamine), then the name of the ligand is placed in parentheses and the prefixes *bis-*, *tris-*, and *tetrakis-* are used instead of *di-*, *tri-*, and *tetra-*.
5. The ligands are listed in alphabetical order, without regard for the prefixes that tell how often each type of ligand occurs in the coordination sphere.
6. A Roman numeral, enclosed in parentheses placed immediately after the name of the metal, specifies the oxidation state of the central metal atom. If the complex ion has a net negative charge, the ending *-ate* is added to the stem of the name of the metal.

A few examples of complexes and their systematic names are shown in Table 8.4.

**TABLE 8.4**

Examples of Complexes and Their Systematic Names

Complex	Systematic Name
$K_3[Fe(CN)_6]$	Potassium hexacyanoferrate(III)
$K_4[Fe(CN)_6]$	Potassium hexacyanoferrate(II)
$Fe(CO)_5$	Pentacarbonyliron(0)
$[Co(NH_3)_5CO_3]Cl$	Penta-amminecarbonatocobalt(III) chloride
$K_3[Co(NO_2)_6]$	Potassium hexanitrocobaltate(III)
$[Cr(OH_2)_4Cl_2]Cl$	Tetra-aquadichlorochromium(III) chloride
$[Pt(NH_2CH_2CH_2NH_2)_3]Br_4$	Tris(ethylenediamine)platinum(IV) bromide
$K_2[CuCl_4]$	Potassium tetrachlorocuprate(II)

## EXAMPLE 8.4

Interpret the names and write the formulas of these coordination compounds:

- (a) sodium tricarbonatocobaltate(III)  
 (b) diamminediaquadichloroplatinum(IV) bromide  
 (c) sodium tetranitratoborate(III)

**Solution**

- (a) In the anion, three carbonate ligands (with  $-2$  charges) are coordinated to a cobalt atom in the  $+3$  oxidation state. Because the complex ion thus has an overall charge of  $-3$ , three sodium cations are required, and the correct formula is  $\text{Na}_3[\text{Co}(\text{CO}_3)_3]$ .

- (b) The ligands coordinated to a Pt(IV) include two ammonia molecules, two water molecules, and two chloride ions. Ammonia and water are electrically neutral, but the two chloride ions contribute a total charge of  $2 \times (-1) = -2$  that sums with the  $+4$  of the platinum and gives the complex ion a  $+2$  charge. Two bromide anions are required to balance this; thus, the formula is  $[\text{Pt}(\text{NH}_3)_2(\text{OH}_2)_2\text{Cl}_2]\text{Br}_2$ .
- (c) The complex anion has four  $-1$  nitrate ligands coordinated to a central boron(III). This gives a net charge of  $-1$  on the complex ion and requires one sodium ion in the formula  $\text{Na}[\text{B}(\text{NO}_3)_4]$ .

**Related Problems: 11, 12**

## 8.2.3 Ligand Substitution Reactions

We discuss a few ligand substitution reactions to give you a feel for the properties and reactions of coordination complexes. These simple reactions are aptly named; one or more ligands are simply substituted for one another. We have already discussed one example of a series of ligand substitution reactions: the exchange of  $\text{NH}_3$  and  $\text{Cl}^-$  in Werner's cobalt complexes.

If the yellow crystalline solid nickel(II) sulfate is exposed to moist air at room temperature, it takes up six water molecules per formula unit. These water molecules coordinate the nickel ions to form a bright green complex:

Heating the green hexaaquanickel(II) sulfate to temperatures well above the boiling point of water drives off the water and regenerates the yellow  $\text{NiSO}_4$  in the reverse reaction. A different coordination complex forms when yellow  $\text{NiSO}_4(s)$  is exposed to gaseous ammonia,  $\text{NH}_3(g)$ . This time, the product is a blue-violet complex:

Heating the blue-violet product drives off ammonia, and the color of the solid returns to yellow. Given these facts, it is not difficult to explain the observation that a green  $[\text{Ni}(\text{OH}_2)_6]^{2+}(aq)$  solution turns blue-violet when treated with  $\text{NH}_3(aq)$  (Fig. 8.7).  $\text{NH}_3$  must have displaced the  $\text{H}_2\text{O}$  ligands from the coordination sphere forming the blue-violet  $[\text{Ni}(\text{NH}_3)_6]^{2+}$  complex.

A **labile complex** is one in which ligand substitution reactions proceed rapidly. One in which substitution proceeds slowly or not at all is called an **inert complex**. These terms are used to describe the different kinetics (rates) of the reactions (see Chapter 18) that are thermodynamically allowed (see Chapter 13). Large activation energy barriers for ligand substitution reactions of inert complexes make those reactions slow even though there may be a thermodynamic driving force for them to proceed. In the substitution reaction,

**FIGURE 8.7** When ammonia is added to the green solution of nickel(II) sulfate on the left (which contains  $[\text{Ni}(\text{OH}_2)_6]^{2+}$  ions), ligand substitution occurs to give the blue-violet solution on the right (which contains  $[\text{Ni}(\text{NH}_3)_6]^{2+}$  ions).

© Cengage Learning/Leon Levandowski

the products are favored thermodynamically by an enormous amount, yet the inert  $[\text{Co}(\text{NH}_3)_6]^{3+}$  complex ion lasts for weeks in acidic solution because there is no low-energy pathway for the reaction. We would say that the cobalt(III) ion,  $[\text{Co}(\text{NH}_3)_6]^{3+}$ , is thermodynamically unstable relative to  $[\text{Co}(\text{OH}_2)_6]^{3+}$ , but kinetically stable (inert). The closely related cobalt(II) complex,  $[\text{Co}(\text{NH}_3)_6]^{2+}$ , reacts with water in a matter of seconds:

The hexa-aminocobalt(II) complex is both thermodynamically unstable and kinetically labile.

Ligand substitution reactions proceed sequentially, and they can usually be stopped at intermediate stages by controlling the reaction conditions. The following series of stable complexes represents all possible four-coordinate complexes of Pt(II) with the two ligands  $\text{NH}_3$  and  $\text{Cl}^-$ .

These mixed-ligand complexes provide wonderful examples of the variety and richness of coordination chemistry.

## 8.3 Structures of Coordination Complexes

### 8.3.1 Octahedral Geometries

What is the geometric structure of the complex  $[\text{Co}(\text{NH}_3)_6]^{3+}$ ? This question naturally occurred to Werner, who suggested that the arrangement should be the simplest and most symmetric possible, with the ligands positioned at the six vertices of a regular octahedron (Fig. 8.8). Modern methods of X-ray diffraction (see Section 21.1) enable us to make precise determinations of atomic positions in crystals and have confirmed Werner's proposed octahedral structure for this complex. X-ray diffraction techniques were not available in the late 19th century, however, so Werner turned to a study of the properties of substituted complexes to test his hypothesis. Having a set of molecular ball-and-stick models at hand as you read this section will make it much easier for you to visualize the structures and transformations described. We also provide line structures for selected complexes to introduce you to the shorthand way inorganic chemists sketch these complexes. As defined in Section 3.8, equatorial ligands are those that lie in the horizontal plane and axial ligands are those that lie along the vertical line (see Fig. 8.8).

**FIGURE 8.8** Ball-and-stick model of the octahedral complex  $[\text{Co}(\text{NH}_3)_6]^{3+}$ , with the hydrogen atoms not shown for clarity. All six ligands are equivalent.

**FIGURE 8.9** (a) The  $\text{cis-}[\text{Co}(\text{NH}_3)_4\text{Cl}_2]^+$  and (b)  $\text{trans-}[\text{Co}(\text{NH}_3)_4\text{Cl}_2]^+$  ions. The *cis* complex is purple in solution, but the *trans* complex is green.

Replacing one ammonia ligand by a chloride ion results in a complex with the formula  $[\text{Co}(\text{NH}_3)_5\text{Cl}]^{2+}$ , in which one vertex of the octahedron is occupied by  $\text{Cl}^-$  and the other five by  $\text{NH}_3$ . Only one structure of this type is possible, because all six vertices of a regular octahedron are equivalent, and the various singly substituted complexes  $[\text{MA}_5\text{B}]$  (where  $\text{A} = \text{NH}_3$ ,  $\text{B} = \text{Cl}^-$ ,  $\text{M} = \text{Co}^{3+}$ , for example) can be superimposed on one another. Now, suppose a second  $\text{NH}_3$  ligand is replaced by  $\text{Cl}^-$ . The second  $\text{Cl}^-$  can lie in one of the four equivalent positions closest to the first  $\text{Cl}^-$  (in the horizontal plane; see Fig. 8.9a) or in position labeled 3, on the opposite side of the central metal atom (see Fig. 8.9b). The first of these *geometric isomers*, in which the two  $\text{Cl}^-$  ligands are closer to each other, is called *cis- $[\text{Co}(\text{NH}_3)_4\text{Cl}_2]^+$* , and the second, with the two  $\text{Cl}^-$  ligands farther apart, is called *trans- $[\text{Co}(\text{NH}_3)_4\text{Cl}_2]^+$* . The octahedral structure model predicts that there can be only two different ions with the chemical formula  $[\text{Co}(\text{NH}_3)_4\text{Cl}_2]^+$ . You may have already encountered geometric isomers in Chapter 7. When Werner began his work, only the green *trans* (across) form was known, but by 1907, he had prepared the *cis* (near) isomer and shown that it differed from the *trans* isomer in color (it was violet rather than green) and other physical properties. The isolation of two, and only two, geometric isomers of this ion was good (although not conclusive) evidence that the octahedral structure was correct. Similar isomerism is displayed by the complex ion  $[\text{CoCl}_2(\text{en})_2]^+$ , which also exists in a purple *cis* form and a green *trans* form (Fig. 8.10).

### EXAMPLE 8.5

How many geometric isomers does the octahedral coordination compound  $[\text{Co}(\text{NH}_3)_3\text{Cl}_3]$  have?

#### Solution

We begin with the two isomers of  $[\text{Co}(\text{NH}_3)_4\text{Cl}_2]^+$  shown in Figure 8.9 and see how many different structures can be made by replacing one of the ammonia ligands with  $\text{Cl}^-$ .

Starting with the *trans* form (see Fig. 8.9b), it is clear that replacement of any of the four  $\text{NH}_3$  ligands at site 2, 4, 5, or 6 gives a set of equivalent structures that can be superimposed on one another by rotation of the starting structure. Figure 8.11b shows the structure that results from substitution at the position 2. What isomers can be made from the *cis* form shown in Figure 8.9a? If either the ammonia ligand at site 3 or the one at site 4 (i.e., one of the two that are *trans* to existing  $\text{Cl}^-$  ligands) is replaced, the result is simply a rotated version of Figure 8.11b; therefore, these replacements do *not* give another isomer. Replacement of the ligand at site 5 or 6, however, gives a different structure (see Fig. 8.11a). (Note that  $\text{Cl}^-$  occupying sites 1, 2, 5 and 1, 2, 6 results in equivalent structures.)

We conclude that there are two, and only two, possible isomers of the octahedral complex structure  $\text{MA}_3\text{B}_3$ . In fact, only one form of  $[\text{Co}(\text{NH}_3)_3\text{Cl}_3]$  has been prepared to date, presumably because the two isomers interconvert rapidly. However, two isomers are known for the closely related coordination complex  $[\text{Cr}(\text{NH}_3)_3(\text{NO}_2)_3]$ .

**Related Problems:** 17, 18

## 8.3.2 Square-Planar, Tetrahedral, and Linear Geometries

Complexes with coordination numbers of 4 are typically either tetrahedral or square planar. The tetrahedral geometry (Fig. 8.12a) predominates for four-coordinate complexes of the early transition metals (those toward the left side of the *d* block of elements in the periodic table). Geometric isomerism is not possible for tetrahedral complexes of the general form  $\text{MA}_2\text{B}_2$ , because all four tetrahedral sites are completely equivalent.

**FIGURE 8.10** The complex ion  $[\text{CoCl}_2(\text{en})_2]^+$  is an octahedral complex that has *cis* and *trans* isomers, according to the relative positions of the two  $\text{Cl}^-$  ligands. Salts of the *cis* isomers are purple, and salts of the *trans* isomers are green. For clarity, hydrogen atoms are not shown.

**FIGURE 8.11** Structural isomers of  $\text{Co}(\text{NH}_3)_3\text{Cl}_3$ . (a) The *fac* isomer with identical ligands arranged *cis* to each other (b) the *mer* isomer with identical ligands lying in the same plane (with the central atom)

**FIGURE 8.12** Four-coordinate complexes. (a) Tetrahedral,  $[\text{FeCl}_4]^-$ . (b, c) Square planar, illustrating (b) the *cis* and (c) the *trans* forms of  $[\text{Pt}(\text{NH}_3)_2\text{Cl}_2]$ .

## CONNECTION TO BIOLOGY

## Coordination Complexes in Heme Proteins

Coordination complexes of the transition metals play central roles in the chemistry of life processes; understanding the nature of these roles is an important goal of the field of bioinorganic chemistry. Nine transition-metal ions are classified as essential minerals that must be present in at least trace amounts to sustain life. These include the micro-minerals Fe, Zn, and Cu (daily requirement, 1–10 mg for adult humans), as well as the trace minerals V, Cr, Mn, Co, Ni, and Mo (daily requirement, few hundred  $\mu\text{g}$  for adult humans). Most of these metals are found in metalloenzymes, biological catalysts in which the metal ion plays a central role, but also in molecules like the chlorophylls (see Section 20.7) in which light absorption initiates a series of redox reactions that ultimately convert solar energy into chemical potential energy. Metalloenzymes are distinguished from the larger class of metalloproteins by their ability to bind the metal ion in the “resting state.” Coordination complexes serve a variety of biological functions that include oxygen binding and transport (see Section 14.4), metal transport and storage, and electron transport and catalysis. Many of the most important complexes in nature are built from a class of chelating ligands called porphyrins. The figures show the parent porphyrin ligand, porphine, and two biologically important coordination complexes, heme and chlorophyll *a*. We briefly discuss the structures and functions of these two complexes and then provide an example of another complex of this type, cytochrome P-450, that illustrates how the variable oxidation states of the transition metals enable enzymes to efficiently catalyze redox reactions.

Porphine (Fig. C8.1) is a planar tetradentate ligand that coordinates to metal ions through the nitrogen lone pairs in the equatorial positions of an octahedral complex. This arrangement leaves one of the axial positions available to bind an amino acid residue in proteins and the other axial position available to bind substrates in enzyme-catalyzed reactions. Heme (Fig. C8.2) is an iron porphyrin complex that is part of *hemoglobin*, the protein

FIGURE C8.1 Porphine.

responsible for oxygen transport in blood. The heme is bound to the globin protein through the fifth coordination site, leaving the sixth coordination site available to bind oxygen reversibly. Hemoglobin's cooperative binding equilibria are discussed in Section 14.4. Chlorophyll *a* (Fig. C8.3) is a magnesium porphyrin that absorbs light as the primary event in photosynthesis, creating excited states that initiate a series of redox reactions that ultimately convert  $\text{CO}_2$  to carbohydrates as our primary energy source (see Section 20.7). There are a number of chlorophyll molecules found in photosynthetic systems that absorb light over different regions of the visible spectrum. The diversity of these molecules enables more efficient conversion of solar energy than could be achieved by a single kind of chlorophyll molecule.

Enzymes are proteins that catalyze biological reactions (see Section 18.8). Cytochromes are heme-based, membrane-bound proteins that catalyze a variety of oxidation-reduction reactions. The cytochrome P-450 family is an important set of enzymes that catalyze the addition of oxygen to hydrocarbon substrates as part of the body's defense against hydrophobic compounds such as pharmaceuticals, steroids, and pesticides. The hydroxylation of  $\text{R-H}$  to  $\text{R-OH}$  makes these compounds more soluble in aqueous solutions, facilitating their elimination from the body. Many, if not most, common pharmaceuticals are metabolized and eliminated by cytochrome P-450 in the liver. An iron porphyrin is bound to the cytochrome protein via a sulfur linkage to the amino acid cysteine on the fifth (axial) coordination site, with the sixth (axial) site available for coordination to the substrate. These cytochromes absorb visible light most strongly at 450 nm, when CO is the sixth ligand, thus giving them their name. Figure C8.4 shows the basic

FIGURE C8.2 Heme.

FIGURE C8.3 Chlorophyll a.

FIGURE C8.4 Cytochrome P-450 catalytic cycle.

catalytic cycle for cytochrome P-450, beginning with the enzyme in its resting state in which water is bound as the sixth ligand and iron is present in the Fe(III) oxidation state. Hydrocarbon (R-H) substrates bind to the active site, displacing water and changing the electronic configuration of iron from low-spin to high-spin (step 1). An electron transferred from an electron donor reduces Fe(III) to Fe(II), and  $O_2$  binds to the sixth site as a free radical, oxidizing Fe(II) to Fe(III) in the process. The transfer of a second electron creates a short-lived peroxy ( $O_2^-$ ) species that reacts with two protons to eliminate water and form a highly reactive Fe(V)-oxo species that is stabilized by the sulfur ligand. This highly reactive oxo ligand is then

thought to insert into the R-H bond as a neutral atom, oxidizing the substrate to R-OH and reducing Fe(V) back to Fe(III) to begin the cycle all over again. The figure shows two alternate reactions that begin with the Fe(II) species. Exposure to CO at this point in the cycle produces the species that gives rise to the strong absorption at 450 nm, as shown in step C. The reaction labeled S shows an alternate route to the production of the Fe(V)-oxo species if stronger oxidizing agents like peroxide (XOOH) are available. This mechanism provides an excellent example of the way in which the variable oxidation states of transition metals in coordination complexes can effect catalytic reactions by electron transfer.

**FIGURE 8.13** Enantiomers of the  $[\text{Pt}(\text{en})_3]^{4+}$  ion. Reflection through the mirror plane transforms one enantiomer into the other. The two cannot be superimposed by simple rotation.

The square-planar geometry (see Figs. 8.12b,c) is common for four-coordinate complexes of  $\text{Au}^{3+}$ ,  $\text{Ir}^+$ ,  $\text{Rh}^+$ , and especially common for ions with the  $d^8$  valence electron configurations:  $\text{Ni}^{2+}$ ,  $\text{Pd}^{2+}$ , and  $\text{Pt}^{2+}$ , for example. The  $\text{Ni}^{2+}$  ion forms a few tetrahedral complexes, but four-coordinate  $\text{Pd}^{2+}$  and  $\text{Pt}^{2+}$  are nearly always square planar. Square-planar complexes of the type  $\text{MA}_2\text{B}_2$  can have isomers, as illustrated in Figures 8.12b and c for *cis*- and *trans*- $[\text{Pt}(\text{NH}_3)_2\text{Cl}_2]$ . The *cis* form of this compound is a potent and widely used anti-cancer drug called cisplatin, but the *trans* form has no therapeutic properties.

Finally, linear complexes with coordination numbers of 2 are known, especially for ions with  $d^{10}$  configurations such as  $\text{Cu}^+$ ,  $\text{Ag}^+$ ,  $\text{Au}^+$ , and  $\text{Hg}^{2+}$ . The central  $\text{Ag}$  atom in a complex such as  $[\text{Ag}(\text{NH}_3)_2]^+$  in aqueous solution strongly attracts several water molecules as well, however, so its actual coordination number under these circumstances may be greater than 2.

**FIGURE 8.14** The structure of (a) the all-*cis*- $[\text{Co}(\text{NH}_3)_2(\text{OH}_2)_2\text{Cl}_2]^+$  complex ion, together with (b) its mirror image.

### 8.3.3 Chiral Structures

Molecules that rotate plane polarized light in opposite directions are called optical isomers (see Section 7.1, Fig. 7.10). They typically have chiral structures that cannot be superimposed on their mirror images by rotation. The two structures shown in Figure 8.13 for the complex ion  $[\text{Pt}(\text{en})_3]^{4+}$  are examples of such a mirror-image pair.

#### EXAMPLE 8.6

Suppose that the complex ion  $[\text{Co}(\text{NH}_3)_2(\text{OH}_2)_2\text{Cl}_2]^+$  is synthesized with the two ammine ligands *cis* to each other, the two aqua ligands *cis* to each other, and the two chloro ligands *cis* to each other (Fig. 8.14a). Is this complex optically active?

#### Solution

We represent a mirror by a plane in Figure 8.14, shown as tilted for clarity, and create the mirror image by making each point in the image lie at the same distance from the plane as the corresponding point in the original structure. Comparing the original (see Fig. 8.14a) with the mirror image (see Fig. 8.14b) shows that *cis*, *cis*- $[\text{Co}(\text{NH}_3)_2(\text{OH}_2)_2\text{Cl}_2]^+$  is chiral, because the two structures cannot be superimposed even after they are turned. Although many chiral complexes contain chelating ligands, this example proves that nonchelates can be chiral.

**Related Problems:** 19, 20

**FIGURE 8.15** (a) The neutral form of EDTA (showing four protons bonded to EDTA<sup>4-</sup> (the protons in each OH group are removed when EDTA binds to metal ions). (b) The chelation complex of EDTA with cobalt(III). Each EDTA ion has six donor sites at which it can bind (by donating lone-pair electrons) to the central metal ion (in (b), the H atoms on the CH<sub>2</sub> groups not shown for clarity).

The hexadentate ligand EDTA (ethylenediaminetetra-acetate ion) forms chiral complexes. Figure 8.15 shows the structure of this chelating ligand coordinated to a Co<sup>3+</sup> ion. The central metal ion is literally “enveloped” by the ligand, forming six coordinate covalent bonds with two nitrogen atoms and four oxygen anions. A chelating agent like EDTA has a strong affinity for certain metal ions and can **sequester** them effectively in solution. EDTA solubilizes the scummy precipitates that Ca<sup>2+</sup> ion forms with anionic constituents of soap by forming a stable complex with Ca<sup>2+</sup>. In so doing it breaks up the main contributor to bathtub rings and it is a “miracle ingredient” in some bathtub cleaners. EDTA is also used to recover trace contaminants from water (some metal ions, especially heavy ones, are toxic). It has been used as an antidote for lead poisoning because of its great affinity for Pb<sup>2+</sup> ions. Iron complexes of EDTA in plant foods permit a slow release of iron to the plant. EDTA also sequesters copper and nickel ions in edible fats and oils. Because these metal ions catalyze the oxidation reactions that turn oils rancid, EDTA preserves freshness.

## 8.4 Crystal Field Theory: Optical and Magnetic Properties

What is the nature of the bonding in coordination complexes of the transition metals that leads to their special properties? Why does Pt(IV) form only octahedral complexes, whereas Pt(II) forms square-planar ones, and under what circumstances does Ni(II) form octahedral, square-planar, and tetrahedral complexes? Can trends in the length and strength of metal–ligand bonds be understood? To answer these questions, we need a theoretical description of bonding in coordination complexes.

### 8.4.1 Crystal Field Theory

**Crystal field theory**, which is based on an ionic description of metal–ligand bonding, provides a simple and useful model for understanding the electronic structure, optical properties, and magnetic properties of coordination complexes. The theory was originally developed to explain these properties of ions in solids, for example, the red color of ruby, which arises from Cr<sup>3+</sup> ions in an Al<sub>2</sub>O<sub>3</sub> lattice. It was quickly applied to the related problem of understanding the bonding, structures, and other properties of coordination complexes. The theory treats the complex as a central metal ion perturbed by negatively charged ligands. In an octahedral complex, the six ligands are treated as negative point charges aligned along the  $\pm x$ ,  $\pm y$ , and  $\pm z$  coordinate axes with respect to a metal atom or ion at the origin. The energy of an electron is the same in any of

the five degenerate  $d$  orbitals of a metal atom or ion in the gas phase. When external charges are present, however (Fig. 8.16), the energies of electrons in the various  $d$  orbitals change by different amounts because of the Coulomb repulsion between the external charges and the electrons in the  $d$  orbitals. The magnitude of the Coulomb repulsion depends inversely on separation between the charge densities of the ligands and of the electron densities in each of the orbitals, which is different for the various orbitals. An electron in a  $d_{x^2-y^2}$  or  $d_{z^2}$  orbital on the central metal atom is most likely to be found along the coordinate axes, where it experiences a strong repulsive interaction with the electrons from the ligand, raising the energy of the orbital. In contrast, an electron in a  $d_{xy}$ ,  $d_{yz}$ , or  $d_{xz}$  orbital of the metal is most likely to be found *between* the coordinate axes, and therefore experiences less repulsion from an octahedral array of charges; the energy of these orbitals is also raised but not by as much as that of the  $d_{x^2-y^2}$  and  $d_{z^2}$  orbitals. The octahedral crystal field breaks the

**FIGURE 8.16** Splitting of the 3d orbital energies by an octahedral crystal field. The energies of electrons in all of the orbitals increase due to Coulomb repulsion by the charged ligands. The energies of electrons in the  $d_{z^2}$  and  $d_{x^2-y^2}$  orbitals increase more than the energies of those in the  $d_{xy}$ ,  $d_{yz}$ , and  $d_{xz}$  orbitals because they are closer to the ligands and experience the greatest repulsion. Ligands that interact very weakly with the  $d$  electrons by virtue of their position have been omitted for clarity.

**FIGURE 8.17** An octahedral crystal field increases the energies of all five  $d$  orbitals, but the increase is greater for the  $d_{z^2}$  and  $d_{x^2-y^2}$  orbitals.

degeneracy of the  $d$  orbitals into two groups: a set of triply degenerate  $t_{2g}$  orbitals at lower energy and a set of doubly degenerate  $e_g$  orbitals at higher energy, as shown in Figure 8.17. The  $d_{xy}$ ,  $d_{yz}$ , and  $d_{xz}$  orbitals of the isolated atom become the three  $t_{2g}$  orbitals in a complex, and the  $d_{x^2-y^2}$  and  $d_{z^2}$  orbitals become the two  $e_g$  orbitals. The labels  $t_{2g}$  and  $e_g$  specify the symmetry and degeneracy (number of orbitals with the same energy) of each set of orbitals.  $t$  orbitals are threefold (triply) degenerate, whereas  $e$  orbitals are twofold (doubly) degenerate. The subscript  $g$  has its usual meaning;  $g$  orbitals are symmetric with respect to inversion of the coordinates (see Section 6.1). The difference in energy between the two levels is called the *crystal field splitting energy*, denoted by the symbol  $\Delta_o$  for an octahedral crystal field. The crystal field splitting is typically measured using optical absorption spectroscopy because the energy level separation corresponds to the energy of photons in the visible region of the spectrum, which is why these complexes often show such vibrant colors.

Figure 8.17 shows the increase in the energies of all of the  $d$  orbitals expected for ions that are surrounded by spherical crystal fields, as well as the splitting caused by octahedral fields. The energy of the  $t_{2g}$  level is lower by  $\frac{2}{5}\Delta_o$  than it would have been without splitting, and the energy of the  $e_g$  level is higher by  $\frac{3}{5}\Delta_o$ . Let's build up the  $d$ -electron configurations of the common ions in the first transition series using the Aufbau principle.  $\text{Ti}^{3+}$  is the first common ion we encounter that has partially filled  $d$  orbitals, with a single electron in one of the lower energy  $t_{2g}$  orbitals.  $\text{Ti}^{2+}$  and  $\text{V}^{3+}$  are isoelectronic with a  $d^2$  configuration. Hund's rule tells us that the lower energy configuration is one in which there is a single electron in each of two  $t_{2g}$  orbitals with parallel spins.  $\text{V}^{2+}$  and  $\text{Cr}^{3+}$  form an isoelectronic pair with a  $d^3$  configuration; the lowest energy state is the one in which a single electron occupies each of the  $t_{2g}$  orbitals with parallel spins. All of these ions have one or more unpaired electrons and are therefore paramagnetic. There are two possibilities for the  $d^4$  configurations of  $\text{Cr}^{2+}$  and  $\text{Mn}^{3+}$ ; the fourth electron can occupy one of the vacant  $e_g$  orbitals with parallel spin or it can be paired with one of the electrons in an occupied  $t_{2g}$  orbital. The lowest energy configuration is determined by comparing the energy cost of pairing an electron (the pairing energy) with the cost of promoting an electron to the higher energy  $e_g$  orbital. Both the crystal field splitting and the pairing energy depend on the metal and the ligands, and so it is not immediately obvious which configuration has the lowest energy in any particular case.

We have illustrated the two possibilities for the electronic configurations of  $\text{Cr}^{2+}$  and  $\text{Mn}^{3+}$  in Figure 8.18. The fourth electron will occupy an orbital in the lower level if the crystal field splitting is much larger than the pairing energy. Conversely, the fourth electron will occupy an orbital in the upper level if the crystal field splitting is much smaller than the pairing energy. The total spin (sum of the spins of the electrons) is lower in stronger crystal fields than in weaker crystal fields, and so the complexes are referred to as **low-spin complexes** with **low-spin configurations**, and **high-spin complexes** with **high-spin configurations**, respectively. Low spin configurations arise from strong crystal fields, so they are also called **strong-field configurations**, and the ligands that produce such fields are

**FIGURE 8.18** Electron configuration for (a) high-spin (small  $\Delta_o$ ) and (b) low-spin (large  $\Delta_o$ ) Mn(III) complexes.

called **strong-field ligands**. Conversely, high-spin configurations arise from weak crystal fields so they are also called **weak-field configurations** and the ligands that produce such fields are called **weak-field ligands**. These terms are used interchangeably (weak-field  $\leftrightarrow$  high-spin; strong-field  $\leftrightarrow$  low-spin); you should be alert, therefore, when reading inorganic texts or the scientific literature. These two configurations are only important for complexes with 4–7  $d$  electrons. There is no ambiguity in assigning configurations for complexes having three or fewer  $d$  electrons or more than seven  $d$  electrons.

Table 8.5 summarizes the electron configurations possible for 10 electrons in an octahedral crystal field, provides specific examples of transition metal ions from the first transition series with these configurations, and tabulates the **crystal field stabilization energy (CFSE)** of each type of octahedral complex. The CFSE is the energy difference between electrons in an octahedral crystal field and those in the hypothetical spherical crystal field introduced in Figure 8.16. If these five orbitals are either fully occupied or half full (as in  $d^{10}$  or high-spin  $d^5$  complexes), then the energy of the ion is predicted to be the same as in a spherical field: the CFSE is zero. If the lower energy orbitals are preferentially occupied, however, the configuration is stabilized. For example, in a low-spin  $d^4$  complex, the energy of each of the four electrons in the  $t_{2g}$  orbitals is lowered by  $\frac{2}{5}\Delta_o$ , resulting in a total CFSE of  $-\frac{8}{5}\Delta_o$ .

The CFSE helps to explain the trends in the enthalpies of hydration of ions in the first transition series shown in Figure 8.3. If each measured value (blue curve) is adjusted by correcting for the CFSE of that complex ion, results quite close to the straight red lines are obtained. The relatively small magnitude of the enthalpy of hydration for  $\text{Mn}^{2+}$  arises from the high-spin  $d^5$  configuration of  $\text{Mn}^{2+}$ , which results in a CFSE of zero. Negative CFSEs lower the enthalpies of hydration for ions on either side of  $\text{Mn}^{2+}$ .

## 8.4.2 Square-Planar and Tetrahedral Complexes

Crystal field theory applies to square-planar and tetrahedral complexes, as well as to octahedral complexes. Let's consider a square-planar complex in which four negative charges are arranged around a metal ion along the  $\pm x$ - and  $\pm y$ -axes, as shown in the upper right and lower left images in Figure 8.16. The relative  $d$ -orbital energy level ordering in a square-planar crystal field can be predicted using the same reasoning we applied to the octahedral case. The magnitude of the repulsive interaction between electrons in a given orbital and the electrons of the ligand depends on the degree to which the electron density is concentrated along the  $x$ - and  $y$ -axes. An electron in the  $d_{x^2-y^2}$  orbital, which is oriented along these axes, experiences the greatest repulsion and lies at the highest energy. The energy of the  $d_{xy}$  orbital is lower than that of the  $d_{x^2-y^2}$

**FIGURE 8.19** Energy-level structure of the 3d orbitals in a square planar crystal field, derived by withdrawing axial ligands from an octahedral field.

(c)

**FIGURE 8.20** (a) Energy level diagram for a tetrahedral crystal field. (b) The energies of the  $d_{z^2}$  (shown) and  $d_{x^2-y^2}$  orbitals lie lower in energy because they point to the cube faces, away from the ligands. (c) The energies of the  $d_{xy}$  (shown),  $d_{yz}$ , and  $d_{xz}$  orbitals lie higher in energy because they point to the cube edges, closer to the ligands.

orbital because the lobes of this orbital are oriented at  $45^\circ$  to the axes. The  $d_{z^2}$  orbital energy level is lower still because its electron density is concentrated along the  $z$ -axis, with a small component in the  $x$ - $y$  plane. Finally, the  $d_{xz}$  and  $d_{yz}$  orbitals experience the least repulsion. These orbitals are the most stable in a square-planar crystal field because they have nodes in the  $x$ - $y$  plane. Figure 8.19 shows the resulting energy level diagram.

Tetrahedral complexes result from ligands located on four of the eight corners of an imaginary cube with the metal ion at its center. The  $d_{x^2-y^2}$  and  $d_{z^2}$  orbitals point toward the centers of the cube faces, but the other three orbitals point toward the centers of the cube edges, which are closer to the corners occupied by the ligands. Electrons in the latter orbitals are therefore more strongly repelled than those in the former. Figure 8.20 shows the result; the energy level ordering is the reverse of that found for octahedral complexes. In addition, the magnitude of the splitting  $\Delta_t$  is about half that of  $\Delta_o$ .

Another way to think of the square-planar crystal field splittings is to consider what happens to the octahedral energy levels shown in Figure 8.17 as the two ligands on the  $\pm z$  axis move away from the metal. Let's consider each of the two degenerate levels separately. As the ligands retreat, the energy of the  $d_{z^2}$  orbital falls because of the decreased repulsion; the energy of the  $d_{x^2-y^2}$  orbital must increase to conserve the total energy of the  $e_g$  level. Similarly, the energies of the  $d_{xz}$  and  $d_{yz}$  orbitals of the  $t_{2g}$  level are stabilized as the ligands are pulled away and the energy of the  $d_{xy}$  orbital increases. So the octahedral crystal field energy levels distort smoothly into the square planar levels as the  $z$  axis ligands are pulled away. Some coordination complexes are described as having distorted octahedral structures, with the two  $z$ -axis ligands moved outward but not removed completely. The level splittings observed in these cases are intermediate between the octahedral and the square-planar patterns. Figure 8.21 tracks the energies of the orbitals for various crystal fields beginning with a spherical field in which the five  $d$  orbitals are degenerate. The tetrahedral crystal field and its associated energy level diagram is shown to the left, the octahedral crystal field is shown to the right, followed by the series of structures derived from the octahedral field by distorting and finally removing the axial ligands.

Octahedral complexes are the most common because the formation of six bonds to ligands, rather than four, confers greater stability. Square-planar arrangements are important primarily for complexes of  $d^8$  ions with strong field ligands. The low-spin configuration that leaves the high-energy  $d_{x^2-y^2}$  orbital vacant is the most stable. The low-spin configuration of a square planar  $d^8$  complex is more stable than the corresponding configuration of an octahedral complex because the energy of the highest occupied orbitals in the square planar complex is lower than those in the octahedral complex. Finally, tetrahedral complexes are less stable than either octahedral or square planar complexes for two reasons. First, the crystal field splitting is smaller so the lower set of energy levels is stabilized less than in the other geometries. Second, because the lower-energy set of levels is only doubly degenerate, electrons must be placed into the upper level at an earlier stage in the filling process.

**FIGURE 8.21** Correlation diagram showing the relationships among  $d$ -orbital energy levels in crystal fields of different symmetries. The five orbitals are degenerate in an isolated ion or atom and shift upwards in a spherical field. Splitting of the levels by an octahedral crystal field and those derived from it are shown to the right; the energy level diagram for a tetrahedral crystal field is shown on the left. Dashed lines track the energies of specific orbitals in the different crystal fields.

Crystal field theory allows us to predict, at least qualitatively, what geometries to expect for different coordination complexes, as determined by the identity and oxidation state of the metal and the characteristics of the ligands. Higher coordination numbers are more frequently observed for elements of the second and the third transition series than for those of the first transition series because the larger atomic and ionic radii of the former can accommodate more ligands. For a given metal in a given oxidation state, lower coordination numbers become favored as the ligands become more bulky. Steric repulsion between the ligands, a nonbonded interaction discussed in Section 7.2, overcomes the attractive interactions between the ligands and the central metal. Tetrahedral coordination is favored over octahedral coordination when the central atom is small and the ligands are bulky, for this reason. The oxoanions of metals in high oxidation states on the left side of the  $d$ -block, for example, generally have tetrahedral geometries, as do complexes of the heavier halides ( $\text{Cl}^-$ ,  $\text{Br}^-$ ,  $\text{I}^-$ ) bound to the  $\text{M}^{2+}$  metals on the right side of the  $d$ -block. Common examples include  $[\text{VO}_4]^{3-}$ ,  $[\text{CrO}_4]^{2-}$ , and  $[\text{MnO}_4]^-$  for the oxoanions and  $[\text{FeCl}_4]^{2-}$  and  $[\text{CuBr}_4]^{2-}$  for the halides. Square planar complexes of metals in the first transition series are typically formed between metal ions with  $d^8$  configurations and ligands that can accept electrons from the metal ion, such as  $\text{CN}^-$  (see Section 8.6), whereas  $d^8$  metals in the second transition series are often square planar, irrespective of the nature of the ligand. Prominent examples include  $[\text{NiCN}_4]^{2-}$  and  $[\text{Pt}(\text{NH}_3)_4]^{2+}$ .

(b)

**FIGURE 8.22** Samples are initially inserted about halfway into a magnetic field to create a field gradient that exerts a force on magnetic dipoles. (a) Paramagnetic compounds are attracted by the field and “weigh” more than they do with no field present. (b) Diamagnetic compounds are repelled slightly by the field and “weigh” less than they do with no field present.

### 8.4.3 Magnetic Properties

The existence of high- and low-spin configurations accounts for the magnetic properties of many different coordination compounds. As discussed in Section 6.5, substances are classified as paramagnetic or diamagnetic according to whether they are attracted into a magnetic field. Figure 8.22 shows a schematic of an experiment that demonstrates the universal *susceptibility* of substances to the influence of magnetic fields. A cylindrical sample is suspended between the poles of a powerful magnet whose field is not uniform throughout space. It is weighed accurately in the absence of a magnetic field and then again in the presence of the field. (There are several ways to do this; either the sample or the magnet may be moved, or the magnet may be switched off and then on.) The net force on the sample (apparent weight) is found to be different in the presence of the magnetic field. The measurements just described provide not only qualitative characterization of a sample’s magnetic properties, but also a quantitative value for its **magnetic susceptibility**, that is, the strength of its interaction with a magnetic field. *Diamagnetic* compounds are slightly repelled by the magnetic field and weigh less, whereas *paramagnetic* compounds are attracted by the magnetic field and weigh more. Diamagnetic compounds have small, negative susceptibilities, whereas paramagnetic compounds have much larger, positive susceptibilities.

Paramagnetic compounds have one or more unpaired electrons, as discussed in Section 6.5, whereas all of the electrons in diamagnetic substances are paired. Magnetic susceptibility measurements not only identify substances as paramagnetic or diamagnetic, but also count the number of unpaired spins; these measurements were very important in validating crystal field theory and more refined theories that followed.

These facts emerge in connection with coordination complexes, because paramagnetism is prevalent among transition-metal complexes, whereas most other chemical substances are diamagnetic. Among complexes of a given metal ion, the number of unpaired electrons, as observed by magnetic susceptibility, varies with the identities of the ligands. Both  $[\text{Co}(\text{NH}_3)_6]^{3+}$  and  $[\text{CoF}_6]^{3-}$  have six ligands surrounding a central  $\text{Co}^{3+}$  ion; yet, the former is diamagnetic (because it is a strong-field, low-spin complex), and the latter is paramagnetic with four unpaired electrons (because it is a weak-field, high-spin complex). Similarly,  $[\text{Fe}(\text{CN})_6]^{4-}$  is diamagnetic, but  $[\text{Fe}(\text{OH}_2)_6]^{2+}$  has four unpaired electrons; these complexes also correspond to the two  $d^6$  configurations shown in Table 8.5.

## EXAMPLE 8.7

The octahedral complex ions  $[\text{FeCl}_6]^{3-}$  and  $[\text{Fe}(\text{CN})_6]^{3-}$  are both paramagnetic, but the former is high spin and the latter is low spin. Identify the  $d$ -electron configurations in these two octahedral complex ions. In which is the octahedral field splitting greater? How does the CFSE differ between the complexes?

**Solution**

The  $\text{Fe}^{3+}$  ion has five  $d$  electrons. A high-spin complex such as  $[\text{FeCl}_6]^{3-}$  has five unpaired spins ( $t_{2g}^3 e_g^2$ ); a low-spin complex such as  $[\text{Fe}(\text{CN})_6]^{3-}$  has one unpaired spin ( $t_{2g}^5$ ). The splitting  $\Delta_o$  must be greater for cyanide than for chloride ion ligands. The CFSE for the  $[\text{FeCl}_6]^{3-}$  complex is zero, whereas that for the  $[\text{Fe}(\text{CN})_6]^{3-}$  complex is  $-2\Delta_o$ .

## 8.5 Optical Properties and the Spectrochemical Series

© Cengage Learning/Charles D. Winters

**FIGURE 8.23** Several colored coordination compounds. (clockwise from top left) They are  $\text{Cr}(\text{CO})_6$  (white),  $\text{K}_3[\text{Fe}(\text{C}_2\text{O}_4)_3]$  (green),  $[\text{Co}(\text{en})_3]^{3+}$  (orange),  $[\text{Co}(\text{NH}_3)_5(\text{OH}_2)]\text{Cl}_3$  (red), and  $\text{K}_3[\text{Fe}(\text{CN})_6]$  (red-orange).

Transition-metal complexes are characterized by their rich colors, which are often deep, vibrant, and saturated (Fig. 8.23). The colors depend on the oxidation state of the metal ion, the number and nature of the ligands, and the geometry of the complex. Earlier figures have shown the color changes that accompany dehydration and ligand substitution reactions and also the different colors of a pair of geometric isomers. The following series of  $\text{Co}(\text{III})$  complexes shows how the colors of coordination complexes of the same ion can vary with different ligands:

$[\text{Co}(\text{NH}_3)_6]^{3+}$	Orange
$[\text{Co}(\text{NH}_3)_4\text{Cl}_2]^+$	A green form and a violet form
$[\text{Co}(\text{NH}_3)_5(\text{OH}_2)]^{3+}$	Purple

Coordination complexes appear colored when they absorb visible light. Recall that atoms absorb light when the energy of an incident photon exactly matches the energy difference between two atomic energy levels (see Fig. 4.15). The missing wavelengths appear as dark lines against the spectral rainbow. The transmitted light still appears quite white to our eyes, however, because atomic absorption lines are so narrow. Only a small fraction of the visible light has been absorbed. Coordination complexes, on the other hand, absorb light over significant regions of the visible spectrum. What we see is the color that is *complementary* to the color that is most strongly absorbed (see Section 20.5). The  $[\text{Co}(\text{NH}_3)_5\text{Cl}]^{2+}$  ion, for example, absorbs greenish yellow light, with the strongest absorption occurring near 530 nm. Only the red and blue components of white light are transmitted through an aqueous solution of this ion, which appears purple to us. Materials that absorb all visible wavelengths appear gray or black, and those that absorb visible light weakly or not at all appear colorless.

Crystal field theory was developed, in part, to explain the colors of transition-metal complexes. It was not completely successful, however. Its failure to predict trends in the optical absorption of a series of related compounds stimulated the development of ligand field and molecular orbital theories and their application in coordination chemistry. The colors of coordination complexes are due to the excitation of the  $d$  electrons from filled to empty  $d$  orbitals ( $d$ - $d$  transitions). In octahedral complexes, the electrons are excited from occupied  $t_{2g}$  levels to empty  $e_g$  levels. The crystal field splitting  $\Delta_o$  is measured directly from the optical absorption spectrum of the complexes. The wavelength of the strongest absorption is called  $\lambda_{\text{max}}$  and it is related to  $\Delta_o$  as follows.  $E = h\nu$ , so

**FIGURE 8.24** The colors of the hexa-aqua complexes of metal ions (from left)  $\text{Mn}^{2+}$ ,  $\text{Fe}^{3+}$ ,  $\text{Co}^{2+}$ ,  $\text{Ni}^{2+}$ ,  $\text{Cu}^{2+}$ , and  $\text{Zn}^{2+}$ , prepared from their nitrate salts. Note that the  $d^{10}$   $\text{Zn}^{2+}$  complex is colorless. The green color of the  $\text{Ni}^{2+}$  is due to absorption of both red and blue light that passes through the solution. The yellow color of the solution containing  $[\text{Fe}(\text{OH})_2]^{3+}$  is caused by hydrolysis of that ion to form  $[\text{Fe}(\text{OH})(\text{OH}_2)_5]^{2+}$ ; if this reaction is suppressed, the solution is pale violet.

© Cengage Learning/Leon Lewandowski

$\Delta_o = h\nu = hc/\lambda_{\text{max}}$ . Because energy is inversely proportional to wavelength, compounds with small crystal field splittings absorb light with longer wavelengths, toward the red end of the visible spectrum, and those with large crystal field splittings absorb light with shorter wavelengths, toward the blue end of the spectrum.

In  $[\text{Co}(\text{NH}_3)_6]^{3+}$ , an orange compound that absorbs most strongly in the violet region of the spectrum, the crystal field splitting  $\Delta_o$  is larger than in  $[\text{Co}(\text{NH}_3)_5\text{Cl}]^{2+}$ , a violet compound that absorbs most strongly at lower frequencies (longer wavelengths) in the yellow–green region of the spectrum.  $d^{10}$  complexes (like those of  $\text{Zn}^{2+}$  or  $\text{Cd}^{2+}$ ) are colorless because all of the  $d$  levels (both  $t_{2g}$  and  $e_g$ ) are filled. Because there are no empty orbitals available to accept an excited electron, the transition is not allowed, which means that the absorption is weak or nonexistent. High-spin  $d^5$  complexes such as  $[\text{Mn}(\text{OH}_2)_6]^{2+}$  and  $[\text{Fe}(\text{OH}_2)_6]^{3+}$  also show only weak absorption bands because excitation of an electron from a filled  $t_{2g}$  level to an empty  $e_g$  level would require its spin to flip in order to satisfy the Pauli principle. (Recall that all unpaired spins are oriented parallel in high-spin complexes.) Light absorption rarely reverses the spin of an electron, so the optical absorption of these compounds is weak, as shown by the pale pink color of the hexa-aqua  $\text{Mn}^{2+}$  complex in Figure 8.24. Table 8.6 lists the crystal field splitting energies (CFSE) expressed in wave numbers  $1/\lambda_{\text{max}}$  in units  $\text{cm}^{-1}$  and absorption wavelengths for a number of coordination complexes to give you a feel for their diversity.

Experimental measurements of the optical absorption spectra and magnetic properties of transition-metal complexes have provided a critical test of the validity of crystal field theory. The theory makes specific predictions about the strengths of

crystal fields produced by different ligands for a given metal cation in a specific oxidation state. It also makes specific predictions about trends in the crystal field splitting with the oxidation state of a particular metal for a series of complexes containing the same ligands. Simple ionic ligands such as the halides should produce much stronger crystal fields than neutral ligands due to the larger electrostatic repulsion between the negatively charged anion and the  $d$  electrons of the metal ion. Coulomb's law also predicts that these repulsive interactions should increase with decreasing ionic ligand radius, for a given metal cation, and with increasing oxidation state for a given metal, which allows closer approach of the ligands. Crystal field theory predicts splittings that increase in the order  $I^- < Br^- < Cl^- < F^-$ . A systematic ranking of the strength of various ligands was obtained by comparing the optical absorption spectra of a series of complexes with the general formula  $[Co(III)(NH_3)_5X]^{n+}$ . The strength of the interaction between a single ligand  $X$  and the  $Co^{3+}$  ion could be measured directly because all other interactions and the geometry of the complex remained constant. Ligands were ranked from weakest to strongest on the basis of their crystal field splittings in the **spectrochemical series** as follows (below, py = pyridine and Ph = phenyl):

Weak-field ligands (high-spin)    Intermediate-field ligands    Strong-field ligands (low-spin)

Although this order is not followed for all metal ions, it is a useful generalization that helps us understand the properties of various coordination complexes. There is a similar spectrochemical series for metal ions that is largely independent of the ligands. It is  $Mn^{2+} < Ni^{2+} < Co^{2+} < Fe^{2+} < V^{2+} < Fe^{3+} < Co^{3+} < Mn^{4+} < Mo^{3+}, Rh^{3+} < Ru^{3+} < Pd^{4+} < Ir^{3+} < Pt^{4+}$ . These spectrochemical series illustrate the failure of crystal field theory to provide a satisfactory account of the factors that govern crystal field splitting. Neutral ligands with lone pairs, such as water and ammonia, produce larger splittings than any of the halides, and ligands with low-lying antibonding  $\pi$  molecular orbitals produce the largest splittings of all. Some of the trends in the series for the metal ions make sense—the increase in  $\Delta_o$  with increasing oxidation number, for example—but others do not. The increase in  $\Delta_o$  moving down a group is inconsistent with a simple electrostatic analysis because the larger ionic radii of the second and third transition series ions would be expected to reduce rather than increase the Coulomb repulsion between the metal  $d$  electrons and the ionic ligands. A more comprehensive theory is clearly required to explain the spectrochemical series. We apply the concepts and methods of molecular orbital theory developed in Chapter 6 to account for the trends observed in the spectrochemical series, as well as to provide a more satisfactory description of structure and bonding in coordination complexes and show how molecular orbital theory correctly accounts for the trend observed in the spectrochemical series.

### EXAMPLE 8.8

Predict which of the following octahedral complexes has the shortest  $\lambda_{max}$ :  $[FeF_6]^{3-}$ ,  $[Fe(CN)_6]^{3-}$ ,  $[Fe(OH_2)_6]^{3+}$ .

#### Solution

$[Fe(CN)_6]^{3-}$  has the strongest field ligands of the three complexes; thus, its energy levels are split by the greatest amount. The frequency of the light absorbed should be greatest, and  $\lambda_{max}$  should be the shortest for this ion.

$[Fe(CN)_6]^{3-}$  solutions are red, which means that they absorb blue and violet light. Solutions of  $[Fe(OH_2)_6]^{3+}$  are a pale violet due to the weak absorption of red light, and  $[FeF_6]^{3-}$  solutions are colorless, indicating that the absorption lies beyond the long wavelength limit of the visible spectrum.

## 8.6 Bonding in Coordination Complexes

### 8.6.1 Valence Bond Theory

Valence bond (VB) theory is used widely in contemporary chemistry to describe structure and bonding in transition-metal compounds, especially coordination complexes. The VB model is intuitively appealing for this purpose for several reasons. Because transition-metal compounds, particularly coordination complexes, often comprise a central atom surrounded by ligands in a symmetric arrangement, forming hybrid orbitals on the central atom with the appropriate symmetry to bond to these ligands is a natural approach to the problem. Often, little interaction occurs among metal–ligand bonds, so the local description is reasonable. Participation of the  $d$  electrons enables a much more varied set of structures and hybrid orbitals than can be formed from only  $s$  and  $p$  orbitals. This section describes two sets of hybrid orbitals used to describe bonding in transition-metal compounds and complexes, and provides examples of each.

Hybridization is justified here for precisely the same reasons we laid out in Section 6.8. The lobes of the hybrid orbitals point toward the ligands and overlap the ligand orbitals more strongly than the standard atomic orbitals. The energy cost to promote electrons from lower energy atomic orbitals (e.g.,  $3d$  and  $4s$ ) to the highest energy orbital ( $4p$ ) to form hybrid orbitals is more than offset by the energy gained by forming a stronger bond with the ligand.

We construct the first set of hybrid orbitals from one  $s$  atomic orbital, the three  $p$  atomic orbitals and the  $d_{z^2}$  atomic orbital; they are called  $sp^3d$  hybrid orbitals. The principal quantum numbers of the participating atomic orbitals depend on the particular metal atom under consideration; for Co, they would be the  $3d$ ,  $4s$ , and  $4p$  atomic orbitals. The  $sp^3d$  hybrid orbitals in the most general case are written out as

(a)

(b)

**FIGURE 8.25** (a) Hybrid orbitals formed from linear combinations of  $d_{z^2}$ ,  $s$ ,  $p_x$ ,  $p_y$ , and  $p_z$  orbitals. The pair of orbitals that point along the positive and negative  $z$ -axes are the same except for their orientation in space; they are called *axial* orbitals. The set of three orbitals in the  $x$ - $y$  plane are equivalent to one another and are called *equatorial* orbitals. All five orbitals have been pulled apart from their proper positions at the origin for clarity. (b) This set of hybrid orbitals can be used to describe the bonding in  $\text{PF}_5$ , for example.

$$\chi_1 = \sqrt{\frac{1}{3}} [s + \sqrt{2} (p_x)]$$

$$\chi_2 = \sqrt{\frac{1}{3}} \left[ s - \sqrt{\frac{1}{2}} (p_x) + \sqrt{\frac{3}{2}} (p_y) \right]$$

$$\chi_3 = \sqrt{\frac{1}{3}} \left[ s - \sqrt{\frac{1}{2}} (p_x) - \sqrt{\frac{3}{2}} (p_y) \right]$$

$$\chi_4 = \sqrt{\frac{1}{2}} [p_z + d_{z^2}]$$

$$\chi_5 = \sqrt{\frac{1}{2}} [p_z - d_{z^2}]$$

As shown in Figure 8.25a, these orbitals point to the vertices of a trigonal bipyramid; there are three equivalent equatorial hybrids and two equivalent axial hybrids. Examples of molecules whose shapes are described by  $sp^3d$  hybridization include  $\text{PF}_5$ , which you have seen in Section 3.8, and  $\text{CuCl}_5^{3-}$ .  $\text{PF}_5$  is shown in Figure 8.25b to show how VB theory using  $sp^3d$  hybrid orbitals can rationalize its structure.

The second set of hybrid orbitals we construct are the  $sp^3d^2$  hybrids; these are six equivalent orbitals directed toward the vertices of an octahedron (Fig. 8.26a). They describe the structures and bonding in all of the octahedral

(a)

(b)

**FIGURE 8.26** (a) Hybrid orbitals formed from linear combinations of  $d_{z^2}$ ,  $d_{x^2-y^2}$ ,  $p_x$ ,  $p_y$ , and  $p_z$  orbitals. All six orbitals are equivalent except for their orientation in space. The six orbitals have been pulled apart from their proper positions at the origin for clarity. (b) This set of hybrid orbitals can be used to describe the bonding in  $\text{SF}_6$ , for example.

coordination complexes discussed in Section 8.3, as well as that in  $\text{SF}_6$ , which we show in Figure 8.26b.

$$\chi_1 = \sqrt{\frac{1}{6}} [s + \sqrt{3} (p_z) + \sqrt{2} (d_{z^2})]$$

$$\chi_2 = \sqrt{\frac{1}{6}} \left[ s + \sqrt{3} (p_z) - \sqrt{\frac{1}{2}} (d_{z^2}) + \sqrt{\frac{3}{2}} (d_{x^2-y^2}) \right]$$

$$\chi_3 = \sqrt{\frac{1}{6}} \left[ s + \sqrt{3} (p_z) - \sqrt{\frac{1}{2}} (d_{z^2}) - \sqrt{\frac{3}{2}} (d_{x^2-y^2}) \right]$$

$$\chi_4 = \sqrt{\frac{1}{6}} \left[ s - \sqrt{3} (p_z) - \sqrt{\frac{1}{2}} (d_{z^2}) + \sqrt{\frac{3}{2}} (d_{x^2-y^2}) \right]$$

$$\chi_5 = \sqrt{\frac{1}{6}} \left[ s - \sqrt{3} (p_z) - \sqrt{\frac{1}{2}} (d_{z^2}) - \sqrt{\frac{3}{2}} (d_{x^2-y^2}) \right]$$

$$\chi_6 = \sqrt{\frac{1}{6}} [s - \sqrt{3} (p_z) + \sqrt{2} (d_{z^2})]$$

Table 8.7 shows the variety of hybrid orbitals that can be constructed from various combinations of  $s$ ,  $p$ , and  $d$  orbitals, the shapes of the molecules that result, and selected examples.

VB theory with hybrid orbitals is widely used to rationalize the structures of coordination complexes. It complements classical valence shell electron-pair repulsion (VSEPR) theory by using methods of quantum mechanics to describe the geometry of coordination complexes. As with main-group elements, VB theory is better suited to rationalize structure and bonding after the fact than to predict structure. And by treating the bonds as local and equivalent, it fails completely to account for the colors and magnetic properties of coordination complexes. These shortcomings motivate the application of molecular orbital theory to describe structure and bonding in coordination chemistry.

### 8.6.2 Molecular Orbital Theory

The failure of crystal field theory and VB theory to explain the spectrochemical series stimulated the development of **ligand field theory**, which applies qualitative methods of molecular orbital theory to describe the bonding and structure of coordination complexes. The terms *ligand field theory* and *molecular orbital theory* are often used interchangeably when discussing bonding in modern

inorganic chemistry; we prefer to use the term *molecular orbital (MO) theory* for consistency throughout this textbook.

Let's apply MO theory to describe bonding in octahedral coordination complexes using the same approach developed in Section 6.5. MOs are formed as linear combinations of atomic orbitals of the different atoms of the complex. We include the valence  $d$ ,  $s$ , and  $p$  orbitals of the central metal, as well as the  $s$  and  $p$  orbitals of the ligands in our minimal basis set. We restrict our discussion to metals of the first transition series, so the valence orbitals of the metal are the  $3d$ ,  $4s$ , and  $4p$  orbitals. The relevant ligand orbitals are the  $2s$ ,  $2p$ ,  $3s$ , and  $3p$  orbitals for most of the ligands we discuss, for example, the  $2p$  orbitals of  $F^-$  or  $OH^-$ , or the  $3p$  orbitals of  $Cl^-$ . They may also be hybrid orbitals constructed from this set of atomic orbitals, for example, the  $sp^3$  orbitals of the aqua ( $H_2O$ ) or ammine ( $NH_3$ ) ligands.

We begin by constructing a set of  $\sigma$  MOs using the metal orbitals and six of the ligand orbitals that point along the metal–ligand bonds, which are oriented along the Cartesian axes in octahedral complexes. Figure 8.27 illustrates the

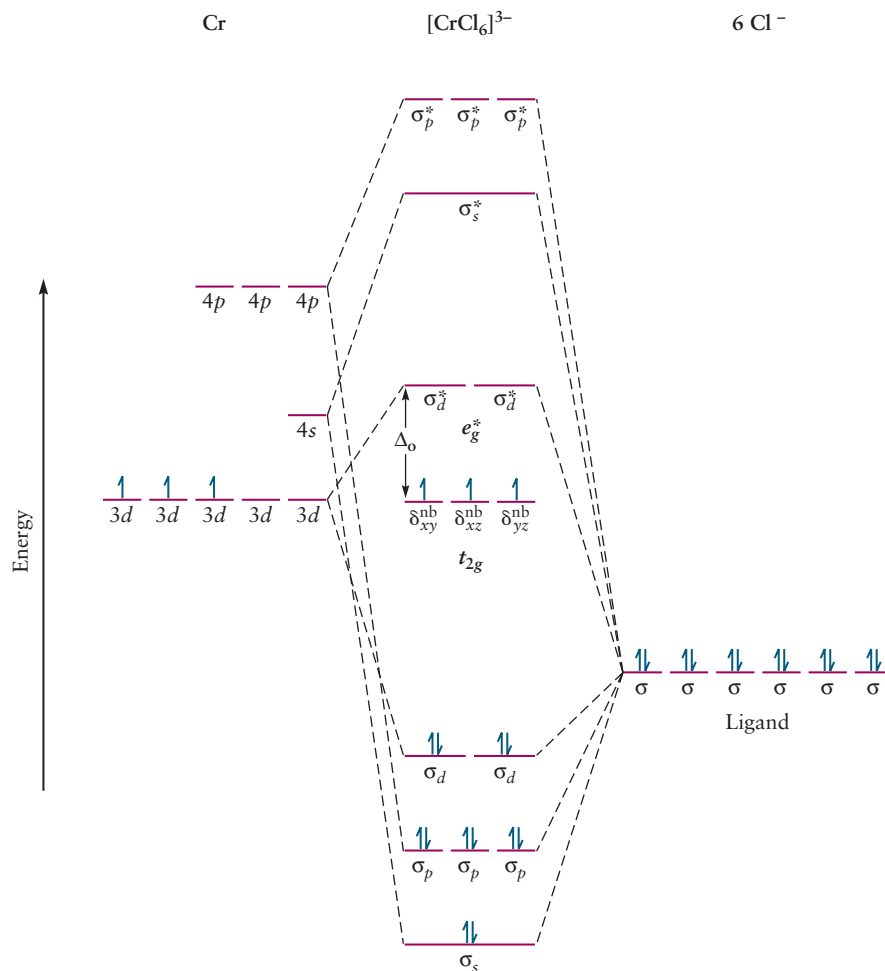

**FIGURE 8.27** Overlap of metal orbitals with ligand orbitals to form  $\sigma$  bonds. The ligand orbitals can be either  $p$  orbitals or hybrid orbitals (for example,  $sp^3$  for water), and thus they are represented only schematically.

bonding MOs; the corresponding antibonding MOs, as well as a set of nonbonding MOs, are not shown. A bonding  $\sigma$  orbital is formed by overlap of the metal 4s orbital with six ligand orbitals of the same phase. Overlap of the 4s metal orbital with six ligand orbitals of the opposite phase forms the corresponding antibonding  $\sigma^*$  MO. We label these orbitals  $\sigma_s$  and  $\sigma_s^*$ , respectively, to identify them by the number of radial nodes (angular momentum) and by their bonding and antibonding character, as well as to keep track of the atomic orbitals from which they were constructed, just as we did in Chapter 6. We then construct another set of bonding and antibonding  $\sigma$  orbitals from the three metal  $p$  orbitals and three ligand orbitals, which we denote  $\sigma_p$  and  $\sigma_p^*$ , respectively; each of these sets of orbitals is triply degenerate, differing only in their orientation in space. Only two of the five metal  $d$  orbitals are aligned along the bond axes in octahedral complexes. Overlap of the metal  $d_{z^2}$  and  $d_{x^2-y^2}$  with ligand orbitals generates a pair of bonding and antibonding MOs that we label  $\sigma_d$  and  $\sigma_d^*$ , respectively. The  $d_{xy}$ ,  $d_{yz}$ , and  $d_{zx}$  orbitals, whose lobes are oriented at  $45^\circ$  to the bond axes (see Fig. 5.13), have zero net overlap with the ligand orbitals, and are therefore nonbonding. We label these orbitals  $\delta_{xy}^{\text{nb}}$ ,  $\delta_{yz}^{\text{nb}}$ , and  $\delta_{zx}^{\text{nb}}$  by analogy to the way we labeled the nonbonding  $\pi$  orbital in HF shown in Figure 6.2; this scheme allows us to keep track of the nodal structure and angular momentum of the orbitals in a consistent way. We have constructed 15 MOs from our minimal basis set of 15 atomic orbitals; there are the six bonding  $\sigma$  orbitals shown in Figure 8.27, the six corresponding antibonding orbitals, and the three nonbonding metal  $\delta^{\text{nb}}$  orbitals.

We have constructed the orbital correlation diagram shown in Figure 8.28 using the same procedure outlined in Section 6.6. The relative energies of the

**FIGURE 8.28** Orbital correlation diagram for an octahedral ligand field, showing the energy-level filling for a  $[\text{CrCl}_6]^{3-}$  ion. We have added an asterisk to the  $e_g$  label to explicitly identify this set of orbitals as antibonding.

metal orbitals and the ligand orbitals were located in an approximate way using the ionization energies plotted in Figure 5.26. The metal orbitals lie at much higher energies than orbitals of the ligands used to construct  $\sigma$  bonds. The relative energies of the metal orbitals of the first transition series increase in the order  $3d < 4s < 4p$ , as shown. The molecular orbitals shown were constructed from the metal orbitals and the ligand orbitals by recalling that atomic orbitals interact strongly with one another to form MOs only when: (1) they are close to one another in energy and (2) they overlap significantly in space. The orbital correlation diagram shown is quite typical for transition metal complexes in which the bonds are primarily  $\sigma$  bonds, complexes that include ligands such as  $F^-$ ,  $H_2O$ , and  $NH_3$ , in which the ligand orbitals lie much lower in energy than the metal orbitals.

Recall from our discussion of bonding in heteronuclear diatomic molecules (see Section 6.6) that the character of bonding MOs is predominately that of the more electronegative element. Metal fluoride  $\sigma$  orbitals, for example, are derived primarily from atomic fluorine orbitals, so we can think of the bonding in metal fluoride complexes as primarily ionic. The fluoride ion acts as a lone pair donor (Lewis base) that forms dative bonds with metal ions. The correlation diagram shows the six bonding MOs being populated by electron pair donation from the ligands, a bonding scheme called **ligand-to-metal** (L→M)  $\sigma$  donation by inorganic chemists. MO theory predicts six bonds, just like VB theory, but each of these six  $\sigma$  bonds is delocalized over the entire complex, in contrast to the set of six localized M–L bonds predicted using VB theory.

Molecular orbital theory produces the same energy level structure for the center of the correlation diagram but the physical origin of the crystal field splitting is quite different, as discussed later. The same general conclusions and considerations apply, therefore, with respect to the optical and magnetic properties of coordination complexes. Orbitals are populated using an Aufbau principle with the metal electrons filling the  $t_{2g}$  and  $e_g^*$  levels as before. Low-spin configurations result when the crystal field splitting is larger than the pairing energy, and high-spin configurations result from the opposite situation. MO theory provides considerably more insight into the origin of the crystal field splitting, however, and a satisfactory explanation for the trends observed in the spectrochemical series that could not be provided by the earlier theories. MO theory identifies the  $t_{2g}$  orbitals as the  $\delta_{xy}^{nb}$ ,  $\delta_{yz}^{nb}$ , and  $\delta_{zx}^{nb}$  nonbonding MOs and the  $e_g^*$  orbitals as the antibonding  $\sigma_d^*$  orbitals; the crystal field splitting  $\Delta_o$  is the energy difference between them. The energies of the  $\delta^{nb}$  orbitals are unaffected by bonding, but the energies of the  $\sigma_d^*$  orbitals that lie above them are determined by the strength of the metal-ligand bonds. Recall from Section 6.5 that the energy of bonding MOs decreases with increasing bond strength while the energy of the corresponding antibonding MOs increases with increasing bond strength. The increase in crystal field splitting observed through the middle of the spectrochemical series correlates well with the strength of the metal-ligand  $\sigma$  bonds, but MO theory cannot account for the order observed throughout the rest of the series without considering  $\pi$  bonding.

Let's consider the effects of  $\pi$  bonding by first examining the nature of the bonds formed between a metal atom or ion and a single ligand. We then extend the treatment to examine the effects of  $\pi$  bonding on the energy level structure and properties of octahedral complexes. Figure 8.29a shows a bonding and an antibonding MO constructed from a metal  $d$  orbital and a ligand  $p$  orbital oriented "side-by-side." These MOs are typical for metals with few  $d$  electrons, such as  $Cr^{3+}$ , and for ligands with filled  $p$  orbitals that lie close to, but somewhat lower than, the energy of the metal  $d$  orbitals, for example, the  $3p$  orbitals of  $Cl^-$ . The empty  $4p$  ligand orbitals are not considered because they lie too high in energy. The bonding  $\pi$  orbital is primarily ligand in character, because the ligand orbitals are lower in energy than the metal orbitals; the antibonding

**FIGURE 8.29** (a) Bonding and antibonding  $\pi$  orbitals formed by “side-by-side” overlap of a metal  $d$  orbital with an atomic ligand  $p$  orbital. (b) Bonding and antibonding  $\pi$  orbitals formed by “side-by-side” overlap of a metal  $d$  orbital with a molecular ligand  $\pi^*$  orbital.

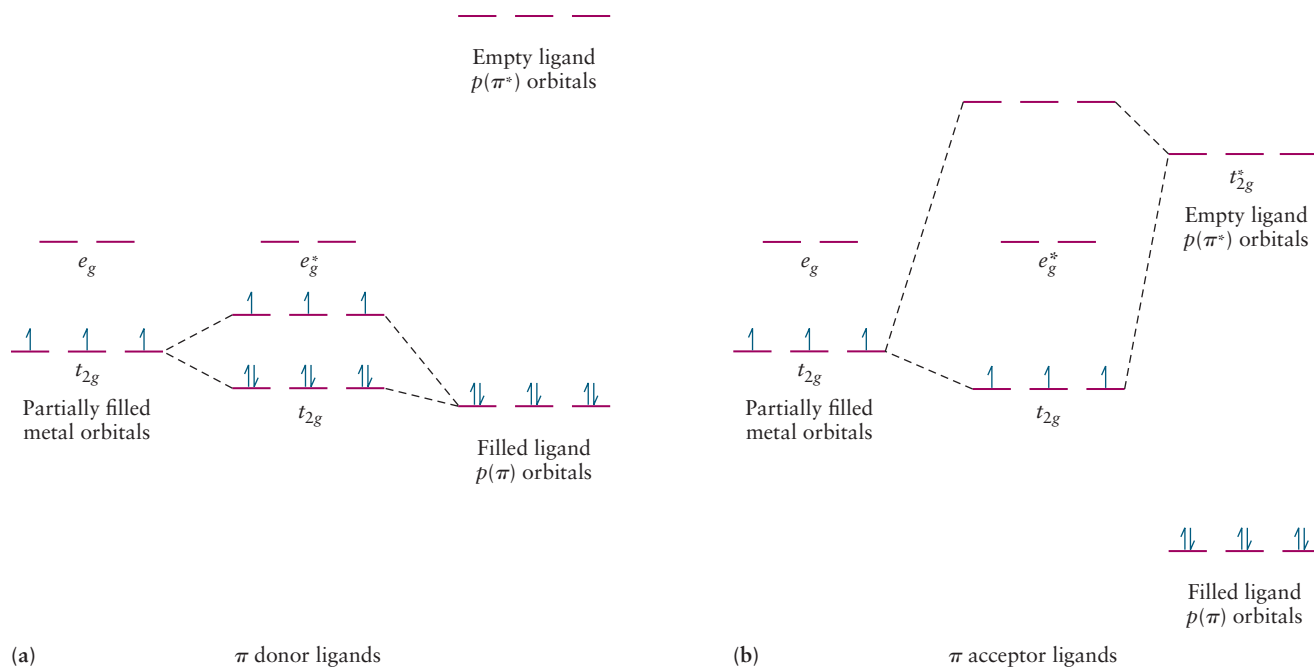

$\pi^*$  orbital is primarily metal in character for the same reason. The bonding orbital is populated by charge donation from the filled ligand orbitals; we call this kind of bonding (L $\rightarrow$ M)  $\pi$  donation, by analogy to that just described for (L $\rightarrow$ M)  $\sigma$  donation. Figure 8.29b illustrates the opposite situation in which the filled ligand orbitals lie at much lower energies than the metal orbitals and do not participate in bonding. There is an empty ligand  $\pi^*$  orbital, however, that is sufficiently close in energy and of the correct symmetry that it can overlap with the metal  $d$  orbital to form a bonding and an antibonding MO by overlapping the metal orbital “side-by-side,” as shown. The character of the bonding MO is largely determined by the character of the lower energy metal orbital, and it is filled by electrons transferred from the metal. Inorganic chemists call this bonding arrangement (M $\rightarrow$ L)  $\pi$  donation. It is important for metals with filled, or nearly filled,  $d$  orbitals and for ligands with  $\pi^*$  orbitals that lie close in energy, CO and  $\text{CN}^-$  being among the most important examples. We see from the figure that the MO is bonding between the metal and one atom of the ligand, but antibonding between the ligand atoms. (M $\rightarrow$ L)  $\pi$  donation strengthens the M–C bond but weakens the C–O bond, restoring electron density on the oxygen atom; it is often called **backbonding** because it transfers charge back to the ligand, reducing excess negative charge on the metal due to (L $\rightarrow$ M)  $\sigma$  donation alone (in an attempt to achieve electroneutrality). (L $\rightarrow$ M)  $\sigma$  donation and (M $\rightarrow$ L)  $\pi$  donation are often called synergistic for these reasons.

We are now in a position to construct  $\pi$  MOs from the nonbonding metal orbitals oriented “side-by-side” with a set of four ligand  $p$  orbitals, an example of which is shown in Figure 8.30. Three pairs of bonding and antibonding MOs are generated in this way; they are labeled  $t_{2g}$  and  $t_{2g}^*$ , and they lie in the  $x$ - $y$ ,  $y$ - $z$ , and  $z$ - $x$  planes, respectively. These orbitals correspond to the  $\pi$  and  $\pi^*$  orbitals just discussed for a single ligand. The character of these  $\pi$  orbitals is determined by the relative energies of the metal and ligand orbitals from which they are constructed, as well as the occupation of those levels before bonds are formed. Let’s focus on the nature of the ligands by choosing a particular metal, say  $\text{Cr}^{3+}$ , and work out the effects of  $\pi$  bonding on the energy level structure for different classes of ligands. We first consider those ligands that have filled  $p$  orbitals with energies that lie slightly lower than the energies of the

**FIGURE 8.30** Bonding  $\pi$  MO formed by constructive overlap of a metal  $d_{xy}$  orbital with four ligand  $p$  orbitals. The corresponding  $\pi^*$  orbital is formed by overlap with  $p$  orbitals of the opposite phase. Equivalent sets of orbitals are formed using the metal  $d_{yz}$  and  $d_{zx}$  orbitals.

metal orbitals, as shown by the energy level diagram in Figure 8.31a. The overlap between the metal  $t_{2g}$  orbitals and the four ligand  $p$  orbitals creates a set of three new bonding  $t_{2g}$  MOs as well as a set of three new antibonding  $t_{2g}^*$  MOs that lie above and below the metal  $t_{2g}$  level. The bonding orbitals are mostly

**FIGURE 8.31** (a) Ligand-to-metal  $\pi$  donation showing the formation of bonding and antibonding MOs and a reduction in  $\Delta_o$  compared with that from  $\sigma$  bonding alone. (b) Metal-to-ligand  $\pi$  donation showing the formation of bonding and antibonding MOs and an increase in  $\Delta_o$  compared with that from  $\sigma$  bonding alone.

ligand in character, for the reasons discussed previously, and they have been completely filled by electrons transferred from the lone pairs of the six ligands. The  $d$  electrons occupy the new  $t_{2g}^*$  antibonding MO, which is located at higher energy than the metal  $t_{2g}$  level. The energy of the metal  $e_g^*$  level is unchanged, so the effect of this ligand-to-metal ( $L \rightarrow M$ )  $\pi$  donation is to increase the energy of the highest occupied molecular orbital and decrease the crystal field splitting  $\Delta_o$ . Strong  $\pi$ -donor ligands include  $I^-$  and  $Br^-$ , with occupied  $p$  orbitals whose energies lie close to the energies of the metal  $d$  orbitals (because they are  $4p$  and  $5p$  orbitals, respectively). The greater spatial extent of these more diffuse orbitals also overlaps strongly with the metal  $d$  orbitals resulting in the large splitting between the bonding and antibonding MOs observed.  $\pi$  donors account for the small crystal field splittings observed for ligands on the left side of the spectrochemical series.

Let's now consider the opposite situation in which the filled  $p$  orbitals of the ligands lie much lower in energy than the metal  $d$  orbitals, so much lower that they do not effectively contribute to the formation of MOs with the metal orbitals. Ligands on the right-hand side of the spectrochemical series have unoccupied  $\pi^*$  orbitals with energies sufficiently close to those of the metal  $d$  orbitals that they can effectively combine with the metal orbitals to form new MOs, as shown in Figure 8.31b. This interaction creates a set of bonding MOs with energy lower than the metal  $t_{2g}$  level that is populated by transfer of the metal electrons. This **metal-to-ligand ( $M \rightarrow L$ )  $\pi$  donation** increases the crystal field splitting  $\Delta_o$  and accounts for the splittings observed on the right side of the spectrochemical series. Ligands are classified according to their abilities to act as  $\pi$  donors,  $\sigma$  donors, or  $\pi$  acceptors, and this classification provides an explanation of the trends observed for the crystal field splitting through the spectrochemical series as follows.

### EXAMPLE 8.9

Construct an MO correlation diagram for the complex ion  $[Ni(NH_3)_6]^{2+}$  and populate the orbitals with electrons. Do you expect  $\pi$  bonding to be important for this complex? What features of this diagram correspond to those predicted using crystal field theory? What kind of bonding would VB theory predict for  $d^8$  complexes, and how does MO theory account for the bonding more accurately, even qualitatively?

#### Solution

The correlation diagram looks like that shown in Figure 8.28, with the bonding sigma orbitals being populated through electron donation from the six ligand lone pairs. The eight metal  $d$  electrons fill the nonbonding  $t_{2g}$  orbitals, with one

electron occupying each of the antibonding  $e_g^*$  orbitals. The electron spins are paired in the  $t_{2g}$  orbitals but are parallel to one another in the  $e_g^*$  orbitals, making the complex paramagnetic. There are no low energy  $\pi$  or  $\pi^*$  orbitals available on the ligands for  $\pi$  bonding. The center portion of the MO diagram is identical to that predicted by crystal field theory, as shown in Figure 8.17, and the magnetic properties are predicted to be the same by both methods. VB theory fails to describe bonding in this complex because it would need eight hybrid orbitals to accommodate the eight  $d$  electrons to form two-center two-electron bonds with the ligands. MO theory correctly accounts for the optical and magnetic properties of the complex.

Figure 8.32 summarizes the molecular orbital picture of bonding in octahedral coordination complexes, identifies the interactions that determine the splitting energy  $\Delta_o$ , and provides guidance for predicting the bonding and energy-level structure for any coordination compound of interest, based on the oxidation state of the metal (number of  $d$  electrons) and the nature and occupancy of the ligand orbitals. The center portion of the figure shows the orbital splitting predicted using the simple molecular orbital picture that includes only  $\sigma$  bonding; the three  $d$  electrons shown could be found in complexes of  $V^{2+}$ ,  $Cr^{3+}$ , or  $Mn^{4+}$ , for example. Crystal field theory would make the same prediction for the

**FIGURE 8.32** Effect of  $\pi$  bonding on the energy-level structure for octahedral coordination complexes. The center energy-level diagram is appropriate for intermediate field ligands that are  $\sigma$  donors only. The left energy-level diagram shows how weak field ligands ( $\pi$  donors) decrease  $\Delta_o$ , and the right energy-level diagram shows how strong field ligands ( $\pi$  acceptors) increase  $\Delta_o$ .

(Adapted from *Concepts and Models of Inorganic Chemistry*, 2nd edition, B. Douglas, D. H. McDaniel, and J. J. Alexander, John Wiley and Sons, New York, 1983, p. 293.)

energy-level structure of  $[\text{Cr}(\text{NH}_3)_6]^{3+}$ , and it can be considered a limiting case of molecular orbital theory.

The left side of Figure 8.32 could represent the bonding interactions and energy-level structure for  $[\text{CrCl}_6]^{3-}$  in which a set of filled ligand orbitals (in this case, Cl  $2p$  orbitals) donate electrons to a set of empty (or only partially filled) metal  $d$  orbitals ( $L \rightarrow M$   $\pi$  donation). The ligand orbitals are assumed to lie lower in energy than the metal orbitals, so the resulting  $t_{2g}$  molecular orbital is mostly ligand in character and lies at a relatively low energy. There is a corresponding  $t_{2g}^*$  orbital, which is mostly metal-like, at higher energy. This antibonding orbital is the highest occupied molecular orbital in this example; six of the nine available electrons go into the bonding  $t_{2g}$  orbital, leaving three to occupy the  $t_{2g}^*$  orbital. There are two important differences between this picture and the one in the center of Figure 8.32. First, the  $t_{2g}$  orbitals that were nonbonding metal  $d$  orbitals in the absence of  $\pi$  bonding have now become antibonding MOs by virtue of  $L \rightarrow M$   $\pi$  donation. Second, the energy-level splitting,  $\Delta_o$ , has been reduced from its value without  $\pi$  bonding interactions. So, we now have an explanation for the mechanism by which weak field ligands lead to the smallest field splittings and a criterion with which to classify them. Weak field ligands have filled low-energy  $p$  orbitals that can donate electron density to empty metal  $d$  orbitals to produce an occupied antibonding molecular orbital at higher energy than the nonbonding metal  $d$  orbitals. All of the weak field ligands identified empirically in the spectrochemical series (the halides) fall into this class.

The right side of Figure 8.32 illustrates the case in which the metal  $d$  orbitals are nearly filled and the ligand has empty  $\pi^*$  orbitals at higher energies. This situation leads to a bonding and antibonding pair of MOs as before, but in this case, the energy of the  $t_{2g}^*$  orbital is too high for it to be occupied. The highest occupied molecular orbital is the bonding  $t_{2g}$  orbital, and  $\Delta_o$  is now the difference in energy between this orbital and the antibonding  $e_g^*$  orbital. In the

language of inorganic chemistry, the  $t_{2g}$  orbital has been stabilized because of  $M \rightarrow L$   $\pi$  donation. These interactions are important for metals with filled or nearly filled  $t_{2g}$  orbitals (such as Fe, Co, and Ni) and ligands with empty, low-lying orbitals such as the  $d$  orbitals of P or S or the  $\pi^*$  orbitals of CO,  $CN^-$ , or  $NO^+$ .

Molecular orbital theory provides a simple yet comprehensive way to understand and predict bonding patterns and energy levels in coordination complexes. Although we have worked out only the octahedral geometry in detail, the same considerations apply for all of the other geometries. Ligands classified empirically by the strengths of their interactions as revealed by the spectrochemical series can now be classified by the bonding interactions responsible. Weak field ligands are  $\pi$  donors, intermediate field ligands are **sigma ( $\sigma$ ) donors** with little to no  $\pi$  interactions at all, and strong field ligands are  **$\pi$  acceptors**. These classifications enable us to determine the nature of the ligand by simply looking for these characteristic features and to understand the bonding in coordination complexes by combining this knowledge with the oxidation state of the metal ion of interest.

## CHAPTER SUMMARY

---

Transition-metal compounds and coordination complexes display a much wider variety of physical and chemical properties than the main-group elements in large part because of the participation of the  $d$  electrons in bonding and chemical reactions. Because the cost of transferring electrons to and from the  $d$  orbitals is low, these elements have several stable oxidation states and can make several kinds of chemical bonds. The ease with which electrons can be transferred to and from transition-metal compounds also makes them excellent catalysts by providing electron transfer reactions as alternate pathways for chemical reactions. Bonding in transition-metal compounds and coordination complexes is well described by molecular orbital theory. The overlap of the  $d$  orbitals of the metal with the  $\sigma$  and  $\pi$  orbitals of ligands forms bonding and antibonding molecular orbitals; these interactions are often described as ligand-to-metal ( $L \rightarrow M$ )  $\sigma$  and  $\pi$  donation and metal-to-ligand ( $M \rightarrow L$ )  $\pi$  donation, respectively.

Coordination complexes are molecules or ions in which a central metal atom is bound to one or more ligands in a symmetric arrangement. Linear, tetrahedral, square-planar, trigonal bipyramidal, and octahedral arrangements are all known; the octahedral geometry is by far the most common. Crystal field theory accounts for the colors and magnetic properties of coordination complexes by considering the strengths of the repulsive interactions between the electrons in the various  $d$  orbitals and the ligands, represented as point charges located along the Cartesian axes. For octahedral geometries, the degenerate set of  $d$  orbitals splits into two levels, one set of three at lower energy and a set of two at higher energy. The colors of coordination complexes, as well as their magnetic properties, are rationalized using this model. Large energy differences between the two sets of levels result in the absorption of light in the blue or ultraviolet portion of the spectrum, and the complexes appear red in color. These strong fields also favor electron configurations in which the electrons preferentially occupy the lower levels in pairs, the low-spin configuration. Weak fields lead to optical absorption in the red or yellow regions of the spectrum, and the compounds appear blue. The electrons occupy both sets of orbitals with their spins parallel, the high-spin configuration.

Crystal field theory is only partially successful in explaining the optical and magnetic properties of the coordination complexes; it cannot explain the relative strengths of the ligands in the spectrochemical series. Molecular orbital

theory (an earlier version of which is called ligand field theory) provides a more complete and quantitative description of bonding, optical, and magnetic properties by allowing for the formation of both  $\sigma$  and  $\pi$  bonds between the central metal ion and the ligands. Molecular orbital theory provides qualitative insight by classifying ligands by their bonding types and by considering the oxidation states of the metal ion.

## CONCEPTS AND SKILLS

### Section 8.1 – Chemistry of the Transition Metals

*Discuss the systematic variation of physical and chemical properties of the transition elements through the periodic table (Problems 1–6).*

- The properties of transition metal compounds and coordination complexes are determined, in large part, by the participation of  $d$  electrons in bonding and chemical reactions. Most transition metals have a number of stable oxidation states that lead to different kinds of chemical bonds and facilitate electron transfer reactions.

*Identify the common oxidation states of the transition metals, rationalize the periodic trends observed, and be able to determine oxidation states in inorganic compounds (Problems 7–10).*

- The highest oxidation state observed for each element on the left side of each period corresponds to ionization to form a noble gas configuration. Higher oxidation states are more common for the heavier members of each group and all higher oxidation states are preferentially stabilized by small anionic ligands such as  $F^-$  and  $O^{2-}$ .

*Use the concept of hard and soft acids and bases to predict the stability and reactivity of ionic compounds (Problems 11–14).*

- Hard acids are small cations with large charge densities whereas soft acids are larger atoms or ions with small charge densities but large polarizabilities. Hard bases include  $F^-$  and neutral Lewis bases whereas soft bases include larger anions with smaller charge densities. Hard acids prefer to pair with hard bases and soft acids prefer to pair with soft bases.

### Section 8.2 – Introduction to Coordination Chemistry

*Define the terms coordination compound, coordination number, ligand, and chelation (Problems 15–18).*

- Coordination complexes comprise a central metal atom or ion coordinated by dative bonds to a number of ligands in a symmetrical arrangement. Linear, tetrahedral, square planar, trigonal bipyramidal, and octahedral geometries are all known, with octahedral being by far the most common.

*Name coordination compounds, given their molecular formulas (Problems 19–22).*

### Section 8.3 – Structures of Coordination Complexes

*Draw geometric isomers of octahedral, tetrahedral, and square-planar complexes (Problems 25–28).*

Describe several coordination complexes that have roles in biology.

- A number of coordination complexes are important in biology, many built around porphyrin ligands; these include the oxygen transport protein hemoglobin and the family of enzymes called cytochromes that catalyze many different biochemical reactions.

**Section 8.4 – Crystal Field Theory: Optical and Magnetic Properties**

Use crystal field theory to interpret the magnetic properties of coordination compounds in terms of the electron configurations of their central ions (Problems 29–33).

- Crystal field theory accounts for the optical and magnetic properties of coordination complexes by considering the electrostatic repulsion between the metal  $d$  electrons and the charges on ionic ligands. The set of five degenerate  $d$  orbitals split into several sets that depend upon the symmetry of each crystal field. Octahedral crystal fields, which are the most common, split the orbitals into a triply degenerate set at lower energy and a doubly degenerate set at higher energy.
- Magnetic properties are determined by the competition between the cost of promoting an electron to the higher level and the cost of pairing an electron with another electron in an occupied orbital.

**Section 8.5 – Optical Properties and the Spectrochemical Spectrum**

Relate the colors of coordination compounds to their crystal field splitting energies and CFSE (Problems 35–44).

- The crystal field splitting is measured by optical absorption spectroscopy, which results from  $d-d$  transitions between the two sets of levels.

**Section 8.6 – Bonding in Coordination Complexes**

Use molecular orbital theory to order the energy levels in coordination compounds and to account for the spectrochemical series.

- Molecular orbital theory that considers only  $\sigma$  bonding produces results similar to crystal field theory but with a different physical interpretation for the physical origin of the splitting.

**CUMULATIVE EXERCISE****Platinum**

The precious metal platinum was first used by South American Indians, who found impure, native samples of it in the gold mines of what is now Ecuador and used the samples to make small items of jewelry. Platinum's high melting point (1772°C) makes it harder to work than gold (1064°C) and silver (962°C), but this same property and a high resistance to chemical attack make platinum suitable as a material for high-temperature crucibles. Although platinum is a noble metal, in the +4 and +2 oxidation states it forms a variety of compounds, many of which are coordination complexes. Its coordinating abilities make it an important catalyst for organic and inorganic reactions.

- The anticancer drug cisplatin, *cis*-[Pt(NH<sub>3</sub>)<sub>2</sub>Cl<sub>2</sub>] (see Figs. 8.12b and 8.33), can be prepared from K<sub>2</sub>PtCl<sub>6</sub> via reduction with N<sub>2</sub>H<sub>4</sub> (hydrazine), giving K<sub>2</sub>PtCl<sub>4</sub>, followed by replacement of two chloride ion ligands with ammonia. Give systematic names to the three platinum complexes referred to in this statement.
- The coordination compound diamminetetracyanoplatinum(IV) has been prepared, but salts of the hexacyanoplatinate(IV) ion have not. Write the chemical formulas of these two species.
- Platinum forms organometallic complexes quite readily. In one of the simplest of these, Pt(II) is coordinated to two chloride ions and two molecules of ethylene (C<sub>2</sub>H<sub>4</sub>) to give an unstable yellow crystalline solid. Can this complex have more than one isomer? If so, describe the possible isomers.

Science Source

**FIGURE 8.33** Cisplatin crystals.

- (d) Platinum(IV) is readily complexed by ethylenediamine. Draw the structures of both enantiomers of the complex ion  $cis-[Pt(Cl)_2(en)_2]^{2+}$ . In this compound, the  $Cl^-$  ligands are *cis* to one another.
- (e) In platinum(IV) complexes, the octahedral crystal field splitting  $\Delta_o$  is relatively large. Is  $K_2PtCl_6$  diamagnetic or paramagnetic? What is its *d* electron configuration?
- (f) Is cisplatin diamagnetic or paramagnetic?
- (g) The salt  $K_2[PtCl_4]$  is red, but  $[Pt(NH_3)_4]Cl_2 \cdot H_2O$  is colorless. In what regions of the spectrum do the dominant absorptions for these compounds lie?
- (h) When the two salts from part (g) are dissolved in water and the solutions mixed, a green precipitate called Magnus's green salt forms. Propose a chemical formula for this salt and assign the corresponding systematic name.

### Answers

- (a) *cis*-Diamminedichloroplatinum(II), potassium hexachloroplatinate(IV), and potassium tetrachloroplatinate(II)
- (b)  $[Pt(NH_3)_2(CN)_4]$  and  $[Pt(CN)_6]^{2-}$
- (c) Pt(II) forms square-planar complexes. There are two possible forms, arising from *cis* and *trans* placement of the ethylene molecules. These are analogous to the two isomers shown in Figures 8.12b and c.
- (d) The structures are the *cis* form shown in Figure 8.10 and its mirror image.
- (e) The six *d* electrons in Pt(IV) are all in the lower  $t_{2g}$  level in a low-spin, large- $\Delta_o$  complex. All are paired; thus, the compound is diamagnetic.
- (f) Diamagnetic, with the bottom four levels in the square-planar configuration (all but  $d_{x^2-y^2}$ ) occupied
- (g) Red transmission corresponds to absorption of green light by  $K_2[PtCl_4]$ . A colorless solution has absorptions at either higher or lower frequency than visible. Because  $Cl^-$  is a weaker field ligand than  $NH_3$ , the absorption frequency should be higher for the  $Pt(NH_3)_4^{2+}$  complex, putting it in the ultra-violet region of the spectrum.
- (h)  $[Pt(NH_3)_4][PtCl_4]$ , tetra-ammineplatinum(II) tetrachloroplatinate(II)

## PROBLEMS

Answers to problems whose numbers are red appear in Appendix G. Problems that are more challenging are indicated with asterisks.

### 8.1 Chemistry of the Transition Metals

- Of the compounds  $PtF_4$  and  $PtF_6$ , predict (a) which is more soluble in water and (b) which is more volatile.
- The melting point of  $TiCl_4$  ( $-24^\circ C$ ) lies below those of  $TiF_4$  ( $284^\circ C$ ) and  $TiBr_4$  ( $38^\circ C$ ). Explain why by considering the covalent-ionic nature of these compounds and the intermolecular forces in each case.
- The decavanadate ion is a complex species with chemical formula  $V_{10}O_{28}^{6-}$ . It reacts with an excess of acid to form the dioxovanadium ion,  $VO_2^+$ , and water. Write a balanced chemical equation for this reaction. In what oxidation state is vanadium before and after this reaction? What vanadium oxide has the same oxidation state?
- What is the chemical formula of vanadium(III) oxide? Do you predict this compound to be more basic or more acidic than the vanadium oxide of Problem 3? Write a balanced chemical equation for the reaction of vanadium(III) oxide with a strong acid.
- Titanium(III) oxide is prepared by reaction of titanium(IV) oxide with hydrogen at high temperature. Write a balanced chemical equation for this reaction. Which oxide do you expect to have stronger basic properties?
- Treatment of cobalt(II) oxide with oxygen at high temperatures gives  $Co_3O_4$ . Write a balanced chemical equation for this reaction. What is the oxidation state of cobalt in  $Co_3O_4$ ?

### 8.2 Introduction to Coordination Chemistry

- What are the oxidation states of manganese in the following series of oxides?  $MnO$ ,  $MnO_2$ ,  $Mn_2O_3$ ,  $Mn_2O_7$ ,  $Mn_3O_4$ ,

and  $[\text{MnO}_4]^-$ ? Recall that you must include the total charge on the ion for ionic species.

- What are the oxidation states of the transition metals in the following series of compounds?  $\text{Nb}_2\text{O}_5$ ,  $\text{MoS}_2$ ,  $\text{RuCl}_3$ ,  $\text{RhO}_2$ ,  $\text{PdF}_2$ , and  $\text{Ag}_2\text{O}$ .
- Why is the highest oxidation state observed for  $\text{CrCl}_4$  only the +4 oxidation state, in contrast to the +6 state observed in  $\text{CrF}_6$ ?
- $\text{OH}^-$  tends to stabilize intermediate oxidation states. Why is this?
- Nickel and copper ores are generally sulfides, whereas aluminum ore is an oxide. Explain this observation on the basis of the hard/soft acid/base concept.
- Would you expect the following reaction to proceed in aqueous solution as written?

- What experimental evidence would allow you to determine whether  $\text{TiCl}_4$  is an ionic compound or a covalent compound? What would you predict based upon oxidation state?
- Which of the two common oxides of chromium,  $\text{CrO}_2$  or  $\text{Cr}_2\text{O}_3$ , would you predict to have the higher melting point and why?
- Will methylamine ( $\text{CH}_3\text{NH}_2$ ) be a monodentate or a bidentate ligand? With which of its atoms will it bind to a metal ion?
- Show how the glycinate ion ( $\text{H}_2\text{N}-\text{CH}_2-\text{COO}^-$ ) can act as a bidentate ligand. (Draw a Lewis diagram if necessary.) Which atoms in the glycinate ion will bind to a metal ion?
- Determine the oxidation state of the metal in each of the following coordination complexes:  $[\text{V}(\text{NH}_3)_4\text{Cl}_2]$ ,  $[\text{Mo}_2\text{Cl}_8]^{4-}$ ,  $[\text{Co}(\text{OH}_2)_2(\text{NH}_3)\text{Cl}_3]^-$ ,  $[\text{Ni}(\text{CO})_4]$ .
- Determine the oxidation state of the metal in each of the following coordination complexes:  $\text{Mn}_2(\text{CO})_{10}$ ,  $[\text{Re}_3\text{Br}_{12}]^{3-}$ ,  $[\text{Fe}(\text{OH}_2)_4(\text{OH})_2]^+$ ,  $[\text{Co}(\text{NH}_3)_4\text{Cl}_2]^+$ .
- Give the chemical formula that corresponds to each of the following compounds:
  - Sodium tetrahydroxozincate(II)
  - Dichlorobis(ethylenediamine)cobalt(III) nitrate
  - Triaquabromoplatinum(II) chloride
  - Tetra-amminedinitroplatinum(IV) bromide
- Give the chemical formula of each of the following compounds:
  - Silver hexacyanoferrate(II)
  - Potassium tetrakisothiocyanatocobaltate(II)
  - Sodium hexafluorovanadate(III)
  - Potassium trioxalatochromate(III)
- Assign a systematic name to each of the following chemical compounds:
  - $\text{NH}_4[\text{Cr}(\text{NH}_3)_2(\text{NCS})_4]$
  - $[\text{Fe}(\text{CO})_5]\text{I}$
  - $\text{K}[\text{Mn}(\text{CN})_5]$
  - $[\text{Co}(\text{NH}_3)_4(\text{OH}_2)\text{Cl}]\text{Br}_2$

- Give the systematic name for each of the following chemical compounds:
  - $[\text{Ni}(\text{OH}_2)_4(\text{OH})_2]$
  - $[\text{HgClI}]$
  - $\text{K}_4[\text{Os}(\text{CN})_6]$
  - $[\text{FeBrCl}(\text{en})_2]\text{Cl}$

### 8.3 Structures of Coordination Complexes

- Suppose 0.010 mol of each of the following compounds is dissolved (separately) in 1.0 L water:  $\text{KNO}_3$ ,  $[\text{Co}(\text{NH}_3)_6]\text{Cl}_3$ ,  $\text{Na}_2[\text{PtCl}_6]$ ,  $[\text{Cu}(\text{NH}_3)_2\text{Cl}_2]$ . Rank the resulting four solutions in order of conductivity, from lowest to highest.
- Suppose 0.010 mol of each of the following compounds is dissolved (separately) in 1.0 L water:  $\text{BaCl}_2$ ,  $\text{K}_4[\text{Fe}(\text{CN})_6]$ ,  $[\text{Cr}(\text{NH}_3)_4\text{Cl}_2]\text{Cl}$ ,  $[\text{Fe}(\text{NH}_3)_3\text{Cl}_3]$ . Rank the resulting four solutions in order of conductivity, from lowest to highest.
- Draw the structures of all possible isomers for the following complexes. Indicate which isomers are enantiomer pairs.
  - Diamminebromochloroplatinum(II) (square-planar)
  - Diaquachlorotricyanocobaltate(III) ion (octahedral)
  - Trioxalatovanadate(III) ion (octahedral)
- Draw the structures of all possible isomers for the following complexes. Indicate which isomers are enantiomer pairs.
  - Bromochloro(ethylenediamine)platinum(II) (square-planar)
  - Tetra-amminedichloroiron(III) ion (octahedral)
  - Amminechlorobis(ethylenediamine)iron(III) ion (octahedral)
- Iron(III) forms octahedral complexes. Sketch the structures of all the distinct isomers of  $[\text{Fe}(\text{en})_2\text{Cl}_2]^+$ , indicating which pairs of structures are mirror images of each other.
- Platinum(IV) forms octahedral complexes. Sketch the structures of all the distinct isomers of  $[\text{Pt}(\text{NH}_3)_2\text{Cl}_2\text{F}_2]$ , indicating which pairs of structures are mirror images of each other.

### 8.4 Crystal Field Theory: Optical and Magnetic Properties

- For each of the following ions, draw diagrams like those in Figure 8.18 to show orbital occupancies in both weak and strong octahedral fields. Indicate the total number of unpaired electrons in each case.
 

(a) $\text{Mn}^{2+}$	(c) $\text{Cr}^{3+}$	(e) $\text{Fe}^{2+}$
(b) $\text{Zn}^{2+}$	(d) $\text{Mn}^{3+}$	
- Repeat the work of the preceding problem for the following ions:
 

(a) $\text{Cr}^{2+}$	(c) $\text{Ni}^{2+}$	(e) $\text{Co}^{2+}$
(b) $\text{V}^{3+}$	(d) $\text{Pt}^{4+}$	
- Experiments can measure not only whether a compound is paramagnetic, but also the number of unpaired electrons. It is found that the octahedral complex ion  $[\text{Fe}(\text{CN})_6]^{3-}$  has fewer unpaired electrons than the octahedral complex ion  $[\text{Fe}(\text{OH}_2)_6]^{3+}$ . How many unpaired electrons are present in each species? Explain. In each case, express the CFSE in terms of  $\Delta_o$ .

32. The octahedral complex ion  $[\text{MnCl}_6]^{3-}$  has more unpaired spins than the octahedral complex ion  $[\text{Mn}(\text{CN})_6]^{3-}$ . How many unpaired electrons are present in each species? Explain. In each case, express the CFSE in terms of  $\Delta_o$ .
33. Explain why octahedral coordination complexes with three and eight  $d$  electrons on the central metal atom are particularly stable. Under what circumstances would you expect complexes with five or six  $d$  electrons on the central metal atom to be particularly stable?
34. Mn, Fe, and Co in the +2 and +3 oxidation states all form hexa-aqua complexes in acidic aqueous solution. The reduction reactions of the three species are represented schematically below, where the water ligands are not shown for simplicity. It is an experimental fact from electrochemistry that  $\text{Mn}^{2+}$  and  $\text{Co}^{2+}$  are more easily reduced than  $\text{Fe}^{3+}$ ; that is, they will more readily accept an electron. Based on the electron configurations of the ions involved, explain why  $\text{Fe}^{3+}$  is harder to reduce than  $\text{Mn}^{2+}$  and  $\text{Co}^{2+}$ .

### 8.5 Optical Properties and the Spectrochemical Series

35. An aqueous solution of zinc nitrate contains the  $[\text{Zn}(\text{OH}_2)_6]^{2+}$  ion and is colorless. What conclusions can be drawn about the absorption spectrum of the  $[\text{Zn}(\text{OH}_2)_6]^{2+}$  complex ion?
36. An aqueous solution of sodium hexaiodoplatinate(IV) is black. What conclusions can be drawn about the absorption spectrum of the  $[\text{PtI}_6]^{2-}$  complex ion?
37. Estimate the wavelength of maximum absorption for the octahedral ion hexacyanoferrate(III) from the fact that light transmitted by a solution of it is red. Estimate the crystal field splitting energy  $\Delta_o$  (in  $\text{kJ mol}^{-1}$ ).
38. Estimate the wavelength of maximum absorption for the octahedral ion hexa-aquanickel(II) from the fact that its solutions are colored green by transmitted light. Estimate the crystal field splitting energy  $\Delta_o$  (in  $\text{kJ mol}^{-1}$ ).
39. Estimate the CFSE for the complex in Problem 29. (Note: This is a high-field (low-spin) complex.)
40. Estimate the CFSE for the complex in Problem 30.
41. The chromium(III) ion in aqueous solution is blue-violet.
- What is the complementary color to blue-violet?
  - Estimate the wavelength of maximum absorption for a  $\text{Cr}(\text{NO}_3)_3$  solution.
  - Will the wavelength of maximum absorption increase or decrease if cyano ligands are substituted for the coordinated water? Explain.
42. An aqueous solution containing the hexa-amminecobalt(III) ion is yellow.
- What is the complementary color to yellow?
  - Estimate this solution's wavelength of maximum absorption in the visible spectrum.
43. (a) An aqueous solution of  $\text{Fe}(\text{NO}_3)_3$  has only a pale color, but an aqueous solution of  $\text{K}_3[\text{Fe}(\text{CN})_6]$  is bright red. Do you expect a solution of  $\text{K}_3[\text{FeF}_6]$  to be brightly colored or pale? Explain your reasoning.
- (b) Would you predict a solution of  $\text{K}_2[\text{HgI}_4]$  to be colored or colorless? Explain.
44. (a) An aqueous solution of  $\text{Mn}(\text{NO}_3)_2$  is very pale pink, but an aqueous solution of  $\text{K}_4[\text{Mn}(\text{CN})_6]$  is deep blue. Explain why the two differ so much in the intensities of their colors.
- (b) Predict which of the following compounds would be colorless in aqueous solution:  $\text{K}_2[\text{Co}(\text{NCS})_4]$ ,  $\text{Zn}(\text{NO}_3)_2$ ,  $[\text{Cu}(\text{NH}_3)_4]\text{Cl}_2$ ,  $\text{CdSO}_4$ ,  $\text{AgClO}_3$ ,  $\text{Cr}(\text{NO}_3)_2$ .
45. Predict the geometry and number of unpaired spins in the following four-coordinate complexes:  $[\text{AuBr}_4]^-$ ,  $[\text{NiBr}_4]^{2-}$ . Explain your reasoning.
46. Predict the geometry and number of unpaired spins in the following four-coordinate complexes:  $[\text{Ni}(\text{CN})_4]^{2-}$ ,  $[\text{NiCl}_4]^{2-}$ . Explain your reasoning.

## ADDITIONAL PROBLEMS

47. Of the ten fourth-period transition metal elements in Table 8.1, which one has particularly low melting and boiling points? How can you explain this in terms of the electronic configuration of this element?
- \*48. Although copper lies between nickel and zinc in the periodic table, the reduction potential of  $\text{Cu}^{2+}$  is above that for both  $\text{Ni}^{2+}$  and  $\text{Zn}^{2+}$  (see Table 8.3). Use other data from Table 8.3 to account for this observation. (Hint: Think of a multistep process to convert a metal atom in the solid to a metal ion in solution. For each step, compare the relevant energy or enthalpy changes for Cu with those for Ni or Zn.)
49. A reference book lists five different values for the electronegativity of molybdenum, a different value for each oxidation state from +2 through +6. Predict which electronegativity is highest and which is lowest.
50. If *trans*- $[\text{Cr}(\text{en})_2(\text{NCS})_2]\text{SCN}$  is heated, it forms gaseous ethylenediamine and solid  $[\text{Cr}(\text{en})_2(\text{NCS})_2][\text{Cr}(\text{en})(\text{NCS})_4]$ . Write a balanced chemical equation for this reaction. What are the oxidation states of the Cr ions in the reactant and in the two complex ions in the product?
51. A coordination complex has the molecular formula  $[\text{Ru}_2(\text{NH}_3)_6\text{Br}_3](\text{ClO}_4)_2$ . Determine the oxidation state of ruthenium in this complex.

52. Heating 2.0 mol of a coordination compound gives 1.0 mol  $\text{NH}_3$ , 2.0 mol  $\text{H}_2\text{O}$ , 1.0 mol  $\text{HCl}$ , and 1.0 mol  $(\text{NH}_4)_3[\text{Ir}_2\text{Cl}_9]$ . Write the formula of the original (six-coordinate) coordination compound and name it.
53. Explain why ligands are usually negative or neutral in charge and only rarely positive.
54. Match each compound in the group on the left with the compound on the right that is most likely to have the same electrical conductivity per mole in aqueous solution.
- |  |                              |
|--|------------------------------|
| (a) $[\text{Fe}(\text{OH}_2)_5\text{Cl}]\text{CO}_3$ | HCN                          |
| (b) $[\text{Mn}(\text{OH}_2)_6]\text{Cl}_3$          | $\text{Fe}_2(\text{SO}_4)_3$ |
| (c) $[\text{Zn}(\text{OH}_2)_3(\text{OH})]\text{Cl}$ | NaCl                         |
| (d) $[\text{Fe}(\text{NH}_3)_6]_2(\text{CO}_3)_3$    | $\text{MgSO}_4$              |
| (e) $[\text{Cr}(\text{NH}_3)_3\text{Br}_3]$          | $\text{Na}_3\text{PO}_4$     |
| (f) $\text{K}_3[\text{Fe}(\text{CN})_6]$             | $\text{GaCl}_3$              |
55. Three different compounds are known to have the empirical formula  $\text{CrCl}_3 \cdot 6\text{H}_2\text{O}$ . When exposed to a dehydrating agent, compound 1 (which is dark green) loses 2 mol water per mole of compound, compound 2 (light green) loses 1 mol water, and compound 3 (violet) loses no water. What are the probable structures of these compounds? If an excess of silver nitrate solution is added to 100.0 g of each of these compounds, what mass of silver chloride will precipitate in each case?
56. The octahedral structure is not the only possible six-coordinate structure. Other possibilities include a planar hexagonal structure and a triangular prism structure. In the latter, the ligands are arranged in two parallel triangles, one lying above the metal atom and the other below the metal atom with its corners directly in line with the corners of the first triangle. Show that the existence of two and only two isomers of  $[\text{Co}(\text{NH}_3)_4\text{Cl}_2]^+$  is evidence against both of these possible structures.
57. Cobalt(II) forms more tetrahedral complexes than any other ion except zinc(II). Draw the structure(s) of the tetrahedral complex  $[\text{CoCl}_2(\text{en})]$ . Could this complex exhibit geometric or optical isomerism? If one of the  $\text{Cl}^-$  ligands is replaced by  $\text{Br}^-$ , what kinds of isomerism, if any, are possible in the resulting compound?
58. Is the coordination compound  $[\text{Co}(\text{NH}_3)_6]\text{Cl}_2$  diamagnetic or paramagnetic?
59. A coordination compound has the empirical formula  $\text{PtBr}(\text{en})(\text{SCN})_2$  and is diamagnetic.
- (a) Examine the  $d$ -electron configurations on the metal atoms, and explain why the formulation  $[\text{Pt}(\text{en})_2(\text{SCN})_2][\text{PtBr}_2(\text{SCN})_2]$  is preferred for this substance.
- (b) Name this compound.
60. We used crystal field theory to order the energy-level splittings induced in the five  $d$  orbitals. The same procedure could be applied to  $p$  orbitals. Predict the level splittings (if any) induced in the three  $p$  orbitals by octahedral and square-planar crystal fields.
61. The three complex ions  $[\text{Mn}(\text{CN})_6]^{5-}$ ,  $[\text{Mn}(\text{CN})_6]^{4-}$ , and  $[\text{Mn}(\text{CN})_6]^{3-}$  have all been synthesized and all are low-spin octahedral complexes. For each complex, determine the oxidation number of Mn, the configuration of the  $d$  electrons (how many  $t_{2g}$  and how many  $e_g$ ), and the number of unpaired electrons present.
62. On the basis of the examples presented in Problem 51, can you tell whether  $\text{Mn}^{2+}(\text{aq})$  is more easily oxidized or more easily reduced? What can you conclude about the stability of  $\text{Mn}^{2+}(\text{aq})$ ?
63. The following ionic radii (in angstroms) are estimated for the +2 ions of selected elements of the first transition-metal series, based on the structures of their oxides:  $\text{Ca}^{2+}(0.99)$ ,  $\text{Ti}^{2+}(0.71)$ ,  $\text{V}^{2+}(0.64)$ ,  $\text{Mn}^{2+}(0.80)$ ,  $\text{Fe}^{2+}(0.75)$ ,  $\text{Co}^{2+}(0.72)$ ,  $\text{Ni}^{2+}(0.69)$ ,  $\text{Cu}^{2+}(0.71)$ ,  $\text{Zn}^{2+}(0.74)$ . Draw a graph of ionic radius versus atomic number in this series, and account for its shape. The oxides take the rock salt structure. Are these solids better described as high- or low-spin transition-metal complexes?
64. The coordination geometries of  $[\text{Mn}(\text{NCS})_4]^{2-}$  and  $[\text{Mn}(\text{NCS})_6]^{4-}$  are tetrahedral and octahedral, respectively. Explain why the two have the same room-temperature molar magnetic susceptibility.
65. The complex ion  $\text{CoCl}_4^{2-}$  has a tetrahedral structure. How many  $d$  electrons are on the Co? What is its electronic configuration? Why is the tetrahedral structure stable in this case?
66. In the coordination compound  $(\text{NH}_4)_2[\text{Fe}(\text{OH}_2)\text{F}_5]$ , the Fe is octahedrally coordinated.
- (a) Based on the fact that  $\text{F}^-$  is a weak-field ligand, predict whether this compound is diamagnetic or paramagnetic. If it is paramagnetic, tell how many unpaired electrons it has.
- (b) By comparison with other complexes reviewed in this chapter, discuss the likely color of this compound.
- (c) Determine the  $d$ -electron configuration of the iron in this compound.
- (d) Name this compound.
67. The compound  $\text{Cs}_2[\text{CuF}_6]$  is bright orange and paramagnetic. Determine the oxidation number of copper in this compound, the most likely geometry of the coordination around the copper, and the possible configurations of the  $d$  electrons of the copper.
68. In what directions do you expect the bond length and vibrational frequency of a free CO molecule to change when it becomes a CO ligand in a  $\text{Ni}(\text{CO})_4$  molecule? Explain your reasoning.
69. Give the number of valence electrons surrounding the central transition-metal ion in each of the following known organometallic compounds or complex ions:  $[\text{Co}(\text{C}_5\text{H}_5)_2]^+$ ,  $[\text{Fe}(\text{C}_5\text{H}_5)(\text{CO})_2\text{Cl}]$ ,  $[\text{Mo}(\text{C}_5\text{H}_5)_2\text{Cl}_2]$ ,  $[\text{Mn}(\text{C}_5\text{H}_5)(\text{C}_6\text{H}_6)]$ .

70. Molecular nitrogen ( $\text{N}_2$ ) can act as a ligand in certain coordination complexes. Predict the structure of  $[\text{V}(\text{N}_2)_6]$ , which is isolated by condensing V with  $\text{N}_2$  at 25 K. Is this compound diamagnetic or paramagnetic? What is the formula of the carbonyl compound of vanadium that has the same number of electrons?
71. What energy levels are occupied in a complex such as hexacarbonylchromium(0)? Are any electrons placed into antibonding orbitals that are derived from the chromium  $d$  orbitals?
- \*72. The compound  $\text{WH}_2(\text{C}_5\text{H}_5)_2$  acts as a base, but  $\text{TaH}_3(\text{C}_5\text{H}_5)_2$  does not. Explain.
73. Discuss the role of transition-metal complexes in biology. Consider such aspects as their absorption of light, the existence of many different structures, and the possibility of multiple oxidation states.

## CUMULATIVE PROBLEMS

---

74. Predict the volume of hydrogen generated at 1.00 atm and  $25^\circ\text{C}$  by the reaction of 4.53 g scandium with excess aqueous hydrochloric acid.
- \*75. Mendeleev's early periodic table placed manganese and chlorine in the same group. Discuss the chemical evidence for these placements, focusing on the oxides of the two elements and their acid–base and redox properties. Is there a connection between the electronic structures of their atoms? In what ways are the elements different?
76. An orange–yellow osmium carbonyl compound is heated to release CO and leave elemental osmium behind. Treatment of 6.79 g of the compound releases 1.18 L  $\text{CO}(\text{g})$  at  $25^\circ\text{C}$  and 2.00 atm pressure. What is the empirical formula of this compound?

# Kinetic Molecular Description of the States of Matter

(a)

(b)

(c)

Spatial arrangement of molecules in a gas (a), a liquid (b), and a solid (c). Because the molecules in a solid or a liquid are in close contact with one another, the volume per molecule of the substance is nearly equal to the volume of the molecule itself. The molecules in a gas are much farther apart, with considerable open space between them.

(Courtesy Dr. Stuart C. Watson and Professor Emily A. Carter/Princeton)

**U**nit III relates the behavior of matter as perceived and measured on the scale of human experience to the structures and interactions of the molecules in the matter. We see that macroscopic properties are determined by nanoscopic structures and the forces between them. We recognize gases, liquids, and solids quite easily because we are surrounded by important examples of each: air, water, and earth. Gases and liquids are fluid, but solids are rigid. A gas expands to fill any container it occupies. A liquid has a fixed volume but flows to conform to the shape of its container. A solid has a fixed volume *and* a fixed shape, both of which resist deformation. These characteristics originate in the arrangements and motions of molecules, which are determined by the sizes and shapes of the molecules and the forces between them. In a solid or liquid, molecules (shown as spheres in the images on the previous page) are in very close contact. At these distances, molecules experience strong mutual forces of attraction. In a liquid, molecules can slide past one another, whereas in a solid, molecules oscillate around particular locations and occasionally hop to new locations. In a gas, the molecules are much farther apart, and the forces between them are strong only during collisions. The molecules in a gas can roam freely throughout the container, unlike those in solids and liquids.

## Unit Chapters

### CHAPTER 9

The Gaseous State

### CHAPTER 10

Solids, Liquids, and Phase Transitions

### CHAPTER 11

Solutions

## Unit Goals

- To define the essential properties of solids, liquids, and gases
- To relate the magnitudes of these properties to the structures and motions of molecules and to the forces between molecules
- To define the properties of solutions and relate their magnitudes to composition of the solutions

Molecular Collisions and Rate Processes

*Connection to Chemical Engineering:* Uranium Enrichment for Nuclear Reactor Fuel

*Cumulative Exercise:* Ammonium Perchlorate as a Rocket Fuel

© Cengage Learning/Charles D. Winters

Lithium metal, in the spoon, reacts with drops of water ( $\text{H}_2\text{O}$ ) to form  $\text{LiOH}$  and  $\text{H}_2$ , which is not visible. The steam observed is water having been evaporated by the heat produced from the reaction.

The *kinetic molecular theory of matter* asserts that the macroscopic properties of matter are determined by the structures of its constituent molecules and the interactions between them. Starting in the latter half of the 19th century, scientists have developed a magnificent theoretical structure called **statistical mechanics** to explain the connection between microscopic structure and macroscopic properties. Statistical mechanics provides this bridge for all types of matter, ranging from biological materials to solid-state integrated circuits. Today, every student of science must be familiar with the concepts that make this connection. We give a qualitative introduction to these concepts, and apply them to numerous cases in the next four chapters.

We start the discussion with gases, because gases provide the simplest opportunity for relating macroscopic properties to the structures and interactions of

molecules. This is possible because gases are much less dense than solids or liquids. On the macroscopic level, gases are distinguished from liquids and solids by their much smaller values of *mass density* (conveniently measured in grams per cubic centimeter). On the microscopic level, the *number density* (number of molecules in 1 cm<sup>3</sup> of the sample) is smaller—and the distances between molecules are much greater—than in liquids and solids. Molecules with no net electrical charge exert significant forces on each other only when they are close. Consequently, in the study of gases it is a legitimate simplification to ignore interactions between molecules until they collide and then to consider collisions between only two molecules at a time.

In this chapter we develop two themes that are key to relating macroscopic behavior to molecular structure. First, we show how to define and measure the macroscopic properties of gases as temperature, pressure, and volume are changed. This discussion leads us to develop and apply the ideal gas law, which—as verified by experiment—accurately represents the bulk properties of gases at low density. Second, we interpret and explain the ideal gas law in terms of the structures and motions of individual molecules. We obtain refinements to the ideal gas law by analyzing the consequences of collisions between pairs of molecules. The results and insights we obtain are essential background for later study of the rate and extent of chemical reactions since chemical reactions occur through molecular collisions.

## 9.1 The Chemistry of Gases

The ancient Greeks considered air to be one of the four fundamental elements in nature. European scientists began to study the properties of air (such as its resistance to compression) as early as the 17th century. The chemical composition of air (Table 9.1) was unknown until late in the 18th century, when Lavoisier, Priestley, and others showed that it consists primarily of two substances: oxygen and nitrogen. Oxygen was characterized by its ability to

**TABLE 9.1**  
Composition of Air

Constituent	Formula	Fraction by Volume
Nitrogen	N <sub>2</sub>	0.78110
Oxygen	O <sub>2</sub>	0.20953
Argon	Ar	0.00934
Carbon dioxide	CO <sub>2</sub>	0.00038
Neon	Ne	1.82 × 10 <sup>-5</sup>
Helium	He	5.2 × 10 <sup>-6</sup>
Methane	CH <sub>4</sub>	1.5 × 10 <sup>-6</sup>
Krypton	Kr	1.1 × 10 <sup>-6</sup>
Hydrogen	H <sub>2</sub>	5 × 10 <sup>-7</sup>
Dinitrogen oxide	N <sub>2</sub> O	3 × 10 <sup>-7</sup>
Xenon	Xe	8.7 × 10 <sup>-8</sup>

Air also contains other constituents, the abundances of which are quite variable in the atmosphere. Examples are water (H<sub>2</sub>O), 0–0.07; ozone (O<sub>3</sub>), 0–7 × 10<sup>-8</sup>; carbon monoxide (CO), 0–2 × 10<sup>-8</sup>; nitrogen dioxide (NO<sub>2</sub>), 0–2 × 10<sup>-8</sup>; and sulfur dioxide (SO<sub>2</sub>), 0–1 × 10<sup>-6</sup>.

**FIGURE 9.1** Carbon dioxide,  $\text{CO}_2$ , is dissolved in aqueous solution to form carbonated beverages. Carbon dioxide also reacts with water to produce  $\text{H}_2\text{CO}_3(\text{aq})$ , which provides some of the acidity in soft drinks. Solid carbon dioxide (dry ice) is used for refrigeration.

**FIGURE 9.2** Sulfur dioxide,  $\text{SO}_2$ , is produced by burning sulfur in air as the first step in the production of sulfuric acid.

**FIGURE 9.3** Sulfur trioxide,  $\text{SO}_3$ , is a corrosive gas produced by the further oxidation of sulfur dioxide.

**FIGURE 9.4** The calcium carbonate in a piece of chalk reacts with an aqueous solution of hydrochloric acid to produce bubbles of carbon dioxide.

support life. Once the oxygen in a volume of air had been used up (by burning a candle in a closed container, for example), the nitrogen that remained could no longer keep animals alive. More than 100 years elapsed before a careful reanalysis of the composition of air using multiple experimental techniques showed that oxygen and nitrogen account for only about 99% of the total volume, most of the remaining 1% being a new gas, given the name “argon.” The other noble gases (helium, neon, krypton, and xenon) are present in air to lesser extents.

Other gases are found on the surface of the Earth and in the atmosphere. Methane ( $\text{CH}_4$ ), formerly known as “marsh gas,” is produced by bacterial processes, especially in swampy areas. It is a major constituent of natural-gas deposits formed over many millennia by decay of plant matter beneath the surface of the Earth. Recovery of methane from municipal landfills for use as a fuel is now a commercially feasible process. Gases also form when liquids evaporate. The most familiar example is water vapor in the air from the evaporation of liquid water; it provides the humidity of air.

Gases are also formed by chemical reactions. Some solids decompose upon heating to give gaseous products. One famous example is the decomposition of mercury(II) oxide to mercury and oxygen (Fig. 1.6):

Joseph Priestly discovered the element oxygen while investigating this reaction. Even earlier, in 1756, Joseph Black showed that marble, which consists primarily of calcium carbonate ( $\text{CaCO}_3$ ), decomposes upon heating to give quicklime ( $\text{CaO}$ ) and carbon dioxide:

Ammonium chloride ( $\text{NH}_4\text{Cl}$ ) decomposes under heat to produce two gases: ammonia and hydrogen chloride:

Some gas-forming reactions proceed explosively. The decomposition of nitroglycerin is a detonation in which all the products are gases:

Several elements react with oxygen to form gaseous oxides. Carbon dioxide (Fig. 9.1) forms during animal respiration and is also produced by burning coal, oil, and other materials that contain carbon compounds. The role of carbon dioxide in global warming is the subject of intense research and policy debates. Oxides of sulfur (see Figs. 9.2 and 9.3) are produced by burning elemental sulfur, and oxides of nitrogen arise from combustion of elemental nitrogen. Sulfur is a common impurity in fossil fuels, and nitrogen is burned in high-temperature environments like automobile engines:

The role of these compounds in air pollution is described in Section 20.6.

Gases can also be produced by the reactions of acids with ionic solids. Carbon dioxide is produced by the reaction of acids with carbonates (Fig. 9.4):

Other examples of this type of reaction include:

In these reactions, the metal ions (sodium, calcium, and potassium) play no direct role; so, parallel reactions can be written for other metal ions.

The gases mentioned earlier vary greatly in their chemical properties. Some, such as HCl and SO<sub>3</sub>, are reactive, acidic, and corrosive, whereas others, such as N<sub>2</sub>O and N<sub>2</sub>, are much less reactive. Whereas the chemical properties of gases vary significantly, their physical properties are quite similar and much simpler to understand. At sufficiently low densities, all gases behave physically in the same way. Their properties are summarized and interpreted by a model system called the “ideal” gas, which is the subject of the following sections.

## 9.2 Pressure and Temperature of Gases

The macroscopic behavior of a fixed mass of a gas is completely characterized by three properties: volume ( $V$ ), pressure ( $P$ ), and temperature ( $T$ ). Volume is self-evident and needs no comment; as stated in Section 2.1, we use the liter as a unit of volume. The definition of pressure and temperature require a little more care.

### 9.2.1 Pressure and Boyle’s Law

The force exerted by a gas on a unit area of the walls of its container is called the **pressure** of that gas. We do not often stop to think that the air around us exerts a pressure on us and on everything else at the surface of the Earth. Evangelista Torricelli (1608–1647), an Italian scientist who had been an assistant to Galileo, demonstrated this phenomenon in an ingenious experiment. He sealed a long glass tube at one end and filled it with mercury. He then covered the open end with his thumb, turned the tube upside down, and immersed the open end in a dish of liquid mercury (Fig. 9.5a), taking care that no air leaked in. The mercury in the tube fell, leaving a nearly perfect vacuum at the closed end, but it did not all run out of the tube. It stopped when its top was about 76 cm above

**FIGURE 9.5** (a) In Torricelli’s barometer, the top of the mercury in the tube is approximately 76 cm higher than that in the open beaker. (b) The mass of mercury in the column of height  $h$  exactly balances that of a column of air of the same diameter extending to the top of the atmosphere.

the level of the mercury in the dish. Torricelli showed that the exact height varied somewhat from day to day and from place to place.

This simple device, called a **barometer**, works like a balance, one arm of which is loaded with the mass of mercury in the tube and the other with a column of air of the same cross-sectional area that extends to the top of the Earth's atmosphere, approximately 150 km above the surface of the Earth (see Fig. 9.5b). The height of the mercury column adjusts itself so that its mass and that of the air column become equal. This means that the two forces on the surface of the mercury in the dish are balanced. Day-to-day changes in the height of the column occur as the force exerted by the atmosphere varies with the weather. Atmospheric pressure varies strongly with altitude; it is lower at higher altitudes because the column of air pressing down is shorter and, therefore, has less mass.

How Torricelli's invention measures the pressure of the atmosphere is explained by Newton's second law of motion, which states:

$$\text{force} = \text{mass} \times \text{acceleration}$$

$$F = ma$$

in which the acceleration of a body ( $a$ ) is the rate at which its velocity changes. The gravitational field of Earth exerts an attractive force that accelerates all bodies toward Earth. The standard acceleration due to the Earth's gravitational field (usually denoted by  $g$  instead of  $a$ ) is  $g = 9.80665 \text{ m s}^{-2}$ . Pressure is the force per unit area, or the total force,  $F$ , divided by the area,  $A$ :

$$P = \frac{F}{A} = \frac{mg}{A}$$

Because the volume of mercury in the barometer is  $V = Ah$ ,

$$P = \frac{mg}{A} = \frac{mg}{V/h} = \frac{mgh}{V}$$

Writing the density as  $\rho = m/V$  and substituting, we get

$$P = \rho gh \quad [9.1]$$

We can use this equation to calculate the pressure exerted by the atmosphere. The density of mercury at  $0^\circ\text{C}$ , in SI units (see Appendix B for a description of SI units), is

$$\rho = 13.5951 \text{ g cm}^{-3} = 1.35951 \times 10^4 \text{ kg m}^{-3}$$

and the height of the mercury column under ordinary atmospheric conditions near sea level is close to 0.76 m (760 mm). Let's use exactly this value for the height in our computation:

$$\begin{aligned} P &= \rho gh = (1.35951 \times 10^4 \text{ kg m}^{-3})(9.80665 \text{ m s}^{-2})(0.760000 \text{ m}) \\ &= 1.01325 \times 10^5 \text{ kg m}^{-1} \text{ s}^{-2} \end{aligned}$$

Pressure is expressed in various units. The SI unit for pressure is the **pascal** (Pa), which is  $1 \text{ kg m}^{-1} \text{ s}^{-2}$ . One **standard atmosphere** (1 atm) is defined as exactly  $1.01325 \times 10^5 \text{ Pa}$ . The standard atmosphere is a useful unit because the pascal is inconveniently small and because "atmospheric pressure" is important as a standard of reference. We must express pressures in pascals when we perform calculations entirely in SI units.

For historical reasons, a number of different pressure units are commonly used in different fields of science and engineering. Although we will work primarily with the standard atmosphere, it is important that you recognize other units and be able to convert among them. For example, the atmospheric pressure (often called the barometric pressure) recorded in weather reports and forecasts is typically expressed as the height (in millimeters or inches) of the column of mercury it supports. One standard atmosphere supports a 760-mm

TABLE 9.2

## Units of Pressure

Unit	Definition or Relationship
pascal (Pa)	$1 \text{ kg m}^{-1} \text{ s}^{-2}$
bar	$1 \times 10^5 \text{ Pa}$
atmosphere (atm)	101,325 Pa
torr	1/760 atm
760 mm Hg (at 0°C)	1 atm
14.6960 pounds per square inch (psi, lb in <sup>-2</sup> )	1 atm

column of mercury at 0°C; thus, we often speak of 1 atm pressure as 760 mm or 30 inches (of mercury [Hg]). Because the density of mercury depends slightly on temperature, for accurate work it is necessary to specify the temperature and make the proper corrections to the density. A more precise term is the “torr,” defined as 1 torr = 1/760 atm (or 760 torr = 1 atm) at *any* temperature. Only at 0°C do the torr and the millimeters of mercury (mm Hg) coincide. These and other units of pressure are summarized in Table 9.2.

Robert Boyle, an English natural philosopher and theologian, studied the properties of confined gases in the 17th century. He noted that a gas tends to spring back to its original volume after being compressed or expanded. Such behavior resembles that of metal springs, which were being investigated by his collaborator Robert Hooke. Boyle published his experiments on the compression and expansion of air in the 1662 monograph titled “The Spring of the Air and Its Effects.”

Boyle studied how the volume of a confined gas responded to changes in pressure while the temperature was held constant. Boyle worked with a simple piece of apparatus: a J-tube in which air was trapped at the closed end by a column of mercury (Fig. 9.6). If the difference in height,  $h$ , between the two

**FIGURE 9.6** (a) Boyle’s J-tube. When the heights of mercury on the two sides of the tube are the same, the pressure of the confined gas must equal that of the atmosphere, 1 atm or 760 mm Hg. (b) After mercury has been added, the pressure of the gas is increased by the number of millimeters in the height difference  $h$ . The compression of the gas causes it to occupy a smaller volume.

(a)

(b)

(c)

**FIGURE 9.7** (a–c) Three ways of depicting Boyle's law. Small deviations from the law (especially apparent in b and c) arise for real gases at higher pressures or smaller volumes.

mercury levels in such a tube is 0, then the pressure of the air in the closed part exactly balances that of the atmosphere; its pressure,  $P$ , is 1 atm. Adding mercury to the open end of the tube increases the pressure applied to the confined air; its internal pressure increases by 1 mm Hg for every 1-mm difference between the levels of mercury on the open and closed sides of the tube. Expressed in atmospheres, the pressure in the closed end of the tube is

$$P = 1 \text{ atm} + \frac{h \text{ (mm)}}{760 \text{ mm atm}^{-1}}$$

The volume of the confined air can be read from the scale on the previously calibrated tube. The temperature is held constant by the ambient surroundings of the tube. Boyle discovered that the product of pressure and volume,  $PV$ , has the constant value  $C$  so long as temperature and the number of moles of confined gas remain fixed. The value of the constant  $C$  depends on the amount of gas and the temperature of the gas.

Boyle's data showed that  $P$  and  $V$  are inversely related, and *suggested* the relationship might be described by the equation  $PV = C$ , as shown in Figure 9.7a. Before the advent of graphing calculators and computers, it was not always easy to determine the mathematical function that best fit experimental data. With a limited amount of data, it is difficult to distinguish  $P = C/V$  from  $P = P^* \exp(-C/V)$ , where  $P^*$  is some fixed reference value of pressure. How are we to know whether Boyle's experiments are best described by  $PV = C$  or some more complicated equation? There are two ways of plotting the data to answer this question. The first is to rewrite Boyle's proposed equation in the form

$$P = \frac{C}{V} = C \left( \frac{1}{V} \right)$$

which makes  $P$  directly or linearly proportional to  $1/V$ . If Boyle's equation correctly fits his data, then replotting the data in the form  $P$  against  $1/V$  (rather than  $V$ ) should give a straight line passing through the origin with slope  $C$  (this is shown to be true in Fig. 9.7b). Alternatively, if  $PV = C$  is correct, replotting the data in the form  $PV$  against  $P$  should give a straight line independent of  $P$  (the results are shown in Fig. 9.7c). Rewriting proposed equations to make them linear ( $y = mx + b$ ) and plotting the data together with a proposed equation provides a good test of that equation's validity. The two plots studied here show convincingly that Boyle's equation accurately describes the relation between pressure and volume, at least over the range of temperatures and pressures measured.

$$PV = C \quad (\text{fixed temperature and fixed amount of gas}) \quad [9.2]$$

This result is known as **Boyle's law**.

Keep in mind that the constant  $C$  depends on the temperature  $T$  and the amount (number of moles  $n$ ) of gas in the closed container. For each combination of  $T$  and  $n$ , the limiting value of  $C$  at low  $P$  can be obtained by extrapolating plots (such as Fig. 9.7c) to zero pressure. For 1 mol gas (for example, 31.999 g  $\text{O}_2$ , 28.013 g  $\text{N}_2$ , or 2.0159 g  $\text{H}_2$ ) at  $0^\circ\text{C}$ , extrapolation of  $PV$  to zero pressure (as shown by the red line in Fig. 9.7c) gives a limiting value of 22.414 L atm for  $C$ . Therefore, for these conditions, Boyle's law takes the special form:

$$PV = 22.414 \text{ L atm} \quad (\text{for 1 mol gas at } 0^\circ\text{C}) \quad [9.3]$$

If the pressure is 1.00 atm, the volume is 22.4 L; if  $P$  is 4.00 atm,  $V$  is  $22.414/4.00 = 5.60$  L.

Boyle's law is an idealized expression that is satisfied exactly by all gases at *very* low pressures. For real gases near 1 atm pressure, small corrections may be necessary for highly accurate studies of  $P$ - $V$ - $T$  behavior. At pressures beyond 50–100 atm, substantial corrections are necessary.

### EXAMPLE 9.1

The long cylinder of a bicycle pump has a volume of 1131 cm<sup>3</sup> and is filled with air at a pressure of 1.02 atm. The outlet valve is sealed shut and the pump handle is pushed down until the volume of the air is 517 cm<sup>3</sup>. Compute the pressure inside the pump. Express its value in atmospheres and pounds per square inch.

#### Solution

Note that the temperature and amount of gas are not stated in this problem; thus, the value of 22.414 L atm cannot be used for the constant  $C$ . It is necessary only to assume that the temperature does not change as the pump handle is pushed down. If  $P_1$  and  $P_2$  are the initial and final pressures and  $V_1$  and  $V_2$  the initial and final volumes, then

$$P_1V_1 = P_2V_2$$

because the temperature and amount of air in the pump do not change. Substitution gives

$$(1.02 \text{ atm})(1131 \text{ cm}^3) = P_2(517 \text{ cm}^3)$$

which can be solved for  $P_2$ :

$$P_2 = 2.23 \text{ atm}$$

In pounds per square inch (see Table 9.2), this pressure is

$$P_2 = 2.23 \text{ atm} \times 14.696 \text{ psi atm}^{-1} = 32.8 \text{ psi}$$

**Related Problems: 11, 12**

## 9.2.2 Temperature and Charles's Law

**Temperature** is one of those elusive properties that we all think we understand but is, in fact, difficult to pin down in a quantitative fashion. We have an instinctive feeling (through the sense of touch) for *hot* and *cold*. Water at its freezing point is obviously colder than at its boiling point, so we assign it a lower temperature. Both the Celsius and Fahrenheit temperature scales were defined using the freezing and boiling points of water. Water freezes at 0°C (32°F) and boils at 100°C (212°F). Although both scales use the same reference points, it is interesting to see how the size of the degree was defined and the reference temperatures were determined. Fahrenheit initially chose as reference points the freezing point for a saturated saltwater solution, which he assigned as 0° (then thought to be as cold as possible), and normal body temperature (that of his wife), assigned to be 96°. His choice of 96° for body temperature is thought to have been stimulated by the earlier work of Newton, who had devised a similar scale by dividing the interval between the boiling and freezing points of water into 12 units. As Fahrenheit's thermometers got better, he increased their resolution by several factors of 2 until the number 96 was reached. Further calibration led to the modern definition based on the freezing and boiling points of pure water cited earlier. The Celsius scale (originally called the centigrade scale) is a bit more logical. Celsius chose the same end points but divided the range into 100 units for ease of calculation.

Assigning two fixed points in this way does not show how to define a temperature scale. Ether boils at atmospheric pressure somewhere between 0°C and 100°C, but what temperature should be assigned to its boiling point? Further arbitrary choices are certainly not the answer. The problem is that temperature is not a mechanical quantity like pressure; therefore, it is more difficult to define.

One way around this problem is to find some mechanical property that depends on temperature and use it to define a temperature scale. If we measure the value of this property of an object immersed in boiling water and again when it is immersed in boiling ether, we can quantitatively compare the boiling points of these two liquids. A number of mechanical properties depend on

**FIGURE 9.8** The volume of a gas confined at constant pressure increases as the temperature increases.

temperature. For example, as liquid mercury is heated from 0°C to 100°C, its volume increases by 1.82%. This change in volume could be used to define a temperature scale. If we *assume* that the volume of mercury is a linear function of temperature, then we can simply measure temperature by measuring the volume of mercury in a tube (a mercury thermometer). The problem is that this definition is tied to the properties of a single substance, mercury, and rests on the assumption that the volume of a sample of mercury is directly proportional to the temperature. Can we define a temperature scale that is more universal, one that does not depend on the properties of a specific material or the assumption of linearity? To answer this question, let's examine the behavior of gases upon heating or cooling.

Boyle observed that the product of the pressure and volume of a confined gas changes on heating, but the first quantitative experiments on the temperature dependence of the properties of gases were performed by the French scientist Jacques Charles more than a century later. Charles observed that *all* gases expand by the same relative amount between the same initial and final temperatures, when studied at sufficiently low pressures. For example, heating a sample of N<sub>2</sub> from the freezing point of water to the boiling point causes the gas to expand to 1.366 times its original volume (Fig. 9.8). The same 36.6% increase in volume occurs for O<sub>2</sub>, CO<sub>2</sub>, and other gases. (In contrast, liquids and solids vary widely in their thermal expansion.) This universal behavior suggests that temperature is a linear function of gas volume. We write this function as

$$t = c \left( \frac{V}{V_0} - 1 \right)$$

where  $V$  is the volume of the gas at temperature  $t$ ,  $V_0$  is its volume at the freezing point of water, and  $c$  is a constant that is the same for all gases. We have written the linear equation in this form to ensure that the freezing point of water (when  $V = V_0$ ) will be at  $t = 0$ , corresponding to the zero of the Celsius scale of temperature. From the measured fractional increase in  $V$  to the boiling point (taken to be 100°C), the value of  $c$  can be determined. In 1802, Gay-Lussac reported a value for  $c$  of 267°C. Subsequent experiments have refined this result to give  $c = 273.15^\circ\text{C}$ . The definition of temperature (in degrees Celsius) is then

$$t = 273.15^\circ\text{C} \left( \frac{V}{V_0} - 1 \right)$$

The temperature of a gas sample at low pressure can be measured by comparing its volume with the volume it occupies at the freezing point of water. For many gases, atmospheric pressure is sufficiently low; but for highly accurate temperature determinations, it is necessary to use pressures below atmospheric or to apply small corrections.

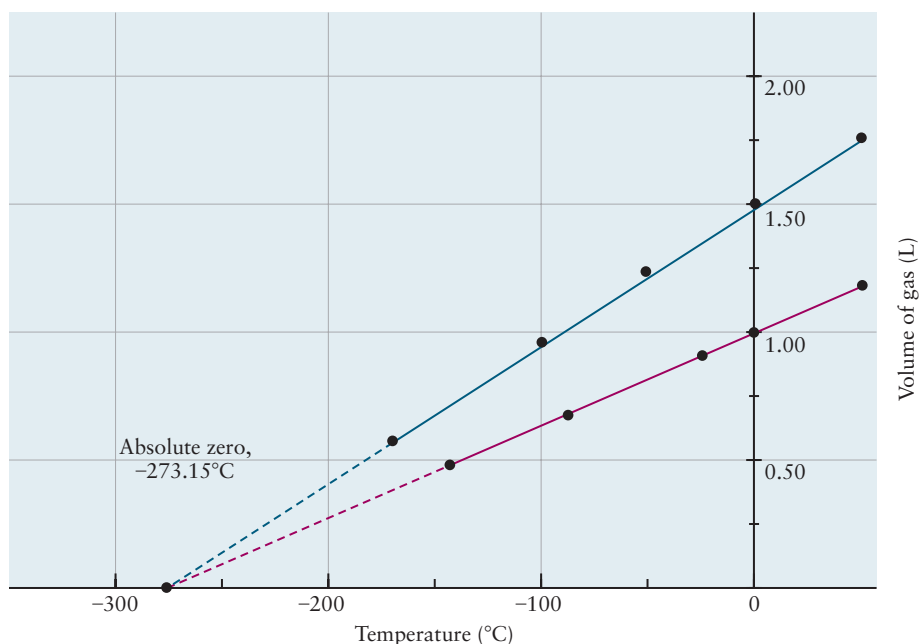

With this definition of temperature in mind, let's return to mercury and measure its *actual* changes in volume with temperature. The result found is almost, but not quite, linear. If a mercury thermometer is calibrated to match the gas thermometer at 0°C and 100°C and if the scale in between is divided evenly into 100 parts to mark off degrees, a small error will result from using this thermometer. A temperature of 40.00°C on the gas thermometer will be read as 40.11°C on the mercury thermometer, because the volume of liquid mercury is not exactly a linear function of temperature.

We can rewrite the preceding equation to express the gas volume in terms of the temperature. The result is

$$V = V_0 \left( 1 + \frac{t}{273.15^\circ\text{C}} \right) \quad [9.4]$$

In words, the volume of a gas varies linearly with its temperature. This is the most common statement of **Charles's law**, but it is somewhat misleading because the linearity is built in through the definition of temperature. The key observation is the universal nature of the constant 273.15°C, which is the same for all gases at low pressures. Written in this form, Charles's law suggests that an interesting lower limit to the temperature exists. Negative temperatures on the Celsius scale correspond to temperatures below the freezing point of water and, of course, are meaningful. But what would happen as  $t$  approached  $-273.15^\circ\text{C}$ ? The volume would then approach zero (Fig. 9.9), and if  $t$  could go below this value, the volume would become negative, clearly an impossible result. We therefore surmise that  $t = -273.15^\circ\text{C}$  is a fundamental limit below which the temperature cannot be lowered. All real gases condense to liquid or solid form before they reach this **absolute zero** of temperature, so we cannot check for the existence of this limit simply by measuring the volume of gases. More rigorous arguments show that *no* substance (gas, liquid, or solid) can be cooled below

**FIGURE 9.9** The volume of a sample of a gas is a function of temperature at constant pressure. The observed straight-line response of volume to temperature illustrates Charles's law. The volume of a particular sample of a gas (red line) is 1.0 L at a temperature of 0°C. Another sample of a gas (blue line) held at the same pressure takes up more volume at 0°C but shrinks faster as cooled. The *percentage* change in volume is the same as that of the first sample for every degree of temperature change. Extrapolation of the trends (dashed lines) predicts that the volumes of the samples go to zero at a temperature of  $-273.15^\circ\text{C}$ . Similar observations are made regardless of the chemical identities of the gases.

−273.15°C. In fact, it becomes increasingly difficult to cool a substance as absolute zero is approached. The coldest temperatures reached to date are less than 1 nanodegree above absolute zero.

The absolute zero of temperature is a compellingly logical choice as the zero point of a temperature scale. The easiest way to create such a new scale is to add 273.15 to the Celsius temperature, which leads to the **Kelvin temperature scale**:

$$T \text{ (Kelvin)} = 273.15 + t \text{ (Celsius)} \quad [9.5]$$

The capital  $T$  signifies that this is an absolute scale, the unit of which is *kelvin* (K). Thus, a temperature of 25.00°C corresponds to  $273.15 + 25.00 = 298.15$  K. (Note: The unit is the kelvin, not the °K.) On this scale, Charles's law takes the following form:

$$V \propto T \quad (\text{fixed pressure and fixed amount of gas}) \quad [9.6]$$

where the proportionality constant is determined by the pressure and the amount (number of moles) of gas present. The ratios of volumes occupied at two different temperatures by a fixed amount of gas at fixed pressure are:

$$\frac{V_1}{V_2} = \frac{T_1}{T_2}$$

### EXAMPLE 9.2

A scientist studying the properties of hydrogen at low temperature takes a volume of 2.50 L hydrogen at atmospheric pressure and a temperature of 25.00°C and cools the gas at constant pressure to −200.00°C. Predict the volume that the hydrogen occupies at the lower temperature.

#### Solution

The first step is always to convert temperatures to kelvins:

$$t_1 = 25.00^\circ\text{C} \Rightarrow T_1 = 273.15 + 25.00 = 298.15 \text{ K}$$

$$t_2 = -200.00^\circ\text{C} \Rightarrow T_2 = 273.15 - 200.00 = 73.15 \text{ K}$$

The ratio in Charles's law is

$$\begin{aligned} \frac{V_1}{T_1} &= \frac{2.50 \text{ L}}{298.15 \text{ K}} = \frac{V_2}{T_2} = \frac{V_2}{73.15 \text{ K}} \\ V_2 &= \frac{(73.15 \text{ K})(2.50 \text{ L})}{298.15 \text{ K}} = 0.613 \text{ L} \end{aligned}$$

**Related Problems: 13, 14, 15, 16, 17, 18**

## 9.3 The Ideal Gas Law

So far, we have empirically deduced several relationships between properties of gases. From Boyle's law,

$$V \propto \frac{1}{P} \quad (\text{at constant temperature, fixed amount of gas})$$

and from Charles's law,

$$V \propto T \quad (\text{at constant pressure, fixed amount of gas})$$

where  $T$  is the absolute temperature in kelvins. From Avogadro's hypothesis (Section 1.3) that equal volumes of different gases held at the same  $T$  and  $P$  contain equal numbers of particles,

$$V \propto n \quad (\text{at constant temperature and pressure})$$

where  $n$  is the number of moles of substance. These three statements may be combined in the form

$$V \propto \frac{nT}{P}$$

A proportionality constant called  $R$  converts this proportionality to an equation:

$$V = R \frac{nT}{P} \quad \text{or} \quad PV = nRT \quad [9.7]$$

Because Avogadro's hypothesis states that equal volumes of all gases contain the same number of molecules (or moles),  $R$  is a *universal* constant. Equation 9.7 states the **ideal gas law**, which holds approximately for all gases near atmospheric pressure and room temperature and becomes increasingly accurate at lower pressure and higher temperature. It is a limiting law that describes the behavior of gases at low *densities*. We obtained the ideal gas law empirically from experimental studies of the  $P$ - $V$ - $T$  behavior of gases, and we shall see in Section 9.5 that the same relation is predicted by a molecular model of gases. The ideal gas law is our first example of a direct connection between the experimentally observed macroscopic behavior of matter and the structure and interactions of its constituent molecules.

Situations frequently arise in which a gas undergoes a change that takes it from some initial condition (described by  $P_1$ ,  $V_1$ ,  $T_1$ , and  $n_1$ ) to a final condition (described by  $P_2$ ,  $V_2$ ,  $T_2$ , and  $n_2$ ). Because  $R$  is a constant,

$$\frac{P_1V_1}{n_1T_1} = \frac{P_2V_2}{n_2T_2} \quad [9.8]$$

This is a useful alternative form of the ideal gas law.

### EXAMPLE 9.3

A weather balloon filled with helium (He) has a volume of  $1.0 \times 10^4$  L at 1.00 atm and  $30^\circ\text{C}$ . It rises to an altitude at which the pressure is 0.60 atm and the temperature is  $-20^\circ\text{C}$ . What is the volume of the balloon then? Assume that the balloon stretches in such a way that the pressure inside stays close to the pressure outside.

#### Solution

Because the amount of helium does not change, we can set  $n_1$  equal to  $n_2$  and cancel it out of Equation 9.8, giving

$$\frac{P_1V_1}{T_1} = \frac{P_2V_2}{T_2}$$

Solving this for the only unknown quantity,  $V_2$ , gives

$$\begin{aligned} V_2 &= V_1 \left( \frac{P_1T_2}{P_2T_1} \right) \\ &= 1.0 \times 10^4 \text{ L} \left( \frac{1.00 \text{ atm}}{0.60 \text{ atm}} \right) \left( \frac{253 \text{ K}}{303 \text{ K}} \right) \\ &= 1.4 \times 10^4 \text{ L} = 14,000 \text{ L} \end{aligned}$$

Remember that temperatures must always be converted to kelvins when using the ideal gas law.

**Related Problems:** 19, 20, 21, 22

The approach outlined in Example 9.3 can be applied when other combinations of the four variables ( $P$ ,  $V$ ,  $T$ , and  $n$ ) remain constant (Fig. 9.10). When  $n$  and  $T$  remain constant, they can be canceled from the equation to give Boyle's law, which was used in solving Example 9.1. When  $n$  and  $P$  remain constant, this relation reduces to Charles's law, used in Example 9.2.

iStock / 360/Getty Images

**FIGURE 9.10** In a hot-air balloon, the volume remains nearly constant (the balloon is rigid) and the pressure is nearly constant as well (unless the balloon rises very high). Thus,  $n$  is inversely proportional to  $T$ ; as the air inside the balloon is heated, its amount decreases and its density falls. This reduced density gives the balloon its lift.

© Cengage Learning/Charles D. Winters

**FIGURE 9.11** When copper metal is immersed in concentrated nitric acid, the copper is oxidized and an aqueous solution of blue copper(II) nitrate forms. In addition, some of the nitrate ion is reduced to brown gaseous nitrogen dioxide, which bubbles off.

The numerical value of  $R$  depends on the units chosen for  $P$  and  $V$ . At the freezing point of water ( $T = 273.15 \text{ K}$ ), the product  $PV$  for 1 mol of any gas approaches the value 22.414 L atm at low pressures; hence,  $R$  has the value

$$R = \frac{PV}{nT} = \frac{22.414 \text{ L atm}}{(1.000 \text{ mol})(273.15 \text{ K})} = 0.082057 \text{ L atm mol}^{-1} \text{ K}^{-1}$$

If  $P$  is measured in SI units of pascals ( $\text{kg m}^{-1} \text{ s}^{-2}$ ) and  $V$  in cubic meters, then  $R$  has the value

$$\begin{aligned} R &= \frac{(1.01325 \times 10^5 \text{ kg m}^{-1} \text{ s}^{-2})(22.414 \times 10^{-3} \text{ m}^3)}{(1.0000 \text{ mol})(273.15 \text{ K})} \\ &= 8.3145 \text{ kg m}^2 \text{ s}^{-2} \text{ mol}^{-1} \text{ K}^{-1} \end{aligned}$$

Because  $1 \text{ kg m}^2 \text{ s}^{-2}$  is defined to be 1 *joule* (the SI unit of energy, abbreviated J), the gas constant may also be expressed as

$$R = 8.3145 \text{ J mol}^{-1} \text{ K}^{-1}$$

### EXAMPLE 9.4

What mass of helium is needed to fill the weather balloon from Example 9.3?

#### Solution

First, solve the ideal gas law for  $n$ :

$$n = \frac{PV}{RT}$$

If  $P$  is expressed in atmospheres and  $V$  is expressed in liters, then the value  $R = 0.08206 \text{ L atm mol}^{-1} \text{ K}^{-1}$  must be used.

$$n = \frac{(1.00 \text{ atm})(1.00 \times 10^4 \text{ L})}{(0.08206 \text{ L atm mol}^{-1} \text{ K}^{-1})(303.15 \text{ K})} = 402 \text{ mol}$$

Because the molar mass of helium is  $4.00 \text{ g mol}^{-1}$ , the mass of helium required is

$$(402 \text{ mol})(4.00 \text{ g mol}^{-1}) = 1610 \text{ g} = 1.61 \text{ kg}$$

**Related Problems:** 23, 24

## 9.3.1 Chemical Calculations for Gases

One of the most important applications of the gas laws in chemistry is to calculate the volumes of gases consumed or produced in chemical reactions. If the conditions of pressure and temperature are known, the ideal gas law can be used to convert between the number of moles and gas volume. Instead of working with the mass of each gas taking part in the reaction, we can then use its volume, which is easier to measure. This is illustrated by the following example.

### EXAMPLE 9.5

Concentrated nitric acid acts on copper to give nitrogen dioxide and dissolved copper ions (Fig. 9.11) according to the balanced chemical equation:

(Continued)

Suppose that 6.80 g copper is consumed in this reaction, and that the  $\text{NO}_2$  is collected at a pressure of 0.970 atm and a temperature of  $45^\circ\text{C}$ . Calculate the volume of  $\text{NO}_2$  produced.

**Solution**

The first step (as in Fig. 2.3) is to convert from the mass of the known reactant or product (in this case, 6.80 g Cu) to the number of moles by using the molar mass of copper,  $63.55 \text{ g mol}^{-1}$ :

$$\frac{6.80 \text{ g Cu}}{63.55 \text{ g mol}^{-1}} = 0.107 \text{ mol Cu}$$

Next, the number of moles of  $\text{NO}_2$  generated in the reaction is calculated using the stoichiometric coefficients in the balanced equation:

$$0.107 \text{ mol Cu} \times \left( \frac{2 \text{ mol NO}_2}{1 \text{ mol Cu}} \right) = 0.214 \text{ mol NO}_2$$

Finally, the ideal gas law is used to find the volume from the number of moles (remember that the temperature must first be expressed in kelvins by adding 273.15):

$$V = \frac{nRT}{P} = \frac{(0.214 \text{ mol})(0.08206 \text{ L atm mol}^{-1} \text{ K}^{-1})(273.15 + 45)\text{K}}{0.970 \text{ atm}} = 5.76 \text{ L}$$

Therefore, 5.76 L  $\text{NO}_2$  is produced under these conditions. This calculation neglects the formation of  $\text{N}_2\text{O}_4(\text{g})$ , dimers of  $\text{NO}_2(\text{g})$  (see Example 9.6).

**Related Problems: 25, 26, 27, 28, 29, 30, 31, 32**

## 9.4 Mixtures of Gases

Suppose a mixture of gases occupies a container at a certain temperature. How does each gas contribute to the total pressure of the mixture? We define the **partial pressure** of each gas as the pressure that gas would exert if it alone were present in the container. John Dalton concluded, from experiment, that the total pressure measured,  $P_{\text{tot}}$ , is the sum of the partial pressures of the individual gases (Fig. 9.12). This should come as no surprise, given the validity of Avogadro's hypothesis. Even so, it is an important result. **Dalton's law** holds under the same conditions as the ideal gas law itself: It is approximate at moderate pressures and becomes increasingly more accurate as the pressure is lowered.

**FIGURE 9.12** According to Dalton's law, the total pressure of a gas mixture is the sum of the pressures exerted by the individual gases. Note that the total volume is the same in all three containers.

For a gas mixture at low pressure, the partial pressure of one component, A, is

$$P_A = n_A \frac{RT}{V}$$

The total pressure is the sum of the partial pressures:

$$P_{\text{tot}} = P_A + P_B + P_C + \cdots = (n_A + n_B + n_C + \cdots) \frac{RT}{V} = n_{\text{tot}} \frac{RT}{V} \quad [9.9]$$

where  $n_{\text{tot}}$  is the total number of moles in the gas mixture. Dividing the first equation by the second gives

$$\frac{P_A}{P_{\text{tot}}} = \frac{n_A}{n_{\text{tot}}} \quad \text{or} \quad P_A = \frac{n_A}{n_{\text{tot}}} P_{\text{tot}}$$

We define

$$X_A = \frac{n_A}{n_{\text{tot}}}$$

as the **mole fraction** of A in the mixture—that is, the number of moles of A divided by the total number of moles present. Then

$$P_A = X_A P_{\text{tot}} \quad [9.10]$$

The partial pressure of any component in a mixture of ideal gases is the total pressure multiplied by the mole fraction of that component. Note that the volume fractions in Table 9.1 are the same as mole fractions.

### EXAMPLE 9.6

When  $\text{NO}_2$  is cooled to room temperature, some of it reacts to form a *dimer*,  $\text{N}_2\text{O}_4$ , through the reaction

Suppose 15.2 g of  $\text{NO}_2$  is placed in a 10.0-L flask at high temperature and the flask is cooled to  $25^\circ\text{C}$ . The total pressure is measured to be 0.500 atm. What partial pressures and mole fractions of  $\text{NO}_2$  and  $\text{N}_2\text{O}_4$  are present?

#### Solution

Initially, there is  $15.2 \text{ g}/46.01 \text{ g mol}^{-1} = 0.330 \text{ mol}$   $\text{NO}_2$ , and therefore, the same number of moles of nitrogen atoms. If at  $25^\circ\text{C}$  there are  $n_{\text{NO}_2}$  moles  $\text{NO}_2$  and  $n_{\text{N}_2\text{O}_4}$  moles  $\text{N}_2\text{O}_4$ , then, because the total number of moles of nitrogen atoms is unchanged,

$$n_{\text{NO}_2} + 2n_{\text{N}_2\text{O}_4} = 0.330 \text{ mol} \quad (\text{a})$$

To find a second relation between  $n_{\text{NO}_2}$  and  $n_{\text{N}_2\text{O}_4}$ , use Dalton's law:

$$P_{\text{NO}_2} + P_{\text{N}_2\text{O}_4} = 0.500 \text{ atm}$$

$$\frac{RT}{V} n_{\text{NO}_2} + \frac{RT}{V} n_{\text{N}_2\text{O}_4} = 0.500 \text{ atm}$$

$$\begin{aligned} n_{\text{NO}_2} + n_{\text{N}_2\text{O}_4} &= 0.500 \text{ atm} \frac{V}{RT} \\ &= \frac{(0.500 \text{ atm})(10.0 \text{ L})}{(0.08206 \text{ L atm mol}^{-1} \text{ K}^{-1})(298 \text{ K})} \end{aligned}$$

$$n_{\text{NO}_2} + n_{\text{N}_2\text{O}_4} = 0.204 \text{ mol} \quad (\text{b})$$

(Continued)

Subtracting Equation b from Equation a gives

$$n_{\text{N}_2\text{O}_4} = 0.126 \text{ mol}$$

and substituting that back into Equation a or Equation b gives

$$n_{\text{NO}_2} = 0.078 \text{ mol}$$

From these results,  $\text{NO}_2$  has a mole fraction of 0.38 and a partial pressure of  $(0.38)(0.500 \text{ atm}) = 0.19 \text{ atm}$ , and  $\text{N}_2\text{O}_4$  has a mole fraction of 0.62 and a partial pressure of  $(0.62)(0.500 \text{ atm}) = 0.31 \text{ atm}$ .

## 9.5 The Kinetic Theory of Gases

The ideal gas law summarizes certain physical properties of gases at low pressures. It is an empirical law, the consequence of experimental observations, but its simplicity and generality prompt us to ask whether it has some underlying microscopic explanation that involves the properties of atoms and molecules in a gas. Such an explanation would allow other properties of gases at low pressures to be predicted and would clarify why real gases deviate from the ideal gas law to small but measurable extents. Such a theory was developed in the 19th century, notably by the physicists Rudolf Clausius, James Clerk Maxwell, and Ludwig Boltzmann. The **kinetic theory of gases** is one of the great milestones of science, and its success provides strong evidence for the atomic theory of matter (see discussion in Chapter 1).

This section introduces a type of reasoning different from that used so far. Instead of proceeding from experimental observations to empirical laws, we begin with a model and use the basic laws of physics with mathematical reasoning to show how this model helps explain the measured properties of gases. In this way, the kinetic theory of gases provides a microscopic understanding of Boyle's law and also a microscopic mechanical definition of temperature as a measure of the average kinetic energy of the molecules in a gas.

The underlying assumptions of the kinetic theory of gases are simple:

1. A pure gas consists of a large number of identical molecules separated by distances that are great compared with their size.
2. The gas molecules are constantly moving in random directions with a distribution of speeds.
3. The molecules exert no forces on one another between collisions, so between collisions they move in straight lines with constant velocities.
4. The collisions of molecules with the walls of the container are *elastic*; no energy is lost during a collision.

**FIGURE 9.13** The path of a molecule in a box.

### 9.5.1 The Meaning of Temperature

We first use the kinetic theory of gases to find a relation among pressure, volume, and the motions of molecules in an ideal gas. Comparing the result obtained with the ideal gas law ( $PV = nRT$ ) provides a deeper understanding of the meaning of temperature.

Suppose a container has the shape of a rectangular box of length  $\ell$ , with end faces, each of which has area  $A$  (Fig. 9.13). A single molecule moving with speed  $v$  in some direction is placed in the box. It is important to distinguish between **speed** and **velocity**. The velocity of a molecule specifies both the rate at which it

**FIGURE 9.14** Velocity is shown by an arrow of length  $v$ . It can be separated into three components,  $v_x$ ,  $v_y$ , and  $v_z$ , along the three Cartesian coordinate axes and projected into the  $x$ - $y$  plane.

is moving (its speed, in meters per second) and the direction of motion. As shown in Figure 9.14, the velocity can be indicated by an arrow (vector)  $\vec{v}$ , which has a length equal to the speed  $v$  and which points in the direction of motion of the molecule. The velocity can also be represented by its components along three coordinate axes:  $v_x$ ,  $v_y$ , and  $v_z$ . These are related to the speed,  $v$ , by the Pythagorean theorem:

$$v^2 = v_x^2 + v_y^2 + v_z^2$$

(If vectors and components are new to you, see Appendix C.7 for introductory examples.) The **momentum** of a molecule,  $\vec{p}$ , is its velocity multiplied by its mass. When the molecule collides elastically with a wall of the box, such as one of the end faces of area  $A$ , the  $y$  and  $z$  components of the velocity,  $v_y$  and  $v_z$ , are unchanged, but the  $x$  component (perpendicular to  $A$ ) reverses sign (Fig. 9.15). Thus  $v_{x,f} = -v_x$  where the subscript  $f$  indicates final (after the collision). The change in the  $x$  component of the momentum of the molecule,  $\Delta p_{x,\text{mol}}$ , is

$$\Delta p_{x,\text{mol}} = \text{final momentum} - \text{initial momentum} = m(-v_x) - mv_x = -2mv_x$$

The total momentum of the system (molecule plus box) must be conserved, so this momentum change of the molecule is balanced by an equal and opposite momentum change given to the wall:

$$\Delta p_{x,\text{wall}} = 2mv_x$$

After colliding with the wall, the molecule reverses direction, strikes the opposite face of the box, and then again approaches the original face. In between, it may strike the top, bottom, and sides. These collisions do not change the magnitude of  $v_x$ , so they do not affect the time between collisions with the original end face (see Fig. 9.13). The distance traveled in the  $x$  direction is  $2\ell$ , and the magnitude of the velocity component in this direction is the absolute value of  $v_x$ , so the time elapsed between collisions with this end face is

$$\Delta t = \frac{2\ell}{|v_x|}$$

The magnitude of the momentum transferred to the wall per second is the magnitude of the momentum change per collision divided by  $\Delta t$ :

$$\frac{|\Delta p_{x,\text{wall}}|}{\Delta t} = \frac{|2mv_x|}{2\ell/|v_x|} = \frac{mv_x^2}{\ell}$$

**FIGURE 9.15** An elastic collision of a molecule with a wall. The component of the molecule's momentum perpendicular to the wall reverses sign, from  $mv_x$  to  $-mv_x$ . The component parallel to the wall,  $mv_y$ , is unchanged. The total momentum is shown by the red arrow. Although the direction of the collision, its length, which represents the magnitude of the momentum, is not changed. Speeds of molecules are not affected by elastic collisions with the walls of the container.

From Newton's second law, the magnitude of the force exerted on the original face by repeated collisions of this molecule is:

$$f = ma = m \frac{|\Delta v|}{\Delta t} = \frac{|\Delta p|}{\Delta t} = \frac{mv_x^2}{\ell}$$

Suppose now that a large number,  $N$ , of molecules of mass  $m$  are moving independently in the box with  $x$  components of velocity,  $v_{x1}$ ,  $v_{x2}$ ,  $v_{x3}$ , and so forth. Then the total force exerted on the face by the  $N$  molecules is the sum of the forces exerted by the individual molecules:

$$F = \frac{mv_{x1}^2}{\ell} + \frac{mv_{x2}^2}{\ell} + \dots + \frac{mv_{xN}^2}{\ell} = \frac{Nm}{\ell} \overline{v_x^2}$$

where

$$\overline{v_x^2} = \frac{1}{N} (v_{x1}^2 + v_{x2}^2 + \dots + v_{xN}^2)$$

Here,  $\overline{v_x^2}$  is the average of the square of the  $x$  component of the velocity of the  $N$  molecules, obtained by summing  $v_x^2$  for the  $N$  molecules and dividing by  $N$ . The pressure is the total force on the wall divided by the area,  $A$ , so

$$P = \frac{F}{A} = \frac{Nm}{A\ell} \overline{v_x^2}$$

Because  $A\ell$  is the volume,  $V$ , of the box, we conclude that

$$PV = Nm \overline{v_x^2}$$

There is no preferred direction of motion for the gas molecules; thus,  $\overline{v_x^2}$ ,  $\overline{v_y^2}$ , and  $\overline{v_z^2}$  should all be equal to one another. We therefore conclude that

$$\overline{v^2} = \overline{v_x^2} + \overline{v_y^2} + \overline{v_z^2} = 3\overline{v_x^2}$$

so

$$PV = \frac{1}{3} Nm \overline{v^2} \quad [9.11]$$

where  $\overline{v^2}$  is the **mean-square speed** of the gas molecules. From the ideal gas law,

$$PV = nRT$$

so, we conclude that

$$\frac{1}{3} Nm \overline{v^2} = nRT$$

We have achieved our major goal with the derivation of this equation: a relationship between the temperature and the speeds of molecules. It can be simplified to provide additional insights. The equation has the number of molecules,  $N$ , on the left and the number of moles,  $n$ , on the right. Because  $N$  is just  $n$  multiplied by Avogadro's number,  $N_A$ , we can divide both sides by  $n$  to find

$$\frac{1}{3} N_A m \overline{v^2} = RT \quad [9.12]$$

Let's examine this equation in two ways. First, we note that the kinetic energy of a molecule of mass  $m$  moving at speed  $v$  is equal to  $\frac{1}{2} mv^2$ , so the *average* kinetic energy of  $N_A$  molecules (1 mol), which we denote by  $\overline{E}$ , is

$\frac{1}{2} N_A m \overline{v^2}$ . This quantity is exactly the same as that in the left side of Equation 9.12, with the factor  $\frac{1}{2}$  replacing  $\frac{1}{3}$ :

$$\bar{E} = \frac{1}{2} N_A m \overline{v^2} = \frac{3}{2} \times \left( \frac{1}{3} N_A m \overline{v^2} \right) = \frac{3}{2} RT \quad [9.13]$$

We obtain the average kinetic energy per molecule,  $\bar{\epsilon}$ , by dividing  $\bar{E}$  by Avogadro's number:

$$\bar{\epsilon} = \frac{3}{2} k_B T \quad [9.14]$$

where  $k_B$  is **Boltzmann's constant** and is defined as  $R/N_A$ . The average kinetic energy of the molecules of a gas depends only on the temperature. It does not depend on the mass of the molecules or their number density in the gas. This relation is the most fundamental result of the kinetic theory of gases, and it is used in all branches of science.

A second way to look at the equation is to recall that if  $m$  is the mass of a single molecule, then  $N_A m$  is the mass of 1 mol of molecules—the molar mass, abbreviated  $\mathcal{M}$ . Solving Equation 9.13 for the mean-square speed, we find that

$$\overline{v^2} = \frac{3RT}{\mathcal{M}} \quad [9.15]$$

The mean-square speed of a gas molecule is proportional to temperature and inversely proportional to its mass. All molecules move faster at higher temperatures, and lighter molecules move faster than heavier ones at the same temperature.

## 9.5.2 Distribution of Molecular Speeds

One of the fundamental assumptions of the kinetic theory is that the molecules travel through the gas with a range of possible speeds. We would like to know how the molecules are distributed over the range of possible speeds.

As a first step, we can get some sense of the typical speeds in the gas by the following method. We define the **root-mean-square speed**,  $v_{\text{rms}}$ , as the square root of the mean-square speed  $3RT/\mathcal{M}$ :

$$v_{\text{rms}} = \sqrt{\overline{v^2}} = \sqrt{\frac{3RT}{\mathcal{M}}} \quad [9.16]$$

To calculate  $v_{\text{rms}}$  in  $\text{m s}^{-1}$ , one uses  $T$  in kelvin units and the molar mass in  $\text{kg mol}^{-1}$  and the following value for the universal gas constant.

$$R = 8.3145 \text{ J mol}^{-1} \text{ K}^{-1} = 8.3145 \text{ kg m}^2 \text{ s}^{-2} \text{ mol}^{-1} \text{ K}^{-1}$$

Note that molar masses  $\mathcal{M}$  must be converted to *kilograms* per mole for use in the equation.

### EXAMPLE 9.7

Calculate  $v_{\text{rms}}$  for (a) a helium atom, (b) an oxygen molecule, and (c) a xenon atom at 298 K.

(Continued)

**Solution**

Because the factor  $3RT$  appears in all three expressions for  $v_{\text{rms}}$ , let's calculate it first:

$$3RT = (3)(8.3145 \text{ kg m}^2 \text{ s}^{-2} \text{ mol}^{-1} \text{ K}^{-1})(298 \text{ K}) = 7.43 \times 10^3 \text{ kg m}^2 \text{ s}^{-2} \text{ mol}^{-1}$$

The molar masses of He, O<sub>2</sub>, and Xe are 4.00 g mol<sup>-1</sup>, 32.00 g mol<sup>-1</sup>, and 131.3 g mol<sup>-1</sup>, respectively. Convert them to  $4.00 \times 10^{-3}$  kg mol<sup>-1</sup>,  $32.00 \times 10^{-3}$  kg mol<sup>-1</sup>, and  $131.3 \times 10^{-3}$  kg mol<sup>-1</sup>, and insert them together with the value for  $3RT$  into the equation for  $v_{\text{rms}}$ :

$$v_{\text{rms}}(\text{He}) = \sqrt{\frac{7.43 \times 10^3 \text{ kg m}^2 \text{ s}^{-2} \text{ mol}^{-1}}{4.00 \times 10^{-3} \text{ kg mol}^{-1}}} = 1360 \text{ m s}^{-1}$$

$$v_{\text{rms}}(\text{O}_2) = \sqrt{\frac{7.43 \times 10^3 \text{ kg m}^2 \text{ s}^{-2} \text{ mol}^{-1}}{32.00 \times 10^{-3} \text{ kg mol}^{-1}}} = 482 \text{ m s}^{-1}$$

$$v_{\text{rms}}(\text{Xe}) = \sqrt{\frac{7.43 \times 10^3 \text{ kg m}^2 \text{ s}^{-2} \text{ mol}^{-1}}{131.3 \times 10^{-3} \text{ kg mol}^{-1}}} = 238 \text{ m s}^{-1}$$

At the same temperature, the He, O<sub>2</sub>, and Xe molecules all have the same average kinetic energy; lighter molecules move faster to compensate for their smaller masses. These rms speeds convert to 3050, 1080, and 532 mph, respectively. The average molecule moves along quite rapidly at room temperature!

**Related Problems:** 41, 42, 43, 44

It is useful to have a complete picture of the entire distribution of molecular speeds. This turns out to be important when we study chemical kinetics (see Chapter 18). There we'll develop an understanding of the rate of a chemical reaction in terms of collisions between reacting molecules. For example, the collision of a gaseous OH radical in the atmosphere with a methane molecule can produce CH<sub>3</sub> radicals. The reaction  $\text{OH} + \text{CH}_4 \rightarrow \text{H}_2\text{O} + \text{CH}_3$  will not occur unless the colliding molecules approach each other with very high relative speeds (like two fast cars on the highway undergoing a head-on collision) because the energetic barrier to this reaction is about 5 kcal/mol (= 21 kJ mol<sup>-1</sup>). Thus, it is not the average relative speed of the colliding OH radicals and methane molecules that is important for this reaction, but rather it is the collisions with the fastest relative speeds that matter.

So how can one calculate the fraction of molecules in a gas with speed between  $v_1$  and  $v_2$ , say the fraction of methane molecules with speeds between  $v_1 = 1000$  and  $v_2 = 1100$  m s<sup>-1</sup>? You need a speed distribution  $f(v)$  (see Eq. 9.19 below and Fig. 9.16) for the molecules to do this and you need the range  $\Delta v = v_2 - v_1$ . Then the fraction of molecules with speed between  $v_1$  and  $v_2$  is  $f(v) \Delta v$  as long as the range  $\Delta v$  is small. The distribution of molecular speeds,  $f(v)$  is shown in the upper frame of Figure 9.16 for methane molecules at 298 K. From this, you can calculate the fraction of methane molecules with speeds between 1000 and 1100 m s<sup>-1</sup> to be  $(0.00041 \text{ s m}^{-1})(1100 \text{ m s}^{-1} - 1000 \text{ m s}^{-1}) = 0.041$ . Thus 4.1% of the methane molecules in a sample of gas at room temperature have speeds between 1000 and 1100 m s<sup>-1</sup>. Note that we used a value for  $f(v)$  in the middle of the speed range,  $f(1050) = 0.00041 \text{ s m}^{-1}$ . If the range of speeds  $\Delta v$  is not small, then the correct formula for calculating the fraction of molecules with speed between  $v_1$  and  $v_2$  is:

$$\text{Fraction of molecules with speed between } v_1 \text{ and } v_2 = \int_{v_1}^{v_2} f(v) dv \quad [9.17]$$

**FIGURE 9.16** The distribution of molecular speeds of gaseous methane at room temperature.

This properly accounts for the fact that the function  $f(v)$  changes with speed  $v$ . The lower frame of Figure 9.16 shows graphically how you would calculate the fraction of methane molecules with speed  $v$  greater than  $v_1 = 1000 \text{ m s}^{-1}$ .

$$\text{Fraction of molecules with speed greater than } v_1 = \int_{v_1}^{\infty} f(v) dv \quad [9.18]$$

The speed distribution  $f(v)$  was predicted theoretically by Maxwell and Boltzmann about sixty years before it was first measured. It is called the **Maxwell–Boltzmann speed distribution** for a gas of molecules of mass  $m$  at temperature  $T$ :

$$f(v) = 4\pi \left( \frac{m}{2\pi k_B T} \right)^{\frac{3}{2}} v^2 e^{-\frac{mv^2}{2k_B T}} \quad [9.19]$$

In this equation  $m$  is the mass of one molecule and  $k_B$  is Boltzmann's constant defined in Equation 9.14. (Alternatively, you can use the molar mass and the gas constant  $R$ .) You can measure this speed distribution experimentally with the apparatus sketched in Figure 9.17. The entire apparatus is enclosed in a large vacuum chamber. The molecules leak out of their container to form a *molecular beam* that passes into a speed analyzer. The analyzer consists of two rotating plates each with a notch in its edge, separated by a fixed distance  $L$ . Molecules

**FIGURE 9.17** A device for measuring the distribution of molecular speeds. Only those molecules with the correct velocity to pass through both rotating sectors will reach the detector, where they will be counted. Changing the rate of rotation of the sectors allows the speed distribution to be determined.

with speed  $v$  that pass through the center of the notch in the first plate will get to the second plate in a time  $t = \frac{L}{v}$ . If the two notches are offset by 90 degrees, the molecules can only pass the second plate if it has rotated enough to bring the second notch up to the molecular beam in that same amount of time. If the plates are rotated at 400 Hz, the second notch moves up to the molecular beam in  $6.25 \times 10^{-4}$  s, so if the distance  $L$  between the plates is 0.2 m then the molecules with speeds near  $v = \frac{L}{t} = 320 \text{ m s}^{-1}$  can pass through the notch to the detector and be counted. (If the notches are wider, molecules with a wider range of speeds  $\Delta v$  near  $v = 320 \text{ m s}^{-1}$  can pass through the second slot.) To measure the number of molecules with speeds near  $160 \text{ m s}^{-1}$  one simply rotates the plates slower, at 200 Hz, so the flight time between the two plates is lengthened to  $12.5 \times 10^{-4}$  s. Then only the slower molecules get to the second plate when the notch in the second plate is crossing the molecular beam, the faster molecules hit the second plate before the notch moves into position. Thus, changing the rotation rate of the plates lets you count the number of molecules in each speed range.

Figure 9.18 shows how the speed distribution  $f(v)$  changes as you change the temperature of the gas. The  $f(v)$  for methane at 500 K is shown in red in Figure 9.18 with the prior 298 K distribution in blue for comparison. We use

**FIGURE 9.18** The distribution of molecular speeds of gaseous methane at room temperature and at 500 K.

Equation 9.18 to first calculate what fraction of methane molecules in a gas at 298 K have a speed greater than  $1000 \text{ m s}^{-1}$ . You can integrate this numerically with your calculator, or simply estimate the area under the curve shown in the lower frame of Figure 9.16. To estimate the area under the curve, count the number of rectangles in the shaded blue area (about 18 adding up the partial rectangles) and multiply by the area of one rectangle (height  $\times$  width =  $0.00005 \text{ s m}^{-1} \times 100 \text{ m s}^{-1} = 0.005$ ). This gives 0.09, so at 298 K about 9 percent of the methane molecules in your container of gas have speeds faster than  $1000 \text{ m s}^{-1}$ . If you pick a molecule out of the gas at random, there is a 9% chance, or probability, that it will have a speed greater than  $1000 \text{ m s}^{-1}$ . (Mathematically, the function  $f(v)$  is one example of a “probability density,” described further in Appendix C.6.) Now, if you raise the temperature to 500 K, the distribution of molecular speeds broadens and has a larger high-speed tail, as shown by the red distribution in Figure 9.18. The most probable speed  $v_{mp}$  (the speed at the peak of each distribution) has only gone up modestly, from  $556 \text{ m s}^{-1}$  at 298 K to  $720 \text{ m s}^{-1}$  at 500 K, but the fraction of molecules with speeds greater than  $1000 \text{ m s}^{-1}$  is now 27%, 3 times what it was at 298 K! These faster methane molecules are the ones that are more likely to react with OH in the atmosphere, so you can expect the rate of this reaction to increase as you increase the temperature.

From the Maxwell–Boltzmann speed distribution at a given temperature, you can calculate some other useful quantities, like the average speed of the gas molecules. The procedure is described in Appendix C.6 for probability densities in general. For the Maxwell–Boltzmann speed distribution this calculation gives the **average speed**  $\bar{v}$ , which is

$$\bar{v} = \sqrt{\frac{8k_{\text{B}}T}{\pi m}} = \sqrt{\frac{8RT}{\pi \mathcal{M}}} \quad [9.20]$$

If a probability distribution is symmetrical about its maximum, like the familiar “bell curve,” the most probable value and the average value are the same. The Maxwell–Boltzmann distribution is not symmetrical; the area under the curve to the right of the maximum is somewhat larger than the area under the curve to the left of the maximum. (The next paragraphs use the mathematical form of the distribution to explain this fact.) Consequently,  $\bar{v}$  will be larger than the most probable value of  $v$ .

The root-mean-square value can be calculated from the probability distribution, as shown in Appendix C.6. For a symmetrical distribution, this would be equal to the average value. For the Maxwell–Boltzmann distribution, we have already seen that

$$v_{\text{rms}} = \sqrt{\frac{3k_{\text{B}}T}{m}} = \sqrt{\frac{3RT}{\mathcal{M}}}$$

which verifies that  $\bar{v} < v_{\text{rms}}$ .

The speed at the peak of the Maxwell–Boltzmann distribution is called the most probable speed,  $v_{mp}$ . It is the easiest to identify from a plot of the distribution. In Figure 9.16, the distribution of molecular speeds for methane at 298 K peaks at about  $556 \text{ m s}^{-1}$ . However it is not as physically important as the root mean square speed,  $v_{\text{rms}}$ , or the average speed  $\bar{v}$ . Earlier in this section, in Equation 9.13, you learned how to calculate the average kinetic energy of a sample of gas from  $v_{\text{rms}}$ . The ratios between them are

$$v_{mp} : \bar{v} : v_{\text{rms}} = 1.000 : 1.128 : 1.225$$

**FIGURE 9.19** Mathematical form of the Maxwell–Boltzmann speed distribution. The factor  $v^2$  cuts off the distribution at small values of  $v$ , whereas the exponential factor causes it to die off at large values of  $v$ . The competition between these effects causes the distribution to achieve its maximum value at intermediate values of  $v$ .

The Maxwell–Boltzmann distribution is not symmetrical because it has the mathematical form

$$f(v) \propto v^2 \exp(-mv^2/2k_B T)$$

which describes a competition between the two factors that depend on  $v^2$ . The competition arises because these factors behave oppositely, for physical reasons, as the value of  $v$  changes. We can get physical insight into the distribution by studying the behavior of these factors separately while  $T$  is held constant.

The exponential factor can be viewed graphically as the right half of a bell curve with its maximum at  $v = 0$  (Fig. 9.19). At low values of  $v$ , this factor behaves as  $\exp(-mv^2/2k_B T) \rightarrow \exp(-0) = 1$ . At very large values of  $v$ , this factor behaves as  $\exp(-mv^2/k_B T) = 1/[\exp(mv^2/k_B T)] \rightarrow 1/\infty = 0$ . The role of this factor is to describe the statistical weight given to each value of  $v$  in relation to  $T$ . The limits we have just examined show this factor gives large statistical weight to small values of  $v$ , and increasingly small weight to large values of  $v$ , eventually forcing the distribution to fall off to zero at extremely high values of  $v$ . This is exactly what we expect on physical grounds.

The factor  $v^2$  can be viewed as the right half of a parabola with its minimum at  $v = 0$  (see Fig. 9.19). The value of this factor approaches zero as  $v$  decreases towards 0, and it grows without bound as  $v$  becomes extremely large. Although we do not provide all the details, the role of this factor is to count the number of different ways molecules in the gas can achieve a particular value of the speed,  $v$ . With Avogadro's number of molecules moving around the vessel, it is physically sensible that many different combinations of  $v_x$ ,  $v_y$ , and  $v_z$  correspond to a given value of the speed. And, we expect the number of such combinations to increase as the value of the speed increases. The shape of this factor strongly favors molecules with large values of  $v$  and it rapidly cuts off the distribution for small values of  $v$ .

The net result of these two competing factors is to keep the probability small for both extremely large and extremely small values of  $v$ . The probability will have a maximum at some intermediate value of  $v$  where the increasing effect of  $v^2$  is just balanced by the decreasing effect of the exponential factor (see Fig. 9.19). This is the *most probable* value of  $v$ , denoted by  $v_{\text{mp}}$ , and it can be identified by setting to zero the derivative of the curve with respect to  $v$ . Because  $v^2$  approaches zero for small values of  $v$  more rapidly than the exponential factor approaches zero for large values of  $v$ , the probability is larger to the right side of the maximum. The area under the curve to the right of the maximum is somewhat larger than the area under the curve to the left of the maximum. Consequently, the average value of  $v$  denoted by  $\bar{v}$  will be larger

than the most probable value of  $v$ . Figure 9.18 shows that the most probable speed, the speed at which the Maxwell–Boltzmann distribution peaks, is about  $556 \text{ m s}^{-1}$  for methane at 298 K (black line), but the average speed is larger,  $627 \text{ m s}^{-1}$ . You can calculate the average speed with Equation 9.20 and the most probable speed using the ratio given earlier in this section.

The behavior of these competing factors also explains why the distribution becomes broader and its maximum moves to a higher value of  $v$  as the temperature increases. Figure 9.18 shows that the most probable speed of the methane molecules increases from  $556 \text{ m s}^{-1}$  at 298 K to  $720 \text{ m s}^{-1}$  at 500 K, (but of course the total integral under the curve is still 1). The speed at which the distribution is a maximum increases and the distribution broadens towards higher speeds, because the exponential factor  $\exp(-mv^2/2k_{\text{B}}T)$  decreases more slowly with increasing  $v$  at high  $T$  than at low  $T$ . Figure 9.18 shows that the fraction of methane molecules with speed greater than  $1000 \text{ m s}^{-1}$  increases by a factor of 3 when the temperature is raised from 298 to 500 K.

The Maxwell–Boltzmann speed distribution defines temperature in the kinetic theory of gases as proportional to the average kinetic energy per molecule through Equation 9.14. Unless the molecular speed distribution for a given gas corresponds to the Maxwell–Boltzmann distribution, temperature has no meaning for the gas. Temperature describes a system of gaseous molecules only when their speed distribution is represented by the Maxwell–Boltzmann function. Consider a closed container filled with molecules whose speed distribution is not “Maxwellian.” Such a situation is possible (for example, just after an explosion), but it cannot persist for long. Any distribution of molecular speeds other than a Maxwell–Boltzmann distribution quickly becomes Maxwellian through molecular collisions that exchange energy. Once attained, the Maxwell–Boltzmann distribution persists indefinitely (or at least until some new disturbance is applied). The gas molecules have come to **thermal equilibrium** with one another, and we can speak of a system as having a temperature only if the condition of thermal equilibrium exists.

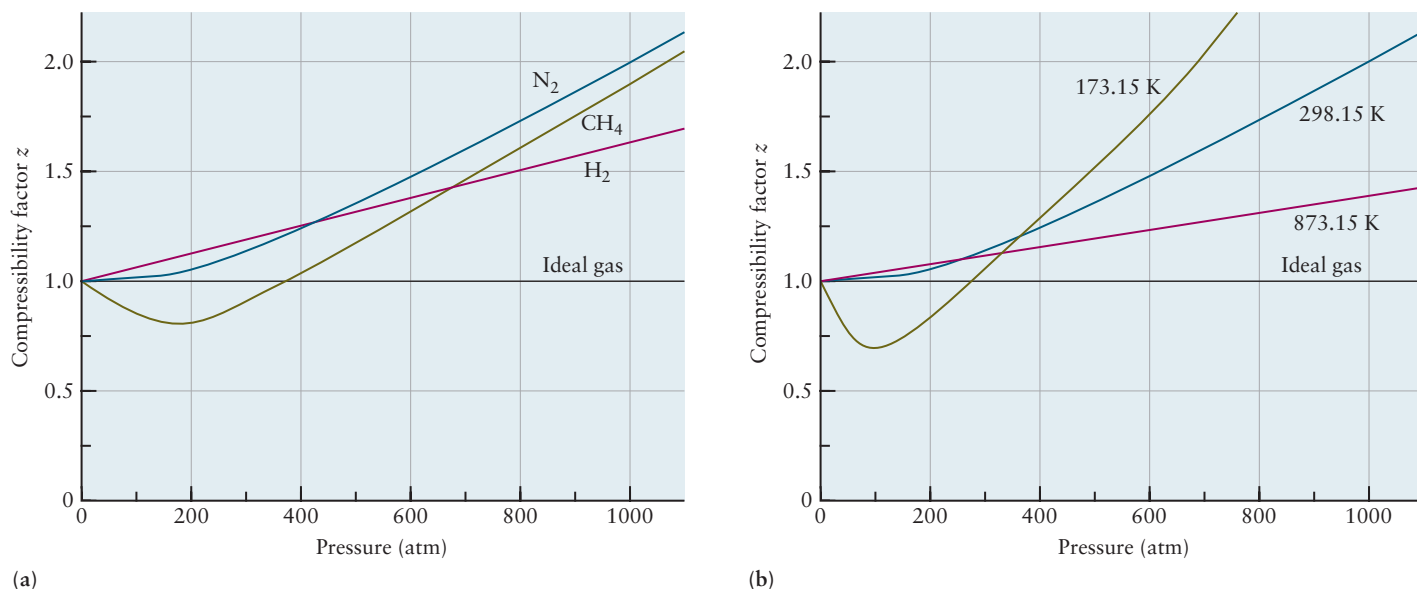

## 9.6 Real Gases: Intermolecular Forces

The ideal gas law,  $PV = nRT$ , is a particularly simple example of an **equation of state**—an equation relating the pressure, temperature, number of moles, and volume to one another. Equations of state can be obtained from either theory or experiment. They are useful not only for ideal gases but also for real gases, liquids, and solids.

Real gases follow the ideal gas equation of state only at sufficiently low densities. Deviations appear in a variety of forms. Boyle’s law,  $PV = C$ , is no longer satisfied at high pressures, and Charles’s law,  $V \propto T$ , begins to break down at low temperatures. Deviations from the predictions of Avogadro’s hypothesis appear for real gases at moderate pressures. At atmospheric pressure, the ideal gas law is quite well satisfied for most gases, but for some with polar molecules (like water vapor and ammonia), there are deviations of 1 to 2%. The easiest way to detect these deviations is to calculate the **compressibility factor**  $z$  from experimental  $P$ - $V$ - $T$  data:

$$z = \frac{PV}{nRT} \quad [9.21]$$

When  $z$  differs from 1 (Fig. 9.20), the ideal gas law is inadequate, and a more accurate equation of state is necessary.

**FIGURE 9.20** A plot of  $z = PV/nRT$  against pressure shows deviations from the ideal gas law quite clearly. For an ideal gas,  $z = 1$ , is represented by a straight horizontal line. (a) Deviation of several real gases at 298.15 K. (b) Deviation of nitrogen at several temperatures.

### 9.6.1 The van der Waals Equation of State

One of the earliest and most important improvements on the ideal gas equation of state was proposed in 1873 by the Dutch physicist Johannes van der Waals. The **van der Waals equation of state** is:

$$\left(P + a \frac{n^2}{V^2}\right)(V - nb) = nRT \quad [9.22a]$$

$$P = \frac{nRT}{V - nb} - a \frac{n^2}{V^2} \quad [9.22b]$$

To obtain this equation, the ideal gas law—which ignores interactions between molecules—requires two modifications to describe the effects of the forces between molecules, which are repulsive at short distances and attractive at large distances. We know from Section 9.5 that pressure is determined by the product of the momentum transferred per collision with the walls of the container times the number of collisions per second. So, it is necessary to see how repulsive and attractive forces modify the collision rate away from the value it would have in the ideal gas. Because of repulsive forces, molecules cannot occupy the same space at the same time. They exclude other molecules from the volumes they occupy; in this way, the effective volume available to a given molecule is not  $V$ , but  $V - nb$ , where  $b$  is a constant describing the *excluded volume* per mole of molecules. This effect pushes the molecules away from each other and toward the walls, thereby increasing the rate of wall collisions. The result is a pressure higher than the ideal gas value, as shown in the first term of Equation 9.22b. Attractive forces hold pairs or groups of molecules together. Any tendency to cluster together reduces the effective number of independent molecules in the

TABLE 9.3

Van der Waals Constants of Several Gases

Name	Formula	$a$ (atm L <sup>2</sup> mol <sup>-2</sup> )	$b$ (L mol <sup>-1</sup> )
Ammonia	NH <sub>3</sub>	4.170	0.03707
Argon	Ar	1.345	0.03219
Carbon dioxide	CO <sub>2</sub>	3.592	0.04267
Hydrogen	H <sub>2</sub>	0.2444	0.02661
Hydrogen chloride	HCl	3.667	0.04081
Methane	CH <sub>4</sub>	2.253	0.04278
Nitrogen	N <sub>2</sub>	1.390	0.03913
Nitrogen dioxide	NO <sub>2</sub>	5.284	0.04424
Oxygen	O <sub>2</sub>	1.360	0.03183
Sulfur dioxide	SO <sub>2</sub>	6.714	0.05636
Water	H <sub>2</sub> O	5.464	0.03049

gas and, therefore, reduces the rate of collisions with the walls of the container. Having fewer wall collisions reduces the pressure below the ideal gas law prediction. Because this reduction depends on attractions between *pairs* of molecules, van der Waals argued that it should be proportional to the *square* of the number of molecules per unit volume ( $N^2/V^2$ ) or, equivalently, proportional to  $n^2/V^2$ . Compared with the ideal gas, this intermolecular attraction reduces the pressure by an amount  $a(n/V)^2$ , where  $a$  is a positive constant that depends on the strength of the attractive forces. This effect gives the second term in Equation 9.22b. Rearranging Equation 9.22b gives the standard form of the van der Waals equation shown in Equation 9.22a.

The constants  $a$  and  $b$  are obtained by fitting experimental  $P$ - $V$ - $T$  data for real gases to Equation 9.22a or 9.22b (Table 9.3). The units for these constants are

$$a: \text{ atm L}^2 \text{ mol}^{-2}$$

$$b: \text{ L mol}^{-1}$$

when  $R$  has the units L atm mol<sup>-1</sup> K<sup>-1</sup>.

### EXAMPLE 9.8

A sample of 8.00 kg gaseous nitrogen fills a 100-L flask at 300°C. What is the pressure of the gas, calculated from the van der Waals equation of state? What pressure would be predicted by the ideal gas equation?

#### Solution

The molar mass of N<sub>2</sub> is 28 g mol<sup>-1</sup>, so

$$n = \frac{8.00 \times 10^3 \text{ g}}{28.0 \text{ g mol}^{-1}} = 286 \text{ mol}$$

The temperature (in kelvins) is  $T = 300 + 273 = 573 \text{ K}$ , and the volume,  $V$ , is 100 L. Using  $R = 0.08206 \text{ L atm mol}^{-1} \text{ K}^{-1}$  and the van der Waals constants for nitrogen given in Table 9.3, we calculate  $P = 151 - 11 = 140 \text{ atm}$ . If the ideal gas law is used instead, a pressure of 134 atm is calculated. This illustrates the magnitude of deviations from the ideal gas law at higher pressures.

**Related Problems: 47, 48, 49, 50**

The effects of the two van der Waals parameters are clearly apparent in the compressibility factor for this equation of state:

$$z = \frac{PV}{nRT} = \frac{V}{V - nb} - \frac{a}{RT} \frac{n}{V} = \frac{1}{1 - bn/V} - \frac{a}{RT} \frac{n}{V} \quad [9.23]$$

Repulsive forces (through  $b$ ) increase  $z$  above 1, whereas attractive forces (through  $a$ ) reduce  $z$ .

We illustrate the effects of  $a$  by comparing Equation 9.23 with the experimental data for the compressibility factor shown in Figure 9.20a. At lower pressures, for example 200 atm, the intermolecular forces reduce  $z$  for CH<sub>4</sub> to a value significantly below the ideal gas value. For N<sub>2</sub>, the effect that decreases  $z$  is readily apparent, but it is smaller than the effect that increases  $z$ . For H<sub>2</sub>, the effect that decreases  $z$  is completely dominated by the forces that increase  $z$ . These results are consistent with the  $a$ -parameter value for CH<sub>4</sub> being about twice that for N<sub>2</sub> and about 10 times that for H<sub>2</sub> (see Table 9.3). The values of  $a$  originate in the structure of the molecules and vary significantly between highly polar molecules such as H<sub>2</sub>O and nonpolar molecules such as H<sub>2</sub>.

The constant  $b$  is the volume excluded by 1 mol of molecules and should therefore be close to  $V_m$ , the volume per mole in the liquid state, where molecules are essentially in contact with each other. For example, the density of liquid nitrogen is 0.808 g cm<sup>-3</sup>. One mole of N<sub>2</sub> weighs 28.0 g, so

$$\begin{aligned} V_m \text{ of N}_2(\ell) &= \frac{28.0 \text{ g mol}^{-1}}{0.808 \text{ g cm}^{-3}} = 34.7 \text{ cm}^3 \text{ mol}^{-1} \\ &= 0.0347 \text{ L mol}^{-1} \end{aligned}$$

This is reasonably close to the van der Waals  $b$  parameter of 0.03913 L mol<sup>-1</sup>, obtained by fitting the equation of state to  $P$ - $V$ - $T$  data for nitrogen. In Table 9.3, the values for  $b$  are all quite similar. All the molecules in Table 9.3 are about the same size and have similar values of molar volume in the liquid state.

## 9.6.2 Intermolecular Forces

Deeper understanding of the attractive force parameter,  $a$ , and the excluded volume per mole,  $b$ , comes from examination of the forces acting between the atoms or molecules in a gas. As a pair of molecules approaches one another, the forces between them generate potential energy, which competes with the kinetic energy associated with their speeds. This potential energy can increase the molar volume through intermolecular repulsions, or decrease the pressure by temporarily attracting molecules to form dimers and so reducing the rate of collisions with the walls. The potential energy is our means to describe systematically how intermolecular forces cause these two effects. The noble gases provide the simplest example. As two noble gas atoms approach one another, attractive forces dominate until the distance between their centers,  $R$ , becomes short enough for the repulsive forces to begin to become significant. If the atoms are forced still closer together, they repel each other with a strongly increasing force as the distance between them is reduced. These interactions can be described by a **potential energy curve**  $V(R)$  (see Section 3.7, Section 6.1, and Appendix B) such as that shown for argon in Figure 9.21. If two molecules can lower their energy by moving closer together, then a net attractive force exists between them; if they can lower their energy only by moving apart, there is a net repulsive force. Graphically, this means that at a separation  $R$  where the slope  $dV/dR$  is positive, the force between the particles is attractive. At very small separations between the two particles, where  $dV/dR$  is negative, the force between the particles is repulsive. The force changes from attractive to repulsive at the minimum of  $V(R)$ , where the net force between atoms is zero. Potential energy curves for atoms are generated by fitting equations for  $V(R)$  to measured properties of real gases. More accurate versions come from experiments in which beams of atoms collide with one another.

For many purposes, the detailed shape of the potential is less important than two characteristic parameters: the depth and location of the potential minimum.

**FIGURE 9.21** Potential energy curves  $V(R)$  for pairs of helium atoms (red) and pairs of argon atoms (blue) obtained from atomic beam collision studies. At any point, the force between atoms is calculated from the negative of the slope of  $V$  (see Section 3.7, Section 6.1, and Appendix B). In regions where the slopes of the curves are negative, the atoms repel each other. In regions where the slopes are positive, the atoms attract one another. The greater well depth for Ar arises from stronger intermolecular attractions, and the location of the minimum for Ar at larger  $R$  correlates roughly with relative molecular size.

A simple expression frequently used to model these interactions between atoms is the **Lennard-Jones potential**:

$$V_{\text{LJ}}(R) = 4\varepsilon \left[ \left( \frac{\sigma}{R} \right)^{12} - \left( \frac{\sigma}{R} \right)^6 \right] \quad [9.24]$$

where  $\varepsilon$  is the depth and  $\sigma$  is the distance at which  $V(R)$  passes through zero. This potential has an attractive part, proportional to  $R^{-6}$ , and a repulsive part, proportional to  $R^{-12}$ . The minimum is located at  $2^{1/6}\sigma$ , or  $1.122\sigma$ . Table 9.4 lists Lennard-Jones parameters for a number of atoms. Note that the depth and range of the potential increase for the heavier noble-gas atoms, but the well depths are quite small compared to well depths for the potential between two atoms that may covalently bond. The interaction between two molecules such as  $\text{N}_2$  that are nearly spherical, neutral, and non-polar can also be described approximately with Lennard-Jones potentials. The two parameters  $\varepsilon$  and  $\sigma$  in the Lennard-Jones potential, like the van der Waals parameters  $a$  and  $b$ , are simple ways of characterizing the interactions between molecules in real gases.

**TABLE 9.4**

Lennard-Jones Parameters for Atoms and Molecules

Substance	$\sigma(\text{m})$	$\varepsilon(\text{J})$
He	$2.56 \times 10^{-10}$	$1.41 \times 10^{-22}$
Ne	$2.75 \times 10^{-10}$	$4.92 \times 10^{-22}$
Ar	$3.40 \times 10^{-10}$	$1.654 \times 10^{-21}$
Kr	$3.60 \times 10^{-10}$	$2.36 \times 10^{-21}$
Xe	$4.10 \times 10^{-10}$	$3.06 \times 10^{-21}$
$\text{H}_2$	$2.93 \times 10^{-10}$	$5.11 \times 10^{-22}$
$\text{O}_2$	$3.58 \times 10^{-10}$	$1.622 \times 10^{-21}$
CO	$3.76 \times 10^{-10}$	$1.383 \times 10^{-21}$
$\text{N}_2$	$3.70 \times 10^{-10}$	$1.312 \times 10^{-21}$
$\text{CH}_4$	$3.82 \times 10^{-10}$	$2.045 \times 10^{-21}$

The Lennard–Jones potential and the Maxwell–Boltzmann distribution (see Section 9.5) together explain how deviations from ideal gas behavior depend on temperature. Qualitatively, the most important effect is the ratio of the well depth  $\varepsilon$  to  $k_B T$ . When  $T$  is low enough to make  $k_B T \ll \varepsilon$ , a pair of molecules remains close together sufficiently long to reduce the rate of wall collisions, and thereby reduce the pressure below its ideal gas value. When  $T$  is such that  $k_B T \gg \varepsilon$ , the molecules are primarily sensitive to the repulsive part of the Lennard–Jones potential, and the pressure is increased above its ideal gas value. These effects are illustrated in Figure 9.20, which shows that at low pressure the compressibility factor for  $N_2$  is dominated by attractive forces at 173.15 K and by repulsive forces at 873.15 K.

At 300 K, the value of  $k_B T$  is  $4.14 \times 10^{-21}$  J, which is comparable to and slightly larger than the well depths for typical gases listed in Table 9.4.

## 9.7 A DEEPER LOOK Molecular Collisions and Rate Processes

The kinetic theory we have developed can be applied to several important properties of gases. A study of the rates at which atoms and molecules collide with a wall and with one another helps to explain phenomena ranging from isotope separation based on gaseous diffusion to gas-phase chemical kinetics.

### 9.7.1 Molecule–Wall Collisions

Let's call  $Z_w$  the rate of collisions of gas molecules with a section of wall of area  $A$ . A full mathematical calculation of  $Z_w$  requires integral calculus and solid geometry. We present instead some simple physical arguments to show how this rate depends on the properties of the gas.

First of all,  $Z_w$  should be proportional to the area  $A$ , because doubling the area will double the number of collisions with the wall. Second,  $Z_w$  should be proportional to the average molecular speed,  $\bar{v}$ , because molecules moving twice as fast will collide twice as often with a given wall area. Finally, the wall collision rate should be proportional to the number density,  $N/V$ , because twice as many molecules in a given volume will have twice as many collisions with the wall. All of these arguments are consistent with the kinetic theory of gases and are confirmed by the full mathematical analysis. We conclude that

$$Z_w \propto \frac{N}{V} \bar{v} A$$

Note that the units of both sides are  $s^{-1}$ , as required for these expressions to represent a rate. The proportionality constant can be calculated from a complete analysis of the directions from which molecules impinge on the wall; it turns out to have the value  $\frac{1}{4}$ . So the wall collision rate is

$$Z_w \propto \frac{1}{4} \frac{N}{V} \bar{v} A = \frac{1}{4} \frac{N}{V} \sqrt{\frac{8RT}{\pi M}} A \quad [9.25]$$

We have used the result for  $\bar{v}$  given earlier in Equation 9.20. This simple equation has many applications. It sets an upper limit on the rate at which a gas may react with a solid. It is also the basis for calculating the rate at which molecules effuse through a small hole in the wall of a vessel.

## EXAMPLE 9.9

Calculate the number of collisions that oxygen molecules make per second on  $1.00 \text{ cm}^2$  of the surface of the vessel containing them if the pressure is  $1.00 \times 10^{-6} \text{ atm}$  and the temperature is  $25^\circ\text{C}$  (298 K).

**Solution**

First compute the quantities that appear in the equation for  $Z_w$ :

$$\begin{aligned}\frac{N}{V} &= \frac{N_A n}{V} = \frac{N_A P}{RT} \\ &= \frac{(6.022 \times 10^{23} \text{ mol}^{-1})(1.00 \times 10^{-6} \text{ atm})}{(0.08206 \text{ L atm mol}^{-1} \text{ K}^{-1})(298 \text{ K})} \\ &= 2.46 \times 10^{16} \text{ L}^{-1} = 2.46 \times 10^{19} \text{ m}^{-3} \\ A &= 1.00 \text{ cm}^2 = 1.00 \times 10^{-4} \text{ m}^2 \\ \bar{v} &= \sqrt{\frac{8RT}{\pi M}} \\ &= \sqrt{\frac{8(8.3145 \text{ J mol}^{-1} \text{ K}^{-1})(298 \text{ K})}{\pi(32.00 \times 10^{-3} \text{ kg mol}^{-1})}} \\ &= 444 \text{ m s}^{-1}\end{aligned}$$

The collision rate is then

$$\begin{aligned}Z_w &= \frac{1}{4} \frac{N}{V} \bar{v} A \\ &= \frac{1}{4} (2.46 \times 10^{19} \text{ m}^{-3})(444 \text{ m s}^{-1})(1.00 \times 10^{-4} \text{ m}^2) \\ &= 2.73 \times 10^{17} \text{ s}^{-1}\end{aligned}$$

**Related Problems:** 51, 52

Equation 9.25 is the basis of explaining **Graham's law of effusion**. In 1846, Thomas Graham showed experimentally that the rate of effusion of a gas through a small hole into a vacuum (Fig. 9.22) is inversely proportional to the square root of its molar mass. Assuming that different gases are studied at the same temperature and pressure, their number density,  $N/V$ , is the same, and the rate of effusion of each gas depends only on the factor  $1/\sqrt{M}$  in Equation 9.25, exactly as observed by Graham. Explaining this experimental result is yet another success for the kinetic theory of gases.

**FIGURE 9.22** A small hole in the box permits molecules to effuse out into a vacuum. The less massive particles (here, helium atoms, red) effuse at greater rates than the more massive oxygen molecules (purple) because their speeds are greater on the average.

Graham's law also describes the effusion of a mixture of two gases through a small hole. The ratio of the rates of effusion of the two species, A and B, is

$$\begin{aligned} \frac{\text{rate of effusion of A}}{\text{rate of effusion of B}} &= \frac{\frac{1}{4} \frac{N_A}{V} \sqrt{\frac{8RT}{\pi \mathcal{M}_A}}}{\frac{1}{4} \frac{N_B}{V} \sqrt{\frac{8RT}{\pi \mathcal{M}_B}}} \\ &= \frac{N_A}{N_B} \sqrt{\frac{\mathcal{M}_B}{\mathcal{M}_A}} \end{aligned} \quad [9.26]$$

This ratio is equal to the ratio of the numbers of molecules of the two species effusing through the hole in a short time interval.  $N_A$  and  $N_B$  are the number of molecules of species A and B, respectively. The emerging gas is enriched in the lighter component because lighter molecules effuse more rapidly than heavier ones. If B is heavier than A, the **enrichment factor** is  $\sqrt{\mathcal{M}_B/\mathcal{M}_A}$  for the lighter species, A.

### EXAMPLE 9.10

Calculate the enrichment factors from effusion for a mixture of  $^{235}\text{UF}_6$  and  $^{238}\text{UF}_6$ , uranium hexafluoride with two different uranium isotopes. The atomic mass of  $^{235}\text{U}$  is 235.04, and that of  $^{238}\text{U}$  is 238.05. The atomic mass of fluorine is 19.00.

#### Solution

The two molar masses are

$$\mathcal{M}(^{238}\text{UF}_6) = 238.05 + 6(19.00) = 352.05 \text{ g mol}^{-1}$$

$$\mathcal{M}(^{235}\text{UF}_6) = 235.04 + 6(19.00) = 349.04 \text{ g mol}^{-1}$$

$$\begin{aligned} \text{enrichment factor} &= \sqrt{\frac{\mathcal{M}(^{238}\text{UF}_6)}{\mathcal{M}(^{235}\text{UF}_6)}} = \sqrt{\frac{352.05 \text{ g mol}^{-1}}{349.04 \text{ g mol}^{-1}}} \\ &= 1.0043 \end{aligned}$$

**Related Problems: 53, 54**

Graham's law of effusion holds true only if the opening in the vessel is small enough and the pressure low enough that most molecules follow straight-line trajectories through the opening without colliding with one another. A related but more complex phenomenon is **gaseous diffusion through a porous barrier**. This differs from effusion in that molecules undergo many collisions with one another and with the barrier during their passage through it. Just as in effusion, the diffusion rate is inversely proportional to the square root of the molar mass of the gas. But the reasons for this dependence are not those outlined for the effusion process. If a mixture of gases is placed in contact with a porous barrier, the gas passing through is enriched in the lighter component, A, by a factor of  $\sqrt{\mathcal{M}_B/\mathcal{M}_A}$ , and the gas remaining behind is enriched in the heavier component.

In order to develop the atomic bomb, it was necessary to separate the more easily fissionable isotope  $^{235}\text{U}$  from  $^{238}\text{U}$ . Because the natural abundance of  $^{235}\text{U}$  is only 0.7%, its isolation in nearly pure form was a daunting task. The procedure adopted was to react uranium with  $\text{F}_2$  gas to form the relatively volatile compound  $\text{UF}_6$  (boiling point,  $56^\circ\text{C}$ ), which can be enriched in  $^{235}\text{U}$  by passing it through a porous barrier. As shown in Example 9.11, each passage gives an enrichment factor of only 1.0043. So, successive passage through many such barriers is necessary to provide sufficient enrichment of the  $^{235}\text{U}$  component. A multi-state gaseous diffusion chamber was constructed in a short time at the Oak Ridge National Laboratories, and the enriched  $^{235}\text{U}$  was used in the first atomic bomb. Similar methods are still used today to enrich uranium for use as fuel in nuclear power plants (Fig. 9.23).

**FIGURE 9.23** Schematic showing uranium isotope enrichment by diffusion through a porous membrane with pores a few nanometers in diameter. Isotope enrichment occurs because the lighter  $\text{UF}_6$  gas molecules (with  $^{235}\text{U}$  atoms) tend to diffuse through the barrier more rapidly than the heavier  $\text{UF}_6$  gas molecules containing  $^{238}\text{U}$ . The enrichment factor has been greatly exaggerated for purposes of illustration. The gas must pass through several hundred barriers in sequence to build up enough  $^{235}\text{U}$  to be useful in reactor fuel, as illustrated in the following *Connection to Chemical Engineering*.

### EXAMPLE 9.11

How many diffusion stages are required if  $^{235}\text{U}$  is to be enriched from 0.70 to 7.0% by means of the gaseous  $\text{UF}_6$  diffusion process?

#### Solution

From Example 9.10, the enrichment factor per stage is 1.0043; thus, the first stage is described by the relation

$$\left(\frac{N^{235}\text{UF}_6}{N^{238}\text{UF}_6}\right)_1 = \left(\frac{N^{235}\text{UF}_6}{N^{238}\text{UF}_6}\right)_0 (1.0043)$$

where the subscripts 0 and 1 denote the initial concentration and that after the first stage, respectively. The ratio of the numbers after  $n$  stages satisfies the equation

$$\left(\frac{N^{235}\text{UF}_6}{N^{238}\text{UF}_6}\right)_n = \left(\frac{N^{235}\text{UF}_6}{N^{238}\text{UF}_6}\right)_0 (1.0043)^n$$

$$\frac{7.0}{93.0} = \frac{0.70}{99.30} (1.0043)^n$$

$$10.677 = (1.0043)^n$$

This equation can be solved by taking logarithms of both sides (see Appendix C):

$$\log_{10}(10.677) = n \log_{10}(1.0043)$$

$$1.02845 = 0.0018635n$$

$$n = 552 \text{ stages}$$

**Related Problems:** 55, 56

## 9.7.2 Molecule–Molecule Collisions

Collisions lie at the very heart of chemistry, because chemical reactions can occur only when molecules collide with one another. The kinetic theory of gases provides methods for estimating the frequency of molecular collisions and the average distance traveled by a molecule between collisions, both important in understanding the rates of chemical reactions (See Chapter 18).

We assume molecules are approximately spherical, with diameters,  $d$ , on the order of  $10^{-10}$  m (see Section 2.1). We initially suppose that a particular molecule moves through a gas of stationary molecules of the same diameter. Such a molecule “sweeps out” a cylinder with cross-sectional area,  $A = \pi d^2$  (Fig. 9.24).

**FIGURE 9.24** An average molecule (red) sweeps out a cylinder of volume  $\pi d^2 \bar{v}_{rel}$  in 1 second. It will collide with any molecules whose centers lie within the cylinder. Using this construction, we can calculate the rate of collisions with other molecules.

This particular molecule collides with any molecule whose center lies inside the cylinder, within a distance,  $d$ , of the center of the moving molecule. In 1 second, the length of such a cylinder is  $\bar{v}\Delta t = \bar{v} \times 1 \text{ s}$ , where  $\bar{v}$  is the average molecular speed. It does not matter that the moving molecule is scattered in another direction when it collides with other molecules; these little cylinders are merely joined together, end to end, to define a cylinder whose length is  $\bar{v} \times 1 \text{ s}$ .

In 1 second, the moving molecule therefore sweeps out the volume

$$V_{\text{cyl}} = \pi d^2 \bar{v} \quad (\text{if blue molecules still})$$

If  $N_2/V$  is the number of blue molecules per unit volume in the gas, then the number of collisions per second experienced by the moving red molecule is:

$$\text{collision rate} = Z_1 = \frac{N_2}{V} V_{\text{cyl}} = \frac{N_2}{V} \pi d^2 \bar{v}_{rel} \quad [9.27]$$

Here we have specified the speed as the average *relative* speed between the red molecule and the blue molecules, rather than the average speed of the red molecule, as the blue molecules are also moving.

If the red and blue molecules do not have the same diameter, then  $d$  is simply the radius of the red molecule plus the radius of a blue molecule.

The average relative speed,  $\bar{v}_{rel}$ , between a red molecule and the blue molecules with which it is colliding (with both averaged over their respective Maxwell-Boltzmann distribution of molecular speeds) is very similar to the average speed in Equation 9.20, except one replaces  $m$  by  $\mu = m_1 m_2 / (m_1 + m_2)$ . (See Chapter 18.) Using this in Equation 9.27 gives

$$Z_1 = \frac{N_2}{V} \pi d^2 \bar{v}_{rel} = \frac{N_2}{V} \pi d^2 \sqrt{\frac{8k_B T}{\pi \mu}} = \frac{N_2}{V} d^2 \sqrt{\frac{8\pi k_B T}{\mu}} \quad [9.28]$$

You can use this to calculate the collision frequency of a single molecule in a pure gas (the number of collisions per second suffered by a single molecule in a pure gas). Using  $\bar{v}_{rel} = \bar{v}\sqrt{2}$  (since  $m_1 = m_2$ ), the expression becomes:

$$Z_1 \text{ in pure gas} = \frac{N}{V} \pi d^2 \bar{v}_{rel} = \frac{N}{V} \pi d^2 \bar{v} \sqrt{2} = 4 \frac{N}{V} d^2 \sqrt{\frac{\pi k_B T}{m}} \quad [9.29]$$

Now, if the number density of the red molecules is  $N_1/V$ , you can easily calculate the number of collisions between red molecules and blue molecules per

second per unit volume of your sample by multiplying Equation 9.28 above by  $N_1/V$ :

$$\begin{aligned}\frac{\text{collisions of type 1 molecules with type 2}}{\text{m}^3 \text{ s}} &= \frac{N_1}{V} \frac{N_2}{V} \pi d^2 \bar{v}_{rel} \\ &= \frac{N_1}{V} \frac{N_2}{V} \pi d^2 \sqrt{\frac{8k_B T}{\pi \mu}}\end{aligned}\quad [9.30]$$

and expressing the volumes in  $\text{m}^3$ , speed in  $\text{m s}^{-1}$ , distances in m, and the reduced mass  $\mu$  in kg (calculated from the mass of each of the colliding molecules in kg). Equation 9.30 is very important in expressing the reaction rate between two molecules, as two molecules can react when they collide with each other (see Chapter 18). Noting that in Equation 9.30 the term  $N_1/V = P_1/k_B T$ , one sees that the number of potentially reactive collisions between molecules of type 1 and molecules of type 2 is proportional to the product of the partial pressures, or the product of the concentrations, of the two molecules. We will use this result in Chapter 18.

Finally, if the gas has only one component, say type 1, the number of collisions between molecules in the gas per unit volume per unit time can be calculated from Equation 9.30, but you have to divide by a factor of 2 so that you don't double count one collision. Also, using  $\bar{v}_{rel} = \bar{v}\sqrt{2}$ , this gives the following:

$$\begin{aligned}\frac{\text{collisions between molecules in a pure gas}}{\text{m}^3 \text{ s}} &= \frac{1}{2} \left( \frac{N}{V} \right)^2 \pi d^2 \bar{v}_{rel} \\ &= \frac{\sqrt{2}}{2} \left( \frac{N}{V} \right)^2 \pi d^2 \bar{v}\end{aligned}$$

### EXAMPLE 9.12

Calculate the collision frequency for (a) a molecule in a sample of oxygen at 1.00 atm pressure and 25°C, and (b) a molecule of hydrogen in a region of interstellar space where the number density is  $1.0 \times 10^{10}$  molecules per cubic meter and the temperature is 30 K. Take the diameter of  $\text{O}_2$  to be  $2.92 \times 10^{-10}$  m and that of  $\text{H}_2$  to be  $2.34 \times 10^{-10}$  m.

#### Solution

$$\begin{aligned}\text{(a)} \quad \frac{N}{V} &= \frac{N_A P}{RT} = \frac{(6.022 \times 10^{23} \text{ mol}^{-1})(1.00 \text{ atm})}{(0.08206 \text{ L atm mol}^{-1} \text{ K}^{-1})(298 \text{ K})} \\ &= 2.46 \times 10^{22} \text{ L}^{-1} = 2.46 \times 10^{25} \text{ m}^{-3}\end{aligned}$$

In Example 9.9, we found  $\bar{v}$  to be  $444 \text{ m s}^{-1}$ . Thus, using Equation 9.29, the collision frequency is

$$\begin{aligned}Z_1 &= (2.46 \times 10^{25} \text{ m}^{-3})(2.92 \times 10^{-10} \text{ m})^2 (444 \text{ m s}^{-1})\sqrt{2}\pi \\ &= 4.14 \times 10^9 \text{ s}^{-1}\end{aligned}$$

This is the average number of collisions experienced by each molecule per second.

(b) An analogous calculation gives

$$Z_1 = 1.4 \times 10^{-6} \text{ s}^{-1}$$

In other words, the average molecule under these conditions waits  $7.3 \times 10^5$  seconds, or 8.5 days, between collisions.

**Related Problems:** 88, 89

## 9.7.3 Mean Free Path and Diffusion

$Z_1$  is the rate at which a particular molecule collides with other molecules. Its inverse,  $Z_1^{-1}$ , therefore measures the average time between collisions. During this interval, a molecule travels an average distance  $\bar{v} Z_1^{-1}$  which is called the **mean free path**,  $\lambda$  in a pure gas.

$$\lambda = \bar{v} Z_1^{-1} = \frac{\bar{v}}{\sqrt{2} (N/V) \pi d^2 \bar{v}} = \frac{1}{\sqrt{2} \pi d^2 N/V}\quad [9.31]$$

**FIGURE 9.25** A gas molecule follows a straight-line path for only a short time before undergoing a collision, so its overall path is a zigzag one. The net displacement  $\Delta r$  of a particular molecule in time,  $\Delta t$ , is shown. The path taken by the molecules is traced out in blue, and the red arrow represents the net displacement during the period  $\Delta t$ . The mean-square net displacement  $\overline{\Delta r^2}$  is equal to  $6Dt$ , where  $D$  is the diffusion constant of the molecules in the gas.

The mean free path, unlike the collision frequency, does not depend on the molar mass. The mean free path must be much larger than the molecular diameter for a gas to show ideal gas behavior. For a molecule of diameter  $3 \times 10^{-10}$  m, the mean free path at  $25^\circ\text{C}$  and atmospheric pressure is  $1 \times 10^{-7}$  m, which is 300 times larger.

Molecules in a gas move in straight lines only for rather short distances before they are deflected by collisions and change direction (Fig. 9.25). Because each molecule follows a zigzag course, they take more time to travel a particular net distance from their starting points than they would if there were no collisions. This fact helps explain why diffusion is slow in gases. Recall that at room temperature the speed of a molecule is on the order of  $1 \times 10^3$  m  $\text{s}^{-1}$ . If molecules traveled in straight-line trajectories, a perfume released in one part of a room would be noticed across the room almost instantaneously. Instead, there is a time lapse because the molecules follow irregular paths that we call “random walks.”

We can describe diffusion in a gas using averaged quantities such as the mean-square displacement,  $\overline{\Delta r^2} = \overline{\Delta x^2} + \overline{\Delta y^2} + \overline{\Delta z^2}$ , from the zig-zag motion. If there are no gas currents to perturb the motion of the gas molecules—a rather strenuous condition requiring strict isolation of the experiment from the surroundings—then  $\overline{\Delta r^2}$  is found to be proportional to the time elapsed,  $t$ :

$$\overline{\Delta r^2} = 6Dt \quad [9.32]$$

The proportionality constant is  $6D$ , where  $D$  is the **diffusion constant** of the molecules. So, the root-mean-square displacement  $\sqrt{\overline{\Delta r^2}}$  is equal to  $\sqrt{6Dt}$ .

The diffusion constant has units of  $\text{m}^2 \text{s}^{-1}$ . It is proportional to the mean free path,  $\lambda$ , and to the mean molecular speed,  $\bar{v}$ , but the proportionality constant is difficult to calculate in general. For the simplest case, a single-component gas, the proportionality constant is  $3\pi/16$ , so

$$\begin{aligned} D &= \frac{3\pi}{16} \lambda \bar{v} = \frac{3\pi}{16} \sqrt{\frac{8RT}{\pi M}} \frac{1}{\sqrt{2\pi d^2 N/V}} \\ &= \frac{3}{8} \sqrt{\frac{RT}{\pi M}} \frac{1}{d^2 N/V} \end{aligned} \quad [9.33]$$

### EXAMPLE 9.13

Calculate the mean free path and the diffusion constant for the molecules in Example 9.12.

#### Solution

(a) The mean free path is

$$\begin{aligned} \lambda &= \frac{1}{\sqrt{2\pi} (2.92 \times 10^{-10} \text{ m})^2 (2.46 \times 10^{25} \text{ m}^{-3})} \\ &= 1.07 \times 10^{-7} \text{ m} \end{aligned}$$

The diffusion constant is

$$\begin{aligned} D &= \frac{3\pi}{16} \lambda \bar{v} = \frac{3\pi}{16} (1.07 \times 10^{-7} \text{ m}) (444 \text{ m s}^{-1}) \\ &= 2.80 \times 10^{-5} \text{ m}^2 \text{ s}^{-1} \end{aligned}$$

(b) An analogous calculation for an average molecule of  $\text{H}_2$  in interstellar space gives

$$\lambda = 4.1 \times 10^8 \text{ m}$$

For comparison, the distance from the Earth to the moon is  $3.8 \times 10^8$  m. The diffusion constant is

$$D = 1.4 \times 10^{11} \text{ m}^2 \text{ s}^{-1}$$

**Related Problems:** 57, 58

## CONNECTION TO CHEMICAL ENGINEERING

## Uranium Enrichment for Nuclear Reactor Fuel

Nuclear energy is an important source of power throughout the world today. In March 2010, the European Nuclear Society (ENS) reported that 437 nuclear power plants are in operation and 55 plants are under construction worldwide. Inside the nuclear reactor in a power plant, nuclei of the uranium isotope  $^{235}\text{U}$  are bombarded with neutrons and break apart into lighter nuclides in a process called fission. (See Section 19.5.) Fission liberates enormous amounts of energy in the form of heat. The heat creates steam to drive turbines that generate electrical power. The isotopic abundance in naturally occurring uranium is 0.7% for  $^{235}\text{U}$  and 99.3% for  $^{238}\text{U}$ , which is not used in the fission process. In order to be used as fuel for nuclear reactors, uranium must have the weight percentage of  $^{235}\text{U}$  lie between 3% and 5%. Increasing the ratio of  $^{235}\text{U}$  to  $^{238}\text{U}$  through an enrichment process is the essential step in preparing fuel for a nuclear reactor. The isotopes of uranium,  $^{235}\text{U}$  and  $^{238}\text{U}$ , are chemically identical, but differ in their physical properties, especially their masses. This small difference in mass allows limited separation of molecules containing these isotopes by the process of gaseous diffusion through a porous barrier. (See Section 9.7.) The uranium to be enriched is converted to uranium hexafluoride,  $\text{UF}_6$ , which is the only compound of uranium that becomes a vapor at a modest temperature ( $56^\circ\text{C}$ ). Because fluorine has only the single isotope  $^{19}\text{F}$ , the mass difference between the molecules  $^{235}\text{UF}_6$  and  $^{238}\text{UF}_6$  is only three units. Consequently, very limited separation is achieved in a single pass through the porous barrier, and multiple stages are required to achieve the levels of enrichment necessary for use as nuclear fuel. (See Example 9.11 in Section 9.7.) This industrial process has been used for over 60 years to increase or enrich the percentage of  $^{235}\text{U}$ .

## Uranium Mining, Refining, and Conversion

Uranium is obtained by mining its ore to recover the stable oxide  $\text{U}_3\text{O}_8$  or  $\text{UO}_3$ . To alleviate environmental concerns, open-pit mining has been replaced in the United States and Australia by *in situ* leaching of uranium ore from the earth. In this process, oxygenated acidic or basic solutions are circulated through the buried deposits of uranium ore via injection and recovery wells.

The uranium obtained in the solution is mostly uranyl sulfate,  $\text{UO}_2(\text{SO}_4)_3^{4-}$ , in acid leach conditions or uranyl carbonate,  $\text{UO}_2(\text{CO}_3)_3^{4-}$  in a carbonate leach

system. In the United States this solution is pumped to the treatment plant where the uranium is removed on an ion exchange resin (Fig. C9.1). In one such system, the resin is rinsed with sulfuric acid and hydrogen peroxide is added to precipitate uranyl peroxide.

After the precipitate dries at a low temperature,  $\text{U}_3\text{O}_8$ , called “yellowcake” because of its bright yellow color, is obtained. This stable oxide is the form in which uranium is marketed and exported.

A solvent extraction process is used to recover uranium from the acidic leaching solution in Australia. Organic amines dissolved in kerosene remove uranium oxide by forming molecular complexes that are soluble in kerosene. Cationic and ionic impurities are removed from this organic phase, after which the uranium complexes are stripped out in a solution of ammonium sulfate. Gaseous ammonia is added to neutralize this solution and to precipitate ammonium diuranate.

The diuranate is treated by a process called dewatering and then roasted to yield  $\text{U}_3\text{O}_8$  as the final product.

For uranium to be enriched via the gaseous diffusion process it must be in a gaseous form. This is achieved by converting uranium oxide to uranium hexafluoride ( $\text{UF}_6$ ) (known as ‘hex’ in the industry), by the following processes.

FIGURE C9.1 In-situ uranium mining process.

First,  $\text{U}_3\text{O}_8$  is reduced to uranium dioxide ( $\text{UO}_2$ ) by hydrogen in a kiln using the “dry process.” Similarly  $\text{UO}_3$  is reduced by the “wet process.”

Next, uranium dioxide is reacted in another kiln with gaseous hydrogen fluoride HF (in the dry process) or aqueous HF (in the wet process) to form uranium tetrafluoride ( $\text{UF}_4$ ).

Finally, uranium tetrafluoride ( $\text{UF}_4$ ) is fed into a flame tower to react with gaseous fluorine (dry process), or into a fluidized bed reactor to react with aqueous fluorine (wet process), to produce  $\text{UF}_6$ .

The  $\text{UF}_6$  product forms a highly corrosive liquid, which is stored in thick-walled steel cylinders. After cooling and pressurization, the  $\text{UF}_6$  in the cylinder becomes a white crystalline solid.

## Gaseous Diffusion

At the gaseous diffusion enrichment plant, solid  $\text{UF}_6$  is heated in its container to a temperature above  $56^\circ\text{C}$  and becomes a vapor. The gas is fed into the plant's pipelines and arrives at special filters called diffusion barriers (semi-porous membranes). The barriers contain hundreds of millions of pores per square inch. The diameter of the pores is extremely small, with an average size on the order of 25 nm. The pores must be uniform in size. The barrier must be fabricated from a material that will not react with  $\text{UF}_6$  gas (which is

highly corrosive), and it must withstand high flow rates for successful operation. Typical barrier materials are aluminum oxide or nickel.

These pores are designed to be just large enough to allow  $\text{UF}_6$  gas molecules to flow through. The kinetic energy of the uranium hexafluoride molecules depends on the temperature, which is held constant at each stage. Since the kinetic energy of a molecule is proportional to the product of its mass and the square of its speed, the lighter molecules ( $^{235}\text{UF}_6$ ) have higher speeds than the heavy molecules ( $^{238}\text{UF}_6$ ). Because they move at a faster speed, the lighter molecules hit the barrier more frequently and have a higher probability of passing through the pores. As the lighter  $^{235}\text{UF}_6$  molecules diffuse through the barriers at a faster rate than the heavier  $^{238}\text{UF}_6$  molecules, isotope enrichment occurs.

Each stage has an input where gas with a particular mole fraction of  $^{235}\text{UF}_6$  is fed in. As the gas travels through each diffusion stage, the gas on the exit side of the barrier is enriched (contains more of the lighter gas) while the gas on the entrance side of the barrier is depleted (contains less of the lighter gas). As this process is repeated throughout multiple diffusion stages the concentration of  $^{235}\text{UF}_6$  relative to  $^{238}\text{UF}_6$  increases. The enrichment factor achieved in each diffusion stage is only 1.0043 due to the small mass difference between these two isotopes. (See Example 9.10.) Thus, many stages are required to achieve the desired level of isotope enrichment.

Figure C9.2 shows one of the 3122 diffusion stages in the gaseous diffusion plant at Oak Ridge National Laboratory. Gaseous  $\text{UF}_6$  entering the left side of the stage is progressively enriched as it moves through the stage from left to right, as indicated by an increase in the number of red dots representing  $^{235}\text{UF}_6$  molecules. There are three diffusion barriers in each stage and gases

**FIGURE C9.2** Schematic of a diffusion stage at the gaseous diffusion plant at Oak Ridge National Laboratory. The concentration of  $^{235}\text{UF}_6$  (red dots) is increased at each stage by only a factor of 1.0043, so the enrichment per stage is much less than that shown.

are recycled through the barriers within a stage, as well as between stages, multiple times, as shown by the arrows flowing back to the left.

At the end of the gaseous diffusion process, the enriched  $\text{UF}_6$  gas is condensed into a liquid that is cooled, pressurized, and solidified before being sent to a fuel fabrication facility for further processing. The enriched  $\text{UF}_6$  is converted into uranium dioxide ( $\text{UO}_2$ ) powder that is processed to form hard, ceramic pellets of enriched uranium with uniform size. These pellets are used to form fuel rods for the reactor.

After running in the reactor for some period of time, the rods are “spent” because the  $^{235}\text{U}$  has been depleted by fission. Spent nuclear fuel is a highly radioactive, complex mixture of uranium oxide and the fission products of  $^{235}\text{U}$ . Safe disposal and storage of spent nuclear material present considerable challenges due to its long-lived radioactivity. Exposure to radiation and to high temperature in the reactor will have altered the physical and chemical structure of the materials in ways that make subsequent processing quite difficult. Active research in

this problem engages chemists, physicists, chemical engineers, and materials experts to devise proper methods. Each of these professions plays a key role at each step of the nuclear fuel cycle, which is the progression of nuclear material from the *front end* (preparation), through the *service period* (use during reactor operation), to the *back end* (safely manage, contain, and re-process or dispose of spent fuel).

Uranium enrichment for commercial applications originated in the United States with the gaseous diffusion process, which is now used worldwide and produces approximately 25% of the world's enriched uranium. Only one gaseous diffusion plant operates in the United States today, in Paducah, Kentucky. According to the United States Energy Commission (USEC), 70% of the production cost at the Paducah plant is due to electricity used for the uranium enrichment process. Due to energy requirements, gaseous diffusion is being phased out in favor of more efficient enrichment processes based on gas centrifuges and laser isotope separation technology.

## CHAPTER SUMMARY

Gases provide the simplest opportunity for relating macroscopic properties of matter to the structure, motions, and interactions of molecules. Because molecules in gases are quite far apart most of the time, we can neglect intermolecular forces and represent the molecules as point masses that have only kinetic energy and collide with the walls of the container but not with each other. The simplest treatment of this physical model predicts the ideal gas law, which was discovered empirically. More elaborate mathematical treatments of the same model produce the full probability distribution for molecular speeds. From this distribution, various average quantities can be calculated and used to interpret numerous experimental phenomena in gases at low density. At higher density, intermolecular forces can no longer be neglected. Their effect is described systematically by the intermolecular potential energy function, which includes both the attractive and repulsive effects. The well depth and location of the minimum in the potential energy curve are very useful parameters for summarizing these effects. They provide deeper insight into the attractive and repulsive constants that are obtained by fitting the van der Waals equation of state to empirical data.

## CONCEPTS AND SKILLS

### Section 9.1 – The Chemistry of Gases

Write chemical equations for several reactions that lead to gas formation (Problems 1–4).

- In addition to the evaporation of liquids (such as water and gasoline), certain classes of chemical reactions lead to gaseous products that can escape into the atmosphere if not confined. Several examples are described in Section 9.1.

### Section 9.2 – Pressure and Temperature of Gases

Describe how pressure and temperature are defined and measured (Problems 5–10).

- The pressure exerted on the walls of a container, either by gas enclosed within it or by the atmosphere outside it, is defined as the force exerted per unit area of wall. Therefore, in SI units pressure has dimensions of  $\text{N m}^{-2}$ , which has the special name pascal (Pa). Other units may be more convenient in particular applications; conversion factors are available in Table 9.2. Torricelli's barometer measures the pressure of the atmosphere quite directly as equivalent to the force per unit area exerted by a mercury column of height  $h$ :  $P = \rho gh$ . Boyle used the J-tube as a means to increase the pressure on a fixed amount of gas, and to measure the resulting decrease in volume. The results are summarized in Boyle's law,  $PV = C$ , where  $C$  is a constant for a fixed amount of gas and fixed temperature. For 1 mol of gas at  $0^\circ\text{C}$ , the value of the constant is 22.414 L atm.
- We cannot measure temperature directly because it is not a mechanical property. Instead, we measure changes in some mechanical property chosen because we believe its changes are proportional to changes in temperature, such as the length of a column of mercury inside a narrow tube, and calibrate these changes against selected reference points to define scales of temperature and practical thermometers. A better illustration is the "gas thermometer" which displays the change in volume of a gas as its temperature increases. (Here the mechanical property, the gas volume, changes more linearly with temperature than does the mercury thermometer volume.) The gas must be held at constant pressure inside a container whose walls can move as the gas expands. See Figure 9.8. These measurements suggest the existence of the absolute zero of temperature at  $t = -273.15^\circ\text{C}$  and lead to the Kelvin temperature scale,  $T(\text{Kelvin}) = 273.15 + t(\text{Celsius})$ . The changes in volume of a gas as temperature is changed are summarized in Charles's law,  $V \propto T$ , but only when temperature is expressed in Kelvin. The proportionality constant depends on the amount of gas and on the fixed pressure at which the measurements are made.

### Section 9.3 – The Ideal Gas Law

Use the ideal gas law to relate pressure, volume, temperature, and number of moles of an ideal gas and to do stoichiometric calculations involving gases (Problems 19–32).

- Boyle's law connects  $V$  and  $P$  at constant  $T$  and constant  $n$  (number of moles). Charles's law connects  $V$  and  $T$  at constant  $P$  and constant  $n$ . Avogadro's hypothesis connects  $V$  and  $n$  at constant  $T$  and  $P$ . Therefore, the experiments show that the four measurable properties  $V$ ,  $T$ ,  $P$ , and  $n$  are all interconnected. Furthermore, experiments show that for a pure gas, holding

any three of them at a fixed value forces the remaining one to assume a specific fixed value. It is very convenient to summarize this vast range of experimental results in a single compact equation, the ideal gas law  $PV = nRT$ . Since any one of these can be considered the “dependent variable” and its value can be calculated as a result of changes in the remaining “independent variables,” the equation can be rearranged into a variety of useful forms for specific applications. When solving any problem, it is a good idea to read the problem as a description of a laboratory measurement. That way you will know immediately which variables are independent (being manipulated directly by the experimenter) and dependent (responding to the changes induced by the experimenter) and you can immediately put the ideal gas law into the most useful form. Chemical reactions involving gaseous products or reactants are described by balanced equations that relate the number of moles of each reactant and product. When describing pure solid substances as in Chapter 2, we determine the number of moles of each participant as the ratio of its mass to its molecular weight. In gaseous reactions we relate the number of moles of each participant to the conditions of the gas through the equation  $n = PV/RT$ .

### Section 9.4 – Mixtures of Gases

*Use Dalton’s law to calculate partial pressures in gas mixtures (Problems 33–38).*

- When several gaseous species are present in a container with volume  $V$  and temperature  $T$ , each of the gases generates its own individual pressure, called the partial pressure, against the walls of the container. The sum of all the partial pressure contributions is the total pressure. Physically this arises because the frequency at which a gas molecule hits the walls of the container, and the velocity it has when it hits the wall, is largely unaffected by the other gaseous molecules present. The equations to describe these events are straightforward. For species  $A$ , we have two expressions for the partial pressure  $P_A = n_A(RT/V)$  and  $P_A = X_A P_{tot}$ , both of which state that the partial pressure contribution of species  $A$  is proportional to the number of moles of species  $A$  that are present. Using either version, the sum of all the partial pressures adds up to the total pressure.

### Section 9.5 – The Kinetic Theory of Gases

*Use the Maxwell–Boltzmann distribution of molecular speeds to calculate root-mean-square, most probable, and average speeds of molecules in a gas. Integrate the distribution from a speed  $v_1$  to a faster speed  $v_2$  to calculate the fraction of molecules with speeds in that range. (Problems 41–46).*

- The kinetic molecular theory views a vessel of gas as a collection of molecules and describes their behavior, in particular the range of speeds at which they move, using statistics and probability. Three standard statistical parameters indicate the typical behavior of a molecule: most probable speed  $v_{mp}$ , average speed  $\bar{v}$ , and root-mean-square speed  $v_{rms}$ . The magnitudes of these parameters are ranked in the order  $v_{mp} < \bar{v} < v_{rms}$  because the Maxwell–Boltzmann distribution is not symmetrical; the area under the curve to the right of the maximum is slightly greater than that to the left of the maximum. Calculations of these quantities are straightforward; equations are provided using the mass of an individual molecule and also the molar mass of the substance. All these statistical indications of a typical molecular speed increase as  $T$  increases and decrease as the molecular mass increases. You can calculate the fraction of molecules with speeds between  $v_1$  and  $v_2$  by integrating the Maxwell–Boltzmann distribution numerically, or estimating the area graphically.

Describe the connection between temperature and the speeds or kinetic energies of the molecules in a gas (Problems 47–48).

- One of the great achievements of the kinetic theory of gases is to explain the meaning of temperature as proportional to the average kinetic energy of the molecules. This makes it quite clear why temperature cannot be represented as a macroscopic mechanical quantity. Two equations are very useful to describe this relation:  $\bar{\epsilon} = \frac{3}{2} k_B T$  for the average kinetic energy and  $\overline{v^2} = 3RT/M$  for the average of the square of the speed.

### Section 9.6 – Real Gases: Intermolecular Forces

Use the van der Waals equation to relate the pressure, volume, temperature, and number of moles of a nonideal gas (Problems 49–52).

- The van der Waals equation can be viewed as a “correction” to the ideal gas law to account for the finite size of the molecules and attractive forces between them. In essence the attractions between molecules, represented by the  $a$  parameter, decrease the pressure the gas would exert on the walls from that expected for an ideal gas. The finite size of the molecules, represented by the  $b$  parameter, increases the volume the gas occupies (compared to the volume an ideal gas). The van der Waals equation describes all the same kinds of experiments as the ideal gas law, and is used in exactly the same way. Always try to interpret the results in terms of the effects of the  $a$  and  $b$  parameters described above and their magnitudes in Table 9.3.

Discuss how forces between atoms and molecules vary with distance.

- Examine the Lennard–Jones potential energy curve for a pair of atoms as presented in Figure 9.21, Equation 9.24, and Table 9.4. Visualize a sequence of curves plotted for the gases listed in Table 9.4 and identify from each curve the typical separations for which the force between the atoms is attractive or repulsive. Note that the minimum of the curves in Figure 9.21 occurs at the distance  $R = 1.122\sigma$ , where  $\sigma$  is the value of  $R$  at which  $V(R) = 0$ . Note the very small well depths for the He–He potential, and the Ar–Ar potential, as compared with well depths of covalently bound atoms.

### Section 9.7 – A Deeper Look . . . Molecular Collisions and Rate Processes

Calculate the rate of collisions of molecules with a wall, and from that calculation determine the effusion rate of a gas through a small hole of known area (Problems 53–54).

- Three physical effects contribute to  $Z_w$ , the rate of collisions with the wall: the rate is proportional to the area  $A$  of the wall, proportional to the average speed of the molecules, and proportional to the number density of the molecules. This reasoning leads directly to Equation 9.25 for  $Z_w$ . If we take  $A$  to be the area of the small hole, all the molecules that collide with this area escape from the vessel, and the effusion rate is the same as  $Z_w$ .

Calculate the enrichment factor for lighter molecules when a gas consisting of a mixture of light and heavy molecules effuses through a small aperture in a vessel wall (Problems 55–58).

- If gas A is lighter than gas B, the escaping gas is richer in A because the A molecules effuse more rapidly. Taking the ratio  $Z_A/Z_B$  shows that the enrichment factor is  $\sqrt{M_B/M_A}$ . See Equation 9.26.

Calculate the collision frequency, mean free path, and diffusion constant for gases (Problems 57–58).

- The key physical idea behind all these applications is to calculate the rate (or frequency) with which one molecule collides with other molecules rather

than with the wall. The reasoning is described in Figure 9.24, which shows the “collision cylinder” swept out by a molecule with diameter  $d$  during 1 sec as it moves through a gas with average relative speed  $\overline{v_{\text{rel}}}$ . This molecule collides with all other molecules that appear in its “collision cylinder.” So  $Z_1$ , the rate (or frequency) of collisions with other molecules, is proportional to the volume of the collision cylinder and the number density of molecules in the gas. This reasoning leads directly to Equations 9.28 and 9.29. The mean free path  $\lambda$  is the distance traveled by a typical molecule between collisions as it moves with average speed  $\overline{v}$ . The time elapsed between collisions is the reciprocal of  $Z_1$ . Therefore,  $\lambda = \overline{v} Z_1^{-1}$ . Equation 9.31 gives the details for calculating  $\lambda$ . Over long periods of time a molecule experiences many collisions and therefore travels a zig-zag path. Its net displacement over a time interval is not given by the simple equation *distance = speed  $\times$  time*, but must be described statistically by the root-mean-square displacement. The mean-square displacement is related to the elapsed time interval by the diffusion constant  $D$ , which is proportional to the mean free path and to the average speed. See Equation 9.33 for the method of calculating  $D$ .

## CUMULATIVE EXERCISE

### Ammonium Perchlorate as a Rocket Fuel

Ammonium perchlorate ( $\text{NH}_4\text{ClO}_4$ ) is a solid rocket fuel that was used in space shuttles (see Fig. 9.26). When heated above  $200^\circ\text{C}$ , it decomposes to a variety of gaseous products, of which the most important are  $\text{N}_2$ ,  $\text{Cl}_2$ ,  $\text{O}_2$ , and water vapor.

**FIGURE 9.26** A space shuttle taking off.

- Write a balanced chemical equation for the decomposition of  $\text{NH}_4\text{ClO}_4$ , assuming the products just listed are the only ones generated.
- The sudden appearance of hot gaseous products in a small initial volume leads to rapid increases in pressure and temperature, which give the rocket its thrust. What total pressure of gas would be produced at  $800^\circ\text{C}$  by igniting  $7.00 \times 10^5$  kg  $\text{NH}_4\text{ClO}_4$  (a typical charge of the booster rockets in the space shuttle) and allowing it to expand to fill a volume of  $6400$  m<sup>3</sup> ( $6.40 \times 10^6$  L)? Use the ideal gas law.
- Calculate the mole fraction of chlorine and its partial pressure in the mixture of gases produced.
- The van der Waals equation applies strictly to pure real gases, not to mixtures. For a mixture like the one resulting from the reaction of part (a), it may still be possible to define effective  $a$  and  $b$  parameters to relate total pressure, volume, temperature, and total number of moles. Suppose the gas mixture has  $a = 4.00$  atm L<sup>2</sup> mol<sup>-2</sup> and  $b = 0.0330$  L mol<sup>-1</sup>. Recalculate the pressure of the gas mixture in part (b) using the van der Waals equation. Why is the result smaller than that in part (b)?
- Calculate and compare the root-mean-square speeds of water and chlorine molecules under the conditions of part (b).
- The gas mixture from part (b) cools and expands until it reaches a temperature of  $200^\circ\text{C}$  and a pressure of  $3.20$  atm. Calculate the volume occupied by the gas mixture after this expansion has occurred. Assume ideal gas behavior.

### Answers

- $2 \text{NH}_4\text{ClO}_4(\text{s}) \longrightarrow \text{N}_2(\text{g}) + \text{Cl}_2(\text{g}) + 2 \text{O}_2(\text{g}) + 4 \text{H}_2\text{O}(\text{g})$
- 328 atm

- (c)  $X_{\text{Cl}_2} = \frac{1}{8} = 0.125$  (exactly);  $P_{\text{Cl}_2} = 41.0$  atm
- (d) 318 atm. The real pressure is less than that calculated using the ideal gas law because half of the products are water molecules that have very strong intermolecular attractions, leading to the large value of the  $a$  parameters for the gas mixture.
- (e)  $v_{\text{rms}}(\text{H}_2\text{O}) = 1220$  m s<sup>-1</sup>;  $v_{\text{rms}}(\text{Cl}_2) = 614$  m s<sup>-1</sup>
- (f)  $2.89 \times 10^5$  m<sup>3</sup>

## PROBLEMS

Answers to problems whose numbers are red appear in Appendix G. Problems that are more challenging are indicated with asterisks.

### 9.1 The Chemistry of Gases

1. Solid ammonium hydrosulfide ( $\text{NH}_4\text{HS}$ ) decomposes entirely to gases when it is heated. Write a chemical equation representing this change.
2. Solid ammonium carbamate ( $\text{NH}_4\text{CO}_2\text{NH}_2$ ) decomposes entirely to gases when it is heated. Write a chemical equation representing this change.
3. Ammonia ( $\text{NH}_3$ ) is an important and useful gas. Suggest a way to generate it from ammonium bromide ( $\text{NH}_4\text{Br}$ ). Include a balanced chemical equation.
4. Hydrogen cyanide ( $\text{HCN}$ ) is a poisonous gas. Explain why solutions of potassium cyanide ( $\text{KCN}$ ) should never be acidified. Include a balanced chemical equation.

### 9.2 Pressure and Temperature of Gases

5. Suppose a barometer were designed using water (with a density of  $1.00$  g cm<sup>-3</sup>) rather than mercury as its fluid. What would be the height of the column of water balancing  $1.00$  atm pressure?
6. A vessel that contains a gas has two pressure gauges attached to it. One contains liquid mercury, and the other an oil such as dibutyl phthalate. The difference in levels of mercury in the two arms of the mercury gauge is observed to be  $9.50$  cm. Given
 
$$\text{density of mercury} = 13.60 \text{ g cm}^{-3}$$

$$\text{density of oil} = 1.045 \text{ g cm}^{-3}$$

$$\text{acceleration due to gravity} = 9.806 \text{ m s}^{-2}$$
  - (a) What is the pressure of the gas?
  - (b) What is the difference in height of the oil in the two arms of the oil pressure gauge?
7. Calcium dissolved in the ocean is used by marine organisms to form  $\text{CaCO}_3(\text{s})$  in skeletons and shells. When the organisms die, their remains fall to the bottom. The amount of calcium carbonate that can be dissolved in seawater depends on the pressure. At great depths, where the pressure exceeds about  $414$  atm, the shells slowly

redissolve. This reaction prevents all the Earth's calcium from being tied up as insoluble  $\text{CaCO}_3(\text{s})$  at the bottom of the sea. Estimate the depth (in feet) of water that exerts a pressure great enough to dissolve seashells.

8. Suppose that the atmosphere were perfectly uniform, with a density throughout equal to that of air at  $0^\circ\text{C}$ ,  $1.3$  g L<sup>-1</sup>. Calculate the thickness of such an atmosphere that would cause a pressure of exactly  $1$  standard atm at the Earth's surface.
9. The "critical pressure" of mercury is  $172.00$  MPa. Above this pressure mercury cannot be liquefied, no matter what the temperature. Express this pressure in atmospheres and in bars ( $1 \text{ bar} = 10^5 \text{ Pa}$ ).
10. Experimental studies of solid surfaces and the chemical reactions that occur on them require very low gas pressures to avoid surface contamination. High-vacuum apparatus for such experiments can routinely reach pressures of  $5 \times 10^{-10}$  torr. Express this pressure in atmospheres and in pascals.
11. Some nitrogen is held in a  $2.00$ -L tank at a pressure of  $3.00$  atm. The tank is connected to a  $5.00$ -L tank that is completely empty (evacuated), and a valve is opened to connect the two tanks. No temperature change occurs in the process. Determine the total pressure in this two-tank system after the nitrogen stops flowing.
12. The Stirling engine, a heat engine invented by a Scottish minister, has been considered for use in automobile engines because of its efficiency. In such an engine, a gas goes through a four-step cycle: (1) expansion at constant  $T$ , (2) cooling at constant  $V$ , (3) compression at constant  $T$  to its original volume, and (4) heating at constant  $V$  to its original temperature. Suppose the gas starts at a pressure of  $1.23$  atm and the volume of the gas changes from  $0.350$  to  $1.31$  L during its expansion at constant  $T$ . Calculate the pressure of the gas at the end of this step in the cycle.
13. The absolute temperature of a  $4.00$ -L sample of gas doubles at constant pressure. Determine the volume of the gas after this change.
14. The Celsius temperature of a  $4.00$ -L sample of gas doubles from  $20.0^\circ\text{C}$  to  $40.0^\circ\text{C}$  at constant pressure. Determine the volume of the gas after this change.

15. The gill is an obscure unit of volume. If some  $\text{H}_2(\text{g})$  has a volume of 17.4 gills at  $100^\circ\text{F}$ , what volume would it have if the temperature were reduced to  $0^\circ\text{F}$ , assuming that its pressure stayed constant?
16. A gas originally at a temperature of  $26.5^\circ\text{C}$  is cooled at constant pressure. Its volume decreases from 5.40 L to 5.26 L. Determine its new temperature in degrees Celsius.
17. Calcium carbide ( $\text{CaC}_2$ ) reacts with water to produce acetylene ( $\text{C}_2\text{H}_2$ ), according to the following equation:

A certain mass of  $\text{CaC}_2$  reacts completely with water to give 64.5 L  $\text{C}_2\text{H}_2$  at  $50^\circ\text{C}$  and  $P = 1.00$  atm. If the same mass of  $\text{CaC}_2$  reacts completely at  $400^\circ\text{C}$  and  $P = 1.00$  atm, what volume of  $\text{C}_2\text{H}_2$  will be collected at the higher temperature?

18. A convenient laboratory source for high purity oxygen is the decomposition of potassium permanganate at  $230^\circ\text{C}$ :

Suppose 3.41 L oxygen is needed at atmospheric pressure and a temperature of  $20^\circ\text{C}$ . What volume of oxygen should be collected at  $230^\circ\text{C}$  and the same pressure to give this volume when cooled?

### 9.3 The Ideal Gas Law

19. A bicycle tire is inflated to a gauge pressure of 30.0 psi at a temperature of  $t = 0^\circ\text{C}$ . What will its gauge pressure be at  $32^\circ\text{C}$  if the tire is considered nonexpandable? (**Note:** The gauge pressure is the *difference* between the tire pressure and atmospheric pressure, 14.7 psi.)
20. The pressure of a poisonous gas inside a sealed container is 1.47 atm at  $20^\circ\text{C}$ . If the barometric pressure is 0.96 atm, to what temperature (in degrees Celsius) must the container and its contents be cooled so that the container can be opened with no risk for gas spurting out?
21. A 20.6-L sample of “pure” air is collected in Greenland at a temperature of  $-20.0^\circ\text{C}$  and a pressure of 1.01 atm and is forced into a 1.05-L bottle for shipment to Europe for analysis.
- (a) Compute the pressure inside the bottle just after it is filled.
- (b) Compute the pressure inside the bottle as it is opened in the  $21.0^\circ\text{C}$  comfort of the European laboratory.
22. Iodine heptafluoride ( $\text{IF}_7$ ) can be made at elevated temperatures by the following reaction:

Suppose 63.6 L gaseous  $\text{IF}_7$  is made by this reaction at  $300^\circ\text{C}$  and a pressure of 0.459 atm. Calculate the volume this gas will occupy if heated to  $400^\circ\text{C}$  at a pressure of 0.980 atm.

23. According to a reference handbook, “The weight of one liter of  $\text{H}_2\text{Te}(\text{g})$  is 6.234 g.” Why is this information nearly valueless? Assume that  $\text{H}_2\text{Te}(\text{g})$  is an ideal gas, and calculate the temperature (in degrees Celsius) at which this statement is true if the pressure is 1.00 atm.

24. A scuba diver’s tank contains 0.30 kg oxygen ( $\text{O}_2$ ) compressed into a volume of 2.32 L.
- (a) Use the ideal gas law to estimate the gas pressure inside the tank at  $5^\circ\text{C}$ , and express it in atmospheres and in pounds per square inch.
- (b) What volume would this oxygen occupy at  $30^\circ\text{C}$  and a pressure of 0.98 atm?
25. Hydrogen is produced by the complete reaction of 6.24 g sodium with an excess of gaseous hydrogen chloride.
- (a) Write a balanced chemical equation for the reaction that occurs.
- (b) How many liters of hydrogen will be produced at a temperature of  $50.0^\circ\text{C}$  and a pressure of 0.850 atm?
26. Aluminum reacts with excess aqueous hydrochloric acid to produce hydrogen.
- (a) Write a balanced chemical equation for the reaction. (*Hint:* Water-soluble  $\text{AlCl}_3$  is the stable chloride of aluminum.)
- (b) Calculate the mass of pure aluminum that will furnish 10.0 L hydrogen at a pressure of 0.750 atm and a temperature of  $30.0^\circ\text{C}$ .
27. The classic method for manufacturing hydrogen chloride, which is still in use today to a small extent, is the reaction of sodium chloride with excess sulfuric acid at elevated temperatures. The overall equation for this process is

What volume of hydrogen chloride is produced from 2500 kg sodium chloride at  $550^\circ\text{C}$  and a pressure of 0.97 atm?

28. In 1783, the French physicist Jacques Charles supervised and took part in the first human flight in a hydrogen balloon. Such balloons rely on the low density of hydrogen relative to air for their buoyancy. In Charles’s balloon ascent, the hydrogen was produced (together with iron(II) sulfate) from the action of aqueous sulfuric acid on iron filings.
- (a) Write a balanced chemical equation for this reaction.
- (b) What volume of hydrogen is produced at 300 K and a pressure of 1.0 atm when 300 kg sulfuric acid is consumed in this reaction?
- (c) What would be the radius of a spherical balloon filled by the gas in part (b)?
29. Potassium chlorate decomposes when heated, giving oxygen and potassium chloride:

A test tube holding 87.6 g  $\text{KClO}_3$  is heated, and the reaction goes to completion. What volume of  $\text{O}_2$  will be evolved if it is collected at a pressure of 1.04 atm and a temperature of  $13.2^\circ\text{C}$ ?

30. Elemental chlorine was first produced by Carl Wilhelm Scheele in 1774 using the reaction of pyrolusite ( $\text{MnO}_2$ ) with sulfuric acid and sodium chloride:

Calculate the minimum mass of  $\text{MnO}_2$  required to generate 5.32 L gaseous chlorine, measured at a pressure of 0.953 atm and a temperature of 33°C.

31. Elemental sulfur can be recovered from gaseous hydrogen sulfide ( $\text{H}_2\text{S}$ ) through the following reaction:

- (a) What volume of  $\text{H}_2\text{S}$  (in liters at 0°C and 1.00 atm) is required to produce 2.00 kg (2000 g) sulfur by this process?
- (b) What minimum mass and volume (at 0°C and 1.00 atm) of  $\text{SO}_2$  are required to produce 2.00 kg sulfur by this reaction?
32. When ozone ( $\text{O}_3$ ) is placed in contact with dry, powdered KOH at  $-15^\circ\text{C}$ , the red-brown solid potassium ozonide ( $\text{KO}_3$ ) forms, according to the following balanced equation:
- $$5 \text{O}_3(g) + 2 \text{KOH}(s) \longrightarrow 2 \text{KO}_3(s) + 5 \text{O}_2(g) + \text{H}_2\text{O}(s)$$
- Calculate the volume of ozone needed (at a pressure of 0.134 atm and  $-15^\circ\text{C}$ ) to produce 4.69 g  $\text{KO}_3$ .

#### 9.4 Mixtures of Gases

33. Sulfur dioxide reacts with oxygen in the presence of platinum to give sulfur trioxide:

Suppose that at one stage in the reaction, 26.0 mol  $\text{SO}_2$ , 83.0 mol  $\text{O}_2$ , and 17.0 mol  $\text{SO}_3$  are present in the reaction vessel at a total pressure of 0.950 atm. Calculate the mole fraction of  $\text{SO}_3$  and its partial pressure.

34. The synthesis of ammonia from the elements is conducted at high pressures and temperatures:

Suppose that at one stage in the reaction, 13 mol  $\text{NH}_3$ , 31 mol  $\text{N}_2$ , and 93 mol  $\text{H}_2$  are present in the reaction vessel at a total pressure of 210 atm. Calculate the mole fraction of  $\text{NH}_3$  and its partial pressure.

35. The atmospheric pressure at the surface of Mars is  $5.92 \times 10^{-3}$  atm. The Martian atmosphere is 95.3%  $\text{CO}_2$  and 2.7%  $\text{N}_2$  by volume, with small amounts of other gases also present. Compute the mole fraction and partial pressure of  $\text{N}_2$  in the atmosphere of Mars.
36. The atmospheric pressure at the surface of Venus is 90.8 atm. The Venusian atmosphere is 96.5%  $\text{CO}_2$  and 3.5%  $\text{N}_2$  by volume, with small amounts of other gases also present. Compute the mole fraction and partial pressure of  $\text{N}_2$  in the atmosphere of Venus.
37. A gas mixture at room temperature contains 10.0 mol CO and 12.5 mol  $\text{O}_2$ .
- (a) Compute the mole fraction of CO in the mixture.
- (b) The mixture is then heated, and the CO starts to react with the  $\text{O}_2$  to give  $\text{CO}_2$ :

At a certain point in the heating, 3.0 mol  $\text{CO}_2$  is present. Determine the mole fraction of CO in the new mixture.

38. A gas mixture contains 4.5 mol  $\text{Br}_2$  and 33.1 mol  $\text{F}_2$ .
- (a) Compute the mole fraction of  $\text{Br}_2$  in the mixture.
- (b) The mixture is heated above  $150^\circ\text{C}$  and starts to react to give  $\text{BrF}_5$ :

At a certain point in the reaction, 2.2 mol  $\text{BrF}_5$  is present. Determine the mole fraction of  $\text{Br}_2$  in the mixture at that point.

39. The partial pressure of water vapor in saturated air at  $20^\circ\text{C}$  is 0.0230 atm.
- (a) How many molecules of water are in 1.00  $\text{cm}^3$  of saturated air at  $20^\circ\text{C}$ ?
- (b) What volume of saturated air at  $20^\circ\text{C}$  contains 0.500 mol water?
40. The partial pressure of oxygen in a mixture of oxygen and hydrogen is 0.200 atm, and that of hydrogen is 0.800 atm.
- (a) How many molecules of oxygen are in a 1.500-L container of this mixture at  $40^\circ\text{C}$ ?
- (b) If a spark is introduced into the container, how many grams of water will be produced?

#### 9.5 The Kinetic Theory of Gases

41. (a) Compute the root-mean-square speed of  $\text{H}_2$  molecules in hydrogen at a temperature of 300 K.
- (b) Repeat the calculation for  $\text{SF}_6$  molecules in gaseous sulfur hexafluoride at 300 K.
42. Researchers recently reported the first optical atomic trap. In this device, beams of laser light replace the physical walls of conventional containers. The laser beams are tightly focused. They briefly (for 0.5 s) exert enough pressure to confine 500 sodium atoms in a volume of  $1.0 \times 10^{-15} \text{ m}^3$ . The temperature of this gas is 0.00024 K, the lowest temperature ever reached for a gas. Compute the root-mean-square speed of the atoms in this confinement.
43. Compare the root-mean-square speed of helium atoms near the surface of the sun, where the temperature is approximately 6000 K, with that of helium atoms in an interstellar cloud, where the temperature is 100 K.
44. The “escape velocity” necessary for objects to leave the gravitational field of the Earth is  $11.2 \text{ km s}^{-1}$ . Calculate the ratio of the escape velocity to the root-mean-square speed of helium, argon, and xenon atoms at 2000 K. Does your result help explain the low abundance of the light gas helium in the atmosphere? Explain.
45. What is the probability that an  $\text{O}_2$  molecule in a sample of oxygen at 300 K has a speed between  $5.00 \times 10^2$  and  $5.10 \times 10^2 \text{ m s}^{-1}$ ? (*Hint:* Try approximating the area under the Maxwell-Boltzmann distribution by small rectangles.)
46. In a sample of argon gas at 298.15 K, what fraction of the Ar atoms have a speed between 600 and 1500 m/s? In a sample of neon gas at the same temperature, what fraction of the Ne atoms have a speed between 600 and 1500 m/s? Give your answers to two significant figures, so that you may estimate the area graphically or integrate numerically. Include a graph of the two Maxwell-Boltzmann distributions with your answer, both in the same plot, shading the relevant area under each curve.

47. Chlorine dioxide ( $\text{ClO}_2$ ) is used for bleaching wood pulp. In a gaseous sample held at thermal equilibrium at a particular temperature, 35.0% of the molecules have speeds exceeding  $400 \text{ m s}^{-1}$ . If the sample is heated slightly, will the percentage of molecules with speeds in excess of  $400 \text{ m s}^{-1}$  then be greater than or less than 35%? Explain.
48. The  $\text{ClO}_2$  described in Problem 47 is heated further until it explodes, yielding  $\text{Cl}_2$ ,  $\text{O}_2$ , and other gaseous products. The mixture is then cooled until the original temperature is reached. Is the percentage of *chlorine* molecules with speeds in excess of  $400 \text{ m s}^{-1}$  greater than or less than 35%? Explain.

### 9.6 Real Gases: Intermolecular Forces

49. Oxygen is supplied to hospitals and chemical laboratories under pressure in large steel cylinders. Typically, such cylinders have an internal volume of 28.0 L and contain 6.80 kg oxygen. Use the van der Waals equation to estimate the pressure inside such cylinders at  $20^\circ\text{C}$  in atmospheres and in pounds per square inch.
50. Steam at high pressures and temperatures is used to generate electrical power in utility plants. A large utility boiler has a volume of  $2500 \text{ m}^3$  and contains 140 metric tons (1 metric ton =  $10^3 \text{ kg}$ ) of steam at a temperature of  $540^\circ\text{C}$ . Use the van der Waals equation to estimate the pressure of the steam under these conditions, in atmospheres and in pounds per square inch.
51. Using (a) the ideal gas law and (b) the van der Waals equation, calculate the pressure exerted by 50.0 g carbon dioxide in a 1.00-L vessel at  $25^\circ\text{C}$ . Do attractive or repulsive forces dominate?
52. When 60.0 g methane ( $\text{CH}_4$ ) is placed in a 1.00-L vessel, the pressure is measured to be 130 atm. Calculate the temperature of the gas using (a) the ideal gas law and (b) the van der Waals equation. Do attractive or repulsive forces dominate?

### 9.7 A Deeper Look . . . Molecular Collisions and Rate Processes

53. A spherical bulb with a volume of  $500 \text{ cm}^3$  is evacuated to a negligibly small residual gas pressure and then closed off. One hour later, the pressure in the vessel is found to be  $1.00 \times 10^{-7} \text{ atm}$  because the bulb has a tiny hole in it.

Assume that the surroundings are at atmospheric pressure,  $T = 300 \text{ K}$ , and the average molar mass of molecules in the atmosphere is  $28.8 \text{ g mol}^{-1}$ . Calculate the radius of the hole in the vessel wall, assuming it to be circular.

54. A  $200\text{-cm}^3$  vessel contains hydrogen gas at a temperature of  $25^\circ\text{C}$  and a pressure of 0.990 atm. Unfortunately, the vessel has a tiny hole in its wall, and over a period of 1 hour, the pressure drops to 0.989 atm. What is the radius of the hole (assumed to be circular)?
55. Methane ( $\text{CH}_4$ ) effuses through a small opening in the side of a container at the rate of  $1.30 \times 10^{-8} \text{ mol s}^{-1}$ . An unknown gas effuses through the same opening at the rate of  $5.42 \times 10^{-9} \text{ mol s}^{-1}$  when maintained at the same temperature and pressure as the methane. Determine the molar mass of the unknown gas.
56. Equal chemical amounts of two gases, fluorine and bromine pentafluoride, are mixed. Determine the ratio of the rates of effusion of the two gases through a small opening in their container.
57. Calculate the theoretical number of stages that would be needed to enrich  $^{235}\text{U}$  to 95% purity by means of the barrier diffusion process, using  $^{235}\text{UF}_6$  and  $^{238}\text{UF}_6$  as the gaseous compounds. The natural abundance of  $^{238}\text{U}$  is 99.27%, and that of  $^{235}\text{U}$  is 0.72%. Take the relative atomic masses of  $^{235}\text{U}$  and  $^{238}\text{U}$  to be 235.04 and 238.05, respectively.
58. A mixture of  $\text{H}_2$  and He at 300 K effuses from a tiny hole in the vessel that contains it. What is the mole fraction of  $\text{H}_2$  in the original gas mixture if 3.00 times as many He atoms as  $\text{H}_2$  molecules escape from the orifice in unit time? If the same mixture is to be separated by a barrier-diffusion process, how many stages are necessary to achieve  $\text{H}_2$  of 99.9% purity?
59. At what pressure does the mean free path of krypton (Kr) atoms ( $d = 3.16 \times 10^{-10} \text{ m}$ ) become comparable with the diameter of the 1-L spherical vessel that contains them at 300 K? Calculate the diffusion constant at this pressure.
60. At what pressure does the mean free path of Kr atoms ( $d = 3.16 \times 10^{-10} \text{ m}$ ) become comparable with the diameter of a Kr atom if  $T = 300 \text{ K}$ ? Calculate the diffusion constant at this pressure. Assume that Kr obeys the ideal gas law even at these high pressures.

## ADDITIONAL PROBLEMS

61. The Earth is approximately a sphere of radius 6370 km. Taking the average barometric pressure on the Earth's surface to be 730 mm Hg, estimate the total mass of the Earth's atmosphere.
- \*62. After a flood fills a basement to a depth of 9.0 feet and completely saturates the surrounding earth, the owner buys an electric pump and quickly pumps the water out of the basement. Suddenly, a basement wall collapses, the structure is severely damaged, and mud oozes in. Explain this event by estimating the difference between the outside pressure at the base of the basement walls and the pressure inside the drained basement. Assume that the density of the mud is  $4.9 \text{ g cm}^{-3}$ . Report the answer both in atmospheres and in pounds per square inch.
63. The density of mercury is  $13.5955 \text{ g cm}^{-3}$  at  $0.0^\circ\text{C}$ , but only  $13.5094 \text{ g cm}^{-3}$  at  $35^\circ\text{C}$ . Suppose that a mercury barometer is read on a hot summer day when the temperature is  $35^\circ\text{C}$ . The column of mercury is 760.0 mm long. Correct for the expansion of the mercury and compute the true pressure in atmospheres.

64. When a gas is cooled at constant pressure, the volume decreases according to the following equation:

$$V = 209.4 \text{ L} + \left(0.456 \frac{\text{L}}{^\circ\text{F}}\right) \times t_{\text{F}}$$

where  $t_{\text{F}}$  is the temperature in degrees Fahrenheit. From this relationship, estimate the absolute zero of temperature in degrees Fahrenheit.

65. Amonton's law relates pressure to absolute temperature. Consider the ideal gas law and then write a statement of Amonton's law in a form that is analogous to the statements of Charles's law and Boyle's law in the text.
66. The density of a certain gas is  $2.94 \text{ g L}^{-1}$  at  $50^\circ\text{C}$  and  $P = 1.00 \text{ atm}$ . What is its density at  $150^\circ\text{C}$ ? Calculate the molar mass of the gas, assuming it obeys the ideal gas law.
67. A lighter-than-air balloon contains 1005 mol helium at  $1.00 \text{ atm}$  and  $25.0^\circ\text{C}$ .
- Compute the difference between the mass of the helium it contains and the mass of the air it displaces, assuming the molar mass of air to be  $29.0 \text{ g mol}^{-1}$ .
  - The balloon now ascends to an altitude of 10 miles, where the temperature is  $-80.0^\circ\text{C}$ . The walls of the balloon are elastic enough that the pressure inside it equals the pressure outside. Repeat the calculation of part (a).
68. Baseball reporters say that long fly balls that would have carried for home runs in July "die" in the cool air of October and are caught. The idea behind this observation is that a baseball carries better when the air is less dense. Dry air is a mixture of gases with an effective molar mass of  $29.0 \text{ g mol}^{-1}$ .
- Compute the density of dry air on a July day when the temperature is  $95.0^\circ\text{F}$  and the pressure is  $1.00 \text{ atm}$ .
  - Compute the density of dry air on an October evening when the temperature is  $50.0^\circ\text{F}$  and the pressure is  $1.00 \text{ atm}$ .
  - Suppose that the humidity on the July day is 100%; thus, the air is saturated with water vapor. Is the density of this hot, moist air less than, equal to, or greater than the density of the hot, dry air computed in part (a)? In other terms, does high humidity favor the home run?

69. Sulfuric acid reacts with sodium chloride to produce gaseous hydrogen chloride according to the following reaction:

A 10.0-kg mass of NaCl reacts completely with sulfuric acid to give a certain volume of  $\text{HCl}(g)$  at  $50^\circ\text{C}$  and  $P = 1.00 \text{ atm}$ . If the same volume of hydrogen chloride is collected at  $500^\circ\text{C}$  and  $P = 1.00 \text{ atm}$ , what mass of NaCl has reacted?

70. Exactly 1.0 lb Hydron, an alloy of sodium with lead, yields (at  $0.0^\circ\text{C}$  and  $1.00 \text{ atm}$ )  $2.6 \text{ ft}^3$  of hydrogen when it is treated with water. All the sodium reacts according to the following reaction:

and the lead does not react with water. Compute the percentage by mass of sodium in the alloy.

71. A sample of limestone (calcium carbonate,  $\text{CaCO}_3$ ) is heated at  $950 \text{ K}$  until it is completely converted to calcium oxide ( $\text{CaO}$ ) and  $\text{CO}_2$ . The  $\text{CaO}$  is then all converted to calcium hydroxide by addition of water, yielding  $8.47 \text{ kg}$  of solid  $\text{Ca}(\text{OH})_2$ . Calculate the volume of  $\text{CO}_2$  produced in the first step, assuming it to be an ideal gas at  $950 \text{ K}$  and a pressure of  $0.976 \text{ atm}$ .
72. A gas exerts a pressure of  $0.740 \text{ atm}$  in a certain container. Suddenly, a chemical change occurs that consumes half of the molecules originally present and forms two new molecules for every three consumed. Determine the new pressure in the container if the volume of the container and the temperature are unchanged.
73. The following arrangement of flasks is set up. Assuming no temperature change, determine the final pressure inside the system after all stopcocks are opened. The connecting tube has zero volume.

$$V = 4.00 \text{ L} \\ P = 0.792 \text{ atm}$$

$$V = 3.00 \text{ L} \\ P = 1.23 \text{ atm}$$

$$V = 5.00 \text{ L} \\ P = 2.51 \text{ atm}$$

- \*74. A mixture of  $\text{CS}_2(g)$  and excess  $\text{O}_2(g)$  in a  $10.0\text{-L}$  reaction vessel at  $100.0^\circ\text{C}$  is under a pressure of  $3.00 \text{ atm}$ . When the mixture is ignited by a spark, it explodes. The vessel successfully contains the explosion, in which all of the  $\text{CS}_2(g)$  reacts to give  $\text{CO}_2(g)$  and  $\text{SO}_2(g)$ . The vessel is cooled back to its original temperature of  $100.0^\circ\text{C}$ , and the pressure of the mixture of the two product gases and the unreacted  $\text{O}_2(g)$  is found to be  $2.40 \text{ atm}$ . Calculate the mass (in grams) of  $\text{CS}_2(g)$  originally present.
75. Acetylene reacts with hydrogen in the presence of a catalyst to form ethane according to the following reaction:

The pressure of a mixture of acetylene and an excess of hydrogen decreases from  $0.100$  to  $0.042 \text{ atm}$  in a vessel of a given volume after the catalyst is introduced, and the temperature is restored to its initial value after the reaction reaches completion. What was the mole fraction of acetylene in the original mixture?

76. Refer to the atomic trap described in Problem 42.
- Assume ideal gas behavior to compute the pressure exerted on the "walls" of the optical bottle in this experiment.
  - In this gas, the mean free path (the average distance traveled by the sodium atoms between collisions) is  $3.9 \text{ m}$ . Compare this with the mean free path of the atoms in gaseous sodium at room conditions.

77. Deuterium ( $^2\text{H}$ ), when heated to sufficiently high temperature, undergoes a nuclear fusion reaction that results in the production of helium. The reaction proceeds rapidly at a temperature,  $T$ , at which the average kinetic energy of the deuterium atoms is  $8 \times 10^{-16}$  J. (At this temperature, deuterium molecules dissociate completely into deuterium atoms.)

- Calculate  $T$  in kelvins (atomic mass of  $^2\text{H} = 2.015$ ).
- For the fusion reaction to occur with ordinary H atoms, the average energy of the atoms must be about  $32 \times 10^{-16}$  J. By what factor does the average speed of the  $^1\text{H}$  atoms differ from that of the  $^2\text{H}$  atoms of part (a)?

78. Molecules of oxygen of the following isotopic composition are separated in an oxygen enrichment plant:  $^{16}\text{O}^{16}\text{O}$ ,  $^{16}\text{O}^{17}\text{O}$ ,  $^{16}\text{O}^{18}\text{O}$ ,  $^{17}\text{O}^{17}\text{O}$ ,  $^{17}\text{O}^{18}\text{O}$ ,  $^{18}\text{O}^{18}\text{O}$ .

- Compare the average translational kinetic energy of the lightest and heaviest molecular oxygen species at  $200^\circ\text{C}$  and at  $400^\circ\text{C}$ .
- Compare the average speeds of the lightest and heaviest molecular oxygen species at the same two temperatures.

\*79. Molecules in a spherical container make wall collisions in a great circle plane of the sphere. All paths traveled between collisions are equal in length.

- Relate the path length  $\Delta\ell$  to the angle  $\theta$  and the sphere radius  $r$ .

- Express the component of the molecular momentum transferred to the wall in a collision in terms of the molecular mass  $m$ , the speed  $v$ , and the angle  $\theta$ .
- Using parts (a) and (b), calculate the average force exerted on the wall by one molecule.
- Derive the relation  $PV = PV = \frac{1}{3}Nm\overline{v^2}$  for a spherical container. This is the same relation found for a rectangular box in Section 9.5.

\*80. The van der Waals constant  $b$  is related to the volume excluded per mole of molecules, so it should be proportional to  $N_A\sigma^3$ , where  $\sigma$  is the distance parameter in the Lennard–Jones potential.

- Make a plot of  $b$  against  $N_A\sigma^3$  for Ar,  $\text{H}_2$ ,  $\text{CH}_4$ ,  $\text{N}_2$ , and  $\text{O}_2$ , using data from Tables 9.3 and 9.4. Do you see an overall correlation between the two?
- The van der Waals constant  $a$  has dimensions of pressure times the square of the molar volume. Rewrite

the units of  $a$  in terms of energy, length, and number of moles, and suggest a relation between  $a$  and some combination of the constants  $\epsilon$ ,  $\sigma$ , and  $N_A$ . Make a plot of  $a$  against this combination of constants for the gases of part (a). Do you see an overall correlation in this case?

\*81. Take the derivative of the Lennard–Jones potential to express the force exerted on one atom by another as a function of the distance  $R$  between them. Calculate the forces (in joules per meter) on a pair of interacting argon atoms at distances of  $3.0$ ,  $3.4$ ,  $3.8$ , and  $4.2 \times 10^{-10}$  m. To calculate the direction of the force on each atom, assume that one Ar atom is at the origin and the other argon atom is at the coordinates  $(-3.0 \text{ \AA}, 0)$ ,  $(-3.4 \text{ \AA}, 0)$ ,  $(-3.8 \text{ \AA}, 0)$ , and  $(-4.2 \text{ \AA}, 0)$ . Calculate the vector components  $F_x$  and  $F_y$  for the force  $\vec{F} = (F_x, F_y)$  on the argon atom at the origin (particle 1 in the solutions) and the vector components for the force on the other atom (particle 2 in the solution), showing explicitly what you are using for the unit vector  $\hat{r}_{21}$  or the unit vector  $\hat{r}_{12}$ . (Hint: Use Eq. 3.4, but with the correct  $V(R)$ .) Is the force attractive or repulsive at each of these distances?

82. A vessel with a small hole in its wall is filled with oxygen to a pressure of  $1.00$  atm at  $25^\circ\text{C}$ . In a  $1.00$ -minute period,  $3.25$  g oxygen effuses out through the hole into a vacuum. The vessel is evacuated and filled with an unknown gas at the same pressure and volume. In this case,  $5.39$  g of the unknown gas effuses in  $1.00$  minute. Calculate the molar mass of the unknown gas.

83. A cylindrical storage tank for natural gas (mostly methane,  $\text{CH}_4$ ) with a  $20$ -ft radius and a  $50$ -ft height is filled to a pressure of  $2000$  psi at  $20^\circ\text{C}$ . A small leak of  $1.0$ -mm<sup>2</sup> area develops at one of the welds. Calculate the mass of  $\text{CH}_4$  (in grams) that leaks out of the tank in one day. What fraction of the total gas escapes per day?

84. A thermos bottle (Dewar vessel) has an evacuated space between its inner and outer walls to diminish the rate of transfer of thermal energy to or from the bottle's contents. For good insulation, the mean free path of the residual gas (air; average molecular mass =  $29$ ) should be at least  $10$  times the distance between the inner and outer walls, which is about  $1.0$  cm. What should be the maximum residual gas pressure in the evacuated space if  $T = 300$  K? Take an average diameter of  $d = 3.1 \times 10^{-10}$  m for the molecules in the air.

85. A tanker truck carrying liquid ammonia overturns, releasing ammonia vapor into the air.

- Approximating ammonia, oxygen, and nitrogen as spheres of equal diameter ( $3 \times 10^{-10}$  m), estimate the diffusion constant of ammonia in air at atmospheric pressure and  $20^\circ\text{C}$ .
- Calculate the time required for a  $100$ -m root-mean-square displacement of ammonia from the truck, and express this time in everyday units (seconds, minutes, hours, days, or years). The actual time for the ammonia to travel this distance is far shorter because of the existence of air currents (even when there is no wind).

86. Molecules of  $\text{UF}_6$  are approximately 175 times more massive than  $\text{H}_2$  molecules; however, Avogadro's number of  $\text{H}_2$  molecules confined at a set temperature exert the same pressure on the walls of the container as the same number of  $\text{UF}_6$  molecules. Explain how this is possible.
87. The number density of atoms (chiefly hydrogen) in interstellar space is about 10 per cubic centimeter, and the temperature is about 100 K.
- Calculate the pressure of the gas in interstellar space, and express it in atmospheres.
  - Under these conditions, an atom of hydrogen collides with another atom once every  $1 \times 10^9$  seconds (that is, once every 30 years). By using the average speed, estimate the distance traveled by a H atom between collisions. Compare this distance with the distance from the Earth to the Sun (150 million km).
88. A sample of 2.00 mol argon is confined at low pressure in a volume at a temperature of  $50^\circ\text{C}$ . Describe quantitatively the effects of each of the following changes on the pressure, the average energy per atom in the gas, the root-mean-square speed, the rate of collisions with a given area of wall, the frequency of Ar–Ar collisions, and the mean free path:
- The temperature is decreased to  $-50^\circ\text{C}$ .
  - The volume is doubled.
  - The amount of argon is increased to 3.00 mol.
89. By assuming that the collision diameter of a  $\text{CH}_4$  molecule is given by its Lennard–Jones  $\sigma$  parameter (see Table 9.4), estimate the rate at which methane molecules collide with one another at  $25^\circ\text{C}$  and a pressure of (a) 1.00 atm and (b)  $1.0 \times 10^{-7}$  atm.

## CUMULATIVE PROBLEMS

90. A gaseous hydrocarbon, in a volume of 25.4 L at 400 K and a pressure of 3.40 atm, reacts in an excess of oxygen to give 47.4 g  $\text{H}_2\text{O}$  and 231.6 g  $\text{CO}_2$ . Determine the molecular formula of the hydrocarbon.
91. A sample of a gaseous binary compound of boron and chlorine weighing 2.842 g occupies 0.153 L at  $0^\circ\text{C}$  and 1.00 atm pressure. This sample is decomposed to give solid boron and gaseous chlorine ( $\text{Cl}_2$ ). The chlorine occupies 0.688 L at the same temperature and pressure. Determine the molecular formula of the compound.
92. A mixture of calcium carbonate,  $\text{CaCO}_3$ , and barium carbonate,  $\text{BaCO}_3$ , weighing 5.40 g reacts fully with hydrochloric acid,  $\text{HCl}(aq)$ , to generate 1.39 L  $\text{CO}_2(g)$ , measured at  $50^\circ\text{C}$  and 0.904 atm pressure. Calculate the percentages by mass of  $\text{CaCO}_3$  and  $\text{BaCO}_3$  in the original mixture.
93. A solid sample of  $\text{Rb}_2\text{SO}_3$  weighing 6.24 g reacts with 1.38 L gaseous  $\text{HBr}$ , measured at  $75^\circ\text{C}$  and 0.953 atm pressure. The solid  $\text{RbBr}$ , extracted from the reaction mixture and purified, has a mass of 7.32 g.
- What is the limiting reactant?
  - What is the theoretical yield of  $\text{RbBr}$ , assuming complete reaction?
  - What is the actual percentage yield of product?
94. (a) A commercial 737 jet transporting 143 passengers and 5 crew members from Kansas City (MCI) to Baltimore (BWI) burned 11,800 lb (about 1700 gallons) of Jet A fuel en route. Jet A fuel is kerosene based, consisting primarily of  $\text{C}_n\text{H}_{2n+2}$  hydrocarbons, with  $n = 6$  to 16, so the carbon:hydrogen ratio is close to 1:2. During this flight, how much  $\text{CO}_2$  was released into the atmosphere? Assume the combustion of the fuel was complete, so all the fuel was burned to form  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . Give both the mass of  $\text{CO}_2$  produced (in kg and in lbs) and the volume it would occupy at 298 K, 1 atm.
- (b) How much  $\text{CO}_2$  would be released into the atmosphere if those passengers and crew made the trip instead, in pairs, in hybrid cars at 40 miles per gallon. Assume the density of the gasoline is  $0.75 \text{ kg L}^{-1}$  and that carbon and hydrogen dominate the composition in a ratio of 1:2. The road trip is 1082 miles.

Solid iodine is converted directly to a vapor (sublimes) when warmed. Here, purple iodine vapor is redeposited as a solid on the cooler upper surfaces of the vessel.

The bulk properties of gases, liquids, and solids—molar volume, density, compressibility, and thermal expansion, among others—differ widely, often by orders of magnitude. All of these properties depend on the temperature and pressure. The local structure—the arrangement of atoms or molecules on the nanometer length scale—is the key microscopic feature that distinguishes the three states of matter from one another and explains the differences in their bulk properties. The average separation between molecules, and the nature of the intermolecular forces, determine the local structure and therefore the properties of the bulk.

We begin with a brief survey of selected bulk properties and describe how the measured results depend on the number density of molecules and the strength of intermolecular forces. Then, we define the types of intermolecular forces and show how these forces originate in the structures of molecules. Finally, we relate the transitions between the states of matter to intermolecular forces. In the previous chapter we derived the ideal gas law using kinetic

molecular arguments and neglecting all intermolecular forces in the gas. In this chapter we apply similar kinetic molecular arguments to solids and liquids. Because we cannot neglect the intermolecular forces, the discussion of solids and liquids is more qualitative than that for gases.

## 10.1 Bulk Properties of Gases, Liquids, and Solids: Molecular Interpretation

Each of the following macroscopic measurements clearly distinguishes gases, liquids, and solids from each other and also probes the strength of the intermolecular forces, albeit indirectly. Each shows that in gases at low densities, molecules are on average far apart and interact only weakly, whereas in condensed phases, molecules are closely packed together and interact quite strongly. These general conclusions apply almost universally to substances consisting of small, nearly rigid molecules such as  $\text{N}_2$ ,  $\text{CO}_2$ ,  $\text{CH}_4$ , and acetic acid  $\text{C}_2\text{H}_4\text{O}_2$ . In contrast, many biological materials and synthetic polymers contain complex chain-like molecules that can become strongly entangled. Clear-cut classification of these materials as solids or liquids becomes difficult.

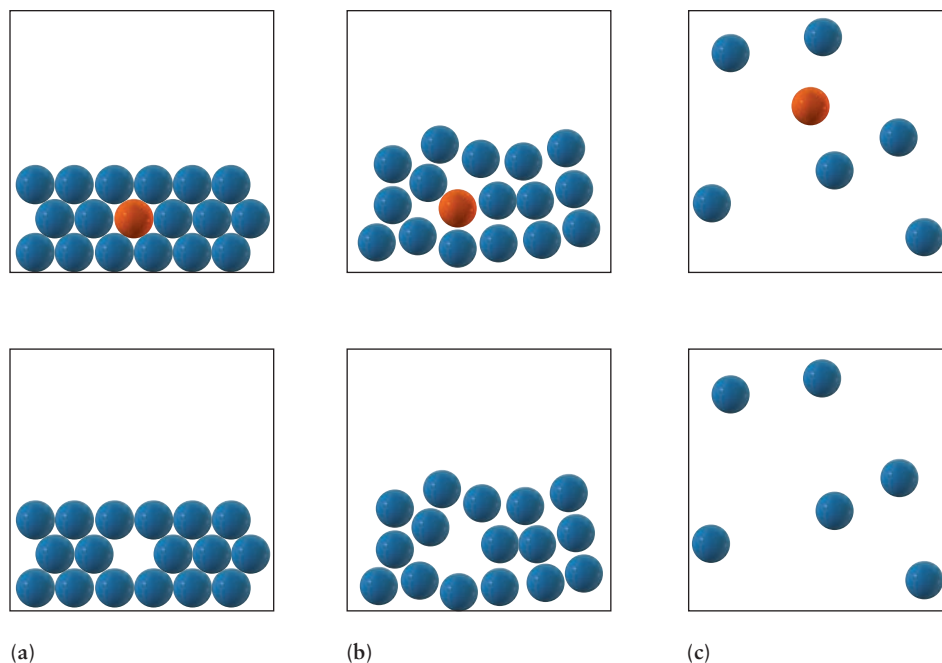

Relating bulk properties qualitatively to microscopic properties requires only consideration of the long-range attractive forces and short-range repulsive forces between molecules; it is not necessary to take into account the details of molecular shapes. We have already shown one kind of potential energy function that describes these long-range and short-range forces, the Lennard–Jones 6–12 potential used in Section 9.6 to obtain corrections to the ideal gas law. In Section 10.2, we discuss more detailed aspects of intermolecular forces, most of which are derived from electrostatic (Coulomb) interactions that depend on molecular structure and shape.

### 10.1.1 Molar Volume

One mole of a typical solid or liquid occupies a volume of 10 to 100  $\text{cm}^3$  at room conditions, but the **molar volume** of a gas under the same conditions is about 24,000  $\text{cm}^3 \text{mol}^{-1}$ . This large difference explains why solids and liquids are called the condensed states of matter. Because a mole of any substance contains Avogadro's number of molecules, the molar volume is inversely related to the **number density** (number of molecules per cubic centimeter) of the different phases. Liquids and solids have high number densities, and gases have very low number densities. On melting, most solids change volume by only 2% to 10%, showing that the solid and liquid states of a given substance are condensed, relative to the gaseous state, by roughly the same amount.

The similarity of the molar volumes of solid and liquid forms of the same substance suggests that the separation between neighboring molecules in the two states is approximately the same. Density measurements (see Section 1.6.3) show that the intermolecular contacts, the distances between the nuclei of atoms at the far edge of one molecule and the near edge of a neighbor, usually range from  $3 \times 10^{-10} \text{ m}$  to  $5 \times 10^{-10} \text{ m}$  in solids and liquids. At these distances, longer range attractive forces and shorter range repulsive forces just balance one another, resulting in a minimum in the potential energy (see Section 9.6). Although these intermolecular separations are significantly greater than chemical bond lengths (which range from  $0.5\text{--}2.5 \times 10^{-10} \text{ m}$ ), they are much shorter than the intermolecular separations in gases, which average about  $30 \times 10^{-10} \text{ m}$  under room conditions. The distinction is shown schematically in Figure 10.1.

**FIGURE 10.1** Intermolecular forces create structure in liquids and solids. If a single atom is removed from a snapshot of the atomic arrangement in a solid (a), it is easy to figure out exactly where to put it back in. For a liquid (b), the choices are limited. If a single atom is removed from a gas (c), no clue remains to tell where it came from.

### 10.1.2 Compressibility

The **compressibility** of a substance is defined as the fractional decrease in volume per unit increase in pressure. (This property is different from the compressibility factor  $Z$  [see Section 9.6], which measures non-ideality in gases.) The compressibility is usually denoted by the Greek letter kappa,  $\kappa$ , where  $\kappa = -\frac{1}{V} \left( \frac{\partial V}{\partial P} \right)_T$ .

The subscript  $T$  indicates that the temperature is held constant as you take the derivative of  $V$  with respect to  $P$ . For small changes in pressure and volume, this is approximately  $\kappa = -(1/V)(\Delta V/\Delta P)$ . A sample with volume  $V$  is subjected to a pressure increase,  $\Delta P$ , and the resulting change in volume,  $\Delta V$ , is measured. The ratio is divided by  $V$ ; thus, the tabulated value depends only on the substance being measured and not on the geometry of the sample. Consequently, the unit of  $\kappa$  is inverse pressure, typically  $\text{atm}^{-1}$ . The minus sign is included in the definition to make  $\kappa$  positive because  $\Delta V$  is negative. The measurements are always performed at fixed temperature to eliminate any thermal effects on the volume (see later). Consequently,  $\kappa$  is called the *isothermal compressibility*, and the temperature of measurement is quoted together with the tabulated values. Both solids and liquids are nearly incompressible, whereas gases are very compressible. According to Boyle's law, doubling the pressure exerted on an ideal gas from 1 to 2 atm reduces its volume to half its original volume (at constant temperature). The corresponding compressibility is pressure dependent, ranging from  $1 \text{ atm}^{-1}$  (or  $10 \text{ MPa}^{-1}$ ) at the beginning of the compression to  $0.5 \text{ atm}^{-1}$  near the end of the compression. (Using the definition of the isothermal compressibility given, it is easy to show that the isothermal compressibility of an ideal gas is  $P^{-1}$ .) In contrast, doubling the pressure exerted on water or steel scarcely changes the volume at all; typical compressibilities for these materials are of the order  $10^{-5}$  to  $10^{-6} \text{ atm}^{-1}$  (Table 10.1). Increasing the pressure on a liquid or solid by a factor of 2 changes its volume by 1% or less. The high compressibility of gases and the low compressibilities of solids and liquids suggest that in the gas phase there is substantial space between the molecules, but in the condensed states the molecules or atoms of a substance are in contact or nearly in contact.

TABLE 10.1

Isothermal Compressibility<sup>†</sup> and Thermal Expansion Coefficients

Compound	$\kappa/(10^{-6} \text{ atm}^{-1})$	$\alpha/(10^{-4} \text{ K}^{-1})$
<b>Liquids</b>		
Benzene	92.1	12.4
Ethanol	76.8	11.2
Mercury	38.7	1.82
Water	49.7	2.1
<b>Solids</b>		
Copper	0.735	0.501
Diamond	0.187	0.030
Iron	0.597	0.354
Lead	2.21	0.861

<sup>†</sup>Values at 20°C.

The much greater separation between molecules in the gas phase than in the condensed phases dramatically influences the effect of intermolecular forces. The repulsive force, although very strong, is very short-ranged and becomes significant only when molecules are quite close together. So, gases require only modest forces to compress them significantly, because the molecules can be pushed much closer together before experiencing repulsive forces. Liquids and solids require much greater forces to oppose the strongly repulsive forces already operating because the molecules are in contact (see Section 9.6).

### 10.1.3 Thermal Expansion

The **coefficient of thermal expansion**  $\alpha$  is defined as the fractional increase in the volume of a substance per degree increase in temperature. It is defined by

$$\alpha = \frac{1}{V} \left( \frac{\partial V}{\partial T} \right)_P$$

where the subscript  $P$  indicates that the pressure is held constant

as you take the derivative of  $V$  with respect to  $T$ . For small changes in volume and temperature, this is approximately  $\alpha = (1/V)(\Delta V/\Delta T)$ . The measurements are performed at constant pressure; thus,  $\alpha$  is called the *isobaric coefficient of thermal expansion*, and the pressure at which the measurements were taken is quoted together with tabulated values. Charles's law shows that this coefficient is the same for all gases and takes the value  $1/273.15(\text{°C})^{-1}$  at  $0^\circ\text{C}$ . You can verify this by substituting  $\Delta V/\Delta T = nR/P$  (from the ideal gas law) into the definition given and simplifying the expression. Increasing the temperature by  $1^\circ\text{C}$  thus causes a gas to expand by  $1/273.15$ , or  $0.366\%$  of its original volume at  $0^\circ\text{C}$ , as long as the pressure is constant. The thermal expansion coefficients of liquids and solids are much smaller. Heating water from  $20^\circ\text{C}$  to  $21^\circ\text{C}$  increases its volume by only  $0.0212\%$ , and the volume of mercury goes up by only  $0.0177\%$  over the same temperature interval. The coefficients of thermal expansion of solids are mostly less than  $0.02\%$  per degree Celsius (see Table 10.1).

The difference in thermal expansion between condensed states and gases is explained by strong intermolecular forces (deep intermolecular potential wells) acting over short distances in the condensed states, but not in the gaseous state. Because of the much greater intermolecular separations, these forces are much weaker in gases. Increasing the volume in a solid or liquid requires that attractive forces between each molecule and its neighbors be partially overcome.

Because the intermolecular distances in a solid or liquid fall in the range where intermolecular attractive forces are strongest, relatively small expansion occurs when the temperature is increased. By contrast, molecules in a gas are so far apart that attractive forces are essentially negligible; the same temperature increase produces much greater expansion in a gas than in condensed phases.

### 10.1.4 Fluidity and Rigidity

The most characteristic property of gases and liquids is their **fluidity**, which contrasts with the **rigidity** of solids. Liquids possess definite volumes but keep no definite shapes of their own; they flow easily under stress (externally applied mechanical force). The resistance of a material to macroscopic flow is measured by its **shear viscosity**. On the microscopic level, shear viscosity arises from the resistance of one thin layer of molecules “dragged across” another thin layer. The shear viscosities of most liquids are about 16 orders of magnitude smaller than those of most solids, and those of gases are smaller yet. A *rigid* material retains its shape under stress; it manifests structural strength by resisting flow when stress is applied. The properties of **hardness** (resistance to indentation) and **elasticity** (capacity to recover shape when a deforming stress is removed) are closely related to rigidity, or high shear viscosity. Solids possess these properties in good measure; gases and liquids do not.

### 10.1.5 Diffusion

When two different substances are placed in contact—for example, a drop of red ink into a beaker of water—they start to mix. Molecules of one type migrate, or **diffuse**, into regions initially occupied only by the other type. Molecules dispersed in gases at room conditions diffuse at rates on the order of centimeters per second. If you have ever passed by a perfume counter, this rate should not surprise you. Molecules in liquids and solids diffuse far more slowly. The **diffusion constant** of a substance measures the rate of diffusive mixing. At room temperature and pressure, diffusion constants for the diffusion of liquids into liquids are about four orders of magnitude smaller than those for gases into gases; diffusion constants of solids into solids are many orders of magnitude smaller yet. Diffusion in solids is really quite slow. Values of the diffusion constant for selected materials are shown in Table 10.2.

Figure 10.1 shows a “snapshot” of a liquid and a solid, fixing the positions of the atoms at a particular instant in time. The paths followed by the molecules in these two states can also be examined over a short time interval (Fig. 10.2).

**FIGURE 10.2** In this computer-simulated picture of the motions of atoms in a tiny melting crystal, the atoms at the center (in the solid) move erratically about particular sites. The atoms at the surface (in the liquid) move over much greater distances.

TABLE 10.2

## Diffusion Constants

Diffusing Species	Host Material	Diffusion Constant ( $\text{m}^2 \text{s}^{-1}$ )	Temperature (K)
Ar	Ar	$2.3 \times 10^{-6}$	100
Ar	Ar	$1.86 \times 10^{-5}$	300
$\text{N}_2$	$\text{N}_2$	$2.05 \times 10^{-5}$	300
$\text{O}_2$	$\text{O}_2$	$1.8 \times 10^{-5}$	273
$\text{CH}_4$	$\text{CH}_4$	$2.06 \times 10^{-5}$	273
HCl	HCl	$1.24 \times 10^{-5}$	295
Cu	Cu	$4.2 \times 10^{-19}$	500
Al	Al	$4.2 \times 10^{-14}$	500
Cu	Al	$4.1 \times 10^{-14}$	500
Cu	Ni	$1.3 \times 10^{-22}$	500
Fe	Fe	$3.0 \times 10^{-21}$	500
Fe	Fe	$1.8 \times 10^{-15}$	900
C	Fe	$1.7 \times 10^{-10}$	900

In liquids, molecules are free to travel through the sample, changing neighbors constantly in the course of their diffusive motion. In a solid, the molecules constantly vibrate about their equilibrium positions, but remain quite close to those positions. The low shear viscosity of a liquid implies that its molecules can quickly change neighbors, finding new interactions as the liquid flows in response to an external stress. The rigidity of solids suggests, in contrast, a durable arrangement of neighbors about any given molecule. The durable arrangement of molecules in a solid, as opposed to the freedom of molecules to diffuse in a liquid at comparable packing density, is the critical difference between the solid and liquid states.

Short-range attractive intermolecular forces in liquids lead to well-defined local structures that persist for short periods. Individual molecules experience interactions with neighbors that lead, at any instant, to a local environment closely resembling that in a solid, but they quickly move on. Their trajectories consist of “rattling” motions in a temporary cage formed by neighbors and superimposed on erratic displacements over larger distances. In this respect, a liquid is intermediate between a gas and a solid. A gas (see Fig. 9.25) provides no temporary cages, so each molecule of a gas travels a longer distance before colliding with a second molecule. Consequently, the diffusion constant of a gas is larger than that of a liquid. In a solid, the cages are nearly permanent, thus diffusion is slow. Melting occurs as thermal energy increases the amplitude of vibration of the molecules around their equilibrium positions in a solid to such a degree that they are free to make major excursions. For these same reasons, liquids can dissolve substances much more rapidly than do solids. Individual molecules of a liquid quickly wander into contact with molecules of an added substance, and new attractions between the unlike molecules have an early chance to replace those existing originally in the pure liquid.

Liquids and gases may also mix through **convection**, as well as by diffusion. In convection, the net flow of a whole region of fluid with respect to another region leads to mixing at far greater rates than occurs through simple diffusion. Convection is the primary mechanism by which mixing occurs in the oceans and in the atmosphere. Convection is not observed in solids.

**FIGURE 10.3** (a) Surface tension causes the spherical shape of the water droplet in this photograph, which was taken an instant after a drop of water hit the surface of a pool and bounced up, pulling with it a column of water. (b) Small droplets of mercury on a tabletop form nearly perfect spheres due to the high surface tension of mercury. Larger droplets are flattened by the force of gravity.

### 10.1.6 Surface Tension

Boundaries between phases have special importance in chemistry and biology. Each type of boundary has its own unique characteristics. The surface of water (or any liquid) in contact with air (or any gas) resists attempts to increase its area (Fig. 10.3a). This **surface tension** causes the surface to behave like a weak, elastic skin. Effects of surface tension are particularly apparent under zero gravity, where liquids float around as spherical drops because spheres contain the largest volume for the smallest surface area of any geometric shape. If two small drops encounter each other, they tend to coalesce into a larger drop because one large drop has a smaller surface area than two small drops. The surface tension of water is larger than that of most other liquids at room temperature, but it is about six times smaller than that for the liquid metal mercury, which has one of the highest values known for any liquid at room temperature and pressure (see Fig. 10.3b).

Surface tension results from the intermolecular attractions among the molecules in a liquid (Fig. 10.4). Increasing the surface area of a liquid requires redistributing some of the molecules that were originally buried in the interior to positions at the enlarged boundaries. Molecules at the edges have no neighbors on one side and experience attractions only from molecules in the bulk of the liquid. Their potential energy is greater than it would be if they were in the interior. Thus, energy is required to increase the surface area of a liquid. Liquids such as water and mercury with high values of surface tension have particularly strong intermolecular attractions, as confirmed by measurement of other properties.

**FIGURE 10.4** The intermolecular attractions acting on a molecule at the surface of a liquid pull it downward and to the sides but not upward. In the interior, a molecule is pulled more or less equally in all directions.

## 10.2 Intermolecular Forces: Origins in Molecular Structure

To provide a more quantitative explanation of the magnitudes of bulk properties, we must describe molecular interactions with more detail than the simple net repulsion and attraction summarized in the Lennard–Jones model potential. For this purpose we introduce other intermolecular forces in the following paragraphs and show how they arise from molecular structure. Intermolecular forces are distinct from intramolecular forces, which lead to the covalent chemical bonds that establish and maintain the structure of discrete molecules. (See Chapters 3 and 6.) Intermolecular forces differ from intramolecular forces in several important ways:

1. Intermolecular forces are generally weaker than covalent chemical bonds. For example, it takes 239 kJ to break 1 mol of Cl–Cl covalent bonds, but only 1.2 kJ to overcome 1 mol of Ar–Ar attractions.
2. Intermolecular forces are much less directional than covalent chemical bonds.
3. Intermolecular forces operate at longer range than covalent chemical bonds.

It is useful to distinguish different classes of intermolecular forces based on their strength, directionality, and range and to relate these aspects to the structure of the molecules.

### 10.2.1 Ion–Ion Forces

Ionic solids and liquids are made up of electrically charged entities, sometimes monatomic ions such as  $\text{Na}^+$ ,  $\text{Cl}^-$ , and  $\text{Ca}^{2+}$ , and sometimes polyatomic ions such as  $\text{NH}_4^+$  and  $\text{SO}_4^{2-}$ . The dominant interaction among these ions is the Coulomb force of electrostatic attraction or repulsion, which leads to the Coulomb potential described in Section 3.3. Ions of like charge repel one another, and ions of unlike charge attract one another. These **ion–ion forces** can be as strong as those in the covalent bond, and they are long ranged. The potential energy is proportional to  $R^{-1}$  and so approaches the value at infinite separation much less rapidly than other types of interactions. Ion–ion forces are not directional; each ion interacts equally strongly with neighboring ions on all sides. Ion–ion forces lead to the formation of ionic bonds through the Coulomb stabilization energy (see Section 3.8).

**FIGURE 10.5** A molecule of HCl can be represented as having a small net negative charge on the Cl end, balanced by a small net positive charge on the H end. The forces between two HCl molecules depend on their orientations. (a) The oppositely charged ends (blue arrows) are closer than the ends with the same charge (red arrows). This gives a net attractive force. (b) Here, the opposite is true, and the net force is repulsive.

### 10.2.2 Dipole–Dipole Forces

The dominant force between polar molecules is the **dipole–dipole force**. This is a second example of electrostatic forces that arise from interactions between fixed charges, in this case the magnitudes of the permanent dipole moments of polar molecules. As shown in Figure 10.5, these forces also depend on the orientations of the two molecules and can be either attractive or repulsive or zero. Random motions of polar molecules in gases and liquids lead to a variety of energetically favorable temporary dipole–dipole orientations. The potential energy between dipoles separated by the distance  $R$  falls off as  $R^{-3}$ . Thus the attractive force gets weaker more rapidly as the separation is increased for a dipole–dipole interaction than for a Coulomb interaction. Increasing the distance between a pair of ions by a factor of 10 changes the Coulomb potential energy to be closer to 0 by only a factor of 10, whereas increasing the distance between a pair of dipoles

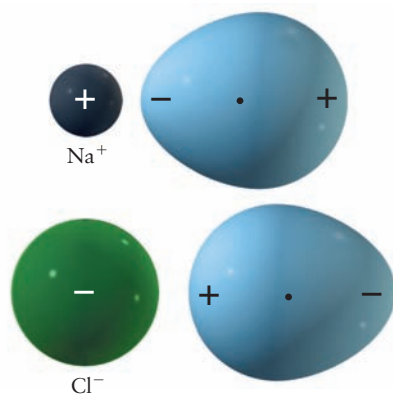

**FIGURE 10.6** Solvation of ions in liquid water. The water molecules have dipole moments; thus, the oxygen (O) atoms bear small, negative charges, whereas the hydrogen (H) atoms bear small, positive charges. (a) Positive ions are attracted to neighboring water molecules in aqueous solution by ion–dipole forces. (b) Negative ions form hydrogen bonds with water, with a nearly linear bond from O to H to the anion.

by a factor of 10 changes the potential energy to be closer to 0 by a factor of 1000. In liquids, thermal energy can overcome dipole–dipole attractions and disrupt favorable orientations; dipole–dipole interactions are too weak to hold molecules in a liquid together in a nearly rigid arrangement. Nonetheless, they are sufficiently strong to influence many physical properties, including boiling points, melting points, and molecular orientations in solids.

### 10.2.3 Ion–Dipole Forces

A third example of electrostatic forces occurs when a polar molecule is near an ion. The interaction between a polar solvent molecule, such as water, and a dissolved ion is the most common case of ion–dipole interaction. Figure 10.6 shows dissolved  $\text{Na}^+$  and  $\text{Cl}^-$  ions interacting with water dipoles. Positive ions are attracted by the negative end of the dipole and repelled by the positive end; thus, the ion is surrounded by a shell of water molecules whose oxygen (O) atoms are near the cation and whose hydrogen (H) atoms point outward into the solution. For many years it was believed that the opposite would be true for negative ions, that they would be surrounded by a shell of water dipoles whose H atoms were both near the anion. Since about 1980, neutron diffraction has been used to determine the distances between atoms in ionic aqueous solutions. A series of such studies has shown that the halide anion interacts with only one of the H atoms, and the atoms O–H– $\text{Cl}^-$  lie nearly in a straight line. The other H atom points in a direction determined by the geometry of the water molecule. The solvation of the anion is not governed by ion–dipole forces. Rather, the O–H– $\text{Cl}^-$  interaction is an example of the *hydrogen bond*, a special intermolecular force that occurs only in liquids. The hydrogen bond is discussed in the next section, and the solvation of ions is discussed more thoroughly in Chapter 11.

**FIGURE 10.7** As an ion approaches an atom or molecule, its electrostatic field distorts the distribution of the outer electrons. The effect of this distortion is to create a dipole moment that exerts an attractive force back on the ion.

### 10.2.4 Charge-Induced Dipole Forces: Polarizability

The electrons in a nonpolar molecule or atom are distributed symmetrically, but the distribution can be distorted by an approaching electrical charge. An argon (Ar) atom has no dipole moment, but an approaching  $\text{Na}^+$ , with its positive charge, attracts the electrons on the side near it more strongly than those on the far side. By tugging on the nearby electrons harder,  $\text{Na}^+$  induces a temporary dipole moment in the Ar atom (Fig. 10.7). The electron distribution of the nonpolar molecule is said to be *polarizable*, and the magnitude of the dipole moment induced measures the **polarizability** of the molecule. As long as the induced dipole is present, the interaction between molecules is similar to the ion–dipole case just described. **Induced dipole forces** also can be caused by a negative ion or by another dipole. These so-called induction forces differ from

the electrostatic forces between permanent fixed charges such as ions or dipoles. Rather, they arise from interactions between the permanent charges or moments on one molecule and the induced moments, or the polarizability, of another molecule. These interactions are weak and are effective only at short range. The induced dipole moment closely tracks the motion of the charge or dipole moment of the inducing molecule. The induced dipole is dynamically correlated with the motion of the inducing molecule. A good way to study induced dipole forces quantitatively is to collide a beam of  $\text{Na}^+$  ions and a beam of Ar atoms in vacuum, measure the energy and direction of their deflections, and deduce the correct potential function to explain these deflections.

### 10.2.5 Induced Dipole–Induced Dipole Forces: London Dispersion Forces

**FIGURE 10.8** A fluctuation of the electron distribution on one atom induces a corresponding temporary dipole moment on a neighboring atom. The two dipole moments interact to give a net attractive force, called a “dispersion force.”

Helium (He) atoms, like the atoms of the other noble gases, are electrically neutral and nonpolar, so none of the forces discussed so far explains the observed fact that there are attractions between He atoms. We know such attractions must exist, because helium becomes a liquid at 4.2 K and 1 atm. Attractions between neutral, nonpolar atoms or molecules arise from the **London dispersion forces** (often called van der Waals forces) that exist between all atoms and molecules. Dispersion forces are, in effect, a mutual interaction between the polarizable charge distributions on two separate molecules, and they are always attractive. Although the electron probability distribution around the molecule is described by the square of the wave function, dynamic motions of charge around the molecule can lead to an instantaneous, temporary dipole moment. Such a temporary dipole on one molecule will induce a temporary dipole in the other molecule. These transient, fluctuating dipoles attract one another in much the same way as do permanent dipoles. Figure 10.8 provides a simple view of the source of this interaction. The polarizability increases with the number of electrons in the atom or molecule. Heavier atoms or molecules interact more strongly by dispersion forces than do lighter ones because their outer electrons are located in shells farther from the nucleus. These electrons are less strongly bound than the outer electrons of the lighter elements, because they are shielded from the full attraction of the nucleus by intervening electrons (see Sections 3.4 and 5.2). Consequently, they are more easily distorted by external fields of neighboring dipoles. Dispersion forces are always attractive and fall off as  $R^{-6}$ . These interactions are short ranged, much more so than dipole–dipole forces. Dispersion forces provide the attractive term in the Lennard–Jones potential (see description in Section 9.6).

### 10.2.6 Repulsive Forces

As atoms or molecules approach each other closely, a **repulsive force** comes into play and can overcome the attractive forces considered so far. The source of this force is the strong repulsion between the core (nonvalence) electrons when neighboring atoms are forced close to each other. This contribution is negligible until the distance between centers becomes small, at which point the potential energy increases rapidly as distance is reduced further. Two mathematical models are used to describe the repulsive region of the potential energy function, although neither has a simple physical foundation to guide the choice of the parameters involved. The exponential form  $Ae^{-R/\rho}$  is successful when  $A$  and  $\rho$  are chosen to fit experimental data such as compressibility measurements. The inverse power form  $R^{-n}$ , where  $n$  is quite large, is also successful. The choice  $n = 12$  is widely used because, when combined with the  $n = 6$  term as shown in Equation 9.24, the resulting Lennard–Jones potential reproduces the trends in experimental data over significant ranges. Regardless of mathematical form, this steep, repulsive interaction at

extremely small distances justifies modeling atoms as hard, nearly incompressible spheres with characteristic dimensions called the **van der Waals radii**. This label honors the early contributions of Johannes van der Waals to the study of non-bonded interactions between molecules and their influence on the properties of materials. The minimum distance between molecules in a condensed phase is determined by the sum of the van der Waals radii of their atoms. Space-filling models and drawings are usually designed to approximate the van der Waals surface of molecules, which represents the distance of closest approach by neighboring molecules. Van der Waals radii for atoms are typically a few angstroms (Å).

### EXAMPLE 10.1

State which attractive intermolecular forces are likely dominant in the following substances:

- (a)  $F_2(s)$
- (b)  $HBr(\ell)$
- (c)  $NH_4Cl(s)$

#### Solution

- (a) Molecules of  $F_2$  are nonpolar, thus the predominant attractive forces between molecules in  $F_2(s)$  come from dispersion.

- (b) The  $HBr$  molecule has a permanent dipole moment. The predominant forces between molecules are dipole–dipole. Dispersion forces will also contribute to associations, especially because Br is a rather heavy atom.
- (c) The ammonium ions are attracted to the chloride ions primarily by ion–ion forces.

## 10.2.7 Comparison of Potential Energy Curves

The relative strengths and effective ranges of several intermolecular forces are illustrated in Figure 10.9, which shows how the potential energy depends on the intermolecular separation (center-to-center distance) for several pairs of ions, atoms, or molecules. The potentials illustrated here include Coulomb ( $R^{-1}$ ), dipole–dipole ( $R^{-3}$ ), dispersion ( $R^{-6}$ ), and repulsive ( $R^{-12}$ ) potentials. The species shown in Figure 10.9 were chosen so that the interacting atoms, ions, or molecules have the same number of electrons (Ar,  $Cl^-$ ,  $K^+$ , HCl). The ion–ion interaction of  $K^+$  with  $Cl^-$  is the strongest, followed by the interaction between two HCl molecules (dipole–dipole and dispersion), and the Ar–Ar interaction (dispersion only). The key points illustrated here (and detailed in the caption for Fig. 10.9) are the dramatically different depths of the wells (several orders of magnitude), as well as the distinctly different distances at which the minima occur. For comparison, the potential energy curve for the covalent bond in  $Cl_2$  is also shown. These graphs demonstrate that the intermolecular forces between atoms or molecules that are close together but not joined by chemical bonds are much weaker than those between two ions involved in an ionic bond, and between two atoms involved in a covalent bond. Because the kinetic energy of translational motions of molecules is on the order of 2–3  $\text{kJ mol}^{-1}$ , molecules of KCl and  $Cl_2$  will almost never be dissociated by collisions, whereas pairs of argon atoms or HCl molecules will break apart readily. The qualitative shape of the potential wells is the same for bonding and non-bonding interactions, but the depth of the well compared to thermal energy of molecules is the fundamental distinction between these two types.

## 10.2.8 The Shapes of Molecules and Electrostatic Forces

The potential energy diagrams in Figure 10.9 depend only on the distance between the two species. Interactions between complex molecules also depend strongly on their relative orientations, so we need a three-dimensional generalization of the

**FIGURE 10.9** The potential energy of a pair of atoms, ions, or molecules depends on the distance between the members of the pair. Here, the potential energy at large separations (to the right side of the graph) is arbitrarily set to zero by convention (see Section 3.3). As pairs of particles approach each other, the potential energy *decreases* (becomes negative) because attractive forces come into effect. The lowest point in each curve occurs at the distance where attractive and repulsive forces exactly balance. The relative potential energy values at these minima measure the relative strength of the attractive forces in the various cases illustrated. Note the shallow potential energy minimum reached when two HCl molecules or two argon atoms near each other. The inset shows these same two curves with the vertical scale expanded by a factor of 100. (The HCl–HCl curve was computed for the relative orientations of Fig. 10.5a.)

potential energy diagram to describe these interactions more fully. This need could be met by constructing a potential energy *surface* where the interaction energy is plotted as a function of all three spatial coordinates that locate the center of one molecule relative to the center of the other. Instead of aiming for quantitative calculations of potential energy surfaces from quantum mechanics, we use approximate representations to describe the influence of shape and orientation as two molecules approach one another. One such approximate representation is the electrostatic potential energy map, which shows the shape and size of the molecule, as well as the sign and magnitude of the electrostatic potential at the “surface” of the molecule. These maps were introduced and the methods by which they are obtained were defined in Section 6.10.

The electrostatic potential energy map for a given molecule, called the “target” molecule, shows the spatial shape of the electrostatic field around the molecule, and so it can be used to predict how the target molecule influences the motion of charged particles as they approach it. Figure 10.10 shows the

**FIGURE 10.10** Electrostatic potential energy map for acetone. Note the charge separation indicated by the red (negative) region on the carbonyl oxygen and the blue (positive) region on the three carbon atoms. Because of this charge separation, acetone is a polar molecule. (© Cengage Learning; Adapted from Brown/Foote Iverson/Anslyn: *Organic Chemistry 5/e*, Ch. 16, p. 564)

**FIGURE 10.11** Electrostatic potential energy map for acetaldehyde showing sites for electrophilic and nucleophilic attack. (© Cengage Learning; Adapted from Brown/Foote Iverson/Anslyn: *Organic Chemistry 5/e*, Ch. 16, p. 566)

electrostatic potential energy map for the molecule acetone,  $\text{CH}_3\text{C}(\text{O})\text{CH}_3$ , whose bonding and structure are discussed in Section 7.6. The key structural feature is the carbonyl group, in which the C has a double bond to O and two single bonds to other atoms. The carbonyl group is quite polar due to the strong difference in electronegativity values for C and O. The dipole moment and partial charge separation are shown in Figure 10.10, and their origin in the electrostatic potential energy map is clearly indicated. Molecules that contain the carbonyl group will interact with each other by dipole–dipole forces. Section 10.3 shows how such forces cause the pure liquids to have higher boiling points than non-polar liquids with comparable molecular weight.

Electrostatic potential energy maps can be used to identify reactive sites on molecules. Figure 10.11 shows the map for acetaldehyde ( $\text{CH}_3\text{CHO}$ ) which contains the carbonyl group and is discussed in Section 7.6. Comparison with Figure 10.10 shows the consequences of replacing one of the terminal  $-\text{CH}_3$  groups in acetone with a single  $-\text{H}$ . Locations with large negative values of the electrostatic potential, such as the red region around the O atom, are relatively rich in electron density and tend to attract reaction partners that lack electron density. Regions with large positive values, indicated in blue, are relatively depleted in electron density and tend to attract electron-rich reaction partners. These maps are now widely used in organic chemistry to predict patterns of reactivity for electrophilic (electron-loving) and nucleophilic (proton-loving) molecules and to explain how the presence of different functional groups in the molecule can affect these patterns. These methods are effective aids in identifying sites for chemical reactivity in more complicated molecules, including those of biological interest. They are widely used in molecular modeling simulations of drug design.

### 10.3 Intermolecular Forces in Liquids

The same intermolecular forces that make gases deviate from ideal behavior (see Sections 9.6 and 10.2) are responsible for the existence of solids and liquids. At very high temperatures, these forces are negligible because the high kinetic energy of the molecules disrupts all possible attractions; all materials are gaseous at sufficiently high temperatures. At lower temperatures, where materials are in the liquid state, molecules are close together and the details of the intermolecular potential energy determine their properties. Section 10.2 describes the influence of molecular structure on the intermolecular potential energy. This section surveys the correlation between the properties of liquids and the structure of their constituent molecules. Special attention is given to the unusual properties of water.

**FIGURE 10.12** Trends in the boiling points of hydrides of some main-group elements and the noble gases.

Substances with strong attractive intermolecular forces tend to remain liquids at higher temperatures than those with weaker intermolecular forces; they have higher normal boiling points,  $T_b$ . Ionic liquids generally have the strongest attractions, because of the Coulomb interaction among charged ions, and thus have high boiling points. Molten NaCl, for example, boils at 1686 K under atmospheric pressure. At the opposite extreme, the boiling point of helium at 1 atm pressure is only 4.2 K. Within a series of related compounds, those of higher molar mass tend to have higher normal boiling points. This trend arises from the increased polarizability of the heavier compounds, not from the increased mass per se. Progressing from helium to xenon, normal boiling points increase (Fig. 10.12), as do the strengths of the attractive dispersion forces among the noble gases. These forces, represented by the well depth  $\varepsilon$  in Table 9.4, arise from the polarizability of the atoms.

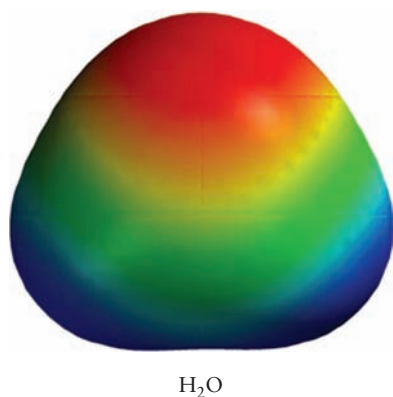

Between the noble-gas and ionic liquids falls a class of liquids called **polar liquids**. In liquid HCl, the molecules arrange themselves to the greatest extent possible with neighboring dipoles oriented to minimize the dipole–dipole potential energy. As described in Section 10.2, the dipole–dipole intermolecular forces in such polar liquids are weaker than the ion–ion Coulombic forces in ionic liquids but stronger than the dispersion forces in **nonpolar liquids** such as N<sub>2</sub>. These three forces operate respectively between molecules in which the bonding is polar covalent, fully ionic, and fully covalent. As shown in Figure 10.12, HCl has a higher boiling point than argon (a nonpolar fluid of atoms with nearly the same molar mass) because of its polar nature. The magnitudes of the intermolecular forces in HCl and argon are compared explicitly in Figure 10.9.

**FIGURE 10.13** A single hydrogen bond between water molecules forms a dimer. This bond is far weaker than a covalent bond but still strong enough to resist dissociation at room temperature. The shared hydrogen (H) atom at the center approaches the neighboring oxygen (O) atom quite closely.

### 10.3.1 Hydrogen Bonds

Figure 10.12 shows the normal boiling points of several series of hydrides, in which the boiling point increases with increasing molar mass in a series of related compounds. The dramatic deviations from these systematic trends shown by HF, NH<sub>3</sub>, and especially H<sub>2</sub>O indicate the strength and importance of the special type of bond that is common to these cases, a **hydrogen bond**. Such a bond forms when an H atom bonded to an O, N, or F atom (highly electronegative atoms) also interacts with the lone electron pair of another such atom nearby. Figure 10.13 shows the interaction of a pair of water molecules to form a dimer in the gas phase. The hydrogen bond that forms is weaker than an

**FIGURE 10.14** Electrostatic potential energy map for  $\text{H}_2\text{O}$ .

ordinary O—H covalent bond, but the interaction is significantly stronger than most other intermolecular interactions. Like most hydrogen bonds, that in water is nearly linear but asymmetric, with the H atom closer to and more strongly bound to one of the O atoms. It is indicated as O—H ··· O.

Water is a polar molecule, like HCl and  $\text{H}_2\text{S}$ . The water molecule is bent, as predicted by valence shell electron-pair repulsion theory and confirmed by experiment, and the orientation of its dipole moment (positive end toward the H atoms and negative end toward the O atom) has been related to its structure in Section 3.9. In the liquid, these molecules orient themselves in directions that minimize the potential energy between them; consequently, H atoms on one molecule are close to O atoms on neighboring molecules. In Figure 10.13, the H—O—H backbone of the water molecule on the right lies in the plane of the paper. If we try to rock this molecule in the plane of the paper in a way that would break up the (nearly) linear arrangement of O—H—O between the two molecules, a significant potential barrier opposes this movement. But the water molecule on the right side is free to rotate about the O—H—O bond and move its other O—H bond out of the plane of the paper to any other orientation consistent with the bent structure of the water molecule. The H atom in a bond such as O—H is surrounded by a relatively low density of negative charge (see Fig. 10.14) because, unlike all other elements, it has no electrons other than valence electrons. As a result, it can approach close to the lone-pair electrons on a neighboring O atom, causing a strong electrostatic (Coulomb) interaction between the two. In addition, a small amount of covalent bonding arises from the sharing of electrons between the two O atoms and the intervening H atom. These effects combine to make the interaction unusually strong. For the same reason, hydrogen bonds form with anions in aqueous solution (see Fig. 10.6).

### 10.3.2 Special Properties of Water

Water makes up about 0.023% of the total mass of the earth. About  $1.4 \times 10^{21}$  kg of it is distributed above, on, and below the earth's surface. The volume of this vast amount of water is about 1.4 billion  $\text{km}^3$ . Most of the earth's water (97.7%) is contained in the oceans, with about 1.9% in the form of ice or snow and most of the remainder (a small fraction of the total) available as freshwater in lakes, rivers, underground sources, and atmospheric water vapor. A small but important fraction is bound to cations in certain minerals, such as clays and hydrated crystalline salts. More than 80% of the surface of the earth is covered with water—as ice and snow near the poles, as relatively pure water in lakes and rivers, and as a salt solution in the oceans.

The unusual properties of water, which come from its network of hydrogen bonds, have profound effects on life on earth. Figure 10.12 compares the boiling points of water and hydrides that lack hydrogen bonds. An extrapolation of the trends from the latter compounds would give a boiling point for “water without hydrogen bonds” near 150 K ( $-123^\circ\text{C}$ ). Life as we know it would not be possible under these circumstances.

If all possible hydrogen bonds form in a mole ( $N_A$  molecules) of pure water, then every oxygen atom is surrounded by four H atoms in a tetrahedral arrangement: its own two and two from neighboring molecules. This tetrahedral arrangement forms a three-dimensional network with a structure similar to that of diamond or  $\text{SiO}_2$ . The result is an ordered array of six-membered rings of water molecules (Fig. 10.15) that manifests itself macroscopically in the characteristic sixfold symmetry of snowflakes.

The density of water reaches its maximum at  $4^\circ\text{C}$  (Fig. 10.16), and it expands on freezing. This unusual behavior, which is seen in few other liquids, also is caused by hydrogen bonds. When ice melts, some of the hydrogen bonds that maintain the open structure shown in Figure 10.15 break and the structure

**FIGURE 10.15** The structure of ice is quite open. Each water molecule has only four nearest neighbors with which it interacts by means of hydrogen bonds (blue dashed lines).

partially collapses, producing a liquid with a smaller volume (higher density). The reverse process, a sudden expansion of water on freezing, can cause bursting of water pipes and freeze/thaw cracking of concrete. Such expansion also has many beneficial effects. If ice were denser than water, the winter ice that forms at the surface of a lake would sink to the bottom and the lake would freeze from the bottom up. Instead, the ice remains at the surface, and the water near the bottom achieves a stable wintertime temperature near 4°C, which allows fish to survive.

### EXAMPLE 10.2

Predict the order of increase in the normal boiling points of the following substances:  $F_2$ , HBr,  $NH_4Cl$ , and HF.

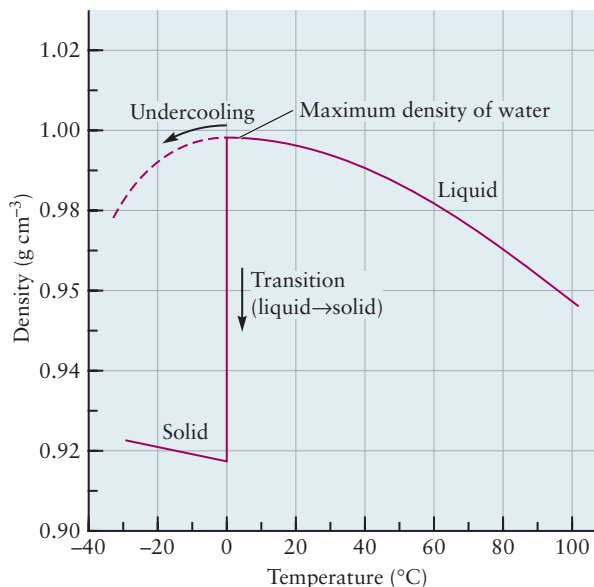

#### Solution

As an ionic substance,  $NH_4Cl$  should have the highest boiling point of the four (measured value: 520°C). HF should have a higher boiling point than HBr, because its molecules form

hydrogen bonds (see Fig. 10.13) that are stronger than the dipolar interactions in HBr (measured values: 20°C for HF, -67°C for HBr). Fluorine,  $F_2$ , is nonpolar and contains light atoms, and thus should have the lowest boiling point of the four substances (measured value: -188°C).

**Related Problems:** 23, 24

**FIGURE 10.16** The density of water rises to a maximum as it is cooled to 3.98°C, then starts to decrease slowly. Undercooled water (water chilled below its freezing point but not yet converted to ice) continues the smooth decrease in density. When liquid water freezes, the density drops abruptly.

## 10.4 Phase Equilibrium

In the fall, if a warm day is followed by a chilly night, dew forms on grass as gaseous water molecules in the air condense to form droplets;  $\text{H}_2\text{O}$  has changed its **phase** from gaseous to liquid. Liquids and solids, like gases, are phases—samples of matter that are uniform throughout in both chemical constitution and physical state. Two or more phases can coexist. Suppose a small quantity of liquid water is put in an evacuated flask, with the temperature held at  $25^\circ\text{C}$  by placing the system in a constant-temperature bath. A pressure gauge is used to monitor changes in the pressure of water vapor inside the flask. Immediately after the water enters the flask, the pressure of water vapor begins to rise from zero. It increases with time and gradually levels off at a value of  $0.03126\text{ atm}$ , which is the **vapor pressure** of water at  $25^\circ\text{C}$ . The contents of the flask have reached **equilibrium**, a condition in which no further changes in macroscopic properties occur as long as the system remains isolated. This passage toward equilibrium is a spontaneous process, occurring in a closed system without any external influence. If some of the water vapor that has formed is removed, additional water evaporates from the liquid to reestablish the same vapor pressure,  $P_{\text{vap}}(\text{H}_2\text{O}) = 0.03126\text{ atm}$ .

What is happening on a microscopic scale to cause this spontaneous movement of the system toward equilibrium? According to the kinetic theory, the molecules of water in the liquid are in a constant state of thermal motion. Some of those near the surface are moving fast enough to escape the attractive forces holding them in the liquid; this process of **evaporation** causes the pressure of the water vapor to increase. As the number of molecules in the vapor phase increases, the reverse process begins to occur: Molecules in the vapor strike the surface of the liquid, and some are captured, leading to **condensation**. As the pressure of the gas increases, the rate of condensation increases until it balances the rate of evaporation from the surface (Fig. 10.17). Once this occurs, there is no further net flow of matter from one phase to the other; the system has reached **phase equilibrium**, characterized by a particular value of the water vapor pressure. Water molecules continue to evaporate from the surface of the liquid,

**FIGURE 10.17** Approach to equilibrium in evaporation and condensation. Initially, the pressure above the liquid is very low, and many more molecules leave the liquid surface than return to it. As time passes, more molecules fill the gas phase until the equilibrium vapor pressure,  $P_{\text{vap}}$ , is approached; the rates of evaporation and condensation then become equal.

**FIGURE 10.18** The vapor pressure of a solid or liquid depends strongly on temperature. The temperature at which the vapor pressure becomes 1 atm defines the normal boiling point of a liquid and the normal sublimation point of a solid.

**TABLE 10.3**

Vapor Pressure of Water at Various Temperatures

Temperature (°C)	Vapor Pressure (atm)
15.0	0.01683
17.0	0.01912
19.0	0.02168
21.0	0.02454
23.0	0.02772
25.0	0.03126
30.0	0.04187
50.0	0.12170

but other water molecules return to the liquid from the vapor at an equal rate. A similar phase equilibrium is established between an ice cube and liquid water at the freezing point.

The vapor pressure of the water is independent of the size and shape of the container. If the experiment is duplicated in a larger flask, then a greater *amount* of water evaporates on the way to equilibrium, but the final pressure in the flask at 25°C is still 0.03126 atm as long as some liquid water is present. If the experiment is repeated at a temperature of 30.0°C, everything happens as just described, except that the pressure in the space above the water reaches 0.04187 atm. A higher temperature corresponds to a larger average kinetic energy for the water molecules. A new balance between the rates of evaporation and condensation is struck, but at a higher vapor pressure. The vapor pressure of water, and of all other substances, increases with rising temperature (Fig. 10.18; Table 10.3).

Phase equilibrium is a *dynamic* process that is quite different from the static equilibrium achieved as a marble rolls to a stop after being spun into a bowl. In the equilibrium between liquid water and water vapor, the partial pressure levels off, not because evaporation and condensation stop, but because at equilibrium their rates become the same. The properties of a system at equilibrium are independent of the direction from which equilibrium is approached, a conclusion that can be drawn by observing the behavior of the liquid–vapor system. If we inject enough water vapor into the empty flask so that initially the pressure of the vapor is *above* the vapor pressure of liquid water,  $P_{\text{vap}}(\text{H}_2\text{O})$ , then liquid water will condense until the same equilibrium vapor pressure is achieved (0.03126 atm at 25°C). Of course, if we do not use enough water vapor to exceed a pressure of 0.03126 atm, all the water will remain in the vapor phase, and two-phase equilibrium will not be reached.

The presence of water vapor above an aqueous solution has an important practical consequence. If a reaction in aqueous solution generates gases, these gases are “wet,” containing water vapor at a partial pressure given by the equilibrium vapor pressure of water at the temperature of the experiment. The

amount of gas generated is determined not by the total pressure but by the partial pressure of the gas. Dalton's law (see Section 9.4) must be used to subtract the partial pressure of water as listed in Table 10.3. This correction is significant in quantitative work.

## 10.5 Phase Transitions

Suppose 1 mol of gaseous sulfur dioxide is compressed at a temperature fixed at 30.0°C. The volume is measured at each pressure, and a graph of volume against pressure is constructed (Fig. 10.19). At low pressures, the graph shows the inverse dependence ( $V \propto 1/P$ ) predicted by the ideal gas law. As the pressure increases, deviations appear because the gas is not ideal. At this temperature, attractive forces dominate; therefore, the volume falls below its ideal gas value and approaches 4.74 L (rather than 5.50 L) as the pressure approaches 4.52 atm.

For pressures up to 4.52 atm, this behavior is quite regular and can be described by the van der Waals equation. At 4.52 atm, something dramatic occurs: The volume decreases abruptly by a factor of 100 and remains small as the pressure is increased further. What has happened? The gas has been liquefied solely by the application of pressure. If the compression of  $\text{SO}_2$  is continued, another abrupt (but small) change in volume will occur as the liquid freezes to form a solid.

Condensed phases also arise when the temperature of a gas is reduced at constant pressure. If steam (water vapor) is cooled at 1 atm pressure, it condenses to liquid water at 100°C and freezes to solid ice at 0°C. Liquids and solids form at low temperatures once the attractive forces between molecules become strong enough to overcome the kinetic energy of random thermal motion.

Six **phase transitions** occur among the three states of matter (Fig. 10.20). Solids typically melt to give liquids when they are heated, and liquids boil to give gases. Boiling is an extension of evaporation, in which the vapor escapes from the surface only. In boiling, gas bubbles form actively throughout the body of a liquid, and then rise to escape at the surface. Only when the vapor pressure of a liquid exceeds the external pressure can the liquid start to boil. The **boiling point** is the temperature at which the vapor pressure of a liquid equals the

**FIGURE 10.19** As 1 mol  $\text{SO}_2$  is compressed at a constant temperature of 30°C, the volume at first falls somewhat below its ideal gas value. Then, at 4.52 atm, the volume decreases abruptly as the gas condenses to a liquid. At a much higher pressure, a further transition to the solid occurs.

**FIGURE 10.20** Direct transitions among all three states of matter not only are possible but are observed in everyday life.

(b)

**FIGURE 10.21** When sugar (a) is heated, it melts and simultaneously decomposes to a dark-colored caramelized mixture (b).

external pressure. The external pressure influences boiling points quite strongly; water boils at 25°C if the external pressure is reduced below 0.03126 atm (recall that the vapor pressure of water at 25°C is just this number) but requires a temperature of 121°C to boil under an external pressure of 2.0 atm. At high elevations, the pressure of the atmosphere is lower than 1 atm; thus, water boils at a temperature less than 100°C and food cooks more slowly in boiling water than it would at a lower elevation. In contrast, the use of a pressure cooker increases the boiling temperature of water and speeds the rate at which food is cooked. The **normal boiling point** is defined as the temperature at which the vapor pressure of the liquid equals 1 atm. Figure 10.12 shows that, in general, a lower normal boiling point implies a higher vapor pressure at any fixed temperature (and, therefore, a more volatile liquid).

**Melting** is the conversion of a solid to the liquid state. The **normal melting point** of a solid is the temperature at which solid and liquid are in equilibrium under a pressure of 1 atm. The normal melting point of ice is 0.00°C, thus liquid water and ice coexist indefinitely (are in equilibrium) at this temperature at a pressure of 1 atm. If the temperature is reduced by even a small amount, then all the water eventually freezes; if the temperature is raised infinitesimally, all the ice eventually melts. The qualifying term *normal* is often omitted in talking about melting points because they depend only weakly on pressure.

It is sometimes possible to overshoot a phase transition, with the new phase appearing only after some delay. An example is the **superheating** of a liquid. Liquid water can reach a temperature somewhat above 100°C if heated rapidly. When vaporization of a superheated liquid does occur, it can be quite violent, with liquid thrown out of the container. Boiling chips (pieces of porous fired clay) may be added to the liquid to avoid this superheating in the laboratory. They help initiate boiling as soon as the normal boiling point is reached, by providing sites where gas bubbles can form. Heating water in a microwave oven in a very clean container can also lead to superheating, and there have been reports of violent boiling resulting in injury as the container is removed from the oven. You should carefully monitor heating times when using a microwave oven to heat water for making coffee or tea. **Supercooling** of liquids below their freezing points is also possible. In careful experiments, supercooled liquid water has been studied at temperatures below  $-30^{\circ}\text{C}$  (at atmospheric pressure).

Many materials react chemically when heated, before they have a chance to melt or boil. Substances whose chemical identities change before their physical state changes do not have normal melting or boiling points. For example, sucrose (table sugar) melts but quickly begins to darken and eventually chars (Fig. 10.21). Temperatures high enough to overcome the intermolecular attractions in sugar are also sufficient to break apart the sugar molecules themselves.

Intermolecular forces exert strong influences on phase transitions. Data presented in Section 10.3 illustrate the trend that the normal boiling point in a series of liquids increases as the strength of intermolecular forces in the liquids increases. The stronger the intermolecular attractions in a liquid, the lower its vapor pressure at any temperature and the higher its temperature must be raised to produce a vapor pressure equal to 1 atm. Melting points depend more strongly on molecular shapes and on the details of the molecular interactions than do boiling points. Consequently, their variation with the strength of the attractive forces is less systematic.

## 10.6 Phase Diagrams

If the temperature of a substance is held constant and the applied pressure is changed, phase transitions between two phases will be observed at particular pressures. Making the same measurements at a number of different temperatures provides the data necessary to draw the **phase diagram** for that substance—a plot of pressure against temperature that shows the stable state for every pressure–temperature combination. Figure 10.22 shows a sketch of the phase diagram for water. A great deal of information can be read from such diagrams. For each substance there is a unique combination of pressure and temperature, called the **triple point** (marked “T”), at which the gas, liquid, and solid phases coexist in equilibrium. Extending from the triple point are three lines, each denoting the conditions for the coexistence of two phases at equilibrium. Along the line TA, solid and gas are in equilibrium; along TB, solid and liquid; and along TC, liquid and gas. The regions bounded by these lines represent conditions where only one phase exists.

The gas–liquid coexistence curve extends upward in temperature and pressure from the triple point. This line, stretching from T to C in the phase diagrams, is the vapor pressure curve of the liquid substance, portions of which were shown in Figure 10.18. The gas–liquid coexistence curve does not continue indefinitely, but instead terminates at the **critical point** (point C in Fig. 10.22). Along this coexistence curve there is an abrupt, discontinuous change in the

**FIGURE 10.22** Phase diagram for water (the pressures and temperatures are not drawn to scale).

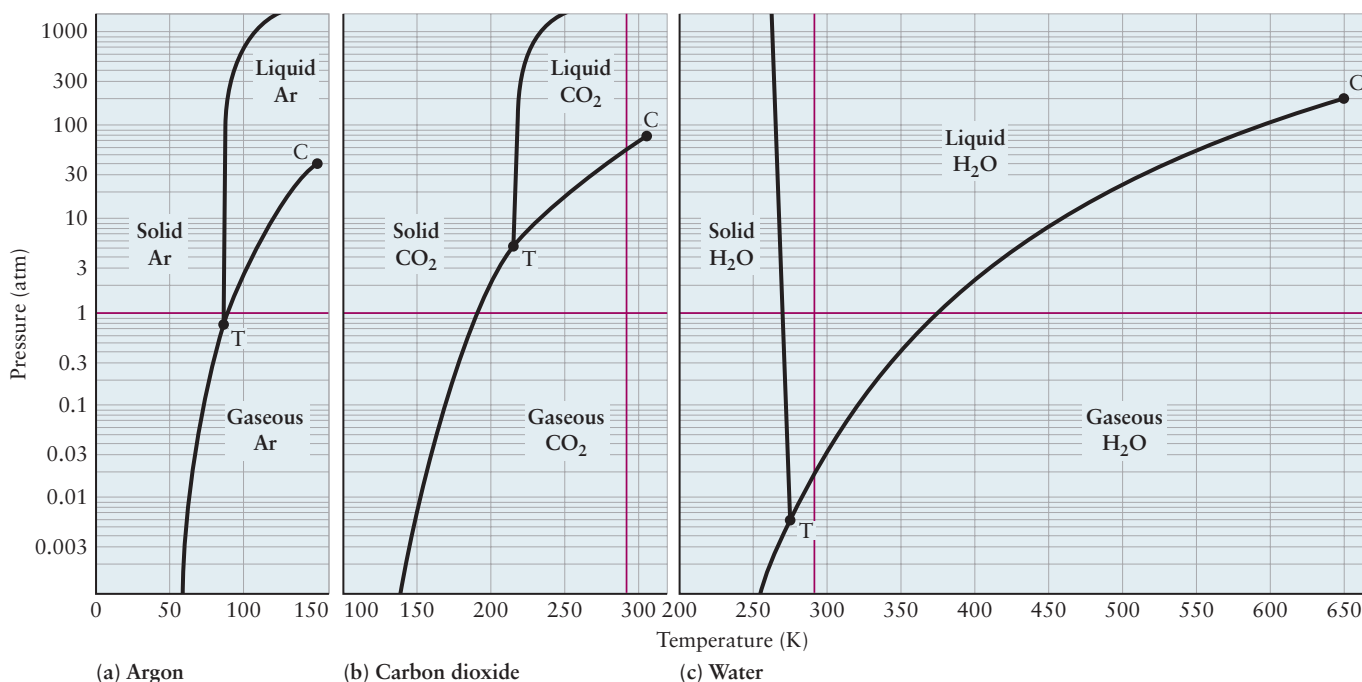

© Cengage Learning/Leon Levandowski

**FIGURE 10.23** When a gas and liquid coexist, the interface between them is clearly visible as a meniscus. The meniscus is useful for reading the volume of a liquid in a buret. It disappears as the critical point is reached.

density and other properties from one side to the other. The differences between the properties of the liquid and the gas become smaller as the critical point is approached and disappear altogether at that point. If the substance is placed in a closed container and is gradually heated, a **meniscus** is observed at the boundary between liquid and gas (Fig. 10.23); at the critical point, this meniscus disappears. For pressures above the critical pressure (218 atm for water), it is no longer possible to identify a particular state as gas or liquid. A substance beyond its critical point is called a **supercritical fluid** because the term *fluid* includes both gases and liquids.

The liquid–solid coexistence curve does not terminate as the gas–liquid curve does at the critical point, but continues to indefinitely high pressures. In practice, such a curve is almost vertical because large changes in pressure are necessary to change the freezing temperature of a liquid. For most substances, this curve inclines slightly to the right (Figs. 10.24a, b): An increase in pressure increases the freezing point of the liquid. In other words, at constant temperature, an increase in pressure leads to the formation of a phase with higher density (smaller volume), and for most substances, the solid is denser than the liquid. Water and a few other substances are anomalous (see Fig. 10.24c); for them, the liquid–solid coexistence curve slopes up initially to the *left*, showing that an increase in pressure causes the solid to melt. This anomaly is related to the densities of the liquid and solid phases: Ice is less dense than water (which is why ice cubes float on water), so when ice is compressed at 0°C, it melts.

For most substances, including water (see Fig. 10.24c), atmospheric pressure occurs somewhere between the triple-point pressure and the critical pressure, so in our ordinary experience, all three phases—gas, liquid, and solid—are observed. For a few substances, the triple-point pressure lies *above*  $P = 1$  atm, and under atmospheric conditions, there is a direct transition called **sublimation**

**FIGURE 10.24** In these phase diagrams, the pressure increases by a factor of 10 at regular intervals along the vertical axis. This method of graphing allows large ranges of pressure to be plotted. The red horizontal and vertical lines mark a pressure of 1 atm and a temperature of 298.15 K, or 25°C. Their intersection identifies room conditions. Argon and carbon dioxide are gases at room conditions, but water is a liquid. The letter T marks the triple points of the substances, and the letter C marks their critical points. The region of stability of liquid water is larger than that of either carbon dioxide or argon.

© Cengage Learning/Charles D. Winters

**FIGURE 10.25** Sublimation of solid carbon dioxide (dry ice). The white clouds are drops of water vapor (moisture in the air) that condense at the low temperatures near the solid surface. Gaseous carbon dioxide itself is transparent.

from solid to gas, without an intermediate liquid state. Carbon dioxide is such a substance (see Fig. 10.24b); its triple-point pressure is 5.117 atm (the triple-point temperature is  $-56.57^{\circ}\text{C}$ ). Solid  $\text{CO}_2$  (dry ice) sublimates directly to gaseous  $\text{CO}_2$  at atmospheric pressure (see Fig. 10.25). In this respect, it differs from ordinary ice, which melts before it evaporates and sublimates only at pressures below its triple-point pressure, 0.0060 atm. This fact is used in freeze-drying, a process in which foods are frozen and then put in a vacuum chamber at a pressure of less than 0.0060 atm. The ice crystals that formed on freezing then sublime, leaving a dried food that can be reconstituted by adding water.

Many substances exhibit more than one solid phase as the temperature and pressure are varied. At ordinary pressures, the most stable state of carbon is graphite, a rather soft, black solid; but at high enough pressures, the hard, transparent diamond form becomes more stable. That diamonds exist at all at atmospheric pressure is a consequence of how slowly they convert to graphite (we study the graphite–diamond case more thoroughly in our discussions of thermodynamics and spontaneous processes in Chapter 14). Below  $13.2^{\circ}\text{C}$  (and at atmospheric pressure), elemental tin undergoes a slow transformation from the metallic white form to a powdery gray form, a process referred to as “tin disease.” This has caused the destruction of tin organ pipes in unheated buildings. No fewer than nine solid forms of ice are known, some of which exist only over a limited range of temperatures and pressures.

### EXAMPLE 10.3

Consider a sample of argon held at  $P = 600$  atm,  $T = 100$  K in Figure 10.24a.

- What phase(s) is (are) present at equilibrium?
  - Suppose the argon originally held at  $P = 600$  atm,  $T = 100$  K is heated at constant pressure. What happens?
  - Describe a procedure to convert all the argon to gas without changing the temperature.
- An increase in temperature at constant pressure corresponds to a movement to the right in the figure, and the solid argon melts to a pure liquid.
  - If the pressure is reduced sufficiently at constant temperature (below the triple-point pressure of 0.75 atm, for example) the argon will be converted completely to gas.

**Related Problems:** 43, 44, 45, 46, 47, 48, 49, 50, 51, 52

#### Solution

- Because this point lies on the liquid–solid coexistence curve, both liquid and solid phases are present.

## CHAPTER SUMMARY

The kinetic molecular theory of matter asserts that the macroscopic properties of a gas, liquid, or solid are determined by the number density of its molecules and the nature and strength of the forces between molecules. Intermolecular forces originate in the structures of the molecules and many can be calculated from the distributions of the charge densities of the particles comprising the molecule. These forces give rise to potential energy between molecules, in magnitudes determined by the distance between the molecules. The repulsive and attractive forces are reflected in the potential energy functions, and their relative influence shown for each value of intermolecular separation. The same intermolecular forces that cause gas imperfection lead to the formation of liquids and solids. The three phases or states of matter can coexist in equilibrium. On the microscopic level, phase equilibrium is a dynamical balance in which each phase gains and loses molecules from the other phase at the same rate.

## CONCEPTS AND SKILLS

### Section 10.1 – Bulk Properties of Gases, Liquids, and Solids: Molecular Interpretation

Relate trends in values of bulk properties to the strength and range of intermolecular forces (Problems 1–12).

The bulk properties of gases, liquids, and solids are defined by their methods of measurement. Their magnitudes depend on the structure of the molecules, the forces between the molecules, and the average distance between molecules.

- Molar volume: the volume per mole of a substance
  - Ideal gases at standard temperature and pressure:  $V_m = 22.4 \text{ L mol}^{-1}$
  - Liquids and solids:  $V_m = \text{molar mass/density}$ , typically  $10\text{--}100 \text{ cm}^3 \text{ mol}^{-1}$
- Compressibility: fractional decrease in volume per unit increase in pressure
  - Large for gases
  - Small for liquids and solids
- Thermal expansion: fractional increase in volume per 1 K rise in temperature
  - Same value for all gases at a given temperature
  - Typical values for solids and liquids are of the order  $\Delta V/V = 10^{-3}/\text{K}$
- Fluidity and rigidity: response to externally applied force (stress)
  - Fluids flow, in amount determined by coefficient of viscosity
  - Solids do not flow but show rigidity and mechanical strength
- Diffusion: the rate at which molecules of one substance move through the bulk of another substance.
  - Quite slow in solids, faster in liquids, rapid in gases
- Surface tension: the energy required to increase the surface area of a liquid. Materials with high surface tensions readily form spherical drops, which have the smallest possible surface area-to-volume ratio.

### Section 10.2 – Intermolecular Forces: Origins in Molecular Structure

Relate magnitudes and distance dependence of intermolecular forces to the structure of molecules (Problems 13–20).

- Intermolecular forces are determined by the structure of the molecules involved. Except for van der Waals forces and hydrogen bonding, all intermolecular forces are *electrostatic*. They originate in the Coulomb interactions among all the charged particles in the molecules, and their magnitudes can be calculated from Coulomb's law when we take proper account of the molecular structures.
  - Ionic forces are the strongest and act over the longest distances (range). Their magnitude is easily calculated from Coulomb's law. They are the dominant force in ionic compounds, which most commonly appear as solids but may be gases or molten salts.
  - Ion–dipole forces act between ions and molecules with permanent dipole moments and are next strongest after ionic forces. They are relatively long-range and are important in ionic solutions.
  - Dipole–dipole forces act between neutral molecules that have permanent dipole moments. They are relatively weak and short-range; the potential energy between two dipoles falls off as  $1/R^3$ .

- Induced forces arise when the electron density of a neutral, nonpolar molecule is distorted or polarized by nearby charges to create a temporary dipole in the nonpolar molecule.
  - Induced dipole forces arise when an ion induces a dipole in a nonpolar atom or molecule and is then attracted to the opposite charge induced.
  - Induced dipole–induced dipole forces arise between neutral nonpolar atoms or molecules and are the only source of attractive forces in substances such as Ar.
- Repulsive forces arise when two atoms or molecules are so close together that their respective core electrons repel each other, overwhelming the attractive forces.

### Section 10.3 – Intermolecular Forces in Liquids

*Describe the effects of different kinds of intermolecular forces on properties of liquids (Problems 21–30).*

- Intermolecular forces in liquids in general are described by the categories discussed above. In addition, hydrogen bonding occurs in substances where H is covalently bonded to N, O, or F.
  - Trends in the boiling points of hydrides reveal the special nature of intermolecular forces when H is bonded to N, O, or F. The attractive forces are much stronger than normal dipole–dipole forces, and the orientation of the bond is linear, with the hydrogen located between the two heavy atoms. Hydrogen bonds are 2 to 5 times stronger than dipole–dipole interactions.
- Water has special properties that arise from hydrogen bonding.
  - Boiling point is about 150 K higher than would occur without H-bonds.
  - Solid is less dense than liquid due to a symmetrical, open, H-bonded network.

### Section 10.4 – Phase Equilibrium

*Discuss the evidence that phase equilibrium is a dynamic process at the molecular level (Problems 31–38).*

- Matter is organized into phases, which may be in equilibrium with each other.
  - Liquids, solids, and gases are the three normal phases of matter.
  - Supercritical fluids and plasmas (ionized gases) are states of matter that appear under specialized conditions and have exotic properties.
  - Two or more phases can coexist in equilibrium under specified conditions of temperature and pressure.
  - Phase equilibria are dynamic events; molecules are constantly shuttling back and forth between phases but with equal rates so that no macroscopic changes are observed.

### Section 10.5 – Phase Transitions

*Describe the effects of different kinds of intermolecular forces on phase transitions (Problems 39–42).*

- Transitions between phases include: evaporation and condensation (liquid to gas and reverse), melting and freezing (solid to liquid and reverse) and sublimation and deposition (solid to gas and reverse).
- When pressure is high enough and temperature is low enough, molecules are close together, in the range where attractive forces are strongest, so gases condense to form liquids.

- When pressure is further increased and temperature is further decreased, the intermolecular attractions become even stronger, the molecules become closely packed, and liquids condense to form solids.

### Section 10.6 – Phase Diagrams

Sketch the pressure–temperature phase diagram for a typical substance and identify the lines, areas, and singular points (Problems 43–52).

- Phase diagrams describe the phases of a substance that exist under various combinations of temperature and pressure in a graphical representation.
- Pressure is plotted on the y-axis and temperature along the x-axis.
- Pressure and temperature conditions under which two phases coexist lie along the *coexistence curves* that divide the two phases.
- The one condition under which three phases can coexist is marked by a single point, the *triple point*, T.
- Above a certain temperature and pressure, marked by the *critical point*, a single *supercritical fluid* exists; its properties are markedly different from normal gases or liquids.

## CUMULATIVE EXERCISE

FIGURE 10.26 Elemental bismuth.

© Cengage Learning/Charles D. Winters

### Alloys of Bismuth and their Applications

Bismuth (see Fig. 10.26) is a rather rare element in the earth's crust, but its oxides and sulfides appear at sufficient concentrations as impurities in lead and copper ores to make its recovery from these sources practical. Annual production of bismuth amounts to several million kilograms worldwide. Although elemental bismuth is a metal, its electrical conductivity is quite poor and it is relatively brittle. The major uses of bismuth arise from its low melting point (271.3°C) and the even lower melting points of its alloys, which range down to 47°C. These alloys are used as temperature sensors in fire detectors and automatic sprinkler systems because, in case of fire, they melt at a well-defined temperature, breaking an electrical connection and triggering an alarm or deluge.

- At its normal melting point, the density of solid bismuth is  $9.73 \text{ g cm}^{-3}$  and that of liquid bismuth is  $10.05 \text{ g cm}^{-3}$ . Does the volume of a sample of bismuth increase or decrease on melting? Does bismuth more closely resemble water or argon (see Fig. 10.24) in this regard?
- Since 1450 (10 years after Gutenberg), bismuth alloys have been used to cast metal type for printing. Explain why those alloys that share the melting behavior of bismuth discussed in part (a) would be especially useful for this application.
- A sample of solid bismuth is held at a temperature of 271.0°C and compressed. What will be observed?
- The vapor pressure of liquid bismuth has been measured to be 5.0 atm at a temperature of 1850°C. Does its normal boiling point lie above or below this temperature?
- At 1060°C, the vapor pressure of liquid bismuth is 0.013 atm. Calculate the number of bismuth atoms per cubic centimeter at equilibrium in the vapor above liquid bismuth at this temperature.
- The normal boiling point of liquid tin is 2270°C. Do you predict that liquid tin will be more volatile or less volatile than liquid bismuth at 1060°C?
- Bismuth forms two fluorides:  $\text{BiF}_3$  and  $\text{BiF}_5$ . As is usually the case, the compound with the metal in the lower oxidation state has more ionic character,

whereas that with the metal in the higher oxidation state has more covalent (molecular) character. Predict which bismuth fluoride will have the higher boiling point.

- (h) Will  $\text{AsF}_5$  have a higher or a lower normal boiling point than  $\text{BiF}_5$ ?

### Answers

- (a) Bismuth resembles water in that its volume decreases on melting.  
 (b) The volume of bismuth increases on freezing; therefore, as the liquid alloy is cast, it fits tightly into its mold rather than shrinking away from the mold as most other metals do. This gives a more sharply defined metal type.  
 (c) The bismuth will melt.  
 (d) Its normal boiling point lies below this temperature.  
 (e)  $7.2 \times 10^{16}$  atoms  $\text{cm}^{-3}$   
 (f) Liquid tin will be less volatile.  
 (g)  $\text{BiF}_3$  will have the higher boiling point; in fact,  $\text{BiF}_3$  boils at  $900^\circ\text{C}$  and  $\text{BiF}_5$  boils at  $230^\circ\text{C}$ .  
 (h) It will have a lower normal boiling point.

## PROBLEMS

Answers to problems whose numbers are red appear in Appendix G. Problems that are more challenging are indicated with asterisks.

### 10.1 Bulk Properties of Gases, Liquids, and Solids: Molecular Interpretation

- A substance is nearly nonviscous and quite compressible, and it has a large coefficient of thermal expansion. Is it most likely to be a solid, a liquid, or a gas?
- A substance is viscous, nearly incompressible, and not elastic. Is it most likely to be a solid, a liquid, or a gas?
- A sample of volume  $258 \text{ cm}^3$  has a mass of 2.71 kg.
  - Is the material gaseous or condensed?
  - If the molar mass of the material is  $108 \text{ g mol}^{-1}$ , calculate its molar volume.
- A sample of volume 18.3 L has a mass of 57.9 g.
  - Is the material gaseous or condensed?
  - If the molar mass of the material is  $123 \text{ g mol}^{-1}$ , calculate its molar volume.
- Heating a sample of matter from  $20^\circ\text{C}$  to  $40^\circ\text{C}$  at constant pressure causes its volume to increase from 546.0 to  $547.6 \text{ cm}^3$ . Classify the material as a nearly ideal gas, a nonideal gas, or condensed.
- Cooling a sample of matter from  $70^\circ\text{C}$  to  $10^\circ\text{C}$  at constant pressure causes its volume to decrease from 873.6 to  $712.6 \text{ cm}^3$ . Classify the material as a nearly ideal gas, a nonideal gas, or condensed.
- At 1.00 atm pressure and a temperature of  $25^\circ\text{C}$ , the volume of 1.0 g water is 1.0 mL. At the same pressure and a temperature of  $101^\circ\text{C}$ , the volume of 1.0 g water is nearly 1700 times larger. Give the reason for this large change in volume.

- Doubling the absolute temperature of a gas essentially doubles its volume at constant pressure. Doubling the temperature of many metals, however, often increases their volumes by only a few percent. Explain.
- Will solid sodium chloride be harder (that is, more resistant to indentation) or softer than solid carbon tetrachloride? Explain.
- Will the surface tension of molten sodium chloride be higher than or lower than that of carbon tetrachloride? Explain.
- Do you expect that the diffusion constant will increase or decrease as the density of a liquid is increased (by compressing it) at constant temperature? Explain. What will happen to the diffusion constant of a gas and a solid as the density increases?
- Do you anticipate that the diffusion constant will increase as the temperature of a liquid increases at constant pressure? Why or why not? Will the diffusion constant increase with temperature for a gas and a solid? Explain.

### 10.2 Intermolecular Forces: Origins in Molecular Structure

- Compare ion–dipole forces with induced dipole forces. In what ways are they similar and different? Give an example of each.
- Compare dipole–dipole forces with dispersion forces. In what ways are they similar and different? Give an example of each.
- Name the types of attractive forces that will contribute to the interactions among atoms, molecules, or ions in the following substances. Indicate the one(s) you expect to predominate.
 

(a) KF	(b) HI	(c) Rn	(d) $\text{N}_2$
--------	--------	--------	------------------

16. Name the types of attractive forces that will contribute to the interactions among atoms, molecules, or ions in the following substances. Indicate the one(s) you expect to predominate.  
 (a) Ne      (b) ClF      (c) F<sub>2</sub>      (d) BaCl<sub>2</sub>
17. Predict whether a sodium ion will be most strongly attracted to a bromide ion, a molecule of hydrogen bromide, or an atom of krypton.
18. Predict whether an atom of argon will be most strongly attracted to another atom of argon, an atom of neon, or an atom of krypton.
19. (a) Use Figure 10.9 to estimate the length of the covalent bond in Cl<sub>2</sub> and the length of the ionic bond in K<sup>+</sup>Cl<sup>-</sup>.  
 Note: The latter corresponds to the distance between the atoms in an isolated single molecule of K<sup>+</sup>Cl<sup>-</sup>, not in KCl(s) (solid potassium chloride).  
 (b) A book states, "The shorter the bond, the stronger the bond." What features of Figure 10.9 show that this is not always true?
20. True or false: Any two atoms held together by nonbonded attractions must be farther apart than any two atoms held together by a chemical bond. Explain.

### 10.3 Intermolecular Forces in Liquids

21. Under room conditions, fluorine and chlorine are gases, bromine is a liquid, and iodine is a solid. Explain the origin of this trend in the physical state of the halogens.
22. The later halogens form pentafluorides: ClF<sub>5</sub>, BrF<sub>5</sub>, and IF<sub>5</sub>. At 0°C, one of these is a solid, one a liquid, and one a gas. Specify which is which, and explain your reasoning.
23. List the following substances in order of increasing normal boiling points, *T*<sub>b</sub>, and explain your reasoning: NO, NH<sub>3</sub>, Ne, RbCl.
24. List the following substances in order of increasing normal boiling points, *T*<sub>b</sub>, and explain your reasoning: SO<sub>2</sub>, He, HF, CaF<sub>2</sub>, Ar.
25. As a vapor, methanol exists to an extent as a tetramer, (CH<sub>3</sub>OH)<sub>4</sub>, in which four CH<sub>3</sub>OH molecules are held together by hydrogen bonds. Propose a reasonable structure for this tetramer.
26. Hypofluorous acid (HOF) is the simplest possible compound that allows comparison between fluorine and oxygen in their abilities to form hydrogen bonds. Although F attracts electrons more strongly than O, solid HOF unexpectedly contains no H · · · F hydrogen bonds! Draw a proposed structure for chains of HOF molecules in the crystalline state. The bond angle in HOF is 101 degrees.
27. Hydrazine (N<sub>2</sub>H<sub>4</sub>) is used as a reducing agent and in the manufacture of rocket fuels. How do you expect its boiling point to compare with that of ethylene (C<sub>2</sub>H<sub>4</sub>)?
28. Hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) is a major industrial chemical that is produced on a scale approaching 10<sup>9</sup> kg per year. It is widely used as a bleach and in chemical manufacturing processes. How do you expect its boiling point to compare with those of fluorine (F<sub>2</sub>) and hydrogen sulfide (H<sub>2</sub>S), two substances with molar masses comparable with that of hydrogen peroxide?
29. A flask contains 1.0 L (1.0 kg) of room-temperature water. Calculate the number of possible hydrogen bonds among the water molecules present in this sample. Each water molecule can accept two hydrogen bonds and also furnish the H atoms for two hydrogen bonds.
30. What is the maximum number of hydrogen bonds that can be formed in a sample containing 1.0 mol (*N*<sub>A</sub> molecules) liquid HF? Compare with the maximum number that can form in 1.0 mol liquid water.

### 10.4 Phase Equilibrium

31. Hydrogen at a pressure of 1 atm condenses to a liquid at 20.3 K and solidifies at 14.0 K. The vapor pressure of liquid hydrogen is 0.213 atm at 16.0 K. Calculate the volume of 1.00 mol H<sub>2</sub> vapor under these conditions and compare it with the volume of 1.00 mol H<sub>2</sub> at standard temperature and pressure.
32. Helium condenses to a liquid at 4.224 K under atmospheric pressure and remains a liquid down to the absolute zero of temperature. (It is used as a coolant to reach very low temperatures.) The vapor pressure of liquid helium at 2.20 K is 0.05256 atm. Calculate the volume occupied by 1.000 mol helium vapor under these conditions and compare it with the volume of the same amount of helium at standard temperature and pressure.
33. The vapor pressure of liquid mercury at 27°C is 2.87 × 10<sup>-6</sup> atm. Calculate the number of Hg atoms per cubic centimeter in the "empty" space above the top of the column of mercury in a barometer at 27°C.
34. The tungsten filament in an incandescent lightbulb ordinarily operates at a temperature of about 2500°C. At this temperature, the vapor pressure of solid tungsten is 7.0 × 10<sup>-9</sup> atm. Estimate the number of gaseous tungsten atoms per cubic centimeter under these conditions.
35. Calcium carbide reacts with water to produce acetylene (C<sub>2</sub>H<sub>2</sub>) and calcium hydroxide. The acetylene is collected over water at 40.0°C under a total pressure of 0.9950 atm. The vapor pressure of water at this temperature is 0.0728 atm. Calculate the mass of acetylene per liter of "wet" acetylene collected in this way, assuming ideal gas behavior.
36. A metal reacts with aqueous hydrochloric acid to produce hydrogen. The hydrogen (H<sub>2</sub>) is collected over water at 25°C under a total pressure of 0.9900 atm. The vapor pressure of water at this temperature is 0.0313 atm. Calculate the mass of hydrogen per liter of "wet" hydrogen above the water, assuming ideal gas behavior.
37. Carbon dioxide is liberated by the reaction of aqueous hydrochloric acid with calcium carbonate:  

$$\text{CaCO}_3(s) + 2 \text{H}^+(aq) \longrightarrow \text{Ca}^{2+}(aq) + \text{CO}_2(g) + \text{H}_2\text{O}(\ell)$$
 A volume of 722 mL CO<sub>2</sub>(g) is collected over water at 20°C and a total pressure of 0.9963 atm. At this temperature, water has a vapor pressure of 0.0231 atm. Calculate the mass of calcium carbonate that has reacted, assuming no losses of carbon dioxide.

38. When an excess of sodium hydroxide is added to an aqueous solution of ammonium chloride, gaseous ammonia is produced:

Suppose 3.68 g ammonium chloride reacts in this way at 30°C and a total pressure of 0.9884 atm. At this temperature, the vapor pressure of water is 0.0419 atm. Calculate the volume of ammonia saturated with water vapor that will be produced under these conditions, assuming no leaks or other losses of gas.

## 10.5 Phase Transitions

39. High in the Andes, an explorer notes that the water for tea is boiling vigorously at a temperature of 90°C. Use Figure 10.18 to estimate the atmospheric pressure at the altitude of the camp. What fraction of the earth's atmosphere lies below the level of the explorer's camp?
40. The total pressure in a pressure cooker filled with water increases to 4.0 atm when it is heated, and this pressure is maintained by the periodic operation of a relief valve. Use Figure 10.24c to estimate the temperature of the water in the pressure cooker.
41. Iridium melts at a temperature of 2410°C and boils at 4130°C, whereas sodium melts at a temperature of 97.8°C and boils at 904°C. Predict which of the two molten metals has the larger surface tension at its melting point. Explain your prediction.
42. Aluminum melts at a temperature of 660°C and boils at 2470°C, whereas thallium melts at a temperature of 304°C and boils at 1460°C. Which metal will be more volatile at room temperature?

## 10.6 Phase Diagrams

43. At its melting point (624°C), the density of solid plutonium is 16.24 g cm<sup>-3</sup>. The density of liquid plutonium is 16.66 g cm<sup>-3</sup>. A small sample of liquid plutonium at 625°C is strongly compressed. Predict what phase changes, if any, will occur.
44. Phase changes occur between different solid forms, as well as from solid to liquid, liquid to gas, and solid to gas. When white tin at 1.00 atm is cooled below 13.2°C, it spontaneously changes (over a period of weeks) to gray tin. The density of gray tin is *less* than the density of white tin (5.75 g cm<sup>-3</sup> vs 7.31 g cm<sup>-3</sup>). Some white tin is compressed to a pressure of 2.00 atm. At this pressure, should the temperature be higher or lower than 13.2°C for the conversion to gray tin to occur? Explain your reasoning.
45. The following table gives several important points on the pressure–temperature diagram of ammonia:

	<i>P</i> (atm)	<i>T</i> (K)
Triple point	0.05997	195.42
Critical point	111.5	405.38
Normal boiling point	1.0	239.8
Normal melting point	1.0	195.45

Use this information to sketch the phase diagram of ammonia.

46. The following table gives several important points on the pressure–temperature diagram of nitrogen:

	<i>P</i> (atm)	<i>T</i> (K)
Triple point	0.123	63.15
Critical point	33.3978	126.19
Normal boiling point	1.0	77.35
Normal melting point	1.0	63.15

Use this information to sketch the phase diagram of nitrogen. The density of N<sub>2</sub>(s) is 1.03 g cm<sup>-3</sup> and that of N<sub>2</sub>(ℓ) is 0.808 g cm<sup>-3</sup>.

47. Determine whether argon is a solid, a liquid, or a gas at each of the following combinations of temperature and pressure (use Fig. 10.24).
- (a) 50 atm and 100 K      (c) 1.5 atm and 25 K  
(b) 8 atm and 150 K      (d) 0.25 atm and 120 K
48. Some water starts out at a temperature of 298 K and a pressure of 1 atm. It is compressed to 500 atm at constant temperature, and then heated to 750 K at constant pressure. Next, it is decompressed at 750 K back to 1 atm and finally cooled to 400 K at constant pressure.
- (a) What was the state (solid, liquid, or gas) of the water at the start of the experiment?  
(b) What is the state (solid, liquid, or gas) of the water at the end of the experiment?  
(c) Did any phase transitions occur during the four steps described? If so, at what temperature and pressure did they occur? (*Hint*: Trace out the various changes on the phase diagram of water [see Fig. 10.24].)
49. The vapor pressure of solid acetylene at –84.0°C is 760 torr.
- (a) Does the triple-point temperature lie above or below –84.0°C? Explain.  
(b) Suppose a sample of solid acetylene is held under an external pressure of 0.80 atm and heated from 10 to 300 K. What phase change(s), if any, will occur?
50. The triple point of hydrogen occurs at a temperature of 13.8 K and a pressure of 0.069 atm.
- (a) What is the vapor pressure of solid hydrogen at 13.8 K?  
(b) Suppose a sample of solid hydrogen is held under an external pressure of 0.030 atm and heated from 5 to 300 K. What phase change(s), if any, will occur?
51. The density of nitrogen at its critical point is 0.3131 g cm<sup>-3</sup>. At a very low temperature, 0.3131 g solid nitrogen is sealed into a thick-walled glass tube with a volume of 1.000 cm<sup>3</sup>. Describe what happens inside the tube as the tube is warmed past the critical temperature, 126.19 K.
52. At its critical point, ammonia has a density of 0.235 g cm<sup>-3</sup>. You have a special thick-walled glass tube that has a 10.0-mm outside diameter, a wall thickness of 4.20 mm, and a length of 155 mm. How much ammonia must you seal into the tube if you wish to observe the disappearance of the meniscus as you heat the tube and its contents to a temperature higher than 132.23°C, the critical temperature?

## ADDITIONAL PROBLEMS

53. Would you classify candle wax as a solid or a liquid? What about rubber? Discuss.
- \*54. When a particle diffuses, its *mean-square displacement* in a time interval  $\Delta t$  is  $6D\Delta t$ , where  $D$  is the diffusion constant. Its *root-mean-square displacement* is the square root of this (recall the analogous root-mean-square speed from Section 9.5). Calculate the root-mean-square displacement at 25°C after 1.00 hour of (a) an oxygen molecule in air ( $D = 2.1 \times 10^{-5} \text{ m}^2 \text{ s}^{-1}$ ), (b) a molecule in liquid water ( $D = 2.26 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ ), and (c) an atom in solid sodium ( $D = 5.8 \times 10^{-13} \text{ m}^2 \text{ s}^{-1}$ ). Note that for solids with melting points higher than sodium, the diffusion constant can be many orders of magnitude smaller.
55. Liquid hydrogen chloride will dissolve many ionic compounds. Diagram how molecules of hydrogen chloride tend to distribute themselves about a negative ion and about a positive ion in such solutions.
- \*56. Section 9.6 explains that the van der Waals constant  $b$  (with units of  $\text{L mol}^{-1}$ ) is related to the volume per molecule in the liquid, and thus to the sizes of the molecules. The combination of van der Waals constants  $a/b$  has units of  $\text{L atm mol}^{-1}$ . Because the liter atmosphere is a unit of energy ( $1 \text{ L atm} = 101.325 \text{ J}$ ),  $a/b$  is proportional to the energy per mole for interacting molecules, and thus to the strength of the attractive forces between molecules, as shown in Figure 10.9. By using the van der Waals constants in Table 9.3, rank the following attractive forces from strongest to weakest:  $\text{N}_2$ ,  $\text{H}_2$ ,  $\text{SO}_2$ , and  $\text{HCl}$ .
57. Describe how the average kinetic and potential energies per mole change as a sample of water is heated from 10 to 1000 K at a constant pressure of 1 atm.
58. As a sample of water is heated from 0.0°C to 4.0°C, its density increases from 0.99987 to 1.00000  $\text{g cm}^{-3}$ . What can you conclude about the coefficient of thermal expansion of water in this temperature range? Is water unusual in its behavior? Explain.
59. At 25°C, the equilibrium vapor pressure of water is 0.03126 atm. A humidifier is placed in a room of volume 110  $\text{m}^3$  and is operated until the air becomes saturated with water vapor. Assuming that no water vapor leaks out of the room and that initially there was no water vapor in the air, calculate the number of grams of water that have passed into the air.
60. The text states that at 1000°C, the vapor pressure of tungsten is  $2 \times 10^{-25}$  atm. Calculate the volume occupied per tungsten *atom* in the vapor under these conditions.
61. You boil a small quantity of water inside a 5.0-L metal can. When the can is filled with water vapor (and all air has been expelled), you quickly seal the can with a screw-on cap and remove it from the source of heat. It cools to 60°C and most of the steam condenses to liquid water. Determine the pressure inside the can. (*Hint*: Refer to Fig. 10.18.)
- \*62. The air over an unknown liquid is saturated with the vapor of that liquid at 25°C and a total pressure of 0.980 atm. Suppose that a sample of 6.00 L of the saturated air is collected and the vapor of the unknown liquid is removed from that sample by cooling and condensation. The pure air remaining occupies a volume of 3.75 L at  $-50^\circ\text{C}$  and 1.000 atm. Calculate the vapor pressure of the unknown liquid at 25°C.
63. If it is true that all solids and liquids have vapor pressures, then at sufficiently low external pressures, every substance should start to boil. In space, there is effectively zero external pressure. Explain why spacecraft do not just boil away as vapors when placed in orbit.
64. Butane-fueled cigarette lighters, which give hundreds of lights each, typically contain 4 to 5 g butane ( $\text{C}_4\text{H}_{10}$ ), which is confined in a 10-mL plastic container and exerts a pressure of 3.0 atm at room temperature (25°C). The butane boils at  $-0.5^\circ\text{C}$  under normal pressure. Butane lighters have been known to explode during use, inflicting serious injury. A person hoping to end such accidents suggests that there be less butane placed in the lighters so that the pressure inside them does not exceed 1.0 atm. Estimate how many grams of butane would be contained in such a lighter.
65. A cooling bath is prepared in a laboratory by mixing chunks of solid  $\text{CO}_2$  with ethanol.  $\text{CO}_2(\text{s})$  sublimates at  $-78.5^\circ\text{C}$  to  $\text{CO}_2(\text{g})$ . Ethanol freezes at  $-114.5^\circ\text{C}$  and boils at  $+78.4^\circ\text{C}$ . State the temperature of this cooling bath and describe what will be seen when it is prepared under ordinary laboratory conditions.
66. Oxygen melts at 54.8 K and boils at 90.2 K at atmospheric pressure. At the normal boiling point, the density of the liquid is  $1.14 \text{ g cm}^{-3}$  and the vapor can be approximated as an ideal gas. The critical point is defined by  $T_c = 154.6 \text{ K}$ ,  $P_c = 49.8 \text{ atm}$ , and (density)  $d_c = 0.436 \text{ g cm}^{-3}$ . The triple point is defined by  $T_t = 54.4 \text{ K}$ ,  $P_t = 0.0015 \text{ atm}$ , a liquid density equal to  $1.31 \text{ g cm}^{-3}$ , and a solid density of  $1.36 \text{ g cm}^{-3}$ . At 130 K, the vapor pressure of the liquid is 17.25 atm. Use this information to construct a phase diagram showing  $P$  versus  $T$  for oxygen. You need not draw the diagram to scale, but you should give numeric labels to as many points as possible on both axes.
67. It can be shown that if a gas obeys the van der Waals equation, its critical temperature, its critical pressure, and its molar volume at the critical point are given by the equations

$$T_c = \frac{8a}{27Rb} \quad P_c = \frac{a}{27b^2} \quad \left(\frac{V}{n}\right)_c = 3b$$

where  $a$  and  $b$  are the van der Waals constants of the gas. Use the van der Waals constants for oxygen, carbon dioxide, and water (from Table 9.3) to estimate the critical-point properties of these substances. Compare with the observed values given in Figure 10.24 and in Problem 66.

- \*68. Each increase in pressure of 100 atm decreases the melting point of ice by about  $1.0^{\circ}\text{C}$ .
- (a) Estimate the temperature at which liquid water freezes under a pressure of 400 atm.
- (b) One possible explanation of why a skate moves smoothly over ice is that the pressure exerted by the skater on the ice lowers its freezing point and causes it to melt. The pressure exerted by an object is the force (its mass  $\times$  the acceleration of gravity,  $9.8\text{ m s}^{-2}$ ) divided by the area of contact. Calculate the change in freezing point of ice when a skater with a mass of 75 kg stands on a blade of area  $8.0 \times 10^{-5}\text{ m}^2$  in contact with the ice. Is this sufficient to explain the ease of skating at a temperature of, for example,  $-5^{\circ}\text{C}$  ( $23^{\circ}\text{F}$ )?
- \*69. (a) Sketch the phase diagram of *temperature* versus *molar volume* for carbon dioxide, indicating the region of each of the phases (gas, liquid, and solid) and the coexistence regions for two phases.
- (b) Liquid water has a maximum at  $4^{\circ}\text{C}$  in its curve of density against temperature at  $P = 1\text{ atm}$ , and the solid is less dense than the liquid. What happens if you try to draw a phase diagram of  $T$  versus molar volume for water?
70. The critical temperature of HCl is  $51^{\circ}\text{C}$ , lower than that of HF,  $188^{\circ}\text{C}$ , and HBr,  $90^{\circ}\text{C}$ . Explain this by analyzing the nature of the intermolecular forces in each case.
71. The normal boiling points of the fluorides of the second-period elements are as follows: LiF,  $1676^{\circ}\text{C}$ ; BeF<sub>2</sub>,  $1175^{\circ}\text{C}$ ; BF<sub>3</sub>,  $-100^{\circ}\text{C}$ ; CF<sub>4</sub>,  $-128^{\circ}\text{C}$ ; NF<sub>3</sub>,  $-129^{\circ}\text{C}$ ; OF<sub>2</sub>,  $-145^{\circ}\text{C}$ ; F<sub>2</sub>,  $-188^{\circ}\text{C}$ . Describe the nature of the intermolecular forces in this series of liquids, and account for the trends in boiling point.

## CUMULATIVE PROBLEMS

---

72. At  $20^{\circ}\text{C}$  and a pressure of 1 atm, 1 mol argon gas occupies a volume of 24.0 L. Estimate the van de Waals radius for argon from the onset of the repulsive part of the argon intermolecular potential curve in Figure 9.21, and calculate the fraction of the gas volume that consists of argon atoms.
73. Other things being equal, ionic character in compounds of metals decreases with increasing oxidation number. Rank the following compounds from lowest to highest normal boiling points: AsF<sub>5</sub>, SbF<sub>3</sub>, SbF<sub>5</sub>, F<sub>2</sub>.

Copper ion complexes in water and ammonia solutions. The pale blue color of the copper sulfate ( $\text{CuSO}_4$ ) solution (left) arises when the  $\text{Cu}^{2+}$  ion is complexed with six water molecules,  $[\text{Cu}(\text{H}_2\text{O})_6]^{2+}$ . When ammonium hydroxide is added (right), four ammonia molecules,  $\text{NH}_3$ , replace water molecules in the complex. The  $[\text{Cu}(\text{NH}_3)_4(\text{H}_2\text{O})_2]^{2+}$  complex is dark blue in color. The oxidation number of copper is +2 in all these species.

A homogeneous system that contains two or more substances is called a **solution**. Usually, we think of a solution as a liquid that contains some dissolved substance, such as a solid or gas, and we use the term in that sense in most of this chapter. But, solutions of one solid in another are also common, one example being an alloy of gold and silver. In fact, any homogeneous system of two or more substances (liquid, solid, or gas) is a solution. The major component is usually called the **solvent**, and any minor component is called a **solute**. The solvent is regarded as a “carrier” or medium for the solute, which can participate in chemical reactions in the solution or leave the solution through precipitation or evaporation. The solvent can also participate in chemical reactions.

Description of these phenomena requires quantitative specifications of the amount of solute in the solution, or the *composition* of the solution. Solutions are formed by mixing two or more pure substances whose molecules interact directly in the mixed state. Molecules experience new intermolecular forces in moving from pure solute or solvent into the mixed state. The magnitude of these changes influences both the ease of formation and the stability of a solution.

Chemical reactions are frequently carried out in solution, and their description requires extensions of the rules of stoichiometry described in Chapter 2. We illustrate these extended rules by the important analytical techniques of titration in acid–base and oxidation–reduction reactions.

Just like pure substances, solutions can be in *phase equilibrium* with gases, solids, or other liquids. These equilibria frequently show interesting effects that depend on the molecular weight of the solute.

This chapter begins by explaining how the composition of solutions is defined and how solutions are prepared. It is important to master these concepts, because the properties and behavior of solutions are determined by their composition. With this background, we give quantitative descriptions of chemical reactions and phase equilibria in solutions, and relate these events to the nature of the species in the solution.

Throughout this chapter, it is helpful to keep in mind one guiding question: How are the properties and reactions of the pure solute modified when it is dispersed in the solvent?

## 11.1 Composition of Solutions

Several measures are used to specify the composition of a solution. **Mass percentage** (colloquially called weight percentage), frequently used in everyday applications, is defined as the percentage by mass of a given substance in the solution. In quantitative chemistry, the most useful measures of composition are mole fraction, molarity, and molality.

The **mole fraction** of a substance in a mixture is the number of moles of that substance divided by the total number of moles present. This term was introduced in the discussion of gas mixtures and Dalton's law (see Section 9.4). In a binary mixture containing  $n_1$  mol of species 1 and  $n_2$  mol of species 2, the mole fractions  $X_1$  and  $X_2$  are

$$X_1 = \frac{n_1}{n_1 + n_2} \quad [11.1a]$$

$$X_2 = \frac{n_2}{n_1 + n_2} = 1 - X_1 \quad [11.1b]$$

The mole fractions of all the species present must add up to 1. When a clear distinction can be made between solvent and solutes, the label 1 denotes the solvent, and higher numbers are given to the solutes. If comparable amounts of two liquids such as water and alcohol are mixed, the assignment of the labels 1 and 2 is arbitrary.

The **concentration** of a substance is the number of moles per unit volume. The SI units moles per cubic meter are inconveniently large for chemical work, so instead we use the **molarity**, defined as the number of moles of solute per liter of solution:

$$\text{molarity} = \frac{\text{moles solute}}{\text{liters solution}} = \text{mol L}^{-1} \quad [11.2]$$

M is the abbreviation for “moles per liter.” A 0.1 M (read “0.1 molar”) solution of HCl has 0.1 mol of HCl (dissociated into ions, as explained later in this chapter) per liter of solution. Molarity is the most common way of specifying the compositions of dilute solutions. For accurate measurements it has the disadvantage of depending slightly on temperature. If a solution is heated or cooled, its volume changes, so the number of moles of solute per liter of solution also changes.

The **molality**, in contrast, involves the ratio of two masses, and so does not depend on temperature. Molality is defined as the number of moles of solute per kilogram of solvent:

$$\text{molality} = \frac{\text{moles solute}}{\text{kilograms solvent}} = \text{mol kg}^{-1} \quad [11.3]$$

Because the density of water is  $1.00 \text{ g cm}^{-3}$  at  $20^\circ\text{C}$ , 1.00 L of water has mass of  $1.00 \times 10^3 \text{ g}$ , or 1.00 kg. It follows that in a dilute aqueous solution, the number of moles of solute per liter is nearly the same as the number of moles per kilogram of water. Therefore, molarity and molality have nearly equal values. For nonaqueous solutions and concentrated aqueous solutions, this approximate equality is no longer valid.

### EXAMPLE 11.1

A solution is prepared by dissolving 22.4 g of  $\text{MgCl}_2$  in 0.200 L of water. Taking the density of pure water to be  $1.00 \text{ g cm}^{-3}$  and the density of the resulting solution to be  $1.089 \text{ g cm}^{-3}$ , calculate the mole fraction, molarity, and molality of  $\text{MgCl}_2$  in this solution.

#### Solution

We are given the *mass* of the  $\text{MgCl}_2$  and the *volume* of the water. The number of moles for each are

$$\text{moles MgCl}_2 = \frac{22.4 \text{ g}}{95.22 \text{ g mol}^{-1}} = 0.235 \text{ mol}$$

$$\begin{aligned} \text{moles water} &= \frac{(0.200 \text{ L})(1000 \text{ cm}^3 \text{ L}^{-1})(1.00 \text{ g cm}^{-3})}{18.02 \text{ g mol}^{-1}} \\ &= 11.1 \text{ mol} \end{aligned}$$

$$\text{mole fraction MgCl}_2 = \frac{0.235 \text{ mol}}{(11.1 + 0.235) \text{ mol}} = 0.0207$$

To calculate the molarity, we must first determine the volume of solution. Its mass is 200 g water + 22.4 g  $\text{MgCl}_2$  = 222.4 g, and its density is  $1.089 \text{ g cm}^{-3}$ , so the volume is

$$\text{volume solution} = \frac{222.4 \text{ g}}{1.089 \text{ g cm}^{-3}} = 204 \text{ cm}^3 = 0.204 \text{ L}$$

$$\text{molarity MgCl}_2 = \frac{0.235 \text{ mol MgCl}_2}{0.204 \text{ L}} = 1.15 \text{ M}$$

$$\text{molality MgCl}_2 = \frac{0.235 \text{ mol MgCl}_2}{0.200 \text{ kg H}_2\text{O}} = 1.18 \text{ mol kg}^{-1}$$

**Related Problems: 3, 4**

### EXAMPLE 11.2

A 9.386 M aqueous solution of sulfuric acid has a density of  $1.5091 \text{ g cm}^{-3}$ . Calculate the molality, the percentage by mass, and the mole fraction of sulfuric acid in this solution.

#### Solution

It is convenient to choose 1 L of the solution, whose mass is

$$(1000 \text{ cm}^3)(1.5091 \text{ g cm}^{-3}) = 1509.1 \text{ g} = 1.5091 \text{ kg}$$

One liter contains 9.386 mol  $\text{H}_2\text{SO}_4$ , or

$$9.386 \text{ mol H}_2\text{SO}_4 \times 98.08 \text{ g mol}^{-1} = 920.6 \text{ g H}_2\text{SO}_4$$

The mass of water in this liter of solution is then obtained by subtraction:

$$\begin{aligned} \text{Mass of water in 1 L of solution} &= 1.5091 \text{ kg} - 0.9206 \text{ kg} \\ &= 0.5885 \text{ kg} \end{aligned}$$

(Continued)

The molality is now directly obtained as

$$\text{Molality H}_2\text{SO}_4 = \frac{9.386 \text{ mol H}_2\text{SO}_4}{0.5885 \text{ kg H}_2\text{O}} = 15.95 \text{ mol kg}^{-1}$$

and the mass percentage is

$$\text{Mass percentage H}_2\text{SO}_4 = \frac{0.9206 \text{ kg}}{1.5091 \text{ kg}} \times 100\% = 61.00\%$$

The number of moles of water is

$$\text{moles H}_2\text{O} = \frac{588.5 \text{ g}}{18.02 \text{ g mol}^{-1}} = 32.66 \text{ mol}$$

so that the mole fraction of  $\text{H}_2\text{SO}_4$  is

$$\text{Mole fraction H}_2\text{SO}_4 = X_2 = \frac{9.386 \text{ mol}}{9.386 + 32.66 \text{ mol}} = 0.2232$$

**Related Problems: 5, 6**

### 11.1.1 Preparation of Solutions

Examples 11.1 and 11.2 show that if a known mass of solute is added to a known volume of solvent, the molarity can be calculated only if the density of the resulting solution is known. If 1 L of solvent is used, the volume of the resulting solution is less than 1 L in some cases and more in others. If a solution is to have a given molarity, it is clearly inconvenient to need to know the solution density. We avoid this problem in practice by dissolving the measured amount of solute in a smaller amount of solvent, then adding solvent continuously until the desired total volume is reached. For accurate work, solutions are prepared in a **volumetric flask**, which has a distinct ring marked around its neck to indicate a carefully calibrated volume (Fig. 11.1). Filling the flask with solvent up to this mark controls the volume of the solution.

Sometimes it may be necessary to prepare a dilute solution of specified concentration from a more concentrated solution of known concentration by adding pure solvent to the concentrated solution. Suppose that the initial concentration (molarity) is  $c_i$  and the initial solution volume is  $V_i$ . The number of moles of solute is  $(c_i \text{ mol L}^{-1})(V_i \text{ L}) = c_i V_i \text{ mol}$ . This number does not change on dilution to a final solution volume,  $V_f$ , because only solvent, and not solute, is being added. Thus,  $c_i V_i = c_f V_f$  and the final molarity is

$$c_f = \frac{\text{moles solute}}{\text{final solution volume}} = \frac{c_i V_i}{V_f} \quad [11.4]$$

This equation can be used to calculate the final concentration after dilution to a given final volume and also to determine what final volume should be used to obtain a given concentration.

#### EXAMPLE 11.3

- (a) Describe how to prepare 0.500 L of a 0.100 M aqueous solution of potassium hydrogen carbonate ( $\text{KHCO}_3$ ).
- (b) Describe how to dilute this solution to a final concentration of 0.0400 M  $\text{KHCO}_3$ .

#### Solution

- (a) moles solute =  $(0.500 \text{ L})(0.100 \text{ mol L}^{-1}) = 0.0500 \text{ mol}$   
 grams solute =  $(0.0500 \text{ mol})(100.12 \text{ g mol}^{-1}) = 5.01 \text{ g}$   
 because 100.12 is the molar mass of  $\text{KHCO}_3$ . We would, therefore, dissolve 5.01 g  $\text{KHCO}_3$  in a small amount of water and dilute the solution to 0.500 L.

- (b) Rearranging Equation 11.4 gives

$$V_f = \frac{c_i}{c_f} V_i = \left( \frac{0.100 \text{ mol L}^{-1}}{0.0400 \text{ mol L}^{-1}} \right) (0.500 \text{ L}) = 1.25 \text{ L}$$

To achieve this, the solution from part (a) is diluted to a total volume of 1.25 L by adding water.

**Related Problems: 9, 10**

**FIGURE 11.1** To prepare a solution of nickel chloride,  $\text{NiCl}_2$ , with accurately known concentration, weigh out an amount of the solid (a), transfer it to a volumetric flask (b), dissolve it in somewhat less than the required amount of water (c), and dilute to the total volume marked on the neck of the flask (d), (e). See Figure 10.23.

## 11.2 Nature of Dissolved Species

In the formation of a solution the attractions among the particles in the original phases (solvent-to-solvent and solute-to-solute attractions) are broken up and replaced, at least in part, by new solvent-to-solute attractions. Unlike a compound, a solution has its components present in *variable* proportions and cannot be represented by a chemical formula. Equations for simple dissolution reactions do not include the solvent as a reactant. They indicate the original state of the solute in parentheses on the left side of the equation and identify the

**FIGURE 11.2** Electrostatic potential energy map for fructose.

solvent in parentheses on the right side. For example, solid (*s*) sucrose dissolves in water to give an **aqueous solution** (*aq*) solution of sucrose:

We will see later how to describe cases in which the solvent participates in a reaction. Although the solute and solvent can be any combination of solid, liquid, and gas phases, liquid water is indisputably the best known and most important solvent. Consequently, we emphasize aqueous solutions in this chapter, but you should always remember that dissolution also occurs in many other solvents. We describe formation of aqueous solutions by considering the intermolecular forces between the solute and water molecules. Because these forces can be quite different for molecular solutes and ionic solutes, we discuss these two cases separately.

### 11.2.1 Aqueous Solutions of Molecular Species

Molecular substances that have polar molecules are readily dissolved by water. Examples are the sugars, which have the general formula  $\text{C}_m(\text{H}_2\text{O})_n$ . Specific cases are sucrose (table sugar),  $\text{C}_{12}\text{H}_{22}\text{O}_{11}$ ; fructose (fruit sugar),  $\text{C}_6\text{H}_{12}\text{O}_6$  (see Fig. 11.2); and ribose,  $\text{C}_5\text{H}_{10}\text{O}_5$ , a subunit in the biomolecules known as ribonucleic acids. Despite their general formula, the sugars do not contain water molecules, but they do include polar OH (hydroxyl) groups bonded to carbon atoms, which provide sites for hydrogen-bonding interactions with water molecules. These attractions replace the solute–solute interactions, and the individual aquated sugar molecules move off into the solution (Fig. 11.3). Many other molecular substances follow the same pattern, provided they are sufficiently polar. Nonpolar substances, such as carbon tetrachloride, octane, and the common oils and waxes, do not dissolve significantly in water.

### 11.2.2 Aqueous Solutions of Ionic Species (Electrolytes)

Potassium sulfate is an ionic solid that dissolves in water up to  $120 \text{ g L}^{-1}$  at  $25^\circ\text{C}$ ; this maximum mass that can be dissolved in 1 L at  $25^\circ\text{C}$  is called the **solubility** in water. The chemical equation for this **dissolution reaction** is written as

**FIGURE 11.3** A molecule of fructose in aqueous solution. Note the attractions between the hydroxyl (O–H) groups of the fructose and molecules of water. The fructose molecule is aquated; the exact number and arrangement of the attached water molecules fluctuates. Also shown is one hydrogen bond between a water molecule and an oxygen atom in the fructose ring.

**FIGURE 11.4** When an ionic solid (in this case,  $K_2SO_4$ ) dissolves in water, the ions move away from their sites in the solid, where they were attracted strongly by ions of opposite electrical charge. New strong attractions replace those lost as each ion is surrounded by a group of water molecules. In a precipitation reaction, the process is reversed.

**FIGURE 11.5** An aqueous solution of potassium sulfate conducts electricity. When metallic plates (electrodes) charged by a battery are put in the solution, positive ions ( $K^+$ ) migrate toward the negative plate, and negative ions ( $SO_4^{2-}$ ) migrate toward the positive plate.

The dissolution of ionic species (Fig. 11.4) occurs through the ion–dipole forces described in Section 10.2. Each positive ion in solution is surrounded by water molecules oriented with the negative end of their dipole moments toward the positive ion. Each  $SO_4^{2-}$  anion in solution is surrounded by water molecules oriented with the positive end of their dipole moments toward the anion (hydrogen bonds may also form). When a halide such as  $KCl$  is dissolved, the anion forms a hydrogen bond with one of the H atoms in a water molecule that places the atoms  $O-H-Cl$  nearly in a straight line as described in Section 10.2.

Each ion dissolved in water and its surrounding **solvation shell** of water molecules constitute an entity held together by ion–dipole forces or by hydrogen bonds. These solvated ions can move as intact entities when an electric field is applied (Fig. 11.5). Because the resulting solution is a conductor of electricity, ionic species such as  $K_2SO_4$  are called *electrolytes*.

In Example 11.1, it is important to note that, although the molarity of  $MgCl_2$  is 1.15 M, the molarity of  $Cl^-$  ions in the solution is twice as large, or 2.30 M, because each formula unit of  $MgCl_2$  dissociates to give two  $Cl^-$  ions.

Different compounds dissolve to different extents in water. Only a small amount (0.0025 g) of solid barium sulfate dissolves per liter of water at 25°C, according to the following reaction:

The near-total insolubility of barium sulfate suggests that mixing a sufficiently large amount of aqueous barium ion with aqueous sulfate ion would cause the reverse reaction to occur and solid barium sulfate would appear. Of course, it is impossible to prepare a solution containing ions of one charge only. Ions of both charges must be present to maintain overall charge neutrality. But it is possible

Richard Megna/Fundamental Photographs

**FIGURE 11.6** A solution of potassium sulfate is being added to one of barium chloride. A cloud of white solid barium sulfate is formed; the potassium chloride remains in solution.

to prepare one solution that contains a soluble barium compound in water (such as barium chloride) and a second solution that contains a soluble sulfate compound in water (such as potassium sulfate). Mixing the two solutions (Fig. 11.6) then produces solid barium sulfate through the following reaction:

which is called a **precipitation reaction**.

Such precipitation reactions are sometimes written as

which suggests ionic exchange—that is, the two anions exchange places. This is misleading, because  $\text{BaCl}_2$ ,  $\text{K}_2\text{SO}_4$ , and  $\text{KCl}$  are all dissociated into ions in aqueous solution. It is more accurate to write

The potassium and chloride ions appear on both sides of the equation. They are each a **spectator ion**, they ensure charge neutrality but do not take part directly in the chemical reaction. Omitting such spectator ions from the balanced chemical equation leads to the **net ionic equation**:

A net ionic equation includes only the ions (and molecules) that actually take part in the reaction.

In dissolution and precipitation reactions, ions retain their identities, and in particular, oxidation states do not change. The ions simply exchange the positions they had in a solid (surrounded by other ions) for new positions in solution (surrounded by solvent molecules). They undergo the reverse process in precipitation.

#### EXAMPLE 11.4

An aqueous solution of sodium carbonate is mixed with an aqueous solution of calcium chloride, and a white precipitate immediately forms. Write a net ionic equation to account for this precipitate.

##### Solution

Aqueous sodium carbonate contains  $\text{Na}^{+}(aq)$  and  $\text{CO}_3^{2-}(aq)$  ions, and aqueous calcium chloride contains  $\text{Ca}^{2+}(aq)$  and  $\text{Cl}^{-}(aq)$  ions. Mixing the two solutions places  $\text{Na}^{+}(aq)$  and  $\text{Cl}^{-}(aq)$  ions and also  $\text{Ca}^{2+}(aq)$  and  $\text{CO}_3^{2-}(aq)$  ions in contact

for the first time. The precipitate forms by the following reaction:

because the other combination of ions leads to sodium chloride, a compound that is known to be soluble in water.

**Related Problems:** 13, 14

## 11.3 Reaction Stoichiometry in Solutions: Acid–Base Titrations

### 11.3.1 Reactions in Solution

Most chemical reactions that occur on the earth's surface, whether in living organisms or among inorganic substances, take place in aqueous solution. Chemical reactions carried out between substances in solution obey the requirements of stoichiometry discussed in Chapter 2, in the sense that the conservation

laws embodied in balanced chemical equations are always in force. But here we must apply these requirements in a slightly different way. Instead of a conversion between masses and number of moles, using the molar mass as a conversion factor, the conversion is now between *solution volumes* and number of moles, with the concentration as the conversion factor.

For instance, consider the reaction that is used commercially to prepare elemental bromine from its salts in solution:

Suppose there is 50.0 mL of a 0.0600 M solution of NaBr. What volume of a 0.0500 M solution of  $\text{Cl}_2$  is needed to react completely with the  $\text{Br}^{-}$ ? To answer this, find the number of moles of bromide ion present:

$$0.0500 \text{ L} \times (0.0600 \text{ mol L}^{-1}) = 3.00 \times 10^{-3} \text{ mol Br}^{-}$$

Next, use the chemical conversion factor 1 mol of  $\text{Cl}_2$  per 2 mol of  $\text{Br}^{-}$  to find

$$\text{moles Cl}_2 \text{ reacting} = 3.00 \times 10^{-3} \text{ mol Br}^{-} \left( \frac{1 \text{ mol Cl}_2}{2 \text{ mol Br}^{-}} \right) = 1.50 \times 10^{-3} \text{ mol Cl}_2$$

Finally, find the necessary volume of aqueous chlorine:

$$\frac{1.50 \times 10^{-3} \text{ mol}}{0.0500 \text{ mol L}^{-1}} = 3.00 \times 10^{-2} \text{ L solution}$$

The reaction requires  $3.00 \times 10^{-2}$  L, or 30.0 mL, of the  $\text{Cl}_2$  solution. (In practice, an excess of  $\text{Cl}_2$  solution would be used to ensure more nearly complete conversion of the bromide ion to bromine.)

The chloride ion concentration after completion of the reaction might also be of interest. Because each mole of bromide ion that reacts gives 1 mol of chloride ion in the products, the number of moles of  $\text{Cl}^{-}$  produced is  $3.00 \times 10^{-3}$  mol. The final volume of the solution is 0.0800 L, so the final concentration of  $\text{Cl}^{-}$  is

$$[\text{Cl}^{-}] = \frac{3.00 \times 10^{-3} \text{ mol}}{0.0800 \text{ L}} = 0.0375 \text{ M}$$

Square brackets around a chemical symbol signify the molarity of that species.

### EXAMPLE 11.5

When potassium dichromate is added to concentrated hydrochloric acid, it reacts according to the following chemical equation

producing a mixed solution of chromium(III) chloride and potassium chloride and evolving gaseous chlorine. Suppose that 6.20 g of  $\text{K}_2\text{Cr}_2\text{O}_7$  reacts with concentrated HCl, and that the final volume of the solution is 100.0 mL. Calculate the final concentration of  $\text{Cr}^{3+}(\text{aq})$  and the number of moles of chlorine produced.

#### Solution

The first step is to convert the mass of  $\text{K}_2\text{Cr}_2\text{O}_7$  to moles:

$$\frac{6.20 \text{ g K}_2\text{Cr}_2\text{O}_7}{294.19 \text{ g mol}^{-1}} = 0.0211 \text{ mol K}_2\text{Cr}_2\text{O}_7$$

(Continued)

The balanced chemical equation states that 1 mol of  $\text{K}_2\text{Cr}_2\text{O}_7$  reacts to give 2 mol of  $\text{Cr}^{3+}$  and 3 mol of  $\text{Cl}_2$ . Using these two chemical conversion factors gives

$$\begin{aligned}\text{moles Cr}^{3+} &= 0.0211 \text{ mol K}_2\text{Cr}_2\text{O}_7 \left( \frac{2 \text{ mol Cr}^{3+}}{1 \text{ mol K}_2\text{Cr}_2\text{O}_7} \right) \\ &= 0.0422 \text{ mol Cr}^{3+}\end{aligned}$$

$$\begin{aligned}\text{moles Cl}_2 &= 0.0211 \text{ mol K}_2\text{Cr}_2\text{O}_7 \left( \frac{3 \text{ mol Cl}_2}{1 \text{ mol K}_2\text{Cr}_2\text{O}_7} \right) \\ &= 0.0633 \text{ mol Cl}_2\end{aligned}$$

Because the final volume of the solution is 0.100 L, the concentration of  $\text{Cr}^{3+}(aq)$  is

$$[\text{Cr}^{3+}] = \frac{0.0422 \text{ mol}}{0.100 \text{ L}} = 0.422 \text{ M}$$

**Related Problems: 15, 16**

### 11.3.2 Titration

**FIGURE 11.7** A titration.

© Cengage Learning/Charles D. Winters

One of the most important techniques in analytical chemistry is **titration**—the addition of a carefully measured volume of one solution, containing substance A in known concentration, to a second solution, containing substance B in unknown concentration (see Fig. 11.7). Solution A is added through a buret, an instrument that accurately measures the volume of solution transferred as a stopcock is opened and then closed. As the solutions are mixed, A and B react quantitatively. Completion of the reaction, the **endpoint**, is signaled by a change in some physical property, such as the color of the reacting mixture. Endpoints can be detected in colorless reaction mixtures by adding a substance called an *indicator* that changes color at the endpoint. At the endpoint, the known number of moles of substance A that has been added is uniquely related to the unknown number of moles of substance B initially present by the balanced equation for the titration reaction. Titration enables chemists to determine the unknown amount of a substance present in a sample. The two most common applications of titrations involve acid–base neutralization reactions and oxidation–reduction (or redox) reactions. We describe both here briefly to illustrate the fundamental importance of solution stoichiometry calculations in titrations. Detailed discussion of acid–base and redox reactions, and the extent to which they go to completion, are presented in Chapter 15 and Chapter 17, respectively.

### 11.3.3 Background on Acid–Base Reactions

Table 11.1 lists the names and formulas of a number of important acids. Acids and bases have been known and characterized since ancient times. Chemical description and explanation of their properties and behavior have progressed through several stages of sophistication and generality. A broadly applicable modern treatment is presented in Chapter 15. Here, we introduce titrations using the treatment of the Swedish chemist Svante Arrhenius, who defined acids and bases by their behavior when dissolved in water.

In pure water, small but equal numbers of hydronium ions ( $\text{H}_3\text{O}^+$ ) and hydroxide ions ( $\text{OH}^-$ ) are present.<sup>1</sup> These arise from the partial ionization of water:

<sup>1</sup>As discussed in Chapter 15, a hydrogen ion in aqueous solution is closely held by a water molecule and is better represented as a hydronium ion,  $\text{H}_3\text{O}^+(aq)$ .

**FIGURE 11.8** Nitric acid,  $\text{HNO}_3$ , is manufactured from ammonia.

**FIGURE 11.9** Hydrochloric acid,  $\text{HCl}$ , is used in the pickling of steel and other metals to remove oxide layers on the surface.

**TABLE 11.1**

Names of Common Acids

Binary Acids	Oxoacids	Organic Acids
$\text{HF}$ , hydrofluoric acid	$\text{H}_2\text{CO}_3$ , carbonic acid	$\text{HCOOH}$ , formic acid
$\text{HCl}$ , hydrochloric acid	$\text{H}_3\text{PO}_3$ , phosphorus acid	$\text{CH}_3\text{COOH}$ , acetic acid
$\text{HCN}$ , hydrocyanic acid <sup>†</sup>	$\text{H}_3\text{PO}_4$ , phosphoric acid	$\text{C}_6\text{H}_5\text{COOH}$ , benzoic acid
$\text{H}_2\text{S}$ , hydrosulfuric acid	$\text{HNO}_2$ , nitrous acid	$\text{HOOCOOH}$ , oxalic acid
	$\text{HNO}_3$ , nitric acid (Fig. 11.8)	
	$\text{H}_2\text{SO}_3$ , sulfurous acid	
	$\text{H}_2\text{SO}_4$ , sulfuric acid	
	$\text{HClO}$ , hypochlorous acid	
	$\text{HClO}_2$ , chlorous acid	
	$\text{HClO}_3$ , chloric acid	
	$\text{HClO}_4$ , perchloric acid	

<sup>†</sup>Contains three elements but is named as a binary acid.

Following Arrhenius, we define an **acid** as a substance that when dissolved in water increases the number of hydronium ions over the number present in pure water. Gaseous hydrogen chloride reacts with water to give hydrochloric acid (Fig. 11.9):

A **base** is defined as a substance that when dissolved increases the number of hydroxide ions over the number present in pure water. Sodium hydroxide dissolves extensively in water according to the following reaction:

Ammonia is another base, as shown by the products of its reaction with water:

When an acidic solution is mixed with a basic solution, a **neutralization reaction** occurs:

This is the reverse of the water ionization reaction shown earlier. If the spectator ions are put back into the equation, it reads

showing that a salt can be defined as the product (other than water) of the reaction of an acid with a base. It is usually preferable to omit the spectator ions and to indicate explicitly only the reacting ions.

### 11.3.4 Acid–Base Titration

In most acid–base reactions, there is no sharp color change at the endpoint. In such cases it is necessary to add a small amount of an indicator, a dye that changes color when the reaction is complete (indicators are discussed in detail

**FIGURE 11.10** Acetic acid,  $\text{CH}_3\text{COOH}$ , is a common organic acid that is found in vinegar as a 3% to 5% solution by mass.

in Section 15.3). Phenolphthalein is such an indicator, changing from colorless to pink when a solution changes from acidic to basic. The concentration of acetic acid (Fig. 11.10) in an aqueous solution can be determined by adding a few drops of a phenolphthalein solution and then titrating it with a solution of sodium hydroxide of accurately known concentration. At the first permanent appearance of a pink color, the stopcock of the buret is closed. At this point, the reaction

has gone stoichiometrically to completion.

### EXAMPLE 11.6

A sample of vinegar is to be analyzed for its acetic acid content. A volume of 50.0 mL is measured out and titrated with a solution of 1.306 M NaOH; 31.66 mL of that titrant is required to reach the phenolphthalein endpoint. Calculate the concentration of acetic acid in the vinegar (in moles per liter).

#### Solution

The number of moles of NaOH reacting is found by multiplying the volume of NaOH solution (31.66 mL = 0.03166 L) by its concentration (1.306 M):

$$0.03166 \text{ L} \times 1.306 \text{ mol L}^{-1} = 4.135 \times 10^{-2} \text{ mol NaOH}$$

Because 1 mol of acetic acid reacts with 1 mol of  $\text{OH}^-(aq)$ , the number of moles of acetic acid originally present must also have been  $4.135 \times 10^{-2}$  mol. Its concentration was then

$$[\text{CH}_3\text{COOH}] = \frac{4.135 \times 10^{-2} \text{ mol}}{0.0500 \text{ L}} = 0.827 \text{ M}$$

## 11.4 Reaction Stoichiometry in Solutions: Oxidation–Reduction Titrations

### 11.4.1 Background on Oxidation–Reduction (Redox) Reactions

In an **oxidation–reduction reaction** (also called a *redox reaction*), electrons are transferred between reacting species as they combine to form products. This exchange is described as a change in the oxidation number of the reactants: The oxidation number of the species giving up electrons increases, whereas that for the species accepting electrons decreases. Oxidation numbers are defined and methods for their calculation are presented in Section 3.12. A prototype redox reaction is that of magnesium (Mg) with oxygen (O) (Fig. 11.11). When this reaction is carried to completion, the product is magnesium oxide:

Magnesium is **oxidized** in this process; it *gives up* electrons as its oxidation number *increases* from 0 (in elemental Mg) to +2 (in MgO). Oxygen, which accepts these electrons, is said to be **reduced**; its oxidation number decreases from 0 to –2. The transfer of electrons ( $e^-$ ) can be indicated with arrows:

The arrows point away from the species being oxidized (giving up electrons) and toward the species being reduced (accepting electrons). The electron

© Cengage Learning/Charles D. Winters

**FIGURE 11.11** Magnesium burning in air gives off an extremely bright light. This characteristic led to the incorporation of magnesium into the flash powder used in early photography. Magnesium powder is still used in fireworks for the same reason.

“bookkeeping” beneath the equation ensures that the same number of electrons are taken up by oxygen as are given up by magnesium:

$$2 \text{ Mg atoms} \times 2 \text{ electrons per Mg atom} = 2 \text{ O atoms per formula unit} \times 2 \text{ electrons per O atom}$$

Originally, the term *oxidation* referred only to reactions with oxygen. It now is used to describe any process in which the oxidation number of a species increases, even if oxygen is not involved in the reaction. When calcium combines with chlorine to form calcium chloride,

the calcium has been oxidized and the chlorine has been reduced.

Oxidation–reduction reactions are among the most important in chemistry, biochemistry, and industry. Combustion of coal, natural gas, and gasoline for heat and power are redox reactions, as are the recovery of metals such as iron and aluminum from their oxide ores and the production of chemicals such as sulfuric acid (Fig. 11.12) from sulfur, air, and water. The human body metabolizes sugars through redox reactions to obtain energy; the reaction products are liquid water and gaseous carbon dioxide.

**FIGURE 11.12** Sulfuric acid,  $\text{H}_2\text{SO}_4$ , is the industrial chemical produced on the largest scale in the world, in amounts exceeding 100 million tons per year.

### EXAMPLE 11.7

Determine whether the following equations represent oxidation–reduction reactions.

- (a)  $\text{SnCl}_2(s) + \text{Cl}_2(g) \longrightarrow \text{SnCl}_4(\ell)$   
 (b)  $\text{CaCO}_3(s) \longrightarrow \text{CaO}(s) + \text{CO}_2(g)$   
 (c)  $2 \text{H}_2\text{O}_2(\ell) \longrightarrow 2 \text{H}_2\text{O}(\ell) + \text{O}_2(g)$

- (b) The oxidation state of Ca remains at +2, that of O at  $-2$ , and that of C at +4. Thus, this is not a redox reaction.  
 (c) The oxidation number of oxygen in  $\text{H}_2\text{O}_2$  is  $-1$ . This changes to  $-2$  in the product  $\text{H}_2\text{O}$  and  $0$  in  $\text{O}_2$ . This is a redox reaction in which the same element is both oxidized and reduced.

#### Solution

- (a) Tin increases its oxidation number from +2 to +4, and the oxidation number of chlorine in  $\text{Cl}_2$  is reduced from 0 to  $-1$ . Some other chlorine atoms are unchanged in oxidation number, but this is still a redox reaction.

**Related Problems:** 27, 28, 29, 30

**FIGURE 11.13** When a piece of copper wire is inserted into a solution of silver nitrate, metallic silver deposits on the wire and the solution turns blue as  $\text{Cu}^{2+}$  ions form.

## 11.4.2 Balancing Oxidation–Reduction Equations in Aqueous Solution

Numerous redox reactions occur in aqueous solution. For example, consider the reaction between solid copper (Cu) and an aqueous solution of silver (Ag) nitrate:

The nitrate ions are spectators that do not take part in the reaction, so they are omitted in the net equation. Two electrons are transferred from each reacting Cu atom to a pair of silver ions. Copper (the electron donor) is oxidized, and silver ion (the electron acceptor) is reduced. This oxidation–reduction reaction occurs when a piece of copper is placed in an aqueous solution of silver nitrate or any other soluble silver salt (Fig. 11.13). Metallic silver immediately begins to plate out on the copper, the concentration of silver ion decreases, and blue  $\text{Cu}^{2+}(aq)$  appears in solution and increases in concentration as time passes.

It is useful to consider this chemical equation as representing the sum of an oxidation and a reduction **half-reaction**, in which electrons ( $e^-$ ) appear explicitly. The oxidation of copper is written as

and the reduction of silver ion as

In the net equation, electrons must not appear explicitly. Thus, the second equation must be multiplied by 2 before being added to the first so that the electrons cancel out on both sides. As before, this gives

Many redox reactions are too difficult to balance by the simple methods of logical reasoning described in Section 2.3. Here, we outline a systematic procedure based on half-reactions and apply it to reactions that occur in acidic or basic aqueous solution. In these reactions, water and  $\text{H}_3\text{O}^+$  (acidic solution) or  $\text{OH}^-$  (basic solution) may take part either as reactants or as products; thus, it is necessary to *complete* the corresponding equations, as well as to balance them.

As an example, let's complete and balance the chemical equation for the dissolution of copper(II) sulfide in aqueous nitric acid (Fig. 11.14):

**Step 1** Write two unbalanced half-equations, one for the species that is oxidized and its product and one for the species that is reduced and its product.

Here, the unbalanced half-reaction involving CuS is

The unbalanced half-reaction involving  $\text{NO}_3^-$  is

**Step 2** Insert coefficients to make the numbers of atoms of all elements except oxygen and hydrogen equal on the two sides of each equation.

In this case, copper, sulfur, and nitrogen are already balanced in the two half-equations, so this step is already completed.

**Step 3** Balance oxygen by adding  $\text{H}_2\text{O}$  to one side of each half-equation.

**Step 4** Balance hydrogen. For an acidic solution, add  $\text{H}_3\text{O}^+$  to the side of each half-equation that is "deficient" in hydrogen and add an equal amount of  $\text{H}_2\text{O}$  to the other side. For a basic solution, add  $\text{H}_2\text{O}$  to the side of each half-equation that is "deficient" in hydrogen and add an equal amount of  $\text{OH}^-$  to the other side.

Note that this step does not disrupt the oxygen balance achieved in step 3. In this case (acidic solution), the result is

© Cengage Learning/Leon Lewandowski

**FIGURE 11.14** Copper(II) sulfide reacts with concentrated nitric acid to liberate nitrogen oxide and produce a solution of copper(II) sulfate, which displays the characteristic blue color of copper(II) ions in water.

**Step 5** Balance charge by inserting  $e^-$  (electrons) as a reactant or product in each half-equation.

**Step 6** Multiply the two half-equations by numbers chosen to make the number of electrons given off by the oxidation equal the number taken up by the reduction. Then add the two half-equations, canceling electrons. If  $\text{H}_3\text{O}^+$ ,  $\text{OH}^-$ , or  $\text{H}_2\text{O}$  appears on both sides of the final equation, cancel out the duplications.

Here, the oxidation half-equation must be multiplied by 3 (so that 24 electrons are produced), and the reduction half-equation by 8 (so that 24 electrons are consumed):

This procedure balances equations that are too difficult to balance by inspection. For basic solutions, remember to add  $\text{H}_2\text{O}$  and  $\text{OH}^-$ , rather than  $\text{H}_3\text{O}^+$  and  $\text{H}_2\text{O}$ , at step 4.

### EXAMPLE 11.8

Balance the following equation, which represents a reaction that occurs in basic aqueous solution:

#### Solution

The other half-reaction is unchanged.

**Step 3**  $\text{H}_2\text{O}$  is now added to the second half-reaction to balance oxygen:

**Step 4** The right side of the silver half-reaction is deficient by 1 H. Add 1  $\text{H}_2\text{O}$  to the right and 1  $\text{OH}^-$  to the left:

In the chromium half-reaction, the left side is deficient by 5 H atoms, so 5  $\text{H}_2\text{O}$  is added to that side and 5  $\text{OH}^-$  to the right side:

(Notice that the  $\text{H}_2\text{O}$  on the right canceled out one of the five on the left, leaving four.)

(Continued)

**Step 5** Electrons are added to the right side of the silver half-reaction and to the left side of the chromium half-reaction to balance charge:

**Step 6** The gain and loss of electrons are equalized. The first equation is multiplied by 3 so that it consumes six electrons, and the second is multiplied by 2 so that it produces six electrons.

**Related Problems: 31, 32, 33, 34**

### EXAMPLE 11.9

Balance the following equation for the reaction of arsenic(III) sulfide with aqueous chloric acid:

**Solution**

**Step 4** The chloric acid makes this an acidic solution, so  $\text{H}_3\text{O}^+$  and  $\text{H}_2\text{O}$  are used:

**Step 5** Balance charge by adding electrons to each half-reaction:

**Step 6** We must find the least common multiple of 28 and 6. This is 84; therefore, we need to multiply the first equation by  $84/28 = 3$  and the second equation by  $84/6 = 14$ :

### 11.4.3 Disproportionation

An important type of redox reaction, **disproportionation**, occurs when a single substance is both oxidized and reduced. Example 11.7, part (c), provided such a reaction:

The oxygen in hydrogen peroxide ( $\text{H}_2\text{O}_2$ ) is in an intermediate oxidation state of  $-1$ ; some of it is oxidized to  $\text{O}_2$  and some is reduced to  $\text{H}_2\text{O}$ . The balancing of equations for disproportionation reactions is described in the following example.

#### EXAMPLE 11.10

Balance the following equation for the reaction that occurs when chlorine is dissolved in basic solution:

#### Solution

**Step 1** We solve this by writing the  $\text{Cl}_2$  on the left sides of two half-equations:

**Step 2**

**Step 3** The first half-equation becomes

**Step 4** Now the first half-equation becomes

**Step 6** Multiply the second equation by 5 and add:

Dividing this equation by 2 gives

**Related Problems: 37, 38**

### 11.4.4 Redox Titration

Redox titrations are illustrated by the reaction in which potassium permanganate oxidizes  $\text{Fe}^{2+}$  in acidic solution and the manganese (Mn) is reduced:

Redox titrations have the advantage that many involve intensely colored species that change color dramatically at the endpoint. For example,  $\text{MnO}_4^-$  is deep purple, whereas  $\text{Mn}^{2+}$  is colorless. Thus, when  $\text{MnO}_4^-$  has been added in slight excess to  $\text{Fe}^{2+}$ , the color of the solution changes permanently to purple.

The titration is begun by opening the stopcock of the buret and letting a small volume of permanganate solution run into the flask that contains the  $\text{Fe}^{2+}$  solution. A dash of purple colors the solution (Fig. 11.15a) but rapidly disappears as the permanganate ion reacts with  $\text{Fe}^{2+}$  to give the nearly colorless  $\text{Mn}^{2+}$  and  $\text{Fe}^{3+}$  products. The addition of incremental volumes of permanganate solution is continued until the  $\text{Fe}^{2+}$  is almost completely converted to  $\text{Fe}^{3+}$ . At this stage, the addition of just one drop of  $\text{KMnO}_4$  imparts a pale purple color to the reaction mixture (see Fig. 11.15b) and signals the completion of the

**FIGURE 11.15** (a) Addition of a small amount of potassium permanganate from a buret gives a dash of purple color to the  $\text{Fe}^{2+}$  solution, which disappears quickly as the permanganate ion reacts to give  $\text{Fe}^{3+}$  and  $\text{Mn}^{2+}$ . (b) When all the  $\text{Fe}^{2+}$  ions have been consumed, additional drops of permanganate solution give a pale purple color to the solution.

reaction. The volume of the titrant  $\text{KMnO}_4$  solution is calculated by subtracting the initial reading of the solution meniscus (see Fig. 10.23) in the buret from the final volume reading.

Suppose that the permanganate solution has a concentration of 0.09625 M, and 26.34 mL (0.02634 L) of it is added to reach the endpoint. The number of moles of  $\text{Fe}^{2+}$  in the original solution is calculated in two steps:

$$\begin{aligned}\text{Amount of MnO}_4^- \text{ reacting} &= 0.02634 \text{ L} \times 0.09625 \text{ mol L}^{-1} \\ &= 2.535 \times 10^{-3} \text{ mol MnO}_4^-\end{aligned}$$

From the balanced chemical equation, each mole of  $\text{MnO}_4^-$  used causes the oxidation of 5 mol of  $\text{Fe}^{2+}$ , so

$$\begin{aligned}\text{Amount of Fe}^{2+} \text{ reacting} &= 2.535 \times 10^{-3} \text{ mol MnO}_4^- \times \left( \frac{5 \text{ mol Fe}^{2+}}{1 \text{ mol MnO}_4^-} \right) \\ &= 1.268 \times 10^{-2} \text{ mol Fe}^{2+}\end{aligned}$$

These direct titrations form the basis of more complicated analytical procedures. Many analytical procedures are indirect and involve additional preliminary reactions of the sample before the titration can be carried out. For example, a soluble calcium salt will not take part in a redox reaction with potassium permanganate. But adding ammonium oxalate to the solution containing  $\text{Ca}^{2+}$  causes the quantitative precipitation of calcium oxalate:

After the precipitate is filtered and washed, it is dissolved in sulfuric acid to form oxalic acid (Fig. 11.16):

Finally, the oxalic acid is titrated with permanganate solution of accurately known concentration, based on the redox reaction

In this way, the quantity of calcium can be determined indirectly by reactions that involve precipitation, acid–base, and redox steps.

**FIGURE 11.16** Oxalic acid,  $\text{H}_2\text{C}_2\text{O}_4$ , is an acid that can give up the two  $\text{H}^+$  ions in aqueous solution to form the oxalate ion,  $\text{C}_2\text{O}_4^{2-}$ .

## 11.5 Phase Equilibrium in Solutions: Nonvolatile Solutes

**FIGURE 11.17** In an ideal solution, a graph of solvent vapor pressure  $P_1$  versus mole fraction of solvent  $X_1$  is a straight line. Nonideal solutions behave differently; examples of positive and negative deviations from the ideal solution are shown. The vapor pressure of pure solvent is  $P_1^\circ$ .

We turn now from the chemical reactions of solutions to such physical properties as their vapor pressures and phase diagrams. Consider first a solution made by dissolving a nonvolatile solute in a solvent. By “nonvolatile” we mean that the vapor pressure of the solute above the solution is negligible. An example is a solution of sucrose (cane sugar) in water, in which the vapor pressure of sucrose above the solution is zero. We study the case of a volatile solute in Section 11.6.

The *solvent* vapor pressure is not zero and changes with the composition of the solution at a fixed temperature. If the mole fraction of solvent ( $X_1$ ) is 1, then the vapor pressure is  $P_1^\circ$ , the vapor pressure of pure solvent at the temperature of the experiment. When  $X_1$  approaches 0 (giving pure solute), the vapor pressure  $P_1$  of the solvent must go to 0 also, because solvent is no longer present. As the mole fraction  $X_1$  changes from 1 to 0,  $P_1$  drops from  $P_1^\circ$  to 0. What is the shape of the curve?

The French chemist François-Marie Raoult found that for some solutions a plot of solvent vapor pressure against solvent mole fraction can be fitted closely by a straight line (Fig. 11.17). Solutions that conform to this straight-line relationship obey the following simple equation:

$$P_1 = X_1 P_1^\circ \quad [11.5]$$

which is known as **Raoult’s law**. Such a solution is called an **ideal solution**. A solution that deviates from straight-line behavior is called a **nonideal solution**. Nonideal solutions may show positive deviations (with vapor pressures higher than those predicted by Raoult’s law) or negative deviations (with lower vapor pressures). On a molecular level, negative deviations arise when the solute attracts solvent molecules especially strongly, reducing their tendency to escape into the vapor phase. Positive deviations arise in the opposite case, when solvent and solute molecules are not strongly attracted to each other. Even nonideal solutions with nondissociating solutes approach Raoult’s law as  $X_1$  approaches 1, just as all real gases obey the ideal gas law at sufficiently low densities.

Raoult’s law forms the basis for four properties of dilute solutions, which are called **colligative properties** (derived from Latin *colligare*, meaning “to collect together”) because they depend on the collective effect of the *number* of dissolved particles rather than on the *nature* of the particular particles involved. These four properties are:

1. The lowering of the vapor pressure of a solution relative to pure solvent
2. The elevation of the boiling point of a solution relative to the pure solvent
3. The depression of the freezing point of a solution relative to the pure solvent
4. The phenomenon of osmotic pressure

### 11.5.1 Vapor-Pressure Lowering

Because  $X_1 = 1 - X_2$  for a two-component solution, Raoult’s law can be rewritten as

$$\Delta P_1 = P_1 - P_1^\circ = X_1 P_1^\circ - P_1^\circ = -X_2 P_1^\circ \quad [11.6]$$

so that the difference in vapor pressure of the pure solvent and the solution is proportional to the mole fraction of solute. The negative sign implies **vapor-pressure lowering**; the vapor pressure is always less above a dilute solution than it is above the pure solvent.

### EXAMPLE 11.11

At 25°C, the vapor pressure of pure benzene is  $P_1^\circ = 0.1252$  atm. Suppose 6.40 g of naphthalene,  $C_{10}H_8$  (molar mass 128.17 g mol<sup>-1</sup>), is dissolved in 78.0 g of benzene (molar mass 78.0 g mol<sup>-1</sup>). Calculate the vapor pressure of benzene over the solution, assuming ideal behavior.

#### Solution

The number of moles of solvent,  $n_1$ , is 1.00 mol in this case (because 78.0 g = 1.00 mol benzene has been used). The

number of moles of solute is  $n_2 = 6.40 \text{ g}/128.17 \text{ g mol}^{-1} = 0.0499$  mol  $C_{10}H_8$ ; thus, the mole fraction  $X_1$  is

$$X_1 = \frac{n_1}{n_1 + n_2} = \frac{1.00 \text{ mol}}{1.00 + 0.0499 \text{ mol}} = 0.9525$$

From Raoult's law, the vapor pressure of benzene above the solution is

$$P_1 = X_1 P_1^\circ = 0.9525 \times 0.1252 \text{ atm} = 0.119 \text{ atm}$$

**Related Problems: 41, 42**

## 11.5.2 Boiling-Point Elevation

The normal boiling point of a pure liquid  $T_b$  or a solution  $T'_b$  is the temperature at which the vapor pressure reaches 1 atm. Because a dissolved solute reduces the vapor pressure, the temperature of the solution must be increased to make it boil. That is, the boiling point of a solution is higher than that of the pure solvent. This phenomenon, referred to as **boiling-point elevation**, provides a method for determining molar masses.

The vapor-pressure curve of a dilute solution lies slightly below that for the pure solvent. In Figure 11.18,  $\Delta P_1 (= P_1 - P_1^\circ, \text{ where } P_1 < P_1^\circ)$  is the change in vapor pressure at  $T_b$  and  $\Delta T_b$  is the change in temperature necessary to hold the vapor pressure at 1 atm (that is,  $\Delta T_b = T'_b - T_b$  is the increase in boiling point caused by addition of solute to the pure solvent). For small concentrations of nondissociating solutes, the two curves are parallel, so

$$\begin{aligned} -\frac{\Delta P_1}{\Delta T_b} &= S \\ \Delta T_b &= -\frac{\Delta P_1}{S} = \frac{X_2 P_1^\circ}{S} \\ &= \frac{1}{S} \left( \frac{n_2}{n_1 + n_2} \right) \quad (\text{from Raoult's law, with } P_1^\circ = 1 \text{ atm}) \end{aligned}$$

The constant  $S$  is a property of the pure solvent only, because it is the slope of the vapor pressure curve  $(P_1^\circ \text{ (at } T_{\text{high}}) - P_1^\circ \text{ (at } T_{\text{low}})) / (T_{\text{high}} - T_{\text{low}})$  near 1 atm pressure. That is,  $S$  is independent of the solute species involved.

For very dilute solutions,  $n_1 \gg n_2$ ; this may be simplified as follows:

$$\Delta T_b = \frac{1}{S} \frac{n_2}{n_1} = \frac{1}{S} \left( \frac{m_2 / \mathcal{M}_2}{m_1 / \mathcal{M}_1} \right)$$

where  $m_1$  and  $m_2$  are the masses of solvent and solute (in grams) and  $\mathcal{M}_1$  and  $\mathcal{M}_2$  are their molar masses in grams per mole. Because  $\mathcal{M}_1$ , like  $S$ , is a property

**FIGURE 11.18** The vapor pressure of the solvent above a dilute solution is lower than that of the pure solvent at all temperatures. As a result, for the solution to boil (that is, for the vapor pressure to reach 1 atm), a higher temperature is required for the solution than for the pure solvent. This amounts to an elevation of the boiling point.

of the solvent only, it is convenient to combine the two and define a new constant  $K_b$  through

$$K_b = \frac{\mathcal{M}_1}{(1000 \text{ g kg}^{-1})S}$$

Then

$$\Delta T_b = K_b \left( \frac{m_2/\mathcal{M}_2}{m_1/(1000 \text{ g kg}^{-1})} \right)$$

Because  $m_1$  is measured in grams,  $m_1/(1000 \text{ g kg}^{-1})$  is the number of kilograms of solvent. Also,  $m_2/\mathcal{M}_2$  is the number of moles of solute. The expression in parentheses is, therefore, the molality ( $m$ ) of the solution.

$$\Delta T_b = K_b m \quad [11.7]$$

For a given solvent,  $K_b$  is obtained by measuring the boiling-point elevations for dilute solutions of known molality (that is, containing a known amount of solute with known molar mass). Table 11.2 gives values of  $K_b$  for a number of solvents. Once  $K_b$  has been found, it can be used either to predict boiling-point

**TABLE 11.2**

Boiling-Point Elevation and Freezing-Point Depression Constants

Solvent	Formula	$T_b$ (°C)	$K_b$ (K kg mol <sup>-1</sup> )	$T_f$ (°C)	$K_f$ (K kg mol <sup>-1</sup> )
Acetic acid	CH <sub>3</sub> COOH	118.1	3.07	17	3.9
Benzene	C <sub>6</sub> H <sub>6</sub>	80.1	2.53	5.5	4.9
Carbon tetrachloride	CCl <sub>4</sub>	76.7	5.03	-22.9	32
Diethyl ether	C <sub>4</sub> H <sub>10</sub> O	34.7	2.02	-116.2	1.8
Ethanol	C <sub>2</sub> H <sub>5</sub> OH	78.4	1.22	-114.7	1.9
Naphthalene	C <sub>10</sub> H <sub>8</sub>	—	—	80.5	6.8
Water	H <sub>2</sub> O	100.0	0.512	0.0	1.86

elevations for solutes of known molar mass or to determine molar masses from measured boiling-point elevations, as illustrated in part (b) of the following example.

### EXAMPLE 11.12

- (a) When 5.50 g of biphenyl ( $C_{12}H_{10}$ ) is dissolved in 100.0 g of benzene, the boiling point increases by  $0.903^\circ\text{C}$ . Calculate  $K_b$  for benzene.
- (b) When 6.30 g of an unknown hydrocarbon is dissolved in 150.0 g of benzene, the boiling point of the solution increases by  $0.597^\circ\text{C}$ . What is the molar mass of the unknown substance?

#### Solution

- (a) Because the molar mass of biphenyl is  $154.2\text{ g mol}^{-1}$ , 5.50 g contains  $5.50\text{ g}/154.2\text{ g mol}^{-1} = 0.0357\text{ mol}$ . The molality,  $m$ , is

$$m = \frac{\text{mol solute}}{\text{kg solvent}} = \frac{0.0357\text{ mol}}{0.1000\text{ kg}} = 0.357\text{ mol kg}^{-1}$$

$$K_b = \frac{\Delta T_b}{m} = \frac{0.903\text{ K}}{0.357\text{ mol kg}^{-1}}$$

$$= 2.53\text{ K kg mol}^{-1}\text{ for benzene}$$

- (b) Solving  $\Delta T_b = K_b m$  for  $m$  gives

$$m = \frac{\Delta T_b}{K_b} = \frac{0.597\text{ K}}{2.53\text{ K kg mol}^{-1}} = 0.236\text{ mol kg}^{-1}$$

The number of moles of solute is the product of the molality of the solution and the mass of the solvent,  $m_1$ :

$$n_2 = (0.236\text{ mol kg}^{-1}) \times (0.1500\text{ kg}) = 0.0354\text{ mol}$$

Finally, the molar mass of the solute is its mass divided by its number of moles:

$$\begin{aligned} \text{molar mass of solute} &= \mathcal{M}_2 = \frac{m_2}{n_2} \\ &= \frac{6.30\text{ g}}{0.0354\text{ mol}} = 178\text{ g mol}^{-1} \end{aligned}$$

The unknown hydrocarbon might be anthracene ( $C_{14}H_{10}$ ), which has a molar mass of  $178.24\text{ g mol}^{-1}$ .

**Related Problems: 43, 44, 45, 46**

So far, only *nondissociating* solutes have been considered. Colligative properties depend on the total number of moles per liter of dissolved species present. If a solute dissociates (as sodium chloride dissolves to furnish  $\text{Na}^+$  and  $\text{Cl}^-$  ions in aqueous solution), then the molality,  $m$ , to be used is the *total* molality. One mole of  $\text{NaCl}$  dissolves to give 2 mol of ions; thus, the total molality and the boiling-point elevation are twice as large as they would be if  $\text{NaCl}$  molecules were present in solution. One mole of  $\text{Ca}(\text{NO}_3)_2$  dissolves to give 3 mol of ions (1 mol of  $\text{Ca}^{2+}$  and 2 mol of  $\text{NO}_3^-$ ), giving 3 times the boiling-point elevation. The corresponding vapor-pressure lowering is greater as well. Ions behave differently than neutral molecules in solution, however, and nonideal behavior appears at lower concentrations in solutions that contain ions.

### EXAMPLE 11.13

Lanthanum(III) chloride ( $\text{LaCl}_3$ ) is a salt that completely dissociates into ions in dilute aqueous solution,

yielding 4 mol of ions per mole of  $\text{LaCl}_3$ . Suppose 0.2453 g of  $\text{LaCl}_3$  is dissolved in 10.00 g of  $\text{H}_2\text{O}$ . What is the boiling point of the solution at atmospheric pressure, assuming ideal solution behavior?

(Continued)

**Solution**

The molar mass of  $\text{LaCl}_3$  is  $245.3 \text{ g mol}^{-1}$ .

$$\begin{aligned} \text{moles of LaCl}_3 &= \frac{0.2453 \text{ g}}{245.3 \text{ g mol}^{-1}} \\ &= 1.000 \times 10^{-3} \text{ mol} \end{aligned}$$

$$\begin{aligned} \text{total molality} = m &= \frac{(4)(1.000 \times 10^{-3}) \text{ mol of ions}}{0.0100 \text{ kg solvent}} \\ &= 0.400 \text{ mol kg}^{-1} \end{aligned}$$

This is inserted into the equation for the boiling-point elevation:

$$\begin{aligned} \Delta T_b &= K_b m \\ &= (0.512 \text{ K kg mol}^{-1})(0.400 \text{ mol kg}^{-1}) = 0.205 \text{ K} \end{aligned}$$

$$T_b = 100.205^\circ\text{C}$$

The actual boiling point is slightly lower than this because the solution is nonideal.

### 11.5.3 Freezing-Point Depression

The phenomenon of **freezing-point depression** is analogous to that of boiling-point elevation. Here, we consider only cases in which the first solid that crystallizes from solution is the pure solvent. If solute crystallizes out with solvent, the situation is more complicated.

Pure solid solvent coexists at equilibrium with its characteristic vapor pressure, determined by the temperature (Section 10.4). Solvent in solution likewise coexists with a certain vapor pressure of solvent. If solid solvent and the solvent in solution are to coexist, they must have the *same* vapor pressure. This means that the freezing temperature of a solution can be identified as the temperature at which the vapor-pressure curve of the pure solid solvent intersects that of the solution (Fig. 11.19). As solute is added to the solution, the vapor pressure of

**FIGURE 11.19** The vapor pressure of solvent above a dilute solution, compared with that above pure liquid and solid solvent. The depression of the freezing point from  $T_f$  to  $T'_f$  is shown.

the solvent falls and the freezing point, the temperature at which the first crystals of pure solvent begin to appear, drops. The difference  $\Delta T_f = T'_f - T_f$  is therefore negative, and a freezing-point depression is observed.

The change in temperature,  $\Delta T_f$ , is once again proportional to the change in vapor pressure,  $\Delta P_1$ . For sufficiently small concentrations of solute, the freezing-point depression is related to the total molality,  $m$  (by analogy with the case of boiling-point elevation), through

$$\Delta T_f = T'_f - T_f = -K_f m \quad [11.8]$$

where  $K_f$  is a positive constant that depends only on the properties of the solvent (see Table 11.2). Freezing-point depression is responsible for the fact that seawater, containing dissolved salts, has a slightly lower freezing point than fresh water. Concentrated salt solutions have still lower freezing points. Salt spread on an icy road reduces the freezing point of the ice, so the ice melts.

Measurements of the drop in the freezing point, like those of elevation of the boiling point, can be used to determine molar masses of unknown substances. If a substance dissociates in solution, the *total* molality of all species present (ionic or neutral) must be used in the calculation.

#### EXAMPLE 11.14

The number of moles of the major dissolved species in a 1.000-L sample of seawater are as follows. Estimate the freezing point of the seawater, assuming  $K_f = 1.86 \text{ K kg mol}^{-1}$  for water.

$\text{Na}^+$	0.458 mol	$\text{Cl}^-$	0.533 mol
$\text{Mg}^{2+}$	0.052 mol	$\text{SO}_4^{2-}$	0.028 mol
$\text{Ca}^{2+}$	0.010 mol	$\text{HCO}_3^-$	0.002 mol
$\text{K}^+$	0.010 mol	$\text{Br}^-$	0.001 mol
Neutral species	0.001 mol		

#### Solution

Because water has a density of  $1.00 \text{ g cm}^{-3}$ , 1.00 L of water weighs 1.00 kg. For dilute *aqueous* solutions, the number of moles per kilogram of solvent (the molality,  $m$ ) is therefore approximately equal to the number of moles per liter. The total molality, obtained by adding the individual species molalities just given, is  $m = 1.095 \text{ mol kg}^{-1}$ . Then

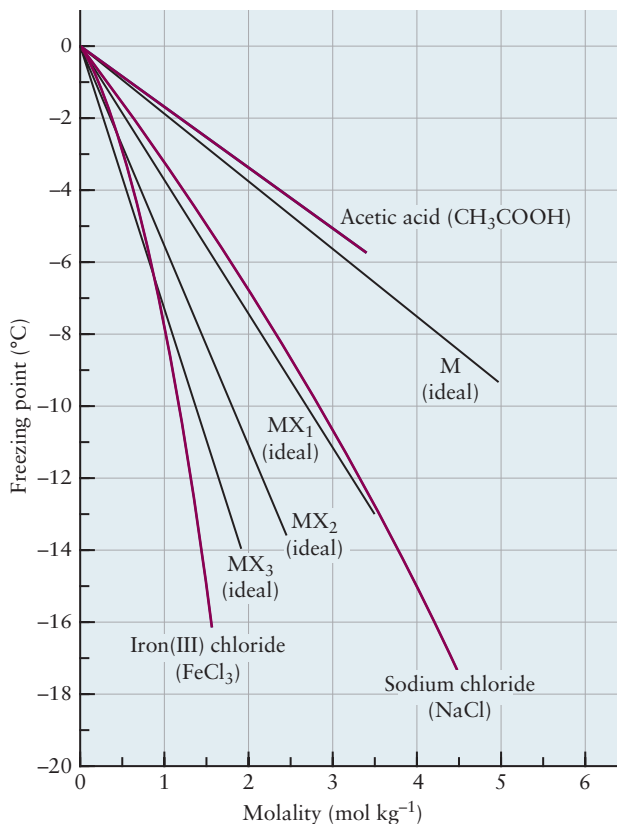

$$\Delta T = -K_f m = -(1.86 \text{ K kg mol}^{-1})(1.095 \text{ mol kg}^{-1}) = -2.04 \text{ K}$$

The seawater should freeze at approximately  $-2^\circ\text{C}$ . Nonideal solution effects make the actual freezing point slightly higher than this.

**Related Problems:** 47, 48

Both freezing-point depression and boiling-point elevation can be used to determine whether a species of known molar mass dissociates in solution (Fig. 11.20), as the following example shows.

**FIGURE 11.20** The heavy colored lines give the observed depression of the freezing point of water by acetic acid, NaCl, and FeCl<sub>3</sub> as the molality of the solutions increases. Straight black lines sketch the predicted ideal behavior for one through four moles of particles per mole in solution. The experimental curve for NaCl (which gives *two* moles of dissolved particles) stays close to the ideal straight line for MX; the experimental curve for FeCl<sub>3</sub> (which gives *four* moles of dissolved particles) stays fairly close to the ideal straight line for MX<sub>3</sub>. The pattern suggests that acetic acid dissolves to give one mole of particles per mole of solute. As the molalities of the solutions increase, the observed freezing-point depressions deviate in varying ways from the straight lines.

### EXAMPLE 11.15

When 0.494 g of K<sub>3</sub>Fe(CN)<sub>6</sub> is dissolved in 100.0 g of water, the freezing point is found to be  $-0.093^{\circ}\text{C}$ . How many ions are present for each formula unit of K<sub>3</sub>Fe(CN)<sub>6</sub> dissolved?

#### Solution

The total molality of all species in solution is

$$m = \frac{-\Delta T_f}{K_f} = \frac{0.093 \text{ K}}{1.86 \text{ K kg mol}^{-1}} = 0.050 \text{ mol kg}^{-1}$$

Because the molar mass of K<sub>3</sub>Fe(CN)<sub>6</sub> is 329.25 g mol<sup>-1</sup>, the total molality if *no* dissociation had taken place would be

$$\left( \frac{0.494 \text{ g}}{329.25 \text{ g mol}^{-1}} \right) \frac{1}{0.100 \text{ kg}} = 0.0150 \text{ mol kg}^{-1}$$

This is between one fourth and one third of the measured total molality in solution, so each K<sub>3</sub>Fe(CN)<sub>6</sub> must dissociate into three to four ions. In fact, the dissociation that occurs is

Deviations from ideal solution behavior have reduced the effective total molality from 0.060 to 0.050 mol kg<sup>-1</sup>.

**Related Problems:** 51, 52

## 11.5.4 Osmotic Pressure

The fourth colligative property is particularly important in cellular biology because it plays a vital role in the transport of molecules across cell membranes. Such membranes are **semipermeable**, allowing small molecules such as water to pass through while blocking the passage of large molecules such as proteins and carbohydrates. A semipermeable membrane (for example, common cellophane) can be used to separate small solvent molecules from large solute molecules. In

**FIGURE 11.21** When a carrot is immersed in saltwater (left), water flows out into the solution, causing the carrot to shrink. The osmotic pressure outside the cells of the vegetable is greater than that inside. A carrot left in pure water (right) does not shrivel. Note that solvent molecules flow through a semi-permeable membrane from regions of low osmotic pressure to regions of high osmotic pressure. This is opposite to the direction of flow caused by differences in ordinary hydrostatic pressure.

Figure 11.21 a carrot shrivels as water in the carrot passes into the salty surrounding solution.

Suppose a solution is contained in an inverted tube, the lower end of which is covered by a semipermeable membrane. This solution has a solute concentration of  $c$  moles per liter. When the end of the tube is inserted in a beaker of pure solvent (Fig. 11.22), solvent flows from the beaker into the tube. The volume of the solution increases, and the solvent rises in the tube until, at equilibrium, it reaches a height,  $h$ , above the solvent in the beaker. The pressure on the solution side of the membrane is greater than the atmospheric pressure on the surface of the pure solvent by an amount given by the **osmotic pressure**,  $\pi$ :

$$\pi = \rho gh \quad [11.9]$$

where  $\rho$  is the density of the solution ( $1.00 \text{ g cm}^{-3}$  for a dilute aqueous solution) and  $g$  is the acceleration due to gravity ( $9.807 \text{ m s}^{-2}$ ).

For example, a height,  $h$ , of 0.17 m corresponds to an osmotic pressure for a dilute aqueous solution of

$$\begin{aligned} \pi &= [(1.00 \text{ g cm}^{-3})(10^{-3} \text{ kg g}^{-1})(10^6 \text{ cm}^3 \text{ m}^{-3})](9.807 \text{ m s}^{-2})(0.17 \text{ m}) \\ &= 1.7 \times 10^3 \text{ kg m}^{-1} \text{ s}^{-2} = 1.7 \times 10^3 \text{ Pa} \end{aligned}$$

$$\pi (\text{atm}) = \frac{1.7 \times 10^3 \text{ Pa}}{1.013 \times 10^5 \text{ Pa atm}^{-1}} = 0.016 \text{ atm}$$

This example illustrates how accurately very small osmotic pressures can be measured.

In 1887, Jacobus van't Hoff discovered an important relation among osmotic pressure,  $\pi$ , concentration,  $c$ , and absolute temperature,  $T$ :

$$\pi = cRT \quad [11.10]$$

$R$  is the gas constant, equal to  $0.08206 \text{ L atm mol}^{-1} \text{ K}^{-1}$  if  $\pi$  is expressed in atmospheres and  $c$  in moles per liter. Because  $c = n/V$ , where  $n$  is the number of moles of solute and  $V$  is the volume of the solution, van't Hoff's equation can be rewritten as

$$\pi V = nRT$$

which bears a striking similarity to the ideal gas law. With this relation, the molar mass of a dissolved substance can be determined from the osmotic pressure of its solution.

**FIGURE 11.22** In this device to measure osmotic pressure, the semipermeable membrane allows solvent, but not solute, molecules to pass through. This results in a net flow of solvent into the tube until equilibrium is achieved, with the level of solution at a height,  $h$ , above the solvent in the beaker. Once this happens, the solvent molecules pass through the membrane at the same rate in both directions.

**EXAMPLE 11.16**

A chemist dissolves 2.00 g of a protein in 0.100 L water. The osmotic pressure is 0.021 atm at 25°C. What is the approximate molar mass of the protein?

**Solution**

The concentration in moles per liter is

$$c = \frac{\pi}{RT} = \frac{0.021 \text{ atm}}{(0.08206 \text{ L atm mol}^{-1} \text{ K}^{-1})(298 \text{ K})}$$

$$= 8.6 \times 10^{-4} \text{ mol L}^{-1}$$

Now 2.00 g dissolved in 0.100 L gives the same concentration as 20.0 g in 1.00 L. Therefore,  $8.6 \times 10^{-4}$  mol of protein must weigh 20.0 g, and the molar mass is

$$M = \frac{20.0 \text{ g}}{8.6 \times 10^{-4} \text{ mol}} = 23,000 \text{ g mol}^{-1}$$

**Related Problems: 53, 54**

Osmotic pressure is particularly useful for measuring molar masses of large molecules such as proteins, whose solubilities may be low. In the case given in Example 11.16, the height difference  $h$  is 22 cm, an easily measured quantity. By contrast, the other three colligative properties in this example would show small effects:

$$\text{Vapor-pressure lowering} = 4.8 \times 10^{-7} \text{ atm}$$

$$\text{Boiling-point elevation} = 0.00044 \text{ K}$$

$$\text{Freezing-point depression} = 0.0016 \text{ K}$$

All these changes are too small for accurate measurement. As with the other techniques, the *total* number of moles of solute species determines the osmotic pressure if dissociation occurs.

Osmosis has other important uses. In some parts of the world, potable water is a precious commodity. It can be obtained much more economically by desalinating brackish waters, through a process called **reverse osmosis**, than by distillation. When an ionic solution in contact with a semipermeable membrane has a pressure applied to it that exceeds its osmotic pressure, water of quite high purity passes through. Reverse osmosis is also used to control water pollution.

## 11.6 Phase Equilibrium in Solutions: Volatile Solutes

The preceding section described the properties of solutions of nonvolatile solutes in liquid solvents. The concept of an ideal solution can be extended to mixtures of two or more components, each of which is volatile. In this case, an ideal solution is one in which the vapor pressure of *each* species present is proportional to its mole fraction in solution over the whole range of mole fraction:

$$P_i = X_i P_i^\circ$$

where  $P_i^\circ$  is the vapor pressure (at a given temperature) of pure substance  $i$ ,  $X_i$  is its mole fraction in solution, and  $P_i$  is its partial vapor pressure over the solution. This is a generalization of Raoult's law to each component of a solution.

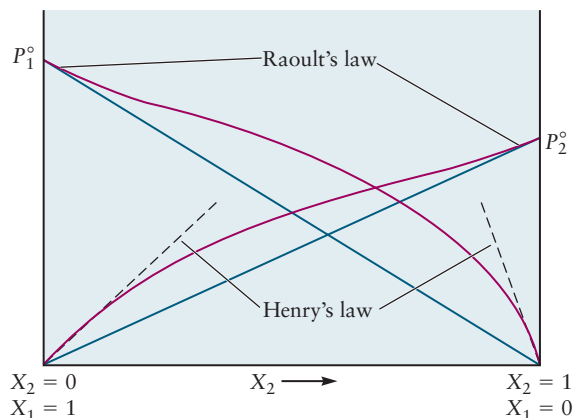

For an ideal mixture of two volatile substances, the vapor pressure of component 1 is

$$P_1 = X_1 P_1^\circ$$

and that of component 2 is

$$P_2 = X_2 P_2^\circ = (1 - X_1) P_2^\circ$$

**FIGURE 11.23** Vapor pressures above a mixture of two volatile liquids. Both ideal (blue lines) and nonideal behaviors (red curves) are shown. Positive deviations from ideal solution behavior are illustrated, although negative deviations are observed for other nonideal solutions. Raoult's and Henry's laws are shown as dilute solution limits for the nonideal mixture; the markers explicitly identify regions where Raoult's law represents the actual behavior of the major component. Henry's law is followed by the component with very small mole fraction, so the dashed lines represent the slope of the tangent line to the red curve as the corresponding mole fraction approaches zero.

The vapor pressures for such an ideal solution are shown in Figure 11.23, together with typical vapor pressures for a solution that shows positive deviations from ideal behavior.

### 11.6.1 Henry's Law

At sufficiently low mole fraction  $X_2$ , the vapor pressure of component 2 (even in a nonideal solution) is proportional to  $X_2$ :

$$P_2 = k_2 X_2 \quad [11.11]$$

where  $k_2$  is a constant. For  $X_1$  small ( $X_2$  near 1),

$$P_1 = k_1 X_1 = k_1 (1 - X_2)$$

This linear vapor pressure of what is called the solute (because it is present at small mole fraction) is known as **Henry's law**: The vapor pressure of a volatile dissolved substance is proportional to the mole fraction of that substance in solution. Whenever Raoult's law is valid for a solvent, Henry's law is valid for the solute (see Fig. 11.23).

One familiar application of Henry's law is in the carbonation of beverages. If the partial pressure of  $\text{CO}_2$  above a solution is increased, the amount dissolved in the solution increases proportionately. When the beverage can is opened, dissolved gas bubbles out of solution in response to the lower  $\text{CO}_2$  pressure outside. Henry's law is important in biology, where gases such as oxygen dissolve in blood and other bodily fluids, and in environmental chemistry, where volatile pollutants can move between bodies of water and the atmosphere.

#### EXAMPLE 11.17

The Henry's law constant for oxygen dissolved in water is  $4.34 \times 10^4$  atm at  $25^\circ\text{C}$ . If the partial pressure of oxygen in air is 0.20 atm under ordinary atmospheric conditions, calculate the concentration (in moles per liter) of dissolved oxygen in water that is in equilibrium with air at  $25^\circ\text{C}$ .

#### Solution

Henry's law is used to calculate the mole fraction of oxygen in water:

$$X_{\text{O}_2} = \frac{P_{\text{O}_2}}{k_{\text{O}_2}} = \frac{0.20 \text{ atm}}{4.34 \times 10^4 \text{ atm}} = 4.6 \times 10^{-6}$$

(Continued)

Next, the mole fraction is converted to molarity. One liter of water weighs 1000 g, so it contains

$$\frac{1000 \text{ g H}_2\text{O}}{18.02 \text{ g mol}^{-1}} = 55.5 \text{ mol water}$$

Because  $X_{\text{O}_2}$  is so small,  $n_{\text{H}_2\text{O}} + n_{\text{O}_2}$  is close to  $n_{\text{H}_2\text{O}}$ , and it can be written as

$$X_{\text{O}_2} = \frac{n_{\text{O}_2}}{n_{\text{H}_2\text{O}} + n_{\text{O}_2}} \approx \frac{n_{\text{O}_2}}{n_{\text{H}_2\text{O}}}$$

$$4.6 \times 10^{-6} = \frac{n_{\text{O}_2}}{55.5 \text{ mol}}$$

Thus, the number of moles of oxygen in 1 L water is

$$n_{\text{O}_2} = (4.6 \times 10^{-6})(55.5 \text{ mol}) = 2.6 \times 10^{-4} \text{ mol}$$

and the concentration of dissolved  $\text{O}_2$  is  $2.6 \times 10^{-4} \text{ M}$ .

**Related Problems: 57, 58**

### 11.6.2 Distillation

The vapor pressures of the pure components of an ideal solution usually differ, and for this reason, such a solution has a composition different from that of the vapor phase with which it is in equilibrium. This can best be seen in an example.

Hexane ( $\text{C}_6\text{H}_{14}$ ) and heptane ( $\text{C}_7\text{H}_{16}$ ) form a nearly ideal solution over the whole range of mole fractions. At  $25^\circ\text{C}$ , the vapor pressure of pure hexane is  $P_1^\circ = 0.198 \text{ atm}$ , and that of pure heptane is  $P_2^\circ = 0.0600 \text{ atm}$ . Suppose a solution contains 4.00 mol of hexane and 6.00 mol of heptane, and that its mole fractions are, therefore,  $X_1 = 0.400$  and  $X_2 = 0.600$ . The vapor in equilibrium with this ideal solution has partial pressures

$$P_{\text{hexane}} = P_1 = X_1 P_1^\circ = (0.400)(0.198 \text{ atm}) = 0.0792 \text{ atm}$$

$$P_{\text{heptane}} = P_2 = X_2 P_2^\circ = (0.600)(0.0600 \text{ atm}) = 0.0360 \text{ atm}$$

From Dalton's law, the total pressure is the sum of these partial pressures:

$$P_{\text{total}} = P_1 + P_2 = 0.1152 \text{ atm}$$

If  $X'_1$  and  $X'_2$  are the mole fractions in the vapor, then

$$X'_1 = \frac{0.0792 \text{ atm}}{0.1152 \text{ atm}} = 0.688$$

$$X'_2 = 1 - X'_1 = \frac{0.0360 \text{ atm}}{0.1152 \text{ atm}} = 0.312$$

The liquid and the vapor with which it is in equilibrium have different compositions (Fig. 11.24), and the vapor is enriched in the more volatile component.

Suppose some of this vapor is removed and condensed to become liquid. The vapor in equilibrium with this new solution would be still richer in the more volatile component, and the process could be continued further (see Fig. 11.24). This progression underlies the technique of separating a mixture into its pure components by **fractional distillation**, a process in which the components are successively evaporated and recondensed. What we have described so far corresponds to a constant-temperature process, but actual distillation is conducted at constant total pressure. The vapor pressure–mole fraction plot is transformed into a boiling temperature–mole fraction plot (Fig. 11.25). Note that the component with the lower vapor pressure (component 2) has the higher boiling point,  $T_b^2$ . If the temperature of a solution of a certain composition is raised

**FIGURE 11.24** The composition of the vapor above a solution differs from the composition of the liquid with which it is in equilibrium. Here, the upper (straight) line is the total pressure of the vapor in equilibrium with an ideal solution having mole fraction  $X_2$  of component 2. By moving horizontally from that line to a point of intersection with the lower curve, we can locate the mole fraction  $X'_2$  of component 2 in the vapor (red arrow). Subsequent condensations and vaporizations are shown by blue arrows.

until it touches the liquid line in the plot, the vapor in equilibrium with the solution is richer in the more volatile component 1. Its composition lies at the intersection of the horizontal constant-temperature line and the equilibrium vapor curve.

A liquid can be vaporized in different ways. It can simply be boiled until it is entirely vaporized and the final composition of the vapor is the same as that of the original liquid. It is clear that such a mixture boils over a range of temperatures, rather than at a single  $T_b$  like a pure liquid. Alternatively, if the boiling is stopped midway, the vapor fraction that has boiled off can be collected and recondensed. The resulting liquid (the condensate) will be richer in component 1 than was the original solution. By repeating the process again and again, mixtures successively richer in component 1 will be obtained. This is the principle behind the *distillation column* (Fig. 11.26). Throughout the length of the tube, such evaporations and recondensations take place, and this allows mixtures to be separated into their constituent substances. Such a process is used to separate nitrogen and oxygen in air; the air is liquefied and then distilled, with the lower boiling nitrogen ( $T_b = -196^\circ\text{C}$ ) vaporizing before the oxygen ( $T_b = -183^\circ\text{C}$ ).

Nonideal solutions may have more complicated behavior. A mixture showing large *negative* deviations from Raoult's law (one in which solute–solvent forces are strongly attractive) will show a boiling-point *maximum* (Fig. 11.27a). A solution at the maximum is called a *maximum-boiling azeotrope*; an example

**FIGURE 11.25** The boiling point of an ideal solution varies with the composition of the solution. The upper curve is the boiling temperature referred to the vapor composition, and the lower curve is the boiling temperature referred to the liquid composition. The vapors boiling off a solution that has a 0.600-mol fraction of component 2 are enriched in the more volatile component 1 to the extent that their mole fraction of component 2 is only 0.312 (red arrow). The subsequent blue arrows show the further steps used in obtaining nearly pure component 1 by fractional distillation.

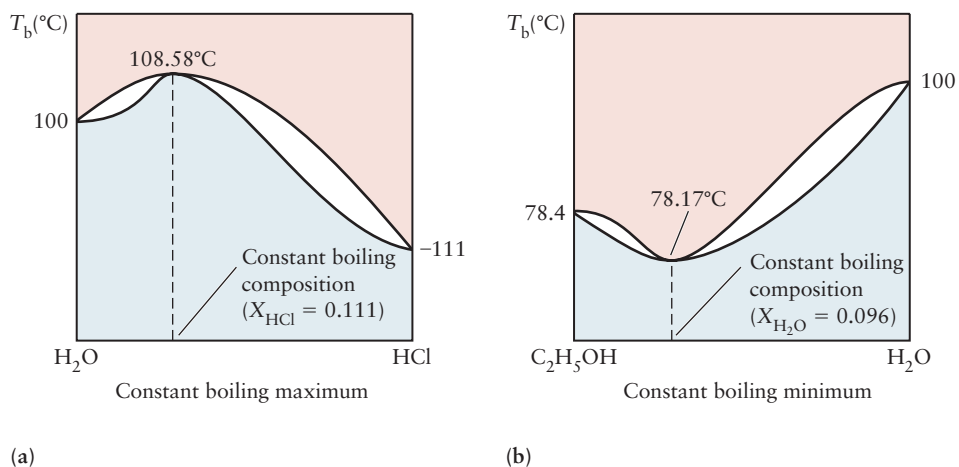

**FIGURE 11.26** In a distillation column, temperature decreases with height in the column. The less volatile components condense and fall back to the flask, but the more volatile ones continue up the column into the water-cooled condenser, where they condense and are recovered in the receiver.

is that formed by the  $\text{H}_2\text{O}/\text{HCl}$  system. The boiling-point maximum occurs in this case at  $108.58^\circ\text{C}$  and 1 atm pressure for a composition of 20.22% HCl by mass. A mixture showing large *positive* deviations from ideal behavior may show a boiling-point *minimum* (see Fig. 11.27b) and a corresponding *minimum-boiling azeotrope*. Ethanol and water form such an azeotrope with a normal boiling point of  $78.17^\circ\text{C}$  and a composition of 4% water by mass. In this case, attractive forces between ethanol molecules and between water molecules are stronger than those between ethanol and water, so the solution boils at a lower temperature than either pure component. An azeotrope behaves like a single-component fluid in that it boils at a well-defined temperature and the solution and vapor have the same composition. A mixture of two substances

**FIGURE 11.27** Dependence of boiling temperature on mole fraction for (a) maximum- and (b) minimum-boiling azeotropes. The coordinates are not to scale.

that form an azeotrope cannot be separated by fractional distillation into two pure substances, but rather into only one pure substance and a mixture with the azeotropic composition. A mixture of 50% ethanol and water, for example, can be distilled to obtain pure water and an azeotropic mixture containing 4% water and 96% ethanol. The last 4% of water cannot be removed by distillation at atmospheric pressure to obtain pure ethanol.

## 11.7 Colloidal Suspensions

© iMfoto/Shutterstock.com

FIGURE 11.28 A natural opal.

A **colloid** is a mixture of two or more substances in which one phase is suspended as a large number of small particles in a second phase. The dispersed substance and the background medium may be any combination of gas, liquid, or solid. Examples of colloids include aerosol sprays (liquid suspended in gas), smoke (solid particles in air), milk (fat droplets and solids in water), mayonnaise (water droplets in oil), and paint (solid pigment particles in oil for oil-based paints, or pigment and oil dispersed in water for latex paints). Colloidal particles are larger than single molecules, but are too small to be seen by the eye; their dimensions typically range from  $10^{-9}$  to  $10^{-6}$  m in diameter. Their presence can be seen most dramatically in the way in which they scatter light; a familiar example is the passage of light from a movie projector through a suspension of small dust particles in air. The gemstone opal has remarkable optical properties that arise from colloidal water suspended in solid silicon dioxide (Fig. 11.28).

Although some colloids settle out into two separate phases if left standing long enough, others persist indefinitely; a suspension of gold particles prepared by Michael Faraday in 1857 shows no apparent settling to date. In many colloids, the particles have net positive or negative charges on their surfaces, balanced by an opposite charge of ions in solution. The settling out of such colloids is speeded by dissolving salts in the solution, a process called **flocculation**. The salts reduce the repulsive electrostatic forces between the suspended particles, causing aggregation and sedimentation (Fig. 11.29). Flocculation occurs in river deltas; when river water containing suspended clay particles meets the salt water of the ocean, the clay settles out as open, low-density sediments. Flocculating agents are deliberately added to paints so that the pigment will settle in a loosely packed sediment. When the paint is stirred, the pigment is redispersed through the medium. In the absence of such agents, the suspended particles tend to settle in compact sediments that are difficult to resuspend.

FIGURE 11.29 When a salt is added to a colloidal dispersion (a), the repulsive forces between the colloidal particles are reduced and aggregation occurs (b). Eventually, the aggregated particles fall to the bottom of the container as low-density sediment (c).

**FIGURE 11.30** (a) This colloidal suspension of  $\text{PbCrO}_4$  appears cloudy. (b) After flocculation, the precipitate settles to the bottom.

In some cases, the formation of a colloid is not desirable, as in the precipitation of a solid from solution (see Section 11.2). Especially with metal sulfides, the solid precipitate may appear as a colloidal suspension with particles small enough to pass through ordinary filter paper (Fig. 11.30). If this happens, a precipitated solid can be separated out only by flocculation, centrifugation, or forcing the suspension through a membrane, such as cellophane, that permits passage of only the small solvent molecules.

Suspended particles are in a constant state of motion, called **Brownian motion** after Robert Brown, a Scottish botanist who used a microscope to observe the motion of pollen particles in water. Brownian motion results from the constant random buffeting of the particles by solvent molecules. In 1905, Albert Einstein showed how the motion of Brownian particles could be described on a microscopic level; his work provided one of the most striking and convincing verifications of the molecular hypothesis and of the kinetic theory of matter and led to a fairly accurate determination of Avogadro's number.

## CHAPTER SUMMARY

When pure substance A is mixed with pure substance B, the resulting solution has properties different from those of the pure substances because the intermolecular forces around each molecule are now quite different. In aqueous solutions, the dissolved species are described as solute ions or molecules surrounded by solvation shells of solvent molecules, perhaps interacting with the solute molecule by hydrogen bonding or ion-dipole forces. Solutions can be in equilibrium in solid, liquid, or vapor phases, but the conditions under which phases coexist are different from those for the pure solvent. Changes in vapor pressure, freezing point, boiling point, and osmotic pressure are explained quantitatively by the number of nonvolatile solute species in the solution. When both species are volatile, the composition of the vapor phase is different from the composition of the solution, as described by Raoult's law and Henry's law, and the solution components can be separated by distillation. Many chemical reactions are carried out in liquid solutions, frequently by mixing solutions of the reactants. We write balanced chemical equations to describe the stoichiometry of reactions in solutions, and we count the number of moles of each reactant in a volume of solution through its concentration expressed in molarity. Solution stoichiometry describes many practical applications in acid-base and redox chemistry and is the basis for quantitative analytical techniques in these fields.

## CONCEPTS AND SKILLS

### Section 11.1 – Composition of Solutions

Express the concentration of a solute in solution in units of mass percentage, molarity, molality, and mole fraction (Problems 1–8).

- Solutions are described by their composition and method of preparation. Each definition of concentration specifies the procedure for preparing the solution.
  - Mole fraction:  $X_i = n_i/n_{\text{tot}}$  where  $n_i$  is the number of moles of component  $i$  and  $n_{\text{tot}}$  is the total number of moles of all components
  - Molarity:  $c = \text{moles of solute per liter of solution}$ . The unit  $\text{mol L}^{-1}$  is given the symbol M.
  - Molality:  $m = \text{moles of solute per kg of solvent}$
  - For dilute, aqueous solutions  $m \approx c$

Describe how a solution of a given molarity is prepared and the effect on dilution of molarity (Problems 9–12).

- The procedure for preparing the solution is illustrated stepwise in Figure 11.1. A volume  $V_i$  of the solution at concentration  $c_i$  contains  $c_i V_i$  moles of solute. Adding solvent to increase the volume to  $V_f$  reduces the concentration to  $c_f = (c_i V_i)/V_f$ , the moles of solute in the final solution divided by the volume of the final solution.

### Section 11.2 – Nature of Dissolved Species

Describe the formation of a solution in molecular terms by comparing intermolecular forces in the pure phases and in the solution.

- Solutions are formed by breaking the bonds between molecules or ions in the solute and dispersing these species throughout the solvent.
  - The solute species are surrounded by solvent molecules, and experience very different intermolecular forces than in their pure, undissolved state.
  - Energy is required to disrupt the structure of the pure solute and solvent, and energy is released due to the attractive interactions between the solute and solvent. Formation of a solution can be endothermic or exothermic, depending on the difference between these energies.
  - Ionic solutes dissociate in solution, whereas molecular solutes remain intact when dispersed in solution.
  - When water is the solvent, the solution is called aqueous and solutes are labeled (aq).
  - In aqueous solutions, solute species are surrounded by solvation shells of solvent molecules held in place by intermolecular forces, primarily hydrogen bonding and ion–dipole forces.

### Section 11.3 – Reaction Stoichiometry in Solutions: Acid–Base Titrations

Calculate the number of moles of substances reacting during a solution-phase reaction such as acid–base titration (Problems 15–26).

- Acid–base titration is an analytical technique for finding the concentration of acid or base in an unknown solution.
  - Stoichiometry of reactions in solutions is described by balanced equations that relate the number of moles of each reactant and product. The number of moles of each reaction species in a volume of solution is given by  $n_i = c_i V$  where  $c_i$  is the concentration in  $\text{mol L}^{-1}$  of species  $i$  in the solution.

- In a neutralization reaction, if the titrant A and the molecule B in the solution of unknown concentration react in a 1:1 stoichiometric ratio, the endpoint is achieved when the number of moles of A added equals the number of moles of B initially in the unknown sample.
- In titrations a measured volume of a solution with known concentration reacts to neutralize a known volume of sample whose concentration is unknown. The endpoint, at which neutralization is achieved, is signified by an endpoint indicator, most often a color change. At the endpoint, we determine the molarity of the unknown sample using the concept in the prior bullet point.

### Section 11.4 – Reaction Stoichiometry in Solutions: Oxidation–Reduction Titrations

*Balance equations for redox reactions in aqueous solution, using the half-reaction method, and calculate the concentrations of substances during redox titrations (Problems 27–40).*

- In oxidation–reduction (redox) reactions electrons are transferred between reacting species as they combine to form products. Reactants that lose electrons are oxidized. Reactants that gain electrons are reduced. These reactions are coupled; it is not possible to have oxidation without reduction, and vice versa.
- Balancing the equations for redox reactions involves special procedures. The steps are:
  - Assign oxidation numbers as described in Section 3.12.
  - Write unbalanced half-equations for the species being oxidized and the species being reduced.
  - Balance all atoms except oxygen and hydrogen.
  - Determine whether the reaction takes place in acidic or basic solution.
  - In acidic solution, add one  $\text{H}_3\text{O}^+$  to the side that needs an extra H atom and then  $\text{H}_2\text{O}$  to the other side.
  - In basic solution, add one  $\text{H}_2\text{O}$  to the side that needs an extra H atom and then  $\text{OH}^-$  to the other side.
  - Balance charge transfer in each half-equation by inserting electrons as reactants or products.
  - Multiply the two half-equations by numbers that make the number of electrons given off in oxidation the same as the number gained in reduction. Add the two half-equations together.
- The number of moles of the reactant A added during the titration is the concentration of the titrant A in  $\text{mol L}^{-1}$  multiplied by the volume of the titrant added in L.
- The number of moles of the reactant B consumed during the titration is determined from the number of moles of titrant (reactant A) added and the coefficients in the balanced equation.

### Section 11.5 – Phase Equilibrium in Solutions: Nonvolatile Solutes

*Calculate the molar mass of a nonvolatile solute from the changes it causes in the colligative properties (vapor-pressure lowering, boiling-point elevation, freezing-point lowering, or osmotic pressure) of its dilute solution (Problems 41–56).*

- Like pure substances, solutions can have solid, liquid, and gaseous phases in equilibrium with one another. The conditions where phases coexist—such as

boiling points, freezing points, and vapor pressure—have different values in solution than in the pure solvent. The colligative properties of solutions describe how nonvolatile solvents cause these changes in properties of the solvent. These changes depend only on the number of solute particles, not on their nature. Vapor pressure lowering, boiling point elevation, freezing point depression, and osmotic pressure are all treated with empirical equations.

- Vapor pressure lowering:  $\Delta P_1 = -X_2 P_1^\circ$  where  $X_2$  is the mole fraction of the solute and  $P_1^\circ$  is the vapor pressure of the pure solvent.
- Boiling point elevation:  $\Delta T = mK_b$  (the constants have been tabulated)
- Freezing point depression:  $\Delta T = -mK_f$  (the constants have been tabulated)
- A solution in contact with its pure solvent across a semi-permeable membrane experiences an increase in pressure as pure solvent flows through the membrane into the solution. This osmotic pressure can be measured quite accurately, and through the equation  $\pi V = nRT$  permits determination of the molecular weight of the solute.

### Section 11.6 – Phase Equilibrium in Solutions: Volatile Solutes

*Discuss the meaning of Henry's law, and use it to calculate the solubilities of gases in liquids (Problems 57–60).*

- Henry's law relates the solubility of a gas in a liquid to the pressure of the gas above the liquid. If the pressure of the gas is increased, more gas will be dissolved.

*Relate the total pressure and composition of the vapor in equilibrium with an ideal two-component solution to the composition of the solution and the vapor pressures of its pure components (Problems 61–64).*

- When the solute is volatile, the vapor pressure in equilibrium with the solution has contributions from both solute and solvent.
  - Raoult's law: vapor pressure of the solvent  $P_1 = X_1 P_1^\circ$
  - Henry's law: vapor pressure of the solute  $P_2 = X_2 k_2$

The partial pressures of the solute and solvent in the vapor will be different from their concentrations in the solution. The vapor will be richer in the more volatile component than is the solution.

*Explain how distillation is used to separate the volatile components of a binary liquid solution.*

- The vapor will be richer in the more volatile component than in the solution. The process of distillation exploits this fact to separate the components of the solution by heating the solution to the temperature where the more volatile component boils, removing the vapor, and condensing it to the liquid state.

### Section 11.7 – Colloidal Suspensions

*Describe the physical properties of a colloidal suspension.*

- A colloidal suspension consists of at least two immiscible substances (such as oil and water) and has one of the substances dispersed throughout the other as small particles, ranging in size from 1 nanometer to 1 micrometer. Particles in this size range effectively scatter incoming light and produce special visual effects.

## CUMULATIVE EXERCISE

**FIGURE 11.31** Tapping sap from sugar maple trees.

### Manufacturing of Maple Syrup

The sap in a maple tree can be described as an approximately 3.0% (by mass) solution of sucrose ( $C_{12}H_{22}O_{11}$ ) in water (see Fig. 11.31). Sucrose does not dissociate to any significant extent in aqueous solution.

- At  $20^{\circ}\text{C}$ , the density of sap is  $1.010\text{ g cm}^{-3}$ . Calculate the molarity of sucrose in sap.
- A typical maple tree yields about 12 gallons of sap per year. Calculate how many grams of sucrose are contained in this volume of sap (1 gallon = 3.785 L).
- The rising of sap in trees is caused largely by osmosis; the concentration of dissolved sucrose in sap is higher than that of the groundwater outside the tree. Calculate the osmotic pressure of a sap solution and the height to which the sap should rise above the ground on a day when the temperature is  $20^{\circ}\text{C}$ . Approximate the groundwater as pure (although, in fact, it typically contains 0.01 to 0.03 M dissolved species). Express the answer in meters and in feet (1 m = 3.28 ft).
- To produce maple syrup from sap, the sap is boiled to reduce its water content. Calculate the normal boiling point of a sap solution.
- Maple syrup is the concentrated sap solution that results when most of the water is boiled off. The syrup has a composition of approximately 64% (by mass) sucrose and 36% water, with flavoring components present in small concentrations. If the density of the maple syrup is  $1.31\text{ g cm}^{-3}$ , calculate the mole fraction, molarity, and molality of sucrose in maple syrup.
- What volume (in gallons) of maple syrup can be obtained from the sap in one typical tree?
- In the presence of vanadium(V) oxide, dinitrogen tetroxide oxidizes sucrose to oxalic acid ( $\text{H}_2\text{C}_2\text{O}_4$ ) according to the following equation:

Calculate the mass of  $\text{N}_2\text{O}_4$  that will react completely with 7.00 L of the sap solution from part (a), and give the concentration of oxalic acid that results.

### Answers

- 0.089 M
- $1.4 \times 10^3$  g sucrose
- $\pi = 2.1\text{ atm}$ ; height = 22 m = 72 ft
- $100.046^{\circ}\text{C}$
- Mole fraction = 0.086; molarity = 2.4 M; molality =  $5.2\text{ mol kg}^{-1}$
- 0.56 gallon
- $5.2 \times 10^2$  g  $\text{N}_2\text{O}_4$ ; 0.53 M

## PROBLEMS

Answers to problems whose numbers are red appear in Appendix G. Problems that are more challenging are indicated with asterisks.

### 11.1 Composition of Solutions

- A patient has a “cholesterol count” of 214. Like many blood-chemistry measurements, this result is measured in units of milligrams per deciliter ( $\text{mg dL}^{-1}$ ).
  - Determine the molar concentration of cholesterol in this patient’s blood, taking the molar mass of cholesterol to be  $386.64 \text{ g mol}^{-1}$ .
  - Estimate the molality of cholesterol in the patient’s blood.
  - If 214 is a typical cholesterol reading among men in the United States, determine the volume of such blood required to furnish  $8.10 \text{ g}$  of cholesterol.
- In many states, a person is legally intoxicated if his or her blood has a concentration of  $0.10 \text{ g}$  (or more) of ethyl alcohol ( $\text{C}_2\text{H}_5\text{OH}$ ) per deciliter. Express this “threshold concentration” in  $\text{mol L}^{-1}$ .
- A solution of hydrochloric acid in water is  $38.00\%$  hydrochloric acid by mass. Its density is  $1.1886 \text{ g cm}^{-3}$  at  $20^\circ\text{C}$ . Compute its molarity, mole fraction, and molality at this temperature.
- A solution of acetic acid and water contains  $205.0 \text{ g L}^{-1}$  of acetic acid and  $820.0 \text{ g L}^{-1}$  of water.
  - Compute the density of the solution.
  - Compute the molarity, molality, mole fraction, and mass percentage of acetic acid in this solution.
  - Take the acetic acid as the solvent, and do the same for water as the solute.
- A  $6.0835 \text{ M}$  aqueous solution of acetic acid ( $\text{C}_2\text{H}_4\text{O}_2$ ) has a density of  $1.0438 \text{ g cm}^{-3}$ . Compute its molality.
- A  $1.241 \text{ M}$  aqueous solution of  $\text{AgNO}_3$  (used to prepare silver chloride photographic emulsions) has a density of  $1.171 \text{ g cm}^{-3}$ . Compute its molality.
- Water is slightly soluble in liquid nitrogen. At  $-196^\circ\text{C}$  (the boiling point of liquid nitrogen), the mole fraction of water in a saturated solution is  $1.00 \times 10^{-5}$ . Compute the mass of water that can dissolve in  $1.00 \text{ kg}$  of boiling liquid nitrogen.
- Some water dissolves in liquid methane at  $-161^\circ\text{C}$  to give a solution in which the mole fraction of water is  $6.0 \times 10^{-5}$ . Determine the mass of water dissolved in  $1.00 \text{ L}$  of this solution if the density of the solution is  $0.78 \text{ g cm}^{-3}$ .
- Concentrated phosphoric acid as sold for use in the laboratory is usually  $90\%$   $\text{H}_3\text{PO}_4$  by mass (the rest is water). Such a solution contains  $12.2 \text{ mol}$  of  $\text{H}_3\text{PO}_4$  per liter of solution at  $25^\circ\text{C}$ .
  - Compute the density of this solution.
  - What volume of this solution should be used in mixing  $2.00 \text{ L}$  of a  $1.00 \text{ M}$  phosphoric acid solution?

- A perchloric acid solution is  $60.0\%$   $\text{HClO}_4$  by mass. It is simultaneously  $9.20 \text{ M}$  at  $25^\circ\text{C}$ .
  - Compute the density of this solution.
  - What volume of this solution should be used in mixing  $1.00 \text{ L}$  of a  $1.00 \text{ M}$  perchloric acid solution?
- Suppose  $25.0 \text{ g}$  of solid  $\text{NaOH}$  is added to  $1.50 \text{ L}$  of an aqueous solution that is already  $2.40 \text{ M}$  in  $\text{NaOH}$ . Then water is added until the final volume is  $4.00 \text{ L}$ . Determine the concentration of the  $\text{NaOH}$  in the resulting solution.
- Suppose  $0.400 \text{ L}$  of a solution of  $0.0700 \text{ M}$  nitric acid is added to  $0.800 \text{ L}$  of a solution of  $0.0300 \text{ M}$  nitric acid, giving a total volume of  $1.200 \text{ L}$ . Calculate the concentration (molarity) of nitric acid in the resulting solution.

### 11.2 Nature of Dissolved Species

- Rewrite the following balanced equations as net ionic equations.
  - $\text{NaCl}(aq) + \text{AgNO}_3(aq) \longrightarrow \text{AgCl}(s) + \text{NaNO}_3(aq)$
  - $\text{K}_2\text{CO}_3(s) + 2 \text{HCl}(aq) \longrightarrow$   
 $2 \text{KCl}(aq) + \text{CO}_2(g) + \text{H}_2\text{O}(\ell) + 2 \text{H}_2\text{O}(\ell)$
  - $2 \text{Cs}(s) + 2 \text{H}_2\text{O}(\ell) \longrightarrow 2 \text{CsOH}(aq) + \text{H}_2(g)$
  - $2 \text{KMnO}_4(aq) + 16 \text{HCl}(aq) \longrightarrow$   
 $5 \text{Cl}_2(g) + 2 \text{MnCl}_2(aq) + 2 \text{KCl}(aq) + 8 \text{H}_2\text{O}(\ell)$
- Rewrite the following balanced equations as net ionic equations.
  - $\text{Na}_2\text{SO}_4(aq) + \text{BaCl}_2(aq) \longrightarrow \text{BaSO}_4(s) + 2 \text{NaCl}(aq)$
  - $6 \text{NaOH}(aq) + 3 \text{Cl}_2(g) \longrightarrow$   
 $\text{NaClO}_3(aq) + 5 \text{NaCl}(aq) + 3 \text{H}_2\text{O}(\ell)$
  - $\text{Hg}_2(\text{NO}_3)_2(aq) + 2 \text{KI}(aq) \longrightarrow \text{Hg}_2\text{I}_2(s) + 2 \text{KNO}_3(aq)$
  - $3 \text{NaOCl}(aq) + \text{KI}(aq) \longrightarrow$   
 $\text{NaIO}_3(aq) + 2 \text{NaCl}(aq) + \text{KCl}(aq)$

### 11.3 Reaction Stoichiometry in Solutions: Acid–Base Titrations

- When treated with acid, lead(IV) oxide is reduced to a lead(II) salt, with the liberation of oxygen:
 
$$2 \text{PbO}_2(s) + 4 \text{HNO}_3(aq) \longrightarrow 2 \text{Pb}(\text{NO}_3)_2(aq) + 2 \text{H}_2\text{O}(\ell) + \text{O}_2(g)$$
 What volume of a  $7.91 \text{ M}$  solution of nitric acid is just sufficient to react with  $15.9 \text{ g}$  of lead(IV) oxide, according to this equation?
- Phosphoric acid is made industrially by the reaction of fluorapatite,  $\text{Ca}_5(\text{PO}_4)_3\text{F}$ , in phosphate rock with sulfuric acid:
 
$$\text{Ca}_5(\text{PO}_4)_3\text{F}(s) + 5 \text{H}_2\text{SO}_4(aq) + 10 \text{H}_2\text{O}(\ell) \longrightarrow 3 \text{H}_3\text{PO}_4(aq) + 5 (\text{CaSO}_4 \cdot 2\text{H}_2\text{O})(s) + \text{HF}(aq)$$
 What volume of  $6.3 \text{ M}$  phosphoric acid is generated by the reaction of  $2.2$  metric tons ( $2200 \text{ kg}$ ) of fluorapatite?

17. The carbon dioxide produced (together with hydrogen) from the industrial-scale oxidation of methane in the presence of nickel is removed from the gas mixture in a scrubber containing an aqueous solution of potassium carbonate:

Calculate the volume of carbon dioxide (at 50°C and 1.00 atm pressure) that will react with 187 L of a 1.36 M potassium carbonate solution.

18. Nitrogen oxide can be generated on a laboratory scale by the reaction of dilute sulfuric acid with aqueous sodium nitrite:

What volume of 0.646 M aqueous  $\text{NaNO}_2$  should be used in this reaction to generate 5.00 L of nitrogen oxide at a temperature of 20°C and a pressure of 0.970 atm?

19. Write a balanced equation for the acid–base reaction that leads to the production of each of the following salts. Name the acid, base, and salt.
- |                              |                                |
|------------------------------|--------------------------------|
| (a) $\text{CaF}_2$           | (c) $\text{Zn}(\text{NO}_3)_2$ |
| (b) $\text{Rb}_2\text{SO}_4$ | (d) $\text{KCH}_3\text{COO}$   |
20. Write a balanced equation for the acid–base reaction that leads to the production of each of the following salts. Name the acid, base, and salt.
- |   |                     |
|---|---------------------|
| (a) $\text{Na}_2\text{SO}_3$                      | (c) $\text{PbSO}_4$ |
| (b) $\text{Ca}(\text{C}_6\text{H}_5\text{COO})_2$ | (d) $\text{CuCl}_2$ |
21. Hydrogen sulfide can be removed from natural gas by reaction with excess sodium hydroxide. Name the salt that is produced in this reaction. (Note: Hydrogen sulfide loses both its hydrogen atoms in the course of this reaction.)
22. During the preparation of viscose rayon, cellulose is dissolved in a bath containing sodium hydroxide and later reprecipitated as rayon using a solution of sulfuric acid. Name the salt that is a by-product of this process. Rayon production is, in fact, a significant commercial source for this salt.
23. Phosphorus trifluoride is a highly toxic gas that reacts slowly with water to give a mixture of phosphorous acid and hydrofluoric acid.
- Write a balanced chemical equation for this reaction.
  - Determine the concentration (in moles per liter) of each of the acids that result from the reaction of 1.94 L of phosphorus trifluoride (measured at 25°C and 0.970 atm pressure) with water to give a solution volume of 872 mL.
24. Phosphorus pentachloride reacts violently with water to give a mixture of phosphoric acid and hydrochloric acid.
- Write a balanced chemical equation for this reaction.
  - Determine the concentration (in moles per liter) of each of the acids that result from the complete reaction of 1.22 L of phosphorus pentachloride (measured at 215°C and 0.962 atm pressure) with enough water to give a solution volume of 697 mL.
25. To determine the concentration of a solution of nitric acid, a 100.0-mL sample is placed in a flask and titrated with a 0.1279 M solution of potassium hydroxide. A volume of 37.85 mL is required to reach the phenolphthalein endpoint. Calculate the concentration of nitric acid in the original sample.
26. The concentration of aqueous ammonia in a cleaning solution is determined by titration with hydrochloric acid. A volume of 23.18 mL of 0.8381 M HCl is needed to titrate a 50.0-mL sample of the ammonia solution to a methyl red endpoint. Calculate the concentration of ammonia in the cleaning solution.

## 11.4 Reaction Stoichiometry in Solutions: Oxidation–Reduction Titrations

27. For each of the following balanced equations, write the oxidation number above the symbol of each atom that changes oxidation state in the course of the reactions.

28. For each of the following balanced equations, write the oxidation number above the symbol of each atom that changes oxidation state in the course of the reaction.

29. Selenic acid ( $\text{H}_2\text{SeO}_4$ ) is a powerful oxidizing acid that dissolves not only silver (as does the related acid  $\text{H}_2\text{SO}_4$ ) but gold, through the following reaction:

Determine the oxidation numbers of the atoms in this equation. Which species is oxidized and which is reduced?

30. Diiodine pentoxide oxidizes carbon monoxide to carbon dioxide under room conditions, yielding iodine as the second product:

This can be used in an analytical method to measure the amount of carbon monoxide in a sample of air. Determine the oxidation numbers of the atoms in this equation. Which species is oxidized and which is reduced?

31. Complete and balance the following equations for reactions taking place in acidic solution.

32. Complete and balance the following equations for reactions taking place in acidic solution.

- (a)  $\text{MnO}_4^-(aq) + \text{H}_2\text{S}(aq) \longrightarrow \text{Mn}^{2+}(aq) + \text{SO}_4^{2-}(aq)$   
 (b)  $\text{Zn}(s) + \text{NO}_3^-(aq) \longrightarrow \text{Zn}^{2+}(aq) + \text{NH}_4^+(aq)$   
 (c)  $\text{H}_2\text{O}_2(aq) + \text{MnO}_4^-(aq) \longrightarrow \text{O}_2(g) + \text{Mn}^{2+}(aq)$   
 (d)  $\text{Sn}(s) + \text{NO}_3^-(aq) \longrightarrow \text{Sn}^{4+}(aq) + \text{N}_2\text{O}(g)$   
 (e)  $\text{UO}_2^{2+}(aq) + \text{Te}(s) \longrightarrow \text{U}^{4+}(aq) + \text{TeO}_4^{2-}(aq)$

33. Complete and balance the following equations for reactions taking place in basic solution.

- (a)  $\text{Cr}(\text{OH})_3(s) + \text{Br}_2(aq) \longrightarrow \text{CrO}_4^{2-}(aq) + \text{Br}^-(aq)$   
 (b)  $\text{ZrO}(\text{OH})_2(s) + \text{SO}_3^{2-}(aq) \longrightarrow \text{Zr}(s) + \text{SO}_4^{2-}(aq)$   
 (c)  $\text{HPbO}_2^-(aq) + \text{Re}(s) \longrightarrow \text{Pb}(s) + \text{ReO}_4^-(aq)$   
 (d)  $\text{HXeO}_4^-(aq) \longrightarrow \text{XeO}_6^{4-}(aq) + \text{Xe}(g)$   
 (e)  $\text{N}_2\text{H}_4(aq) + \text{CO}_3^{2-}(aq) \longrightarrow \text{N}_2(g) + \text{CO}(g)$

34. Complete and balance the following equations for reactions taking place in basic solution.

- (a)  $\text{OCl}^-(aq) + \text{I}^-(aq) \longrightarrow \text{IO}_3^-(aq) + \text{Cl}^-(aq)$   
 (b)  $\text{SO}_3^{2-}(aq) + \text{Be}(s) \longrightarrow \text{S}_2\text{O}_3^{2-}(aq) + \text{Be}_2\text{O}_3^{2-}(aq)$   
 (c)  $\text{H}_2\text{BO}_3^-(aq) + \text{Al}(s) \longrightarrow \text{BH}_4^-(aq) + \text{H}_2\text{AlO}_3^-(aq)$   
 (d)  $\text{O}_2(g) + \text{Sb}(s) \longrightarrow \text{H}_2\text{O}_2(aq) + \text{SbO}_2^-(aq)$   
 (e)  $\text{Sn}(\text{OH})_6^{2-}(aq) + \text{Si}(s) \longrightarrow \text{HSnO}_2^-(aq) + \text{SiO}_3^{2-}(aq)$

35. The following balanced equations represent reactions that occur in aqueous acid. Break them down into balanced oxidation and reduction half-equations.

- (a)  $2 \text{H}_3\text{O}^+(aq) + \text{H}_2\text{O}_2(aq) + 2 \text{Fe}^{2+}(aq) \longrightarrow 2 \text{Fe}^{3+}(aq) + 4 \text{H}_2\text{O}(\ell)$   
 (b)  $\text{H}_3\text{O}^+(aq) + \text{H}_2\text{O}(\ell) + 2 \text{MnO}_4^-(aq) + 5 \text{SO}_2(aq) \longrightarrow 2 \text{Mn}^{2+}(aq) + 5 \text{HSO}_4^-(aq)$   
 (c)  $5 \text{ClO}_2^-(aq) + 4 \text{H}_3\text{O}^+(aq) \longrightarrow 4 \text{ClO}_2(g) + \text{Cl}^-(aq) + 6 \text{H}_2\text{O}(\ell)$

36. The following balanced equations represent reactions that occur in aqueous base. Break them down into balanced oxidation and reduction half-equations.

- (a)  $4 \text{PH}_3(g) + 4 \text{H}_2\text{O}(\ell) + 4 \text{CrO}_4^{2-}(aq) \longrightarrow \text{P}_4(s) + 4 \text{Cr}(\text{OH})_4^-(aq) + 4 \text{OH}^-(aq)$   
 (b)  $\text{NiO}_2(s) + 2 \text{H}_2\text{O}(\ell) + \text{Fe}(s) \longrightarrow \text{Ni}(\text{OH})_2(s) + \text{Fe}(\text{OH})_2(s)$   
 (c)  $\text{CO}_2(g) + 2 \text{NH}_2\text{OH}(aq) \longrightarrow \text{CO}(g) + \text{N}_2(g) + 3 \text{H}_2\text{O}(g)$

37. Nitrous acid ( $\text{HNO}_2$ ) disproportionates in acidic solution to nitrate ion ( $\text{NO}_3^-$ ) and nitrogen oxide ( $\text{NO}$ ). Write a balanced equation for this reaction.

38. Thiosulfate ion ( $\text{S}_2\text{O}_3^{2-}$ ) disproportionates in acidic solution to give solid sulfur and aqueous hydrogen sulfite ion ( $\text{HSO}_3^-$ ). Write a balanced equation for this reaction.

39. Potassium dichromate in acidic solution is used to titrate a solution of iron(II) ions, with which it reacts according to

A potassium dichromate solution is prepared by dissolving 5.134 g of  $\text{K}_2\text{Cr}_2\text{O}_7$  in water and diluting to a total volume of 1.000 L. A total of 34.26 mL of this solution is required to reach the endpoint in a titration of a 500.0-mL sample containing  $\text{Fe}^{2+}(aq)$ . Determine the concentration of  $\text{Fe}^{2+}$  in the original solution.

40. Cerium(IV) ions are strong oxidizing agents in acidic solution, oxidizing arsenious acid to arsenic acid according to the following equation:

A sample of  $\text{As}_2\text{O}_3$  weighing 0.217 g is dissolved in basic solution and then acidified to make  $\text{H}_3\text{AsO}_3$ . Its titration with a solution of acidic cerium(IV) sulfate requires 21.47 mL. Determine the original concentration of  $\text{Ce}^{4+}(aq)$  in the titrating solution.

## 11.5 Phase Equilibrium in Solutions: Nonvolatile Solutes

41. The vapor pressure of pure acetone,  $\text{CH}_3\text{C}(\text{O})\text{CH}_3$ , at  $30^\circ\text{C}$  is 0.3270 atm. Suppose 15.0 g of benzophenone,  $\text{C}_{13}\text{H}_{10}\text{O}$ , is dissolved in 50.0 g of acetone. Calculate the vapor pressure of acetone above the resulting solution.

42. The vapor pressure of diethyl ether (molar mass,  $74.12 \text{ g mol}^{-1}$ ) at  $30^\circ\text{C}$  is 0.8517 atm. Suppose 1.800 g of maleic acid,  $\text{C}_4\text{H}_4\text{O}_4$ , is dissolved in 100.0 g of diethyl ether at  $30^\circ\text{C}$ . Calculate the vapor pressure of diethyl ether above the resulting solution.

43. Pure toluene ( $\text{C}_7\text{H}_8$ ) has a normal boiling point of  $110.60^\circ\text{C}$ . A solution of 7.80 g of anthracene ( $\text{C}_{14}\text{H}_{10}$ ) in 100.0 g of toluene has a boiling point of  $112.06^\circ\text{C}$ . Calculate  $K_b$  for toluene.

44. When 2.62 g of the nonvolatile solid anthracene,  $\text{C}_{14}\text{H}_{10}$ , is dissolved in 100.0 g of cyclohexane,  $\text{C}_6\text{H}_{12}$ , the boiling point of the cyclohexane is raised by  $0.41^\circ\text{C}$ . Calculate  $K_b$  for cyclohexane.

45. When 39.8 g of a nondissociating, nonvolatile sugar is dissolved in 200.0 g of water, the boiling point of the water is raised by  $0.30^\circ\text{C}$ . Estimate the molar mass of the sugar.

46. When 2.60 g of a substance that contains only indium and chlorine is dissolved in 50.0 g of tin(IV) chloride, the normal boiling point of the tin(IV) chloride is raised from  $114.1^\circ\text{C}$  to  $116.3^\circ\text{C}$ . If  $K_b = 9.43 \text{ K kg mol}^{-1}$  for  $\text{SnCl}_4$ , what are the approximate molar mass and the probable molecular formula of the solute?

47. The Rast method for determining molar masses uses camphor as the solvent. Camphor melts at  $178.4^\circ\text{C}$ , and its large  $K_f$  ( $37.7 \text{ K kg mol}^{-1}$ ) makes it especially useful for accurate work. A sample of an unknown substance that weighs 0.840 g reduces the freezing point of 25.0 g of camphor to  $170.8^\circ\text{C}$ . What is its molar mass?

48. Barium chloride has a freezing point of  $962^\circ\text{C}$  and a freezing-point depression constant of  $108 \text{ K kg mol}^{-1}$ . If 12 g of an unknown substance dissolved in 562 g of barium chloride gives a solution with a freezing point of  $937^\circ\text{C}$ , compute the molar mass of the unknown, assuming no dissociation takes place.

49. Ice cream is made by freezing a liquid mixture that, as a first approximation, can be considered a solution of sucrose ( $\text{C}_{12}\text{H}_{22}\text{O}_{11}$ ) in water. Estimate the temperature at which the first ice crystals begin to appear in a mix that

consists of 34% (by mass) sucrose in water. As ice crystallizes out, the remaining solution becomes more concentrated. What happens to its freezing point?

50. The solution to Problem 49 shows that to make homemade ice cream, temperatures ranging downward from  $-3^{\circ}\text{C}$  are needed. Ice cubes from a freezer have a temperature of about  $-12^{\circ}\text{C}$  ( $+10^{\circ}\text{F}$ ), which is cold enough, but contact with the warmer ice cream mixture causes them to melt to liquid at  $0^{\circ}\text{C}$ , which is too warm. To obtain a liquid that is cold enough, salt ( $\text{NaCl}$ ) is dissolved in water, and ice is added to the saltwater. The salt lowers the freezing point of the water enough so that it can freeze the liquid inside the ice cream maker. The instructions for an ice cream maker say to add one part salt to eight parts water (by mass). What is the freezing point of this solution (in degrees Celsius and degrees Fahrenheit)? Assume that the  $\text{NaCl}$  dissociates fully into ions, and that the solution is ideal.
51. An aqueous solution is 0.8402 molal in  $\text{Na}_2\text{SO}_4$ . It has a freezing point of  $-4.218^{\circ}\text{C}$ . Determine the effective number of particles arising from each  $\text{Na}_2\text{SO}_4$  formula unit in this solution.
52. The freezing-point depression constant of pure  $\text{H}_2\text{SO}_4$  is  $6.12\text{ K kg mol}^{-1}$ . When 2.3 g of ethanol ( $\text{C}_2\text{H}_5\text{OH}$ ) is dissolved in 1.00 kg of pure sulfuric acid, the freezing point of the solution is 0.92 K lower than the freezing point of pure sulfuric acid. Determine how many particles are formed as 1 molecule of ethanol goes into solution in sulfuric acid.
53. A 200-mg sample of a purified compound of unknown molar mass is dissolved in benzene and diluted with that solvent to a volume of  $25.0\text{ cm}^3$ . The resulting solution is found to have an osmotic pressure of 0.0105 atm at 300 K. What is the molar mass of the unknown compound?
54. Suppose 2.37 g of a protein is dissolved in water and diluted to a total volume of 100.0 mL. The osmotic pressure of the resulting solution is 0.0319 atm at  $20^{\circ}\text{C}$ . What is the molar mass of the protein?
55. A polymer of large molar mass is dissolved in water at  $15^{\circ}\text{C}$ , and the resulting solution rises to a final height of 15.2 cm above the level of the pure water, as water molecules pass through a semipermeable membrane into the solution. If the solution contains 4.64 g polymer per liter, calculate the molar mass of the polymer.
56. Suppose 0.125 g of a protein is dissolved in  $10.0\text{ cm}^3$  of ethyl alcohol ( $\text{C}_2\text{H}_5\text{OH}$ ), whose density at  $20^{\circ}\text{C}$  is  $0.789\text{ g cm}^{-3}$ . The solution rises to a height of 26.3 cm in an osmometer (an apparatus for measuring osmotic pressure). What is the approximate molar mass of the protein?
- 11.6 Phase Equilibrium in Solutions: Volatile Solutes**
57. The Henry's law constant at  $25^{\circ}\text{C}$  for carbon dioxide dissolved in water is  $1.65 \times 10^3\text{ atm}$ . If a carbonated beverage is bottled under a  $\text{CO}_2$  pressure of 5.0 atm:
- Calculate the number of moles of carbon dioxide dissolved per liter of water under these conditions, using  $1.00\text{ g cm}^{-3}$  as the density of water.
  - Explain what happens on a microscopic level after the bottle cap is removed.
58. The Henry's law constant at  $25^{\circ}\text{C}$  for nitrogen dissolved in water is  $8.57 \times 10^4\text{ atm}$ , that for oxygen is  $4.34 \times 10^4\text{ atm}$ , and that for helium is  $1.7 \times 10^5\text{ atm}$ .
- Calculate the number of moles of nitrogen and oxygen dissolved per liter of water in equilibrium with air at  $25^{\circ}\text{C}$ . Use Table 9.1.
  - Air is dissolved in blood and other bodily fluids. As a deep-sea diver descends, the pressure increases and the concentration of dissolved air in the blood increases. If the diver returns to the surface too quickly, gas bubbles out of solution within the body so rapidly that it can cause a dangerous condition called "the bends." Use Henry's law to show why divers sometimes use a combination of helium and oxygen in their breathing tanks in place of compressed air.
59. At  $25^{\circ}\text{C}$ , some water is added to a sample of gaseous methane ( $\text{CH}_4$ ) at 1.00 atm pressure in a closed vessel, and the vessel is shaken until as much methane as possible dissolves. Then 1.00 kg of the solution is removed and boiled to expel the methane, yielding a volume of 3.01 L of  $\text{CH}_4(\text{g})$  at  $0^{\circ}\text{C}$  and 1.00 atm. Determine the Henry's law constant for methane in water.
60. When exactly the procedure of Problem 59 is conducted using benzene ( $\text{C}_6\text{H}_6$ ) in place of water, the volume of methane that results is 0.510 L at  $0^{\circ}\text{C}$  and 1.00 atm. Determine the Henry's law constant for methane in benzene.
61. At  $20^{\circ}\text{C}$ , the vapor pressure of toluene is 0.0289 atm and the vapor pressure of benzene is 0.0987 atm. Equal numbers of moles of toluene and benzene are mixed and form an ideal solution. Compute the mole fraction of benzene in the vapor in equilibrium with this solution.
62. At  $90^{\circ}\text{C}$ , the vapor pressure of toluene is 0.534 atm and the vapor pressure of benzene is 1.34 atm. Benzene (0.400 mol) is mixed with toluene (0.900 mol) to form an ideal solution. Compute the mole fraction of benzene in the vapor in equilibrium with this solution.
63. At  $40^{\circ}\text{C}$ , the vapor pressure of pure carbon tetrachloride ( $\text{CCl}_4$ ) is 0.293 atm and the vapor pressure of pure dichloroethane ( $\text{C}_2\text{H}_4\text{Cl}_2$ ) is 0.209 atm. A nearly ideal solution is prepared by mixing 30.0 g of carbon tetrachloride with 20.0 g of dichloroethane.
- Calculate the mole fraction of  $\text{CCl}_4$  in the solution.
  - Calculate the total vapor pressure of the solution at  $40^{\circ}\text{C}$ .
  - Calculate the mole fraction of  $\text{CCl}_4$  in the vapor in equilibrium with the solution.
64. At 300 K, the vapor pressure of pure benzene ( $\text{C}_6\text{H}_6$ ) is 0.1355 atm and the vapor pressure of pure *n*-hexane ( $\text{C}_6\text{H}_{14}$ ) is 0.2128 atm. Mixing 50.0 g of benzene with 50.0 g of *n*-hexane gives a solution that is nearly ideal.
- Calculate the mole fraction of benzene in the solution.
  - Calculate the total vapor pressure of the solution at 300 K.
  - Calculate the mole fraction of benzene in the vapor in equilibrium with the solution.

## ADDITIONAL PROBLEMS

65. Veterinarians use Donovan's solution to treat skin diseases in animals. The solution is prepared by mixing 1.00 g of  $\text{AsI}_3(s)$ , 1.00 g of  $\text{HgI}_2(s)$ , and 0.900 g of  $\text{NaHCO}_3(s)$  in enough water to make a total volume of 100.0 mL.
- Compute the total mass of iodine per liter of Donovan's solution, in grams per liter.
  - You need a lot of Donovan's solution to treat an outbreak of rash in an elephant herd. You have plenty of mercury(II) iodide and sodium hydrogen carbonate, but the only arsenic(III) iodide you can find is 1.50 L of a 0.100 M aqueous solution. Explain how to prepare 3.50 L of Donovan's solution starting with these materials.
66. Relative solubilities of salts in liquid ammonia can differ significantly from those in water. Thus, silver bromide is soluble in ammonia, but barium bromide is not (the reverse of the situation in water).
- Write a balanced equation for the reaction of an ammonia solution of barium nitrate with an ammonia solution of silver bromide. Silver nitrate is soluble in liquid ammonia.
  - What volume of a 0.50 M solution of silver bromide will react completely with 0.215 L of a 0.076 M solution of barium nitrate in ammonia?
  - What mass of barium bromide will precipitate from the reaction in part (b)?
- \*67. A 5.0-L flask contains a mixture of ammonia and nitrogen at 27°C and a total pressure of 3.00 atm. The sample of gas is allowed to flow from the flask until the pressure in the flask has fallen to 1.00 atm. The gas that escapes is passed through 1.50 L of 0.200 M acetic acid. All the ammonia in the gas that escapes is absorbed by the solution and turns out to be just sufficient to neutralize the acetic acid present. The volume of the solution does not change significantly.
- Will the electrical conductivity of the aqueous solution change significantly as the gas is absorbed? Give equations for any reactions, and calculate the final concentrations of the principal ions present (if any) at the end.
  - Calculate the percentage by mass of ammonia in the flask initially.
- \*68. It was desired to neutralize a certain solution X that had been prepared by mixing solutions of potassium chloride and hydrobromic acid. Titration of 10.0 mL X with 0.100 M silver nitrate required 50.0 mL of the latter. The resulting precipitate, containing a mixture of  $\text{AgCl}$  and  $\text{AgBr}$ , was dried and found to weigh 0.762 g. How much 0.100 M sodium hydroxide should be used to neutralize 10.0 mL solution X?
- \*69. Vanadic ion,  $\text{V}^{3+}$ , forms green salts and is a good reducing agent, being itself changed in neutral solutions to the nearly colorless ion  $\text{V}(\text{OH})_4^+$ . Suppose that 15.0 mL of a 0.200-M solution of vanadic sulfate,  $\text{V}_2(\text{SO}_4)_3$ , was needed to reduce completely a 0.540-g sample of an unknown substance X. If each molecule of X accepted just one electron, what is the molecular weight of X? Suppose that each molecule of X accepted three electrons; what would be the molecular weight of X then?
- \*70. A new antibiotic, A, which is an acid, can readily be oxidized by hot aqueous permanganate; the latter is reduced to manganous ion,  $\text{Mn}^{2+}$ . The following experiments have been performed with A: (a) 0.293 g A consumes just 18.3 mL of 0.080 M  $\text{KMnO}_4$ ; (b) 0.385 g A is just neutralized by 15.7 mL of 0.490 M  $\text{NaOH}$ . What can you conclude about the molecular weight of A from (a), from (b), and from both considered together?
71. Suppose 150 mL of a 10.00% by mass solution of sodium chloride (density = 1.0726  $\text{g cm}^{-3}$ ) is acidified with sulfuric acid and then treated with an excess of  $\text{MnO}_2(s)$ . Under these conditions, all the chlorine is liberated as  $\text{Cl}_2(g)$ . The chlorine is collected without loss and reacts with excess  $\text{H}_2(g)$  to form  $\text{HCl}(g)$ . The  $\text{HCl}(g)$  is dissolved in enough water to make 250 mL of solution. Compute the molarity of this solution.
- \*72. The amount of ozone in a mixture of gases can be determined by passing the mixture through an acidic aqueous solution of potassium iodide, where the ozone reacts according to
- $$\text{O}_3(g) + 3 \text{I}^-(aq) + \text{H}_2\text{O}(\ell) \longrightarrow \text{O}_2(g) + \text{I}_3^-(aq) + 2 \text{OH}^-(aq)$$
- to form the triiodide ion  $\text{I}_3^-$ . The amount of triiodide produced is then determined by titrating with thiosulfate solution:
- $$\text{I}_3^-(aq) + 2 \text{S}_2\text{O}_3^{2-}(aq) \longrightarrow 3 \text{I}^-(aq) + \text{S}_4\text{O}_6^{2-}(aq)$$
- A small amount of starch solution is added as an indicator because it forms a deep-blue complex with the triiodide solution. Disappearance of the blue color thus signals the completion of the titration. Suppose 53.2 L of a gas mixture at a temperature of 18°C and a total pressure of 0.993 atm is passed through a solution of potassium iodide until the ozone in the mixture has reacted completely. The solution requires 26.2 mL of a 0.1359-M solution of thiosulfate ion to titrate to the endpoint. Calculate the mole fraction of ozone in the original gas sample.
73. The vapor pressure of pure liquid  $\text{CS}_2$  is 0.3914 atm at 20°C. When 40.0 g of rhombic sulfur is dissolved in 1.00 kg of  $\text{CS}_2$ , the vapor pressure of  $\text{CS}_2$  decreases to 0.3868 atm. Determine the molecular formula for the sulfur molecules dissolved in  $\text{CS}_2$ .
74. The expressions for boiling-point elevation and freezing-point depression apply accurately to *dilute* solutions only. A saturated aqueous solution of  $\text{NaI}$  (sodium iodide) in water has a boiling point of 144°C. The mole fraction of  $\text{NaI}$  in the solution is 0.390. Compute the molality of this solution. Compare the boiling-point elevation predicted by the expression in this chapter with the elevation actually observed.

75. You take a bottle of soft drink out of your refrigerator. The contents are liquid and stay liquid, even when you shake them. Presently, you remove the cap and the liquid freezes solid. Offer a possible explanation for this observation.
76. Mercury(II) chloride ( $\text{HgCl}_2$ ) freezes at  $276.1^\circ\text{C}$  and has a freezing-point depression constant  $K_f$  of  $34.3 \text{ K kg mol}^{-1}$ . When  $1.36 \text{ g}$  of solid mercury(I) chloride (empirical formula  $\text{HgCl}$ ) is dissolved in  $100 \text{ g}$  of  $\text{HgCl}_2$ , the freezing point is reduced by  $0.99^\circ\text{C}$ . Calculate the molar mass of the dissolved solute species and give its molecular formula.
- \*77. The vapor pressure of an aqueous solution of  $\text{CaCl}_2$  at  $25^\circ\text{C}$  is  $0.02970 \text{ atm}$ . The vapor pressure of pure water at the same temperature is  $0.03126 \text{ atm}$ . Estimate the freezing point of the solution.
78. Ethylene glycol ( $\text{CH}_2\text{OHCH}_2\text{OH}$ ) is used in antifreeze because, when mixed with water, it lowers the freezing point below  $0^\circ\text{C}$ . What mass percentage of ethylene glycol in water must be used to reduce the freezing point of the mixture to  $-5.0^\circ\text{C}$ , assuming ideal solution behavior?
79. A new compound has the empirical formula  $\text{GaCl}_2$ . This surprises some chemists who, based on the position of gallium in the periodic table, expect a chloride of gallium to have the formula  $\text{GaCl}_3$  or possibly  $\text{GaCl}$ . They suggest that the " $\text{GaCl}_2$ " is really  $\text{Ga}[\text{GaCl}_4]$ , in which the bracketed group behaves as a unit with a  $-1$  charge. Suggest experiments to test this hypothesis.
- \*80. Suppose two beakers are placed in a small closed container at  $25^\circ\text{C}$ . One contains  $400 \text{ mL}$  of a  $0.100\text{-M}$  aqueous solution of  $\text{NaCl}$ ; the second contains  $200 \text{ mL}$  of a  $0.250\text{-M}$  aqueous solution of  $\text{NaCl}$ . Small amounts of water evaporate from both solutions. As time passes, the volume of solution in the second beaker gradually increases, and that in the first gradually decreases. Why? If we wait long enough, what will the final volumes and concentrations be?
- \*81. The walls of erythrocytes (red blood cells) are permeable to water. In a salt solution, they shrivel (lose water) when the outside salt concentration is high and swell (take up water) when the outside salt concentration is low. In an experiment at  $25^\circ\text{C}$ , an aqueous solution of  $\text{NaCl}$  that has a freezing point of  $-0.046^\circ\text{C}$  causes erythrocytes neither to swell nor to shrink, indicating that the osmotic pressure of their contents is equal to that of the  $\text{NaCl}$  solution. Calculate the osmotic pressure of the solution inside the erythrocytes under these conditions, assuming that its molarity and molality are equal.
82. Silver dissolves in molten lead. Compute the osmotic pressure of a  $0.010 \text{ M}$  solution of silver in lead at  $423^\circ\text{C}$ . Compute the height of a column of molten lead ( $\rho = 11.4 \text{ g cm}^{-3}$ ) to which this pressure corresponds.
83. Henry's law is important in environmental chemistry, where it predicts the distribution of pollutants between water and the atmosphere. Benzene ( $\text{C}_6\text{H}_6$ ) emitted in wastewater streams, for example, can pass into the air, where it is degraded by processes induced by light from the sun. The Henry's law constant for benzene in water at  $25^\circ\text{C}$  is  $301 \text{ atm}$ . Calculate the partial pressure of benzene vapor in equilibrium with a solution of  $2.0 \text{ g}$  of benzene per  $1000 \text{ L}$  of water. How many benzene molecules are present in each cubic centimeter?
- \*84. Refer to the data of Problem 62. Calculate the mole fraction of toluene in a mixture of benzene and toluene that boils at  $90^\circ\text{C}$  under atmospheric pressure.
85. What is the difference between a solution and a colloidal suspension? Give examples of each, and show how, in some cases, it may be difficult to classify a mixture as one or the other.

## CUMULATIVE PROBLEMS

86. A student prepares a solution by dissolving  $1.000 \text{ mol}$  of  $\text{Na}_2\text{SO}_4$  in water. She accidentally leaves the container uncovered and comes back the next week to find only a white, solid residue. The mass of the residue is  $322.2 \text{ g}$ . Determine the chemical formula of this residue.
87. Complete combustion of  $2.40 \text{ g}$  of a compound of carbon, hydrogen, and oxygen yielded  $5.46 \text{ g CO}_2$  and  $2.23 \text{ g H}_2\text{O}$ . When  $8.69 \text{ g}$  of the compound was dissolved in  $281 \text{ g}$  of water, the freezing point of the solution was found to be  $-0.97^\circ\text{C}$ . What is the molecular formula of the compound?
- \*88. Imagine that two  $1\text{-L}$  beakers, A and B, each containing an aqueous solution of fructose (a nonvolatile sugar with molecular weight = 180) are placed together in a box, which is then sealed. (The concentrations of the solutions are not necessarily the same.) The temperature remains constant at  $26^\circ\text{C}$ . Initially, there is  $600 \text{ mL}$  of solution in A and  $100 \text{ mL}$  of solution in B. As the solutions stand in the sealed box, their volumes change slowly for a while. When they stop changing, beaker A contains  $400 \text{ mL}$  and beaker B contains  $300 \text{ mL}$ . It is then determined that the solution in A is  $1.5 \text{ M}$  in fructose and has a density of  $1.10 \text{ g mL}^{-1}$ .
- What is the molar concentration of fructose in the solution in beaker B at the end? Explain.
  - Calculate the concentration of fructose in the solution in A at the start.
  - Calculate the concentration of the fructose in the solution in B at the start.
  - The vapor pressure of pure water at  $26^\circ\text{C}$  is  $25.2 \text{ torr}$ . What is the pressure of water vapor in the box at the end, after the volumes have stopped changing?

# Equilibrium in Chemical Reactions

© AG-PHOTOS/Shutterstock.com

**Stalactites (top) and stalagmites (bottom) consist of calcium carbonate.** They form when a water solution containing  $\text{Ca}^{2+}$  and  $\text{HCO}_3^-$  ions running through a cave loses water by evaporation. The concentration of ions then exceeds the equilibrium solubility of calcium carbonate. Carbon dioxide is released, and solid calcium carbonate precipitates out of the solution:  $\text{Ca}^{2+}(\text{aq}) + 2 \text{HCO}_3^-(\text{aq}) \longrightarrow \text{CaCO}_3(\text{s}) + \text{H}_2\text{O} + \text{CO}_2(\text{g})$ .

In chemical reactions, bonds are broken in the reactants, and the atoms re-arrange themselves with new bonds to form the products. How far do reactions proceed toward completely converting the reactants to products? What determines the extent of their progress? Experience shows that many reactions do not go to completion, but approach instead an equilibrium state in which products and unreacted reactants are both present in specific relative amounts. Once equilibrium has been achieved, the composition of the reaction mixture does not change further. The equilibrium composition of the mixture is related quantitatively to the equilibrium constant for the reaction. If we know the equilibrium constant, we can calculate the equilibrium composition that will result from any mixture of reactants and products present initially. This calculation is one of the most important tools available to chemists because it is used to predict and maximize the yield of reactions throughout fundamental and applied chemistry.

Temperature influences the progress of chemical reactions—driving some forward while retarding others—and is quantitatively connected to chemical equilibrium by the science of thermodynamics. Thermodynamics predicts the value of the equilibrium constant from simple physical properties of the reactants and products, and explains how that value depends on the reaction temperature. In that way, thermodynamics shows how to maximize yield of the reaction by manipulation of the temperature.

**NOTE TO THE READER:**

It is purely a matter of preference whether one should first study chemical equilibrium from the empirical point of view, and then study thermodynamics to provide the fundamental explanation of equilibrium, or learn thermodynamics first as essential background for the study of equilibrium. We have written this textbook to allow either approach. If your instructor prefers to cover thermodynamics before equilibrium, you should read Chapters 12, 13, and 14 straight through in the order written. If your instructor prefers to cover equilibrium from the empirical point of view before studying thermodynamics, you should skip now to Chapter 14 and omit those sections of Chapter 14 (clearly marked) that require background in thermodynamics. You should come back and read those sections later after you have studied Chapters 12 and 13.

## Unit Chapters

### CHAPTER 12

Thermodynamic Processes and Thermochemistry

### CHAPTER 13

Spontaneous Processes and Thermodynamic Equilibrium

### CHAPTER 14

Chemical Equilibrium

### CHAPTER 15

Acid–Base Equilibria

### CHAPTER 16

Solubility and Precipitation Equilibria

### CHAPTER 17

Electrochemistry

## Unit Goals

- To relate composition in the equilibrium state to the equilibrium constant
- To calculate composition in the equilibrium state from the equilibrium constant
- To describe the influence of temperature on the equilibrium constant
- To apply thermodynamics to explain these connections and maximize reaction yield

Methanol as a Gasoline Substitute

The steam locomotive operates by converting thermal energy into mechanical energy. The diesel locomotive converts chemical energy into electrical energy, then electrical energy into mechanical energy to generate motion. All these energy conversion processes are governed by thermodynamics.

Experience shows that heat is the most important factor influencing the extent of chemical reactions. Heat drives some reactions toward completion, but retards the progress of others. Therefore, it is appropriate to launch our study of chemical equilibrium by learning how to measure the heat transfer in a chemical reaction. This objective leads us into the branch of physical science called thermodynamics, which describes the meaning of heat and gives procedures for measuring heat transfer quantitatively.

Thermodynamics is a broad and general subject with applications in all branches of the physical and biological sciences and engineering; thus, we limit our discussion to those aspects necessary for chemical equilibrium. In this chapter, we demonstrate that heating a substance, the chemical system, can change the energy content of the system just as doing work on the system (e.g. pushing a ball uphill) does. Interestingly, heating a substance need not increase its temperature; when you boil water the temperature stays constant as the phase

change occurs. The total amount of energy (in system and surroundings) is conserved during any such processes. The previous sentence in more concise form is the first law of thermodynamics, which is the unifying theme of this chapter. We see how to measure quantitatively the heat transfer into a system through its *heat capacity*. We see how the transfer depends on experimental conditions such as constant pressure or constant volume. Finally, we apply these methods to measure the heat transfer in chemical reactions conducted at constant pressure. Then we are ready to connect heat transfer to chemical equilibrium at the beginning of Chapter 13.

We conclude this introduction with a general overview of thermodynamics, as context for the specific studies in this and the next chapter. Thermodynamics, in which a few apparently simple laws summarize a rich variety of observed behavior, is one of the surest and most powerful branches of science. The distinctive feature of thermodynamics is the universality of its basic laws, and the beauty of the subject is the many conclusions that can be deduced from those few laws. The laws of thermodynamics cannot themselves be derived or proved. Instead, they are generalizations drawn from a great many observations of the behavior of matter. The history of thermodynamics, like that of other fields of science, has been fraught with misconceptions. As we look back on the beginnings of the discipline in the 19th century, it appears to have developed with agonizing slowness. But it *has* developed, and its laws are the pillars on which much of modern science rests. The foundations of thermodynamics are completely understood today. It is being applied in research at the forefront of science, on systems ranging from black holes in distant parts of the universe to the growth and development of the biological cell. Many new results and insights are being acquired, but the foundations are not challenged.

Thermodynamics is an *operational* science, concerned with macroscopic, measurable properties and the relations among them. Its goal is to predict what types of chemical and physical processes are possible, and under what conditions, and to calculate quantitatively the properties of the equilibrium state that ensues when a process is conducted. For example, with thermodynamics we can answer the following types of chemical questions:

1. If hydrogen and nitrogen are mixed, is it possible for them to react? If so, what will be the percentage yield of ammonia?
2. How will a particular change in temperature or pressure affect the extent of the reaction?
3. How can the conditions for the reaction be optimized to maximize its yield?

Thermodynamics is an immensely practical subject. The knowledge from thermodynamics that a particular chemical process is impossible under certain proposed conditions can prevent great loss of time and resources spent vainly trying to conduct the reaction under those conditions. Thermodynamics can also suggest ways to change conditions so that a process becomes possible.

The power of thermodynamics lies in its generality: It rests on no particular model of the structure of matter. In fact, if the entire atomic theory of matter were to be found invalid and discarded (a *very* unlikely event!), the foundations of thermodynamics would remain unshaken. Nonetheless, thermodynamics has some important limitations. Thermodynamics asserts that substances have specific measurable macroscopic properties, but it cannot explain why a particular substance has particular numerical values for these properties. Thermodynamics can determine whether a process is possible, but it cannot say how rapidly the process will occur. For example, thermodynamics predicts that diamond is an unstable substance at atmospheric pressure and will eventually become graphite, but cannot predict how long this process will take.

## 12.1 Systems, States, and Processes

Thermodynamics uses abstract models to represent real-world systems and processes. These processes may appear in a rich variety of situations, including controlled laboratory conditions, industrial production facilities, living systems, the environment on Earth, and space. A key step in applying the methods of thermodynamics to such diverse processes is to formulate the thermodynamic model *for each process*. This step requires precise definitions of thermodynamic terms. Students (and professors!) of thermodynamics encounter—and sometimes create—apparent contradictions that arise from careless or inaccurate use of language. Part of the difficulty is that many thermodynamic terms also have everyday meanings different from their thermodynamic usage. This section provides a brief introduction to the language of thermodynamics.

A **system** is that part of the universe of immediate interest in a particular experiment or study. The system always contains a certain amount of matter and is described by specific parameters that are controlled in the experiment. For example, the gas confined in a closed box may constitute the system, characterized by the number of moles of the gas and the fixed volume of the box. But in other experiments, it would be more appropriate to consider the gas molecules in a particular cubic centimeter of space in the middle of a room to be the system. In the first case, the boundaries are physical walls, but in the second case, the boundaries are conceptual. We explain later that the two kinds of boundaries are treated the same way mathematically. In the second example, the system is characterized by its volume, which is definite, and by the number of moles of gas within it, which may fluctuate as the system exchanges molecules with the surrounding regions.

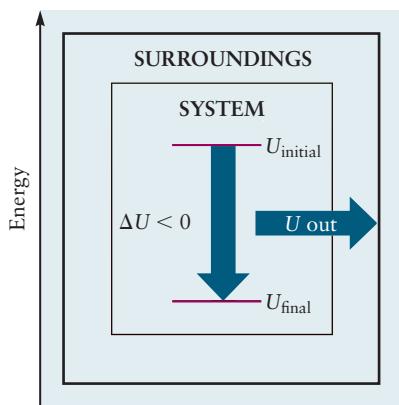

Systems are classified by the extent to which their boundaries permit exchange of matter and energy with the surrounding regions. In a **closed system**, the boundaries prevent the flow of matter into or out of it (the boundaries are **impermeable**), whereas the boundaries in an **open system** permit such flow. The amount of matter in an open system can change with time. An **isolated system** exchanges neither matter nor energy with the rest of the universe. **Rigid walls** prevent the system from gaining energy by mechanical processes such as compression and deformation; nonrigid walls permit mechanical energy transfer. **Adiabatic walls** prevent heat transfer (described in detail later) between the system and surroundings, whereas **diathermal walls** permit heat transfer. The energy content directly related to temperature is called *thermal energy*.

The definition of “the system” must be tailored to the specific process under consideration. Simple physical processes such as heating or cooling a metal object are modeled as closed systems (no matter is gained or lost) with diathermal (thermal energy is transferred) and nonrigid walls (the object may expand or contract). Most chemical reactions and phase changes can be modeled as closed systems (no matter is exchanged) with diathermal (heat is transferred) and nonrigid walls. For example, the system might be a mole of water initially in the liquid phase, with a pressure of 1 atm and a temperature of 100°C. Heating the system while holding the pressure constant causes the water to evaporate. At the end of the process the system is now gaseous water at 1 atm, so it occupies a much larger volume, but no mass has been transferred to the surroundings. You will gain confidence in these classifications through experience as we examine many processes in this chapter.

The portion of the remainder of the universe that can exchange energy and matter with the system during the process of interest is called the **surroundings**. The surroundings provide the external forces that cause changes in the properties of the system during a process. The system and the surroundings together constitute the **thermodynamic universe** for that process. The thermodynamic universe for that process is isolated. Matter and energy are conserved in the thermodynamics universe while they are exchanged between the system and the

(a)

(b)

**FIGURE 12.1** The thermodynamic universe. (a) The system gains energy from the surroundings. (b) The system loses energy to the surroundings.

surroundings during the process. Figure 12.1a shows a process in which the system gains energy  $U$  while the surroundings lose energy  $U$ .

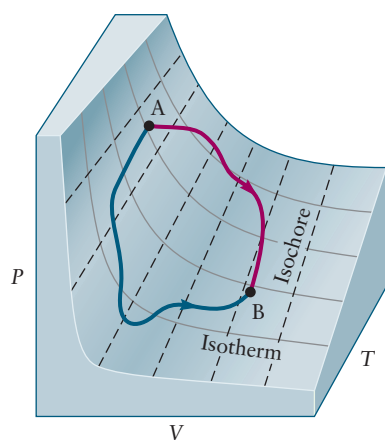

Thermodynamics is concerned with macroscopic properties of systems and changes in these properties during processes. Such properties are of two kinds: *extensive* and *intensive*. To distinguish between them, consider the following “thought experiment.” Place a thin wall through the middle of a system, dividing it into two subsystems, each of which, like the system itself, is characterized by certain properties. An **extensive property** of the system can be written as the *sum* of the corresponding property in the two subsystems. Volume, mass, and energy are typical extensive properties; the volume of a system is the sum of the volumes of its subsystems. An **intensive property** of the system is the *same* as the corresponding property of each of the subsystems. Temperature and pressure are typical intensive properties; if a system at 298 K is divided in half, the temperature of each half will still be 298 K.

A **thermodynamic state** is a macroscopic condition of a system in which the properties of the system are held at selected fixed values independent of time. The properties of the system are held constant by its boundaries and the surroundings. For example, a system comprising 2 mol helium (He) gas can be held in a piston–cylinder apparatus that maintains the system pressure at 1.5 atm, and the apparatus may be immersed in a heat bath that maintains the system temperature at 298 K. The intensive properties of pressure ( $P$ ) and temperature ( $T$ ) are then held constant at the values 1.5 atm and 298 K, respectively, by the surroundings. The extensive properties of the system are held constant by **constraints** at its boundaries. For example, a system comprising 2 mol helium (He) gas in a volume fixed at 5 L has constraints on its volume and the composition and mass of its contents.

After the system has been prepared by establishing a set of constraints in the surroundings, after all disturbances caused by the preparation cease and none of its properties changes with time, the system is said to have reached **equilibrium**. The same equilibrium state can be reached from different directions. The thermodynamic state of a system comprising a given quantity of a liquid or gaseous pure substance is fixed when any two of its independent properties are given. Thus, the specification of  $P$  and  $T$  for 1 mol of a pure gas fixes not merely the volume,  $V$ , but all other properties of the material, such as the internal energy,  $U$ , which is defined in Section 12.2. These relations among properties can be displayed as three-dimensional plots of any property as a function of two other properties. For 1 mol of a gas, a plot of pressure against volume and temperature is shown in Figure 12.2. The resulting surface is represented by an equation giving  $P$  as a function of  $V$  and  $T$ ; this is called the *equation of state* of the substance (see Section 9.6). If we avoid regions of small  $V$  and low  $T$  where gas nonideality becomes important, the experimentally determined surface is that shown in Figure 12.2, and the equation of state is given by the ideal gas law  $PV = nRT$ . The points on this surface (A, B, . . .) represent experimentally measured values of  $P$  in equilibrium thermodynamic states of the system fixed by particular values of  $V$  and  $T$ . Experience shows that the values of all other macroscopic properties take on definite values at each of these states. For example, we can visualize the internal energy,  $U$ , as a similar three-dimensional plot versus  $T$  and  $V$ .

A **thermodynamic process** changes the thermodynamic state of a system. A process may be *physical*, such as changing the pressure of a gaseous system or boiling a liquid. A *chemical* process involves a chemical reaction (for example, the decomposition of solid  $\text{CaCO}_3$ , at 900 K and 1 atm pressure, to give solid  $\text{CaO}$  and gaseous  $\text{CO}_2$  at the same temperature and pressure).

Because a process changes the state of a system, the process must start with the system in a particular equilibrium state and must also end with the system in a particular equilibrium state. Two such states A and B are indicated in

**FIGURE 12.2** The  $P$ - $V$ - $T$  surface of 1 mol of ideal gas. Each point on the surface represents a combination of pressure ( $P$ ), volume ( $V$ ), and temperature ( $T$ ) allowed by the equation of state of the gas. Along an isotherm ( $T$  constant), the pressure varies inversely with volume; along an isochore ( $V$  constant), it varies linearly with temperature. Two processes are shown connecting states A and B along paths that satisfy the equation of state at every point.

**FIGURE 12.3** Stages in an irreversible expansion of a gas from an initial state (a) of volume  $V_1$  to a final state (c) of volume  $V_2$ . In the intermediate stage shown (b), the gas is not in equilibrium; because of turbulence, pressure and temperature cannot be defined.

Figure 12.2. You might wonder whether we can sketch a *path* on the surface of equilibrium thermodynamic states to summarize the progress of the system during a process. Only special processes of the type called *reversible* can be represented in this way (see discussion in the following paragraphs).

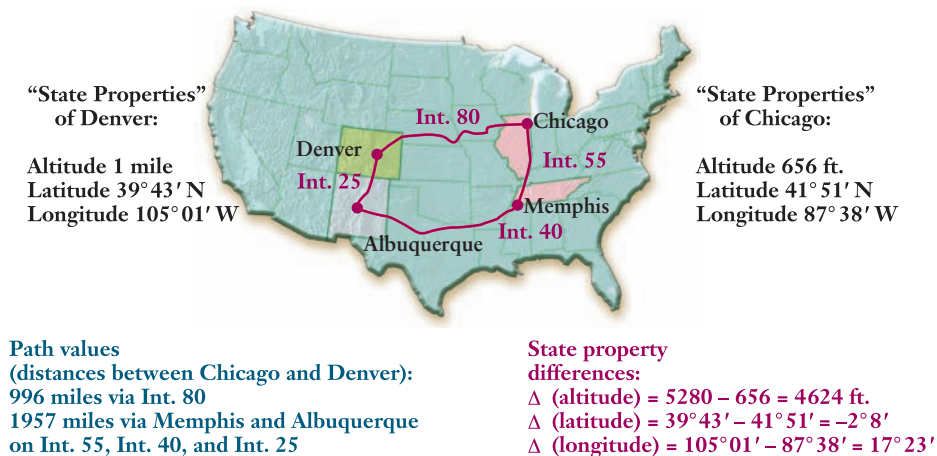

Many conditions of a system do not correspond to any equilibrium thermodynamic state. Suppose a gas is confined by a piston in a cylinder with volume  $V_1$  (thermodynamic state A). If the piston is abruptly pulled out to increase the volume to  $V_2$  (Fig. 12.3), chaotic gas currents arise as the molecules begin to move into the larger volume. These intermediate stages are not thermodynamic states, because such properties as density and temperature are changing rapidly through space and in time. Eventually, the currents cease and the system approaches a new equilibrium thermodynamic state, B. States A and B are thermodynamic states, but the conditions in between cannot be described by only a few macroscopic variables, and therefore are not thermodynamic states. Such a process is called an **irreversible process**. An irreversible process cannot be represented as a path on a thermodynamic surface (as in Fig. 12.2), because the intermediate stages are not thermodynamic equilibrium states and thus do not correspond to points on the equation-of-state surface.

In contrast, a **reversible process** proceeds through a continuous series of thermodynamic states, and thus can be shown as a path on the equation-of-state surface. The term reversible is used because an infinitesimal change in external conditions suffices to reverse the direction of motion of the system. For example, if a gas is expanded by slowly pulling out a piston, only a tiny change in the force exerted from the outside is required to change the direction of motion of the piston and begin to compress the gas. Such a process is an idealization, because the final equilibrium state would be reached only after an infinite length of time; therefore, such a process could never occur in a finite time. If a real process is conducted slowly enough and in sufficiently small steps, the process can be approximated by an idealized limiting reversible process. A gas confined inside a piston–cylinder assembly will experience an irreversible compression when a kilogram of sand is suddenly dropped onto the piston. The same compression can be achieved (almost) reversibly by transferring the same kilogram of sand onto the piston one grain at the time.

An infinite number of reversible paths can be identified between any two thermodynamic states A and B. Two of them shown in Figure 12.2 could be realized by slowly changing the values of  $T$  and  $V$  in the proper sequence by manipulating the apparatus in the surroundings. We use such reversible paths throughout this textbook as a tool for calculating changes in properties caused by processes.

Certain properties of a system, called **state functions**, are uniquely determined by the thermodynamic state of the system. Volume, temperature, pressure, and the internal energy,  $U$ , are examples of state functions. The Greek letter delta ( $\Delta$ ) is used to indicate *changes* in the value of state functions in a

**FIGURE 12.4** Differences in state properties (such as the difference in altitude between two points) are independent of the path followed. Other properties (such as the total distance traveled) depend on the particular path.

thermodynamic process. Thus,  $\Delta V = V_{\text{final}} - V_{\text{initial}}$  (or  $V_f - V_i$ ) is the change in volume between initial and final states, and  $\Delta U = U_{\text{final}} - U_{\text{initial}}$  is the change in internal energy. Because  $U$ ,  $V$ , and  $T$  are all state functions, the value of  $\Delta U$  (or  $\Delta V$  or  $\Delta T$ ) depends only on the initial and final states of the system, not on the path by which the process got the system from initial state to final state. The same change in any of these state functions will be measured no matter which path (reversible or irreversible) is followed between any given pair of thermodynamic states. *The change in any state function between two states is independent of path.* The converse statement is also true: If the change in a property of a system is independent of path, the property is a state function. Figure 12.4 illustrates two different paths that connect a given initial state and a common final state.

## 12.2 The First Law of Thermodynamics: Internal Energy, Work, and Heat

The first law of thermodynamics (which is stated at the end of this section) relates the energy change in a thermodynamic process to the amount of work done on the system and the amount of heat transferred to the system. It is first necessary to examine the ways in which amounts of heat and work are measured to understand the significance of this law. You will see that heat and work are simply different means by which energy is transferred into or out of a system.

### 12.2.1 Work

The mechanical definition of **work** is the product of the external force on a body times the distance through which the force acts. If a body moves in a straight line from point  $r_i$  to  $r_f$  with a constant force,  $F$ , applied along the direction of the path, the work done on the body is

$$w = F(r_f - r_i) \quad (\text{force along direction of path})$$

To illustrate how work can change the energy of a system, we will examine the relation between work and energy in an ordinary mechanical system.

As the first example, consider a block of mass,  $m$ , moving with initial speed  $v_i$  along a frictionless surface. We know that a force acting on an object in the direction of the initial velocity increases the speed, and therefore the kinetic

energy of the object. In the following derivation, we show how the kinetic energy of an object changes when work is done on it. If a constant force,  $F$ , is exerted on it in the direction of its motion, it will experience a constant acceleration,  $a = F/m$ . After a time,  $t$ , the speed of the block will have increased from  $v_i$  to  $v_f$ , and its position will have changed from  $r_i$  to  $r_f$ . The work done on the block is

$$w = F(r_f - r_i) = ma(r_f - r_i)$$

The distance traveled,  $r_f - r_i$ , is given by the average speed, in this case  $(v_i + v_f)/2$ , multiplied by the elapsed time,  $t$ :

$$r_f - r_i = \left( \frac{v_i + v_f}{2} \right) t$$

When the acceleration is constant, it is equal to the change in speed,  $v_f - v_i$ , divided by the elapsed time:

$$a = (v_f - v_i)/t$$

Substituting both of these results into the expression for the work done gives

$$\begin{aligned} w &= m \left( \frac{v_f - v_i}{t} \right) \left( \frac{v_i + v_f}{2} \right) t \\ &= \frac{m}{2} (v_f - v_i)(v_f + v_i) \\ &= \frac{m}{2} v_f^2 - \frac{m}{2} v_i^2 \\ &= \Delta E_{\text{kin}} \end{aligned}$$

The expression on the right side of the equations is the change in kinetic energy,  $\frac{1}{2}mv^2$ , of the block. For this idealized example with a frictionless surface, the work done in moving the block from  $r_i$  to  $r_f$  is equal to the change in energy (in this case, kinetic) of the block.

As a second mechanical example, consider the work done in lifting an object in a gravitational field. To raise a mass,  $m$ , from an initial height,  $h_i$ , to a final height,  $h_f$ , an upward force sufficient to counteract the downward force of gravity,  $mg$ , must be exerted. The work done on the object in this case is

$$w = mg(h_f - h_i) = mg\Delta h = \Delta E_{\text{pot}}$$

This is the change in *potential* energy,  $mgh$ , of the object, showing once again that the mechanical work done in moving a body is equal to the change in energy of the body.

One important kind of mechanical work in chemistry is *pressure-volume work*, which results when a system is compressed or expanded under the influence of an outside pressure. Imagine that a gas has pressure  $P_i$  and is confined in a cylinder by a frictionless piston of cross-sectional area  $A$  and negligible mass (Fig. 12.5). The force exerted on the inside face of the piston by the gas is  $F_i = P_i A$ , because pressure is defined as force divided by area. If there is a gas on the outer side of the piston with pressure  $P_{\text{ext}}$  (“ext” for “external”), then if  $P_{\text{ext}} = P_i$ , the piston will experience no net force. If  $P_{\text{ext}}$  is increased, the gas will be compressed, and if it is decreased, the gas will expand. Consider first the case in which the external force is less than the initial force exerted by the gas,  $P_i A$ . Then the gas will expand and lift the piston from  $h_i$  to  $h_f$ . The work in this case is

$$w = -F_{\text{ext}}(h_f - h_i)$$

**FIGURE 12.5** As the gas inside this cylinder is heated, it expands, pushing the piston against the pressure  $P_{\text{ext}}$  exerted by the gas outside. As the piston is displaced over a distance  $h_i - \Delta h_i = \Delta h$ , the volume of the cylinder increases by an amount  $A \Delta h$ , where  $A$  is the surface area of the piston.

The negative sign is inserted because the force from the gas outside opposes the direction of displacement of the piston during expansion of the gas inside the cylinder. This is rewritten as

$$w = -P_{\text{ext}} A \Delta h$$

The product  $A \Delta h$  is the volume change of the system,  $\Delta V$ , so the work is

$$w = -P_{\text{ext}} \Delta V \quad [12.1]$$

For an expansion,  $\Delta V > 0$ , thus  $w < 0$  and the system does work; it pushes back the surroundings. For a compression (by making  $P_{\text{ext}} > P_i$ ), work is done *on* the system; it is pushed back by the surroundings. Again,  $w = -P_{\text{ext}} \Delta V$ , but now  $\Delta V < 0$ , so  $w > 0$ . If there is no volume change,  $\Delta V = 0$ , and no pressure–volume work is done. Finally, if there is no mechanical link to the surroundings (that is, if  $P_{\text{ext}} = 0$ ), then once again no pressure–volume work can be performed.

If the pressure  $P_{\text{ext}}$  is expressed in pascals and the volume in cubic meters, their product is in joules (J). These are the International System of Units (SI) units for these quantities. For many purposes, it is more convenient to express pressures in atmospheres and volumes in liters; therefore, work has the unit liter-atmospheres (L atm). The two work units are related by

$$1 \text{ L atm} = (10^{-3} \text{ m}^3)(1.01325 \times 10^5 \text{ kg m}^{-1} \text{ s}^{-2}) = 101.325 \text{ J}$$

### EXAMPLE 12.1

A cylinder confines 2.00 L gas under a pressure of 1.00 atm. The external pressure is also 1.00 atm. The gas is heated slowly, with the piston sliding freely outward to maintain the pressure of the gas close to 1.00 atm. Suppose the heating continues until a final volume of 3.50 L is reached. Calculate the work done on the gas and express it in joules.

#### Solution

This is an expansion of a system from 2.00 to 3.50 L against a constant external pressure of 1.00 atm. The work done on the system is then

$$\begin{aligned} w &= -P_{\text{ext}} \Delta V \\ &= -(1.00 \text{ atm})(3.50 \text{ L} - 2.00 \text{ L}) \\ &= -1.50 \text{ L atm} \end{aligned}$$

(Continued)

Conversion to joules gives

$$\begin{aligned} w &= (-1.50 \text{ L atm})(101.325 \text{ J L}^{-1} \text{ atm}^{-1}) \\ &= -152 \text{ J} \end{aligned}$$

Because  $w$  is negative, we see that  $-152 \text{ J}$  of work was done *on* the gas. Put another way,  $+152 \text{ J}$  of work was done *by* the gas as it expanded against atmospheric pressure.

**Related Problems: 1, 2**

## 12.2.2 Internal Energy

In the two simple mechanical cases discussed earlier, we saw how performing work on an object changes the amount of two types of energy: the kinetic energy of a moving object and the potential energy of an object in a gravitational field. In the same way, performing work can change the amount of energy in more complex cases. A third type of energy, less apparent but equally important, is **internal energy**, defined as the total energy content of a system arising from the potential energy between molecules, from the kinetic energy of molecular motions, and from chemical energy stored in chemical bonds. Potential energy between molecules includes the lattice energy of solids and the attractive and repulsive interactions between molecules in gases and liquids. Kinetic energy appears in the translation and the internal motions of individual molecules (Fig. 12.6). Gas molecules are in a constant state of motion (see Section 9.5) even when no overall gas flow is taking place in the container; the same is true of molecules in liquids and solids. In the next section we describe an experiment by James Joule and Benjamin Thompson in which they did mechanical work on water (the system) and found that the temperature of the water increased. Any mechanical or electrical work done on a system can change its internal energy (unless heat is transferred out of the system to compensate). *We conclude that  $P$ - $V$  work is a means of changing the internal energy of a macroscopic system through purely mechanical interaction between the system and its surroundings.*

## 12.2.3 Heat

Now, how do we describe the role of heat in the process in Example 12.1? After all, heating the gas caused it to expand, which enabled it to move the piston and do work on the surroundings. The heater in Figure 12.5 has no mechanical “moving parts,” yet it set in motion a train of events that led to a mechanical result. To explain this result, we interpret **heat** as *a means of increasing the internal energy of a system without mechanical interaction*. Justification for this interpretation is provided later in this chapter.

Heat,  $q$ , may be transferred between two objects initially at different temperatures, potentially changing the thermal energy of each. When a hot body is brought into contact with a colder body, the two temperatures change until they become equal. If a piece of hot metal is plunged into a container of water, the temperature of the water increases as its molecules begin to move faster, corresponding to an increase in the internal energy of the water. This process is sometimes described as the “flow” of heat from the hotter to the colder body. Although this picture is useful, it is based on the antiquated (and erroneous) notion that heat is a sort of fluid contained in matter.

The idea of heat flow has inspired methods for measuring the amount of energy transferred as heat; this branch of science is called **calorimetry**. One simple way is to use an **ice calorimeter** (Fig. 12.7), which consists of a bath containing ice and water, well insulated to prevent heat transfer to the surroundings.

**FIGURE 12.6** A ball dropped from a height increases its internal energy on impact with the ground. After impact, the molecules near the surface of the ball are pushed against one another, increasing the potential energy between the molecules. As the ball bounces, the molecules readjust their positions, after which they move a little faster. The kinetic energy of the molecules is higher than it was just before impact with the ground.

**FIGURE 12.7** An ice calorimeter. As the ice melts, the volume of the ice–water mixture decreases, an effect that can be read off the scale on the left.

If heat is transferred to the bath from the system, some of the ice melts. Because a given mass of water has a smaller volume than the same mass of ice, the total volume of the ice–water mixture decreases as heat enters the bath. If twice as much heat is transferred, twice as much ice will melt and the volume change will be twice as great. The amount of heat transferred is determined from the change in volume of the contents of the calorimeter. Heat transferred from the ice bath *into* the system causes water to freeze and *increases* the total volume of the ice bath.

More contemporary versions of calorimetry use the fact that when heat is transferred to or removed from a substance in a single phase at constant pressure, the temperature changes in a reproducible way. The **specific heat capacity** of a material is the amount of heat required to increase the temperature of a 1-g mass by 1°C. If twice as much heat is transferred, the resulting temperature change will be twice as large (provided the specific heat capacity itself does not change appreciably with temperature). Thus, the temperature change of a fixed amount of a given substance is a measure of the thermal energy transferred to or from it. This is described by

$$q = mc_s\Delta T \quad [12.2]$$

where  $q$  is the heat transferred to a body of mass  $m$  with specific heat capacity  $c_s$  to cause a temperature change of  $\Delta T$ . (Be careful not to use Eq. 12.2 if a phase change or chemical reaction is occurring in the mixture being heated. Heating a pot of boiling water does not increase its temperature, it simply provides the energy for more molecules to evaporate.)

Because heat, like work, is energy in the process of being transferred, the appropriate unit for it is also the joule. Historically, however, the connections among work, heat, and energy were not appreciated until the middle of the 19th century, by which time a separate unit for heat, the calorie, was already well established. One calorie was defined as the amount of heat required to increase the temperature of 1 g water from 14.5°C to 15.5°C (or, in other words, the specific heat capacity of water,  $c_s$ , at 15°C was *defined* as 1.00 cal K<sup>-1</sup> g<sup>-1</sup>).

The equivalence of heat and work as means of energy transfer was suggested in 1798 by Benjamin Thompson, Count Rumford. In the course of his work as military advisor to the King of Bavaria, Thompson observed that the quantity of heat produced in boring cannons was proportional to the amount of work done in the process. Moreover, the operation could be continued indefinitely, demonstrating that heat was not a “fluid” contained in the metal of the cannon. More quantitative measurements were conducted by the German physician Julius Mayer and by the English physicist James Joule. In the 1840s, these scientists showed that the temperature of a substance could be increased by doing work on the substance, as well as by adding heat to it. Figure 12.8 shows an apparatus in which a paddle, driven by a falling weight, churns the water in a tank. Work is performed on the water, and the temperature increases. The work done on the water is  $-mg\Delta h$ , where  $\Delta h$  is the (negative) change in the height of the weight and  $m$  is its mass. The experiment is conducted in an insulated container, so no heat enters the container or leaks out to the surroundings. Because all this work goes to increase the water temperature, the specific heat capacity of the water in *joules* per gram per degree is equal to the quantity of work done divided by the product of the mass of water and its temperature increase.

**FIGURE 12.8** The falling weight turns a paddle that does work on the system (the water), causing an increase in its temperature.

### EXAMPLE 12.2

Suppose a 10.00-kg mass drops through a height difference of 3.00 m, and the resulting work is used to turn a paddle in 200.0 g water, initially at 15.00°C. The final water temperature is found to be 15.35°C. Assuming that the work done is used entirely to increase the water temperature, calculate the conversion factor between joules and calories.

#### Solution

The total work done on the water is

$$w = -mg\Delta h = -(10.00 \text{ kg})(9.807 \text{ m s}^{-2})(-3.00 \text{ m}) = 294 \text{ J}$$

The heat (in calories) required to increase the water temperature by the same amount is

$$q = mc_s\Delta T = (200.0 \text{ g})(1.000 \text{ cal K}^{-1} \text{ g}^{-1})(0.35 \text{ K}) = 70 \text{ cal}$$

Because the work done has the same effect on the water as direct transfer of heat, these two expressions can be set equal to each other, giving

$$70 \text{ calories} = 294 \text{ joules}$$

$$1 \text{ calorie} \approx 4.2 \text{ joules}$$

**Related Problems:** 3, 4

These and other experiments eliminated the need for the calorie as an independent unit, and the calorie is now *defined* as

$$1 \text{ cal} = 4.184 \text{ J} \quad (\text{exactly})$$

This book uses the joule as the primary unit for heat and energy. Because much of the chemical literature continues to use the calorie as the unit of heat, it is important to be familiar with both units.

## 12.2.4 The First Law of Thermodynamics

Both heat and work are forms in which energy is transferred into and out of a system; they can be thought of as energy in transit. If the energy change is caused by *mechanical* contact of the system with its surroundings, work is done; if it is caused by *thermal* contact, heat is transferred. In many processes, both heat and work cross the boundary of a system, and the change in the internal energy,  $U$ , of the system is the sum of the two contributions. We denote the internal energy by  $U$  to distinguish it from the sum of the potential and kinetic energy in a simple mechanical or electrical process, for which we use the symbol  $E$  throughout this book. This statement, called the **first law of thermodynamics**, takes the mathematical form<sup>1</sup>

$$\Delta U = q + w \quad [12.3]$$

<sup>1</sup>Some books, especially engineering ones, define work as positive when it is done by the system. The reason is that many engineering applications focus on the work done by a particular heat engine; therefore, it is helpful to define that quantity as positive. Thus, the work is given by

$$w = P_{\text{ext}} \Delta V \quad (\text{engineering convention})$$

and the first law reads

$$\Delta U = q - w \quad (\text{engineering convention})$$

Although we do not use the engineering convention, you should check which convention is used when consulting other books. In particular, the MCAT has used the engineering convention.

**FIGURE 12.9** The first law of thermodynamics states that the change in internal energy of a system during a process is the sum of the heat transferred to the system,  $q$ , and the work done on the system,  $w$ . If heat is transferred out of the system,  $q$  is negative. Likewise, if the system does work on the surroundings,  $w$  is negative.

A system cannot be said to “contain” work or heat, because both “work” and “heat” refer not to states of the system but to *processes* that transform one state into another. In the Joule experiment shown in Figure 12.8, the work done on the water (the system) by the falling weight increased the temperature of the water. Work was performed on the system, and no heat was transferred; thus, the first law for this process takes the form  $\Delta U = w$ . The same change in state of the system can be achieved by transferring heat to the system without work being done; for this process,  $\Delta U = q$ . Because  $q$  and  $w$  depend on the particular process (or path) connecting the states, they are not state functions. But their sum,  $\Delta U = q + w$ , is independent of path; therefore, internal energy is a function of state (see Fig. 12.9). The fundamental physical content of the first law of thermodynamics is the following observation:

*There exists a state function called internal energy represented by  $U$  whose changes  $\Delta U = q + w$  are independent of path, although the values of  $q$  and  $w$  individually depend on the path of the process.*

We stated earlier that the laws of thermodynamics cannot be derived or proved; they are generalizations of the results of countless experiments on a tremendous variety of substances. It is not possible even to “check” the first law by independently measuring  $\Delta U$ ,  $w$ , and  $q$ , because no “energy gauges” exist to determine energy changes  $\Delta U$ . But what we *can* do is to measure  $w$  and  $q$  for a series of different processes connecting the same initial and final states. Every time, we find that their sum,  $q + w$ , is always the same.

In any process, the heat *added* to the system is *removed* from the surroundings; thus,

$$q_{\text{sys}} = -q_{\text{surr}}$$

In the same way, the work done *on* the system is done *by* the surroundings; thus,

$$w_{\text{sys}} = -w_{\text{surr}}$$

Adding these two and invoking the first law give

$$\Delta U_{\text{sys}} = -\Delta U_{\text{surr}}$$

Thus, the energy changes of system and surroundings have the same magnitude but opposite signs. The total energy change of the thermodynamic universe for a given process (system plus surroundings) is then

$$\Delta U_{\text{univ}} = \Delta U_{\text{sys}} + \Delta U_{\text{surr}} = 0 \quad [12.4]$$

Our conclusion is that, in any process, the total energy of the thermodynamic universe remains unchanged; the total energy is conserved while it is exchanged between the system and the surroundings.

## 12.3 Heat Capacity, Calorimetry, and Enthalpy

Section 12.2 defines specific heat capacity as the amount of heat required to increase the temperature of 1 g of material by 1 K. That definition is somewhat imprecise, because, in fact, the amount of heat required depends on whether the process is conducted at constant volume or at constant pressure. This section describes precise methods for measuring the amount of energy transferred as heat during a process and for relating this amount to the thermodynamic properties of the system under investigation.

### 12.3.1 Heat Capacity and Specific Heat Capacity

The **heat capacity**,  $C$ , is defined as the amount of energy that must be added to the system to increase its temperature by 1 K. The heat capacity is a property of the system as a whole and has units of  $\text{J K}^{-1}$ .

$$q = C\Delta T$$

Now consider a case in which two gaseous systems containing identical masses of the same substance are heated to produce identical changes in temperature. During the experiment, system 1 is held at constant volume, and system 2 at constant pressure. Which system absorbed more heat in these identical temperature changes? All the energy gained by system 1 contributed to increasing the temperature of the substance, and therefore the speed of the molecules, subject to the fixed volume. But in system 2, some of the energy gained was promptly lost as the system performed expansion work against the surroundings at constant pressure. Consequently, system 2 must absorb more thermal energy from the surroundings than does system 1 to achieve the identical temperature change. Two independent heat capacity functions must be defined:  $C_p$ , the heat capacity at constant pressure, and  $C_v$ , the heat capacity at constant volume. For any system,  $C_p$  is greater than  $C_v$ . This difference can be quite large for gases. It is usually negligible for solids and liquids, because their only volume change at constant pressure is the small expansion or contraction on heating and cooling.

In thermodynamics, the *molar* heat capacities  $c_v$  and  $c_p$  (the system heat capacities  $C_v$  and  $C_p$  divided by the number of moles of substance in the system) are particularly useful:  $c_v$  is the amount of heat required to increase the temperature of 1 mol of substance by 1 K at constant volume, and  $c_p$  is the corresponding amount required at constant pressure. If the total heat transferred to  $n$  moles at constant volume is  $q_v$ , then

$$q_v = nc_v(T_2 - T_1) = nc_v\Delta T \quad [12.5]$$

If an amount  $q_p$  is transferred at constant pressure, then

$$q_p = nc_p\Delta T \quad [12.6]$$

provided that  $c_v$  and  $c_p$  do not change significantly between the initial and final temperatures. The *specific heat capacity* at constant  $V$  or constant  $P$  is the system heat capacity reported per gram of substance. Extensive tabulations of molar and specific heat capacities at constant volume and at constant pressure are available. The specific heat capacities of some common substances are listed in Table 12.1, and a more extensive tabulation of molar heat capacities at constant pressure is provided in Appendix D. We relate the heat capacity of a substance to its molecular structure in Section 12.5.

TABLE 12.1

Specific Heat Capacities at Constant Pressure (at 25°C)

Substance	Specific Heat Capacity ( $\text{J K}^{-1} \text{g}^{-1}$ )
Hg( $\ell$ )	0.140
Cu(s)	0.385
Fe(s)	0.449
SiO <sub>2</sub> (s)	0.739
CaCO <sub>3</sub> (s)	0.818
O <sub>2</sub> (g)	0.917
H <sub>2</sub> O( $\ell$ )	4.18

The importance of the heat capacity is illustrated by placing two objects initially at different temperatures into contact. Energy in the form of heat is exchanged between them until they reach a common temperature. If the two objects are insulated from the rest of the universe during the process, the amount of heat  $q_2$  taken up by the cooler object is equal to  $-q_1$ , the amount of heat given up by the hotter object. As always, the convention followed is that energy transferred to an object has a positive sign; thus,  $q_2$  is positive when  $q_1$  is negative. This analysis is broadly applicable; a typical example follows.

**FIGURE 12.10** A Styrofoam cup calorimeter. As the piece of metal cools, it releases heat to the water. The amount of heat released can be determined from the temperature change of the water. The hot metal is the “system”; the water is the “surroundings.” The Styrofoam cup wall prevents energy exchange with the remainder of the room and is the boundary of the “thermodynamic universe” for this problem.

### EXAMPLE 12.3

A piece of iron weighing 72.4 g is heated to 100.0°C and plunged into 100.0 g water that is initially at 10.0°C in a Styrofoam cup calorimeter. Assume no heat is lost to the Styrofoam cup or to the environment (Fig. 12.10). Calculate the final temperature that is reached.

#### Solution

The “coffee cup calorimeter” operates at constant pressure determined by the atmosphere; therefore, we need specific heat data at constant pressure. Because the data involve masses, it is easier to work with specific heat capacities (see Table 12.1) than with molar heat capacities. If  $t_f$  is the final temperature (in degrees Celsius), then the equation for heat balance gives

$$m_1(c_{s1})\Delta T_1 = -m_2(c_{s2})\Delta T_2$$

$$(100.0 \text{ g H}_2\text{O})(4.18 \text{ J } ^\circ\text{C}^{-1} \text{ g}^{-1})(t_f - 10.0^\circ\text{C}) = -(72.4 \text{ g Fe})(0.449 \text{ J } ^\circ\text{C}^{-1} \text{ g}^{-1})(t_f - 100.0^\circ\text{C})$$

This is a linear equation for the unknown temperature  $t_f$ , and its solution is

$$418t_f - 4180 = -32.51t_f + 3251$$

$$t_f = 16.5^\circ\text{C}$$

Note that specific heat capacities are numerically the same whether expressed in  $\text{J K}^{-1} \text{ g}^{-1}$  or  $\text{J } (^\circ\text{C})^{-1} \text{ g}^{-1}$  (because the degree Celsius and the kelvin have the same size). Converting 10.0°C and 100.0°C to kelvins and using specific heat capacities in units of  $\text{J K}^{-1} \text{ g}^{-1}$  gives  $t_f = 289.7 \text{ K}$ , which is equivalent to the previous answer.

**Related Problems:** 11, 12

## 12.3.2 Heat Transfer at Constant Volume: Bomb Calorimeters

Suppose some reacting species are sealed in a small closed container (called a *bomb*) and the container is placed in a calorimeter like the one in Figure 12.11. The reaction is initiated by a heated wire inside the bomb. As the molecules react chemically, heat is given off or taken up, and the change in temperature of the calorimetric fluid is measured. Because the container has rigid walls, its volume is constant and no pressure–volume work is done. Therefore, the change in internal energy is equal to the measured heat absorbed from the chemical reaction at constant volume:

$$\Delta U = q_V$$

Such experiments at constant volume are often inconvenient or difficult to perform. They require the use of a well-constructed reaction vessel that can resist the large pressure changes that occur in many chemical reactions.

**FIGURE 12.11** The combustion calorimeter is also called a “bomb calorimeter”; the combustion reaction in it is conducted at a fixed volume.

### 12.3.3 Heat Transfer at Constant Pressure: Enthalpy

Most chemical reactions are carried out under constant (atmospheric) pressure conditions rather than at constant volume. It is desirable to identify a state function whose change in a process is equivalent to the heat transferred at constant pressure,  $q_p$ , just as is  $\Delta U$  is equivalent to  $q_v$ .

If the work done is entirely pressure–volume work, and if the external pressure is held constant, then

$$\Delta U = q_p + w = q_p - P_{\text{ext}}\Delta V$$

If the external pressure is now assumed to be equal to the internal pressure of the system  $P$ , then

$$U = q_p - P\Delta V$$

$$q_p = \Delta U + P\Delta V$$

Because  $P$  is constant,  $P\Delta V = \Delta(PV)$ , and this equation becomes

$$q_p = \Delta(U + PV)$$

The combination  $U + PV$  appearing on the right side is now defined as the **enthalpy  $H$** :

$$H = U + PV \quad [12.7a]$$

thus,

$$q_p = \Delta(U + PV) = \Delta H \quad [12.7b]$$

Because  $U$ ,  $P$ , and  $V$  are state functions,  $H$  must also be a state function. Heat transfer in a process at constant pressure has therefore been related to the change in a state function.

It is important to remember that

$$\Delta H = q_p = \Delta U + P\Delta V \quad (\text{constant pressure})$$

holds only at constant internal pressure. If the pressure changes, the more general relationship

$$\Delta H = \Delta U + \Delta(PV)$$

must be used. Like the energy, the enthalpy change is determined by the initial and final states and is independent of the particular path along which the process is performed. This is always true for a state function.

Physical interpretation of the enthalpy function follows immediately from the equation  $\Delta H = \Delta U + P\Delta V$  at constant pressure. Clearly,  $H$  has physical dimensions of energy and is, in effect, a “corrected” internal energy that reflects the consequences of changing  $V$  while thermal energy is being absorbed at constant pressure. The “correction term”  $P\Delta V$  accounts precisely for the energy used by the system to do expansion work, rather than for increasing the temperature of the system. Thus, the value of  $q$  in constant pressure processes where only pressure–volume work is done is equivalent to the change in the state function enthalpy,  $\Delta H$ .

## 12.4 The First Law and Ideal Gas Processes

We stated the first law of thermodynamics in a general form, applicable to any process that begins and ends in equilibrium states. We analyzed the heat and work terms separately and presented methods for calculating, measuring, and interpreting each. All the concepts are now in place for applying thermodynamics to the discussion of specific processes. Applications require data on certain properties of the substance being studied, such as its equation of state and its heat capacities. Thermodynamic arguments alone cannot provide the actual values of such properties; instead, thermodynamics establishes universal relations among such properties. The actual values must be obtained by methods other than thermodynamics, such as experimental measurements or theoretical calculations in statistical thermodynamics. To illustrate these points, in the next few paragraphs we obtain data on the heat capacities of ideal gases by methods outside thermodynamics. Then we use these data to apply thermodynamics to analyze particular processes carried out on ideal gases.

### 12.4.1 Heat Capacities of Ideal Gases

The pair of molar heat capacities  $c_V$  and  $c_p$  for an ideal monatomic gas can be calculated from the results of the kinetic theory of gases and the ideal gas equation of state. From Section 9.5, the average translational kinetic energy of  $n$  moles of an ideal gas is

$$\bar{E}_{\text{kin}} = \frac{3}{2}nRT$$

In a *monatomic* gas, changes in the total internal energy  $\Delta U$  measured in thermodynamics can be equated to changes in the average translational kinetic energy of the atoms. If  $n$  moles of a monatomic gas is taken from a temperature  $T_1$  to a temperature  $T_2$ , the internal energy change is

$$\Delta U = \frac{3}{2}nR(T_2 - T_1) = \frac{3}{2}nR\Delta T$$

Note that the pressure and volume do not affect  $U$  explicitly (except through temperature changes), so this result is independent of the change in pressure or volume of the gas.

Now, consider changing the temperature of an ideal gas at constant volume from the point of view of thermodynamics. Because the volume is constant (the

gas is confined in a vessel with rigid, diathermal walls), the pressure–volume work,  $w$ , must be zero; therefore,

$$\Delta U = q_V = nc_V\Delta T \quad (\text{ideal gas})$$

where  $q_V$  is the heat transferred at constant volume. Equating this thermodynamic relation with the previous expression for  $\Delta U$  (from kinetic theory) shows that

$$c_V = \frac{3}{2}R \quad (\text{monatomic ideal gas}) \quad [12.8]$$

Similarly, the molar heat capacity at constant pressure,  $c_P$ , is calculated by examining the heating of a monatomic ideal gas at constant pressure from temperature  $T_1$  to  $T_2$ . Experimentally, such a process can be performed by placing the gas in a cylinder with a piston that moves out as the gas is heated, keeping the gas pressure equal to the outside pressure. In this case,

$$\Delta U = \frac{3}{2}nR\Delta T = nc_V\Delta T$$

still holds (because the energy change depends only on the temperatures for an ideal gas), but we now have

$$\Delta U = q_P + w$$

because the work is no longer zero. The work for a constant-pressure process is easily calculated from

$$w = -P\Delta V = -P(V_2 - V_1)$$

and the heat transferred is

$$q_P = nc_P\Delta T$$

Because  $w$  is negative,  $q_P$  is larger than  $q_V$  by the amount of work done by the gas as it expands. This gives

$$\Delta U = q + w$$

$$nc_V\Delta T = nc_P\Delta T - P(V_2 - V_1)$$

From the ideal gas law,  $PV_1 = nRT_1$  and  $PV_2 = nRT_2$ ; thus,

$$nc_V\Delta T = nc_P\Delta T - nR\Delta T$$

$$c_V = c_P - R$$

$$c_P = c_V + R$$

For a monatomic ideal gas, this shows that  $c_P = \frac{5}{2}R$ . It is important to use the proper units for  $R$  in these expressions for  $c_V$  and  $c_P$ . If heat is to be measured in joules,  $R$  must be expressed as

$$R = 8.315 \text{ J K}^{-1} \text{ mol}^{-1}$$

For a diatomic or polyatomic ideal gas,  $c_V$  is greater than  $\frac{3}{2}R$ , because energy can be stored in rotational and vibrational motions of the molecules; a greater amount of heat must be transferred to achieve a given temperature change. (See Section 12.5.) Even so, it is still true that

$$c_P = c_V + R \quad (\text{any ideal gas}) \quad [12.9]$$

and that internal energy changes depend only on the temperature change; therefore, for a small temperature change  $\Delta T$ ,

$$\Delta U = nc_V\Delta T \quad (\text{any ideal gas}) \quad [12.10]$$

For an ideal gas process,

$$\begin{aligned}\Delta H &= \Delta U + \Delta(PV) = nc_V\Delta T + nR\Delta T \\ \Delta H &= nc_P\Delta T \text{ (any ideal gas)}\end{aligned}\quad [12.11]$$

because  $c_p = c_v + R$ . This result holds for any ideal gas process and shows that enthalpy changes, like internal energy changes, depend only on the temperature difference between initial and final states. These equations are not valid for systems other than ideal gases.

### EXAMPLE 12.4

Suppose that 1.00 kJ of heat is transferred to 2.00 mol argon (at 298 K, 1 atm). What will the final temperature  $T_f$  be if the heat is transferred (a) at constant volume, or (b) at constant pressure? Calculate the energy change,  $\Delta U$ , in each case.

#### Solution

Because argon is a monatomic, approximately ideal gas,

$$c_V = \frac{3}{2}R = 12.47 \text{ J K}^{-1} \text{ mol}^{-1}$$

$$c_P = \frac{5}{2}R = 20.79 \text{ J K}^{-1} \text{ mol}^{-1}$$

At constant volume,

$$q_V = nc_V\Delta T$$

$$1000 \text{ J} = (2.00 \text{ mol})(12.47 \text{ J K}^{-1} \text{ mol}^{-1})\Delta T$$

$$\Delta T = 40.1 \text{ K}; T_f = 298 + 40.1 = 338 \text{ K}$$

$$\Delta U = nc_V\Delta T = q_V = 1000 \text{ J}$$

At constant pressure,

$$q_P = nc_P\Delta T$$

$$1000 \text{ J} = (2.00 \text{ mol})(20.79 \text{ J K}^{-1} \text{ mol}^{-1})\Delta T$$

$$\Delta T = 24.0 \text{ K}; T_f = 298 + 24.0 = 322 \text{ K}$$

$$\Delta U = nc_V\Delta T$$

$$= (2.00 \text{ mol})(12.47 \text{ J K}^{-1} \text{ mol}^{-1})(24 \text{ K}) = 600 \text{ J}$$

Note that the expression for  $\Delta U$  involves  $c_V$  even though the process is conducted at constant pressure. The difference of 400 J between the input  $q_P$  and  $\Delta U$  is the work done by the gas as it expands.

**Related Problems:** 17, 18, 19, 20, 21, 22

**FIGURE 12.12** States A and B of a system are connected by two different ideal gas processes, one passing through state C and the other through state D.

### 12.4.2 Heat and Work for Ideal Gases

Now we have all the data needed to calculate heat and work for a variety of processes involving an ideal gas. To illustrate that  $q$  and  $w$  individually depend on the path followed, but their sum does not, consider the expansion of 1.00 mol of an ideal monatomic gas following two different paths. The system begins at state A ( $P_A = 2.00 \text{ atm}$ ,  $V_A = 10.0 \text{ L}$ ) and reaches a final state, B ( $P_B = 1.00 \text{ atm}$ ,  $V_B = 30.0 \text{ L}$ ), via either of two paths shown in Figure 12.12. Along path ACB (red arrows in Fig. 12.12), the system is first heated at constant pressure ( $P_{\text{ext}} = P_A = 2 \text{ atm}$ ) until the volume has tripled; then it is cooled at constant volume until the pressure is halved. Along path ADB (blue arrows in Fig. 12.12), the system is cooled at constant volume until the pressure is halved, and then heated at constant pressure ( $P_{\text{ext}} = P_B = 1 \text{ atm}$ ) until the volume has tripled.

The calculations of heat and work for each step are of the type already performed and are straightforward. Thus,

$$w_{AC} = -P_{\text{ext}}\Delta V = -P_A(V_B - V_A)$$

$$w_{CB} = 0 \text{ because } V_C = V_B$$

$$q_{AC} = q_P = nc_P\Delta T = \frac{5}{2}nR(T_C - T_A)$$

$$q_{CB} = q_V = nc_V\Delta T = \frac{3}{2}nR(T_B - T_C)$$

From the ideal gas law,  $nRT_A = P_A V_A$ ,  $nRT_B = P_B V_B$ , and  $nRT_C = P_C V_C = P_A V_B$  (because  $P_A = P_C$  and  $V_B = V_C$ ). Using these relations and summing over the two steps give

$$w_{ACB} = w_{AC} + w_{CB} = -P_A(V_B - V_A) = -40.0 \text{ L atm} = -4050 \text{ J}$$

$$\begin{aligned} q_{ACB} &= q_{AC} + q_{CB} = \frac{5}{2} nR(T_C - T_A) + \frac{3}{2} nR(T_B - T_C) \\ &= \frac{5}{2} P_A(V_B - V_A) + \frac{3}{2} V_B(P_B - P_A) = (100.0 - 45.0) \text{ L atm} = 5570 \text{ J} \end{aligned}$$

The sum of these is  $\Delta U = w_{ACB} + q_{ACB} = 1520 \text{ J}$ . (This could also have been obtained by using the ideal gas law to calculate the initial and final temperatures  $T_A$  and  $T_B$ .)

The corresponding calculation for path ADB gives

$$w_{ADB} = -2030 \text{ J and } q_{ADB} = 3550 \text{ J}$$

Even though both the work and the heat have changed, their sum is still 1520 J, illustrating that  $U$  is a state function, whereas  $q$  and  $w$  are not.

## 12.5 Molecular Contributions to Internal Energy and Heat Capacity

The internal energy of a system is the total of the energy involved in the motions of its molecules and the interactions between them, and so must depend on the structures of the molecules. The heat capacity at constant volume, defined as the change in internal energy per degree temperature increase, measures the ability of these mechanical motions and interactions to accommodate thermal energy.

The bridge between thermodynamics and the mechanics of molecules is provided by the kinetic theory of matter. The kinetic theory of gases (see Section 9.5) views each molecule in an ideal gas as a point particle moving independently of the others, and describes the probability of molecular speeds by the Maxwell-Boltzmann distribution. From this, the average kinetic energy per molecule is calculated to be  $\bar{\epsilon} = \left(\frac{3}{2}\right) k_B T$ , and multiplying by the total number of molecules,  $N$ , gives the total kinetic energy in  $n$  moles of an ideal gas as  $E_{\text{kin}} = \left(\frac{3}{2}\right) nRT$ . This model calculation interprets the internal energy of a monatomic ideal gas as consisting solely of the translational kinetic energy of the atoms. Calculating the change in this internal energy as  $T$  is increased predicts the molar heat capacity at constant pressure of a monatomic ideal gas to be (see Equations 12.8 and 12.9)

$$c_p = \frac{3}{2} R + R = \frac{5}{2} R = 20.785 \text{ J mol}^{-1} \text{ K}^{-1}$$

independent of the temperature. Comparison with the experimental results in Table 12.2 shows that this model calculation accurately predicts the heat capacity for monatomic gases.

The measured heat capacity values for diatomic and polyatomic molecules are significantly larger than those for monatomic gases. The explanation must lie in the existence of molecular motions, or **degrees of freedom**, in addition to translation that can accommodate thermal energy.

Figure 12.13a shows the degrees of freedom for a diatomic molecule. The molecule as a whole can undergo translational motion of its center of mass, behaving as if it were a point particle with mass equal to the total mass of the molecule, in the  $x$ -,  $y$ -, or  $z$ -directions. The molecule has three translational degrees of freedom, so the total kinetic energy is  $\frac{1}{2} m v_x^2 + \frac{1}{2} m v_y^2 + \frac{1}{2} m v_z^2 = E_{\text{trans}} = \frac{1}{2} m v^2$ . Each of these three degrees of freedom contributes  $\frac{1}{2} RT$  to the

molar heat capacity at constant volume. The molecule can rotate about its center of mass with both atoms in a plane. (See Section 3.9.) It can also tumble end-over-end, which amounts to rotation about its center of mass in a different plane. It has two rotational degrees of freedom, in each of which the kinetic energy takes the form  $E_{\text{rot}} = \frac{1}{2} I \omega^2$  where  $I$  is the moment of inertia and  $\omega$  is the angular speed. The molecule can stretch, or vibrate, about its equilibrium bond length  $R_e$  along the internuclear axis. (See *Connection to Instrumental Analysis* in Section 3.9) The potential energy of vibration is  $PE_{\text{vib}} = \frac{1}{2} k(R_{\text{AB}} - R_e)^2$ , and the kinetic energy is  $KE_{\text{vib}} = \frac{1}{2} \mu \left( \frac{dR_{\text{AB}}}{dt} \right)^2$ . In total, the diatomic molecule has three degrees of freedom for translational motion (kinetic energy only), two

degrees of rotational freedom (kinetic energy only), and one degree of vibrational freedom (both kinetic and potential energy).

Figure 12.13b shows a similar description of the degrees of freedom of a nonlinear polyatomic molecule. Translational motion of the center of mass requires three degrees of freedom. Rotational motion can be visualized as an oblong object (such as an American football or a rugby ball) tumbling end-over-end in two separate planes, and also spiraling about its long axis. These motions require three degrees of freedom. The two planes are the same as described for the diatomic molecule. Because the spiraling motion does not occur for the diatomic molecule—it would be analogous to rotating a wire about its long axis—the diatomic molecule has one fewer degree of rotational freedom. To count the vibrational degrees of freedom, we start with the maximum total degrees of freedom that would be needed to describe the motions of all the atoms in a molecule of  $N$  atoms ( $3N$ ), subtract away those already assigned to the center of mass (3), and those assigned to rotation (2 for a linear molecule, 3 for a molecule of general shape), and obtain  $3N-5$  vibrational degrees of motion for a linear molecule and  $3N-6$  for a nonlinear molecule.

To see how these modes contribute to the internal energy, let's return to the calculation of the average kinetic energy per molecule in Equations 9.12–9.14. The kinetic energy of a molecule is proportional to the square of its speed, and the second power of its speed also appears in the statistical weighting factor of the Maxwell–Boltzmann equation in Equation 9.19. Averaging the kinetic energy over this distribution produces the result  $RT/2$  for each translational degree of freedom. The same result is obtained for each degree of freedom whose energy has a quadratic dependence on the speeds or coordinates, when its average is calculated over the Maxwell–Boltzmann distribution. This general conclusion is a result of the **equipartition theorem** of classical kinetic theory which depends on the mathematical form of the Maxwell–Boltzmann distribution. The result is that each translational degree of freedom contributes  $RT/2$ , and each rotational degree of freedom contributes  $RT/2$  to the internal energy. Each vibrational degree of freedom contributes  $RT$  to the internal energy because it has one quadratic term for the kinetic energy and another for the potential energy.

We can determine the contribution of each mode to the heat capacity  $c_V$  by calculating the ratio  $\Delta U/\Delta T$  as the temperature is increased at constant volume from  $T_1$  to  $T_2$  (for small temperature changes), sum these contributions to find the total value of  $c_V$  and then calculate  $c_p$  by adding  $R$  to  $c_V$ , as in Equation 12.8. The results are summarized in Table 12.3 for several gases. The last two columns in Table 12.3 show that the results predicted for  $c_p$  by equipartition are significantly larger than the experimental values of  $c_p$  measured at 298 K. Figure 12.14 shows that the measured results depend on temperature, and how each mode contributes to the total heat capacity, for several gases. The translational motions contribute  $(5/2)R$  at all temperatures above 0 K. The rotational contribution for  $H_2$  increases with  $T$ , and by room temperature has reached its equipartition value of  $R$ ; the total heat capacity at constant pressure for  $H_2$  due to translational and rotational motion is  $(7/2)R$  at room temperature. Heavier diatomics reach this equipartition value at even lower temperatures. Vibrational motions in  $H_2$ ,  $N_2$ , and  $O_2$  contribute significantly to the heat capacity only above room temperature. At these higher temperatures the difference between the measured values for these diatomics and  $(7/2)R$  is essentially the magnitude of the vibrational contribution. At sufficiently high temperature the measured heat capacities for these diatomic gases approach the equipartition value of  $(9/2)R = 37.41 \text{ J mol}^{-1} \text{ K}^{-1}$ . Similarly the measured heat capacities for  $H_2O$  and  $CO_2$  approach their equipartition values of  $(14/2)R = 58.18 \text{ J mol}^{-1} \text{ K}^{-1}$  and  $(15/2)R = 62.37 \text{ J mol}^{-1} \text{ K}^{-1}$ , respectively.

The fact that predictions of the equipartition theorem agree with experiment at high temperature but not at low temperature is explained by quantum

TABLE 12.3

mechanics. The equipartition theorem is a consequence of classical mechanics, and it assumes that each mode of energy accommodation is always active. The quantum analysis starts by calculating the energy levels for each mode of motion and setting up probability for finding the molecules in excited energy states when the system is at temperature  $T$ . The probability function contains the factor

**FIGURE 12.14** The temperature dependence of  $c_p$  for selected gases. Condensation to liquid and solid states at low temperatures is not included. Comparison with Table 12.3 shows that the diatomic molecules and the linear triatomic molecule CO<sub>2</sub> have contributions from two rotational degrees of freedom, and the non-linear triatomic H<sub>2</sub>O has contributions from three. Vertical arrows represent the vibrational contributions for H<sub>2</sub> and for H<sub>2</sub>O at specific temperatures. (Adapted from Donald R. Olander, *General Thermodynamics*, New York, CRC Press, 2007, Figure 2.5, page 57; © Cengage Learning)

$\exp(-\Delta\varepsilon/k_{\text{B}}T)$ , where  $\Delta\varepsilon$  is the gap between the ground state and a typical excited energy level. The dominant physical question is whether the temperature is sufficiently high to make  $k_{\text{B}}T \gg \Delta\varepsilon$ . If  $T$  is high enough, the quantum states will be populated and the system will behave essentially as predicted by classical mechanics. This analysis is illustrated in Example 4.8 by showing that the energy levels of He atoms confined in a three-dimensional box of macroscopic size are so closely spaced in energy that the classical prediction is a good one. We show in Chapter 20 that many rotational quantum states are populated at room temperature for the same reason. The spacing between vibrational energy levels is larger, and each case must be examined to determine whether a significant number of molecules are vibrationally excited at a particular  $T$ . The detailed procedures are demonstrated in Section 12.8, *A Deeper Look . . . Distribution of Energy among Molecules*.

### EXAMPLE 12.5

Calculate the value of  $c_p$  at 298 K and 1 atm pressure predicted for CO and Br<sub>2</sub> by the classical equipartition theorem. Compare the predicted results with the experimental results and calculate the percent of the measured value that arises from vibrational motions.

#### Solution

Table 12.3 summarizes the predicted results for CO and Br<sub>2</sub>. The total value of  $c_p = (9R/2)$  because a diatomic molecule has 3 degrees of translational motion (each contributing  $(R/2)$ ), 2 degrees of rotational motion (each contributing  $(R/2)$ ), and 1 degree of vibrational motion contributing  $R$  for a total  $(7R/2)$  to  $c_v$ . One additional term of  $R$  must be added to obtain  $c_p = (9R/2)$ . The numerical value is  $c_p = 37.41 \text{ J mol}^{-1} \text{ K}^{-1}$ .

Neglecting the vibrational motion predicts  $c_p = (7R/2) = 29.10 \text{ J mol}^{-1} \text{ K}^{-1}$ .

For CO:

The measured value is  $c_p = 29.12 \text{ J mol}^{-1} \text{ K}^{-1}$ .

The vibrational contribution =  $29.12 - 29.10 = 0.02 \text{ J mol}^{-1} \text{ K}^{-1}$ .

Percent of  $c_p$  due to vibration =  $(0.02/29.12) \times 100 = 0.1\%$

For Br<sub>2</sub>:

The measured value is  $c_p = 36.02 \text{ J mol}^{-1} \text{ K}^{-1}$ .

The vibrational contribution =  $36.02 - 29.10 = 6.92 \text{ J mol}^{-1} \text{ K}^{-1}$ .

Percent of  $c_p$  due to vibration =  $(6.92/36.02) \times 100 = 19.2\%$

Additional insight into the different behavior of these two molecules is provided by the Boltzmann distribution for CO and Br<sub>2</sub> over vibrational states at room temperature in Figure 12.23 and Example 12.12 in Section 12.8.

**Related Problems:** 23, 24, 25, 26

The heat capacity values for solids also display quantum effects. The law of Dulong and Petit, known since about 1820, states that at room temperature the molar heat capacities of elemental solids have the value  $3R$ , or  $24.9 \text{ J K}^{-1} \text{ mol}^{-1}$ . Research has shown that the values are substantially lower at low temperatures, approaching the value 0 as  $T$  approaches absolute 0, and increasing to the Dulong and Petit value at room temperature. See Figure 12.15a. The physical basis of the Dulong and Petit value is explained by modeling the solid as a three-dimensional stack of oscillators, in which each atom is located between a pair of “springs” along the  $x$ -axis, another pair along the  $y$ -axis, and a third pair along the  $z$ -axis. The three degrees of freedom for each atom are therefore tied up in three vibrational modes, each having a quadratic term in its potential energy and its kinetic energy. By the equipartition theorem, these modes

**FIGURE 12.15** The temperature dependence of  $c_v$  for solids. (Note that  $c_v = c_p$  because the volume of a solid does not change substantially when you exert pressure on it.) (a) Measured values for selected elemental solids.

(b) Debye and Einstein models for  $c_v$  for aluminum. (Adapted from D.R. Gaskell, *Introduction to the Thermodynamics of Materials* (5th ed.), New York, Taylor and Francis, 2008, Figures 6.1, 6.2. © Cengage Learning)

contribute  $6R/2 = 3R$  to  $c_v$  for the solid, as shown in Table 12.3. Einstein explained the behavior at low  $T$  in 1907 as an early application of Planck's quantum hypothesis which was introduced to explain blackbody radiation (see Section 4.2). He assumed each atom in the solid behaved as a harmonic oscillator, all moving with the same frequency  $\nu$ . He calculated the average vibrational energy for these oscillators as a function of  $T$ , multiplied the result by Avogadro's number to obtain the internal energy per mole, and calculated  $c_v$  by taking the derivative with respect to  $T$ . This model leads to a characteristic temperature called the Einstein temperature  $\Theta_E = h\nu/k_B$  at which the vibrational energies are excited. Einstein's calculated curve for  $c_v$  is plotted as a function of  $T/\Theta_E$  in Figure 12.15b. As  $T$  increases  $c_v \rightarrow 3R$  in accord with the law of Dulong and Petit, and as  $T \rightarrow 0$ ,  $c_v \rightarrow 0$  in accord with experiment. Debye refined Einstein's model by allowing the atoms in the solid to vibrate about their equilibrium positions with a range of frequencies up to a maximum frequency  $\nu_{\max} = \nu_D$  called the Debye frequency. The Debye frequency corresponds to the shortest possible wavelength at which neighboring atoms would vibrate in opposition to each other; this is equal to twice the distance between atoms. Debye summed up Einstein's  $c_v$  contributions up to the Debye frequency, and plotted the result against the Debye temperature  $\Theta_D = h\nu_D/k_B$  at which the maximum vibrational frequency becomes active. The result shown in Figure 12.15(b) reproduced the experimental data almost exactly.

We started this section with the statement that the heat capacity measures the ability of molecular motions and interactions to accommodate thermal energy. We now understand that accommodating thermal energy is fundamentally a quantum mechanical process. It is straightforward to identify modes of molecular motion and the corresponding degrees of freedom, but we must have a quantum description of the allowed energy levels for each mode in order to identify the temperature range in which each mode becomes active. If the temperature is not high enough, the modes are ineffective and might as well be absent. Figure 12.14 shows that the heat capacity of a gas plotted as a function

of temperature evidences a series of individual “jumps” as  $kT$  becomes large enough to efficiently populate excited rotational, and then vibrational, quantum states. This illustrates how each of these degrees of freedom becomes active and contributes to the total heat capacity as the temperature is increased.

## 12.6 Thermochemistry

Up to this point, all the energy changes we have considered are simple physical processes that involve direct mechanical work on a system (as in the paddle wheel driven by a falling weight) or direct thermal contact between two systems at different temperatures. The same methods apply to the heat given off or taken up in the course of a chemical reaction. The study of these heat transfers during chemical reactions is referred to as **thermochemistry**. Because chemical reactions are usually studied at constant pressure, heat transfers in reactions are measured at constant pressure. We obtain these numbers by conducting the chemical reaction in a constant-pressure calorimeter and measuring the heat transferred as  $q_p$ . This number is the enthalpy change of the reaction, viewed as a thermodynamic process:

$$q_p = \Delta H = H_f - H_i = H_{\text{products}} - H_{\text{reactants}} = \Delta H_{\text{reaction}}$$

The result,  $\Delta H_{\text{reaction}}$ , is called the **reaction enthalpy** or enthalpy of reaction.

### 12.6.1 Enthalpies of Reaction

When carbon monoxide is burned in oxygen to produce carbon dioxide,

heat is given off. Because this energy is transferred out of the reaction vessel (the system) and into the surroundings, it has a *negative* sign. Careful calorimetric measurements show that 1.000 mol CO reacted completely with 0.500 mol  $\text{O}_2$ , at 25°C and a constant pressure of 1 atm, leads to an enthalpy change of

$$\Delta H = q_p = -2.830 \times 10^5 \text{ J} = -283.0 \text{ kJ}$$

The kilojoule (kJ), equal to  $10^3$  J, is used because most enthalpy changes for chemical reactions lie in the range of thousands of joules per mole.

When heat is given off by a reaction ( $\Delta H$  is negative), the reaction is said to be an **exothermic reaction** (Fig. 12.16). A reaction in which heat is taken up ( $\Delta H$  positive) is called **endothermic reaction** (Fig. 12.17). One example of an endothermic reaction is the preceding reaction written in the opposite direction:

If the direction of a chemical reaction is reversed, the enthalpy change reverses sign. Heat is required to convert  $\text{CO}_2$  to CO and  $\text{O}_2$  at constant pressure. The decomposition of  $\text{CO}_2$  into CO and  $\text{O}_2$  is difficult to perform in the laboratory, whereas the reverse reaction is straightforward. Thermodynamics allows us to predict  $\Delta H$  of the decomposition reaction with complete confidence, even if a calorimetric experiment is never actually performed for it.

Chemists have agreed on a convention for attaching reaction enthalpy values to balanced chemical equations. A reaction enthalpy written after a balanced chemical equation refers to the enthalpy change for the complete conversion of stoichiometric amounts of reactants to products; the numbers of moles of reactants and products are given by the coefficients in the equation. The preceding

(c)

**FIGURE 12.16** The thermite reaction,  $2 \text{Al}(s) + \text{Fe}_2\text{O}_3(s) \longrightarrow 2 \text{Fe}(s) + \text{Al}_2\text{O}_3(s)$ , is among the most exothermic of all reactions, liberating 16 kJ of heat for every gram of aluminum that reacts. (a) A piece of burning magnesium acts as a source of ignition when inserted into a pot containing a finely divided mixture of aluminum powder and iron(III) oxide. (b) After the ignition, the reaction continues on its own. (c) Enough heat is generated to produce molten iron, which can be seen flowing out of the broken pot onto the protective mat and the bottom of the stand.

equation shows the enthalpy change when 1 mol  $\text{CO}_2$  is converted to 1 mol  $\text{CO}$  and  $\frac{1}{2}$  mol  $\text{O}_2$ . If this equation is multiplied by a factor of 2, the enthalpy change must also be doubled because twice as many moles are then involved (enthalpy, like energy, is an *extensive* property).

The molar amounts need not be integers, as the following example illustrates.

**FIGURE 12.17** (a) When mixed in a flask, the two solids  $\text{Ba}(\text{OH})_2 \cdot 8\text{H}_2\text{O}(s)$  and  $\text{NH}_4\text{NO}_3(s)$  undergo an acid–base reaction:  $\text{Ba}(\text{OH})_2 \cdot 8\text{H}_2\text{O}(s) + 2 \text{NH}_4\text{NO}_3(s) \longrightarrow \text{Ba}(\text{NO}_3)_2(aq) + 2 \text{NH}_3(aq) + 10 \text{H}_2\text{O}(\ell)$ . (b) The water produced dissolves excess ammonium nitrate in an endothermic reaction. The dissolution absorbs so much heat that the water on the surface of the wet wooden block freezes to the bottom of the flask, and the block can be lifted up with the flask.

## EXAMPLE 12.6

Red phosphorus reacts with liquid bromine in an exothermic reaction (Fig. 12.18):

Calculate the enthalpy change when 2.63 g phosphorus reacts with an excess of bromine in this way.

**Solution**

First, convert from grams of phosphorus to moles, using the molar mass of phosphorus,  $30.97 \text{ g mol}^{-1}$ :

$$\text{moles P} = \frac{2.63 \text{ g P}}{30.97 \text{ g mol}^{-1}} = 0.0849 \text{ mol}$$

Given that an enthalpy change of  $-243 \text{ kJ}$  is associated with  $2 \text{ mol P}$ , it is readily seen that the enthalpy change associated with  $0.0849 \text{ mol}$  is

$$\Delta H = 0.0849 \text{ mol P} \times \left( \frac{-243 \text{ kJ}}{2 \text{ mol P}} \right) = -10.3 \text{ kJ}$$

This reaction is exothermic,  $q_p = -10.3 \text{ kJ}$ , so  $10.3 \text{ kJ}$  of heat is released to the surroundings.

**Related Problems: 27, 28, 29, 30**

© Cengage Learning/Charles D. Winters

**FIGURE 12.18** Red phosphorus reacts exothermically in liquid bromine. The rising gases are a mixture of the product  $\text{PBr}_3$  and unreacted bromine that has boiled off.

The enthalpy change for the reaction of  $1 \text{ mol}$  carbon monoxide with oxygen to form  $\text{CO}_2$  was stated to be  $-283.0 \text{ kJ}$ . In a second experiment, the heat evolved when  $1 \text{ mol}$  carbon (graphite) is burned in oxygen to carbon dioxide at  $25^\circ\text{C}$  is readily measured to be  $q_{\text{surr}} = 393.5 \text{ kJ}$  and  $q_{\text{surr}} = -q_{\text{sys}}$  so the enthalpy of reaction is  $-393.5 \text{ kJ}$ :

Now, suppose we need to know the enthalpy change for the reaction

This reaction cannot be performed simply in the laboratory. If  $1 \text{ mol}$  graphite is heated with  $\frac{1}{2} \text{ mol}$  oxygen, almost half the carbon burns to  $\text{CO}_2(g)$ , and the remainder is left as unreacted carbon. Nevertheless, thermodynamics allows us to predict the heat that *would* evolve if we could perform the reaction as written. This is possible because  $H$  is a state function, and thus  $\Delta H$  for the reaction is independent of the path followed from reactants to products. We are free to select any path for which we have all the data needed for the calculation. In Figure 12.19, we illustrate the path in which  $1 \text{ mol C}$  is burned with  $\text{O}_2$  to  $\text{CO}_2$  (with  $\Delta H = -393.5 \text{ kJ}$ ), and to this is added the calculated enthalpy change for the (hypothetical) process in which  $\text{CO}_2$  is converted to  $\text{CO}$  and  $\text{O}_2$  ( $\Delta H = +283.0 \text{ kJ}$ ). The total  $\Delta H$  is the sum of the two known enthalpy changes,  $-393.5 \text{ kJ} + 283.0 \text{ kJ} = -110.5 \text{ kJ}$ . To see this more clearly, the reactions are written out as follows:

*If two or more chemical equations are added to give another chemical equation, the corresponding enthalpies of reaction must be added.*

This statement is known as **Hess's law** and derives from the fact that enthalpy is a state function. It is proper to include in the pathway any convenient reaction for which the enthalpy change is known, even if that reaction is difficult to study directly and its enthalpy change is known only from studies of the reverse reaction. The step labeled (hypothetical) earlier is a good example.

The corresponding internal energy change  $\Delta U$  might be desired for this reaction. The quantity  $\Delta U$  is simple to calculate because of the relation

$$\Delta H = \Delta U + \Delta(PV)$$

**FIGURE 12.19** Because enthalpy is a state property, the enthalpy change for the reaction of carbon with oxygen to give carbon monoxide (red arrow) can be determined through measurements along a path that is less direct but easier to study (blue arrows). The enthalpy change sought is the sum of the enthalpy change to burn carbon to carbon dioxide and that to convert carbon dioxide to carbon monoxide and oxygen.

or

$$\Delta U = \Delta H - \Delta(PV)$$

The gases can be assumed to obey the ideal gas law, so

$$\Delta(PV) = \Delta(nRT) = RT \Delta n_g$$

because the temperature is constant at 25°C. Here,  $\Delta n_g$  is the change in the number of moles of *gas* in the reaction as written:

$$\begin{aligned} \Delta n_g &= \text{total moles of product gases} - \text{total moles of reactant gases} \\ &= 1 \text{ mol} - \frac{1}{2} \text{ mol} = \frac{1}{2} \text{ mol} \end{aligned}$$

(Graphite is a solid, and its volume is negligible compared with the volumes of the gases.) Hence,

$$\Delta(PV) = RT \Delta n_g = (8.315 \text{ J K}^{-1} \text{ mol}^{-1})(298 \text{ K})(\frac{1}{2} \text{ mol}) = 1.24 \times 10^3 \text{ J} = 1.24 \text{ kJ}$$

Note that  $R$  must be expressed in  $\text{J K}^{-1} \text{ mol}^{-1}$  to obtain the result in joules. Therefore,

$$\Delta U = -110.5 \text{ kJ} - 1.24 \text{ kJ} = -111.7 \text{ kJ}$$

For reactions in which only liquids and solids are involved, or those in which the number of moles of gas does not change, the enthalpy and energy changes are almost equal, and their difference can be neglected.

Phase changes are not chemical reactions, but their enthalpy changes can be analyzed in the same way. Heat must be absorbed by ice to transform to water, so the phase change is endothermic, with  $\Delta H$  positive:

Here,  $\Delta H_{\text{fus}}$  is the **molar enthalpy of fusion**, the heat that must be transferred at constant pressure to melt 1 mole of substance. When a liquid freezes, the reaction is reversed and an equal amount of heat is given off to the surroundings; that is,  $\Delta H_{\text{freez}} = -\Delta H_{\text{fus}}$ . The vaporization of 1 mole of liquid at constant pressure and temperature requires an amount of heat called the **molar enthalpy of vaporization**,  $\Delta H_{\text{vap}}$ ,

whereas the condensation of a liquid from a vapor is an exothermic process, with  $\Delta H_{\text{cond}} = -\Delta H_{\text{vap}}$ . Table 12.4 lists enthalpies of fusion and vaporization.

TABLE 12.4

Enthalpy Changes of Fusion and Vaporization<sup>†</sup>

Substance	$\Delta H_{\text{fus}}$ (kJ mol <sup>-1</sup> )	$\Delta H_{\text{vap}}$ (kJ mol <sup>-1</sup> )
NH <sub>3</sub>	5.650	23.35
HCl	1.992	16.15
CO	0.836	6.04
CCl <sub>4</sub>	2.500	30.00
H <sub>2</sub> O	6.007	40.66
NaCl	28.800	170.00

<sup>†</sup>The enthalpy changes are measured at the normal melting point and the normal boiling point, respectively.

## EXAMPLE 12.7

To vaporize 100.0 g carbon tetrachloride at its normal boiling point, 349.9 K, and  $P = 1$  atm, 19.5 kJ of heat is required. Calculate  $\Delta H_{\text{vap}}$  for CCl<sub>4</sub> and compare it with  $\Delta U$  for the same process.

**Solution**

The molar mass of CCl<sub>4</sub> is 153.8 g mol<sup>-1</sup>; thus, the number of moles in 100.0 g is

$$\frac{100.0 \text{ g CCl}_4}{153.8 \text{ g mol}^{-1}} = 0.6502 \text{ mol CCl}_4$$

The enthalpy change for vaporizing 1 mol CCl<sub>4</sub> is then

$$\left( \frac{19.5 \text{ kJ}}{0.6502 \text{ mol CCl}_4} \right) \times 1.00 \text{ mol CCl}_4 = 30.0 \text{ kJ} = \Delta H_{\text{vap}}$$

The internal energy change is then

$$\Delta U = \Delta H_{\text{vap}} - \Delta(PV) = \Delta H_{\text{vap}} - RT \Delta n_{\text{g}}$$

Inserting  $T = 349.9$  K and  $\Delta n_{\text{g}} = 1$  (because there is an increase of 1 mol of gaseous products for each mole of liquid that is vaporized) gives

$$\begin{aligned} \Delta U &= 30.0 \text{ kJ} - (8.315 \text{ J K}^{-1} \text{ mol}^{-1})(349.9 \text{ K})(1.00 \text{ mol})(10^{-3} \text{ kJ J}^{-1}) \\ &= (30.0 - 2.9) \text{ kJ} = +27.1 \text{ kJ} \end{aligned}$$

Thus, of the 30.0 kJ of energy transferred from the surroundings in the form of heat, 27.1 kJ is used to increase the internal energy of the molecules ( $\Delta U$ ) and 2.9 kJ is used to expand the resulting vapor,  $\Delta(PV)$ .

**Related Problems: 31, 32, 33, 34**

## 12.6.2 Standard-State Enthalpies

Absolute values of the enthalpy of a substance, like absolute values of the internal energy, cannot be measured or calculated. Only *changes* in enthalpy can be measured. Just as altitudes are measured relative to a standard altitude (sea level), it is necessary to adopt a reference state for the enthalpies of substances. To cope with this problem, chemists define *standard states* for chemical substances as follows:

For solids and liquids, the standard state is the thermodynamically stable state at a pressure of 1 atm and at a specified temperature.

For gases, the standard state is the gaseous phase at a pressure of 1 atm, at a specified temperature and exhibiting ideal gas behavior.

For dissolved species, the standard state is a 1-M solution at a pressure of 1 atm, at a specified temperature and exhibiting ideal solution behavior.

Standard-state values of enthalpy and other quantities are designated by attaching a superscript  $^\circ$  (pronounced “naught”) to the symbol for the quantity and writing the specified temperature as a subscript. Any temperature may be chosen as the “specified temperature.” The most common choice is 298.15 K (25°C exactly); if the temperature of a standard state is not explicitly indicated, 298.15 K should be assumed to be the value.

Once standard states have been defined, the zero of the enthalpy scale is defined by arbitrarily setting the enthalpies of selected reference substances to zero in their standard states. This is completely analogous to assigning zero as the altitude at sea level. Chemists have agreed to the following: *The chemical elements in their standard states at 298.15 K have zero enthalpy.* A complication immediately arises because some elements exist in various allotropic forms that differ in structure and all physical properties, including enthalpy. For example, oxygen can be prepared as  $\text{O}_2(\text{g})$  or  $\text{O}_3(\text{g})$  (ozone), and carbon exists in numerous allotropic forms, including graphite, diamond, and the fullerenes (see Section 7.5). Chemists have agreed to assign zero enthalpy to the form that is most stable at 1 atm and 298.15 K. Thus,  $\text{O}_2(\text{g})$  is assigned zero enthalpy in its standard state at 298.15 K, whereas the standard-state enthalpy of  $\text{O}_3(\text{g})$  is not zero in its standard state at 298.15 K. The most stable form of carbon at 1 atm and 298.15 K is graphite, which is assigned zero enthalpy; the standard state enthalpy values for diamond and all the fullerenes are not zero.<sup>2</sup>

The enthalpy change for a chemical reaction in which all reactants and products are in their standard states and at a specified temperature is called the **standard enthalpy** (written  $\Delta H^\circ$ ) for that reaction. The standard enthalpy is the central tool in thermochemistry because it provides a systematic means for comparing the energy changes due to bond rearrangements in different reactions. Standard enthalpies can be calculated from tables of reference data. For this purpose, we need one additional concept. The **standard enthalpy of formation**  $\Delta H_f^\circ$  of a compound is defined to be the enthalpy change for the reaction that produces 1 mol of the compound from its elements in their stable states, all at 25°C and 1 atm pressure. For example, the standard enthalpy of formation of liquid water is the enthalpy change for the reaction

Here, the superscript  $^\circ$  indicates standard-state conditions (e.g., the partial pressure of each ideal gas is 1 atm), and the subscript f stands for *formation*.

The  $\Delta H_f^\circ$  for an *element* that is already in its standard state is clearly zero, because no further change is needed to bring it to standard-state conditions. But the standard enthalpy of formation of a mole of *atoms* of an element is often a large positive quantity. That is, the reaction to generate them is endothermic:

For dissolved species the standard state is defined as an ideal solution with a concentration of 1 M (this is obtained in practice by extrapolating the dilute solution behavior up to this concentration). A special comment is in order on

<sup>2</sup>There is one exception to this choice of standard state. The standard state of phosphorus is taken to be white phosphorus, rather than the more stable red or black form, because the latter are less well characterized.

the standard enthalpies of formation of ions. When a strong electrolyte dissolves in water, both positive and negative ions form; it is impossible to produce one without the other. It is therefore also impossible to measure the enthalpy change of formation of ions of only one charge. Only the sum of the enthalpies of formation of the positive and negative ions is accessible to calorimetric experiments. Therefore, chemists have agreed that  $\Delta H_f^\circ$  of  $\text{H}^+(\text{aq})$  is set to zero to establish a reference point for the enthalpies of formation of cations and anions.

Tables of  $\Delta H_f^\circ$  for compounds are the most important data source for thermochemistry. From them it is easy to calculate  $\Delta H^\circ$  for reactions of the compounds, and thereby systematically compare the energy changes due to bond rearrangements in different reactions. Appendix D gives a short table of standard enthalpies of formation at 25°C. The following example shows how they can be used to determine enthalpy changes for reactions performed at 25°C and 1 atm pressure.

### EXAMPLE 12.8

Using Appendix D, calculate  $\Delta H^\circ$  for the following reaction at 25°C and 1 atm pressure:

#### Solution

Because enthalpy is a function of state,  $\Delta H$  can be calculated along any convenient path. In particular, two steps can be chosen for which  $\Delta H$  is found easily. In step 1, the reactants are decomposed into the elements in their standard states:

The minus sign appears because the process chosen is the reverse of the formation of NO; the factor of 2 is present because 2 mol NO is involved. Because oxygen is already an

element in its standard state, it does not need to be changed [equivalently,  $\Delta H_f^\circ(\text{O}_2(\text{g}))$  is 0].

In step 2, the elements are combined to form products:

The enthalpy change of the overall reaction is then the sum of these two enthalpies:

$$\begin{aligned} \Delta H^\circ &= \Delta H_1 + \Delta H_2 = -2 \Delta H_f^\circ(\text{NO}) + 2 \Delta H_f^\circ(\text{NO}_2) \\ &= -(2 \text{ mol})(90.25 \text{ kJ mol}^{-1}) + (2 \text{ mol})(33.18 \text{ kJ mol}^{-1}) \\ &= -114.14 \text{ kJ} \end{aligned}$$

**Related Problems:** 39, 40, 41, 42

The general pattern should be clear from this example. The change  $\Delta H^\circ$  for a reaction at atmospheric pressure and 25°C is the sum of the  $\Delta H_f^\circ$  for the *products* (multiplied by their coefficients in the balanced chemical equation) minus the sum of the  $\Delta H_f^\circ$  for the *reactants* (also multiplied by their coefficients). For a general reaction of the form

the standard enthalpy change is

$$\Delta H^\circ = c \Delta H_f^\circ(\text{C}) + d \Delta H_f^\circ(\text{D}) - a \Delta H_f^\circ(\text{A}) - b \Delta H_f^\circ(\text{B})$$

This equation can be extended to calculate the standard-state enthalpy change for any chemical reaction by adding up the standard-state enthalpy of formation for all the products (each multiplied by its stoichiometric coefficient in the balanced chemical equation) and subtracting off the total for all the reactants (each multiplied by its stoichiometric coefficient in the balanced chemical equation). In mathematical form, this procedure is represented by the equation

$$\Delta H^\circ = \sum_{i=1}^{prod} n_i \Delta H_f^\circ - \sum_{j=1}^{react} n_j \Delta H_f^\circ \quad [12.12]$$

### 12.6.3 Bond Enthalpies

Chemical reactions between molecules require existing bonds to break and new ones to form in a new arrangement of the atoms. Chemists have developed methods to study highly reactive intermediate species in which one or more bonds have been broken, and to find the energy required to break a particular bond. For example, a hydrogen atom can be removed from a methane molecule,

leaving two fragments, neither of which has a stable valence electron structure in the Lewis electron dot picture. Both will go on to react rapidly with other molecules or fragments and eventually form the stable products of that reaction. Nonetheless, we can measure many of the properties of these reactive species during the short time they are present.

One such important measurable quantity is the enthalpy change when a bond is broken in the gas phase, called the **bond enthalpy**. This change is invariably positive because atoms bonded together have lower energy than when separated (see Fig. 6.1). For example, the bond enthalpy of a C—H bond in methane is  $438 \text{ kJ mol}^{-1}$ , measured as the standard enthalpy change for the reaction

in which 1 mol of C—H bonds is broken, one for each molecule of methane. Bond enthalpies are fairly constant from one compound to another. Each of the following gas-phase reactions involves the breaking of a C—H bond:

The approximate constancy of the measured enthalpy changes (all lie within 8% of their average value) suggests that the C—H bonds in all five molecules are similar. Because such bond enthalpies are constant from one molecule to another, it is useful to tabulate *average* bond enthalpies from measurements on a series of compounds (Table 12.5). Any given bond enthalpy will differ

**TABLE 12.5**

Average Bond Enthalpies

	Molar Enthalpy of Atomization ( $\text{kJ mol}^{-1}$ )‡	Bond Enthalpy ( $\text{kJ mol}^{-1}$ )†

†From Appendix D.

‡Data from L. Pauling, *The Nature of the Chemical Bond*, 3rd ed. Ithaca, NY: Cornell University Press, 1960.

somewhat from those shown, but in most cases, the deviations are small. The constant of bond energies in a series of molecules was introduced in Section 3.9, and representative values were listed in Table 3.4. Bond energy values are related to bond enthalpy values by the relation  $\Delta H = \Delta U + \Delta(PV)$ , described in the paragraphs following Example 12.6.

The bond enthalpies in Table 12.5 can be used, together with enthalpies of atomization of the elements from the same table, to estimate standard enthalpies of formation  $\Delta H_f^\circ$  for molecules in the gas phase and enthalpy changes  $\Delta H^\circ$  for gas-phase reactions. This is illustrated by the following example.

### EXAMPLE 12.9

Estimate the standard enthalpy of formation of dichlorodifluoromethane,  $\text{CCl}_2\text{F}_2(\text{g})$  (Fig. 12.20). This compound is also known as Freon-12 and was used as a refrigerant because of its low reactivity and high volatility. It and other related chlorofluorocarbons (CFCs) have been phased out because of their role in depleting the ozone layer in the outer atmosphere, as discussed in Section 20.6.

#### Solution

The standard enthalpy of formation of  $\text{CCl}_2\text{F}_2(\text{g})$  is the enthalpy change for the process in which it is formed from the elements in their standard states at  $25^\circ\text{C}$ :

This reaction can be replaced by a hypothetical two-step process: All the species appearing on the left are atomized, and then the atoms are combined to make  $\text{CCl}_2\text{F}_2$ .

The enthalpy change  $\Delta H_1$  for the first step is the sum of the atomization energies:

$$\begin{aligned} \Delta H_1 &= \Delta H_f^\circ(\text{C}(\text{g})) + 2 \Delta H_f^\circ(\text{Cl}(\text{g})) + 2 \Delta H_f^\circ(\text{F}(\text{g})) \\ &= 716.7 + 2(121.7) + 2(79.0) = 1118 \text{ kJ} \end{aligned}$$

The enthalpy change  $\Delta H_2$  for the second step can be estimated from the bond enthalpies of Table 12.5. This step involves the

formation (with release of heat and, therefore, negative enthalpy change) of two C—Cl and two C—F bonds per molecule. The net  $\Delta H$  for this step is then

$$\Delta H_2 \approx -[2(328) + 2(441)] = -1538 \text{ kJ}$$

$$\Delta H_1 + \Delta H_2 = -1538 + 1118 = -420 \text{ kJ}$$

This  $\Delta H_f^\circ$ ,  $-420 \text{ kJ mol}^{-1}$ , compares fairly well with the experimental value,  $-477 \text{ kJ mol}^{-1}$ . In general, much better agreement than this is not to be expected, because tabulated bond enthalpies are only average values.

## 12.7 Reversible Processes in Ideal Gases

Most thermodynamic processes conducted in laboratory work are irreversible, in the sense of Section 12.1. Except in the initial and final states, the system is not at equilibrium, and the equation of state relationship between observable properties does not exist. Consequently, changes in thermodynamic quantities during an irreversible process cannot in general be calculated. Nonetheless, the changes in those quantities that are state functions are well defined, as long as the initial and final equilibrium states are known. Because these changes are independent of the detailed path of the process, they can be evaluated for any known process that connects these initial and final states. Changes can be directly calculated along *reversible* paths, during which the system proceeds through a sequence of equilibrium states in which observable properties are related by the equation of state.

This section demonstrates calculations of changes in macroscopic properties caused during several specific reversible processes in ideal gases. These will serve as auxiliary calculation pathways for evaluating changes in state functions during irreversible processes. We use this procedure extensively in Chapter 13 on spontaneous processes and the second law of thermodynamics.

Recall from Section 12.1 that a true reversible process is an idealization; it is a process in which the system proceeds with infinitesimal speed through a series of equilibrium states. The external pressure  $P_{\text{ext}}$ , therefore, can never differ by more than an infinitesimal amount from the pressure,  $P$ , of the gas itself. The heat, work, energy, and enthalpy changes for ideal gases at constant volume (called an **isochoric process**) and at constant pressure (called an **isobaric process**) have already been considered. This section examines *isothermal* (constant temperature) and *adiabatic* ( $q = 0$ ) processes.

### 12.7.1 Isothermal Processes

An **isothermal process** is one conducted at constant temperature. This is accomplished by placing the system in a large reservoir (bath) at fixed temperature and allowing heat to be transferred as required between system and reservoir. The reservoir is large enough that its temperature is almost unchanged by this heat transfer. In Section 12.4,  $U$  for an ideal gas was shown to depend only on temperature; therefore,  $\Delta U = 0$  for any isothermal ideal gas process. (Of course the change in energy will not be zero if a liquid evaporates to an ideal gas at constant temperature, or if a chemical reaction between ideal gases occurs.) From the first law it follows that

$$w = -q \text{ (isothermal process, ideal gas)}$$

In a *reversible* process,  $P_{\text{ext}} = P_{\text{gas}} \equiv P$ . But the relation  $w = -P_{\text{ext}} \Delta V$  from Section 12.2 cannot be used to calculate the work, because that expression applies only if the external pressure remains constant as the volume changes. In the reversible isothermal expansion of an ideal gas,

$$P_{\text{ext}} = P = \frac{nRT}{V} \quad [12.13]$$

By Boyle's law, the pressure falls as the volume is increased from  $V_1$  to  $V_2$ , as shown by the solid line in Figure 12.21. In this case, the work is calculated by approximating the process as a *series* of expansions by small amounts  $\Delta V$ ,

**FIGURE 12.21** The area under the graph of external pressure against volume can be approximated as the sum of the areas of the rectangles shown.

during each of which  $P_{\text{ext}}$  is held constant at  $P_i$ , with  $i = 1, 2, 3$ , and so on labeling the step. The work done in step  $i$  is  $-P_i\delta V$ , and thus the total work done is the sum of the work in all steps:

$$w = -P_1\delta V - P_2\delta V - \dots$$

The work in the complete process is the sum of the areas of the rectangles in the figure. As the step size  $\delta V$  is made smaller, it approaches the infinitesimal volume change that is written  $dV$ , and the corresponding increment of work becomes

$$dw = -P_{\text{ext}} dV$$

In this limit the sum of the areas of the rectangles approaches the area under the graph of  $P$  versus  $V$ . This limiting sum is the *integral* of  $P_{\text{ext}}$  from  $V_1$  to  $V_2$  and is written symbolically using an integral sign:

$$w = -\int_{V_1}^{V_2} P dV \quad (\text{reversible process}) \quad [12.14]$$

Note that we used Equation 12.13 to replace  $P_{\text{ext}}$  with the internal pressure  $P$  in this reversible process. This is a compact way of saying that the work,  $w$ , for a reversible expansion process is (with a minus sign) the area under the graph of  $P$  plotted against  $V$  from  $V_1$  to  $V_2$ .
